Antigen-presenting cells (APCs) of the innate immune system (e.g., macrophages, NK cells, neutrophils, mucosal epithelial cells, endothelial cells, and dendritic cells [DCs]) play pivotal roles in the initiation of an inflammatory response to invading pathogens. As depicted in Fig. 47.6, the macrophage is activated by endotoxin (LPS) binding to the CD14 receptor (the main LPS binding receptor) by an LPS-binding protein. CD14 also exists in a soluble form that is shed from the macrophage cell surface through the action of serine proteases. Circulating LPS-CD14 complexes can attach to endothelial cells or epithelial cells. Through this mechanism, endothelial cells are activated to produce other cytokines and mediators (e.g., PAF, nitric oxide, and IL-6) that contribute to the pro-inflammatory response. CD14 is also required for the recognition of other bacterial products, including peptidoglycans and lipoteichoic acid from gram-positive bacteria. The formation of the CD14-LPS complex significantly reduces the concentration of LPS needed for activation.

CD14 lacks transmembrane and intracellular domains and cannot initiate a cellular response. Another pathway involving toll-like receptors (TLRs) is responsible for cell activation and signal transduction. CD14 seems to be able to discriminate between bacterial products and sort their signals to different TLRs. The TLRs are named from Toll, a plasma membrane receptor in Drosophila, which has a cytoplasmic domain homologous to the IL-1 receptor protein. Toll receptors induce signal transduction pathways that lead to the activation of the transcription factor NF-κB.[36] In mammalian species, there are at least 10 TLRs (Table 47.6), which represent type I transmembrane proteins characterized by an extracellular domain, a transmembrane domain, and an intracellular domain. TLRs are pattern recognition receptors that recognize pathogen-associated molecular patterns. Pathogen-associated molecular patterns are shared by many pathogens but are not expressed in host cells. TLR4 is responsible for the recognition of bacterial endotoxin. It is essential for signaling but requires a small protein (MD-2) to confer responsiveness. Other TLRs bind cell wall products from gram-positive bacteria and fungi.

When activated, TLRs initiate a signaling cascade that shares many of the same molecules used by the IL-1 receptor. Activated, macrophages synthesize and secrete the cascade of pro-inflammatory cytokines, chemokines, and mediators described earlier. Some of these cytokines activate neutrophils to release proteases and free radicals that have

TABLE 47.5 Human CXC and CC Chemokines and Relative Receptors

Chemokines	Systematic Name	Chemokine Receptors
Growth-related oncoprotein (GRO)-α	CXC-motif ligand (CXCL)1	CXC receptor (CXCR) 2
GRO-β	CXCL2	CXCR2
GRO-γ	CXCL3	CXCR2
Epithelial neutrophil chemoattractant (ENA-78)	CXCL5	CXCR2
Granulocyte chemoattractant protein (GCP)-2	CXCL6	CXCR2, CXCR1
Neutrophil-activating peptide (NAP)-2	CXCL7	CXCR2
IL-8	CXCL8	CXCR2, CXCR1
Monokine induced by gamma interferon (MIG)	CXCL9	CXCR3
Interferon-gamma-inducible protein 10 (IP-10)	CXCL10	CXCR3
Interferon-inducible T-cell alpha chemoattractant (I-TAC)	CXCL11	CXCR3
Stromal cell-derived factor 1 (SDF-1)	CXCL12	CXCR4
B-cell chemoattractant (BCA-1)	CXCL13	CXCR5
Monocyte chemoattractant protein (MCP)-1	CCL2	CCR2
MCP-2	CCL8	CCR3
MCP-3	CCL7	CCR1, CCR2, CCR3
	CCL13	CCR2, CCR3
Macrophage inflammatory protein (MIP)-1α	CCL3	CCR1, CCR5
MIP-1β	CCL4	CCR5
RANTES (regulated upon activation, normally T-expressed, and presumably secreted)	CCL5	CCR1, CCR3, CCR5
Eotaxin	CCL11	CCR3
Eotaxin-2	CCL24	CCR3
Eotaxin-3	CCL26	CCR3
Liver and activation-regulated chemokine (LARC)	CCL20	CCR6
Thymus expressed chemokine (TECK)	CCL25	CCR9
Cutaneous T-cell-attracting chemokine (CTACK)	CCL27	CCR10
T-cell-directed CC chemokine (TARC)	CCL17	CCR4
Macrophage-derived chemokine (MDC)	CCL22	CCR4
Dendritic cell-specific chemokine (DC-CK1)	CCL18	?
Epstein-Barr virus–induced molecule 1 ligand chemokine (ELC)	CCL19	CCR7
Secondary lymphoid tissue chemokine (SLC)	CCL21	CCR7

the capacity to damage endothelium and promote capillary leak. Upregulation of adhesion molecules on the neutrophils allows them to bind to counter-receptors on the endothelial cells and migrate to sites of inflammation. The pro-inflammatory cascade is interrupted by the initiation of counter-regulatory mechanisms. Because most patients with life-threatening infections (i.e., systemic inflammatory response syndrome) are not admitted early in the course of their sepsis episode, pro-inflammatory cytokines are detected in only a subset of patients. Anti-inflammatory cytokines (which appear later in the cascade) are found in most of these infected individuals.

• **Fig. 47.6** Role of macrophages in mediating the inflammatory response. Lipopolysaccharide (LPS) binding to the CD14 receptor (with or without LPS binding protein) activates the macrophage (MØ) to synthesize and secrete cytokines, chemokines, and other mediators. These soluble factors stimulate polymorphonuclear neutrophils (PMNs) to release proteases and oxygen-free radicals that are important for microbial killing but that also may injure endothelium and cause capillary leak. Binding of soluble LPS-CD14 complexes to endothelial cells promotes biosynthesis of other cytokines and small molecular mediators (e.g., nitric oxide, interleukin-6). Endothelial activation also results in upregulation of cell surface adhesive molecules that interact with neutrophil-adhesive molecules and promote neutrophil extravasation. DIC, disseminated intravascular coagulation.

TABLE 47.6 Role of Toll-Like Receptors (TLRs) in Pathogen Recognition and Pathophysiology of Human Disease

Toll-Like Receptor	Ligands	Pathogens or Disease State
TLR1	Signals as a dimer only when combined with TLR2 for all its ligands; recognizes Borrelia burgdorferi OspA; required for adaptive immune response	Lyme disease
	Tri-acyl lipopeptides (bacteria, e.g., Mycobacterium tuberculosis)	
	Soluble factors (Neisseria meningitidis)	N. meningitides
TLR2	Associates with CD11/CD18, CD14, MD-2, TLR1, TLR6, dectin 1; lipoprotein/lipopeptides (various microbial pathogens)	M. tuberculosis
	Peptidoglycan	Apoptosis of Schwann cells in leprosy
	Lipoteichoic acid	
	Lipoarabinomannan (mycobacteria)	
	Phenol-soluble modulin (Staphylococcus epidermidis)

The concentration of anti-inflammatory substances (e.g., IL-1ra and soluble receptors) increases substantially with time and has been termed the compensatory anti-inflammatory response syndrome. This is a response of the host to limit the toxicity of proinflammatory substances. Shortly after the onset of an infectious episode, the mononuclear cell becomes refractory and is unable to respond to proinflammatory cytokines. In contrast, the capacity to produce anti-inflammatory substances such as IL-1ra and IL-10 is preserved. This phenomenon has been referred to as monocyte deactivation or immunoparalysis. Although the mechanism responsible for monocyte deactivation is unclear, it probably involves increased production of IL-10. The risk of infection is greatly increased during this period of hyporeactivity.

Acquired Immunity

Cell-Mediated and Antibody-Mediated Responses

Overview

Lymphocytes constitute almost 20% of blood leukocytes and specialize in the recognition of invading foreign antigens in the context of major histocompatibility antigens.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Lymphocytes are of two major types: (1) B lymphocytes that are produced in the bone marrow, mature in secondary lymphoid organs, and subsequently differentiate into antibody-secreting plasma cells, and (2) T lymphocytes that mature and differentiate into CD4+ and CD8+ subsets in the thymus and subsequently seed the peripheral blood system, including the spleen and the lymph nodes. T-cell functions include helping B cells to make antibody; killing virally infected cells; regulating the level of the immune response; and stimulating the microbial and cytotoxic activity of the immune cells, including macrophages.

Each lymphocyte expresses a cell surface receptor that recognizes a particular antigen. In the case of T cells, it is called the T-cell receptor (TCR), and in the case of B cells, it is called the B-cell receptor (BCR). Each lymphocyte is engineered to express a receptor that is specific for only one antigen. In this way, the lymphocyte population as a whole can recognize a wide range of antigens. The antigen receptors are generated during development by a process known as somatic mutation and recombination involving a few germline genes. The antigen receptors used by B cells and T cells are different. The BCR is a surface immunoglobulin, a membrane-bound form of the antibody that eventually gets secreted. The TCR is generated from a different set of genes that encode only the cell-surface receptor.

T cells and B cells recognize antigens in different forms: B cells recognize an unmodified antigen molecule, either free in solution or on the surface of other cells. T cells recognize antigen only when it is presented to them in association with molecules encoded by the MHC. The functional consequence of these differences in antigen recognition is that T cells must be presented processed antigens in the form of short peptides by accessory cells such as macrophages or dendritic cells (DCs), whereas B cells can directly recognize antigens in tissue fluids.

The acquired immune response arises through the process of clonal recognition. An antigen selects the clones of B and T cells that express the cell surface receptors that recognize the antigen. Because the number of different lymphocyte antigen specificities is large, the number of lymphocytes available to recognize each antigen is relatively small—only a few hundred lymphocytes in an adult. In addition, because so few cells are insufficient to eradicate an invading pathogen, the first step toward the generation of a specific immune response involves a rapid expansion of antigen-specific lymphocytes. This step is followed by further differentiation of antigen-specific cells into effector cells. These events underlie the difference between primary and secondary immune responses. During the primary response, the small number of specific cells increases, and the cells undergo differentiation. If the antigen is encountered again (or persists), there is a larger population of specific cells to react with the antigen, and these cells are able to respond more quickly because they have already undergone several steps along their differentiation pathway. These lymphocytes that have been stimulated by antigen (primed) and their progeny either may differentiate fully into effector cells or may form the expanded pool of cells (memory cells) that can respond more efficiently to a future (secondary) challenge with the same antigen.

T Lymphocytes

Overview

T cells develop and differentiate in the thymus before seeding the secondary lymphoid tissues. T cells recognize both antigens and MHC molecules through the TCR. This receptor consists of an antigen-binding portion formed by two different polymorphic chains in association with CD3, a complex of proteins involved in signal transduction. The antigen-binding portion of the TCR is most commonly formed by the αβ polypeptide chain heterodimer. In humans, the markers CD2 and CD5 are also present on all T cells (Table 47.7). Activated T cells may also be induced to express CD25, which forms part of the high-affinity IL-2 receptor and is important in clonal expansion.

There are two main subpopulations of T cells, which are distinguished according to their expression of CD4+ or CD8+. These molecules act as receptors for class II (CD4+) and class I (CD8+) MHC molecules and contribute to T-cell immune recognition and cellular activation. The

TABLE 47.7 Cluster-Designated Molecules Found on Human T Cells

Antigen	Molecular Weight (kDa)	Comment
CD1a	49	Expressed on thymocytes
CD1b	45	Expressed on thymocytes
CD1c	43	Expressed on thymocytes
CD2	50	Sheep erythrocyte receptor
CD3	22	Part of T-cell antigen receptor complex
CD4	55	MHC class II immune recognition
CD5	67	
CD6	120	
CD7	40	Possibly IgM Fc receptor
CD8	32	MHC class I immune recognition
CD25	55	Low-affinity interleukin-2 receptor
CD45	180	Expressed on memory T cells (also known as UCHLI)
CD45R	200	Expressed on virgin T cells (also known as Leu-18)

MHC, major histocompatibility complex.

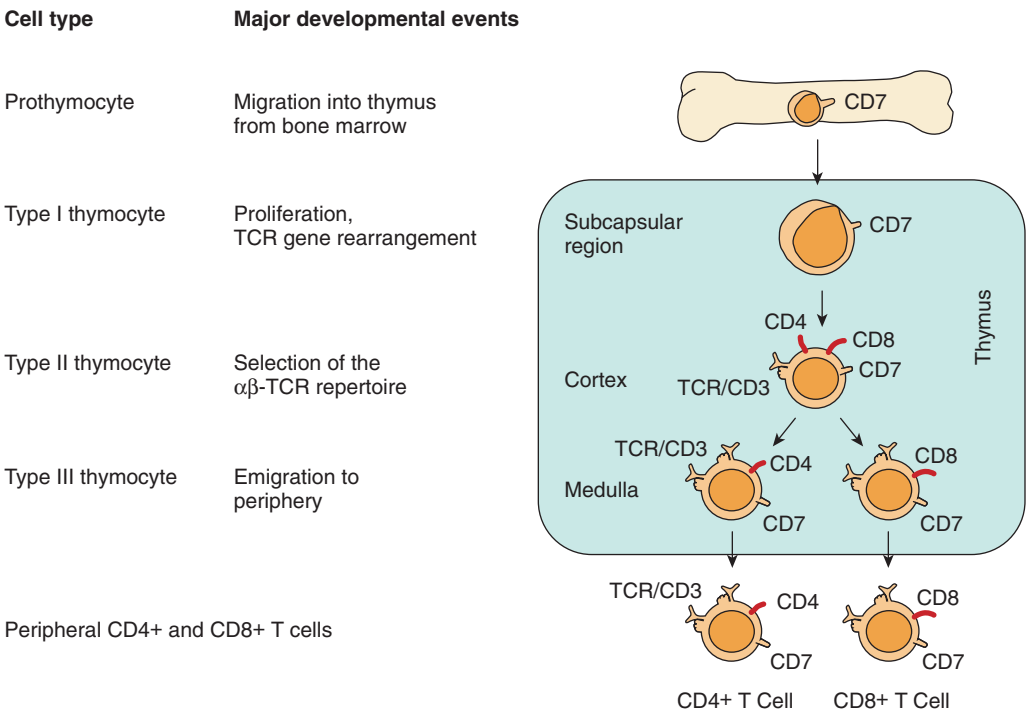
CD4+ T-helper (Th) cells recognize antigens associated with class II MHC and participate in immune responses to extracellular pathogens by close coordination with other immune cells like macrophages, neutrophils, and B lymphocytes. However, CD8+ cytotoxic T cells recognize antigens associated with class I MHC and mount immune responses to intracellular pathogens leading to destruction of infected cells.



Clones of mature CD4+ T cells are functionally categorized into two major subgroups: Th1 cells that interact preferentially with mononuclear phagocytes, and Th2 cells that tend to promote B-cell division and differentiation. The balance of activity between these two subsets is related in part to how antigen is presented to the cells, and it ultimately determines the type of immune response that develops. Three other subgroups of CD4+ cells also exist, Th17 cells, T-regulatory cells (Treg), and T-follicular helper (Tfh) cells (discussed further below).[23]

Surface markers of T-cell populations change during T-cell development. In humans, naive T cells express the cell surface molecule CD45RA, whereas activated cells express the CD45RO isoform and higher levels of adhesion molecules, such as the β1 integrin (CD29). The mechanism resulting in the generation of activated T cells from resting memory T cells is still unclear.

T-Cell Development

Lymphocytes destined to become T cells must undergo several maturational steps in the thymus before they become mature effector T cells. In humans, the thymus develops embryologically as an outgrowth from the third and fourth pharyngeal pouches between weeks 6 and 7 of gestation. The cortex and medulla of the thymus begin to differentiate by the 10th week of gestation, and Hassall corpuscles appear by the 12th week of gestation.

The undifferentiated but committed lymphoid progenitor cells that first enter the thymus from the bone marrow (at approximately 7 weeks' gestation) are initially double-negative for both CD4 and the CD8 antigen but do express the T-cell markers CD7 and CD45 (CD7 may be the IgM Fc receptor, and CD45 is the common leukocyte antigen). With maturation, the thymocytes first become CD4+ CD8+ double-positive and appear in the thymic cortex at approximately 10 weeks' gestation (Fig. 47.7). At this stage, αβ TCRs are first expressed on their cell surface. Production of the T-cell α chain precedes production of the β chain. In the thymus, T-cell maturation is accompanied by the sequential appearance of surface phenotypic markers (see Table 47.7). CD1, CD2, and CD5 surface antigens appear soon after CD7 expression, whereas CD3 appears later. As gestation progresses, most cells leaving the thymus become

• **Fig. 47.7** Putative stages of human thymocyte development. Prothymocytes from the bone marrow enter the thymus and give rise to three major stages of αβ–T-cell receptor (αβ-TCR) lineage thymocytes. TCR-α and TCR-β chain genes are rearranged during stage I; thymic selection occurs mainly during stage II; and emigration of mature CD4+ and CD8+ cells occurs in stage III. (From Lewis DB, et al.: Developmental immunology and role of host defenses in neonatal susceptibility to infection. In: Remington JS, et al., eds. *Infectious diseases of the fetus and newborn infant*. 4th ed. Philadelphia: Saunders; 1995, with permission.)

single-positive for either CD4+ or CD8+ surface antigen. Cells that lack both antigens (double-negative cells) retain stem cell function and possess a receptor (CD25, Tac antigen) for IL-2, which plays an essential role in T-cell proliferation. Mice lacking Notch-1 have blocked T-cell development with B cells developing in the thymus instead, suggesting that Notch signaling may play an important role in early T-cell commitment and differentiation.[45]

By the 12th week of gestation, occasional CD3+ cells can be identified in human fetal peripheral blood. As gestation progresses, the percentage of CD3+ cells in the peripheral blood increases, coming to represent more than 50% of T lymphocytes by 22 weeks' gestation. These CD3+ cells also express either CD4+ or CD8+ antigen. By 13 weeks of gestation, CD3+ T cells appear in the fetal liver and spleen, and these cells represent more than 50% of the T lymphocytes in those organs by the end of the second trimester.

Role of Cytokine Receptor Signaling in Lymphocyte Development

In humans, X-linked severe combined immunodeficiency (X-SCID) syndrome is characterized by defective T-cell development and function. Affected patients lack T cells but possess near normal numbers of B cells. B cells from patients with X-SCID tend to secrete predominantly IgM antibody. Altered B cell–mediated antibody production in patients with X-SCID has also been attributed to defective T-helper cells. The mapping of the gene that encodes the common subunit of cytokine receptors, including the IL-2 receptor, has been linked to the X-SCID locus. Patients with X-SCID possess mutations in the common subunit, establishing a correlation between defects in this gene and the cause of X-SCID. Based on these observations, it was predicted that lymphocytes deficient in the expression of the IL-2 receptor would mimic some of the phenotypic abnormalities associated with patients with X-SCID. However, deficiency of IL-2 or the IL-2 receptor does not result in any of the defects observed in patients with X-SCID. These observations have since been attributed to the presence of the common subunit in multiple other cytokine receptors as well, including the IL-4, IL-7, IL-9, and IL-15 receptors. All these receptors are expressed on T cells, and mutations in the common subunit in X-SCID are likely to affect the function of all these receptors, thus providing an explanation for the pathophysiologic process of this disease.

T-Lymphocyte Activation and Maturation

The T-cell receptor (TCR) is a multisubunit complex that consists of TCR-αβ chains noncovalently associated with the invariant CD3 chains and the TCR-ζ chains. Generally, interaction between the TCR and antigen-presenting cells (APC) results in the activation of Src homology (SH) 2 and SH3 domain containing signaling proteins that belong to the Src family of lymphocyte-specific tyrosine kinase (LCK). Activated LCK associates intracellularly with the TCR and with the CD8+ and CD4+ coreceptors. Once activated, LCK activates the cytoplasmic domain of CD3/ζ complex, which contains the ITAM motif. ITAM allows the binding of additional signaling molecules containing SH2 domains, such as the SYK kinase ZAP70. When recruited to ITAM, ZAP70 is phosphorylated and subsequently activates a major adapter protein in T-cell signaling termed linker for activation of T cells (LAT). Activation of LAT and several other signaling molecules downstream in this cascade results in the activation of nuclear proteins, including transcription factors such as nuclear factor of activated T cells and mitogen-activated protein kinases. This results in the transcription of important T cell–specific genes that are crucial for development, differentiation, and function of T cells.

T cells require two signals for activation: a signal provided through the TCR involving priming with an antigen by class I or II MHC complexes, and a second, costimulatory signal provided when the CD28 receptor on T cells binds to B7-1 (CD80) or B7-2 (CD86) on APCs.[23] A key feature of the costimulatory signal provided by CD28 is that, in conjunction with a TCR stimulus, it allows high-level IL-2 production and provides an essential survival signal for T cells. The combined costimulatory signal prevents T-cell apoptosis or the induction of anergy (unresponsiveness) that may occur in response to activation of either signal alone. In the case of CD4+ cells, a third signal provided by growth factors or cytokines is also needed for activation and subsequent differentiation into different subtypes.[23]

Naive CD4+ helper T cells can be divided into two main subsets based on the profile of cytokines they produce. Th1 cells produce IL-2, IFN, TNF, IL-3, and GM-CSF; Th2 cells produce IL-4, IL-5, IL-6, IL-10, 1L-12, and IL-13. This differential pattern of cytokine expression contributes to differences in the function of these two subsets of T cells. Th1 cells are inflammatory cells responsible for mediating cell-mediated immunity. In contrast, Th2 cells act to help B cells produce antibodies. Naive T cells generally do not express mRNA for cytokines such as IFN, IL-4, or TNF. The decision of a naive T cell to mature into either Th1 or Th2 is partly regulated by the interaction between growth factors/cytokines and their receptors and transcription factors. For Th1 differentiation, interaction between naive Th cells and APCs, especially dendritic cells (DC), results in the synthesis of IL-12. IL-12 in conjunction with transcription factors signals transducer and activator of transcription (STAT4), and T-bet drives the maturation of IFN-producing Th1 cells. Likewise, IL-4, STAT6, and the transcription factor GATA-3 are essential for the generation of Th2 cells. A balance between cytokines, signaling molecules, and transcription factors is thus essential for driving the differentiation of Th1 and Th2 cells from naive Th cells.[23]

Along with Th1 and Th2 cells, as previously stated, three other subsets of helper T cells have also been described. Th17 cells produce IL-17A, IL-17F, IL-21, IL-22, and IL26. Differentiation of these cells occurs with stimulation by TGF-β and IL-6 and requires the transcription factors

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

RORγ, RORα, and STAT3. T-regulatory (Treg) cells are a subclass of CD4+ cells that play an important role in suppressing the effector activity of multiple T-helper subsets and mediating immune self-tolerance. Treg cells constitutively express the transcription factor forkhead/winged-helix family transcriptional repressor-p3 (Foxp3).[35] These cells can be thymically derived like other T-cell subsets or can be induced in the periphery. The transcription factors Foxp3 and STAT5 cooperate with TGF-β and control Treg differentiation. T-regulatory cells (Tregs) downregulate T-cell responses to both foreign and self-antigens. Although current knowledge about Tregs early in life is limited, recent studies suggest deficiencies in Treg function in both term and preterm infants when compared to adults.[40]

The T-follicular helper (Tfh) cells are a distinct class of helper T cells that are normally found in the B-cell follicles in secondary lymphoid organs. These cells are controlled by the Bcl-6 transcription factor and mediate B-cell activation and assist in germinal center formation.

Role of Cytokines in T-Cell Function

IL-2 was originally described as a T-cell growth factor, but it is now known to have activity on various other cell types, including NK cells, B cells, macrophages, and monocytes. The synthesis and secretion of this cytokine is triggered by the activation of mature T cells. Binding of IL-2 initiates clonal expansion of activated T cells. High-affinity IL-2 receptor expression is induced on B cells by exposure to IL-4 and immunoglobulin receptor binding. The activity of IL-2 on other cell types (NK cells, macrophages, neutrophils, and lymphokine-activated killer cells) is mainly through the intermediate-affinity IL-2 receptor. A key role of the IL-2 receptor γ chain (which is also found in the receptors for IL-4, IL-7, IL-9, and IL-13) in the immune response is highlighted by the consequences of its genetic malfunction. Mutations in the IL-2 receptor γ chain are responsible for X-SCID in humans.

IL-4 is produced by a subpopulation of T cells and by mast cells. Its production follows T-cell activation or cross-linkage of FcRI receptors on basophils or mast cells. IL-4 affects many cell types, promoting the growth of T cells, B cells, mast cells, myeloid cells, and erythroid cell progenitors. It promotes class switching in B cells to IgE and augments IgG1 production. The IL-4 effect on T-cell development is to drive T-cell differentiation toward a Th2 type at the expense of a Th1 response. In the neonatal Th1 cell, antigen presentation by APCs upregulates IL-13Rα, which forms a complex with IL-4Rα on the surface of Th1 cells. IL-4 produced by Th2 cells acts on the IL-4Rα/ IL-13Rα complex and induces Th1 cell apoptosis, skewing the T-helper cell response to a predominant Th2 response in neonates. IL-4 has also been shown to initiate cytotoxic responses against tumor cells. The pleiotropic activity of IL-4 is reflected in the range of cell types that express IL-4 receptor. This high-affinity receptor is found on T cells, B cells, mast cells, myeloid cells, fibroblasts, muscle cells, neuroblasts, stromal cells, endothelial cells, and monocytes.

IL-7 signaling promotes cell-cycle entry and proliferation of developing T-lymphocytes and B-lymphocytes. In thymocytes, IL-7 signaling has been implicated in the induction and maintenance of the antiapoptotic protein Bcl-2 and has been shown to inhibit the expression of the pro-apoptotic factor Bax. These results suggest that one of the principal functions of IL-7 signaling in developing thymocytes is to promote cell survival.

IL-12 is made by B cells, monocytes, and macrophages, and acts synergistically with IL-2 to induce IFN production by T cells and NK cells. In the absence of IL-12, cytotoxic CD8+ T cells can proliferate but fail to differentiate and do not produce important effector proteins such as IFN-γ and granzyme B. IL-12 thus enhances the cytotoxic activity of T cells.[32]

IL-10 has important biologic effects on T-cell function. Although initially described as a cytokine produced by Th2 cells capable of decreasing the activation of Th1 cells, it is now known to be produced by multiple immune cell types, including macrophages, monocytes, DC, T cells, and B cells. IL-10 primarily functions as an anti-inflammatory cytokine and may mediate some of the immunosuppressive effects of CD4+ CD25+ Treg cells.[19]

T-Cell Function in Neonates

T cells form an important component of the adaptive immune system in the neonate. While overall T-cell counts are higher in cord blood of term newborns compared to adults' blood,[48] both CD4+ and CD8+ lymphocyte counts decrease with gestational age and are lower at birth in preterm compared to term infants.[14] This deficiency in T-cell subsets could possibly contribute to the increased susceptibility to infections in the preterm infant. Treg cells are interestingly higher in cord blood of preterm compared to term infants or adults.[14] Given their important role in immune suppression, quantitative deficiencies in Tregs may be important in inflammatory diseases in neonates. Indeed, in infants with necrotizing enterocolitis, ileal Treg to CD4+ T-cell ratio or Treg to CD8+ T-cell ratio is lower than that in age-matched control infants.[49]

Along with quantitative differences, neonatal T cells are also functionally distinct from adult cells. Cord-blood T cells have reduced ability to proliferate and synthesize cytokines such as IL-2, IFN-γ, IL-4, and GM-CSF. Studies also suggested a greater propensity of neonatal naive Th cells to differentiate toward the Th2 phenotype rather than Th1 in the presence of endogenous neonatal APCs. Multiple factors contribute to this skewed Th2 phenotype in neonates. Th1 responses are dependent on IL-12 production by APCs like DC that are decreased in numbers and are functionally immature in neonates compared to adults (described below). In addition, the neonatal CD4+ cells are epigenetically poised to increase production of Th2 cytokines, such as IL-4 and IL-13. This results from a hypomethylated state in a key regulator element, CNS-1, at the Th2 cytokine locus in neonatal CD4+ cells. Thus with antigenic stimulation there is immediate release of Th2 cytokines and development of

Th2 effector cells. In addition, as previously described, IL-4 elaborated from Th2 cells can act on the IL4Rα/IL13Rα heteroreceptor present on Th1 cells leading to Th1 cell apoptosis. The relative lack of Th1 differentiation from naive Th cells in neonates could thus result in impaired cell-mediated immunity.

While there is a bias toward a Th2 phenotype in neonatal CD4+ cells, an adult type Th1 response can be generated with the right inciting stimulus as demonstrated by responses in the human neonate to the mycobacterium bovis bacillus Calmette-Guerin (BCG). This is also observed in neonatal mouse studies, where altering the dose of the viral antigen or addition of costimulatory molecules leads to a deviation from the expected Th2 to an adult type Th1 response.[39] Thus although neonatal CD4+ cells are functionally distinct and manifest a Th2 skewed response, they have plasticity and retain the ability to mount an adult type Th1 response.

Compared with neonatal CD4+ cells, neonatal CD8+ cells have a normal frequency of precursors and are free of cytokine promoter modifications, such as the methylation changes that are commonly associated with neonatal CD4+ Th cells. Neonates show the presence of functional CD8+ cytotoxic T cells against congenital human CMV and Rous sarcoma virus. They also show the presence of functional memory CD8+ cells against congenital CMV. These results suggest that under certain conditions of stimulation, despite the absence of adequate CD4+ T-cell help, long-lived, functional memory CD8+ T cells can be generated by in utero CMV infection. This type of antiviral immunity in neonates persists partly because of persistent and prolonged viral secretion associated with some viral infections, such as CMV infection. This type of infection is likely to result in sustained and continuous stimulation of CD4+ and CMV-specific, long-lived memory CD8+ T cells in utero.

Studies have shown that neonatal T cells do not lack the ability to undergo proliferation and cytokine production when stimulated in a manner that does not require signaling through their TCR-CD3 complex. Studies comparing TCR-CD3-independent responses between adult and neonatal T cells have shown no differences in the ability of neonatal and adult T cells to synthesize IL-2 and undergo proliferation.

Other T-Cell Subgroups

Dendritic Cells. Efficient T-cell responses in vivo require the presence of mature and functional antigen-presenting cells (APCs). Dendritic cells (DC) are an important class of APCs stimulating naive T cells. DC populations have been grown from separated hematopoietic precursors, suggesting that there is a common granulocyte-monocyte-dendritic cell progenitor. Cells with a dendritic/macrophage morphology are present in the yolk sac, mesenchyme, and the liver at 4-6 weeks of age. DCs are detectable in skin by 6-7 weeks of gestation.

Human peripheral blood DCs include mainly two subgroups: (1) myeloid DCs (or mDCs) are $CD11c^+$ cells that express myeloid markers such as CD13, CD33, and CD11b; and (2) plasmacytoid DCs (or pDCs) are $CD11c^-$ and have a plasmacytoid morphology with well-developed rough endoplasmic reticulum and Golgi apparatus. Neonatal DCs have been shown to express low levels of costimulatory molecules, including CD40, CD80, and CD86, compared with adult DCs. The inability of neonatal DCs to deliver adequate levels of costimulatory signals to neonatal T cells is likely to be an important cause of neonatal tolerance, in addition to lack of adequate IL-12 production by APCs and IFN-γ by naive Th cells, preventing the differentiation of these cells into Th1 cells. In addition, the expression of MHC class II is also reduced on neonatal APCs. The reduced Th1 polarizing effect of fetal and neonatal APCs may help to reduce the risk of allo-immune reactions between the mother and the developing fetus. Similarly, recent studies indicate that while fetal DCs retain the ability to respond to immunostimulatory agents, at baseline they are programmed to suppress inflammation.[7] While this immunosuppresant tone in DCs may protect the neonate from a proinflammatory milieu on exposure to environmental antigens it also leaves the neonate susceptible to infections from viruses and other intracellular pathogens that need effective Th1 defenses for clearance.

Neonatal APCs also synthesize low levels of proinflammatory cytokines, including TNF, IL-1β, and IL-12, in response to LPS stimulation (i.e., TLR4 ligand) and in response to other TLR ligands. Upregulation of TLR4 and CD14 expression is not observed in neonatal APCs on LPS stimulation, and the expression of MyD88, a crucial adapter molecule in TLR signaling, is also reduced in neonatal APCs. TLR4 expression is further reduced on APCs derived from premature infants compared with full-term infants. It is conceivable that premature infants are more susceptible to infections because of impaired TLR expression.

Examples of additional complexity in this process have also been documented. Studies have shown a differential response to TLR ligands on neonatal APCs. TNF-α synthesis is reduced in neonatal monocytes that are stimulated with LPS, whereas this response seems to be normal when these same cells are stimulated with R-848, a ligand for TLR7 and TLR8. Neonatal APCs also show reduced IFN-γ responsiveness, which is associated with defects in phagocytosis. The ability of neonatal monocytes to differentiate into DCs is significantly modulated, as reflected by differences in the morphologic characteristics of cord blood–derived DCs compared with adult DCs. Taken together, studies so far implicate significant defects in TLR activation in neonatal monocyte/macrophage APCs.

Most studies related to neonatal DCs have been performed using in vitro–generated monocyte-derived DCs (mDCs). These cells have several defects relative to adult mDCs. They tend to be immature based on low-level expression of MHC class II and surface markers such as CD80, CD86, and CD40. Even on LPS stimulation, the phenotype of these cells remains immature as reflected by continued lack of upregulation of MHC and costimulatory molecules. The immaturity of neonatal DCs can be

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

attributed to impaired TLR signaling, a phenomenon also observed in monocyte/macrophage-derived APCs discussed earlier. Neonatal cord blood–derived DCs produce reduced levels of IL-12p70 and INF-β, and less INF-β-inducible genes like CXCL9 and CXCL10 in response to LPS. The defect in IL-12p70 production can, however, be rescued by providing exogenous IFN-γ to cultures. Although the NF-κB pathway appears to be preserved in neonatal DCs with TLR agonist stimulation, TRIF-dependent signaling is decreased. Consistent with the above-described defects associated with neonatal DCs, these cells also show significant reduction in the priming of allogeneic cord blood–derived T cells relative to adult DCs. Neonatal DCs apparently require additional mechanisms of activation to achieve the activation status of adult DCs. When activated, they seem to be relatively competent, however.

In addition to monocyte-derived myeloid DCs, studies have suggested the presence of another group of DCs called plasmacytoid DCs (pDCs) that are characterized on the basis of lack of CD11c (a marker for myeloid DCs) expression and presence of CD123. Cord blood contains a higher frequency of pDCs compared with peripheral blood. An enhanced ratio of pDC to mDC (3:1) is also observed in neonatal cord blood compared with adult blood (1:3). Similar to mDCs, neonatal pDCs also show functional defects. They produce reduced levels of IFN-α and IFN-β in response to TLR7 and TLR9 agonists. Although cord blood pDCs respond to R-848 by upregulating the expression of CD40, CD80, CD86, and MHC antigens, the extent of upregulation is less in these cells compared with adult pDCs. Likewise, R-848-stimulated TNF-α synthesis in cord blood pDCs is also reduced compared with adult pDCs. In adults, Flt3 ligand treatment of cells results in significant growth of cultured mDCs and pDCs derived from peripheral blood. Treatment of hematopoietic progenitors from human fetal tissues and cord blood with Flt3 ligand induces differentiation of these cells into pDCs that synthesize significant amounts of IFN-α/β in response to viral stimulation. Flt3 ligand could likely be used clinically to induce the expression of IFN in neonatal pDCs.

Cytotoxic T-Lymphocytes (CTLs). CTLs are important in host defense against intracellular infections, in allograft rejection, and tumor cell surveillance. CTLs utilize two well-established mechanisms for cell lysis, one involving release of extracellular mediators (such as the pore-forming perforin/granzyme system), and a second fas/fas ligand–dependent pathway that leads to target cell apoptosis.

CTL cytotoxicity is evident by 18 weeks of gestation but is far less efficient that adult cells even at term (<20% of adult CTL activity). Perforin expression in neonatal CTLs is about 30% of adult levels. CD28, which is a T-cell activation marker, is also expressed to significantly lower levels. Similar results are also observed in other assays; neonatal cells showed only 33% of lectin/mitogen-dependent cytotoxicity of adult cells. Circulating inhibitors such as α-fetoprotein and prostaglandins may also lead to lower CTL activity in neonates.

γδ T cells. The γδ T cells represent a distinct functional subset, with a majority lacking surface expression of both CD4 and CD8. These cells are detectable in the fetal thymus and liver at 6-8 weeks of gestation and comprise nearly 10% of the peripheral blood T cells at 16 weeks. Subsequently, the numbers decline gradually to reach about 3% at term. These cells are mainly present on skin and mucosal surfaces and closely interact with αβ T and B cells and dendritic cells. Although the exact functions of γδ T cells are not well understood, they can lyse target cells with the perforin/granzyme system like the cytotoxic T cells and can secrete cytokines like interferon (IFN)-γ and tumor necrosis factor (TNF)-α upon activation. Subsets of γδ T cells, including those present in the intestinal lamina propria and in the dermis, also produce IL-17.[46] The cytotoxicity of neonatal γδ T cells is significantly less than adults.

Fetal γδ T cells have a more diverse repertoire but a more limited junctional diversity than adults. This diversity is retained throughout the first year of life and then decreases gradually over the first decade of life. Overall, however, γδ T cells have a relatively restricted repertoire in comparison to the αβ T or B cells.

Natural Killer T Cells. Natural killer (NK) T cells are a subset of T cells that express the T-cell receptor chains in addition to a variety of NK cell markers.[24] In the presence of MHC-like molecule CD1d, these cells recognize both exogenous and endogenous lipid antigens. NK T cells are classified into two main subtypes: type I or invariant NK T cells and type II or diverse NK T cells. Type I NK T cells are less than 1% of T cells in cord blood[27] and express the conserved αβ TCR. Type II NK T cells are more abundant and express a more diverse TCR α and β chain repertoire.

Summary

Neonatal T cells are impaired in producing a robust Th1 response and produce less IFN-γ and TNF under conditions of physiologic stimulation, including in response to TCR-CD3 stimulation. Neonatal T cells are not intrinsically incapable of mature function, however. Adult-level cytokine production can be elicited in human neonatal T cells by increasing the magnitude of Th1-promoting costimulatory signals. In contrast, neonatal cytotoxic T lymphocytes are capable of generating long-lasting memory effectors against several viral infections, including CMV and Rous sarcoma virus. These findings could be exploited in the future to generate vaccines for the treatment of viral infections.

Qualitative differences in neonatal T cells and APCs compared with adult cells might contribute to these deficient T cell–mediated responses of neonates. Compared with adult T cells, neonatal T cells seem to require more costimulation to achieve robust Th1 responses in vitro and in vivo. Neonatal APCs might be poorly functional in vivo and normally unable to promote vigorous Th1 responses. If APC function is augmented or supplemented, however, mature Th1 responses can be promoted.

B Lymphocytes and Antibody Production

Overview of B-Cell Function and Phenotypic Appearance

B lymphocytes represent 5%-15% of circulating lymphocytes in the peripheral blood and are characterized by the presence of cell surface immunoglobulin. Most B lymphocytes simultaneously express endogenously synthesized IgM and IgD and various other cell surface receptors (Table 47.8). Relatively few cells express cell surface IgG, IgA, or IgE. Cell surface immunoglobulin is similar in structure to secreted antibody and consists of four polypeptide chains (two identical heavy chains and two identical light chains) joined by disulfide bonds. Surface immunoglobulin is inserted into the lymphocyte membrane at the constant region of the immunoglobulin molecule.

Immune responses to foreign antigens can be classified as primary or secondary (Table 47.9). The primary immune response results in an increase in the titer of antibody, which plateaus and then is catabolized. In the secondary immune response, the antibody titer is usually greater, appears more quickly, and consists almost entirely of IgG antibody (versus IgM in the primary immune response). Most important, after the primary response, the host acquires an immunologic memory of that foreign antigen by expanding the population of antigen-specific T cells and B cells. Memory B cells are prone to making IgG earlier and exhibit higher affinity antigen receptors. Although a few foreign antigens are considered T-cell independent (i.e., they do not require the help of T cells), the antibody response to most antigens requires the coordinated response of T cells, B cells, and APCs (B cells, macrophages, and DCs). Two kinds of signals are required to activate B cells. The first signal is provided by the interaction of the foreign antigen with surface immunoglobulin, and the second signal originates from Th cells, which are needed for amplification of the immune response.

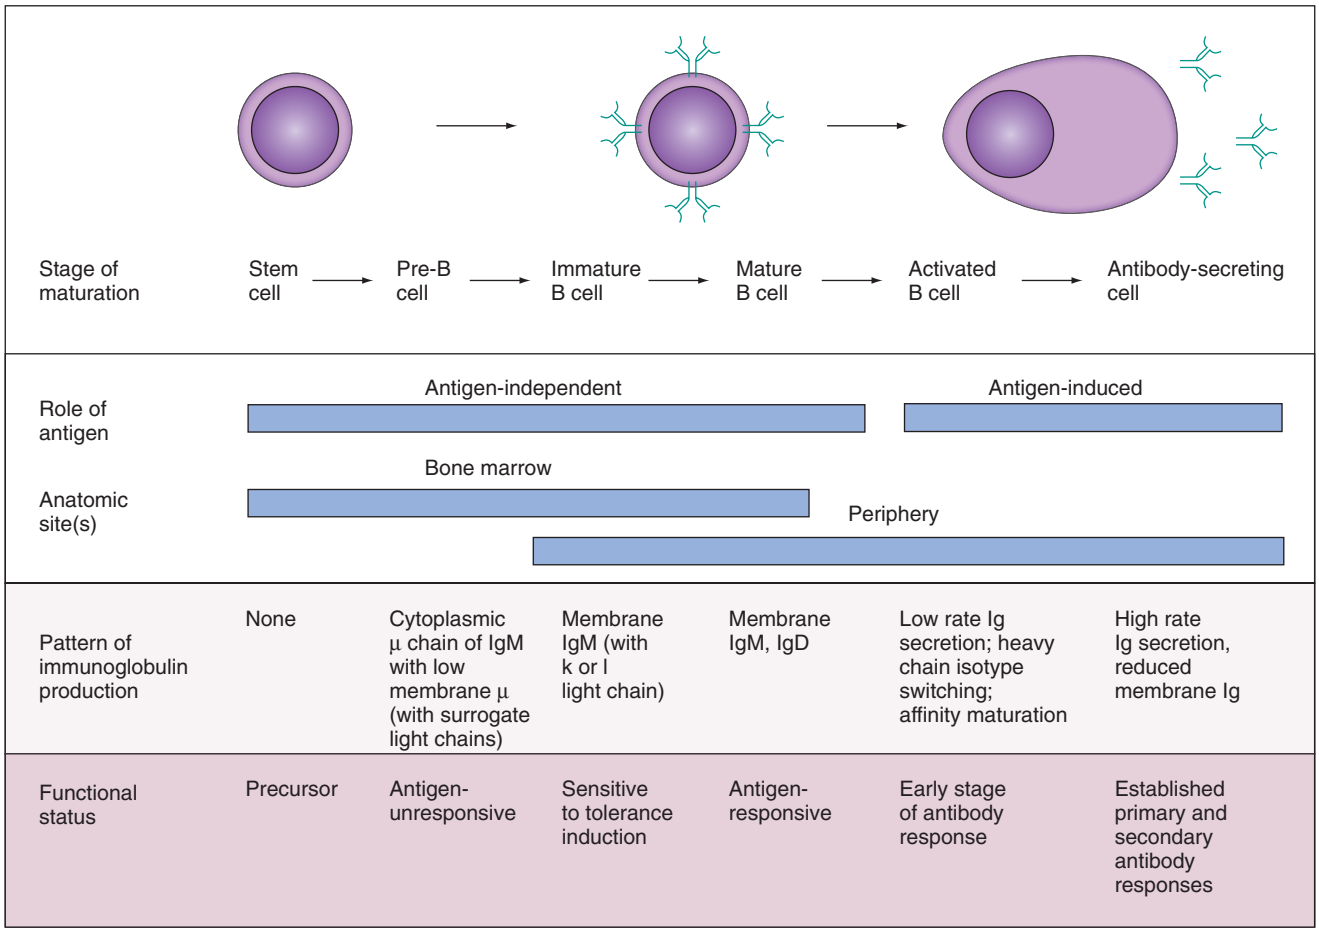
TABLE 47.8 Cluster-Designated Molecules Found on Human B Cells*

Antigen	Molecular Weight (kDa)	Comment
CD5	67	B-cell subset marker
CD10	100	Pre-B-cell marker
CD19	95	
CD20	95	
CD21	35	Complement receptor CR2 (C3b receptor)
CD22	140	
CD23	45	IgE low-affinity receptor on activated B cells
CD25	55	Interleukin-2 receptor (low-affinity) chain
CDw32	40	Fc receptor (FcR11)
CD35	220	Complement receptor CR1 (C3d receptor)
CD45	180-220	Leukocyte common antigen
CD45R	220, 205	Restricted leukocyte common antigen

*All human B cells express surface immunoglobulin, and most B cells express class I and class II major histocompatibility antigens.

B-Cell Development

B-cell maturation occurs in two stages. In the first stage, undifferentiated stem cells mature into cells identifiable as B lymphocytes; this is an antigen-independent phase that occurs in the fetal liver and bone marrow in humans. The second stage of lymphoid differentiation is antigen dependent; during this phase, B lymphocytes are transformed into plasma cells.



The first recognizable cell in the B-cell lineage is the pre–B cell (Fig. 47.8). This cell can be detected in fetal liver by 7-8 weeks of gestation and is characterized by cytoplasmic staining for the heavy chain of IgM (μ chain). As gestation progresses, pre–B cells can be detected in the fetal bone

TABLE 47.9 Features of Primary and Secondary Antibody Responses

Feature	Primary Response	Secondary Response
Lag after immunization	Usually 5-10 days	Usually 1-3 days
Peak response	Smaller	Larger
Antibody isotype	Usually IgM > IgG	Relative increase in IgG and, under certain circumstances, in IgA or IgE
Antibody affinity	Lower average affinity, more variable	Higher average affinity (“affinity maturation”)
Induced by	All immunogens	Only protein antigens
Required immunization	Relatively high doses of antigens, optimally with adjuvants	Low doses of antigens, with adjuvants usually not necessary

marrow. Clonal diversity is generated at the pre–B cell stage of development. Intact immunoglobulin genes are formed by the rearrangement of gene segments composing each heavy-chain and light-chain family. Genes encoding the human heavy chain are located on chromosome 14; the κ light-chain genes are located on chromosome 2, and the λ light-chain genes are located on chromosome 22. The heavy-chain family consists of several hundred variable genes (VH), a smaller number of diversity genes (DH), and six joining genes (JH). The JH genes are linked to constant genes, which encode for the heavy-chain classes. The light-chain genes are similarly constructed. Antibody-variable regions are generated from multiple smaller gene segments; the potential number of different antigen-combining sites is the product of the number of VH, DH, and JH genes. Antibody diversity is additionally increased by the random addition of nucleotides at the splice site junctions of V, D, and J segments and by point mutations in variable-region gene segments.

Pre–B cells give rise to immature B lymphocytes, which express surface IgM and complement receptors but no other immunoglobulin classes. These cells can be detected in the fetal liver at 8-9 weeks of gestation. Immature B lymphocytes have a unique functional property; when exposed to an antigen or ligand in the absence of activated T cells, they are rendered tolerant to additional stimulation with the same antigen; this process, called clonal anergy, accounts for the tolerance of B lymphocytes to self-antigens. Immunoglobulin class diversity occurs by a process of isotype switching, during which cells that express surface IgM with a particular specificity generate daughter cells that express another immunoglobulin class (Fig. 47.9). Cells that express other membrane immunoglobulin isotypes (IgG, IgA) can be seen by the 12th week of gestation. These other immunoglobulin classes almost always appear on cells that express membrane IgM concurrently.

At a later stage (the mature B-cell stage), cells express membrane-bound IgG or IgA in association with membrane IgM and IgD. Cells that express surface IgD are incapable of being deactivated by antigen. In cells that express three heavy-chain classes, all three isotypes exhibit the same specificity and express the same variable-region genes. During the antigen-dependent phase of B-lymphocyte differentiation, most B lymphocytes express only a single isotype, and plasma cells do not express surface immunoglobulin (see Fig. 47.8). By the 15th week of gestation, a normal fetus has levels of circulating B lymphocytes that are equal to or higher than the levels of adults. Fetal

• **Fig. 47.9** Development of B-cell surface immunoglobulin expression. Immunoglobulin class diversity occurs by a process of isotype switching. Immature B lymphocytes express surface IgM, but as cells mature, surface IgM and IgD in association with IgA or IgG are expressed. During the antigen-dependent phase of B-cell maturation, B cells express a single immunoglobulin isotype, and mature plasma cells are devoid of surface immunoglobulin.

B lymphocytes can be shown in highest proportions in the spleen (30%), blood (35%), and lymph nodes (13%).

B-Cell Activation by B-Cell Antigen Receptors and Coreceptors

The B-cell receptor (BCR) serves multiple functions on B cells that can differ substantially through various stages of their development. Proliferative expansion and differentiation are triggered through the pre-BCR and BCR complexes in pre–B cells and mature resting cells. At the opposite extreme, apoptosis is triggered in immature B cells on excessive clustering of newly expressed BCRs as a mechanism to eliminate autoreactive membrane IgM-expressing B cells. Strong BCR ligation in mature B cells has also been shown to inhibit V(D)J recombination at the membrane immunoglobulin locus, whereas weak ligation promotes recombination, presumably to generate higher affinity antibodies. Finally, the BCR serves as a specific receptor to internalize antigen efficiently for processing and peptide presentation to Th cells. The B cell has devised a complex network of BCR signaling cascades to perform such a diverse array of functions.

Role of Cytokines in B-Cell Function

The cytokines IL-1, IL-2, and IL-4 affect B-cell and T-cell function. IL-2 stimulates the growth and differentiation of B cells. The ability of IL-4 to induce class switching in B cells has been documented earlier. This section deals in more detail with other cytokines having more specific effects on B cells.

IL-5 is produced by activated T cells. On B cells, IL-5 functions as a late-acting B-cell differentiation factor, playing a major role in the production of IgA. IL-5 is perhaps better known, however, for its effect on eosinophil differentiation. It not only induces the generation of eosinophils from human bone marrow precursors but also upregulates expression of CD11b on human eosinophils and activates IgA-induced eosinophil degranulation. T-cell production of this cytokine is stimulated by parasitic infections.

IL-6 is a pleiotropic cytokine produced by many cell types, including T cells. Its effect on B cells is to promote growth and facilitate maturation of the B cells, causing immunoglobulin secretion. Resting B cells do not express the IL-6 receptor but are induced to express the IL-6 receptor after activation.

IL-7 has been described previously in the T-cell section, but this cytokine, which is secreted by stromal cells, has a great effect on the development of progenitor B cells. IL-10 also affects T cells and B cells, acting synergistically with other cytokines on the growth of hematopoietic lineages, including those giving rise to B cells. Antibody depletion of IL-10 in vivo results in a reduced IgM and IgA response with an increase in IgG2 and a depletion of certain B-cell subsets.

IL-13 is predominantly expressed in activated Th2 cells and regulates human B-cell and monocyte activity. It acts as a costimulant with CD40 receptor engagement of human B cells. Interaction between CD40 and CD40 ligand in the presence of IL-13 induces isotype switching and IgE synthesis, as does IL-4.

IL-14 is believed to play a role in the development of B-cell memory. IL-14 enhances the proliferation of activated B cells and inhibits the synthesis of immunoglobulin. It is produced by follicular DCs and activated T cells. IL-14

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

expression in reactive lymph nodes suggests that, during a secondary immune response, surface IgD B cells migrating through the lymph node encounter antigen, become activated, and express IL-14 receptor; after binding of IL-14, the increased Bcl-2 expression prevents apoptosis and permits B-cell memory development.

B-Cell Responses in Neonates

Several distinctions between neonatal and adult splenic B cells have been identified. Neonatal B cells express reduced levels of costimulatory molecules CD40, CD80, and CD86, which results in defective T-cell responses via CD40 ligand (CD40L) and IL-10. Marginal zone B cells derived from spleens of neonates tend to express reduced levels of CD21. In addition, expression of a critical costimulatory receptor, TACI, is impaired in neonatal B cells, in particular in premature infants.

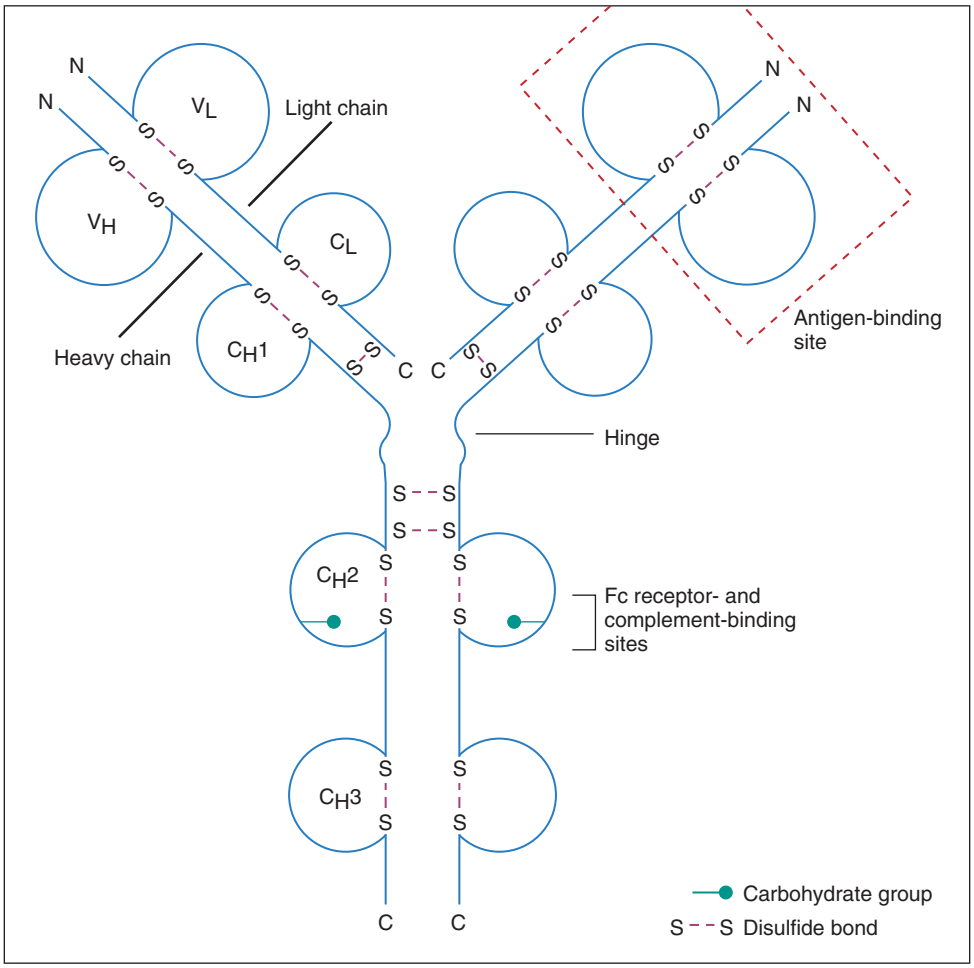
Although these cell-intrinsic factors contribute significantly to defects in antibody responses in neonates, B-cell responses in neonates are also affected by external factors. Maternal-derived antibodies can bind to vaccine antigens and inhibit neonatal B cells from recognizing them. Additionally, serum complement levels, in particular C3 levels, in neonates are reduced; this results in reduction in the formation of antigen-antibody complexes. The number of marginal zone macrophages in neonate spleens is also reduced compared with adults. These cells play an essential role in trapping antigens. Defects are also observed in the maturation of follicular DCs in neonates. Follicular DCs are crucial for attracting B cells and provide signals that result in somatic hypermutation and class switching of antibodies.

Additional defects include a lack of prolonged antibody response; this is due partly to impairment in the establishment and maintenance of antibody-secreting plasma cells in the bone marrow of neonates. Although plasma cells in neonates do migrate to the bone marrow, they are impaired in their ability to thrive as long-lasting cells largely because of lack of survival and differentiation signals from bone marrow–derived stromal elements. Finally, studies have also shown that in some instances administration of vaccines to neonates preferentially leads to the generation of memory B cells rather than plasma cells. This situation has been largely attributed to reduced overall B-cell receptor affinity of neonatal naive B cells for antigens resulting in an overall reduction in the strength of the intracellular signal, which may preferentially lead to the generation of memory B cells rather than plasma cells. In neonates, a significant number of B-cell intrinsic factors and microenvironmental factors cooperate to regulate the development and maintenance of antibody-producing plasma cells and the preferential generation of memory B cells.

CD5-Expressing B Cells

B cells with surface expression of CD5, which is a T-cell antigen, may represent a functionally and ontogenically distinct subset. Some believe that CD5 positivity defines a so-called "B-1" subset of cells, distinct from the conventional adult "B2" population by virtue of their earlier appearance in ontogeny, capacity for bone marrow–independent self-renewal, and constitutively expressing signal transducer and activator of transcription-3 (STAT3). B-1 cells express the B cell–lineage antigens CD19 and CD45R, although CD45R is present at lower levels on B-1 cells than on B-2 cells. B-1 cells in the peritoneal and pleural cavities can be identified by their unusual CD11b+ $sIgM^{hi}$ $sIgD^{low}$ phenotype and can be further subdivided on the basis of differential expression of the cell-surface antigen CD5, into CD5+ CD11b+ $sIgM^{hi}$ $sIgD^{low}$ B-1a cells and CD5- CD11b+ $sIgM^{hi}$ $sIgD^{low}$ B-1b cells.

These cells are the predominant B-cell type during fetal life and have a distinctive anatomic localization in the fetal spleen and the peritoneal cavity. They appear in the spleen at 15 weeks and are seen in the lymph node primary follicles at about 17 weeks of gestation. In adults, CD5 expression can be found on about 25%-35% of total B cells and 1%-7% of all the peripheral blood mononuclear cells. In contrast, CD5+ B cells represent approximately 90% of the total cord blood B cells. This number decreases to 75%-80% during infancy and reaches adult levels only by late adolescence.



The exact function of B-1 cells in the fetus is still unclear. The functional characteristics of B-1 cells such as the unique localization, broad polyspecific specificities, and a restricted Ig repertoire have been considered to indicate a role of these cells in the innate rather than in adaptive immunity. Unlike follicular B-2 cells that respond to protein antigens, and with T-cell help undergo immunoglobulin heavy chain class-switching and affinity maturation, B-1 cells respond mainly to T cell–independent immunogens that include carbohydrate antigens. Observations indicate that the two types of B-1 cell, B-1a and B-1b, show functional differences during the immune response.[4] B-1a cells spontaneously secrete IgM, which provides a first line of defense against certain encapsulated bacteria, such as *Streptococcus pneumoniae*, whereas antibody production by B-1b cells is induced and has a role in the ultimate clearance of the pathogen and in providing long-term protection.

Immunoglobulin Structure and Function

Specific antibody may be produced in response to direct microbial exposure or through immunization by an almost infinite spectrum of antigens (e.g., proteins, carbohydrates, bacteria, viruses, fungi, and drugs). Antibodies are synthesized and secreted by B lymphocyte–derived plasma cells that reside in the lymph nodes, spleen, mucosal linings of the gastrointestinal and respiratory tracts, and bone marrow.

Antibodies comprise a unique family of glycoproteins called immunoglobulin, which in humans consists of five major classes: IgG, IgA, IgM, IgD, and IgE. The basic structure of the IgG molecule is depicted in Fig. 47.10. The IgG molecule is composed of four polypeptide chains—two heavy chains and two light chains—held together by covalent disulfide bonds and noncovalent forces. In a given IgG molecule, the two heavy chains and two light chains have

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• **Fig. 47.10** Schematic diagram of an immunoglobulin molecule. In this drawing of an IgG molecule, the antigen-binding sites are formed by the juxtaposition of light-chain (V_L) and heavy-chain (V_H) variable domains. The locations of complement-binding and Fc receptor-binding sites within the heavy-chain constant (C_H) regions are approximations. S-S refers to intrachain and interchain disulfide bonds; N and C refer to amino and carboxyl termini of the polypeptide chains. (From Abbas AK, et al., eds. *Cellular and molecular immunology*. 2nd ed. Philadelphia: Saunders; 1994, with permission.)

identical amino acid sequences. The different immunoglobulin classes are distinguished by antigenic and amino acid sequence differences in their heavy chains. Some of the immunoglobulin classes are composed of subclasses; IgG has four subclasses—IgG1, IgG2, IgG3, and IgG4—that arise from antigenic differences in the heavy chains. In addition to these differences between the immunoglobulin classes and subclasses, there are antigenic and amino acid sequence variations in the amino-terminal portions of the heavy chains and light chains in the so-called variable regions. The structural variability in this region permits different antibody molecules to react specifically with different antigens. In contrast, the amino acid sequences of the carboxyl-terminal portions of the heavy (Fc region) and light chains do not vary between molecules of the same immunoglobulin class or subclass; these are called the constant regions. The variable regions of immunoglobulin molecules confer the antigen-binding specificity, and the constant regions differ among the various immunoglobulin classes; these regions' biologic properties and functions vary as well. Only IgM and IgG activate the complement system through the classic pathway, and only IgG can be actively transported across the placenta.

The chemical characteristics and biologic properties of the immunoglobulin classes are summarized in Table 47.10. IgG is the major immunoglobulin in the serum and interstitial fluid and has a long half-life of approximately 21 days. It is responsible for immunity to bacteria (particularly gram-positive bacteria), bacterial toxins, and viral agents. IgG antibodies can neutralize viruses and toxins and facilitate the phagocytosis and destruction of bacteria and other particles to which they are bound. IgG can also activate the complement pathway and amplify the inflammatory response by increasing leukocyte chemotaxis and complement-mediated opsonization.

IgA is the second-most abundant immunoglobulin in serum, but it is the predominant one in the gastrointestinal and respiratory tracts and in human colostrum and breast milk. In secretions, IgA occurs as a dimer joined by a J chain and bears an additional polypeptide chain, called the

Mucosal immunity	+	+++	+	0	++

*Secretory IgA.
0-+++ Indicates increasing ability to protect mucosal surfaces from pathogen invasion.

secretory component. This moiety endows the molecule with resistance against degradation by proteolytic enzymes. Secretory IgA is uniquely suited for functioning in the secretions of the respiratory and gastrointestinal tracts. IgA provides local mucosal immunity against viruses and limits bacterial overgrowth on mucosal surfaces. It also may limit absorption of antigenic dietary proteins. IgA does not activate the classic complement pathway but can activate the alternative pathway.

IgM antibodies exist in serum primarily as pentamers joined together by a J chain. IgM provides protection against blood-borne infection. It occurs only in small quantities in interstitial fluids and secretions. IgM antibodies are potent bacterial agglutinins and activate the classic complement pathway. Through activation of the complement system, IgM antibodies cause deposition of C3b on bacterial cell surfaces and facilitate phagocytosis. There are no phagocytosis-promoting receptors for IgM. Most serum antibodies to gram-negative bacteria are of the IgM type. Intrauterine and neonatal infections elicit the formation of predominantly IgM antibodies. Because IgM does not cross the placenta, the presence of specific IgM antibody in cord blood to spirochetes, rubella, CMV, or other microorganisms can be taken as reliable evidence of intrauterine infection with these agents. The absence of IgM does not exclude the possibility of congenital intrauterine infection, however.

IgE antibodies are present in extremely small quantities in serum and secretions. These antibodies play a major role in allergic reactions of the immediate hypersensitivity type. IgE antibodies bind to the cell membranes of basophils (mast cells) by a receptor for the carboxyl-terminal portion of the heavy chain. Binding of antigen (allergen) to the IgE fixed to the basophil results in the liberation of histamine, leukotrienes, and other pharmacologic mediators of immediate allergic reactions. IgD, which occurs in low concentration in serum, is present on the surface of B lymphocytes. The role of circulating IgD is unclear.

Antibody Production in Fetuses and Neonates

The fetus acquires the ability to produce serum immunoglobulins early in gestation. In vitro studies have shown the ability of fetal cells to produce antibody (IgM) by 8 weeks' gestation. IgG synthesis occur slightly later, and IgA synthesis begins at approximately 30 weeks' gestation. For numerous reasons (i.e., the sterile environment in utero, the inability of the fetus to respond to certain kinds of antibody, T-cell suppression of B-cell differentiation), the fetus makes little antibody before the time of birth. As discussed later, at the time of birth, most of the circulating antibodies are IgG antibodies that have been transported across the placenta from the maternal circulation. Low levels of "fetal" IgM (<10% of adult levels) are present at term gestation and reach adult levels by 1-2 years of age. The concentration of IgG decreases postnatally (because of the catabolism of maternal IgG) and reaches a nadir (physiologic hypogammaglobulinemia) at approximately 3-4 months of age. Adult concentrations of IgG are reached by 4-6 years of age, and adult levels of IgA are attained near puberty (Table 47.11).

Innate Lymphoid System

The innate lymphoid cells (ILC) include cytotoxic natural killer (NK) cells and noncytotoxic ILC populations.[2] These cells are characterized by a classic lymphoid cell morphology, but unlike adaptive T and B cells, they do not show antigen specificity and function as a part of the innate immune system.

Natural Killer Cells

Phenotypic and Functional Characteristics

Generally, NK cells are defined by their large granular morphology. These cells make up almost 15% of peripheral blood lymphocytes in adults and are found in several tissues, including liver, peritoneal cavity, placenta, and

TABLE 47.11 Normal Values for Immunoglobulins at Various Ages

Age	IgG (mg/dL)	IgA (mg/dL)	IgM (mg/dL)
Newborn	600-1670	0-5	5-15
1-3 mo	218-610	20-53	11-51
4-6 mo	228-636	27-72	25-60
7-9 mo	292-816	27-73	12-124
10-18 mo	383-1070	27-169	28-113
2 y	423-1184	35-222	32-131
3 y	477-1334	40-251	28-113
4-5 y	540-1500	48-336	20-106
6-8 y	571-1700	52-535	28-112
14 y	570-1570	86-544	33-135
Adult	635-1775	106-668	37-154

From Buckley RH, et al. Serum immunoglobulins, I: levels in normal children and in uncomplicated childhood allergy. *Pediatrics.* 1968;41:600.

bone marrow. Human NK cells are defined by the expression of cell surface proteins CD56 and CD16.[25] NK cells share some T-cell markers but are not affected in many natural/experimental disruptions of the T-cell system. It is conceivable that the two lineages derive from a common progenitor. Morphologically, NK cells display characteristic surface markers including the CD56/neural cell adhesion molecule and CD16/Fcγ receptor IIIa (FcγRIIIa), a low affinity IgG receptor. They also express CD2, LFA-1, and cytokine receptors such as IL-2$R_{\beta\gamma c}$, IL-12R, IFN-γR, and IL-15R_{α}.

NK cells can be detected as early as 6 weeks of gestation, and the number then increases progressively until birth. In cord blood, 10%-15% of all lymphocytes are NK cells, which is comparable to adult peripheral blood. The phenotype of fetal NK cells, however, is different from that of adults' cells. NK cell numbers are highest in cord blood and in the newborn period and decline through childhood.[25] Fifty to eighty percent fetal NK cells express CD3γ, ε, λ, and σ proteins, unlike a much smaller number in term infants or in adults where only CD3σ is expressed. On the other hand, only 30%-50% of fetal NK cells express CD16 (compared with more than 90% of neonatal and adult NK cells). Similarly, CD56 and CD57 are expressed poorly on fetal or neonatal NK cells compared to nearly 50% positivity in adult NK cells.

NK cells recognize viral-infected and tumor cells by the absence or decreased expression of MHC class I molecules on the cell surface. Their MHC-unrestricted killing is mediated by perforin/granzyme apoptotic pathways. The other mechanism of cytolysis is antibody-dependent cell-mediated cytotoxicity (ADCC), where target cell-bound IgG1 or IgG3 triggers the FcγRIIIa receptor on the NK cell. NK cells are also believed to play a key role in maintaining immunologic tolerance at the maternal–fetal interface.

Fetal NK cells have a significantly lower cytolytic activity (including ADCC) against tumor cell target cell lines than adults, but it increases with gestational age parallel to increasing expression of CD56 and CD16. However, even at term, the cytolytic activity is only 50%-80% of adult levels.

NK cells should not be confused with the natural killer T cells, a heterogeneous group of T cells that are discussed elsewhere in the chapter, which express an αβ T-cell receptor along with some NK cell markers. Many of these cells recognize the nonpolymorphic CD1d molecule, an antigen-presenting molecule that binds self- and foreign lipids and glycolipids. NK T cells constitute only 0.2% of all peripheral blood T cells. These cells play an important role in mucosal immunity and in the pathogenesis of inflammatory/allergic conditions; the role during fetal life remains unclear.

Noncytotoxic ILC

Phenotypic and Functional Characteristics

Noncytotoxic ILCs and NK cells are thought to be derived from a common lymphoid progenitor that then differentiates into committed precursors. Recent studies have confirmed that NK cells and noncytotoxic ILCs belong to distinct cell lineages.[13,22] Noncytotoxic ILCs are characterized by a classic lymphoid cell morphology. While these cells express IL2 receptor-α and IL7 receptor-α, unlike adaptive T and B cells, they do not exhibit antigen specificity. ILCs are divided into 3 groups: group 1 ILCs (ILC1s), group 2 ILCs (ILC2s), and group 3 ILCs (ILC3s). This grouping is based on the differential requirement for specific transcription factors during development by these cells, their expression of specific cytokines, and their distinct effector functions.

Although the three ILC subsets demonstrate remarkable similarity with the T-helper cell subsets, Th1, Th2, and Th17 in relation to cytokine expression and effector function,[2] they can function in the absence of antigen specificity. ILC1s express the T-bet transcription factor and produce Th1-associated cytokines that protect against intracellular bacteria and parasites. ILC2s express GATA-binding protein 3 transcription factor, produce Th2-associated cytokines (including IL-4, IL-5, IL-9, and IL-13) and mediate type 2 inflammation seen during tissue repair and allergic disorders. ILC3s express the RAR-related orphan receptor-γT transcription factor. These cells have a cytokine profile similar to Th17 cells and produce IL-17A, IL-17F, IL-22, GM-CSF, and TNF. ILC3s are further subdivided into two distinct subsets based on their expression of the chemokine receptor CCR6.

While little is known about the role of ILCs in the fetus and neonate, this is currently an area of active investigation. ILC2 cells are present in cord blood and may be present in higher proportions in male than in female neonates. In a murine model of gastroschisis, organs exposed to amniotic

fluid were shown to contain high numbers of ILC2 and ILC3.[18] In another recent study, ILC3s were identified as the source of increased IL-17 levels seen in patients with preeclampsia and gestational diabetes.[3]

Summary

The ability to mount cell-mediated or antibody-mediated immune responses to specific antigens is acquired sequentially during the course of embryonic development. Early in gestation, fetuses can respond to certain antigens, whereas other antigens elicit antibody production or cell-mediated immune reactions only after birth. The well-known inability of children younger than 18 months of age to induce antibodies to polysaccharides from Pneumococcus and Haemophilus organisms is a clinically important example of the sequential acquisition of antigen-specific immunocompetence in humans.

Antibody responses of fetuses and premature and full-term newborns differ from responses of children and adults. Fetuses and newborns do not respond to some antigens (e.g., pneumococcal polysaccharide), and the antibody responses to other antigens (e.g., rubella, CMV, Toxoplasma) are predominantly of the IgM type. T lymphocytes are less experienced in neonates and may tend to suppress rather than stimulate B-cell differentiation. In addition, B cells of newborns differentiate predominantly into IgM-secreting plasma cells, whereas activated adult B cells produce IgG-secreting and IgA-secreting plasma cells as well. The adult pattern of B-cell differentiation develops during the first year of life.

Passive Immunity

Passive immunity is the acquisition of specific antibody or sensitized lymphocytes from another individual, and it represents a means by which specific immunity can be acquired without previous exposure to antigen or the mounting of a specific immune response. Such immunity is transient but nonetheless may provide sufficient antimicrobial protection during a vulnerable period of life. The development of an antibody response to an antigen seen for the first time requires 7-14 days. Active antibody-mediated immunity is of little value during the crucial first few days of an infection with a new microorganism. The presence of circulating specific antibody to that organism (i.e., passive immunity) permits the mobilization of multiple host defense mechanisms (e.g., complement system, neutrophils) to eliminate the invading microorganism and limit its colonization. In humans, the major avenues for the acquisition of passive immunity are the transfer of IgG across the placenta and the transfer of secretory IgA through colostrum and breast milk.

Placental Transport of Antibodies

Although B lymphocytes are present in a fetus by the end of the first trimester, there is little active fetal immunoglobulin production, because this process depends on exposure to antigens. Serum immunoglobulin levels in fetuses are extremely low until 20-22 weeks of gestation, at which time an accelerated active transport of IgG across the placenta begins. Only maternal IgG is transported. The specificity of this transport process is due to the presence of specific placental receptors for the heavy chain (Fc region) of the IgG molecule. The transport of IgG is an active placental process. Prematurely delivered infants have lower IgG levels than infants delivered at term. Fetal IgG concentrations are estimated to be only 5%-10% of the maternal levels at 17-22 weeks of gestation. IgG acquisition by the fetus occurs predominantly during the last 4 weeks of pregnancy, and neonatal IgG concentrations may exceed maternal levels by 20%-30% at full term.[38] Infants who are small for gestational age have lower IgG levels than infants who are an appropriate size at any gestational age. The placental dysfunction that reduces the nutrient supply to these poorly growing infants may also limit transfer of IgG. This phenomenon is manifested further by the progressive decrease in IgG transport after 44 weeks of gestation, a period when the placenta is known to become increasingly dysfunctional.

Elevated levels of IgM or IgA in cord blood usually indicate that the infant has been exposed to antigen in utero and has synthesized antibody itself. Congenital infections with syphilis and rubella characteristically produce elevation of the cord blood IgM concentration, and specific fetal antibody of the IgM type directed against the infecting agent can be detected. Elevated levels of IgM and IgA also may be found if maternal-to-fetal transplacental bleeding has occurred.

Immunologic Properties of Human Breast Milk

Maternal transfer of immunity to the newborn infant is also possible through breast milk. Table 47.12 lists specific and nonspecific protective factors that are transferred to the neonate by breast milk. Although all immunoglobulin classes can be detected in colostrum, secretory IgA constitutes most of the immunoglobulin in human breast milk.[10] Secretory IgA consists of two "serum" IgA subunits, a J chain and a secretory component, which render it resistant to digestion by trypsin and pepsin and to hydrolysis by gastric acid. There is no evidence that immunoglobulins present in breast milk enter the systemic circulation of the human neonate.

The levels of IgA, IgM, and IgG have been studied serially in milk. The IgG concentration is relatively constant during the first 180 days of lactation, whereas IgM and IgA are highest in colostrum, decrease during the first 5 days of lactation, and remain relatively constant during the next 175 days. Breast milk contains antibodies to a broad spectrum of enteric bacteria and viruses (e.g., poliovirus, echovirus, coxsackievirus), and the antibody titers to these agents decrease in parallel to the decrease in concentrations of IgA in the milk.

TABLE 47.12 Immunologically and Pharmacologically Active Components and Hormones Found in Human Colostrum and Milk

Soluble	Cellular	Hormones and Hormone-like Substances
• Immunologically specific • Immunoglobulin: secretory IgA (11S), 7S IgA, IgG, IgM • IgE, IgD, secretory component • T-cell products • Histocompatibility antigens • Nonspecific factors • Complement • Chemotactic factors • Properdin • Interferon • α-fetoprotein • Bifidus factor • Antistaphylococcal factors • Antiadherence substances • Epidermal growth factor • Folate uptake enhancer • Antiviral factors • Migration inhibition factor • Carrier proteins • Lactoferrin • Transferrin • Vitamin B_{12}-binding protein • Corticoid-binding protein • Enzymes • Lysozyme • Lipoprotein lipase • Leukocyte enzymes	• Immunologically specific • T lymphocytes • B lymphocytes • Accessory cells • Neutrophils • Macrophages • Epithelial cells	• Epidermal growth factor • Prostaglandins • Relaxin • Neurotensin • Somatostatin • Bombesin • Gonadotropins • Ovarian steroids • Thyroid-releasing hormone • Thyroid-stimulating hormone • Thyroxine and triiodothyronine • Adrenocorticotropic hormone • Corticosteroids • Prolactin • Erythropoietin • Insulin

From Ogra PL, et al. Human breast milk. In: Remington JS, et al., eds. *Infectious diseases of the fetus and newborn infant.* 4th ed. Philadelphia: Saunders; 1995, p. 114.

Most immunoglobulins present in human breast milk are believed to be produced by plasma cells located in the breast itself, and very little milk immunoglobulin is derived from maternal serum immunoglobulins. Milk antibodies are directed predominantly against enteric bacterial and viral antigens; the concentration of such antibodies is much higher in colostrum than in maternal serum. The antibody composition of breast milk compensates partly for the deficiency of antibodies directed against enteric antigens in placentally transferred IgG. This unique spectrum of antibody specificity is achieved by the "homing" of B lymphocytes, sensitized in the mother's gastrointestinal tract, to her mammary glands. B cells stimulated by enteric bacterial or viral antigens in the Peyer patches of the small intestine migrate to the mucosal linings of the lactating mammary gland, where they differentiate into plasma cells and secrete their antibodies. Antigens introduced into the gastrointestinal tract stimulate the development of antibodies in breast milk; however, antibodies to these antigens do not develop in the serum. A mother transfers antibodies specific for microbial agents present in her own gastrointestinal tract to her infant through breast milk. As the neonate is being freshly colonized by primarily maternal flora, these antibodies limit bacterial growth in the gastrointestinal tract and protect against overgrowth.

The cellular components of human breast milk consist of macrophages, T and B lymphocytes, neutrophils, and epithelial cells.[10] The cellular content of colostrum or early milk is higher than that of later milk and varies greatly among women. Neutrophils are present in significant numbers early in lactation, and their presence may be related to breast engorgement during the initial days of lactation. Although the function of the breast milk neutrophil is unclear, its presence does not imply infection. Epithelial cells occasionally present in milk may originate from the skin of the nipple.

Breast milk macrophages are mononuclear phagocytic cells that constitute approximately 80% of the leukocytes in milk. This is an active phagocytic cell that contains large amounts of intracytoplasmic lipid and IgA; bears cell surface receptors for IgG and C3b; and synthesizes several important host resistance factors, including lysozyme, C3 and C4 complement components, and lactoferrin. Milk macrophages are capable of phagocytizing and killing gram-positive and gram-negative bacteria and apparently interact with the lymphocytes present in breast milk.

The host defense factors that the breast milk macrophage synthesizes provide important nonspecific antimicrobial protection for neonates. Lysozyme is capable of lysing the cell walls of many bacteria. This enzyme is synthesized by the milk macrophage, and its concentration in human milk is 300 times that found in cow milk. It is stable in an acid environment comparable with that of the gastric contents. Lactoferrin is synthesized by the milk macrophage, and its concentration in breast milk is higher than in any other body fluid. Lactoferrin antimicrobial activity derives from its ability to chelate iron, depriving bacteria of a cofactor important for their growth. The growth of Staphylococcus organisms and *E. coli* is limited by lactoferrin.

The C3 and C4 complement components are also actively synthesized by breast macrophages. The function of these proteins in milk is unclear, because there is little IgG and IgM or the early complement components, C1 and C2, which are necessary for activation of C3 to its biologically active forms. IgA may activate C3 through the alternative pathway; however, it is found in highest concentrations in the breast macrophage itself. This macrophage-associated IgA is not synthesized but rather is ingested by the macrophage. Viable in situ macrophages have been shown to release this IgA slowly, and this has led to the hypothesis that the breast milk macrophage may represent a vehicle for immunoglobulin transport down the neonate's gastrointestinal tract.

Viable T and B lymphocytes are present in human breast milk. T lymphocytes represent 50% of the milk lymphocytes early in lactation, declining to less than 20% as lactation progresses. The spectrum of responses of breast milk T cells differs from that of peripheral blood T cells from the same donor. Milk T cells are often unresponsive to C. albicans antigen, whereas peripheral blood T cells from the same donor are highly reactive. In contrast, milk T cells respond well to the K1 capsular antigen of *E. coli*, whereas peripheral blood lymphocytes exhibit minimal or no response to K1. This phenomenon may be related to the previously described homing of lymphocytes sensitized in the gastrointestinal tract to mammary glands.

The transfer of cell-mediated immunity from tuberculin-sensitive mothers to their breastfed infants has been reported. If these reports are substantiated, this form of passive transfer of cellular immunity could be of major clinical significance. It is unlikely that intact T lymphocytes are passing from the mother's milk across the mucous membranes of the infant's gastrointestinal tract. A soluble T-cell growth factor or lymphokine more likely is involved. The B lymphocytes present in milk have IgG, IgA, IgM, and IgD on their surfaces. These cells synthesize IgA almost exclusively, however. The contribution of B cells as passive immune effectors in breast milk is as yet unclear.

Summary

Maternal transfer of IgG antibodies across the placenta provides a newborn with a measure of immune protection. Antibodies to viral agents, diphtheria, and tetanus antitoxins, which are usually of the IgG class, are efficiently transported across the placenta and attain protective levels in the fetus. In contrast, antibodies to agents that evoke primarily IgA or IgM antibody responses are transported poorly or not at all, leaving the neonate unprotected against those organisms. An infant cannot be protected against agents to which the mother has not made significant amounts of antibody. Breast milk constituents may interact with the neonate's immune system in ways other than those already mentioned. A significant increase in the secretory IgA content of nasal and salivary secretions has been observed in breast-fed versus formula-fed newborns during the first few days of life. It is postulated that this increase may reflect the influence of a soluble factor in milk that acts to stimulate the mucosal immune system of breast-fed infants. Factors that enhance IgA synthesis by B cells and promote epithelial cell growth are also secreted by milk macrophages.

Evaluation of Host Defenses in Neonates

Some disorders of immunologic function may become clinically apparent in the neonatal period or first year of life. Because of differences in the developmental status of the newborn's host defense mechanisms and the lack of vast exposure to antigens, evaluation of the function of host defense mechanisms in the infant is different from the evaluation performed for older children and adults. Infants who have experienced two or more significant bacterial or fungal infections should be suspected of having a defect in host defense mechanisms. Patients with unusual infections (e.g., from Pneumocystis jiroveci) or infections that respond incompletely to therapy and recur are also suspect. Growth failure, chronic diarrhea, chronic dermatitis, hepatosplenomegaly, and recurrent abscesses commonly occur in infants with immunologic deficiency. Primary immunodeficiency disorders are relatively uncommon, however, and numerous other predisposing conditions should be considered that may be predisposing an infant to multiple infectious episodes.

In evaluating a patient for a possible host defense mechanism defect, natural (cellular and humoral components) and acquired (cellular and humoral components) immune mechanisms should be considered and investigated. The evaluation should be divided into initial screening tests and definitive tests that allow one to establish a specific diagnosis (Box 47.2).

• BOX 47.2 Tests to Evaluate Neonatal Host Defense Mechanisms

Natural Immunity

Cellular Components

- White blood cell count and differential*
- Nitroblue tetrazolium (NBT) dye reduction test*
- Random mobility and chemotaxis assay
- Phagocytosis assay
- Quantitative bactericidal assay
- Flow cytometric analysis of cell surface receptor expression
- Analysis of oxidative metabolism and enzyme activity

Humoral Components (Complement)

- Total hemolytic complement assay (CH_{50})*
- Determination of C3 and C4 concentrations*
- Assay of individual components of classic and alternative pathways
- Functional measurement of alternative pathway
- Functional assay for C3a and C5a

Acquired Immunity

B Lymphocytes and Antibody Production

- Quantitation of serum IgG, IgA, and IgM*
- Measurement of specific antibodies after immunization*
- Isoagglutinin titer (anti-A and anti-B)*
- Determination of IgE and IgD concentrations
- Flow cytometric enumeration and analysis of B-cell phenotype
- Tests of B-cell-to-plasma-cell maturation and antibody production in vitro

T Lymphocytes

- Total lymphocyte count and morphology*
- Delayed hypersensitivity skin tests to common antigens*
- Chest radiograph for thymic size*
- Proliferative responses to mitogens, antigens, and allogeneic cells
- Flow cytometric enumeration and analysis of T-cell subsets
- Cytotoxicity assays
- Lymphokine production assays

*Considered one of the initial screening tests.

Key Points

- The ability to mount cell-mediated or antibody-mediated immune responses to specific antigens is acquired sequentially during the course of embryonic development.
- Maternal transfer of IgG antibodies across the placenta provides a newborn with a measure of immune protection.
- PMNs of term and preterm infants are limited in chemotactic, phagocytic, and microbicidal activities.
- The influx of mononuclear phagocytes to sites of inflammation is delayed and attenuated in newborns.
- Neonatal T cells are impaired in producing a robust Th1 response and produce less IFN-γ and TNF under conditions of physiologic stimulation.
- In evaluating a patient for a possible host defense mechanism defect, natural (cellular and humoral components) and acquired (cellular and humoral components) immune mechanisms should be considered and investigated.

Postnatal Bacterial Infections

FRANK ESPER

Neonatal Sepsis

Newborns are extremely susceptible to infection, and sepsis is a significant cause of morbidity and mortality in this population. Neonatal sepsis is a systemic inflammatory response syndrome (SIRS) that is secondary to infection. Systemic inflammatory response syndrome is defined by the presence of two or more of the following variables: fever or hypothermia, tachycardia, tachypnea or hyperventilation, and an abnormally high or low white blood cell count. Although this chapter focuses on bacterial infections, it is important to also consider viral, fungal, and parasitic causes in the differential diagnosis of newborns with SIRS.

Epidemiology and Microbiology

Neonatal sepsis is categorized according to the infant's postnatal age at onset of disease. Although the definitions for early-onset and late-onset sepsis vary slightly, most reports define early-onset sepsis as that occurring at or before 72 hours of life and late onset occurring at greater than 72 hours to 7 days.[102] The categories are meant to reflect the different etiologies and pathophysiologic changes associated with timing of disease onset.

In early-onset sepsis, infants acquire infection by vertical transmission either through ascending amniotic fluid infection or through acquisition of bacterial flora from the mother's anogenital tract during vaginal delivery. Examples of bacteria that cross the placenta to cause fetal infection are *Treponema pallidum* and *Listeria monocytogenes*. Over the past decade, our understanding of the maternal vaginal and infant microbiome has substantially increased. Exposure of the neonate to maternal vaginal microbiota during delivery is essential for healthy development during the newborn period, providing the primary source for normal gut colonization, initiating host immune maturation, and metabolism.[55] However, these same bacteria are responsible for early-onset sepsis, including group B streptococci (GBS) and Gram-negative enteric bacilli. The development and makeup of the infant microbiome can be altered by cesarean section (C-section), perinatal antibiotics, and formula feeding.[72]

Factors that increase the risk for infection can be divided into those that are intrapartum and those related to the infant after delivery. Maternal intrapartum conditions that increase the risk of infection include maternal GBS colonization, maternal fever, chorioamnionitis, prolonged rupture of membranes (>18 hours), and inadequate intrapartum antibiotic administration before delivery. Newborn conditions that increase the risk of infection include the degree of prematurity and lower birth weight.[9,90]

The epidemiology of neonatal sepsis has changed significantly over the past several decades and continues to change. Universal antenatal screening for GBS colonization with intrapartum antibiotic prophylaxis for women colonized with GBS has significantly reduced the rate of early-onset GBS sepsis.[121] The overall incidence of early-onset sepsis in the United States is estimated to be 0.77 per 1000 live births, with the highest rates occurring among preterm, low birth weight, and African American infants.[124] For those infants with a birth weight less than 1500 g, the rate is 10.96 per 1000 live births, and for those with a birth weight between 1500 and 2500 g, the rate is 1.38. Mortality rates are also inversely proportional to gestational age. Although the case fatality rate among full-term infants has dramatically decreased over the past several decades to 2.5%-3%,[9,124] the mortality rates for early preterm infants remain high between 30%-54%.[113,124] The most common causative bacteria are GBS and *Escherichia coli*, accounting for 38% and 24% of early-onset cases, respectively.[101,113,124] *Staphylococcus aureus*, viridans group Streptococci, Enterococci, group A Streptococci, *Listeria monocytogenes*, Haemophilus, and other enteric Gram-negative organisms, including *Klebsiella*, *Enterobacter*, *Citrobacter*, *Acinetobacter*, and *Pseudomonas*, are also known pathogens associated with early-onset neonatal sepsis. Among preterm infants, *E. coli* was the most common infection with the highest case fatality ratio (32.1%).

In late-onset sepsis, acquisition of infection is predominantly through the infant's environment. The infant becomes colonized with pathogenic bacteria that are ubiquitous in their physical environments, including part of the flora of their caregivers. The gut microbiome is often involved in the pathogenesis of late-onset sepsis. While the agent can

Abstract

Bacterial diseases of the newborn continue to cause significant morbidity and mortality in infants throughout the world. Many of these infections can be broadly categorized according to the infant's postnatal age at onset of disease. With early-onset infections, pathogens often originate through ascending amniotic fluid infection or through acquisition of bacterial flora during delivery. Conversely, in late-onset infections, acquisition of infection is predominantly through the infant's environment or caused by slow-growing organisms. Clinicians must maintain a low index of suspicion to diagnose and initiate potentially lifesaving empirical antibiotic therapy.

vary, the causative organism is usually found to be abundant in the infant's gastrointestinal tract.[108] Extreme prematurity is one of the greatest risk factors for late-onset sepsis. A 2010 National Institute of Child Health and Human Development Neonatal Research Network study of morbidity and mortality rates for extremely preterm infants showed that late-onset sepsis is a frequent complication for these patients. Among 9575 infants born between 22 and 28 weeks' gestation, 36% developed late-onset sepsis.[111] As compared with term infants, premature infants have more impaired innate and adaptive immune function and thus are more susceptible to invasive infections.[58]

As overall care and survival rates for premature and low birth weight infants continue to improve, long hospital stays and indwelling vascular catheters provide additional infectious risk factors for these infants.[9] Common causes of late-onset infection in this population of infants include coagulase-negative staphylococci and *S. aureus*, as well as invasive candidiasis. Group B streptococcus and *E. coli* are also commonly implicated in late-onset sepsis. *Escherichia coli* is frequently a cause of urosepsis in young infants. Although screening for maternal GBS colonization and intrapartum antibiotic prophylaxis have markedly decreased the incidence of early-onset GBS, it has not reduced the incidence of late-onset GBS disease in either term or preterm infants.[26] Similarly, improved surgical care and survival for neonates with congenital heart disease have led to prolonged hospitalizations with associated risk for sepsis. Coagulase-negative staphylococci, *S. aureus*, *E. coli*, and candidiasis are common causes of bloodstream infection in this population, which has been associated with an increased mortality risk compared with uninfected infants with congenital heart disease.[4] The use of histamine-2 blockers and proton pump inhibitors, as well as gastrointestinal tract pathology, have been associated with an increased risk for late-onset Gram-negative bloodstream infections.[40] Numerous efforts are under way to decrease the incidence of late-onset sepsis, including comprehensive catheter-care bundles and aggressive enteral feeding programs with early line removal.[19,50]

Clinical Presentation

The clinical signs of sepsis in a neonate are varied and often nonspecific. Detection requires that clinicians maintain a high index of suspicion. Familiarity with epidemiologic risk factors is crucial to determining the threshold index of suspicion. For early-onset infection, consider any perinatal risk factors that may be present, including maternal GBS status, chorioamnionitis, prolonged rupture of membranes, and gestational age. For late-onset infection, consider whether the patient has indwelling foreign bodies such as a central venous catheter or endotracheal tube, is dependent on parenteral nutrition, or receives proton-pump inhibitor or histamine-2 blocking therapy.

Clinical signs and symptoms are variable and nonspecific and can reflect noninfectious etiologies. These include, but are not limited to, findings of hyper- or hypothermia, lethargy or irritability, hypotonia, respiratory distress, cyanosis, apnea, feeding difficulties, poor perfusion, bleeding problems, and abdominal distention.[99] Lethargy or poor feeding may be the only symptoms initially. Metabolic changes may include hyperglycemia or hypoglycemia, acidosis, and jaundice. Meningismus is uncommon in neonates with central nervous system (CNS) infection. Full fontanelle, irritability, lethargy, and seizures may occur. Noninfectious etiologies that can mimic newborn sepsis are numerous and include respiratory distress syndrome, cardiogenic pulmonary edema, metabolic acidosis, and meconium aspiration syndrome. Lethargy, irritability, and seizures can also occur secondary to electrolyte, endocrine, or metabolic disturbances.

Diagnosis

Because signs and symptoms are nonspecific, the clinical diagnosis of neonatal sepsis is extremely challenging. A definitive diagnosis requires the isolation of a pathogen from a normally sterile body site, including blood, cerebrospinal fluid (CSF), and urine. Isolation of bacteria from blood is considered the gold standard for the diagnosis of sepsis.[39] A blood culture should be drawn in any infant with suspected sepsis. A collection volume of at least 1 mL is recommended for improved recovery of microorganisms in culture, particularly for those patients with low colony count bacteremia. A lumbar puncture should also be considered in any infant with suspected sepsis. (See Table 48.1 for normal values for CSF cell counts, protein, and glucose according to gestational age, postnatal age, and birth weight.) If the infant is critically ill with respiratory or hemodynamic instability, the procedure can be deferred until the patient is more stable. Studies have shown poor correlation between results of blood and CSF cultures, so blood culture results alone should not be used to determine which patients should receive a lumbar puncture. In infants with bacteremia, the incidence of meningitis has been shown to be as high as 23%. A study among very low birth weight infants with meningitis showed that one-third of them had negative blood cultures.[86,110]

For suspected early-onset sepsis, a urine culture is not part of the recommended work-up. In newborns, urinary tract infections are primarily caused by renal seeding during bacteremia, and thus urine cultures are of low yield in early-onset sepsis. In older infants, urinary tract infections increasingly result from ascending infection, so urine cultures should be part of the evaluation of late-onset sepsis.[86] Suprapubic aspiration or sterile catheterization are the preferred procedures to obtain cultures.

To date, no single blood cell index has been shown to be sensitive enough to safely exclude sepsis. Numerous indirect markers of infection have been studied. Although none of these tests can definitively confirm or exclude infection, they can be used to help identify infected infants and guide decisions on duration of antimicrobial therapy. A

Cerebrospinal fluid values in the very low birthweight infant. *J Pediatr*. 1990;116(6):971-974.

peripheral white blood cell (WBC) count with differential is commonly obtained with sepsis evaluations. It is recommended to wait 6-12 hours after birth before obtaining a WBC with differential, as later counts are more likely to reflect a pathologic inflammatory response compared with those obtained at birth.[75] Studies have shown leukopenia and a high percentage of immature to total white blood cells (>0.2) were associated with early-onset sepsis.[47] Late-onset sepsis has been associated with both high and low WBC, high absolute neutrophil count, and high percentage of immature to total white blood cells.[47,48] Newer technology allows automated calculation of the immature granulocyte, which accurately identifies sepsis.[77,79]

C-reactive protein (CRP) and procalcitonin are two acute-phase reactants that have been studied extensively in neonatal sepsis. C-reactive protein levels increase within 6-8 hours after infection and peak after 24 hours.[33] The sensitivity of CRP for neonatal sepsis is lowest early in infection and then increases over the next 10-12 hours after the onset of infection.[99] Serial determinations may be useful for identifying infants who do not have a bacterial infection or in monitoring response to treatment for infected infants.[46] The specificity and positive predictive value of CRP range from 93%-100%.[76,99] However, it is worth noting that preterm infants have lower CRP values and response which affect its predictive value.

Procalcitonin concentrations peak as early as 6-8 hours following infection, although there is a physiologic increase within the first 24 hours after birth. Also, unlike CRP, the serum procalcitonin concentration is not affected by gestational age.[99] Increased levels can be seen with noninfectious causes such as respiratory distress syndrome. Thus, procalcitonin appears to have better sensitivity but less specificity than CRP for identifying neonatal sepsis.[7] Given that neither CRP nor procalcitonin values have been shown to be entirely sensitive or specific, the most important information guiding clinical decisions continues to be the patient's overall clinical status and culture data.

Specific cytokines have also been evaluated for potential roles in the diagnosis of neonatal sepsis. Serum concentrations of interleukin (IL)-1β, IL-6, IL-8, tumor necrosis factor-α, interleukin-2 soluble receptor (sIL2R), and granulocyte colony-stimulating factor all increase in newborns with bacterial infection.[99] Several have been shown to rise early in the course of infection, often before clinical findings become apparent.[7] Newer technologies using cytometry to accurately identify immature granulocytes have also shown to be as effective, with faster turnaround time and less operator variability than manual differentials. While cytokine and cytometry assays may be helpful in diagnosis or in guiding decisions regarding therapy, their use is not widely employed related to issues of cost, the need for specialized equipment, and the processing time.[93,99] These tests hold promise for the future.

Real time online/mobile applications are now available that predict the probability of early-onset sepsis based on objective maternal risk factors available at the time of birth. In early studies, these algorithms perform better than those

based on risk-factor threshold values. These have allowed improved recognition as well as reduced use of unnecessary antibiotics by 50%[59,90] and separation of mother and infant.[64]

Management

Ampicillin and an aminoglycoside are recommended as empiric therapy for early-onset sepsis. This combination provides coverage against GBS and *E. coli*, the most common causative pathogens, as well as *Listeria monocytogenes*. Empiric use of third-generation cephalosporins is not recommended because of concerns for development of resistance and the increased risk for invasive candidiasis with prolonged administration. However, if Gram-negative meningitis is suspected, then it is recommended to add cefotaxime to the empiric regimen, given its excellent CNS penetration. Cefotaxime is preferred over ceftriaxone for use in neonates because of ceftriaxone's potential to displace bilirubin and increase the risk for kernicterus and its association with biliary sludging. However, recent shortages of cefotaxime have required the use of alternative agents in infants with invasive Gram-negative disease, including ceftriaxone (in term infants with normal bilirubin) or cefipime.

Empiric therapy for late-onset sepsis usually consists of ampicillin and an aminoglycoside or cefotaxime, providing coverage for common pathogens like group B streptococci and Gram-negative organisms. As with early-onset disease, if Gram-negative meningitis is suspected, consider adding a third-generation cephalosporin. In preterm infants or infants with complex medical problems necessitating surgeries or prolonged indwelling central catheters, vancomycin should be given in lieu of ampicillin if suspected of having coagulase-negative Staphylococci or *S. aureus* disease. Carbapenems may be considered depending on local resistance patterns or if the patient had previously received therapy with a third-generation cephalosporin.[101] It is also important to consider empiric antifungal coverage for invasive candidiasis for severe sepsis unresponsive to antibiotics, infants on chronic TPN, or those with unexplained cytopenias. Experience with fungal biomarkers including beta-D-glucan assays for the diagnosis of candidemia in infants is limited.[23,92]

Once a pathogen is identified, therapy should be tailored to the species and antimicrobial susceptibilities. Duration will be determined by the site of infection and the patient's clinical response. There is little evidence from randomized, controlled trials on the appropriate duration of treatment for culture-proven sepsis, especially in preterm and low birth weight infants. Bacteremia without a focus of infection is usually treated for 10 days.[86] It is reasonable to expect that early preterm infants (<32 weeks' gestational age) may require slightly longer treatment courses of 10-14 days.[104,118] In addition, Gram-negative bacteremia tends to be treated with longer courses of 10-14 days. In general, uncomplicated GBS meningitis is treated for 14-21 days. Longer courses are needed for other focal complications of GBS infection (see Specific Pathogens). For Gram-negative bacterial meningitis, treatment is for 21 days, or 2 weeks beyond the first negative CSF culture, whichever is longer.[94,117] The use of systemic ciprofloxacin is indicated in those infants with multidrug-resistant Gram-negative disease when alternative antibiotics are not available.[53]

It is often difficult to determine an appropriate duration of antibiotic therapy for suspected sepsis when cultures are negative. In well-appearing infants without clinical or hematologic evidence for infection, standard practice is to discontinue antibiotics if cultures have been negative after 36-48 hours. Management decisions are much more challenging for those infants in whom sepsis is highly suspected but cultures are negative, which is often the case for preterm infants. Infants whose mothers received antibiotics during labor may have false negative blood cultures because of antibiotic suppression. Cerebrospinal fluid culture data may be lacking in infants who are not clinically stable enough to tolerate a lumbar puncture. Noninfectious conditions mimicking sepsis can also complicate the clinical picture. Still, studies have shown potential harm associated with longer duration (>5 days) of empiric antibiotics, including increased risk for necrotizing enterocolitis, candidemia, and mortality among premature infants.[20,86] There is also concern that early antibiotic exposure may permanently alter the microbiome and predispose to obesity.[5] There is little available evidence on when it is safe to discontinue antimicrobials in such cases, and clinicians must consider each patient's clinical course as well as the risks associated with longer courses of antibiotics.[104] The CDC has led efforts to decrease antibiotic exposure in a campaign entitled "Choosing Wisely."[44] These efforts have championed use of sepsis risk calculators and early stopping rules.[64]

Prevention

As mentioned, universal antenatal screening for GBS colonization and intrapartum antibiotic prophylaxis for the prevention of early onset GBS disease has been highly successful, although it has not had an effect on the incidence of late-onset GBS.[121] Details of the current recommendations for antenatal GBS screening and intrapartum antibiotic prophylaxis are included in a later section. Preventive efforts to reduce the risk of late-onset sepsis have focused on infection control in the postnatal environment. Successful measures include hand hygiene, proper management of central venous catheters, appropriate use of antibiotics, and limited use of histamine-2 blockers and proton pump inhibitors.[40,114] A Cochrane review on oral lactoferrin prophylaxis in preterm infants showed a reduced incidence of late-onset sepsis in infants weighing less than 1500 g. The roles of exclusive maternal milk feeding and probiotic prophylaxis in prevention of late-onset sepsis require further study.[83,84]

Bacterial Infections by Organ System

Meningitis

Bacterial meningitis is more common in the first month of life than at any other age.[63] Incidence of neonatal bacterial meningitis varies across the globe. While the incidence is estimated to be 0.3 per 1000 live births in developed countries, neonatal meningitis is much higher (0.8-6.1 per 1000 live births) in developing nations.[63] As with neonatal sepsis, neonatal meningitis can be categorized into two patterns of disease: early onset and late onset. Infants with early-onset meningitis present within the first week of life, usually within 72 hours of birth. These infections are vertically transmitted and are associated with the complications of labor and delivery. Late-onset disease occurs after the first week of life and reflects community or nosocomial transmission. Among infants with bacteremia, as many as 25% of them will also have meningitis.[86]

The causative pathogens for neonatal meningitis are similar to those for neonatal sepsis with group B streptococcus and *E. coli* predominant. Group B streptococcus is the most common cause of neonatal meningitis and occurs in up to 40% of infants with early onset meningitis. Gram-negative enteric bacilli cause 30%-40% of cases of neonatal meningitis, and *E. coli* accounts for approximately 50% of the Gram-negative isolates.[63,87,113] *E. coli* is now recognized as the most common cause of early-onset meningitis among very low birth weight (<1500 g birth weight) infants.[63,112] The majority of *E. coli* strains causing meningitis contain the K1 polysaccharide capsular antigen, which assists the organism in evading host defenses. Other important Gram-negative organisms include *Klebsiella*, *Enterobacter*, *Citrobacter*, and *Serratia* species. A known complication of *Citrobacter koseri* and *Enterobacter sakazakii* meningitis in neonates and young infants is the formation of brain abscesses, so it is important to obtain brain imaging whenever these species are isolated from the CSF.[11,27,122] Although *Listeria monocytogenes* is a relatively uncommon cause of neonatal meningitis, it can lead to significant morbidity and mortality because of its association with rhombencephalitis. It has been estimated to cause 5%-20% of neonatal meningitis cases.[49,87] Nosocomial pathogens include coagulase-negative *Staphylococci*, *Candida*, and resistant Gram-negative organisms, particularly *Pseudomonas*, are more prominent in late-onset meningitis.[63]

The clinical presentation of neonatal meningitis is often nonspecific and is similar to that of neonatal sepsis. The most common finding is temperature instability, which occurs in approximately 60% of infants with meningitis. Common neurologic signs include irritability, emesis, lethargy, poor tone, and seizures. Most infants present with a full, but not bulging, fontanelle without meningeal signs. Other signs include poor feeding, respiratory distress, apnea, and diarrhea.

Neonates with suspected bacterial meningitis should undergo a complete sepsis evaluation—including blood culture, complete blood count with differential, urine culture if greater than 6 days of age, and lumbar puncture for CSF Gram stain and culture—cell count with differential, glucose, and protein in order of priority. For clinically stable infants, the lumbar puncture should be performed before administration of antibiotics.

Cerebrospinal fluid studies need to be interpreted based on the infant's gestational age, postnatal age, and birth weight (see Table 48.1). A CSF WBC count of greater than 20-30 cells/μL is consistent with meningeal inflammation. However, neonatal meningitis has been shown to occur with normal CSF parameters, and there is some overlap in CSF WBC values between neonates with and without meningitis.[35] If CSF findings are not definitive in an infant whose clinical picture is otherwise suspicious for meningitis, a repeat lumbar puncture obtained 24-48 hours later will still show pleocytosis if true meningeal inflammation is present even with use of antibiotics. Cerebrospinal fluid protein and glucose values are highly variable in neonates with and without meningitis. Cerebrospinal fluid Gram stain may be helpful in providing an early presumptive etiologic diagnosis, although a negative Gram stain certainly does not exclude the diagnosis. If the lumbar puncture is traumatic, it is not recommended to adjust the CSF white blood cell count based on the red blood cell counts, as this does not improve the diagnostic utility for neonates.[41] Ultrasound to guide lumbar puncture may reduce the incidence of traumatic taps.[82] Infants who have had a traumatic lumbar puncture may be treated presumptively for meningitis pending CSF culture results. Increasingly, PCR against common newborn pathogens has been utilized as a diagnostic in situations where the CSF is uninterpretable.[18] Automated systems are now commercially available and may reduce antibiotic exposure.[65]

Empiric therapy for early-onset meningitis includes ampicillin and an aminoglycoside. If infection with a Gram-negative organism is suspected, the regimen may be expanded to include cefotaxime or higher generation cephalosporin in addition to ampicillin. Aminoglycosides are not used as monotherapy because of their poor CNS penetration. Once a pathogen is identified, therapy should be tailored according to the causative organism.

Group B streptococcus meningitis is treated initially with ampicillin (or penicillin) plus an aminoglycoside. Group B streptococcus has thus far been shown to be uniformly susceptible to penicillins while resistance to clindamycin and erythromycin is reported.[15,43] Combination therapy is used because synergy is seen in vitro and animal studies have shown improved outcomes with combination therapy versus penicillin alone.[115,119] When the patient shows clinical improvement and the CSF is sterilized, therapy can be narrowed to ampicillin or penicillin monotherapy to continue for 14 days after the first negative culture. Although not all patients with GBS meningitis require a lumbar puncture at the end of therapy to confirm treatment response, it should be considered in patients with a complicated clinical course, including seizures, abnormal neuroimaging,

prolonged positive CSF cultures, or slow clinical response to therapy.

Gram-negative meningitis is treated with a third-generation cephalosporin (cefotaxime) for at least 21 days or for 14 days after the first negative CSF culture. An aminoglycoside is added until CSF sterilization, which usually takes longer for meningitis caused by Gram-negative organisms than for GBS meningitis. A fourth-generation cephalosporin (cefepime) or a carbapenem (meropenem) in combination with an aminoglycoside may be considered for infection with members of the *Enterobacteriaceae* family with inducible beta-lactamase resistance (e.g., *Citrobacter*, *Enterobacter*, *Serratia*) and for *Pseudomonas.* Studies have shown that recommended meningitic doses of meropenem may be toxic at lower gestational ages and may produce seizures.[105] A lumbar puncture may be considered before discontinuation of antibiotics to confirm response to treatment.

Listeria monocytogenes is not susceptible to cephalosporins and should be treated with ampicillin and an aminoglycoside until CSF sterilization, followed by ampicillin monotherapy for 14 days after first negative culture. The same therapy is recommended for infection with *Enterococcus.* Vancomycin should be avoided, if able, in patients with infection by *Listeria monocytogenes* as treatment failures are reported.[45] Meningitis with coagulase-negative *Staphylococci* is seen in preterm infants and is often associated with the presence of a foreign body in the CNS. Most of these organisms are resistant to penicillin, and treatment with vancomycin is often required. Duration is generally 14-21 days after CSF sterilization, with removal of any foreign body if feasible. Adjunctive use of corticosteroids has not shown improvement in the outcome for neonatal bacterial meningitis other than tuberculosis meningitis.[25]

Mortality from neonatal meningitis has decreased dramatically over the past several decades, although substantial neurologic morbidity continues to be seen among affected patients. Mortality rates were estimated at almost 50% in the 1970s and have decreased to current estimates of 10%-15%,[36,63,87] with higher mortality rates among preterm infants and those in developing countries. Neurologic sequelae include developmental delay, seizures, hydrocephalus, cerebral palsy, blindness, and hearing loss. Studies estimate that among survivors, 21%-38% will have mild deficits and 24%-29% will have severe neurologic sequelae.[32,63] Predictors of poor neurologic outcomes include seizures lasting >72 hours, presence of coma, hypotension requiring the use of inotropes, leukopenia (<5.0), and abnormal electroencephalogram findings.[61,63]

Pneumonia

Pneumonia is a significant cause of morbidity and mortality in neonates, especially in developing countries where it is a leading cause of death for all children under 5 years of age.[52] The incidence of lower respiratory tract infection in developed countries is estimated at less than 1% among full-term infants, but may be as high as 10% in low birth weight infants. In developed countries, the morbidity and mortality from neonatal pneumonia depend largely on the gestational age of the patient, severity of disease, and underlying medical conditions, especially chronic lung disease. Neonatal pneumonia is also categorized into two patterns of disease according to timing and route of acquisition. Early-onset pneumonia is usually acquired within the first 3 days of life via vertical transmission, including aspiration of infected amniotic fluid and transplacental transmission. Late-onset pneumonia occurs after the first week of life, and infection arises from pathogenic organisms in the infant's environment. The risk for late-onset pneumonia is highest among infants who require mechanical ventilation. Other risk factors include extreme prematurity, prolonged hospitalization, and previous bloodstream infection.[2]

The most common cause of early-onset pneumonia in developed countries is GBS. Other common causes include *S. pneumoniae*, nontypable *H. influenzae*, *S. aureus*, *E. coli*, *Klebsiella*, and atypical organisms. *Ureaplasma urealyticum* has been potentially linked to the development of chronic lung disease in colonized infants. However, the significance of this association is unknown, and the efficacy of antimicrobial therapy for those colonized infants is also uncertain.[123] *Chlamydia trachomatis* pneumonia can occur in the first week of life but more typically presents between 2 and 4 weeks of age, given its long incubation. *Chlamydia trachomatis* pneumonia and ophthalmia neonatorum are discussed in more detail elsewhere. While syphilis, *Listeria monocytogenes,* and *Mycobacterium tuberculosis* can be transmitted across the placenta, these pathogens are uncommon causes of neonatal pneumonia.

Definitive culture data are often lacking for cases of late-onset, community-acquired neonatal pneumonia. *Streptococcus pneumoniae* is considered a predominant causative pathogen in this population. Other important pathogens include *S. aureus*, *S. pyogenes*, nontypable *H. influenza*, and Gram-negative enteric organisms. *Staphylococcus aureus*, *Streptococci*, *Klebsiella pneumoniae*, *Citrobacter*, *Enterobacter*, *Serratia*, and *Pseudomonas* have all been shown to have the potential to cause extensive lung injury, including abscess formation, empyema, and pneumatoceles.[38,60,100] Although it generally causes self-limiting illness in older children and adults, *Bordetella pertussis* infection in young infants can lead to respiratory failure and death. The Centers for Disease Control and Prevention (CDC) updated their vaccination guidelines in January 2013 to include a recommendation that all pregnant women get a dose of the tetanus, diphtheria, and pertussis (Tdap) vaccine during each pregnancy. Receipt of Tdap vaccine during pregnancy allows for increased maternal pertussis antibody transfer to the neonate. This provides added protection for infants from birth to the time of infant pertussis vaccination at 2 months.[88]

The clinical presentation of early-onset pneumonia often includes respiratory distress within the first few hours of life, with tachypnea, retractions, nasal flaring, or grunting.

Other associated signs are apnea, lethargy, poor feeding, temperature instability, abdominal distention, poor perfusion, and metabolic acidosis. None of these signs is specific for pneumonia, and any infant with these symptoms should undergo a complete sepsis evaluation. Copious or purulent tracheal secretions may also be present.

The diagnosis of neonatal pneumonia can be difficult. The differential diagnosis is broad and includes many noninfectious causes such as transient tachypnea of the newborn, respiratory distress syndrome, meconium aspiration, pulmonary hemorrhage, pneumothorax, hypoglycemia, and metabolic acidosis. Anatomic abnormalities that can cause respiratory distress include primary pulmonary hypoplasia, tracheoesophageal fistula, choanal atresia, congenital diaphragmatic hernia, and congenital heart disease, among many others. Causative pathogens are rarely obtained and identified from the lower respiratory tract. Blood and CSF cultures should be obtained from any neonate with suspected pneumonia. Chest radiographs can be helpful in making the clinical diagnosis, although there is significant radiologic overlap between pneumonia and other respiratory disorders of the newborn. In pneumonia, radiographs often reveal bilateral alveolar densities with air bronchograms, or irregular, patchy pulmonary infiltrates. Pleural effusions are seen in up to two-thirds of pneumonia cases and are almost never seen in uncomplicated respiratory distress syndrome. The chest radiograph may appear normal in up to 15% of pneumonia cases.[70] Tracheal aspirate Gram stain and culture results must be interpreted with caution. These specimens may be of some value if obtained immediately following intubation. If an infant has been intubated for several days, the endotracheal tube will invariably become colonized and will be of little value in the evaluation for sepsis.[86]

Like most early-onset newborn infections, empiric antibiotic treatment includes ampicillin and an aminoglycoside. Therapy can then be tailored to susceptibility results if a causative organism is identified. Empiric antibiotic therapy for late-onset pneumonia will depend on local bacterial resistance patterns in both the hospital and the community. Vancomycin and a cephalosporin, often cefotaxime, are commonly used as empiric therapy to provide coverage against newborn pathogens as well as coagulase-negative Staphylococci and methicillin-resistant *S. aureus* (MRSA). If *Pseudomonas* is suspected, an aminoglycoside plus an antipseudomonal beta-lactam, such as ceftazidime, cefipime, or piperacillin-tazobactam, should be given. Recommended duration of therapy for uncomplicated pneumonia is 7-10 days.

Urinary Tract Infections

The incidence of bacteriuria in term newborns is estimated to be 0.1%-1%. The incidence is higher in preterm infants and is thought to be around 2%. In the neonatal period, urinary tract infection (UTI) is more common among males than females. Over the first 6 months of life, the incidence of UTI in males decreases, whereas in females it increases. By 1 year of age or older, girls are more likely than boys to have UTIs.[54,95] Uncircumcised males are at higher risk for UTI than are circumcised males. This is owing to enhanced bacterial adherence to the foreskin and increased bacterial colonization in the urogenital tract.[103] It is rare for a UTI to occur in the first 3 days of life; therefore, urine cultures are not recommended as part of the routine early-onset sepsis evaluation.

Infection of the urinary tract in neonates is thought to be acquired either through hematogenous spread or by ascending infection, often associated with anatomic abnormalities. Hematogenous spread is thought to be the cause for many young infants with UTI, because bacteremia with the same organism is seen in approximately one-third of neonates with upper tract infection.[95] Preterm infants are at higher risk for UTI with concordant bacteremia. Associated meningitis is also seen in 1%-2% of these cases.[28,116] Urinary tract abnormalities are seen in approximately 20%-50% of infants with UTI.[51,95] The most common abnormality seen is vesicoureteral reflux (VUR). Other abnormalities that may increase the risk for UTI include ectopic ureter, duplicated collecting system, renal dysplasia, and causes of obstruction, such as posterior urethral valves and ureteropelvic junction stricture. An additional risk factor for UTI is the presence of an indwelling urinary catheter.

The most common causative pathogen for neonatal UTI is *E. coli*, which has been isolated in approximately 80% of cases in some large series.[51,95] *E. coli* has several virulence factors that confer an increased ability to cause UTI. Uropathogenic *E. coli*, the causative organism in most UTIs, can invade and replicate within uroepithelial cells. Adhesins on the bacterial surface allow for increased adhesion to urogenital tract cells, and fimbriae are important in promoting persistence of infection. Other common causative organisms include other Enterobacteriaceae: *Klebsiella*, *Enterobacter*, *Proteus*, *Citrobacter*, *Salmonella*, and *Serratia*. Gram-positive organisms are isolated much less frequently than Gram-negative organisms, although Enterococci, *S. aureus*, and coagulase-negative Staphylococci are also known to cause UTI in newborns.

The signs of neonatal UTI are nonspecific and may include fever, lethargy, failure to thrive, poor feeding, abdominal distention, vomiting, tachypnea, and cyanosis. The clinical presentation of preterm infants is similar to that of term infants, although preterm infants may also have hypoxia or apnea with bradycardia. Definitive diagnosis must be made by urine culture with specimens obtained by catheterization or suprapubic bladder aspiration. Samples collected into a bag are less helpful, because they are frequently contaminated. Any growth of a urinary pathogen from bladder aspirate is considered significant. Catheterization cultures with greater than 1000 colony-forming units per milliliter are considered meaningful. Urinalysis lacks specificity and sensitivity for diagnosis of UTI in neonates and is not recommended as part of the evaluation. Blood cultures should be obtained for all infants with suspected

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

UTI, as one-third with UTI will have bacteremia with the same organism.[37] Clinicians should have a very low threshold for performing a lumbar puncture in neonates with UTI, because the risk for concomitant meningitis is 1%-2%.[28,116]

Empiric antibiotic treatment for neonatal UTI includes ampicillin and an aminoglycoside. Hospitalized infants with late-onset infections should be given vancomycin and an aminoglycoside to provide coverage for hospital-associated infections with coagulase-negative Staphylococci and MRSA. If the infection is caused by a highly resistant pathogen, or if there is a known anatomical abnormality, a urine culture may be repeated 2-3 days after start of treatment to confirm sterilization of the urine. If cultures remain positive despite adequate therapy, the infant should be further evaluated for a potential reservoir of infection. The duration of therapy is generally 7-14 days for uncomplicated bacterial UTI in a newborn.[95] Neonates and newborns with delayed clinical response, prematurity, bacteremia, or presence of anatomic abnormalities are usually given intravenous antibiotics for the entire course. Older infants with uncomplicated disease may be switched to oral antibiotics after demonstration of clinical improvement. The use of systemic ciprofloxacin is indicated in those infants with multidrug-resistant, Gram-negative disease or orally when alternative oral antibiotics are not available.[53,91] Reviews of use of ciprofloxacin in children show the risk of arthropathy is low and reversible.[1]

All neonates with UTI should undergo imaging evaluation because of the high prevalence of urinary tract abnormalities. If prenatal ultrasound data are not available, a renal ultrasound should be performed after the infant has clinically stabilized. Ultrasound can detect structural abnormalities, although it cannot detect vesicoureteral reflux or renal scarring. Voiding cystourethrogram is performed to detect vesicoureteral reflux, and this is usually done 3-6 weeks after completion of antibiotic treatment. Long-term outcomes of UTI can include renal scarring with subsequent hypertension and chronic kidney disease. If renal damage is suggested by ultrasound, renal cortical scintigraphy can be performed to better assess for renal scarring.[95]

Osteomyelitis and Septic Arthritis

Osteomyelitis and septic arthritis are uncommon infections in neonates, and can be difficult to diagnose in this population. In neonates, the most common route for infection to the bone or joint is by hematogenous spread. There are important differences in the pathophysiology of musculoskeletal infections in neonates compared with older children and adults. In all ages, metaphyses are susceptible to hematogenous seeding of infection because of the reduced rate of blood flow within metaphyseal blood vessels. In infants, secondary ossification centers have not yet formed, and their cartilaginous epiphyses are supplied with blood directly from transphyseal vessels from the bone metaphysis.[97] Therefore, osteomyelitis in infants commonly leads to epiphyseal damage and joint infections. This contiguous infection rarely occurs in older children and adults with osteomyelitis, because the epiphyses and metaphyses have separate blood supplies. Similarly, anatomic differences in the blood supply to the spinal column render neonates more susceptible to discitis than to vertebral body osteomyelitis.[81]

The most common causative organisms are *S. aureus*, *E. coli*, and GBS.[81] Less common pathogens include group A Streptococcus, *N. gonorrhoeae*, other enteric Gram-negative bacilli and Candida. The signs and symptoms of osteomyelitis and joint infections in neonates are often subtle and similar to signs of sepsis. Infants may present with irritability, poor feeding, or fever. Some will show positional preference, lack of use of the involved extremity (pseudoparalysis), joint or limb swelling, or pain with passive motion as with diaper changes. Infections are often multifocal. If left untreated, septic arthritis of the hip can lead to spontaneous drainage along the internal obturator muscle, resulting in a lower abdominal mass just above the inguinal canal.

Imaging studies should be obtained for any patient with suspected osteomyelitis or septic arthritis. The radiologic investigation usually starts with plain radiographs. Findings can include deep soft tissue swelling, widening of the joint space or joint dislocation, osteoporosis, periosteal new bone formation, and bony destruction.[81] Soft tissue swelling is the earliest finding and can be detected as early as 48 hours after onset of infection. Bony changes, however, are not apparent until 7-10 days after onset of infection. For this reason, further imaging is often required for patients in whom there is a high index of suspicion. Ultrasound can detect subperiosteal collections and joint effusions, so it is very useful in cases of suspected septic arthritis. Ultrasound can also detect findings of subperiosteal abscesses and fluid collections, although this is highly dependent on the duration of infection as well as operator experience. Bone scintigraphy is more sensitive than plain films for detecting osteomyelitis early on, and it is useful for detecting multiple foci of infection.[96] Magnetic resonance imaging (MRI) is extremely useful in the evaluation for osteomyelitis. Bony changes can be detected within 24-48 hours after onset of symptoms. Magnetic resonance imaging provides excellent anatomic detail without exposing infants to ionizing radiation. It also provides better information on growth plate involvement than does bone scintigraphy. However, careful interpretation of bone scans and MRI is necessary to distinguish physiologic from pathologic increased uptake owing to increased vascularity of the metaphyseal region in neonates.[120]

Fluid collections in soft tissue or bone should be aspirated and sent for Gram stain and culture. Patients with joint involvement should have synovial fluid sent for Gram stain and culture. Blood cultures yield the causative organism in approximately 50% of cases.[10] Lumbar puncture should be performed on ill-appearing infants or those with positive blood cultures.

Recommended empiric antibiotic treatment includes vancomycin for broad Gram-positive coverage and an

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

aminoglycoside or third-generation cephalosporin for Gram-negative coverage. Therapy can be narrowed once the causative organism is isolated. Most patients with osteomyelitis can be managed with conservative, or nonsurgical, treatment. Joint infections and bony abscesses require surgical drainage. The total duration of therapy is 4-6 weeks for uncomplicated cases. Therapy should be 8 weeks for osteomyelitis caused by MRSA and 6-12 months for infants with fungal disease caused by candida.[34,67] Parenteral therapy should be continued at least until the patient demonstrates clinical improvement and the inflammatory markers have normalized.

Significant morbidity may be associated with neonatal musculoskeletal infections, and prompt diagnosis and treatment are needed to minimize complications. Septic arthritis of the hip in particular is associated with serious long-term sequelae. Complications include growth plate damage, avascular necrosis, limb length discrepancies, and angular joint deformities, among many others.[81] These patients should be followed for the development of long-term complications, as many will require surgical intervention.

Ophthalmia Neonatorum

Ophthalmia neonatorum is conjunctivitis occurring in the first month of life. Bacterial causes include *S. aureus*, nontypable *H. influenzae*, *S. pneumoniae*, enteric Gram-negative bacilli, GBS, *N. gonorrhoeae*, and *Chlamydia trachomatis.* The differential also includes viral causes, particularly herpes simplex virus, and noninfectious causes, such as chemical conjunctivitis. Conjunctivitis in neonates is managed aggressively because of the high risk for associated systemic illness and complications. Prophylactic administration of ophthalmic antibiotic agents shortly after birth greatly reduces the risk of gonococcal conjunctivitis but not chlamydial disease.

In the United States, it is recommended that prophylaxis is provided to all newborns.[30] Regimens with equal efficacy include 0.5% erythromycin ointment, 1% tetracycline ointment, and silver nitrate solution, although the latter two are not commercially available in the United States. Chemical conjunctivitis is usually seen soon after birth and improves over 48 hours.

The clinical presentation of bacterial conjunctivitis in neonates is similar to that in older patients. Typical signs include purulent ocular discharge, erythema and edema of the eyelids, and injection of the conjunctivae. Gonococcal infection in the newborn is typically acquired during delivery, with perinatal transmission occurring in 30%-40% of cases of maternal cervical infection.[126] Infants usually show signs of infection 2-5 days after birth, with profuse, purulent ocular discharge and swelling of the eyelids. Untreated, infection can spread into the subconjunctival connective tissue and cornea, leading to ulceration, scarring, and visual loss. In addition to conjunctivitis, infection of other mucosal surfaces can occur, and scalp abscess may be associated with the use of fetal monitoring electrodes. Disseminated infection can lead to septic arthritis or, less commonly, bacteremia or meningitis.

Chlamydia trachomatis is usually transmitted to the neonate during vaginal delivery, and approximately 20% of infants born to mothers with cervical infection will develop conjunctivitis.[6] Chlamydial conjunctivitis is also known as inclusion conjunctivitis. The serovariants of *C. trachomatis* causing infection in neonates (D through K) reflect the primary serotypes causing genital disease in adults. The onset of conjunctivitis is often 5-14 days after birth. Findings may range from mild eyelid swelling with minimal discharge to mucopurulent discharge; significant swelling; and red, thickened conjunctivae. If the exudate adheres to the conjunctivae, a pseudomembrane may form. Bloody discharge may also be noted with intense inflammation. Without treatment, infection may lead to corneal and conjunctival scarring or progression toward pneumonia 2-8 weeks after birth. Approximately half of the infants with chlamydia pneumonia have a history of conjunctivitis.

All newborns who develop conjunctivitis after the first days of life should have laboratory testing performed to determine the etiology, because there is significant overlap in clinical presentation among the causative pathogens. If gonococcal infection is suspected, CSF and blood cultures are obtained to determine if dissemination occurred.[94] Purulent ocular discharge is sent for Gram stain and culture. Culture on selective media (e.g., Thayer-Martin) is needed to evaluate for gonococcal infection. Additionally, conjunctival specimens should be sent for *C. trachomatis* testing. These are obtained from an everted eyelid using a Dacron-tipped swab. *Chlamydia trachomatis* is an obligate intracellular organism, so specimens must contain conjunctival epithelial cells; ocular exudates are not adequate specimens for testing. Culture of the organism is the gold standard for diagnosis of *C. trachomatis* infection in infants. Nucleic acid amplification tests may also be considered because they have been found to have high specificity and sensitivity, although none has been approved by the Food and Drug Administration for use on conjunctival specimens.[22] In infants with signs of pneumonia, testing for *C. trachomatis* can be sent from nasopharyngeal specimens. Any infant with signs of systemic illness should have blood and CSF cultures obtained.

Systemic antibiotics are required to treat conjunctivitis resulting from *N. gonorrhoeae* and *C. trachomatis.* For other causes of bacterial conjunctivitis, topical antibiotic ointment or solution given for 7-10 days provides adequate therapy. Infants with gonococcal eye disease should be hospitalized and monitored for response to treatment as well as for signs of disseminated disease. Recommended treatment for conjunctivitis is a single dose of intramuscular or intravenous ceftriaxone. Note that infants, especially preterm, with hyperbilirubinemia should not be treated with ceftriaxone. The eyes should also be irrigated frequently with sterile saline until the discharge has resolved. Recommended treatment for either chlamydial conjunctivitis or pneumonia is

oral erythromycin for 14 days or with azithromycin for 3 days.[94]

Omphalitis

Omphalitis is an infection of the umbilicus or surrounding tissues. Newborns are predisposed to umbilical infections following colonization of the umbilicus by a wide array of microorganisms shortly after birth as devitalized tissues of the cord stump provide for excellent bacterial growth. Bacteria can reach the bloodstream through patent vessels of the newly cut cord and lead to systemic infection and severe complications. The incidence of omphalitis in developed countries is low and is estimated to be less than 1%.[109] Although complete data are lacking from developing countries, the incidence is expected to be much higher. The risk may be six times greater for infants delivered at home than for hospital births. Other risk factors include low birth weight, prolonged rupture of membranes, umbilical catheterization, and improper cord care. Cord care varies according to accepted practices and culture. In many parts of the world, unhygienic substances are applied to speed up cord separation and result in increased risk for infection.

Organisms that colonize the umbilicus or surrounding skin can produce omphalitis. Common pathogens include *S. aureus*, group A Streptococci, GBS, and Gram-negative bacilli, including *E. coli*, *Klebsiella*, and *Pseudomonas*. Polymicrobial infections may occur. Anaerobic bacteria can contribute to infection, especially in infants born to mothers with chorioamnionitis.

The clinical presentation is characterized by purulent drainage from the umbilical stump (or from the navel after the cord has separated), with surrounding erythema, induration, and tenderness. The drainage may be foul smelling, which is suggestive of infection with anaerobic bacteria. Infants with more severe infection will display systemic signs of illness, including fever, lethargy, poor feeding, and irritability. Involvement of the abdominal wall or extensive edema should prompt consideration for necrotizing fasciitis as a complication. Other complications of omphalitis include peritonitis, intra-abdominal abscess, suppurative thrombophlebitis of portal or umbilical veins, and umbilical hernia with bowel ischemia.

Purulent discharge should be sent for Gram stain and culture. Blood and CSF cultures should be obtained from infants with signs of systemic illness, including fever, lethargy, and irritability. Treatment consists of broad-spectrum parenteral antibiotics. Typically, an anti-staphylococcal penicillin and an aminoglycoside are given to provide Gram-positive and Gram-negative coverage. If the community prevalence of methicillin-resistant *S. aureus* is high, vancomycin should be used instead of anti-staphylococcal penicillin. The addition of clindamycin or metronidazole may be considered if there is suspicion for anaerobic involvement, especially for infants with foul-smelling discharge or if there is a history of maternal chorioamnionitis. For uncomplicated cases, duration of treatment is typically 10 days. A switch to oral therapy for completion of the course of treatment may be considered, depending on the patient's age, culture results, and clinical response.

Prevention of omphalitis involves both clean delivery services and hygienic cord care. It is generally agreed upon that the umbilical cord should be cut with clean hands using a sterile blade or scissors. This helps to prevent both omphalitis and neonatal tetanus. However, optimal care of the cord stump after the cord has been cut is an area of active research and some debate. A 2004 Cochrane review of 21 studies, most of them performed in high-income countries, showed no difference in risk for omphalitis among cords treated with antiseptics (such as alcohol, iodine, and chlorhexidine) compared with dry cord care or placebo.[129] Application of antiseptics may be beneficial for infants in resource-poor countries where the risk for omphalitis and associated complications is high and some traditional unhygienic cord practices continue. Two randomized studies from Nepal and Pakistan showed that application of chlorhexidine significantly reduced the risk of omphalitis compared with dry cord care.[73,106]

Specific Pathogens

Group B Streptococcus

Group B Streptococcus (GBS), or *Streptococcus agalactiae*, is the most common cause of early-onset sepsis in the United States. The primary risk factor for early-onset disease in the neonate is maternal intrapartum GBS colonization of the genitourinary or gastrointestinal tract leading to vertical acquisition of GBS during passage through the birth canal. The introduction of universal screening for maternal GBS colonization and use of intrapartum antibiotic prophylaxis has led to 80% reduction in the burden of early-onset GBS disease, yet has had no impact on late-onset disease.[14,74]

Following several clinical trials and observational studies, which demonstrated that early-onset GBS disease in neonates could be prevented by administering intravenous antibiotics during labor to women at risk for transmitting GBS, the Centers for Disease Control and Prevention (CDC) published the first set of guidelines for the prevention of perinatal GBS disease. The guidelines, most recently revised in 2010, recommended the use of either a risk-based approach or a culture-based screening approach to prevention.[56] The risk-based prevention method identified candidates for intrapartum antibiotic prophylaxis according to the presence of known intrapartum risk factors for early-onset disease (delivery before 37 weeks' gestation, intrapartum temperature 38° C or higher, or rupture of membranes for 18 hours or longer). The screening-based prevention method involved screening all pregnant women for vaginal and rectal GBS colonization between 35 and 37 weeks' gestation. All colonized women were then offered intrapartum antibiotic prophylaxis at the time of labor. Both the risk- and screening-based prevention methods offered

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

intrapartum antibiotic prophylaxis to women with a history of GBS bacteriuria during the current pregnancy or with previous delivery of an infant with early-onset GBS disease. Continued active surveillance of GBS disease showed that the screening-based approach was superior to the risk-based approach.

Current recommendations include universal screening for rectal and vaginal GBS colonization of pregnant women between 35 and 37 weeks' gestation. All women with positive cultures, a history of GBS bacteriuria during the current pregnancy, or a history of having a previous infant with invasive GBS disease, should receive intrapartum antibiotic prophylaxis. Women with GBS colonization who have cesarean delivery performed before onset of labor or rupture of membranes do not require intrapartum antibiotic prophylaxis. The guidelines also contain recommendations for management of women with unknown GBS status at onset of labor, expanded recommendations for laboratory identification of GBS, a change in the recommended dose of penicillin G prophylaxis, and recommendations for women with penicillin allergy. Algorithms are included to assist in management of women with preterm labor, women with preterm, premature rupture of membranes, and newborns at risk for early-onset GBS disease.

Before the initiation of active prevention with intrapartum antibiotic prophylaxis, the estimated incidence of invasive neonatal GBS disease in the United States was 1.8 cases per 1000 live births (1.5/1000 for early onset and 0.35/1000 for late onset).[128] Following implementation of the CDC guidelines in the mid-1990s, the incidence of early-onset disease had decreased by 80% to 0.3-0.4 cases per 1000 live births after 2002.[56]

Despite the dramatic decrease in the incidence of newborn GBS disease, GBS disease remains the leading infectious cause of morbidity and mortality among newborns in the United States.[99] Rates of maternal GBS colonization are unchanged since the 1970s.[56] The use of intrapartum antibiotic prophylaxis has had no effect on the incidence rate of late-onset GBS disease, which has remained approximately 0.30 cases per 1000 live births.[8] Continued monitoring is needed to evaluate for potential adverse consequences of intrapartum antibiotic prophylaxis, including the emergence of drug resistance and a possible increase in incidence of non-GBS neonatal pathogens. Clinical trials are underway to evaluate administration of conjugate GBS vaccines in pregnant women.[80] Maternal vaccination has the potential to provide a simpler strategy for prevention, without the concerns about antibiotic resistance and emergence of non-GBS pathogens associated with intrapartum antibiotic prophylaxis.[98] However, licensing of GBS vaccines remains problematic due to the low incidence of neonatal diseases.

Early-onset GBS disease most commonly presents within the first day of life. Invasive early-onset disease may lead to bacteremia, pneumonia, meningitis, or bone or joint involvement. Late-onset GBS disease occurs after the first week of life, and patients commonly present with bacteremia and meningitis.[62] Recommended definitive antibiotic therapy for GBS disease is penicillin G, given its narrow spectrum and excellent in vitro activity. GBS is consistently susceptible to penicillin, ampicillin, first- and second-generation cephalosporins, and vancomycin. Approximately 30% of GBS isolates are resistant to erythromycin, and approximately 20% are resistant to clindamycin.[15] Duration of therapy depends on location of disease involvement. Therapy should be continued for 7-10 days for bacteremia without a focus, 14-21 days for meningitis, 14-21 days for septic arthritis, and 4-6 weeks for osteomyelitis.

The widespread use of intrapartum antibiotic prophylaxis has led to a substantial decrease in mortality associated with all causes of early-onset neonatal sepsis. In the period just before implementation of intrapartum antibiotic prophylaxis (1985-1991), mortality from early-onset sepsis was 24.9 per 100,000 cases. In the years following implementation of intrapartum antibiotic prophylaxis (1995-1999), mortality rates had decreased to 15.6 per 100,000.[68] As with all pathogens causing neonatal sepsis, mortality from GBS disease is higher among preterm and low birth weight infants. Data published in 2008 showed mortality rates from early-onset GBS disease of 20% in preterm infants and 2%-3% in term infants. Late-onset GBS mortality was 5%-6% in preterm infants and 1%-2% in term infants.[85]

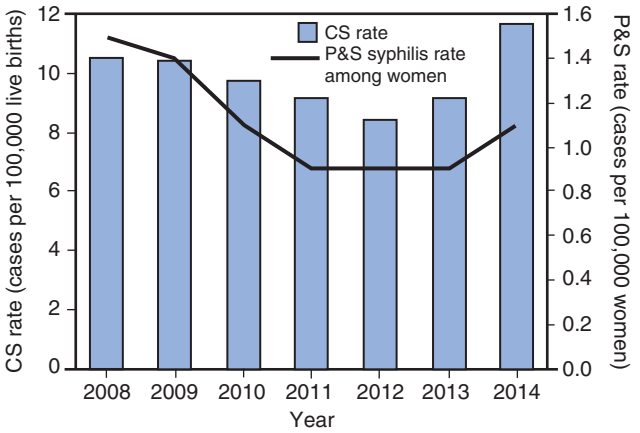
Staphylococcus aureus

Staphylococcus aureus is a facultative anaerobic Gram-positive coccus, and it is frequently found as a commensal organism in the respiratory tract and on the skin. Although it is not always pathogenic, it is a common cause of infection, leading to diseases that range from mild to severe and life threatening.

In neonates, *S. aureus* is more often seen as a cause of late-onset infection and does not commonly occur within the first 72 hours of life. It is a common cause of hospital-acquired infection among neonates in the intensive care unit. Bloodstream infections are often associated with umbilical or central venous catheters. Other frequent manifestations include pneumonia, conjunctivitis, and skin and soft tissue infections. The spread of drug-resistant *S. aureus* is a continuing problem that affects patients of all ages. There are increasing reports of methicillin-resistant *S. aureus* (MRSA) outbreaks in neonatal intensive care units (NICUs) across the United States. Data from the Emerging Infections Program Network Report on Methicillin-Resistant *Staphylococcus aureus* shows African Americans have nearly twice the rate of invasive disease than Caucasians (29.9 vs. 17.7 per 100,000 population).[16] The incidence of MRSA infections in NICUs has increased, stressing the importance of continued efforts at infection control and prevention.[66]

Community-acquired *S. aureus* infections among previously healthy neonates have a wide variety of clinical manifestations. These include pustulosis, cellulitis, skin abscess, and mastitis, as well as invasive disease with bacteremia,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.



urinary tract infection, pneumonia, and musculoskeletal infections. Symptoms often begin after the first week of life. Neonatal infection may be associated with recent or current maternal infection, such as mastitis, cellulitis, abscess, or cesarean wound infection. As with hospital-acquired infection, drug resistance is increasing among community-acquired *S. aureus* isolates, with rates of MRSA among neonates reflecting increasing rates among the general population in the community.[31]

Initial diagnostic evaluation and empiric antibiotic therapy depend on the extent and severity of illness at presentation. In any infant with systemic signs of illness, or in whom invasive disease is suspected, a full sepsis evaluation with blood, urine, and CSF cultures should be obtained. Empiric *S. aureus* coverage with vancomycin and nafcillin should be given until final susceptibility results are available. Completion of therapy with nafcillin alone is appropriate for infections caused by methicillin-susceptible *S. aureus*. Vancomycin is the preferred therapy for MRSA infections in neonates. At this time there is little data on the use of intravenous Daptomycin in infants. Clindamycin or linezolid may provide an alternative to vancomycin therapy. However, clindamycin is bacteriostatic rather than bactericidal against *S. aureus*, so it should not be used to treat bacteremia or severe infections. For bloodstream infections associated with central venous or umbilical catheters, the catheter should be removed if possible and antibiotics administered for at least 14 days, given the high virulence of *S. aureus* and its propensity to colonize foreign material and create biofilms.[71] A common conundrum is the lack of vascular access in a critically ill neonate that may prevent removal of the affected line.

There is little evidence available to guide clinicians in the treatment and evaluation of otherwise healthy, full-term neonates with mild, localized *S. aureus* skin infections. Localized pustulosis and omphalitis without associated cellulitis or systemic symptoms can be treated with topical antibiotics such as mupirocin, whereas localized disease in premature or very low-birth-weight infants is treated with IV medication.[67] A more thorough evaluation (including blood and CSF cultures) and parenteral antibiotics should be given to infants with systemic symptoms, premature or low birth weight infants, or infants with more widespread infection. Empiric treatment options for staphylococcal skin and soft tissue infections (SSTI) include vancomycin, clindamycin, and linezolid. Infants initially started on parenteral therapy who have shown clinical improvement and have negative blood and CSF cultures can often be switched to oral therapy. Oral antibiotic options for staphylococcal SSTI include cephalexin, clindamycin, linezolid, and amoxicillin-clavulanate. A total duration of 7-14 days of therapy is recommended.

Syphilis

Syphilis is caused by *Treponema pallidum*, a thin, motile spirochete. Syphilis is generally acquired through sexual contact, in which the spirochete enters through breaches in squamous or columnar epithelium. Transmission of congenital syphilis is most frequently transplacental, although infection is rarely acquired by contact with genital lesions during delivery. The incidence of congenital syphilis parallels that of primary and secondary disease in women. In the late 1980s and early 1990s, the incidence of acquired and congenital syphilis increased dramatically in the United States. Decreasing incidence was seen in the late 1990s, but since 2001, the rates of primary and secondary syphilis have increased. From 2004-2007, a 38% increase in rates of primary and secondary syphilis was seen among females. This was associated with a subsequent 23% increase in the rate of congenital syphilis (8.2 cases per 100,000 live births in 2005 to 10.1 during 2008).[17] The number of congenital syphilis cases declined in 2008-2012, followed by another sharp increase from 2012-2014, representing an increase in rate from 8.4-11.6 cases per 100,000 live births (Fig. 48.1). Rates of infection are highest in large urban areas and the southern United States with rate among blacks remaining approximately 10 times the rate among whites.[12]

• **Fig. 48.1** Congenital syphilis (CS) rate* among infants aged <1 year and rate of primary and secondary (P&S) syphilis among women† — United States, 2008-2014§. *CS rates during 2008-2013 were calculated by using annual live birth data as denominators. (Available at http://wonder.cdc.gov/natality-current.html.) †P&S syphilis rates during 2008-2013 were calculated by using bridged race U.S. census population estimates as denominators. (Available at http://wonder. cdc.gov/bridged-race-v2013.html.) §The CS rate and P&S syphilis rate for 2014 were calculated by using 2014 case counts and 2013 denominators. (From Centers for Disease Control and Prevention. Morbidity and mortality weekly report. November 13, 2015; 64[44].)

Transplacental transmission can occur at any time during pregnancy and at any stage of maternal disease. Rates of transmission are higher during primary and secondary maternal syphilis than with later stages of disease (early latent and late latent). Intrauterine infection may result in spontaneous abortion, hydrops fetalis, or stillbirth. Infection also increases the risk for preterm birth, low birth weight, and perinatal death. Clinical manifestations in infected infants within the first 1-2 months of age include hepatosplenomegaly, lymphadenopathy, rash, mucocutaneous lesions, copious nasal secretions (snuffles), pneumonia,

• BOX 48.1 Clinical Findings of Early Congenital Syphilis*

Nonimmune hydrops fetalis
Intrauterine growth restriction
Failure to thrive
Generalized lymphadenopathy
Bone abnormalities
- Periostitis
- Osteochondritis (Wimberger sign)
- Osteitis

Hepatosplenomegaly (with or without elevated aminotransferases, jaundice)
Mucocutaneous lesions
- Pemphigus syphiliticus (vesiculobullous eruption, contagious)
- Maculopapular eruption
- Mucous patches of palate, perineum, intertriginous areas
- Condyloma latum

Persistent rhinitis (snuffles, contagious)
Pneumonitis (pneumonia alba)
Nephrotic syndrome
Neurologic abnormalities
Syphilitic leptomeningitis
Hematologic abnormalities
- Leukocytosis
- Leukopenia
- Anemia, Coombs-negative hemolytic
- Thrombocytopenia

Ocular abnormalities
- Chorioretinitis
- Uveitis

*Defined as age <2 years.

• BOX 48.2 Clinical Manifestations of Late Congenital Syphilis*

Dental
- Hutchinson teeth (notched, peg-shaped upper central incisors)†
- Mulberry molars (multiple small cusps)

Bone
- Frontal bossae of Parrot
- Saddle nose deformity
- Short maxillae
- High-arched palate
- Higoumenakía sign (sternoclavicular thickening)
- Flaring scapulae
- Saber shins (anterior bowing of tibia)
- Clutton joints (painless synovitis, hydrarthrosis)

Cutaneous
- Rhagades (linear scars radiating from mouth, nares, and anus)

Ocular
- Interstitial keratitis†

Neurologic
- Eighth cranial nerve deafness†
- Mental retardation
- Hydrocephalus
- Cranial nerve palsies
- Seizure disorder

*Defined as age >2 years.
†Features of Hutchinson triad.

hemolytic anemia, thrombocytopenia, and skeletal involvement (osteochondritis, periostitis, and osteitis) (Box 48.1). The nasal secretions and skin lesions in untreated infants are highly infectious. Infected infants may also be completely asymptomatic.

Treatment of early-stage infection can prevent late manifestations of infection. Left untreated, late-stage findings usually appear after 2 years of age and include CNS, skeletal, dental, ocular, and skin involvement (Box 48.2). Several of these findings may not occur until many years later. The Hutchinson triad refers to interstitial keratitis, eighth cranial nerve deafness, and notched central incisors (Hutchinson teeth). Other manifestations include frontal bossing, saddle nose deformity, and anterior bowing of the shins.

All women should be screened for syphilis with serologic testing early in pregnancy and again at delivery.[125] Initial screening should be done with a nontreponemal test (e.g., RPR, rapid plasma regain; VDRL, Venereal Diseases Research Laboratory). The result of a positive nontreponemal test should be confirmed with a treponemal antibody test (e.g., FTA-ABS, fluorescent treponemal antibody absorption; TP-EIA, *T. pallidum* enzyme immunoassay; MHA-TP, microhemagglutination test for antibodies to *T. pallidum*; TP-PA, *T. pallidum* particle agglutination). Any woman treated for syphilis during pregnancy should have follow-up testing with a nontreponemal titer to assess response to therapy. Penicillin is the recommended treatment for pregnant women. Admission for desensitization to penicillin is recommended for women with penicillin allergies.

Low-titer, false-positive nontreponemal test results do sometimes occur during pregnancy. A false-positive nontreponemal test result is confirmed if a woman has a reactive nontreponemal test but a consistently negative treponemal test result. Some laboratories screen pregnant women using a treponemal TP-EIA test. If a woman has a reactive TP-EIA, she should have confirmatory testing done with an RPR or VDRL. Subsequent evaluation of the infant should be based on the infant's RPR or VDRL titer results as compared with the mother's.

An infant should be fully evaluated for congenital syphilis if the maternal RPR/VDRL titer has increased fourfold, the infant's RPR/VDRL titer is fourfold greater than the mother's, or the infant is symptomatic or has an abnormal exam. If an infant is born to a mother adequately treated for syphilis with penicillin before the pregnancy with a stable low titer and has a normal physical examination, the infant does not require further evaluation or treatment. If the mother was adequately treated with penicillin during pregnancy more than 4 weeks before delivery, the infant has

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

a normal examination, and the infant's RPR/VDRL is the same as or less than fourfold the maternal titer, then the infant may be treated with penicillin without further evaluation. If a mother has untreated or inadequately treated syphilis (received no treatment or treatment is not documented, treatment was 4 weeks or less before delivery, or treatment was with a non-penicillin drug), then the infant requires full evaluation and treatment.

Full evaluation for congenital syphilis includes RPR/VDRL; complete blood count; and CSF examination for cell count, protein, and quantitative VDRL. Other tests should be done as clinically indicated, including long bone radiographs, eye examination, liver function tests, neuroimaging, hearing tests, and chest radiographs. A definite or highly probable diagnosis of congenital syphilis is based on presence of any of the following: physical, laboratory, or radiographic evidence of active infection; a positive CSF VDRL; an infant RPR/VDRL titer fourfold or more than that of the mother; or a positive specific treponemal stain of the placenta or umbilical cord.

The recommended treatment for definite or probable congenital syphilis is intravenous penicillin G. The dose is based on chronologic rather than gestational age. The recommended dose is 50,000 U/kg every 12 hours if 1 week of age or younger, or every 8 hours if older than 1 week, for a total duration of 10 days. If more than 1 day of therapy is missed, the entire course should be restarted.

All infants with reactive RPR/VDRL or those who were seroreactive at delivery require careful follow-up during the first year of life. Nontreponemal tests should be performed every 2-3 months until the test becomes nonreactive or the titer has decreased at least fourfold. If the infant was adequately treated in the neonatal period, the nontreponemal titer should be nonreactive by 6 months of age. Infants with increasing or persistently stable titers 6-12 months after treatment should be re-evaluated (including CSF VDRL) and treated with a 10-day course of intravenous penicillin G. Infants diagnosed with congenital neurosyphilis should have a repeat clinical evaluation with CSF examination every 6 months until the CSF is normal. If the CSF VDRL is positive 6 months after initial treatment course, the infant should be retreated with another 10-day course of penicillin.[94]

Listeriosis

Listeriosis is caused by *Listeria monocytogenes*, a non-spore-forming, short, Gram-positive bacillus. It is an intracellular pathogen that is able to survive and multiply within host phagocytic cells. Listeriosis primarily affects older adults, pregnant women, neonates, and immunocompromised hosts. Listeria is found in soil and decaying vegetable matter. It is also found in the intestinal tracts of several mammals, birds, fish, and crustaceans. In adults, most infections are thought to arise from oral ingestion of contaminated material, leading to intestinal mucosal penetration and systemic infection. Impaired cell-mediated immunity and macrophage function are associated with increased susceptibility to infection with Listeria.[107] In pregnant women, the bacterium is able to cross the placenta during maternal bacteremia and infect the fetus. Infection in pregnant women can lead to spontanous abortion, stillbirth, preterm labor, or neonatal infection.

In a systematic review of peer-reviewed literature, the WHO estimated that listeriosis resulted in 23,150 illnesses worldwide in 2010 leading to 5463 deaths. In this review of listeriosis cases, 20.7% were perinatal infections with septicemia occurring in 30.7% of infected neonates.[24] Most cases of listeriosis occur as sporadic illnesses, likely after ingestion of contaminated food. Several foodborne outbreaks have also been reported and are associated with a variety of foods. The most common foods implicated in infections are delicatessen meats, hot dogs, soft cheeses, smoked seafood, and pâtés.

Among all organisms causing neonatal sepsis, *L. monocytogenes* is a relatively uncommon cause. Listeria infection in neonates is classified as early onset or late onset. The signs and symptoms of listeriosis in neonates are indistinguishable from the signs and symptoms of other postnatal bacterial infections. Early-onset disease is most often acquired by transplacental transmission, and affected infants are symptomatic soon after birth. Meconium passage is often associated with intrauterine Listeria infection. Common manifestations of early-onset infection include neonatal sepsis and pneumonia. Late-onset infection may be acquired by vertical transmission from a colonized mother during passage through the birth canal or by transmission from other colonized or infected caregivers. Symptoms usually arise after the first week or two of life. The most common manifestation of late-onset listeriosis is meningitis, often with insidious onset.

As for any neonate with suspected sepsis, blood and CSF cultures should be obtained. In addition, isolation of *L. monocytogenes* from cultures of amniotic fluid or placental tissue may support the diagnosis of early-onset disease. Recommended empiric antibiotic treatment for neonatal sepsis includes ampicillin and an aminoglycoside. This regimen provides important coverage for listeriosis, as cephalosporins have no activity against *L. monocytogenes*. When infection with Listeria has been confirmed, the antibiotic of choice is ampicillin. The addition of gentamicin is recommended to provide synergy. After the patient demonstrates clinical improvement, gentamicin can be discontinued and ampicillin given alone to complete the remainder of treatment. For all cases of Listeria meningitis, a repeat lumbar puncture should be performed 1-2 days after the start of treatment to confirm sterilization of the CSF. Treatment duration of 10-14 days is recommended for uncomplicated bacteremia. For meningitis, treatment should be continued for 14-21 days. All patients with Listeria meningitis should have neuroimaging obtained near the anticipated end of treatment to determine whether there is parenchymal involvement and whether the patient may require a more prolonged course of treatment.

TABLE 48.2 Perinatal Transmission of Tuberculosis

Maternal Focus of Infection	Mode of Spread	Timing	Relative Frequency
Pneumonia with cavitary lesion*	Inhalation of infected droplets	Postnatal	Most common
Amniotic infection after rupture of placental caseous lesion	Aspiration or ingestion of infected fluid	Congenital or intrapartum	Less common
Placentitis after miliary or endometrial tuberculosis	Hematogenous through umbilical vein	Congenital	Rare
Cervicitis	Direct contact, aspiration, or ingestion	Intrapartum	Rare
Mastitis	Ingestion of infected milk	Postnatal	Extremely rare

*Any caregiver with cavitary pulmonary tuberculosis can transmit infection to the infant.

Tuberculosis

Although perinatal tuberculosis (TB) is rare in the United States, the burden of tuberculosis, especially worldwide, among women of childbearing age is quite high.[29] The risk for perinatal TB is much higher in areas with high prevalence for both TB and HIV infection among young women.[69] Perinatal TB includes both congenital and neonatal TB (Table 48.2). Mother-to-child transmission of congenital TB may occur in utero by hematogenous dissemination via the umbilical vein or by intrapartum aspiration of infected amniotic fluid or genital secretions. Tuberculosis during pregnancy is also associated with increased risk for preterm labor, low birth weight, and fetal and perinatal death. Clinical manifestations of congenital TB are often nonspecific and include respiratory distress, lethargy, irritability, fever, low birth weight, hepatosplenomegaly, and poor feeding.

Neonatal TB, which is somewhat more common than congenital TB, is transmitted through inhalation or ingestion of respiratory droplets or through ingestion of infected breast milk. Clinical manifestations include failure to thrive, fever, vomiting, cough, and tachypnea. Because perinatal disease is very rare, there are little data on mortality rates and outcomes. Without prompt evaluation and treatment, mortality rates are quite high and are estimated at 50%.[42]

Any neonate with suspected TB disease should undergo a complete evaluation for both TB and bacterial sepsis. A tuberculin skin test (TST) should be placed, although newborns may have a nonreactive TST in the presence of active disease. Interferon-gamma release assays (IGRA) are not reliable in children younger than 4 years and should not be used in the diagnostic work-up of either latent or active TB infection in infants. A chest radiograph should be obtained. Mycobacterial stains and cultures should be obtained from three consecutive, early-morning gastric aspirates to evaluate for pulmonary TB. Mycobacterial stains and cultures can also be obtained from other sites if extrapulmonary TB is suspected. Cerebrospinal fluid obtained for evaluation of routine bacterial meningitis should also be sent for mycobacterial stains and cultures.

Regardless of the initial TST result and while other studies are pending, the infant should be promptly started on antituberculosis therapy with isoniazid, rifampin, pyrazinamide, and either ethambutol or an aminoglycoside such as amikacin, kanamycin, or streptomycin. The infant's mother should undergo a full evaluation for pulmonary and extrapulmonary TB (including uterine infection). The placenta should be examined for the presence of granulomas and sent for mycobacterial stains and culture. If the infant's physical examination and diagnostic work-up are consistent with TB, a full treatment regimen should be administered. This should consist of 2 months of the described four-drug regimen, followed by at least 4 months of isoniazid and rifampin. If TB meningitis is confirmed, corticosteroids should be added.[94]

Management of the asymptomatic newborn whose mother or another household contact has TB will depend on whether the contact has latent TB infection or active disease. If the mother has a positive TST or IGRA, a normal chest radiograph, and is asymptomatic, no separation between mother and baby is required. The infant needs no special evaluation or therapy. The mother is a candidate for latent TB infection treatment after the initial postpartum period. Breastfeeding is not contraindicated.

If the mother (or household contact) has a positive TST/IGRA along with clinical symptoms or an abnormal chest radiograph consistent with active TB disease, the infant and mother should be separated until the mother has been fully evaluated, including testing for HIV. The infant should be evaluated for congenital TB, and all household contacts should be evaluated for TB infection. If the mother is diagnosed with active TB, separation from the infant is only required until the mother is on antituberculosis treatment and the infant is receiving isoniazid. Continued separation is necessary if the mother has suspected multidrug-resistant TB or has poor adherence to therapy. The mother may breastfeed if she has been on therapy for at least 2 weeks and is not considered contagious. If congenital TB is excluded, the infant should be given isoniazid until 3 or 4 months of age, when a repeat TST is performed. If the TST

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

is positive, repeat evaluation for TB disease is required. If the TST is negative, the infant should receive a total of 9 months of isoniazid.[94]

Botulism

Infant botulism is caused by *Clostridium botulinum*, a heterogeneous group of ubiquitous, spore-forming, obligate anaerobic, Gram-positive bacilli. The spores are found across the globe in soil, water, agricultural products, and honey. When appropriate environmental conditions are present, the spores germinate and grow into toxin-producing bacteria. Eight serologically distinct types of *C. botulinum* toxin have been described. Toxin types A, B, E, and rarely F and G cause disease in humans.[78] After entry into the body, the toxin disperses widely throughout the body and binds to a specific receptor on peripheral cholinergic synapses of ganglia and neuromuscular junctions.[57] Binding of the toxin leads to irreversible disruption of acetylcholine release by the presynaptic nerve terminal, which in turn leads to a severe neuroparalytic syndrome. Different types of botulism infection are classified according to the mode of acquisition. Foodborne botulism occurs after ingestion of preformed botulinum toxin in contaminated food. Infant botulism occurs after ingestion of the spores, which then colonize the host's GI tract and release toxin produced in vivo.

Infant botulism was first recognized as a distinct entity in 1976. On average, 100-150 cases of botulism are reported each year in the United States. Of these, approximately 75% are cases of infant botulism.[89] Incidence is highest in California (which accounts for over 50% of cases), Texas, and Pennsylvania. Although infant botulism has long been associated with the ingestion of raw honey, most cases likely result from ingestion of environmental dust containing *C. botulinum* spores. The spores have been isolated from several types of environmental samples, including yard soil and vacuum dust.

Clinical manifestations of infant botulism range from mild disease to sudden death, and onset may be insidious or fulminant. The diagnosis must be considered in any infant presenting with hypotonia, constipation, and poor feeding. In the United States, the median age of affected infants is approximately 17 weeks, ranging from 1-60 weeks of age.[89] Presenting symptoms often include lethargy, poor feeding, drooling, constipation, and progressive, symmetric weakness. The weakness may involve descending or global hypotonia. Patients are typically afebrile. Early in the course, the physical examination may be normal. As the infection progresses, cranial nerve palsies, poor head control, and weak cry develop. Loss of gag, swallow, and suck reflexes can lead to airway compromise. Initially, deep tendon reflexes may be normal, although these become diminished or absent as the descending, symmetric, flaccid paralysis progresses.

Because confirmatory stool studies and electrophysiologic studies can be nonspecific and may require several days to obtain results, a presumptive diagnosis should be made based on clinical presentation, and therapy should be administered as soon as possible. For assistance with management of any suspected case of infant botulism in the United States, the California Department of Health Services, Infant Botulism Treatment and Prevention Program may be contacted (www.infantbotulism.org, [510] 231-7600) to discuss with an on-call physician.

The diagnosis is supported by isolation of *C. botulinum* spores from the stool and confirmed by identification of the botulinum toxin in the stool. Stool sample collection is often difficult because most patients are constipated, and it takes several days to obtain results from these stool studies (which must be sent out to reference laboratories at state health departments or the CDC). While stool study results are pending, electromyography (EMG) may be obtained. Electromyography findings that are consistent with infant botulism include short-duration, low-amplitude motor unit potentials, as well as abnormal incremental response to repetitive nerve stimulation.[21]

Treatment includes supportive care and very close monitoring for signs of respiratory failure. All suspected cases should receive botulism immune globulin intravenous (BIG-IV or BabyBIG) as early as possible. Botulism immune globulin intravenous is a human-derived botulinum antitoxin, and it has been shown to be safe and effective treatment for infant botulism. A randomized, placebo-controlled trial showed that patients who received BIG-IV had reduced duration of hospital stay, intensive care, mechanical ventilation, and tube or intravenous feedings. Botulism immune globulin intravenous was not associated with any serious adverse events.[3] Antibiotics are not recommended for infant botulism because lysis of *C. botulinum* organisms within the gastrointestinal lumen could increase the amount of toxin available for absorption.[13]

Recovery often requires several weeks, although most patients are expected to achieve complete recovery. Botulinum toxin does not cross the blood–brain barrier and thus does not affect the CNS. The case fatality rate for infant botulism is currently less than 1%.[89]

Tetanus

Neonatal tetanus is very rare in developed countries because of widespread hygienic birth conditions and maternal immunization, although it remains a significant cause of morbidity and mortality in developing countries. Tetanus is acquired through exposure to the spores of *Clostridium tetani*, a slender, anaerobic, Gram-positive bacillus. When the spores germinate, the bacteria produce the tetanospasmin toxin (also known as tetanus toxin). The toxin reaches the spinal cord and brainstem and binds tightly and irreversibly to receptors at the neuromuscular synapse. Its effects occur through disinhibition of neurons that modulate excitatory impulses from the motor cortex. This results in increased muscle tone, spasms, and autonomic instability.

Clostridium tetani is present in the soil and can be found in human and animal feces. Because it is impossible to eliminate the bacteria or its spores from the environment,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

control of the disease relies on widespread immunization and proper wound care. The World Health Organization (WHO) reports that neonatal tetanus resulted in approximately 34,019 deaths in 2015, representing a 96% reduction in deaths since the late 1980s.[127] Neonatal tetanus remains a problem in several countries because of inadequate maternal immunization coverage and unhygienic birth practices leading to infection of the umbilical stump.

Disease onset typically occurs at 1 week of age, with incubation periods ranging from 1 day to 1 month. Clinical manifestations include irritability, poor suck, fever, rigidity, muscle spasms, and seizures. Spasms are exacerbated by stimulation. On examination, infants usually have hyperreflexia and extreme flexion of the toes. Although trismus is commonly seen in generalized tetanus in adults, it is seen less often in infants. Other signs include tachycardia, tachypnea, and apnea. Laryngospasm may lead to aspiration pneumonia, and pulmonary processes are a frequent cause of death in neonatal tetanus.

The diagnosis is based strictly on clinical presentation. Treatment is largely supportive. Intramuscular human tetanus immune globulin is given to neutralize unbound toxin, and metronidazole is given to reduce the number of toxin-producing bacteria. Airway management and maintaining adequate ventilation are essential, although unfortunately, critical care services are often not available in resource-poor settings where most neonatal tetanus occurs. Benzodiazepines and baclofen can be given to help control muscle spasms. Because stimulation can precipitate spasms and seizures, efforts should be made to reduce environmental stimulation as much as possible. Magnesium sulfate and beta-blockers can help control autonomic dysfunction.

Since the introduction of mechanical ventilation and benzodiazepines in the 1960s and 1970s, the morbidity and mortality of tetanus patients of all ages has significantly decreased. If modern critical care services are available, mortality rates may be less than 20%. If basic medications and high-quality nursing care are provided, mortality rates can be reduced to under 50%. Survivors may have full recovery or varying degrees of neurologic sequelae, ranging from minor deficits to cerebral palsy.

Acknowledgments

The author would like to acknowledge the contributions of Drs. Morven Edwards, Katherine Dobbs, and Ethan Leonard, who were authors of this chapter in previous editions.

Key Points

- Newborns are extremely susceptible to infection.
- Current recommendations include universal screening for rectal and vaginal GBS colonization of pregnant women between 35 and 37 weeks' gestation. Antibiotics should be given to those mothers identified at risk.
- The introduction of universal screening for maternal GBS colonization and use of intrapartum antibiotic prophylaxis has led to 80% reduction in the burden of early-onset GBS disease yet has had no impact on late-onset disease.
- The use of ciprofloxacin is indicated in those infants with multidrug-resistant Gram-negative disease when alternative antibiotics are not available.
- There are increasing reports of methicillin-resistant *S. aureus* (MRSA) disease in newborns across the United States, paralleling the spread of drug-resistant *S. aureus* in the community.

Fungal and Protozoal Infections of the Neonate

DAVID A. KAUFMAN AND PAOLO MANZONI

Fungal infections in the neonatal intensive care unit (NICU) remain an important health problem associated with substantial morbidity and mortality. Invasive fungal infections encompass infections largely caused by *Candida* species and with a small portion caused by *Aspergillus*, *Zygomycetes*, *Malassezia*, *and Trichosporin*. Invasive *Candida* infections occur in two main patient groups in the NICU: (1) the extremely premature infant and (2) NICU patients with complex gastrointestinal disease such as necrotizing enterocolitis (NEC), gastroschisis, and spontaneous bowel perforation.[26,33,49,54,62] Strategies for prevention and management of invasive *Candida* infections are paramount for improving outcomes for neonates (Fig. 49.1).

The incidence of candidiasis correlates with advances in medical therapy and increased survival of extremely low birth weight and gestational age preterm neonates. In developed countries, increases occurred in the 1980s and 1990s, then began to fall after 2001, primarily in infants less than 1000 g, owing to various factors including antifungal prophylaxis, antibiotic and medication stewardship, and central line–associated bloodstream infection (CLABSI) bundles.[24,38,52]

Definitions

Invasive *Candida* infections (ICI) in neonates include: congenital cutaneous candidiasis (CCC) and late-onset cutaneous candidiasis, bloodstream infections (BSIs), urinary tract infections (UTIs), meningitis, peritonitis, and infection of other sterile sites (bone and joint infections). These infections are often classified similar to other neonatal infections into early-onset (<72 hours after birth) and likely vertically transmitted and late onset (≥72 hours after birth) and potentially horizontally transmitted infections. This is a worthy system to standardize definitions, recognizing that *Candida* species are slow-growing organisms and some infections in the first weeks of life have been shown by molecular studies to be vertically transmitted.

Microbiology

Candida albicans and *C. parapsilosis* account for 80%-90% of invasive *Candida* infections in centers not using antifungal prophylaxis. Less-common *Candida* species include *C. glabrata* and *C. tropicalis*, and a smaller percentage of infections are caused by *C. lusitaniae*, *C. guilliermondii,* and *C. dubliniensis. C. parapsilosis* isolates have been found to be genetically heterogeneous, with 10% being identified as two different species: *C. metapsilosis* and *C. orthopsilosis*. These three species are phenotypically indistinguishable, and molecular methods are needed for their detection. Centers using antifungal prophylaxis have a very low incidence of infections, and the few that occur are primarily by non-*albicans* species in NICUs using fluconazole prophylaxis. The change in epidemiology of *Candida* species with antifungal prophylaxis is important because fluconazole prophylaxis has virtually eliminated the more virulent *C. albicans* infections.

Pathogenesis and Pathophysiology

Most *Candida* species are commensal organisms and part of the normal human microbiome in the skin and gastrointestinal tract. They may exist primarily as budding yeast cells, filamentous hyphal structures, or both. Adherence and colonization are normal, and fungi become pathogenic owing to fungal and host factors (Fig. 49.2).

The slow-growing nature of *Candida* facilitates its ability to progress from colonization to dissemination into the bloodstream and body tissues before clinical signs and symptoms of infection become apparent. In preterm neonates, similar to other hosts, four major steps can be identified in infected infants after exposure to *Candida* spp.: (1) adhesion, (2) colonization, (3) dissemination, and (4) abscess formation (see Fig. 49.2). These steps are related to the size of the inoculum (e.g., the number of fungal organisms), their virulence, and the characteristics of the host response.

Abstract

Invasive *Candida* infection is associated with significant mortality and morbidity with extremely preterm infants comprising the highest risk patients. NICU patients are at risk due to their developing skin, gastrointestinal tract and immune system; need for intensive care, catheters, and tubes that breech important protective barriers; and exposure to antibiotics and certain medications that can favor fungal growth. Standardization of treatment regimens is key to improving outcomes including appropriate dosing and prompt central catheter removal with *Candida* bloodstream infections. Cutaneous manifestations of *Candida* and molds such as aspergillosis warrant prompt recognition, culturing of the skin in addition to other sites, and systemic empiric treatment at the time of rash presentation. Empiric antifungal treatment when invasive *Candida* infection is suspected should also be given in high-risk patients. The majority of infected infants despite empiric and optimal treatment still have significant sequelae or do not survive making prevention critical for every NICU. Prevention in high-risk patients is highly effective and recommended by pediatric infection control groups using a combination of antifungal prophylaxis, central catheter infection prevention measures, and antibiotic and medication stewardship. Targeted antifungal prophylaxis with infection control practices administered to infants with birth weights less than 1000 g and/or less than 28 weeks' gestational age can significantly reduce invasive *Candida* infections, their associated neurodevelopmental impairment, and *Candida*-related mortality. Both nystatin and fluconazole prophylaxis have level A-I evidence demonstrating efficacy in the prevention of invasive *Candida* infection with fluconazole having the better efficacy in extremely low birth weight infants.

• **Fig. 49.2** Pathogenesis of invasive *Candida* infections.

Adhesion is the key step in colonization. Candidal species can adhere to epithelial and endothelial cells as well as catheters. Biofilm formation limits penetration of antifungals and shielding *Candida* from the host response. Surface glycoproteins such as INT1p, which binds to beta-integrins present on the endothelium and white blood cells, facilitate fungal adherence. The absence of a functional *INT1* gene diminishes adherence in yeast cells.[40]

The preterm infant has an immature immune system and is frequently exposed to broad-spectrum antibacterial and other medications that can suppress their immune response. Studies examining the effect of steroids and antibiotics have been performed in mice orally inoculated with *C. albicans* to mimic conditions in the preterm infant.[12] Antibiotic treatment alone led to increased *Candida* colonization but did not affect dissemination. When dexamethasone was added to the antibiotic regimen, both colonization and dissemination increased in these animal models. Additionally, dexamethasone plus antibiotics led to an increase in the percentage of filamentous forms in the gastrointestinal tract compared with antibiotics alone. These studies also showed that *C. albicans* strains with two functional copies of the *INT1* gene increased the number of fungi colonizing the cecum and disseminating to extraintestinal sites.

Studies consistently demonstrate higher associated mortality in preterm infants with *C. albicans* compared with non-*albicans* BSIs.[16,103] Its virulence encompasses a combination of factors involving adhesion, cytotoxicity, hydrolytic enzymes (aspartyl proteinases, phospholipases, lipases, and hemolysins), morphologic switching, and genes. In addition to the adhesion factors discussed, *C. albicans* produces higher concentration of hydrolytic enzymes compared to non-*albicans* species.

C. albicans can alternate its morphology in response to specific environmental cues, has an obligate diploid genome, lacking a complete sexual cycle, and has several genes important for virulence. Studies have found a strong correlation between virulence and the ability to alternate among three morphological forms—yeasts, hyphae, and pseudohyphae. The morphologic switch is a complex process involving changes in cellular shape, mechanical properties, interactions with other cells, and differential expression of multiple genes. Because of their size and shape, filamentous forms increase virulence of *C. albicans* in part by escaping phagocytosis.

To further examine the role of yeast and filamentous forms, three strains of *C. albicans* were studied: (1) a wild-type strain that had both yeast cell and filamentous forms, (2) a strain only producing yeast cells, and (3) a strain that was constitutively filamentous.[11] The mortality rate was significantly greater in both the wild-type (92%) and yeast-cell (56%) strains compared with the filamentous strain alone (0%). The filamentous strain had no dissemination, and cecal colonization was significantly less than that of the other two strains. The wild-type strain had diffuse hyphal invasion with increased tissue necrosis compared with the yeast-cell strain. The researchers speculated that the yeast forms are critically important for adherence and tissue dissemination and that hyphal formation in the tissues contributes to parenchymal destruction.

Prematurity

The immature lymphocyte and antibody system predisposes preterm infants to skin and mucosal fungal adherence and colonization, whereas deficient innate host defense mechanisms predispose them to dissemination and overwhelming infection.[54] With compromise of the barrier defense system, invasive *Candida* infections may occur, owing to deficient neutrophil function and when neutropenia is present. Neutrophils provide the major role in antifungal defense, ingesting and killing *Candida* in a process requiring production of oxygen metabolites, antibodies, cytokines, and activation of the C3 complement component, all of which are decreased in preterm infants compared with term infants and adults. Also deficient are neutrophil granules and cytokines that play a critical role in the

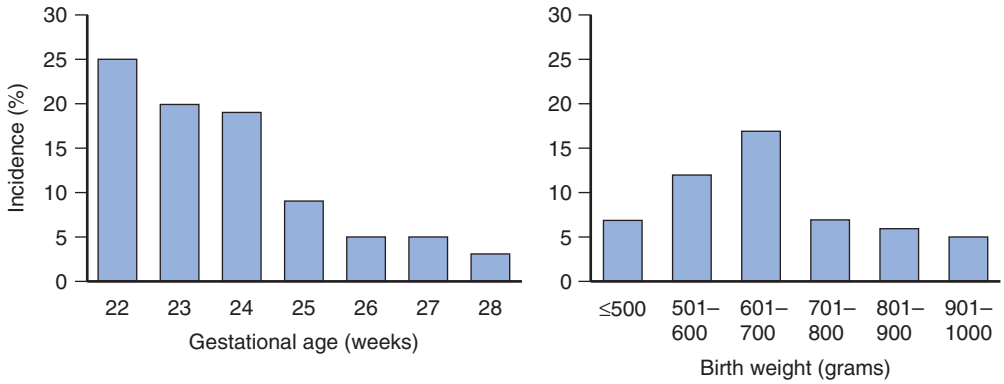
lysis of *Candida* hyphae and pseudohyphae, which are too large to be engulfed by phagocytosis. Macrophages have impaired adherence, phagocytosis, and oxidative killing in preterm infants, affecting their ability to contain fungal colonization and infection. In addition, dysregulation of the cytokine response of the innate immunity against fungal infection impairs cytokine enhancement of cell-mediated fungicidal activity. Pulmonary host defense is also diminished by immature or deficient alveolar macrophages, cilia and mucous, and surfactant in preterm infants.

Additionally, studies in animal models showed that the hypoxic insult effect on cellular function and tissues that can be common in preterm infants around delivery or with apnea events is associated with increased gut fungal colonization and dissemination to mesenteric lymph nodes.[60]

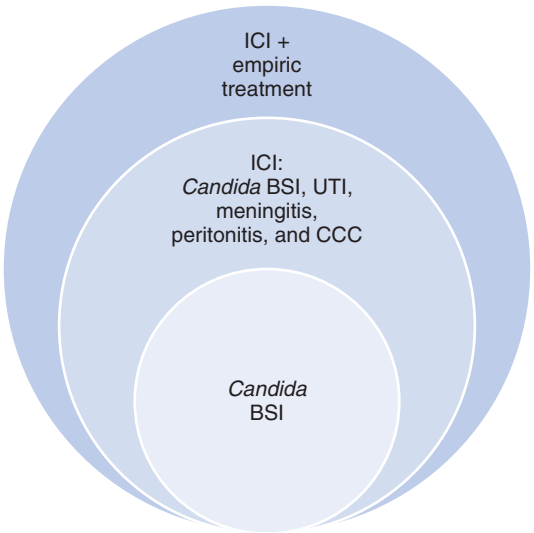
Candida species produce proteases that may be lytic for the thin keratin layer produced by the immature stratum corneum in the first weeks after birth and phospholipases against lipid membranes that both may facilitate epithelial invasion.[54] Recently the first cytolytic peptide toxin of *C. albicans* that can directly damage epithelial membranes was identified.[78] Increased transepidermal water loss from preterm skin creates a moist environment that facilitates fungal colonization and growth. Because of the increased permeability of the preterm skin, substrates such as glucose may diffuse to the epithelial surface, facilitating *Candida* growth. *Candida* may alter its surface structure in the presence of high glucose, increasing its adherence and proliferative properties. Skin maturation occurs by 2 weeks of life in extremely preterm infants, after which new fungal skin colonization occurs less frequently.



Incidence

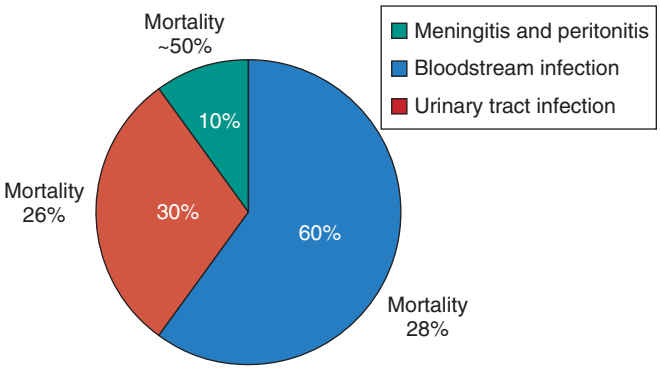
There is variation between rates in different NICUs and the incidence reported in the literature. These differences reflect a wide range of factors and are not a mere indicator of the overall quality of care. Based on patient demographics; use of antifungal prophylaxis; surgical population; resuscitation of extremely preterm infants; and practices related to feeding, medication, and antibiotic usage of individual NICUs, considerable variation exists between rates and risk for invasive *Candida* infections. Fridkin et al. reported the rate of *Candida* BSIs ranged between 3% and more than 23% among NICUs in infants less than 1000 g, and other studies have reported similar findings[17,30,38] (Fig. 49.3). Centers that care for infants with gastroschisis, NEC, and other complex gastrointestinal diseases have an increased risk for invasive *Candida* infections.[33] Resuscitation practices may be the most significant area of practice variation affecting invasive *Candida* infection rates; NICUs that do not resuscitate infants less than 25 weeks, for example, would have a lower rate of invasive *Candida* infections in infants less than 1000 grams compared with centers caring for 23- and 24-week-gestation infants.

The literature has limitations owing to definitions of incidence. Studies including all invasive *Candida* infections in both preterm and full-term infants are limited, and most studies of incidence or risk factors focus on only *Candida* BSIs. The burden of all invasive *Candida* infections is nearly twice as high as BSI rates (Figs. 49.4 and 49.5).



The incidence of invasive *Candida* infections in extremely low birth weight (ELBW, <1000 grams at birth) infants, not including congenital cutaneous candidiasis, is around 10% in the absence of antifungal prophylaxis.[17] The highest incidence of invasive *Candida* infections occurs in the most extremely preterm infants and is greater than 20% for infants less than 25 weeks' gestation (see Fig. 49.3). Many studies only report BSI incidence, but *Candida* UTIs account for an additional 3%-4% of invasive *Candida* infections in ELBW infants.[17,52,117] Multicenter studies have reported that *Candida* UTIs have a high associated mortality similar to *Candida* BSIs in ELBW infants, confirming their invasive nature in neonates.[17] Finally, meningitis and peritonitis contribute an additional 1%-2% to the incidence of invasive *Candida* infections in ELBW infants.[26]

Examining candidemia alone, the largest is a report from 128 US NICUs using US National Nosocomial Infections



• **Fig. 49.3** Incidence of invasive *Candida* infection (ICI) by gestational age and birth weight groups in infants less than 1000 grams birth weight not receiving antifungal prophylaxis. Gestational age has a linear relationship to ICI compared to birth weight and aids in defining the highest-risk patients. Data from 137 infections in 1515 infants less than 1000 grams from 19 centers of the NICHD Neonatal Research Network.

• **Fig. 49.4** Burden of invasive *Candida* infections (ICI). BSI, Bloodstream infection; CCC, congenital cutaneous candidiasis; UTI, urinary tract infection.

• **Fig. 49.5** Invasive *Candida* infections by site and mortality in extremely low birth weight infants. Although 60% were bloodstream infections, urinary tract infections and other sites accounted for an additional 40% and had similar or higher all-cause mortality. All-cause mortality at ≥2 sites was 57%. (Data from Benjamin DK Jr, Stoll BJ, Gantz MG, et al. Neonatal candidiasis: epidemiology, risk factors, and clinical judgment. *Pediatrics.* 2010;126(4):e865-e873.)

Surveillance (NNIS) system data from 1995-2004 (N = 130,523 neonates).[38] For infants less than 1000 g, the median infection rate was 7.5%, whereas 25% of NICUs had rates 13.5% or higher. The incidence decreases significantly for infants greater than 1000 g. Candidemia rates for infants of birth weights 1001-1500 g is 1.32%, for 1501-2500 g is 0.36%, and for those greater than 2501 g is 0.29%. The incidence increases in an inverse linear pattern when examining rates by gestational age. The rate of invasive *Candida* infections increases from around 3% at 28 weeks' gestation to 24% at 23 weeks' gestation (see Fig. 49.3).

Since 2001, several epidemiologic studies have tracked the incidence of *Candida* blood and cerebrospinal infections and have correlated a decrease in these infections with an increased use of fluconazole prophylaxis, decrease in broad spectrum antibiotics, and initiation of CLASBI prevention interventions.[2,24]

Complex Gastrointestinal Disease

Complex gastrointestinal diseases can be complicated by invasive *Candida* infections. Feja et al. found that candidemia was increased in patients with gastrointestinal pathology (OR = 4.57; 95% CI = 1.62-12.92).[33] Gastrointestinal pathology was defined in their study as tracheoesophageal fistula, gastroschisis, omphalocele, Hirschsprung disease, intestinal atresia, or episodes of NEC. The incidence of candidemia has been reported between 10 and 16.5% in patients with NEC.[20,23,81] Peritoneal cultures isolating *Candida* species have been found in ~50% of focal bowel perforations and 15% of surgical NEC cases.[26,91] In a study of the pathology from 66 surgical NEC cases, 7.5% had intestinal candidiasis with *C. albicans*.[85]

Congenital Heart Disease

Congenital heart disease is an emerging patient population that may develop invasive *Candida* infections. Candidemia accounts for 9% of BSIs in patients with congenital heart disease cared for in NICUs in the first 4 months of life.[4] *Candida* BSI occurred at a rate of 6.3 per 1000 admissions and had an overall mortality rate of 21%.

Extracorporeal Membrane Oxygenation

Candida species are the second most common cause of infection in neonates on extracorporeal membrane oxygenation (ECMO), responsible for 10% of infections.[19] Compared with the first 7 days on ECMO, *Candida* infections are twofold and fourfold more common between 8 and 14 days and more than 14 days on ECMO, respectively.

Outcomes

For preterm infants, invasive *Candida* infections are associated with neurodevelopmental impairment and high mortality.

Neurodevelopmental Impairment

Invasive *Candida* infections may lead to significant neurodevelopmental impairment even in the absence of documented fungal meningitis. Neurodevelopmental impairment in most studies is the presence of one or more of the following: low mental and motor development using Bayley Scales of Infant Development II, cerebral palsy, deafness, and/or blindness. Using these criteria, the incidence of neurodevelopmental impairment is 57% with candidemia versus 29% in noninfected ELBW infants.[16] The incidence is similar for *Candida* meningitis as well as with candiduria.[16,119] In another study demonstrating similar neurodevelopment impairment of 59% of *Candida*-infected patients, earlier

treatment within 2.1 ± 1.3 days of the blood culture was associated with normal or mildly impaired cases compared with later antifungal therapy (5.1 ± 3.0 days after blood culture was drawn), which was associated with severe disability or death ($p < .0001$).[39]

Survival

Candida-Related Mortality

Identifying *Candida*-related mortality is difficult to determine and in the literature may include attributable mortality, death within a specified number of days from onset of infection (3, 7, 14, or 30 days) or review of each death using predetermined definitions. Many studies simply report overall mortality. In infants less than 1000 g with invasive *Candida* infections, these rates range from an attributable mortality of 13% to 20% to overall mortality rates of 23% to 66% when examining overall mortality rates of patients in the placebo or control groups in the prophylaxis studies.[17,55,120] Mortality increases at lower gestational ages, and variation of mortality rates by NICU, similar to infection rates, is influenced by admission rates of these extremely preterm infants. Additionally, a standardized approach with prompt treatment with appropriate drug dosing and line removal with BSIs decreases *Candida*-related mortality rates.

Mortality is high with all types of invasive *Candida* infections in ELBW infants. In a multicenter epidemiologic study of patients less than 1000 grams, all-cause mortality rates were 28% for *Candida* BSI, 26% for *Candida* UTI, 50% for other sterile sites (meningitis and peritonitis), and if two or more culture sites were involved (BSI + UTI or UTI + meningitis), the mortality rate was 57% (see Fig. 49.5).[17] In this study, the overall mortality was 34% for infants with invasive *Candida* infections compared with 14% without infections.

There is a marked difference in overall and attributable mortality between infants less than 1000 grams and larger and more mature infants with invasive *Candida* infections. In infants less than 1000 g with infections, all-cause mortality rate was 26% compared with 13% in infants without candidiasis. For infants greater than 1000 g with invasive *Candida* infections versus those without, mortality was 2% compared with 0.4%.[120]

The *Candida* species causing the infection also affects survival. *C. albicans* is more virulent than nonalbicans species. In infants less than 1000 grams, *Candida*-associated mortality was 43% in infants with *C. albicans* candidemia compared with 19% with *C. parapsilosis* sepsis.[17]

Hospital Costs

The financial costs of invasive fungal infections are high. Two case control studies have examined the effect of these infections on cost of hospitalization and length of hospital stay.[102,120] They are limited, because they were based on ICD-9 codes, which may not have captured all invasive *Candida* infections. The mean increase in hospital costs was $39,045 for infants less than 1000 g with no difference in length of stay, and for infants ≥1000 g, there was an increase of $122,302 with an additional length of stay of 16 days.

Risk Factors

As neonatal candidiasis can be fatal among premature infants, an understanding of the risk factors that lead to infection is critical (Table 49.1). Conditions that facilitate fungal colonization and proliferation increase the risk for invasive infection and include gastrointestinal dysmotility, ileus, antibiotics, acid inhibition, steroids, and the immaturity of the patient's immune system. Several risk factors have been identified, with gestational age having the strongest effect. This correlates with the degree of underdevelopment of the immune system and immaturity of the skin and gastrointestinal and respiratory tracts in these infants.

The extremely preterm infant has the unique combination of being immune compromised, requiring prolonged intensive care (parenteral nutrition, mechanical ventilation/endotracheal tube, central venous access), being exposed to medications that promote fungal growth (H_2 blocking agents, proton pump inhibiting agents, postnatal corticosteroids,

TABLE 49.1 Patient-Related Risk Factors for Progression to Invasive *Candida* Infections in Colonized Patients in the NICU

Immunity	Medications That Facilitate Fungal Growth	Medications That Suppress Immune Defense	Diseases	Conditions
Undeveloped immune system Immunosuppression Neutropenia	Cephalosporins Carbapenems Postnatal steroids	Acid suppression (H_2 antagonists and proton pump inhibitors) Postnatal steroids	Necrotizing enterocolitis Focal bowel perforation Complicated gastrointestinal diseases (e.g., gastroschisis) Prior blood stream infection	Extreme prematurity Maternal vaginal colonization Vaginal delivery Male Central venous catheter Intubated Lack of enteral feedings Hyperglycemia

and broad-spectrum antibiotics), and being predisposed to gastrointestinal dysmicrobism, dysmotility, and disease (NEC and focal bowel perforation).[17,33,99] Infants, both term and preterm, with complicated gastrointestinal diseases such as gastroschisis or NEC also have multiple risk factors of prolonged ileus, central venous access, parenteral nutrition, surgery, and exposure to prolonged and/or broad-spectrum antibiotics.[33]

Medications such as broad-spectrum antibiotics and third- and fourth-generation cephalosporin and carbapenem antibiotics and the lack of feeding are associated with increased risk for candidemia.[13,30,99] It is hypothesized that these medications accumulate in high concentrations in bile and alter the balanced gastrointestinal microflora, eradicating competitive gram-negative and anaerobic bacteria, thus facilitating proliferation and dissemination of fungal organisms. Other classes of drugs found to be risk factors for neonatal fungal infection are H_2 antagonists and postnatal corticosteroids.[99,105] In examining risk factors present at 3 days after birth in infants less than 1000 g, lack of enteral feedings and third-generation cephalosporin use increased risk for infecion.[16] For infants not feeding by day of life 3, 8.7% developed *Candida* BSI or meningitis, compared with 3.4% of those receiving enteral feedings by day of life 3.

A few multivariate analyses have examined risk factors, finding that central venous catheter use, previous bacterial BSIs, broad spectrum antibiotics, presence of an endotracheal tube, and gastrointestinal pathology were significantly associated with candidemia.[33,99] Gastrointestinal pathology was defined in the study as tracheoesophageal fistula, gastroschisis, omphalocele, Hirschsprung disease, intestinal atresia, or episodes of NEC.[33]

The microflora of the oral mucosa and gastrointestinal tract play an important role in fungal colonization and infection. A normal bacterial flora inhibits *Candida* growth by competing for both adhesion sites and nutrients as well as various anticandidal actions. The commensal gut microflora can also enhance immunomodulatory activities against the most common pathogens, including *Candida* spp. This may explain, in part, the protective role of enteral feeding in the absence of antibiotics. In athymic compared to euthymic adult neonatal mice exposed to *Candida* spp., probiotics (*Lactobacillus acidophilus*, *L. reuteri*, *L.casei GG*, or *Bifidobacterium animalis*) decreased the incidence of systemic candidiasis and were associated with prolonged survival.[112] Probiotic bacteria also affected antibody- and cell-mediated immune responses to *C. albicans*. This highlights the fact that the intestinal microflora may be as important as a mature immune system in preventing fungal colonization and infection.

There are some differences in risk factors for infection by species. Risk factors for *C. albicans* and *C. parapsilosis* include exposure to third-generation cephalosporins, central vascular catheters, parental nutrition and lipid emulsions, and high acuity while, additionally, vaginal delivery increases risk for *C. albicans* and H_2 antagonists for *C. parapsilosis* infection.[99] Risk for *C. glabrata* infection is increased with gastrointestinal disease, exposure to fluconazole or antibiotics, prolonged hospitalization, and prior infection with other fungi. *C. tropicalis* infections are associated with gastrointestinal mucosal injury, antibiotic suppression of bacterial flora, neutropenia, and parenteral nutrition.[54]

Colonization

Colonization is the key step in the pathway that leads from exposure to disseminated infection. Colonization may occur via vertical (maternal) or horizontal (nosocomial) transmission. Most fungal colonization occurs by 2-3 weeks of life. Fungal colonization of the skin and respiratory or gastrointestinal tract occurs in 10% of full-term infants compared with 26.7%-62.5% of very low birth weight (VLBW, <1500 grams at birth) infants in the first weeks of life.[54] Fungal colonization and subsequent infection depend on exposure, size of inoculum, host susceptibility, and properties of the pathogen (see Fig. 49.2).

Vertical transmission leading to colonization is common and has been confirmed in studies using genotyping techniques. *Candida* yeast cells adhere preferentially to intermediate layers of the vaginal tract that are increased during pregnancy, increasing maternal fungal colonization and exposure of vaginally delivered infants. Maternal risk factors include gestational diabetes and need for steroid treatment outside of antenatal steroids. The incidence of vaginal fungal colonization during pregnancy has been reported to be between 25% and 50%, with up to 90% due to *C. albicans* and the remainder predominantly *C. glabrata* and *C. tropicalis*.[54] Despite the frequent fungal colonization, chorioamnionitis caused by *Candida* occurs less frequently, with almost all vertical transmission occurring when the infant passes through the birth canal via mucocutaneous contact, swallowing, or aspiration of fungi. Treatment of maternal *Candida* vaginosis and UTIs during pregnancy may decrease the inoculum the infant is exposed to and potentially prevent vertical transmission. However, maternal exposure during pregnancy to repeated courses of antifungal products (mainly topical azoles) may alter yeast susceptibility and if maternal symptoms persist, follow-up cultures to confirm clearance and/or identify resistance should be performed.[37]

Candida colonization may also be acquired horizontally, primarily from the hands of health care workers. In a multicenter trial examining fungal colonization in six NICUs, *Candida* species were isolated on the hands of 29% of health care workers.[62] Whereas *C. albicans* was the more common fungal isolate in all NICU patients (14% versus 7%), *C. parapsilosis* was the most common species isolated from the hands of NICU staff. *C. parapsilosis* was isolated from 19% and *C. albicans* from 5% of the cultures from health care personnel ($p < .001$). *C. lusitaniae* (2%), *C. guilliermondii* (1%), *C. tropicalis* (<1%), and *C. glabrata* (<1%) were also recovered from hand cultures. Increased handling required by sicker preterm infants increases the risk of acquiring

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

fungal colonization, because there is an average of 32 direct infant touches during a 12-hour shift.[27,62]

Candida species causing invasive infection rarely colonize environmental sources. Despite the tendency of fungus to grow in moist environments, studies have not isolated fungi from incubators, wash basins, water faucets, chest tubes, intravenous drug pumps, ventilators, inanimate objects, or radiant warmers.

Colonization by Site

Risk factors for *Candida* colonization and sepsis are similar, as adhesion and colonization of the skin, mucosal membranes, and/or vascular catheters occur prior to most infections.[98,99] Colonization is inversely proportional to gestational age and birth weight. Both *C. albicans* and *C. parapsilosis* colonize multiple sites in the majority of infants, whereas colonization at three or more sites occurs more frequently with *C. albicans*.[59]

Biofilm formation on catheters inhibits the host's defense mechanisms and the penetration of antifungal agents. Elements of catheter care related to sterile placement; hub and dressing care; sterile preparation of parenteral nutrition, intravenous fluids, and medications; and line changes at the bedside are critical infection control practices.[24] Infusates may also become contaminated and directly seed the bloodstream. In vitro growth curves demonstrate that *Candida* species have a selective growth advantage compared with bacteria in parenteral nutrition fluid.[61]

Candida colonization characteristics aid in identifying which colonized infants have the highest odds to progress toward invasive *Candida* infections (Table 49.2). Although skin and gastrointestinal colonization are more common and precede respiratory tract colonization, endotracheal colonization has a higher risk for infection.[52,59,95] The highest risks for progression are from colonization of indwelling devices (endotracheal tubes and central catheters) and when more than one site is colonized.[65,66] Rowen et al. demonstrated that with endotracheal fungal colonization, candidemia was 15.4 times more likely to occur compared with infants without any fungal colonization.[95] Controlling for fungal colonization at other sites, endotracheal colonization alone increased the risk for fungal sepsis nearly six-fold.

TABLE 49.2 Odds of Progression From *Candida* Colonization to Infection

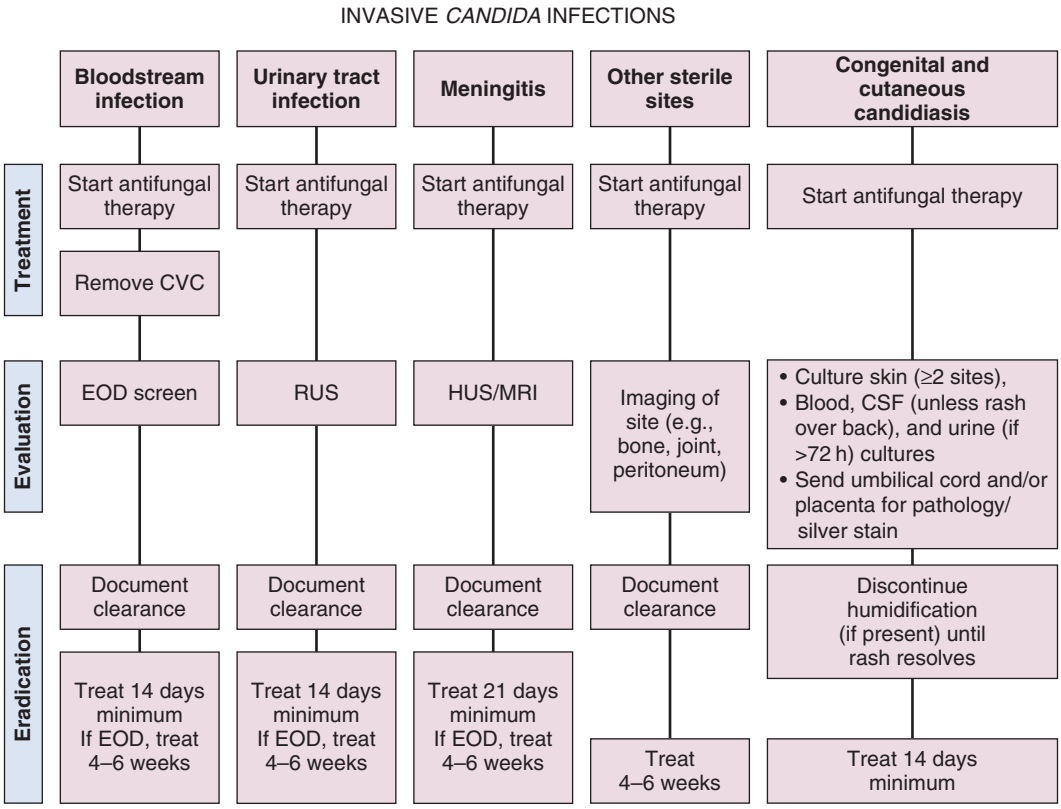
	Odds Ratio	Reference
Endotracheal tube	15.4	Rowen et al., 1994
Respiratory tract colonization	35.5	Kaufman et al., 2001
Colonization in multiple sites	6.2 (3 or more) 3.0 (for each additional site)	Manzoni et al., 2006 Kaufman et al., 2001
Urine	11.6	Manzoni et al., 2006
Colonization of central venous catheter	10.8	Manzoni et al., 2006

Diagnosis

Evaluation and Diagnosis

Cultures

Cultures of blood, urine, cerebrospinal, and peritoneal fluid or other sterile body fluids remain the best method for diagnosing invasive *Candida* infections (Fig. 49.6). Focus on obtaining sufficient blood culture volumes (≥1 mL) and performing urine and cerebrospinal fluid cultures at the time of evaluation for sepsis remains critical to making prompt diagnoses. One study of neonates demonstrated that isolation of fungus in blood cultures occurred at 37 ± 14 hours, and 97% of blood cultures were positive by 72 hours.[101] Laboratory capabilities to culture fungi, identify *Candida* species, and perform susceptibility testing are critical to diagnosis and management.



End-Organ Dissemination

Most commonly, with bloodstream infections, an initial end-organ dissemination (EOD) screen including an echocardiogram, liver and renal ultrasound, cranial ultrasound, and ophthalmologic examination should be performed. This could be performed at presentation or after 5-7 days of antifungal therapy. If there is significant bowel pathology such as NEC or focal bowel perforation, a complete abdominal ultrasound should be performed to rule out peritoneal, liver, or splenic involvement. If signs and symptoms of septic arthritis (joint swelling) or osteomyelitis (swelling or immobility) are present, a clinical diagnosis can be made, and evaluation with joint aspiration, bone scan, or magnetic resonance image (MRI) may help define the extent of involvement but should not be used to rule out joint or bone involvement in neonates. If candidemia persists, end-organ dissemination is even more likely, and surveillance after 5-7 days should also include: (1) ultrasound at location of the tip of any previous or current central catheters for infected thrombus, (2) complete abdominal ultrasound for abscesses (laparotomy is sometimes considered if high clinical suspicion), and (3) cranial ultrasound/MRI to detect brain dissemination. Abscesses that are amenable to drainage should be drained.

Molecular Techniques and (1-3)-Beta-D-Glucan (BDG)

Laboratory adjunctive tests have not been able to replace cultures but can be useful in identifying high-risk patients who would benefit from early empiric antifungal therapy (pending culture results) and to follow response to antifungal therapy. Polymerase chain reaction (PCR) and fungal cell wall polysaccharides such as (1-3)-beta-D-glucan (BDG) and mannan can be extremely helpful in high-risk patients in determining the need for early empiric antifungal therapy while cultures are pending, detecting infections

• **Fig. 49.6** Algorithm for evaluation and treatment of invasive *Candida* infections in neonates. Initiate therapy pending susceptibilities (see Table 49.5). Initial end-organ dissemination screening should be performed at presentation or after 5-7 days of appropriate antifungal treatment. With end-organ dissemination (EOD) meningitis, persistent candidemia greater than 7 days, combination therapy with a second antifungal is recommended based on susceptibilities (fluconazole is most commonly selected due to water solubility and CSF penetration). EOD screen includes surveillance for cardiac, renal, eye, and brain involvement. If bowel disease such as necrotizing enterocolitis or focal bowel perforation is present, complete abdominal ultrasound for abscess should be performed. BSI, Bloodstream infection; CCC, congenital cutaneous candidiasis; CVC, central venous catheter; HUS, head ultrasound; ICI, invasive *Candida* infections; MRI, magnetic resonance imaging; RUS, renal ultrasound; UTI, urinary tract infection.

when there is a high suspicion for infection that is not in the bloodstream (e.g., urine, peritoneal cavity, abscesses), and determining if length of treatment needs to be extended.

Molecular techniques to identify fungi and their antifungal susceptibilities more rapidly and with higher sensitivity than with blood cultures are being studied. Examples include polymerase chain reaction (PCR) and DNA microarray technology. One challenge is that these tests are mainly compared only with blood culture results, but often detect infection or only colonization at other sites. Fungal PCR to detect the gene for 18S ribosomal RNA in VLBW infants has yielded promising results but requires additional study. Results of PCR tests showed a broader number of infections, because they not only detect patients with candidemia but are also positive in those with *Candida* peritonitis, candiduria, previous candidal infections, and endotracheal colonization.

BDG levels are helpful if there is uncertainty in deciding need for empiric antifungal therapy and in following response to therapy as levels decrease over time with antifungal therapy. Various cut-off points have been recommended for interpreting BDG levels in neonates. A recent neonatal study of BDG found higher levels in infants with ICI (364 pg/mL vs. 89 pg/mL in non-infected neonates), and levels decreased significantly with antifungal therapy to 58 pg/mL (28-81).[43] They suggested the cut-off for BDG be higher (>125 pg/mL) for neonates than adults (>80 pg/mL) due to the effect colonization and other infections (Gram-negative and coagulase-negative *Staphylococcus* [CoNS]) can have on BDG levels. The BDG levels in infants infected with CoNS were 116 pg/mL (46-128) and 118 pg/mL (52-304) in patients without bacteremia. One challenge is that BDG can be elevated to the same degree with fungal colonization as with ICI, and studies have not critically examined this effect.[29] As several studies have demonstrated there are high-risk sites that when colonized (e.g., the respiratory tract) may benefit from empiric treatment.[89,109] One study used endotracheal lavage aspirates with mannan levels ≥0.5 ng/mL to decide on preemptive treatment and significantly decreased ICI.[89] Further study of preemptive treatment at certain BDG levels may be beneficial.

BDG may also give false-positive results following transfusion of blood products in adults and neonates.[42] A study

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

of 133 VLBWs found BDG to be higher in transfused (red blood cells or fresh frozen plasma) neonates (170 pg/mL, 65-317) compared to nontransfused infants (57 pg/mL, 34-108; $p < 0.001$).

Another method that may help with the decision to start early empiric therapy is direct fluorescent assay in buffy coat.[47] This test is a fluorescent stain that binds to structures containing cellulose and chitin. This diagnostic test has been successfully used for identifying hyphae and spores, and results are obtained after only 1-2 hours. Other markers of fungal disease being studied include anti-*Candida* antibodies, D-arabinitol (candidal metabolite), and fungal chitin synthase. These markers have some of the same challenges, because they may be present with bloodstream infections, nonbloodstream infections, previous infections, or with colonization alone.

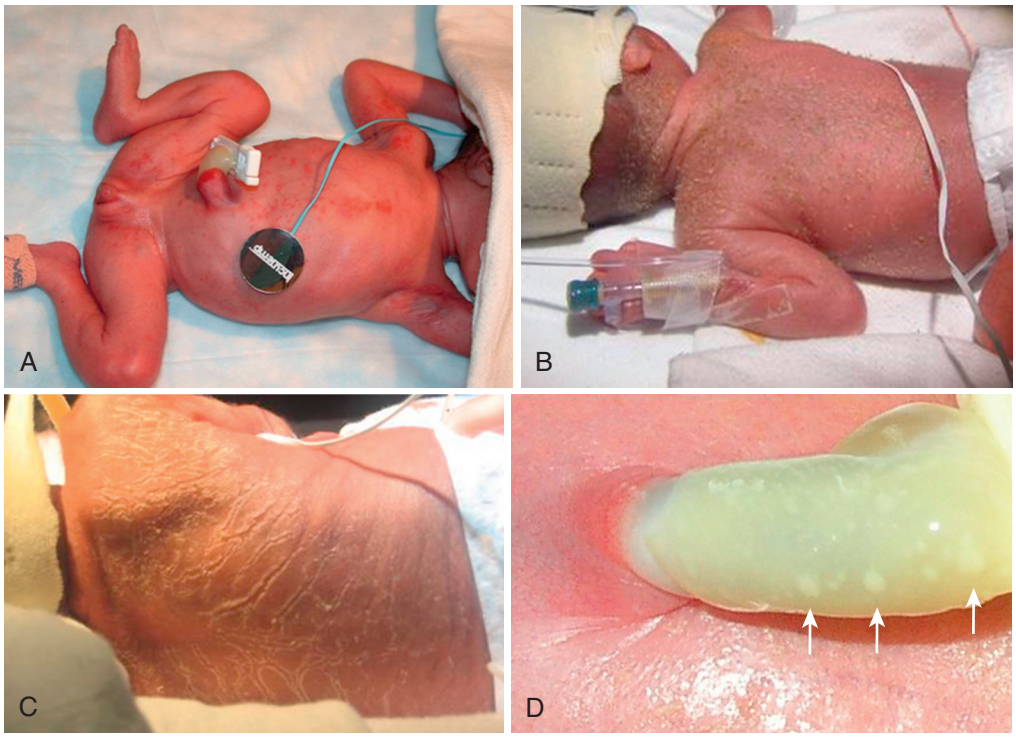
Clinical Manifestations

Invasive *Candida* Infections

Skin-Invasive Infections

Congenital Cutaneous Candidiasis

Congenital cutaneous candidiasis (CCC) (Table 49.3, Fig. 49.7) presents most commonly at birth but can occur within the first week. Dermatologic findings include desquamating maculopapular, papulopustular, and/or erythematous rashes. The most common finding from a recent study included desquamation alone (scaling, peeling, flaking, or exfoliation) or with other rash presentations.[57] CCC usually occurs only as a rash but dissemination such as pneumonia or bloodstream infection may also be present. Without prompt identification and systemic treatment, dissemination to the blood, urine, or CSF can occur in infants with CCC ranging from 11% in term infants to 33% in infants 1000-2500 grams and highest at 66% in infants <1000 grams.[31] A study examining the pathology and pathogenesis of CCC demonstrate a high burden of yeast with invasion into the epidermis and dermis with inflammation and injury including granulomas, focal necrosis, and hemorrhage.[94] These data from biopsies give insight into the invasive nature of the cutaneous involvement. For these reasons, preterm and term infants should be treated promptly at the time of rash presentation with systemic antifungal therapy and for a minimum of 14 days similarly to other invasive fungal infections. Delaying systemic treatment, solitary use of topical therapy (nystatin), and treating for <10 days is associated with *Candida* dissemination to the bloodstream.[57]



By culturing for both fungal and bacterial organisms by performing aerobic skin cultures of the rash, the source of infection can be confirmed in a timely fashion, but empiric therapy should be administered at time of rash presentation. Differential diagnosis includes staphylococcal as well as other bacterial and fungal skin infections. Pathology with fungal staining of the umbilical cord and placenta can also aid in diagnosis.

TABLE 49.3 Cutaneous Candidiasis Definition

Presentation	**Extensive Candida Skin Rash** • Covering 2 or more affected areas (see below) OR • Covering 1 affected area (see below) PLUS umbilical plaques or placental pathology (silver or H&E) would count as 1 affected area
Affected Areas	**Skin** • Chest • Abdomen • Back • Extremity • Groin or perineal area • Neck • Face or scalp **Umbilical Cord and Placenta** • White plaques on umbilical cord • Placenta with yeast invasion
Skin Rash	• Erythematous maculopapular • Papulopustular • Scaly • Dry, flaking • Desquamating • Burnlike erythematous
Timing	**Congenital Cutaneous Candidiasis** • Presenting in the 1 week after birth—most commonly present at birth to 3 days **Cutaneous Candidiasis** • Presenting after 7 days of life
Evaluation	**Congenital Cutaneous Candidiasis** • Culture skin rash (≥2 sites) (aerobic culture) • Blood, CSF (unless rash over back), and urine (if >72 h) cultures • Send umbilical cord and/or placenta for pathology/silver stain **Cutaneous Candidiasis** • Skin rash sites, blood, urine, CSF (unless rash over back)
Diagnosis	**Skin Findings and 1 or More of the Following:** • Surface culture isolating *Candida* species • Placental or cord identification (culture or silver stain) of yeast or *Candida* species for congenital cutaneous candidiasis • Positive blood, urine, CSF cultures for *Candida* species
Treatment	• 14-day course of systemic antifungal therapy

CSF, Cerebrospinal fluid.

Congenital cutaneous candidiasis: prompt systemic treatment is associated with improved outcomes in neonates. *Clin Infect Dis*. 2017;64:1387–1395.)

Cutaneous Candidiasis

Cutaneous candidiasis, referred to in past literature as mucocutaneous infection, presents with similar skin manifestations to CCC but occurs later than CCC. In the era prior to antifungal prophylaxis, the incidence was reported to be as high as 8% in VLBW infants. Risk factors include extreme prematurity, vaginal birth, postnatal steroids, and hyperglycemia. The importance of candida-like dermatitis often goes unrecognized prior to dissemination to the blood.[17] Cutaneous candidiasis, similar to CCC, is an invasive infection of the skin; empiric therapy should be started at the time of rash presentation and needs treatment for a minimum of 14 days in preterm infants.

Bloodstream Infection

Candidemia

Clinical signs and symptoms of candidemia are similar to bacteremia[54] (Table 49.4). Most importantly, candidemia can be associated with disseminated disease (see End-Organ Dissemination). Evaluation of cardiac, liver, renal, ophthalmologic, and central nervous systems is warranted and discussed in the following.

TABLE 49.4 Presenting Signs and Symptoms of Candidemia in Very Low Birth Weight Infants

Common (>50%)	Frequent (~33%)
Thrombocytopenia <100,000/μL (84%)	Lethargy and/or hypotonia
Immature-to-Total Neutrophil Ratio ≥0.2 (77%)	Gastrointestinal symptoms (e.g., gastric aspirates, distention, bloody stools)
↑C-reactive protein (CRP)	
(1-3)-Beta-D-glucan >125 pg/dL	
↑Apnea and/or bradycardia	
↑Oxygen requirement	
↑Assisted ventilation	
Less Common (10–15%)	**Can Occur (3%)**
Hypotension	Absolute neutrophil count <1500/μL
Hyperglycemia	
Elevated white blood cell count >20,000/μL	
Metabolic acidosis	

Renal Candidiasis

Candida infection of the kidney may occur because of an ascending urinary tract infection or via hematogenous spread. Studies demonstrate that *Candida* UTIs without bloodstream involvement are more common than with a BSI, suggesting that the ascending route via the urinary tract is more common than hematogenous spread. *Candida* can attach to human uroepithelial cells. Colonization and proliferation is augmented by proteinuria, nitrogenous compounds, acidic pH, hydrophobic *Candida* cells, and the presence of Enterobacteriaceae such as *Escherichia coli*. Signal-activated phospholipases (SAPs) and phospholipases

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

play a role in the renal system as well, attacking structural and immunologic defenses leading to tissue injury and invasion.[34] Risk factors for candiduria include vaginal birth, lower birth weight and gestational age, male gender, and prolonged antibiotic therapy.[119]

Urinary Tract Infection

Evaluation of late-onset sepsis should include a urine culture obtained via sterile catheterization or suprapubic bladder aspiration. Infection is defined as growth of 10,000 or more colony-forming units (CFU)/mL from a sterile catheterization or 1000 or more CFU/mL for bladder aspiration. Many neonatal studies have used lower CFUs as well. Lower CFUs, while likely not infection, indicate colonization at a high-risk site in which a follow-up urine culture should be obtained and empiric antifungal therapy started pending culture results. Preemptive treatment for 14 days would be appropriate as well for lower CFUs. Additionally, empiric antifungal therapy should be used with subsequent sepsis evaluations.

Signs and symptoms of urinary tract infections can be similar to sepsis and near-term and term infants may also present with fever.[92] Additionally, an elevated creatinine value in the absence of other pathology should prompt evaluation for a urinary tract infection. If the urine culture is positive for fungus, renal ultrasonography is needed to evaluate for abscess formation. In the absence of antifungal prophylaxis, candiduria occurs in approximately 2% of VLBW infants and up to 6% of ELBW infants.[17,52] Mortality is similar in infants with *Candida* UTI alone (26%) compared with *Candida* BSIs (28%) in ELBWs and older infants and studies showing increased neurodevelopmental impairment as well.[17,92,119] These findings emphasize the need for prompt treatment for a minimum duration of 14 days.

Renal Abscess

Renal abscess formation may occur by dissemination of candidemia or as an ascending infection with candiduria.[34] Two studies of candiduria from 1982-1993 and 2001-2003 found that renal abscesses developed in 42% (36 screened) and 12% (26 screened) of infants with candiduria (±candidemia), while a more recent study during 2004-2007 found the incidence to be 0% (0 of 23 evaluated) with candiduria alone and 22% (2 of 9) with concordant *Candida* infection.[92,119] One study found ultrasound examinations were normal in one-third of patients who later developed renal abscesses 8-39 days later, which may have been related to antifungal dosing used or delay in treatment. Between these two study periods, antifungal prophylaxis, pharmacokinetic and safety studies of appropriate initial antifungal dosing (e.g., amphotericin B deoxycholate at 1 mg/kg compared with 0.25 mg/kg in the previous era), and increased empiric antifungal therapy may be attenuating the formation of renal abscesses. These studies have small numbers but suggest that in infants with candiduria, prompt initial antifungal therapy has improved outcomes, and renal imaging should be performed at presentation and repeated in cases with persistent candiduria.

Central Nervous System Candidiasis

Meningitis and Meningoencephalitis

Central nervous system fungal infection may involve meningitis, ventriculitis, or abscess formation in infants. Studies have found around 50% of meningitis cases occur in the absence of candidemia, pointing to the importance of CSF evaluation when performing sepsis evaluations.[16,28] Culture of the CSF is important in diagnosing fungal meningitis prior to the initiation of antifungal therapy, because CSF cell counts and chemistries often are not abnormal.[28] This may be because of the number of organisms in the CSF or difficulty of interpretation caused by blood contaminating the lumbar puncture, the location of the central nervous system infection (brain tissue versus spinal fluid), and host response of the preterm or term infant.

Central Nervous System Abscess

Fungal abscesses of the central nervous system have been reported to be microscopic and not readily detectable by ultrasonography. In a study of 46 ELBW patients with fungal sepsis and/or meningoencephalitis, only 6 of 13 cases with fungal central nervous system abscesses (detected by neuroimaging or on autopsy) had abnormal results on lumbar puncture.[39] Studies have found an association between invasive fungal infection and periventricular leukomalacia in preterm infants, possibly related to release of cytokines, which may damage the periventricular white matter. These findings and animal studies demonstrate the need for central nervous system imaging (ultrasonography or MRI) in all patients with fungal sepsis regardless of the results of CSF studies in addition to meningitis cases.

Gastrointestinal Disease

Peritonitis

In patients presenting with NEC or focal bowel perforation, invasive *Candida* infections can complicate these gastrointestinal diseases. Peritonitis with bowel perforation owing to NEC or focal bowel perforation often presents with abdominal distention with or without erythema. *Candida* species are the predominant organism causing peritonitis in 15% of the perforated NEC cases and 44% of focal bowel perforation patients.[26] Radiographs help confirm perforation, but at times ultrasound or an exploratory laparotomy may be needed if clinically indicated. Persistent leukopenia, severe thrombocytopenia, hypotension, or low urine output (<1 mL/kg/hr) after 48 hours of treatment even if radiographs and ultrasound are negative should also prompt consideration for an exploratory laparotomy to evaluation for perforation(s) and/or abscesses. When exploratory laparotomy is performed or drains are placed, cultures should be obtained to determine organisms associated with bowel perforation, peritonitis, and potential abscesses.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Necrotizing enterocolitis can be complicated by fungal infections, and associated bloodstream infections occur in up to 16.5% cases of NEC.[23,81] Screening the gastrointestinal tract for the presence of *Candida* species (by culture of rectum, stool, or oral flora) should prompt the addition of a systemic antifungal to the antimicrobials selected as part of the treatment of NEC. If *Candida* is not detected on screening, antifungal prophylaxis should be considered while treating NEC until full enteral feedings are reached.

Respiratory Disease

Pneumonia

The diagnosis of pneumonia remains difficult in ventilated preterm and term infants with chronic lung disease, as atelectasis, fluid, scar tissue, and infection have similar radiologic findings. *Candida* colonization of the respiratory tract occurs after colonization of the skin and gastrointestinal tract. Respiratory colonization is a high-risk site for invasive *Candida* infections (see Table 49.2). Pre-emptive treatment when *Candida* species are isolated in the lungs by culture, polymerase chain reaction (PCR), or *Candida* mannan antigen have been shown to prevent dissemination.[89]

End-Organ Dissemination

At the time fungal infection is clinically apparent, the organisms have often disseminated from the blood, urine, or CSF to adhere and proliferate in body fluids, tissues, and organs. *Candida* species can cause endocarditis, endophthalmitis, dermatitis, peritonitis, osteomyelitis, and septic arthritis, and fungal abscesses may form in the central nervous system, kidneys, liver, spleen, skin, bowel, and peritoneum (see Fig. 49.2). Fungal end-organ dissemination has been noted since the earliest reports of *Candida* sepsis in neonates, being as high as 66% in the 1970s, reflecting prolonged periods of fungemia, uncertainty of significance of positive fungal cultures, underdosing of antifungals, and poor diagnostics, as many infections were diagnosed late or at the time of autopsy. A meta-analysis of studies reporting fungal end-organ dissemination in neonates spanning various practices from 1979-2002 found median prevalence of cardiac vegetations or thrombi was 5%, endophthalmitis 3%, renal involvement 5%, and central nervous system abscesses 4%.[15] Dissemination may be higher in the more extremely preterm infant.[63]

Persistent candidemia of 5-7 days was associated with increased end-organ dissemination, as each day of candidemia increases the risk by 10%.[63,81] When amphotericin B was administered and central vascular catheters removed within 2 days of the first positive blood culture, outcomes such as end-organ dissemination and mortality were decreased.[81]

Endocarditis and Infected Vascular Thrombi

Candida endocarditis or infected vascular thrombi have been reported in 5.5%-15.2% of cases of fungal sepsis, with equal prevalence for *C. albicans* and *C. parapsilosis*. Fungal endocarditis may be associated with higher mortality than fungemia alone.[23,81] Central vascular catheters place neonates at increased risk. Catheters can cause local trauma to valvular, endocardial, or endothelial tissue, creating a nidus for thrombus and infection at insertion and while in situ. When antifungal therapy alone is unsuccessful in resolution of the endocarditis or thrombus, thrombolytic or anticoagulation therapy may be indicated in some cases, depending on infant's gestational age and accompanying conditions.

Endophthalmitis and Retinopathy of Prematurity

Endophthalmitis represents intraocular dissemination from the bloodstream. Exogenous infection can also occur secondary to retinopathy of prematurity (ROP) surgery or trauma. Endophthalmitis begins as a chorioretinal lesion that gradually elevates and breaks free in the vitreous, appearing as a white fluffy ball. The infection appears as solitary or multiple yellow-white elevated lesions with indistinct borders that are most often seen in the posterior retina and vitreous.[10] The clear cell-free vitreous becomes hazy, owing to an influx of inflammatory cells. This vitreous reaction is more difficult to recognize in preterm infants because of the vitreous haze that is present in the first weeks of life. The most immature infants appear to be at highest risk for fungal endophthalmitis. The incidence of retinal endophthalmitis with candidemia has decreased over the years, likely because of more rapid diagnosis, treatment, and prevention of invasive *Candida* infections. Incidence may be affected by timing of screening, as antifungal treatment effectively treats this infection. The incidence has decreased from 6% to 0.8% of preterm infants with candidemia who had indirect ophthalmoscopic examination.[35,81]

Even in the absence of visible retinal abscesses or chorioretinitis, there is some epidemiologic evidence that *Candida* sepsis may predispose preterm infants to severe ROP. Noyola and colleagues, in a case control study of VLBW infants less than 28 weeks' gestation, found that 52% (24 of 46) of infants with candidemia developed threshold ROP compared with 24% (11 of 46) of controls without candidemia (p = .008).[80] Although this has been shown only as an association between fungal sepsis and ROP, early and frequent screening for retinal pathology is recommended in preterm infants with candidemia.

Treatment

Adequate dosing of antifungal therapy has been understudied in neonates and remains a critical issue (Table 49.5). Most of the literature lacks good data on dosing and outcomes. As more data are emerging, it has been learned that underdosing and delaying optimal therapy occurred, which may have contributed to delayed clearance, treatment failures, and increased dissemination, morbidity, and mortality. In the NICU, most *Candida* species have favorable susceptibility to amphotericin B, fluconazole and the

TABLE 49.5 Antifungals

Treatment	Dose	Interval	Comments
Invasive *Candida* Infection			
Amphotericin B deoxycholate	1.0-1.5 mg/kg	Every 24 hours	Monitor electrolytes; 4 mEq/kg/day NaCl recommended.
Amphotericin B lipid formulations	5-7 mg/kg	Every 24 hours	
Fluconazole	12 mg/kg	Every 24 hours	Monitor liver function tests during therapy.
Caspofungin	2.5-3 mg/kg	Every 24 hours	Monitor electrolytes, calcium, phosphorus, and liver function tests during therapy.
Micafungin	10 mg/kg	Every 24 hours	Monitor liver function tests during therapy.
Anidulafungin	3 mg/kg, followed by 1.5 mg/kg	Every 24 hours	Monitor liver function tests during therapy. Dosing still being studied.
Invasive *Aspergillosis*			
Voriconazole	6 mg/kg x 2, then 4 mg/kg	Every 12 hours	Monitor levels in neonates if feasible.
Micafungin	10 mg/kg	Every 24 hours	Monitor liver function tests during therapy.
Caspofungin	3 mg/kg	Every 24 hours	Monitor liver function tests during therapy.
Prevention			
Invasive *Candida* Infection			
Fluconazole	3 mg/kg	Twice a week	IV while central or peripheral access present
Nystatin	1 mL (100,000 units)	Every 6-8 hours	Oral and/or enteral (1 mL to stomach OR 0.5 mL to oral mucosa and 0.5 mL to stomach)

echinocandins. Susceptibilities should be confirmed with all clinical isolates. Antifungal resistance is associated with inferior clinical outcomes.[86] *C. parapsilosis* and *C. glabrata* isolates can have resistance to both azole and echinocandin antifungal agents.[87]

In addition to dosing, prompt central line removal with *Candida* bloodstream infection is needed for clearance and to improve outcomes. Information on central line removal is often lacking in studies of antifungal efficacy, making it difficult to assess the efficacy of the agents being studied. In the area of pharmacokinetics, premature neonates, full-term neonates, pediatric patients, and adults often have different plasma clearance rates and drug half-lives, which affect dosing decisions as well as drug efficacy, safety, and toxicity for each of those groups.

Amphotericin B Preparations

Amphotericin B deoxycholate is often chosen for treatment because of its excellent coverage for almost all *Candida* species causing infections in neonates due to its efficacy, low cost compared with other antifungals, safety, and possible better renal penetration compared with lipid amphotericin preparations. Resistance to amphotericin B is rare, making it a good initial choice pending speciation.[86] When fluconazole is being used for prophylaxis in a NICU for any patient, a different antifungal should be used for treatment of invasive *Candida* infections in that NICU to decrease antifungal pressure that may lead to azole resistance.

Amphotericin B deoxycholate binds to the sterol component (ergosterol) of the cell membrane, creating pores that lead to cell death. Amphotericin B is combined with deoxycholate to make it soluble in water. In the bloodstream, it dissociates from deoxycholate, and 90% of it binds with lipoproteins. The drug distributes and binds to most tissues, with higher accumulation in the reticuloendothelial system.

There are three lipid preparations of amphotericin B. Liposomal amphotericin B is produced by incorporation of amphotericin B into tiny unilamellar liposomes (<100 nm in diameter). Liposomal amphotericin B is small in size and has a negative charge, which prevents significant uptake with the mononuclear phagocyte system. Its properties lead to high peak plasma levels and a larger area under the concentration-time curve. Tissue concentrations are highest in the liver and spleen and lower in the kidney and lungs. In the amphotericin B lipid complex, the drug is complexed in a 1:1 ratio with two lipids in a sheetlike formation (500-5000 nm). Its size facilitates rapid uptake by the mononuclear phagocyte system and sequestration in tissues such as the lung, liver, and spleen. This increased volume of distribution is associated with lower serum levels. Amphotericin B colloidal dispersion is a complex with cholesteryl sulfate in a 1:1 ratio with amphotericin

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

B in a disclike structure (100 nm). These lipid complexes remain intact and are rapidly taken up by the macrophage phagocyte system. Lipases at the sites of infection then aid in the release of the drug. Liposomes can also bind to the fungal cell membrane, with fungal phospholipases aiding in its release. It is theorized that there are fewer side adverse effects if there is more targeted release of drug at the sites of infection.

Amphotericin B deoxycholate should be started at 1 mg/kg and lipid preparations at 5 mg/kg.[84] Serum electrolytes and urine output should be monitored, as additional sodium and potassium supplementation is often required. Fluids and enteral feedings should be adjusted to maintain urine output of 2 mL/kg/hour.

Several studies in the past decade have demonstrated no adverse renal or systemic effects of daily amphotericin B deoxycholate at 1 mg/kg. Linder et al. demonstrated that dosing of 1 mg/kg of amphotericin B deoxycholate (N = 34) did not affect renal function.[64] Creatinine levels (mg/dL) remained unchanged from the start of treatment (0.8 ± 0.4), at 24 hours after beginning treatment (0.8 ± 0.4), and through the end of therapy (0.6 ± 0.2). This is an important difference compared to older children and adults for whom infusion-related reactions and nephrotoxicity are frequent concerns with amphotericin B deoxycholate. Lower "test" dosages of amphotericin B deoxycholate are not needed in neonates,[64] as renal and other adverse effects commonly seen in older patients do not occur in neonates. Moreover, lower dosages in neonates only delay the time to achieve optimal therapy and may contribute to morbidity and mortality by delaying clearance of *Candida* species. If the initial treatment is ineffective, studies have demonstrated safety with increasing the dosing of amphotericin B deoxycholate to 1.5 mg/kg per day.[50]

Lipid preparations starting with doses of 5-7 mg/kg are effective and safe with an eradication rate of 95%.[51,67] Juster-Reicher et al. reported that eradication was achieved more rapidly when liposomal amphotericin B was started at the target dose of 5-7 mg/kg per day.

A few retrospective studies have examined whether lipid formulations are better than amphotericin B deoxycholate, but none has shown superiority.[5,64] Some studies help guide treatment, whereas other studies may raise questions. Antifungal studies in which the dosing and specific antifungal were known have not found a difference in mortality between lipid preparations of amphotericin B and other antifungals, whereas one study from an administrative database found higher mortality when examining all amphotericin B lipid products grouped together compared with amphotericin B deoxycholate or fluconazole.[5,64] It is probable that the lipid preparations were underdosed in the later study. Without knowing dosing and the specific antifungal used, as well as controlling for line removal, the data are difficult to interpret, as these factors affect mortality. Additionally, the three lipid products may be associated with different outcomes and should not necessarily be combined into one group.

Other major differences that still need to be evaluated in prospective studies include risk for phlebitis when given via peripheral IV, and whether amphotericin B deoxycholate has an advantage in treating UTIs and renal abscesses. Animal studies have demonstrated significantly higher renal concentrations of deoxycholate, which has led most experts to recommend preference over lipid formulations for UTIs and renal candidiasis. None of the studies have compared optimal dosing of 1-1.5 mg/kg of amphotericin deoxycholate with 5-7 mg/kg of lipid preparations of amphotericin B. A rodent study examining 1 mg/kg of both amphotericin B deoxycholate and liposomal amphotericin B found kidney tissue concentrations of 735 ng/gram compared with 298 ng/gram, respectively. With dosing having a linear concentration for liposomal amphotericin B, a fivefold increase would be expected with dosing of 5 mg/kg, and kidney concentrations would be equivalent or even higher.[114] Studies examining efficacy for the treatment of UTIs are needed, because many treatment studies have focused only on bloodstream infections.[64]

Azole Agents

Fluconazole

Fluconazole, an azole that inhibits the enzyme C-14 lanosterol demethylase in the formation of ergosterol, has demonstrated similar efficacy to amphotericin B deoxycholate. Fluconazole is readily bioavailable and has excellent tissue penetration. As mentioned above, fluconazole should be reserved and used for prophylaxis primarily and added when combination therapy is desired. Enteral systemic fluconazole treatment is also a good selection when the *Candida* species is susceptible, infant is tolerating feedings, and IV access is not needed for other reasons.

Susceptibility information is important to know when using fluconazole. Clinical outcomes are significantly improved at lower MICs.[86] Resistance to azoles can occur from a change in the quantity or binding of the target enzyme (lanosterol), an increase in MDR (multidrug resistance) or CDR (*Candida* drug resistance) efflux pump activity pumping more drug out of the fungus, leading to reduced drug concentrations in the fungus, or a combination of these mechanisms.

Population pharmacokinetic study of fluconazole in 23- to 40-week-gestation infants demonstrated that dosing at the higher end of the recommended range (12 mg/kg/day) may yield better efficacy, although the safety of this dosing awaits further clinical study.[111] Standard dosing of fluconazole for treatment of invasive *Candida* infections had been 6 mg/kg with every 48- to 72-hour dosing until daily dosing began at 4 weeks of age. A loading dose of 25 mg/kg has been studied in a small number (n = 8) of mature neonates (median 37 weeks' gestation) to achieve higher levels (>8 mcg/mL) within 24 hours, but safety, side effects, and improved efficacy have not been evaluated.[88] For patients on ECMO, a higher dose may be needed due to the increased volume of distribution added with the ECMO

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

circuit.[115] Most *Candida* species have minimum inhibitory concentration (MIC) values less than 1-2 mcg/mL, so rarely levels of more than 8 mcg/mL are needed, which explains why 6 mg/kg dosing was associated with similar efficacy as other antifungals in the past. With higher dosing, safety in relation to liver function, drug–drug interactions, and effect on fungal resistance needs to be monitored and studied further.

Voriconazole

Voriconazole, another azole, has a broader spectrum of antifungal activity, and it is the first-line treatment option in cases of Aspergillus infection. Unlike fluconazole, it is mostly protein bound and also tends to accumulate in infants with renal insufficiency; drug levels should be monitored. From a few case reports in the neonatal literature and the adult and pediatric data, suggested dosing is 6 mg/kg every 12 hours (for 24 hours), followed by 4 mg/kg every 12 hours, with monitoring of serum hepatic enzymes weekly and drug levels obtained if there is oliguria or renal impairment.[36,79]

Echinocandin Agents

The newest class of antifungals is the echinocandins, which include caspofungin, micafungin, and anidulafungin. Echinocandins are noncompetitive inhibitors of (1,3)-b-D-glucan synthase, a fungus-specific enzyme crucial to the biosynthesis of the cell wall component glucan and, therefore, compromise fungal cell wall integrity, causing fungal cell death. Echinocandins have a broad-spectrum *Candida* coverage, activity against Aspergillus, and a high degree of antifungal activity against both developing and well-organized biofilms. Acquired resistance of *Candida* species to echinocandins can occur via acquisition of point mutations of the major subunit of the target enzyme (1,3)-b-D-glucan synthase. Susceptibility patterns to common neonatal *Candida* species such as *C. parapsilosis* will be important to follow as their use increases.[87]

Micafungin is currently the only echinocandin licensed for neonatal use in Europe. It has good activity against biofilms and most nonalbican *Candida* species. Neonatal pharmacokinetic data and animal models demonstrate that 10 mg/kg is needed in neonates for effective central nervous system penetration and clearance of meningitis, and two small neonatal studies have confirmed its safety and efficacy at this dose.[6,18,48,73] A randomized controlled trial comparing micafungin and amphotericin B deoxycholate found similar efficacy and safety of 10 mg/kg of micafungin compared to 1 mg/kg of amphotericin B deoxycholate.[18]

Caspofungin and anidulafungin are other echinocandins with potent activity against *Candida* species. Caspofungin pharmacokinetic data in neonates points to dosing of 2.5-3 mg/kg or of 25-30 mg/m^2.[97] Anidulafungin dosing is still being studied with a loading dose of 3 mg/kg, followed by 1.5 mg/kg/day. A much higher dose appears to be needed from preliminary animal models of central nervous system infection, suggesting that the current regimen is suboptimal, but safety of higher dosing needs further study.[113]

Combination Therapy

The selection of a second antifungal may aid in treatment when there is central nervous system disease, disseminated infection, or persistent candidemia after 7 days of antifungal therapy. Susceptibility testing is important to help guide the selection of a second antifungal drug. Some experts would use the second agent for the entire treatment course, whereas others change back to monotherapy after resolution of abscess or persistent candidemia.

Linder et al. reported on outcomes with combination therapy.[64] A second antifungal agent, most commonly fluconazole, was administered if candidemia was associated with the presence of any abscess, a positive urine culture, or after 10 days of persistent culture-positive infection. Patients were treated for 14 days after negative culture or more until radiographic resolution of any abscess. Central catheters were removed at onset of infection. Sterilization occurred in 67% with monotherapy and increased to 96% with polytherapy.

Central Venous Catheter Removal With Bloodstream Infections

The removal of central venous catheters with *Candida* BSIs when culture results become positive improves outcomes. Several studies have demonstrated that prompt removal is associated with lower mortality rates, a shorter duration of infection, and reduced end-organ dissemination.[16,23,81] National Institute of Child Health and Human Development (NICHD) Neonatal Research Network data showed that mortality was reduced from 37% to 21% ($p < .024$) when catheters were removed promptly (<24 hours) compared with delayed removal.[16] The combined outcome of neurodevelopmental impairment and death were associated with delayed removal/replacement of catheters; although there was a trend, no difference in neurodevelopmental impairment alone was observed (45% for prompt removal versus 63% for delayed removal; $p = .08$). The strongest effect of prompt catheter removal and mortality was with *C. parapsilosis*; prompt removal was associated with a 10% mortality compared with 31% when catheter removal was delayed.

It is important to note that catheter removal, not simply catheter replacement, is recommended.[81] *Candida* can quickly form resilient biofilms on catheters and prevent the penetration of antifungal agents. A new central catheter can be placed after documentation of clearance of *Candida* infection from the blood with three or more negative cultures in the first 3 days of therapy or two or more after 4 days of antifungal treatment. Further study of catheter replacement at a different site while still candidemic is needed but may be an option when peripheral IV access cannot be maintained or central access is needed. It is better

to immediately remove and replace rather than delay removal if IV access is a major concern.

Time to Clearance of Blood and Persistent Candidemia

Another crucial management issue regarding neonatal candidiasis is how to determine that a patient's bloodstream is clear of infection. Antifungal dosing and line removal also play a role in the length of persistent candidemia. Time to clear *Candida* from the blood is on average 2 days less with prompt catheter removal from the first positive blood culture.[16] Complete clearance of BSI has a median of 3 days after antifungal therapy is started. Of note is that in 21% of cases of infants with *Candida* BSI, intermittent negative cultures occurred between positive cultures. In this epidemiologic study, only 30% of catheters were promptly removed, which may have contributed to persistent candidemia and intermittent release of *Candida* from catheter biofilms. Similarly, it is possible all infections have undetectable microabscesses that may be slowly dissolving. Based on this high incidence of false negatives, daily blood cultures of 1 mL or more should be drawn until three negative cultures are documented in the first 3 days of treatment to confirm sterilization of the bloodstream; then a (new) central access device can be placed if needed for treatment. Another approach would be to obtain two or more negative blood cultures after 4 days from both the initiation of antifungal therapy and line removal. Treatment is recommended for 14 days after the bloodstream is clear of *Candida*.[64] Persistent candidemia >5-7 days as discussed previously should prompt re-evaluation of end-organ dissemination and addition of a second antifungal.

Adjunctive Therapies

Infection is affected by fungal load, virulence, and host factors, with neutrophil function being critical for *Candida* killing and clearance. Neutropenia should be corrected if it persists after receiving 48 hours of antifungal therapy. As an adjunctive therapy for invasive *Candida* infections, granulocyte colony-stimulating factor (in the absence of neutropenia), other colony-stimulating factors, and immunoglobulin therapy have not improved the efficacy of treatment.[54]

Treatment Summary

In summary, several measures are proving to be critical with regard to the effective treatment of neonatal candidiasis: (1) prompt and appropriate antifungal dosing, (2) central line removal if present with BSI, and (3) screening for end-organ dissemination. Amphotericin B deoxycholate starting at 1 mg/kg/day is a good choice for initial treatment based on efficacy, cost, and safety, but the liposomal amphotericin antifungals and echinocandins such as micafungin are also appropriate choices. The optimal doses of some new and older antifungal agents without adverse effects in neonates are still being studied. When faced with persistent candidemia, consultation with pediatric infectious disease specialists is beneficial. The addition of a second agent is one area of ongoing investigation. Comparison studies to determine the best choice of antifungal for each type of invasive infection, when combined with prompt central catheter removal, hopefully will serve to lower the high rate of mortality and morbidity caused by invasive *Candida* infections in these infants. Preventing these infections with antifungal prophylaxis as discussed below not only decreases these infections significantly but removes invasive *Candida* infections as a cause of neurodevelopmental impairment and *Candida*-related mortality.

Empiric Therapy

The value of empiric therapy and its ability to improve outcomes in neonatal candidiasis continue to be investigated. Antibacterial agents are routinely prescribed when clinicians are concerned about late-onset sepsis in neonates, and perhaps in certain cases antifungals also should be added pending culture results. A few retrospective studies have demonstrated inconclusive data, as they were unable to control for important variables that would affect survival, such as timing of empiric therapy, dose and antifungal used, central line removal with BSIs, and standardization of protocols for patient selection for empiric antifungal therapy.[44]

One prospective study using a specified protocol for empiric antifungal therapy in neonates less than 1500 g, as well as older critically ill infants in the NICU, demonstrated a decrease in mortality.[90] This NICU did not use antifungal prophylaxis. Empiric antifungal therapy was started in high-risk patients who had received vancomycin plus third-generation cephalosporin for 7 days and had one or more of the following infection risk factors: total parenteral nutrition, mechanical ventilation, corticosteroids, H_2 blocking agents, or signs of a *Candida* rash or thrush. The *Candida*-related mortality was 61% (11 of 18) in patients who did not receive empiric therapy compared with no deaths (0 of 6) from invasive *Candida* infections in infants receiving empiric therapy.

Although empiric or prompt standardized treatment may reduce *Candida*-related deaths, neurodevelopmental impairment may still occur in almost 60% of the survivors, particularly those with birth weights less than 1000 grams. More prospective studies controlled for timing, antifungal type, dose and duration, antifungal prophylaxis, and central line removal need to be performed.

Pre-Emptive Treatment

Pre-emptive treatment has been proposed in a few neonatal studies following early detection of *Candida* colonization by culture or mannan antigen from the endotracheal tube in infants 28 weeks' or less gestation.[89,108] Respiratory colonization, as discussed, is a high-risk site in preterm infants.[52,95] With this approach of early identification from

tracheal aspirates followed by 14 days of antifungal treatment, invasive *Candida* infections were reduced from 75% (12 of 16 with positive growth of *Candida* in culture) to 0% (0 of 16 with *Candida* mannan detected) of these patients with *Candida* species identified in their respiratory tracts.[108] Both approaches eliminated all *Candida*-associated mortality. This may be an approach to be studied in patients with NEC in whom *Candida* is isolated in their gastrointestinal tract.

Prevention

The NICUs successful in eliminating infections view infections as preventable and focus on prevention instead of early detection and treatment. As with other infectious diseases, prevention is vital to achieving the best clinical outcomes. Mortality and morbidity are high, and for extremely low birth weight infants, 73% either do not survive or survive with neurodevelopmental delay.[16,104] To date, antifungal prophylaxis is the only intervention that has been subjected to evidence-based randomized controlled trials for the prevention of invasive *Candida* infections. Prophylactic antifungal therapy has been shown to reduce both colonization and invasive *Candida* infections in high-risk preterm infants. A summary of neonatal fluconazole and nystatin prophylaxis studies has been recently reviewed in detail.[7,25,32,55]

Prophylaxis prevents invasive *Candida* infections by decreasing *Candida* colonization of the skin, gastrointestinal and respiratory tracts, and central venous catheter, as well as colonization at multiple (two or more) sites.[8,52,72] At birth, most infants are not colonized or have low colony counts of yeast, making them ideal candidates for antifungal prophylaxis. In the absence of antifungal prophylaxis, up to 60% of ELBW infants become colonized in the first 2-3 weeks after birth.[52] In addition to the effect on fungi with therapeutic concentrations, subinhibitory concentrations of fluconazole improve white blood cell phagocytosis and killing of *C. albicans* from 50%-90%.[45]

Fluconazole

Currently, there are more than 20 studies examining fluconazole prophylaxis for the prevention of invasive *Candida* infections in more than 6400 neonates and consistently demonstrating efficacy, with an overall reduction in invasive *Candida* infections of 80% and a greater than 90% decrease in *Candida*-related mortality.[55] The overall incidence of invasive *Candida* infections in the placebo or control (untreated) groups was 9.1% compared with 1.3% in the fluconazole prophylaxis groups ($p < .0001$). Efficacy is highest in the smallest infants (<1000 g) and youngest infants (≤27 weeks) when prophylaxis is started shortly after birth and given while there is central or peripheral IV access. All of the studies have demonstrated the safety of fluconazole prophylaxis and lack of emergence of resistance over several-year periods.[52,53,68]

The first study of fluconazole prophylaxis against fungal colonization and infection in preterm infants was a prospective, randomized, double-blind clinical trial involving 100 high-risk preterm infants weighing less than 1000 g.[52] Infants were randomly assigned during the first 5 days of life to receive either 3 mg/kg fluconazole IV or placebo for up to 6 weeks. Results demonstrated that fluconazole prophylaxis significantly decreased invasive fungal infection. None of the infants in the treatment group developed infection compared with 20% of infants in the placebo group ($p = .008$). A subanalysis of infants less than 24 weeks' gestational age, approximately 10% of the cohort, revealed that fluconazole treatment was efficacious even in the most immature of infants.

From a systems viewpoint, the dosing schedule, while effective and safe in the first study, was complicated and changed every 2 weeks. Therefore, the efficacy of a twice-weekly dosing regimen was studied as a simplified schedule in a randomized controlled trial and was as effective in preventing invasive *Candida* infections compared to the more frequent dosing schedule used in the previous study.[53] This dosing has been confirmed in several other studies.[14,55] Twice-weekly dosing can occur on the same two days (e.g., Tuesday and Friday) and a specific time, reducing pharmacy preparation time as well as administration and drug costs over the prophylaxis period. Twice-weekly administration of 3 mg/kg is also associated with a decreased risk for development of azole resistance among fungi.[52,53]

Fluconazole prophylaxis has similar efficacy with either 3-mg/kg or 6-mg/kg dosing. A multicenter, randomized, placebo-controlled trial investigating two different fluconazole doses (3 mg/kg and 6 mg/kg) was compared with a placebo group in 322 infants less than 1500 g.[72] Fungal colonization was significantly decreased for both doses from 29.2% in the placebo patients to 7.7% and 9.8% in the 3- and 6-mg/kg groups, respectively. Invasive *Candida* infections were significantly decreased with either dose from 13.2% in the placebo patients to 3.8% and 2.7% in the 3- and 6-mg/kg groups, respectively. The results also showed a significant effect in infants less than 1000 g as well as infants less than 27 weeks.

Healy and colleagues also demonstrated that by targeting fluconazole prophylaxis to infants less than 1000 g, *Candida*-related mortality can be eliminated in the NICU for all patients.[46] Their study examined IV fluconazole prophylaxis over the course of 4 years and found the incidence of invasive candidiasis in infants less than 1000 g decreased from 7.3% to 2% ($p = .003$) with mortality related to *Candida* infection decreasing to 0 ($p = .01$). This demonstrated that *Candida*-related mortality for the entire NICU can be eliminated by targeting antifungal prophylaxis in high-risk patients less than 1000 grams.

Safety of Fluconazole Prophylaxis

No significant adverse effects have been reported in randomized trials in infants treated with fluconazole prophylaxis compared to control patients.[55] Preventing invasive

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Candida infections has not led to an increased incidence in other infections. The incidence of bacterial infections and necrotizing enterocolitis is similar in all studies between treatment and control groups. Focal bowel perforation was also similar in infants less than 1000 g (4% in fluconazole compared with 10% in placebo patients).[52] Fluconazole-related cholestasis has been examined closely in several studies. No cholestasis was seen between groups in the randomized controlled trials. Retrospective studies have shown by multivariate analysis that cholestasis is related to other factors such as NEC and bacterial infections and not fluconazole prophylaxis.[46] Cholestasis is also not associated with increasing doses or days of fluconazole. In addition, dosing of 3 mg/kg twice a week compared with more frequent dosing is associated with less cholestasis.[9]

Fluconazole prophylaxis has also been evaluated in two studies demonstrating long-term neurodevelopmental safety. At 18-22 months, neurodevelopmental impairment using the Bayley III cognition composite scores did not differ (31% in the fluconazole-treated patients and 27% in the placebo group).[14] At 8-10 years old, neurodevelopmental status and quality of life of survivors from the first randomized controlled trial were evaluated.[58] There were no differences in the Vineland Adaptive Behavior Scales-II scores for the fluconazole-treated compared with the placebo group. Patients scored well in the four domains: communication (95 versus 93), daily living skills (88 versus 87), socialization (97 versus 94), and motor skills (92 versus 95). There were also no differences between groups regarding emotional difficulties or behavioral problems. Regarding quality of life, self-esteem scores were 87 versus 90. Survivors were happy or satisfied with school (90% versus 100%), friendships (90% versus 88%), and life (95% versus 100%).

Azole Resistance

Studies of MIC values have demonstrated no significant resistance among fungal strains causing colonization or infection over 4- to 13-year time periods in various NICUs.[46,52,53,56,68] These studies have also shown a relationship with frequency of dosing and fungal resistance. Twice-weekly dosing of 3 mg/kg of fluconazole prophylaxis compared with more frequent dosing is associated with colonization with fungal isolates with lower MICs.[52,53]

A retrospective evaluation of all clinical and surveillance fungal isolates obtained from infants during a 10-year period (1997-2006) revealed no significant evidence of colonization or infection with *C. glabrata* or *C. krusei* strains.[68] A comparison was made between the 6-year prophylaxis period (2001-2006) and a 4-year period prior to the start of fluconazole prophylaxis. The rate of *C. glabrata* or *C. krusei* colonization remained approximately 4% and the rate of infection 1%, with no significant differences detected comparing the two study periods. It is important to note that in these studies invasive *Candida* infections were treated with amphotericin B preparations, which decrease the overall exposure to fluconazole and may intermittently eliminate resistant organisms.

Dosing may play a role in resistance. Sarvikivi et al. used fluconazole prophylaxis over a 12-year period (1991-2002) in infants less than 1000 g and less than 30 weeks and reported minimal resistance.[100] They found no *C. albicans* BSIs or resistance and no *C. glabrata* or *C. krusei* BSIs. After 10 years of targeted prophylaxis in preterm infants, the NICU expanded its protocol to the entire NICU and increased the daily dose to 6-12 mg/kg. In the 2 years following that change, it reported two infants who developed a fluconazole-resistant strain of *C. parapsilosis*. Further investigation revealed that a single strain with decreasing susceptibility was responsible for these BSIs in their NICU over the entire 12-year study period. This study and others have revealed a higher risk of emergence of resistance with higher (≥6 mg/kg) and more frequent (daily) dosing of fluconazole.[100,118] This study illustrated two important points. First, it is important to use a different antifungal agent for treatment than the one used for prophylaxis, so that if an infection by a resistant organism occurs, treatment will be with an effective antifungal agent. Second, although a rare occurrence, high doses and total NICU exposure to fluconazole may have led to the resistant strains. By using fluconazole for both prophylaxis and treatment, patients in the NICU were exposed to higher doses for longer periods of time. It is important to note that higher doses of daily fluconazole over longer time periods are associated with resistance in adult HIV patients. These mechanisms of resistance include increases in efflux pumps, point mutations, and gene overexpression.[118]

Systematic Reviews of Fluconazole Prophylaxis

Fluconazole prophylaxis has been the subject of several meta-analyses, all demonstrating safety and efficacy. One systematic review of randomized and nonrandomized trials investigated the effect of fluconazole prophylaxis on invasive *Candida* infections and analyzed all-cause mortality, *Candida*-related mortality, combined outcomes, adverse drug reactions, and fluconazole sensitivities.[25,55] Fluconazole prophylaxis decreased the incidence of invasive *Candida* infections in infants less than 1000 g by 91% (OR, 0.09; 95% CI, 0.04-0.24; $p = .0004$) and in all infants less than 1500 g by 85% (OR, 0.15; 95% CI, 0.080.26; $p < .0001$). The all-cause mortality was 11% for the fluconazole-treated group compared to 16.3% for controls (OR, 0.74; 95% CI, 0.58-0.95; $p = .017$). *Candida*-related mortality was virtually eliminated (OR, 0.04; 95% CI, 0.01-0.31, $p = .006$), and a 96% decrease in mortality was found.

In a high-level analysis using patient-level data from available randomized trials in premature infants performed in the United States, fluconazole prophylaxis reduced the odds of invasive *Candida* infections or death by 52%, invasive *Candida* infections by 80%, and *Candida* colonization by 72% during the drug exposure period compared with infants given placebo.[32] The majority of patients were <750 grams (73%), which makes this analysis particularly important as these are the infants at highest risk for infection, mortality from infection, and long-term impairment. This

study provided the most complete analysis of the safety of fluconazole prophylaxis for premature infants and found no difference in the number of infants with abnormal ALT, AST, alkaline phosphatase, or conjugated bilirubin levels. Resistance was also evaluated, and no difference was found in azole susceptibility testing between the fluconazole and placebo groups, and no emergence of resistance.

Cochrane review of these trials has also demonstrated efficacy of this treatment.[25] They examined invasive infections during the entire hospitalization compared to while on prophylaxis used in the other analyses. The number needed to treat varies depending on incidence of invasive *Candida* infections in individual NICUs but should not be the only factor used to determine high-risk patients. Our approach to prevention should not be restricted to an arbitrary number needed to treat. Patients at risk for mortality and neurodevelopmental impairment from invasive *Candida* infections are at high risk and should be protected from the harm of invasive *Candida* infections.

Nystatin Prophylaxis

Nystatin, an enteral and/or orally administered nonabsorbable antifungal agent, was the first antifungal studied for prophylaxis in preterm infants and has been the subject of randomized, quasi-randomized, retrospective, and epidemiologic studies. These studies have added to our understanding of antifungal prophylaxis by demonstrating its efficacy and use in NICUs with low rates of infection,[49] demonstrating the greater efficacy of prophylaxis when it is started early (by 72 hours after birth) versus later when colonization is detected,[83] and a decrease in all-cause mortality.

Antifungal prophylaxis started after colonization is detected is not as effective as starting shortly after birth in preventing infections. Ozturk et al. examined the efficacy of starting antifungal prophylaxis within 72 hours after birth compared with starting later and targeting only colonized infants once colonization was detected by surveillance cultures.[83] In their multigroup study, they demonstrated that nystatin prophylaxis was more effective in reducing *Candida* BSI when started in the first 72 hours after birth compared with identifying colonization first prior to instituting prophylaxis. Three groups were studied: (1) patients who received prophylactic therapy within the first 72 hours following birth ($n = 475$), (2) infants who, if they became colonized, were started on prophylaxis at the time colonization was detected ($n = 115$), and (3) control patients who did not receive antifungal prophylaxis ($n = 358$).[83] Fungal BSI was decreased by 90% when nystatin prophylaxis was started in the first 72 hours (47 ± 12 hours, mean ± SD) compared to only 62% when started after colonization was detected (12.6 ± 2.4 days). The rates of candidemia decreased significantly with oral nystatin prophylaxis in both ELBW and VLBW infants. There was no benefit for infants greater than 1500 grams.

Two large retrospective studies of nystatin prophylaxis demonstrated the use of antifungal prophylaxis even in NICUs with low *Candida* bloodstream rates.[41,49] In the largest multicenter epidemiologic study to date ($n = 14,778$), comparing preterm infants who received nystatin prophylaxis to those who did not receive antifungal prophylaxis (1993-2006; Australia and New Zealand), oral nystatin prophylaxis was associated with a decrease in BSI or meningitis in infants less than 1500 g (1.23% to 0.54%, $p < .0001$) and in less than 1000-g infants (2.67% to 1.23%, $p < .0001$).[49] Rates did not include *Candida* UTIs, which may occur alone without BSI in 3% of infants less than 1000 grams.[17]

Another large retrospective study of nystatin (1459 infants in the United Kingdom) demonstrated similar efficacy of nystatin prophylaxis in reducing invasive *Candida* infections in preterm infants less than 33 weeks. The study compared invasive *Candida* infection rates before (1998-2000) and after starting nystatin prophylaxis (2000-2003). There was a 56% decrease in invasive *Candida* infections in infants less than 33 weeks, from 4.1% to 1.8%, and a 54% decrease in those infants less than 1500 grams (5.5% to 2.5%) with nystatin prophylaxis. This study also found that all-cause mortality was lower in the nystatin prophylaxis group (11.8%) compared to patients not receiving prophylaxis (17.8%) ($p < .0001$).[41]

While effective for most preterm patients, study data are still sparse with the use and efficacy of nystatin prophylaxis for infants at the lower extremes of prematurity and with gastrointestinal diseases. Limitations of the nystatin studies are that few infants less than 25 weeks' gestation and less than 750 grams have been studied and that nystatin can be given to the oral mucosa but may not always be able to be administered enterally or effective when there is an ileus, gastrointestinal disease, feeding intolerance, or hemodynamic instability.

Fluconazole Versus Nystatin Prophylaxis

Antifungal prophylaxis with parenteral fluconazole is effective in preventing colonization of the skin, gastrointestinal and respiratory tracts, central venous catheter, and dissemination to multisite colonization (Table 49.6), as well as eradicating colonization with *Candida albicans*, the most virulent yeast for preterm infants. Aydemir has demonstrated that nystatin (given 0.5 mL to the oral cavity and 0.5 mL via the feeding tube every 8 hours) decreases skin, gastrointestinal, and respiratory fungal colonization but not at other sites.[8]

Some questions regarding fluconazole and nystatin prophylaxis remain unanswered, but there are two studies that have compared both agents. Nystatin is less efficacious compared to fluconazole and in one nystatin study a third of the eligible patients were excluded because of hemodynamic instability or gastrointestinal concerns. Additionally, the oral suspension of nystatin has a very high osmolarity of 3002 mOsm/L, and there is a concern with the use of hyperosmolar medications and NEC.

TABLE 49.6 Antifungal Prophylaxis

	Fluconazole	Nystatin
Effect on colonization	Decreased CVC, skin, GI, and respiratory colonization	Decreased skin, GI, and respiratory colonization
Level of evidence	Level A-1 RCT data	Level A-1 RCT data
Efficacy	80% in all studies >90% in <1000 g	50%-60%
Evidence in extremely preterm infants	Efficacy in the most extreme preterm infants (<25 weeks' gestation and <750 grams)	Fewer infants <750 g or <25 weeks' gestation have been studied
Effect on mortality	*Candida*-related mortality decreased by 96%	Lower mortality in one study
Administration with GI disease or ileus	Can be given in infants with NEC, ileus, or GI disease	Cannot be given if GI disease or ileus
Resistance	No resistance	Lack of data on resistance
Dosing	Twice-a-week dosing	Dosing 3-4 times/day
Route of administration	Given IV*	Oral/enteral administration
Osmolarity	300 mOsm/L	3002 mOsm/L
Start prophylaxis	Soon after birth	Soon after birth
End prophylaxis	No longer need IV access	Full enteral feedings
Cost	Cost effective	Cost effective Costs more in U.S. compared to fluconazole

CVC, Central venous catheter; GI, gastrointestinal; NEC, necrotizing enterocolitis; RCT, randomized controlled trial.
*Some studies gave drug orally after IV access removed to complete 4 weeks (for infants 1000-1500 grams) and 6 weeks (for infants <1000 grams) of prophylaxis.

Aydemir et al., in a three-arm RCT of antifungal prophylaxis, compared intravenous fluconazole (n = 93) and oral/enteral nystatin (n = 94) with placebo (n = 91) in infants less than 1500 grams.[8] Patients were randomized (1:1:1) to fluconazole, nystatin, or placebo. This study demonstrated that nystatin prophylaxis resulted in decreased *Candida* colonization of the gastrointestinal tract, skin, and respiratory tract. Invasive *Candida* infections were significantly lower in both the fluconazole (3.2%) and nystatin (4.3%) groups compared with the placebo (16.5%) patients ($p < .0001$). Although a previous study had raised concerns regarding nystatin use and NEC and all-cause mortality,[110] this study demonstrated no difference between both groups regarding NEC (fluconazole 8.6%, nystatin 9.6%, placebo 9.9%) or mortality (fluconazole 8.6%, nystatin 8.5%, placebo 12.1%).

Whereas oral fluconazole for prophylaxis was used in one of the above studies, almost all other fluconazole prophylaxis studies have used intravenous administration in the first weeks. Although enteral fluconazole is 90% absorbed, absorption characteristics in preterm infants are variable and not well studied. Additionally, as discussed above, oral mucosa can be treated but enteral prophylaxis may not always be able to be given if patients have an ileus, NEC, intestinal perforation, or hemodynamic instability. It is during these patient conditions that fungal colonization, proliferation, and dissemination are likely to occur. For these reasons and to prevent colonization of central venous catheters, the intravenous route is recommended for fluconazole prophylaxis in preterm infants while peripheral or central intravenous catheters are present. In some studies, fluconazole was changed to enteral administration when patients achieved full enteral feedings, and intravenous access was discontinued in order to complete 4-6 weeks of prophylaxis.

For antifungal prophylaxis, the evidence favors fluconazole for prophylaxis owing to A-I evidence, greater efficacy compared with nystatin prophylaxis (80%-90% compared with 50-60%), safety in infants less than 1000 grams, lower cost in some NICUs, twice-weekly administration, and ability to administer to all high-risk infants less than 1000 grams, even in the face of gastrointestinal disease or hemodynamic instability (see Table 49.6). Some studies state nystatin is less expensive, based on comparing one dose of each medication, but for a complete course of prophylaxis, because nystatin is dosed 3-4 times a day compared with only twice a week for fluconazole, nystatin is approximately twice as expensive in the United States. Cost of the medications may vary by country and NICU.

Timing of Prophylaxis

Targeted antifungal prophylaxis has been aimed at the time period when high-risk patients have additional risk factors for invasive *Candida* infections and when these *Candida* infections most commonly occur in preterm infants. All studies have targeted high-risk patients whether defined by birth weight, gestational age, or a combination birth weight and gestational age with additional risk factors (e.g., central venous catheter, prolonged antibiotics, NEC). Studies can also be defined by starting prophylaxis early (in the first 3 days) compared with later (after a week).

The most effective approach is to define a high-risk group and begin antifungal prophylaxis in the first day after birth and continue until the additional risk factors (other than birth weight and gestational age) are no longer present. For example, the initial fluconazole study targeted high-risk infants less than 1000 grams who were intubated or had a central venous catheter.[52] Prophylaxis was continued until intravenous access was no longer needed, which correlates with risk factors of receiving parenteral nutrition, antibiotics, gastrointestinal diseases, or having a central venous catheter. If a 26-week infant does well, achieves full enteral feedings at 3 weeks of life, and has IV (central or peripheral) access removed, the patient would require only 6 doses of fluconazole prophylaxis. Comparatively, if a 24-week infant takes 8 weeks to reach full enteral feedings, 16 doses of fluconazole prophylaxis would be administered. If a patient needs intravenous access after a period of being on full enteral feedings (e.g., treatment of an infection or NEC), then antifungal prophylaxis would be restarted until intravenous access is no longer needed again. Targeting prophylaxis to an individual patient's risk factors limits drug exposure to the patient and fungi and reduces drug toxicity, costs, and the emergence of fungal resistance.

Starting prophylaxis later, during prolonged antibiotic courses for more than 2-3 days, or after colonization is detected, has been examined in retrospective studies. The goal of these studies was to prevent invasive *Candida* infections but further limit drug exposure, cost, and potential fungal resistance. Some of these studies targeting late risk factors were 30% less effective.[74,83] There were also no significant differences in the number of prophylaxis drug doses with this approach. From a system's standpoint, it is more effective to identify patients on admission compared to successful initiation with daily assessment. One study demonstrated only 75% compliance when identifying patients based on several risk factors that need to be evaluated daily.[74]

The other major factor is that when starting prophylaxis later, colonization has likely occurred in high-risk patients. When prophylaxis is started after 5 days, it has been found to be less effective, especially if colonization has occurred at high-risk sites. Delaying antifungal prophylaxis until after colonization has been detected is 30% less effective compared with starting within 72 hours after birth.[83] Manzoni et al. also reported decreased efficacy of antifungal prophylaxis in infants who were colonized later.[69] If colonization of high-risk sites is detected, a pre-emptive approach should be considered as discussed above.

Cost Effectiveness of Antifungal Prophylaxis

There are several ways to examine costs, including financial costs, cost of life, and cost of disability. Fluconazole prophylaxis provides a financial cost advantage across most invasive *Candida* infection rates seen in the youngest premature infants. In a cost-analysis study using cost of fluconazole prophylaxis related to costs associated with infection, it was found the average cost per patient attributed to invasive *Candida* infection in patients receiving fluconazole prophylaxis was $785 versus $2617 in those not receiving fluconazole prophylaxis.[106] Invasive infection rates would need to be <2.8% for fluconazole prophylaxis to lose its cost benefit. In Monte Carlo simulation, targeting infants <1000 g would lead to $50,304,333 in cost savings per year in the United States.

When examining financial costs, it is important to realize that treating one invasive *Candida* infection costs approximately the same as the cost of antifungal prophylaxis for a NICU for 1 year. Several studies have examined the use and cost of antifungals after the institution of fluconazole prophylaxis in their NICUs. Rueda et al. examined the expense of antifungals during the year before and after instituting fluconazole prophylaxis. In their NICU, there was a cost savings of approximately $31,500. The cost of antifungals was $56,826 in the year prior and decreased to $25,397 after fluconazole prophylaxis was started.[96] Uko and colleagues reported a significant cost benefit of $516,702 over 18 months in their institution's NICU after instituting fluconazole prophylaxis.[107] In the United States, the pharmacy cost of a single dose of fluconazole is $18; the cost of a 4- to 6-week course (at twice-weekly dosing = 8-12 doses) is $144-$216 per patient. Comparatively, nystatin prophylaxis would cost twice as much. Nystatin costs $3.75 per dose; dosing at 3 times daily for 4-6 weeks would cost $315-$473 per patient. Nystatin dosing at 4 times daily would cost $420-$630 for a 4- to 6-week course.

Conclusions

Infection Control and Prevention Group Recommendations

According to Centers for Disease Control and Prevention, there are an estimated 30,000 preterm infants less than 1000 g or less than 28 weeks' gestation born each year in the United States. Instituting antifungal prophylaxis would prevent up to 2700 infections, 400 *Candida*-related deaths, and 570 infants with neurodevelopmental impairment yearly. A unified, dedicated approach similar to group B *Streptococcus* prophylaxis in all NICUs could achieve the largest impact on the prevention of invasive *Candida* infections. For group B *Streptococcus*, the number needed to

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

treat to prevent one infection is 135. Using the National Nosocomial Infections Surveillance System (NNIS) data, the overall number needed to treat would be 13 for each *Candida* BSI prevented. Including all invasive *Candida* infections, bloodstream, urine, cerebrospinal, and peritoneal infections, the number needed to treat is closer to 10 for infants less than 1000 grams. Because of the severity of these infections, with 73% of infants less than 1000 grams dying or having neurodevelopmental impairment, prevention is critical.

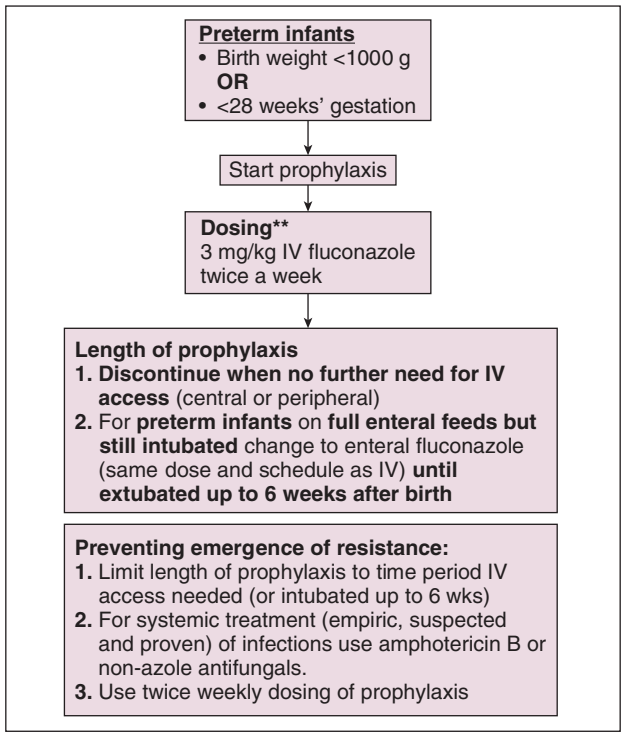
The Red Book 2015 released guidelines regarding antifungal prophylaxis for preterm infants less than 1000 grams.[21] This report states that: "On the basis of current data, fluconazole is the preferred agent for prophylaxis, because it has been shown to be effective and safe. Fluconazole prophylaxis is recommended for extremely low birth weight infants cared for in neonatal intensive care units with moderate (5%-10%) or high (≥10%) rates of invasive candidiasis. The recommended regimen for extremely low birth weight neonates is to initiate fluconazole treatment intravenously during the first 48 to 72 hours after birth at a dose of 3 mg/kg, and administer it twice a week for 4-6 weeks, or until intravenous access no longer is required for care. This chemoprophylaxis dosage, dosing interval, and duration has not been associated with emergence of fluconazole-resistant *Candida* species." The Infectious Disease Society of America has similar recommendations.

Preterm infants in each 100-gram birth weight group less than 1000 grams and each gestational week less than 28 weeks' gestation average invasive *Candida* infection rates ≥5% (see Fig. 49.3). For NICUs with rates less than 5% in preterm infants less than 1000 grams, invasive *Candida* infection rates should be analyzed by both gestational age and 100-gram birth weight groups in those infants to find the break point where the rate falls below 5%. Invasive *Candida* infection rates should be determined including BSIs, UTI, meningitis, and peritonitis *Candida* cases over a period of a few years. It is advisable to consider criteria for antifungal prophylaxis to include both birth weight and gestational age because gestational age has a more linear relationship compared to birth weight to both incidence and mortality. Some very extremely preterm infants may be excluded if birth weight is solely used to establish a different cutoff for prophylaxis. For example, a 24-week-gestation infant can weigh between 468 and 940 g (between the 3rd and 97th percentile).

Those NICUs transitioning to resuscitate infants at younger gestational ages need to develop an infection prevention and control guideline. Decisions to resuscitate and manage extremely preterm infants should include antifungal prophylaxis in the care of these patients, as prophylaxis would contribute to decreasing mortality and neurodevelopmental impairment in these extremely preterm infants. Improving outcomes for these infants is multifactorial and needs to include all beneficial approaches as a "bundle" to have the largest effect, and antifungal prophylaxis should be included.

For NICUs with significant rates of invasive *Candida* infections in infants 1000-1500 g, some retrospective studies have proposed either presence of a central venous catheter or treatment with antibiotics for greater than 3 days as guidelines for the use of antifungal prophylaxis. A retrospective study by Bertini and colleagues reported that 10% of infants 1000-1500 grams had central venous catheters and were treated with fluconazole prophylaxis.[55] Another study targeted fluconazole prophylaxis (3 mg/kg) to infants in whom a decision was made to give broad-spectrum antibiotics for greater than 3 days. In this study, 40% of 1000- to 1500-gram infants in their NICU were targeted for prophylaxis.[107] Data from nystatin trials and a multicenter fluconazole study indicate that approaches starting prophylaxis after the first week of life would be more effective if fungal colonization has not already occurred.[18,32]

Antifungal Prophylaxis Summary



Targeted Prophylaxis in High-Risk Patients

Although individualizing NICUs to base antifungal prophylaxis is one method, a standardized approach for high-risk infants in every NICU may be more effective in preventing harm from and eliminating invasive *Candida* infections (Fig. 49.8). High-risk patients for targeted prophylaxis should be defined as NICU patients with a significant incidence, mortality, or neurodevelopmental morbidity from invasive *Candida* infections. Preterm infants less than 1000 grams at birth and less than 28 weeks' gestation have substantial *Candida*-associated mortality and neurodevelopmental impairment irrespective of specific rates. High-risk infants greater than 1000 g in the NICU who also have invasive *Candida* infections rates ≥5% or substantial *Candida*-associated mortality and morbidity include those with gastrointestinal diseases, including NEC and gastroschisis, and infants with Gram-negative infections being treated with broad spectrum antibiotics (third- or fourth-generation cephalosporins, carbapenems).

Fluconazole Prophylaxis Dosing Recommendation

Taking into consideration the issue of emerging antifungal resistance, a dosage of 3 mg/kg fluconazole administered intravenously twice weekly appears to be the safest and most effective schedule. This provides similar efficacy with less risk for resistance compared with higher and more frequent doses of treatment. Administering fluconazole prophylaxis (3 mg/kg) twice weekly on the same days, every Tuesday and Friday, at a specified time, also reduces pharmacy costs and may limit medication errors. With drug shortages this also reduces waste as one bag can be utilized for all the NICU patients needing prophylaxis that day.

• **Fig. 49.8** Targeted antifungal prophylaxis (AP) for high-risk neonates. *Other high-risk patients in which to consider antifungal prophylaxis:* 1. **Treatment of infection requiring third- or fourth-generation cephalosporins or carbapenems**. Cover with AP while the patient is receiving these antibiotics. **2. Acquired complicated gastrointestinal disease**. Cover patients with necrotizing enterocolitis or spontaneous intestinal perforation until no longer needing IV access (central or peripheral). Consider evaluating for gastrointestinal colonization at time of presentation for fungal colonization and, if present, treat empirically with nonazole antifungal for 14 days. If laparotomy performed, send peritoneal cultures and treat peritonitis if present. **3. Congenital gastrointestinal diseases** with expected NPO period >7 days and/or need for prolonged antibiotics use >7 days. Examples would be gastroschisis or Hirschsprung disease. Start AP on day of birth and continue until no longer a need for IV access. ***Dosing notes:* First dose on day of birth, then twice a week (e.g., Tuesdays, Fridays at 10 AM); give over 60 min; if central line present, give via central line; 3 or 6 mg/kg dosing has similar efficacy in clinical trials.

This schedule continues until IV access (central or peripheral) is no longer required. Additionally, a different antifungal (amphotericin B) is selected for treatment or empiric therapy.

Infection Control Measures to Prevent Invasive *Candida* Infections

Prenatal Detection and Eradication of Maternal Vaginal Candidiasis

In pregnancies complicated by preterm labor or prolonged rupture of membranes, screening and treatment of vaginal candidiasis may be beneficial in preventing candidal colonization and subsequent infection in the newborn.[37,57] Vulvovaginal fungal colonization is more common during pregnancy, occurring in up to 30%. During pregnancy, correct diagnosis of maternal vulvovaginal candidiasis followed by appropriate treatment with confirmation of clearance if symptoms persist or in high risk cases may help prevent neonatal candidiasis.[37,76] Infection is increased in pregnancies complicated by preterm labor, premature rupture of membranes, cervical cerclage, history and/or presence of intrauterine contraceptive device, or broad spectrum antibiotic use. Germany screens many pregnant women for vaginal candidiasis during the third trimester.[77] Some data suggest that vaginal candidiasis in pregnancy may be associated with increased risk of pregnancy complications, such as premature rupture of membranes, preterm labor, and chorioamnionitis, and vaginal treatment may decrease preterm birth within the first trimester.[1]

Medication and Feeding Stewardship

Practices reducing medications that increase the risk for invasive *Candida* infections should be avoided if possible and instituted with stewardship, guidelines, tracking/auditing, and accountability. Medications that increase risk for invasive *Candida* infections as discussed previously include: broad-spectrum antibiotics (third- or fourth-generation cephalosporins or carbapenems), gastric acid inhibitors (H_2 blockers and proton pump inhibitors), and postnatal dexamethasone. Data from a multicenter study of postnatal hydrocortisone in infants less than 1000 grams did not demonstrate an increase with hydrocortisone, with both treated and placebo groups having an incidence of *Candida* BSIs of 10%.[116] One small retrospective study of VLBWs demonstrated a decrease in *Candida* BSI with a bundled reduction in antibiotics days, H_2 blocker, carbapenem, and third-generation cephalosporin use (replaced cephalosporin with gentamicin in early-onset antibiotic coverage).[22] Development of using feeding protocols (starting early and trophic and slow feed advances) and the promotion of practices that can lower NEC rates, such as breast milk feedings, may aid in decreasing the risk for invasive *Candida* infections as well.

Central Line–Associated Bloodstream Infection Bundles

Standardized protocols for insertion and management of central venous catheters, attention to sterile practices, hub and dressing care, and closed medication delivery systems may reduce CLABSIs, including *Candida*-related BSIs.[3,24] Aly et al. reported significant reduction in all CLABSIs and elimination of *Candida* infection using a "bundled approach," which included antifungal prophylaxis in addition to line placement and maintenance interventions.[3]

Candida CLABSIs among NICUs between 1999-2009 have decreased from 0.92 to 0.2 per 1000 line days.[24] These data represent preterm and term NICU patients, with infants less than 1000 grams representing nearly 70% of these infections. This fall is attributed to multiple factors, including antifungal prophylaxis, CLABSI bundles, and antibiotic stewardship.

Lactoferrin

In a randomized controlled trial of bovine lactoferrin (bLF) in infants less than 1500 grams, subanalysis found that invasive fungal infections were also significantly less common with lactoferrin alone compared with placebo.[71] One limitation of the study was that there were only 9-18 infants ≤750 g in each group. Confirmation of the findings in extremely preterm infants is needed.

Probiotics

Microbes begin to colonize the neonate around birth, as the offspring ingests microorganisms from the normal commensal flora of the maternal genitourinary tract. Probiotics have immunomodulating and anti-infective activities that compete for adhesion to gut cells, displacing the pathogens, and influence intestinal permeability. Among all probiotics, *L. rhamnosus GG* and *L. reuterii* proved effective in preventing gut colonization by *Candida* species, a process that often precedes fungal sepsis (Table 49.7).[70,93] Whether prevention of fungal colonization in the gut might translate into prevention of fungal systemic disease in such patients still needs further study.

Invasive *Candida* Infection Summary

Invasive *Candida* infection is a major problem for preterm infants. Strategies to reduce invasive *Candida* infection and its morbidity and mortality in NICU patients are summarized in Box 49.1. Standardization of treatment regimens (appropriate dosing with prompt central catheter removal for documented candidal BSI) has been shown to decrease invasive *Candida* infection mortality, but it may not reduce the risk of neurodevelopmental impairment and other morbidities associated with these infections. Empiric antifungal treatment when invasive *Candida* infection is suspected should be given and may decrease mortality but needs further study. Infection control practices are likely to contribute to reducing the rate of invasive *Candida* infections, but this has not yet been shown in prospective studies. Both nystatin and fluconazole prophylaxis have level A-I evidence demonstrating efficacy in the prevention of invasive *Candida* infection. Prevention with fluconazole prophylaxis in extremely preterm infants is favorable and recommended by pediatric infection control groups. Antifungal prophylaxis with infection control practices administered to infants with birth weights less than 1000 g and/or less than 28 weeks' gestational age can reduce and potentially eliminate invasive *Candida* infections, their contribution to neurodevelopmental impairment, and *Candida*-related mortality.

Aspergillus, Mucormycosis, Malassezia, and Trichosporin Infections in the Neonatal Intensive Care Unit

Aspergillus and Mucormycosis (formerly Zygomycosis) are filamentous fungi, and while they rarely cause infections in neonates, these infections can be severe in preterm infants. *Aspergillus* may present as cutaneous, pulmonary, or disseminated disease. The major host defense against aspergillosis is macrophage chemotaxis and phagocytosis, both of which are diminished in the preterm infant. Infections are generally the result of environmental contamination such as dust from hospital construction or faulty cleaning practices that can carry spores that may settle in wounds or be inhaled. Regular cleaning of the ventilation systems in the NICU to avoid buildup of dust contaminated with spores, as well as appropriate containment of dust during hospital renovation and construction, can help to prevent aspergillosis infection in the high-risk neonate. Voriconazole as a first-line agent would be indicated in neonatal aspergillosis cases (see Table 49.5). The cutaneous manifestations in a preterm infant are shown in Fig. 49.9.

Mucormycosis initially present as a black eschar at the site of local trauma, intravenous catheter, or infiltrate, progressing to necrotizing soft tissue infections. *Rhizopus* and *Mucor* species most commonly cause infections in neonates and importantly are resistant to azoles. These fungi may contaminate adhesive tape, monitor leads, and wooden tongue blades used for splints in the NICU. Early diagnosis, amphotericin B, and surgical debridement are needed to prevent ulceration, necrosis, and rapid fatal dissemination. A high degree of suspicion is needed, and a tissue biopsy must be obtained to diagnose these right angle–branched,

TABLE 49.7 Probiotics and Colonization by *Candida* Species in Preterm Infants

	Probiotic Used	Primary Outcome	Incidence		*P*-Value
			Probiotic Group	Placebo Group	
Manzoni et al., 2006[79]	Lactobacillus rhamnosus GG	*Candida* gut colonization in <1500-g neonates	23.1%	48.8%	.01
Romeo et al., 2011[9]	Lactobacillus reuterii	*Candida* gut colonization in <2500-g neonates	7.1%	22.9%	.01
Romeo et al., 2011[9]	Lactobacillus rhamnosus GG	*Candida* gut colonization in <2500-g neonates	10.7%	22.9%	.01

• BOX 49.1 Strategies to Reduce Invasive *Candida* Infections and Their Morbidity and Mortality in NICU Patients

- Use antifungal prophylaxis with IV fluconazole starting after birth and while requiring IV access (central or peripheral) for infants with birth weight less than 1000 grams and/or less than 28 weeks' gestational age (A-I).
  - There is also A-I evidence for antifungal prophylaxis with nystatin. Data are limited for infants less than 750 g and less than 26 weeks' gestation. Because fluconazole prophylaxis has greater efficacy compared to nystatin, efficacy in the most immature patients, and can be given to infants not feeding, current evidence would favor fluconazole prophylaxis in preterm infants less than 1000 grams.
- Start treatment of documented infections with appropriate antifungal dosing and prompt catheter removal for candidal BSI (A-II).
  - Promptly treat congenital cutaneous candidiasis with presentation of rash.
  - Consider starting empiric antifungal therapy if ICI is suspected.
- Decrease broad-spectrum antibiotic use (B-II).
  - Restrict third- and fourth-generation cephalosporins and carbapenems to treatment of proven Gram-negative infections.
  - Use antifungal prophylaxis while patients are receiving these agents.
- Decrease H_2 blocker and proton-pump inhibitor use (B-II).
  - Use only for proven gastritis, and restrict use to 3 days or until symptoms resolve.
- Decrease postnatal dexamethasone use (B-II).
  - Use only for severe lung disease.
- Institute central line–associated bloodstream infection reduction bundles (B-II).
- Monitor rates of ICI, including BSI, UTI, meningitis, and peritonitis infections, and provide feedback to staff (B-II).
- Probiotic supplementation (Lactobacillus rhamnosus GG or Lactobacillus reuterii) to decrease enteric fungal colonization (C-I).
- Bovine lactoferrin supplementation to decrease candidal bloodstream infections and to decrease the progression from enteric fungal colonization to systemic infection (B-I).

Level of Evidence: US Public Health Service Grading System for ranking recommendations in clinical guidelines: Strength of recommendation and levels of evidence. A, Good evidence; B, moderate evidence; C, poor evidence; I, at least one randomized clinical trial; II, at least one well-designed but nonrandomized trial; III, expert opinions based on experience or limited clinical reports.

BSI, Bloodstream infection; ICI, invasive *Candida* infection; IV, intravenous; UTI, urinary tract infection.

nonseptated hyphae. Mortality from the infection is reported as 61% (11 of 18) of infants.[82]

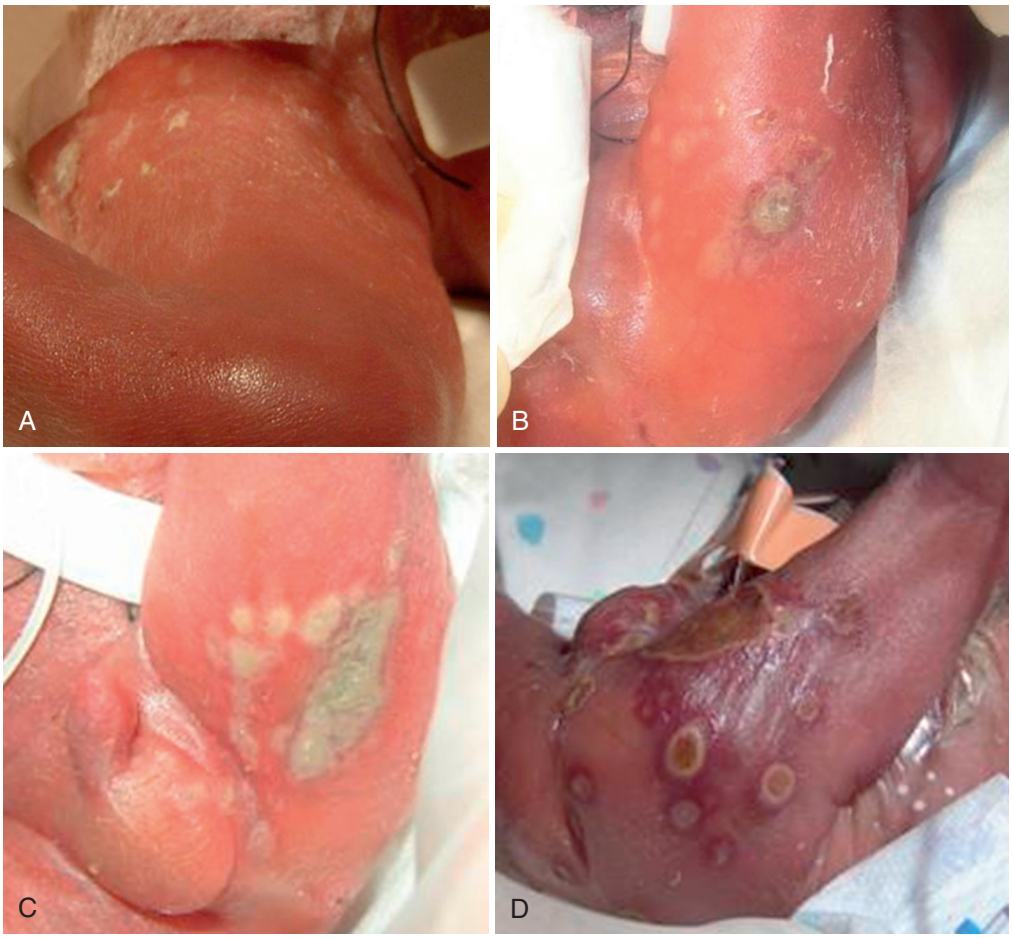
Malassezia furfur and *M. pachydermatis* are not highly virulent but have been associated with nosocomial infections in preterm infants. *M. furfur* is a lipid-dependent fungus that can colonize the skin, gastrointestinal tract, and intralipid solutions of NICU patients and can be spread from patient to patient via hands of health care workers or family members. Bloodstream infection with *M. furfur* is more common in infants of lower birth weight, gestational age, and longer NICU stays. The infection may clear simply with discontinuation of intralipid infusion and/or removal of central vascular catheters. Amphotericin B should be used for treatment until a clinical response and negative blood culture are documented. However, in preterm infants with significant symptomatology and documented *M. furfur* fungemia, treatment with systemic antifungal therapy is warranted. *M. pachydermatis* invasive infections have also been described in neonates, including an outbreak that may point to infection control strategies. *M. pachydermatis* infections should prompt infection control measures and potential screening as the source may be other infants, health care workers, and dogs. *Trichosporin* infections can occur in outbreaks and have high mortality in ELBW infants. They are susceptible to amphotericin. For both *Malassezia* and *Trichosporin* outbreaks, education on hand washing and treatment of infections is successful in eradicating this organism from the NICU.

Other Fungal Infections

Coccidioidomycosis

Incidence

Coccidioidomycosis is endemic in the San Joaquin Valley in California and in other areas of the southwestern United States, Mexico, Argentina, Venezuela, and Paraguay. Most susceptible individuals living in endemic areas acquire asymptomatic infection within 5 years. Disease can occur in any geographic location after reactivation of infection. Despite the high incidence of infection in endemic areas, perinatal coccidioidomycosis rarely occurs.



Microbiology

Coccidioides immitis, the causative agent of coccidioidomycosis, is a biphasic fungus. Highly contagious mycelia grow on culture media and soil, whereas the less infectious spherules grow in tissues. The spherule contains hundreds of endospores that, when released, can become spherules.

Pathogenesis

The infectious arthrospores can become airborne or can be transferred from inanimate objects contaminated with dust. Infection is acquired from inhalation of arthrospores and less commonly from direct inoculation into cutaneous lacerations or abrasions. The incubation period is 7-21 days. Infection occurring in infants younger than 1 week of age has been described, suggesting vertical transmission. Despite

• **Fig. 49.9** Cutaneous aspergillosis. **A,** Cutaneous findings initially presented as small dry, flaky white lesions on day of life 3. **B,** Three days later, lesions had evolved into flat yellow-white target and nontarget lesions with dermal penetration. **C,** Five days into infection there was progression to deeper invasion with yellow-white ulceration **D,** Eight days after presentation there were multiple target lesions and surrounding erythema.

several reports of disseminated infection during pregnancy, placental and perinatal infections are rare.

After arthrospore inhalation, mature spherules develop within several days. Granuloma formation with tracheobronchial lymph node involvement can follow. In extensive disease polymorphonuclear leukocytes infiltrate the lung, similar to the process seen with bacterial pneumonia. Hematogenous dissemination occurs frequently in infants.

Clinical Manifestations

In contrast to older children and adults whose primary infection is often asymptomatic, pneumonia is usually present in most infants with recognized infection. Chest radiographs can show focal consolidation or diffuse nodular infiltrates, hilar adenopathy, and pleural effusions. Fever, anorexia, and respiratory distress often accompany neonatal coccidioidomycosis. If the disease becomes disseminated, lesions can develop in the skin, bone, lymph nodes, liver, spleen, and meninges.

Diagnosis

Clinical and radiographic features of coccidioidomycosis can resemble features seen with histoplasmosis, pulmonary tuberculosis, and viral pneumonitis. If meningitis develops, an elevated protein concentration and hypoglycorrhachia can be seen on CSF examination. Early in the course, a neutrophilic pleocytosis can be seen, but this quickly progresses to a lymphocytic predominance.

The diagnosis is best established using serologic and histologic methods. An IgM response is usually detectable 1-3 weeks after the onset of symptoms. A high IgG titer indicates severe disease, and decreasing titers suggest improvement. Transplacental passage of complement-fixing antibody occurs, so an increase in the infant's titer must be shown to document neonatal infection. Antibodies are detectable in CSF in patients with meningitis. Spherules occasionally can be observed on silver-stained tissue samples. Culture of the organism is feasible but is potentially hazardous to laboratory personnel. Coccidioidin skin tests are not helpful in

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

the neonatal period, and these skin tests are not currently available in the United States.

Treatment

In older children and adults, primary infection is often self-limited and requires no therapy. The frequency of disseminated disease in young infants and the high case-fatality rate warrant treatment of all neonatal infections, however. Amphotericin B is the drug of choice for the initial treatment of infection. The duration of therapy is prolonged, and anecdotal therapy suggests that fluconazole administered orally can be given to complete the course of treatment.

Cryptococcosis

Incidence

Cryptococcosis occurs worldwide. Many infections are likely to be asymptomatic, and most symptomatic infections occur in individuals older than 30 years. Infection can occur in otherwise healthy individuals but is more common in immunocompromised hosts, including patients with acquired immunodeficiency syndrome (AIDS), malignancies, and diabetes mellitus. Cryptococcal infection in the newborn period is an extremely rare disease.

Microbiology

Cryptococcus neoformans is an encapsulated yeast that reproduces by budding. Its natural habitat is soil, and it has been commonly found in soil contaminated with pigeon excreta.

Pathogenesis and Pathology

Cryptococcosis is acquired from inhalation of the yeast with resulting primary pulmonary infection. Ingestion or cutaneous inoculation is possible; a central venous catheter may have been the source of cryptococcemia in one neonate. Case reports of disease with onset shortly after birth suggest that in utero or intrapartum transmission is possible. Otherwise, there has been no evidence of human-to-human transmission. Pulmonary infection can remain localized or can disseminate hematogenously to any organ, with the meninges most commonly affected. In adults, the infection is usually subacute or chronic, with large, solitary pulmonary nodules frequently observed. Diffuse pulmonary infiltration or miliary disease with dissemination is more common in infants.

Pathologic findings vary from minor inflammatory responses to abscess formation. Noncaseating granulomas, hepatitis, and cirrhosis of the liver are common findings. Meningitis frequently leads to obstructive hydrocephalus. Granulomas of the brain have been reported.

Clinical Manifestations

Infantile cryptococcosis is a multisystemic infection. The signs and symptoms are similar to congenital infection caused by *T. pallidum*, *Toxoplasma*, cytomegalovirus, and rubella, and include failure to thrive, jaundice, hepatosplenomegaly, chorioretinitis, rash, and intracranial calcifications. Other symptoms suggestive of a central nervous system process, such as lethargy, irritability, vomiting, and seizures, can be observed. Respiratory symptoms are minimal, but occasionally interstitial pneumonitis can be present. Infants with meningeal involvement can show a pleocytosis ranging from 40-1000 leukocytes/mm^3 with a lymphocytic predominance, elevated protein, and slightly decreased glucose concentrations on CSF examination.

Diagnosis

Definitive diagnosis of cryptococcosis requires isolation of the organism from body fluids or tissue specimens. Fungal cultures of CSF, blood, sputum or tracheal aspirates, material from abscess cavities, and bone marrow can yield growth of *Cryptococcus*. The presence of encapsulated, budding yeast on India ink–stained CSF or respiratory tract samples is usually indicative of cryptococcal disease. Serologic investigation includes antibody and antigen detection tests, but antigen detection is the preferred technique. Latex agglutination and enzyme immunoassay for detection of cryptococcal antigen in serum or CSF are excellent rapid diagnostic tests.

Treatment

In healthy adults, pulmonary cryptococcosis is usually self-limited and requires no therapy. Pulmonary disease frequently disseminates in immunocompromised patients if left untreated, however. Before the introduction of amphotericin B, cryptococcosis was almost uniformly fatal. The case-fatality rate has significantly decreased with amphotericin B therapy, but at least one-third of adults fail to respond to therapy and another one-fourth have relapse after discontinuation of therapy. The combination of amphotericin B and flucytosine or fluconazole is indicated as initial therapy for patients with meningeal and other serious manifestations of cryptococcal infection. Because only six cases have been reported in neonates, only anecdotal data exist for treatment. One infant with VLBW survived cryptococcemia after receiving a 6-week course of therapy with amphotericin B.

Histoplasmosis

Incidence

Histoplasmosis is one of the most common pulmonary fungal infections in immunocompetent humans. It occurs worldwide in temperate climates and is endemic in the Ohio and Mississippi river valleys of the United States. In older children and adults, most infections are asymptomatic; however, in young infants, infections are often apparent and frequently disseminate. Despite the high incidence of infection in endemic areas, neonatal histoplasmosis is rare.

Microbiology

Histoplasma capsulatum is the causative agent. It is not encapsulated, but artifacts resembling a capsule can be seen

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

with some staining techniques. It is a thermally dimorphic fungus, growing as mycelia (mold) with microconidia and macroconidia (spores) in soil and converting to yeast form at human body temperatures. Soil is its natural habitat, and it thrives in moist soil contaminated with avian or bat excreta.

Pathogenesis

Inhalation of conidia is the most common mode of transmission. Other routes, such as ingestion or cutaneous inoculation, occur rarely. Human-to-human transmission, if possible, has not been well described. Several days after inhalation, the spores germinate in the alveoli, releasing yeast forms. An inflammatory response, initially neutrophilic, followed by an influx of lymphocytes and macrophages, ensues. The yeasts are phagocytosed, but not killed, and begin to proliferate within macrophages and can spread hematogenously to the liver, spleen, and other organs or to regional lymph nodes through the lymphatics. The inflammatory response can result in discrete granulomas resembling sarcoid, or caseating, lesions that frequently calcify during resolution.

Clinical Manifestations

The clinical spectrum of histoplasmosis in children includes asymptomatic infection, pulmonary disease that can be complicated by mediastinal lymphadenopathy and subsequent tracheobronchial obstruction, primary cutaneous infection, and disseminated infection. Asymptomatic infection occurs mostly in older children and adults, whereas acute disseminated infection with pulmonary disease is most common in young infants. The most frequently observed signs and symptoms in disseminated disease are prolonged fever, hepatosplenomegaly, anemia, and thrombocytopenia. Because the infection can disseminate to the lymph nodes, adrenal glands, gastrointestinal tract, bone marrow, central nervous system, kidneys, heart, and bones, many other signs and symptoms can be present.

Diagnosis

Fungal cultures from patients with acute, self-limited pulmonary infection rarely yield the organism but frequently are positive from patients with disseminated disease. *Histoplasma* can be isolated from lower respiratory tract specimens, blood, bone marrow, hepatic and splenic biopsy specimens, and CSF, but growth may not be detected for 8-12 weeks. Lysis-centrifugation of blood samples submitted for fungal culture has increased the sensitivity and reduced the interval until cultures become positive. Demonstration of intracellular yeast forms supports the diagnosis when the clinical picture is compatible. Detection of *H. capsulatum* polysaccharide antigen in serum, urine, or bronchoalveolar lavage specimens is a rapid and specific diagnostic method. Complement fixation titers greater than 1:32 or a fourfold increase in yeast-phase or mycelial-phase titers suggest acute infection.

Chest radiographs in pulmonary histoplasmosis often are negative or reveal nodular infiltrates with mediastinal and hilar adenopathy. In disseminated disease, chest radiographs most frequently are negative, but hilar adenopathy, bronchopneumonia, or miliary nodules can be present. Pulmonary and splenic calcifications can be seen on subsequent radiographs after recovery from infection. Findings common in adult disease, including pleural effusions or cavitary formation associated with chronic pulmonary infection, are not seen in infantile disease.

Treatment

Primary pulmonary histoplasmosis in a healthy child usually does not require treatment. Therapy is recommended for disease in infancy, because the risk of dissemination is higher, and untreated disseminated disease is almost uniformly fatal. Amphotericin B is effective for initial treatment of disseminated disease and other serious infections. In patients older than neonates, itraconazole is effective, either as initial treatment or after clinical improvement has been observed.

Other Fungi

Blastomyces dermatitidis is a dimorphic fungus endemic to the midwestern, southeastern, and Appalachian areas of the United States. Blastomycosis occurs more commonly in adults than in children and is rare in neonates. Infections can be asymptomatic, limited to the respiratory tract, or disseminated. Cutaneous and skeletal lesions are the most common extrapulmonary sites of infection. Cutaneous and genital diseases have been documented during pregnancy and, if inadequately treated, can result in neonatal blastomycosis. The diagnosis should be considered in infants with reticulonodular pneumonia born to mothers with chronic skin infections who live in endemic areas.

Dermatophyte infections, caused by *Microsporum*, *Trichophyton*, or *Epidermophyton*, are acquired postnatally from contact with contaminated soil, infected animals, or household members. Because lesions associated with dermatophytosis can resemble the lesions seen with psoriasis, seborrhea, or impetigo, they can easily be misdiagnosed.

Protozoal Infections

Malaria

Incidence

Worldwide, there are 300-500 million cases of malaria annually and greater than 2 million deaths, most of which occur in children. Malaria remains an important cause of abortion, stillbirth, and neonatal death in many parts of the world. Congenital malaria cases in the United States occur almost exclusively in infants of foreign-born women who were exposed within the year before the infant's delivery.

Microbiology

Malaria is caused by an obligate, intracellular protozoan of the genus *Plasmodium*. Congenital malaria has been recorded with each species, including *Plasmodium vivax*, *Plasmodium malariae*, *Plasmodium ovale*, and *Plasmodium falciparum.* Most congenital cases have been caused by *P. vivax* and *P. falciparum*.

Pathology and Pathogenesis

Malaria is transmitted by the bite of infected female *Anopheles* mosquitoes or from transfusions (maternal–fetal, blood products, or contaminated needles) of infected blood. Anemia is the result of hemolysis. Parasites can be found in other organs of the body, including the intestinal tract, liver, spleen, lung, and brain. Because *P. falciparum* and *P. malariae* have no persistent exoerythrocytic phase, relapses do not occur. *P. vivax* and *P. ovale* are associated with relapses from dormant exoerythrocytic organisms. Transfusion-related malaria and congenital malaria have no exoerythrocytic phase.

The placenta is involved in most women who acquire malaria during pregnancy. It is unclear whether transmission to the infant is transplacental or from direct contact with maternal blood during labor or parturition. Most pregnancies resulting in congenital malaria are associated with a malaria attack during pregnancy; however, congenital infection has been described after uncomplicated asymptomatic pregnancies.

Host factors that can decrease the risk of malarial infections include abnormal hemoglobin and malaria-specific antibodies. Erythrocytes with fetal hemoglobin or hemoglobin S are less likely to become infected than erythrocytes with hemoglobin A. Women living in endemic areas are continuously exposed to malaria and develop antimalarial antibodies. Maternal antibody is believed to exhibit a protective effect for the fetus. One survey found that 7% of infants born to women evaluated at seven African sites had congenital malaria.

Clinical Manifestations

Most infants with congenital malaria have onset of symptoms by the eighth week of life, with an average age at onset of 10-28 days. Occasionally, onset has been documented at several months of age. The most common clinical findings are fever, anemia, and splenomegaly. Approximately one-third of infants have jaundice and direct or indirect hyperbilirubinemia. Hepatomegaly can be present. Nonspecific symptoms include irritability, failure to thrive, loose stools, and reluctance to feed. Congenital malaria often is complicated by bacterial illnesses in developing countries. In rare cases, malaria can be complicated by hypoglycemia, central nervous system infection, splenic rupture, renal failure, and, in *P. falciparum* infections, blackwater fever (severe hemolysis, hemoglobinuria, and renal failure). Untreated *P. falciparum* infection is associated with a high case-fatality rate.

Diagnosis

Although a maternal history of a febrile illness during pregnancy can be elicited in most cases, congenital disease after an asymptomatic pregnancy in women has been reported. The diagnosis of congenital malaria should be considered in any infant presenting with fever, anemia, and hepatosplenomegaly born to a mother who at any time resided in an endemic area. The diagnosis depends on demonstration of parasites in the bloodstream. Thin and thick smears should be prepared and examined on several different occasions to maximize the possibility of parasite detection.

Treatment

Several types of antimalarial drugs act at different stages of the *Plasmodium* life cycle. Tissue schizonticides such as primaquine are effective against exoerythrocytic forms, whereas blood schizonticides such as chloroquine, quinine, and quinidine act only on parasites in the erythrocytic phase. Because transfusion-acquired disease, including congenital infection, does not have an exoerythrocytic phase, primaquine is not required. Chloroquine, given in an initial dose of 10 mg of chloroquine base per kilogram of body weight administered orally, followed by doses of 5 mg base/kg at 6, 24, and 48 hours after the initial dose, is frequently used. For treatment of congenital disease caused by chloroquine-resistant *P. falciparum,* quinidine gluconate or the combination of quinine administered orally and clindamycin has been suggested. Mefloquine is effective against most *P. falciparum* strains but is not approved for use in infants. Experience with newer treatment options in young infants, such as artemisinin derivatives, is limited. Severe congenital malaria can require intensive care, and exchange transfusion can be necessary for high-grade parasitemia. Current recommendations regarding treatment of congenital malaria can be obtained from the malaria branch of the Centers for Disease Control and Prevention in Atlanta, Georgia.

Pneumocystis

Incidence

Pneumocystis pneumonia occurs in patients with congenital immune defects or hematologic malignancies or patients receiving immunosuppressive medications for organ transplantation. *Pneumocystis* is an unusual cause of pneumonia in the first year of life, but it can be observed as epidemic disease, first recognized during World War II and presumed to be related to malnutrition, and as sporadic disease associated with congenital immunodeficiency or AIDS. Some surveys suggest that rare cases can develop in healthy infants.

Microbiology

Because of difficulties in laboratory cultivation, the taxonomy of *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) is inconclusive; it has features in common with protozoan parasites and fungi. *Pneumocystis* is a unicellular organism

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

that can be found in three forms: a thick-walled cyst, a thin-walled trophozoite, and an intracystic sporozoite. Each cyst can contain up to eight sporozoites. Organisms can be detected on tissue samples stained with Grocott-Gomori methenamine silver nitrate.

Pathology and Pathogenesis

Serologic studies suggest that asymptomatic infection with *Pneumocystis* is widespread and commonly occurs in the first years of life. The organisms are believed to persist in a latent stage until impairment in host defense mechanisms permits their reactivation. Disease associated with *Pneumocystis* usually is limited to the lungs. There is now evidence that person-to-person transmission is the most likely mode of acquiring new infections. Airborne transmission from mother to infant has been proposed.

Postmortem examination reveals a diffuse process, with the posterior and dependent regions of the lung most significantly affected. Microscopic examination reveals an eosinophilic, foamy, honeycombed intra-alveolar exudate composed of cysts. In epidemic infantile disease, a plasma cellular infiltrate is observed (hence the name interstitial plasma cell pneumonia), whereas in sporadic disease associated with immunodeficiency or immunosuppression, there is hyperplasia of the cells lining the alveoli and minimal cellular infiltrate with a paucity of lymphocytes.

Clinical Manifestations

The clinical characteristics of sporadic *Pneumocystis* pneumonia are different from the characteristics observed in epidemic infantile disease. In sporadic cases associated with congenital or acquired immunodeficiency, there is an abrupt onset of high fever, coryza, nonproductive cough, and tachypnea. There is a quick progression to dyspnea and cyanosis. Radiographic findings most commonly reveal diffuse infiltrative disease. Concurrent infections, most commonly with cytomegalovirus, occur in more than 50% of immunocompromised infants with *Pneumocystis* pneumonia.

In epidemic infantile *Pneumocystis* pneumonia, a rare disease in developed countries, the onset is slow and insidious, with nonspecific symptoms such as anorexia, diarrhea, and restlessness. Cough is not prominent initially, and fever is absent. In the subsequent weeks, infants become tachypneic, cyanotic, and dyspneic, with sternal retractions and flaring of the nasal alae. Auscultatory findings are minimal, consisting of fine, crepitant rales on deep inspiration. The chest radiograph can be negative early in the course or can reveal a perihilar or diffuse haziness that progresses to a finely granular, interstitial pattern. Coalescent nodules can form in the periphery. Pneumothorax with interstitial and subcutaneous emphysema and pneumomediastinum can occur.

Diagnosis

Typical findings on radiographic studies can suggest *P. jiroveci* pneumonia but are not diagnostic. Demonstration of *Pneumocystis* cysts or extracystic trophozoite forms establishes the diagnosis. *P. jiroveci* can be detected in induced sputum or in tracheal or gastric aspirates, but the yield is low, and detection does not imply disease. Bronchoalveolar lavage or open lung biopsy can yield the organism. Serologic tests are not useful.

Treatment

Trimethoprim-sulfamethoxazole is the drug of choice for treatment of *P. jiroveci* pneumonia in infants. It must be used with caution in young infants because of its potential for displacement of bilirubin from albumin-binding sites. The therapeutic dose is 15-20 mg/kg per day of the trimethoprim component in divided doses every 6-8 hours. The intravenous route of administration is preferable in infants with moderate or severe disease. Treatment is usually continued for 3 weeks. In infants who do not respond to trimethoprim-sulfamethoxazole or in whom adverse reactions develop, pentamidine isethionate, 4 mg/kg given parenterally as a single daily dose for 14 days, can be used.

Although radiographic improvement can take several weeks, clinical improvement is usually seen within 4-6 days after beginning therapy. Local reactions at the injection site, tachycardia, hypotension, pruritus, hypoglycemia, and nephrotoxicity have been associated with pentamidine administration. Trimethoprim-sulfamethoxazole is the standard for prophylaxis against *Pneumocystis* pneumonia and has been used for that purpose in infants 2 months old and older with HIV infection.

Toxoplasmosis

Incidence

Among 22,845 pregnant women analyzed by the Collaborative Perinatal Research Study in the United States, 38% had *Toxoplasma* IgG antibodies, reflecting past infection, and the incidence of acute maternal infection during pregnancy was estimated to be 1.1 per 1000 women. A higher incidence is seen in women born in Cambodia or Laos. In the United States, 1-3 infants per 1000 live births have *Toxoplasma*-specific IgM antibody. Worldwide, 3-8 infants per 1000 live births are infected in utero. An estimated 400-4000 cases of congenital toxoplasmosis occur in the United States each year.

Microbiology

Toxoplasmosis is caused by *Toxoplasma gondii,* an obligate intracellular protozoan parasite. This ubiquitous organism exists in three forms: an oocyst excreted by infected cats that produces sporozoites, a proliferative form (trophozoite or tachyzoite), and a cyst (cystozoite) found in tissues of infected animals. *Toxoplasma* can be propagated in tissue cell cultures or by animal inoculation in research laboratories.

Transmission and Pathogenesis

The cat is the only definitive host, but other mammals can be infected incidentally. Farm animals (cattle, pigs, sheep) can acquire infection after ingestion of food or water

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

contaminated with infected cat feces that contain oocysts. Humans can acquire infection by ingestion of raw or poorly cooked meat containing the *Toxoplasma* cysts or by ingestion of food or water contaminated with oocysts. Risk factors include any exposure to cat feces, such as changing cat litter boxes, playing in sandboxes, or gardening in areas used by cats.

Congenital toxoplasmosis occurs almost exclusively as a result of primary maternal infection during pregnancy. Rarely, reactivation of infection in immunocompromised women during pregnancy can result in congenital toxoplasmosis. Most maternal infections are asymptomatic or result in mild illnesses. Fatigue and lymphadenopathy involving only a single posterior cervical node or generalized lymphadenopathy may be the only manifestation. Less commonly, acute maternal infection can manifest as an infectious mononucleosis-like syndrome with fever, nonsuppurative lymphadenopathy, headache, fatigue, sore throat, and myalgias. The general risk of transmission of acute infection from mother to fetus is estimated to be 40%; however, the actual risk and the severity of congenital infection vary with gestational age. The risk of transmission increases with increasing gestational age, but the earlier during pregnancy that fetal infection is acquired, the more severe the manifestations of congenital disease.

Clinical Manifestations

The classic clinical presentation of congenital toxoplasmosis is the triad of hydrocephalus, chorioretinitis, and intracranial calcifications, but there is a wide spectrum of manifestations, and more than 75% of infected newborns are asymptomatic in early infancy. As described by McAuley and colleagues, the four most common presentations include (1) a healthy-appearing term infant with subclinical infection in whom symptoms develop later in childhood, (2) a healthy-appearing term infant in whom clinical evidence of disease develops in the first few months of life, (3) an infant with generalized disease at birth, and (4) an infant with predominantly neurologic involvement at birth.

Many infants with subclinical infection who were believed to be normal at birth have evidence of infection on closer evaluation, including CSF abnormalities such as lymphocytic pleocytosis, hypoglycorrhachia, and elevated protein concentrations. Continued parasite proliferation may actually occur in the fetal brain despite maternal immunologic control in other tissues.

If the disease goes unrecognized and untreated, these infants can present with chorioretinitis, late-onset seizures, mental retardation, developmental delay, and hearing loss later in infancy or childhood. The second group of healthy-appearing, infected infants present with hydrocephalus and chorioretinitis in the first few months of life. Manifestations of generalized infection at birth include prematurity and intrauterine growth restriction, jaundice, hepatosplenomegaly, pneumonitis, temperature instability, lymphadenopathy, and cutaneous lesions (e.g., exfoliative dermatitis, petechiae, ecchymoses, and maculopapular lesions). Other signs of generalized infection include myocarditis; nephrotic syndrome; and gastrointestinal symptoms, such as vomiting, diarrhea, or feeding difficulties. The fourth group of infected infants has predominantly neurologic disease but can have systemic manifestations as well. Subtle neurologic deficits, obstructive hydrocephalus, or acute encephalopathy can be seen. Unilateral or bilateral macular chorioretinitis frequently occurs, and infants often have rash, hepatosplenomegaly, thrombocytopenia, granulocytopenia, and typical CSF findings.

Diagnosis

Maternal infection occurring during gestation can lead to fetal infection. Most infants with congenital toxoplasmosis have normal results on physical examination at birth. Visual and neurologic impairment results when the infection is not diagnosed and adequately treated. Generally, all suspected maternal, fetal, and neonatal infections should have confirmatory diagnostic testing performed in an experienced reference laboratory. Screening for IgG antibody in pregnancy is usually performed by indirect fluorescent antibody test or enzyme-linked immunosorbent assay and confirmed by the Sabin-Feldman dye test. Several tests are available to determine the duration of maternal infection when IgG and IgM antibodies are positive. Fetal infection is best determined using amniotic fluid polymerase chain reaction amplification of the *Toxoplasma* gene *B1*.

Infection of an infant is best established definitively by intraperitoneal inoculation of placental tissue into laboratory mice, yielding cultivation of *Toxoplasma* organisms. When this is not feasible, strong evidence for the diagnosis is provided by the presence of *Toxoplasma*-specific IgM, IgA, or IgE antibody. Infants with suspected toxoplasmosis should undergo MRI, evaluation of CSF, and indirect ophthalmologic examination.

Treatment

Pyrimethamine combined with sulfadiazine and supplemented with folinic acid is recommended for treatment of symptomatic and asymptomatic congenital infection. Therapy is continued for 1 year. Consultation with appropriate specialists should be sought when treating congenital toxoplasmosis.

Prognosis

A comprehensive maternal–fetal and infant strategy is needed to improve the outcomes of congenital toxoplasma infection. French experiences show that adoption of a scheduled, monthly prenatal screening strategy decreases the transmission rate and improves the clinical outcome at the age of 3 years in the offspring.

McLeod and colleagues published the results of the national collaborative Chicago-based treatment trial for 120 infants with congenital toxoplasmosis.[75] The duration of follow-up was a mean of 10.5 ± 4.8 years. A normal outcome was documented for 100% of infants treated with pyrimethamine and sulfadiazine for 1 year when there was

no evidence of substantial neurologic disease at birth. Cognitive, neurologic, and auditory outcomes all were normal for these children. Normal neurologic or cognitive outcomes were also observed in greater than 72% of infants who did have moderate or severe neurologic disease at birth. None had sensorineural hearing loss, and most children in each group did not develop new eye lesions. These outcomes in patients treated for 1 year were markedly better than the outcomes in earlier years for infants who were untreated and infants who received only a 1-month course of therapy. There is a low but significant risk of late ocular manifestation because up to 12.6% of patients may develop ocular lesions during follow-up, mostly peripheral, with a first ocular lesion possibly occurring as late as 12 years after birth. Vaccine development to prevent feline oocyst shedding is ongoing, mostly with live vaccines.

The Society of Obstetricians and Gynecologists has developed an excellent clinical practice guideline that is available online at http://sogc.org/wp-content/uploads/2013/02/gui285CPG1301E-Toxoplasmosis.pdf (accessed December 21, 2017).

Acknowledgment

The author and editors acknowledge the important contribution of Morven S. Edwards to previous editions of this chapter, portions of which remain unchanged.

Key Points

- *Candida* pathogenesis involves exposure, adherence, and colonization, followed by infection/dissemination.
- The prevention bundle of "antifungal prophylaxis, antibiotic stewardship of broad spectrum antibiotics, and CLABSI prevention measures" has contributed to lowering invasive *Candida* infections in high-risk patients.
- The highest risk patients are infants <1000 grams where infection is associated with high mortality and neurodevelopmental impairment.
- Starting appropriate dosing, adding antifungals to empiric therapy in high-risk patients, and prompt central venous catheter removal improve infection-related outcomes of survival and development.
- Cutaneous candidiasis is an invasive infection needing prompt recognition, evaluation, and systemic treatment for 14 days.
- Future prevention may involve lactoferrin, probiotics, and broader antenatal screening and treatment.

Viral Infections in the Neonate

JILL E. BALEY AND BLANCA E. GONZALEZ

Certain viruses seem to have a predilection for the fetus and may cause abortion, stillbirth, intrauterine infection, congenital malformations, acute disease during the neonatal period, or chronic infection with subtle manifestations that may be recognized only after a prolonged period. It is important to recognize the manifestations of viral infections in the neonatal period not only to diagnose the acute infection but also to anticipate the potential abnormal growth and development of the infant.

Herpesvirus Family

The herpesvirus family consists of numerous closely related viruses. They all have a DNA core and are enveloped in an icosahedral (20-sided) nucleocapsid. Eight viruses in the family infect infants: herpes simplex virus (HSV) types 1 and 2; cytomegalovirus (CMV); varicella-zoster virus (VZV); Epstein-Barr virus (EBV); and human herpesviruses (HHV) 6, 7, and 8. These viruses are also characterized by the development of latent states after the primary infection.

Herpes Simplex Virus

Neonatal HSV infections are being diagnosed with increasing frequency, at a rate of 1 in every 3200 live births per year in the United States, resulting in an estimated 1500 new cases per year. The primary source of HSV infection for neonates is acquisition of the virus during delivery, and yet infected genital tract secretions in women are more common compared with neonatal infections. In addition, in numerous countries, neonatal infection is less common than in the United States despite the high prevalence of genital infections, suggesting other unknown means of protection to the neonate.

HSVs are a group of large double-stranded DNA viruses within an icosahedral nucleocapsid and a lipid envelope. There is considerable cross-reactivity between the two serotypes, HSV-1 and HSV-2. Glycoprotein G is responsible for the antigenic specificity between them, as shown by the antibody response. The seroprevalence of HSV in the United States has continued to increase for HSV-1 and HSV-2. HSV-1 is now responsible for 50% of neonatal infections, probably resulting from its increased seroprevalence and its increased maternal-to-neonatal transmission during reactivation of genital infection. Maternal HSV-2 infections recur more commonly than HSV-1, and there is more viral shedding in HSV-2 than in HSV-1 with recurrences, but the antibody to HSV-2 is more protective. The virus enters via breaks in the skin and mucous membranes, attaches to the epithelial cells, and begins to replicate. The virus is transported by retrograde axonal flow from the sensory nerve endings in the dermis to the sensory ganglia, where at least some portion of the viral DNA persists for the lifetime of the individual. HSV-1 usually persists in the trigeminal ganglion, whereas genital herpes persists in the sacral dorsal root ganglia or other local sensory ganglia.

Fever, ultraviolet light, stress, and many undetermined sources may cause the virus to reactivate, at which time the virus is transported antegrade down the sensory nerve axon to the skin or the mucous membrane, where it again results in either symptomatic or asymptomatic disease. Either way, the virus is infectious. Analyses of viral DNA from individuals with recurrent lesions indicate that the identical virus is virtually always responsible. Superinfection with a different viral strain is uncommon. Infection is not seasonal, and humans are the only known carriers of the infection.

HSV infections are labeled as first-episode, primary infections when the individual who has neither HSV-1 nor HSV-2 antibody (indicating prior infection) acquires either HSV-1 or HSV-2 in the genital tract. A first-episode, nonprimary infection occurs when an individual who already has HSV-1 antibody acquires HSV-2 genital infection, or vice versa. Recurrent infections occur with reactivation of latent infections.[123]

Epidemiology and Transmission

Labial and oropharyngeal infections are predominantly caused by HSV-1 and may be transmitted by respiratory droplet spread or direct contact with infected secretions or vesicular fluid. Most HSV-1 infections occur in childhood and are usually asymptomatic, sometimes causing gingivostomatitis or mononucleosis-like syndrome. Girls have a higher seroprevalence compared with boys. Black children have a 35% seroprevalence by age 5 years compared with 18% in white children, and the seroprevalence remains

Abstract

Although many viruses are well known, many new viruses are being discovered which may have devastating effects on the fetus and newborn. Most therapeutic measures are of little efficacy so prevention is of prime importance. Congenital CMV remains the largest source of non-genetic hearing loss and developmental disorders in children, and yet therapy is of little efficacy and there is no vaccine. Mother-to-child transmission of HIV, the most common source of infection in infants and children, may be nearly eliminated with antenatal testing, Caesarian delivery, antiretroviral therapy during pregnancy and prohibition of breast feeding. Polio, measles, mumps, rubella, varicella and hepatitis B may largely be prevented. However, apart from palivizumab, there are few therapies or preventive measures for respiratory viruses. Acyclovir can be used to treat HSV but there remain no vaccines.

twice as high through the teen years but is equivalent by age 60 years.[123]

Because genital infections are usually transmitted by direct sexual contact with HSV-2, transmission most often occurs during or after adolescence. Most genital herpes infections are asymptomatic, but symptomatic and asymptomatic individuals may transmit infection. Primary genital infection may cause localized pain and burning of the labia and vaginal mucosa 2-14 days after contact. After a period of paresthesia, vesicles full of seropurulent fluid develop. These vesicles break down easily, forming shallow ulcers and releasing numerous infectious virus particles. There is often copious watery vaginal discharge, edema, dysuria, and bilateral pelvic and inguinal lymphadenopathy, accompanied by systemic symptoms of fever, malaise, and headache. Healing may occur several weeks later. Many primary genital infections, however, are asymptomatic. Children may infect themselves genitally by autoinoculation from an oral HSV-1 infection, but sexual abuse should always be considered.

Seroprevalence rates among pregnant women have indicated that at least 30% of women have serologic evidence of infection with HSV-2, but most of these women lack a history or symptoms of infection. Not only was this seroprevalence largely unsuspected among these pregnant women, but asymptomatic viral shedding also occurred among them at a rate (roughly 1% viral shedding at any time in pregnancy) similar to that in women with symptomatic recurrences. Seroprevalence increases dramatically as the number of sexual partners increases. Recurrence is higher among women with genital HSV-2 infection than among women with HSV-1, probably because HSV-2 is more likely than HSV-1 to establish latency in the inguinal dorsal root ganglia. When viral replication is not medically suppressed, there are four HSV-2 recurrences, on average, in the first year after a primary infection. HSV-1 recurs about once a year. Finally, for 70% of all women whose infants develop HSV infection, there is no history of infection or symptoms or of intercourse with a partner who has had the infection.

About 10% of HSV-2 seronegative women have HSV-2 seropositive partners. These women may remain uninfected with HSV-2 over prolonged periods despite continued, unprotected contact with a partner who is HSV-2 seropositive. Because the seroconversion rate is 20% per year for these women and most genital HSV-2 infections are asymptomatic, these women are at high risk of an unsuspected, primary HSV-2 genital infection during pregnancy.[123] Seroconversion rates are similar among pregnant and nonpregnant women. It is estimated that about one third of women who asymptomatically shed HSV during labor have been recently infected and that their infants have a 10-fold or greater risk of being infected than the infants of mothers with recurrent disease.

Women who are seronegative for HSV-1 and HSV-2 and have HSV-1–seropositive partners may acquire HSV-1 genital infection through oral sex. Oral sex has become more popular among teens because they believe it is safer sex. Overall, a woman who is seronegative for HSV-1 and HSV-2 with a discordant partner has a 3.7% chance of acquiring infection with either virus during pregnancy, and a woman who is seropositive for HSV-1 and seronegative for HSV-2 with an HSV-2–seropositive partner acquires HSV-2 infection in 1.7% of pregnancies.[123]

Transmission from mother to infant may occur via many different routes, including transplacental, intrapartum, and postnatal transmission. Transplacental transmission (5%), which is responsible for in utero infection, is inferred by the documentation of HSV skin lesions and viremia at birth and by elevated specific cord immunoglobulin M (IgM) levels. Primary and recurrent maternal infections have been associated with congenital infection.

Intrapartum transmission is responsible for 85% of neonatal infections. The actual transmission is influenced by the type of maternal infection. A high titer of viral particles ($>10^6$/0.2 mL inoculum) is excreted for about 3 weeks with a primary maternal infection, which is more likely to involve cervical shedding than a recurrent maternal infection, in which 10^2 to 10^3 viral particles per 0.2 mL inoculum are shed for only 2-5 days. Maternal neutralizing antibodies may also be partially protective for a newborn in recurrent infections and may not yet be present (and available to cross the placenta) in a primary maternal infection. In a 20-year trial, 0.3% of women were found to be shedding either HSV-1 or HSV-2 asymptomatically at delivery. Neonatal disease resulted in 57% of first-episode primary maternal infections (defined as HSV-1 or HSV-2 isolated from genital secretions without having concurrent HSV antibodies), 25% of first episode nonprimary maternal infections (defined as HSV-2 isolated from genital secretions of a woman with only HSV-1 antibodies, or HSV-1 isolated from a woman with only HSV-2 antibodies), and 2% of recurrent maternal infections (present when the virus isolated from genital secretions was the same type as antibodies present in the serum at the time of labor).[34]

Because recurrent infections are so much more common, half of all neonatal HSV-2 infections occur secondary to recurrent maternal infection, even though transmission from mother to infant occurs in only 2% of the cases. The amount of neutralizing antibody also affects the severity of neonatal disease. Infants who do not receive much transplacental transfer of antibody are more likely to develop disseminated disease. Prolonged rupture of membranes (>4-6 hours) also increases the risk of viral transmission, presumably from ascending infection. Delivery via cesarean section, preferably before rupture of membranes, but at least before 4-6 hours of rupture, can reduce the risk sevenfold.[34]

Neonatal infection does still occur, however, even with cesarean delivery. Fetal scalp electrodes may accelerate transcervical infection and breach the infant's skin barrier, also increasing risk of infection. It was shown more recently that vacuum extraction may cause scalp lacerations resulting in HSV skin lesions at the site of application. The relative risk of vacuum extraction resulting in HSV infection was nearly 7.5 times that of spontaneous vaginal or cesarean delivery.

Antenatal maternal viral culture screening for HSV shedding is of no predictive value in determining who will be shedding virus at delivery.

Finally, transmission may occur postnatally (10%). Restriction enzyme DNA analysis has been used to document postnatal acquisition of HSV and its spread within a nursery by identifying infection with the same herpes strain in infants of different mothers. The father and the mother, as well as maternal breast lesions, have been implicated in neonatal infections. There is also concern regarding symptomatic and asymptomatic shedding among hospital personnel, one third of whom may have a history of HSV-1 lesions and 1% of whom still have recurrent labial lesions. Individuals with a herpetic whitlow should be removed from the nursery. Removal of health care workers with other lesions would pose significant risk to neonates because it would cause significant disruption of care. Orolabial lesions should be covered with a mask, and skin lesions should be covered with clothing or a bandage. Workers should be counseled on good hand hygiene and to not touch a lesion.

Congenital Herpes Simplex Virus Infection

Congenital infection was found in 5% of the infants in the National Institute of Allergy and Infectious Disease (NIAID) Collaborative Antiviral Study Cohort.[283] These infants with growth restriction characteristically have skin lesions, vesicles and scarring, neurologic damage (intracranial calcifications, microcephaly, hypertonicity, and seizures), and eye involvement (microphthalmia, cataracts, chorioretinitis, blindness, and retinal dysplasia). Congenital infections are described throughout pregnancy and after primary and recurrent infections but are most likely with a primary infection or if the mother has disseminated infection and is in the first 20 weeks of pregnancy. Most cases are caused by HSV-2. The manifestations probably result from destruction of normally formed organs rather than from defects in organogenesis because the lesions are similar to lesions of neonatal herpes. A few children have isolated skin lesions, usually in association with prolonged rupture of membranes, and these lesions may be more amenable to antiviral therapy.

Neonatal Herpes Simplex Virus Infection

Although asymptomatic HSV infections are common in adults, they are exceedingly rare in neonates. Of all neonatal infections, 50% are caused by HSV-1 rather than HSV-2. Half of the infants are born prematurely, usually between 30 and 37 weeks of gestation, and many have complications of prematurity, particularly respiratory distress syndrome. Two thirds of term newborns have a normal neonatal course and are discharged before the onset of disease. They may also have simultaneous bacterial infections. One fourth of the infants have symptoms on the first day of life and two thirds by the end of the first week.

Clinically, neonatal infections are classified as (1) disseminated, involving multiple organs, with or without central nervous system (CNS) involvement; (2) encephalitis, with or without skin, eye, or mouth involvement; and (3) localized to the skin, eyes, or mouth. Approximately 25% of cases are disseminated; 30% have CNS involvement; and 45% are localized to the skin, eyes, or mouth.

Among the 202 infants with HSV infections followed up in the NIAID Collaborative Antiviral Study Group, mortality was significantly greater with disseminated infection (57%) than with encephalitis (15%) and did not occur with disease limited to the skin, eyes, or mouth.[283] The relative risk of death was 5.2 for infants in or near coma at onset of treatment, 3.8 for those with disseminated intravascular coagulopathy, and 3.7 for premature infants.[281] Among infants with disseminated disease, mortality was higher among those with pneumonitis. Sequelae among survivors were more common with encephalitis or disseminated infection, particularly with HSV-2 infection, or in the presence of seizures but also were more likely in infants with SEM infection who had three or more recurrences of vesicles within 6 months.[281] Sequelae were found in 75% of survivors with HSV-2 and in only 27% of survivors with HSV-1 infection, and this may be related to the in vitro susceptibility of HSV-1 to acyclovir.[282]

Disseminated Infection

Infants with disseminated infections have the worst prognosis. Disseminated infections may involve virtually every organ system, but predominantly involve the liver, adrenal glands, and lungs. Infants usually present by 10-12 days of life with signs of bacterial sepsis or shock but often have unrecognized symptoms several days earlier. Although the presence of cutaneous vesicles is helpful in diagnosis, 20% of infants never develop vesicles. Disseminated intravascular coagulation (DIC) with decreased platelets and with petechiae and purpura are common, and bleeding often occurs in the gastrointestinal tract. Pneumatosis intestinalis may also be present. Hepatomegaly or hepatitis, or both, is usually present, with or without jaundice. Respiratory distress, often with pneumonitis or pleural effusion seen on the chest radiograph, has a poorer prognosis.

Many infants die before manifesting symptoms of CNS involvement, which is common (60%-80%). These infants may present with irritability, apnea, a bulging fontanel, focal or generalized seizures, opisthotonos, posturing, or coma. Cerebrospinal fluid (CSF) may be normal or may show evidence of hemorrhage. Virus can be isolated from CSF of only one third of infants with CNS symptoms. The routine use of polymerase chain reaction (PCR) on CSF has aided considerably in recognition of the disease. Death usually occurs at about age 2 weeks, roughly 1 week from the onset of symptoms, and often involves respiratory failure, liver failure, and DIC with shock.

Encephalitis

Encephalitis may occur as a component of disseminated disease, via blood-borne seeding of the brain, resulting in multiple lesions of cortical hemorrhagic necrosis often in

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

association with oral, eye, or skin lesions, at 16-19 days of life. Brain involvement results from neuronal transmission of the virus. Regardless of the source of neurologic infection, only about 60% of infants have skin vesicles, and less than half have virus isolated from CSF. Although CSF is occasionally normal, it usually shows mild pleocytosis, with predominance of mononuclear cells, elevated protein concentration, and normal glucose concentration. Infections that are discovered late may have significant numbers of erythrocytes in CSF. Lethargy, poor feeding, irritability, and localized or generalized seizures may be the presenting manifestations. Nearly all electroencephalograms show nonspecific abnormalities.

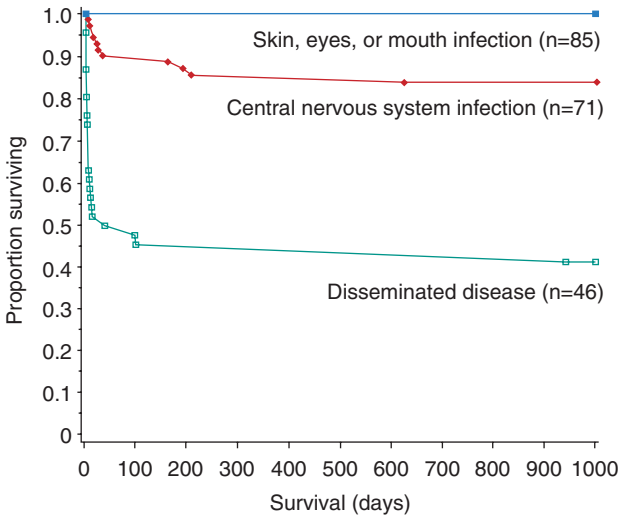
In 12 infants with HSV-2 encephalitis, diffusion-weighted magnetic resonance imaging (MRI) showed extensive, often bilateral changes that were not visible on computed tomography (CT) or conventional MRI in eight infants. Disease was found in the temporal lobes, cerebellum, brainstem, and deep gray nuclei. Hemorrhage and watershed distribution ischemic injury were also seen. These areas progressed to cystic changes on follow-up imaging.[271] Nearly half of untreated children die from neurologic deterioration 6 months after onset, and virtually all survivors have severe sequelae (microcephaly and blindness or cataracts).

Fever is a known symptom of HSV infection and is a common reason for an infant in the first month of life to be taken to the emergency department. The American Academy of Pediatrics (AAP) Committee on Infectious Diseases recommends considering HSV infection in neonates with fever, irritability, and abnormal CSF findings, especially in the presence of seizures. In a study of nearly 6000 infants with laboratory-confirmed viral or serious bacterial infections admitted from the emergency department, only 30% of the infants with HSV infections were febrile; 50% were fever free, and 20% were hypothermic. Of the febrile infants with CSF pleocytosis, bacterial meningitis (1.3%) was more common than HSV infection (0.3%), but not statistically so. Similarly, febrile infants with mononuclear CSF pleocytosis were not statistically more likely to have HSV infections (1.6%) than bacterial meningitis (0.8%), and 1.1% of hypothermic infants presenting with a sepsis-like syndrome had HSV infection.[40] In all of these infants, HSV infection should be considered when they present in the first month of life, especially if they fail to improve on antibiotics and bacterial cultures remain negative for the first 24-48 hours.

Skin, Eye, and Mouth Infections

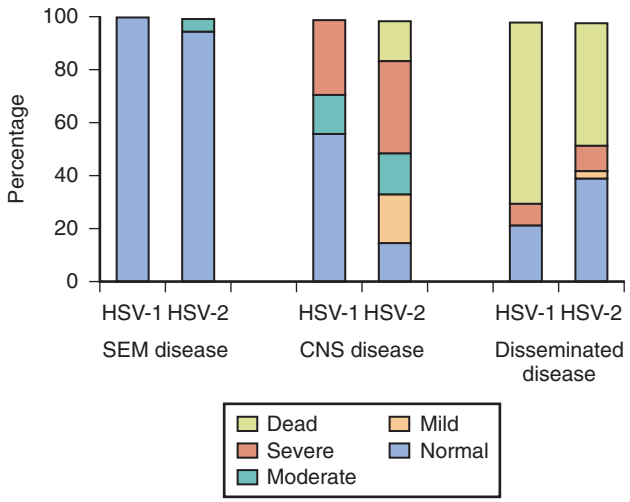
Infants with disease localized to the skin, eyes, or mouth usually present by 10-11 days of life. Greater than 90% of these infants have skin vesicles, usually over the presenting part at birth and appearing in clusters. Recurrences are common for at least 6 months. Infants at risk should be monitored for localized infections (vesicles) of the oropharynx. Either HSV-1 or HSV-2 can cause keratoconjunctivitis, chorioretinitis, microphthalmos, and retinal dysplasia, later possibly leading to cataracts. One third of these infants later develop neurologic sequelae indicative of undiagnosed neurologic involvement.

Diagnosis



Isolation of virus is definitive diagnostically. Cultures of the newborn (scrapings of mucocutaneous lesions, CSF, stool, urine, nasopharynx, and conjunctivae) should be delayed to 24-48 hours after birth to differentiate viral replication in the newborn from transient colonization of the newborn at birth. The specimens for culture may be combined to save money because it is not important where the virus is located, but whether the virus is present, with the exception of CSF specimens, which are needed to determine CNS involvement.[123] If the culture shows cytopathic effects, typing should be done. Serologic testing is not useful in neonatal disease because transplacentally transferred maternal antibody confounds the interpretation, but finding low-avidity HSV-2 IgG in the maternal serum near term does indicate an elevated risk of neonatal disease. PCR testing has become invaluable, especially for CSF, which has a very low recovery rate for HSV cultures. PCR can also be used to test blood, scrapings of lesions, the conjunctiva, or the nasopharynx. However, PCR has detected HSV DNA in the amniotic fluid of women with symptomatic infection, and yet the infants were uninfected and healthy.[7] In addition, all three forms of neonatal disease (disseminated, CNS, and skin, eyes, and mouth [SEM] disease) may have viremia, so blood PCR should not solely be relied upon to determine extent of disease, and blood PCR should not be used to monitor response to therapy.

Therapy



Vidarabine was the first antiviral agent used to treat HSV and was efficacious despite its toxicity. Acyclovir, a deoxyguanosine analogue, is preferentially taken up by virus-infected cells and phosphorylated by thymidine kinase, which is encoded in the virus. Host cell enzymes then effect di- and triphosphorylation. Acyclovir triphosphate prevents DNA polymerase and is a chain terminator, preventing viral DNA synthesis. Acyclovir is the only drug recommended for use in neonates. When a low-dose acyclovir (30 mg/kg/day in three divided doses) was compared with vidarabine, the morbidity and mortality were equivalent, but the ease of acyclovir administration and decreased toxicity resulted in it readily supplanting vidarabine in use. High-dose intravenous (IV) acyclovir (60 mg/kg/day in three divided doses) was then compared with low-dose acyclovir for a longer treatment duration (21 days for disseminated or CNS disease and 14 days for disease localized to the skin, eyes, or mouth). High-dose acyclovir resulted in a much improved survival rate: Infants with disseminated infection had an odds ratio of survival of 3.3, and infants with CNS disease had a similar survival. The likelihood of developmentally normal survival had an odds ratio of 6.6 compared with infants treated with the lower dose.[127,128]

Infants with an abnormal creatinine clearance need to have the acyclovir dose adjusted, and all infants need to be

• **Fig. 50.1** Survival of infants with neonatal herpes simplex virus infection, according to the extent of disease. More recent data show improved survival. (From Whitley R, et al. Predictors of morbidity and mortality in neonates with herpes simplex virus infections. The National Institute of Allergy and Infectious Diseases Collaborative Antiviral Study Group. *N Engl J Med*. 1991;324:450.)

• **Fig. 50.2** Morbidity and mortality among patients after 12 months of age by viral type, 1981-1997. CNS, Central nervous system; HSV, herpes simplex virus; SEM, skin, eyes, or mouth. (From Kimberlin DW, et al. Safety and efficacy of high-dose intravenous acyclovir in the management of neonatal herpes simplex virus infections. *Pediatrics* 2001;108:223.)

monitored for neutropenia. All neonates should have ophthalmologic and MRI examinations. CT and ultrasonography may be used alternatively but are not as sensitive to abnormalities. Infants with CNS disease need to have a repeat lumbar puncture at the end of the course of treatment. Treatment should be continued until CSF is PCR negative. Infants who continue to have detectable HSV DNA in CSF by PCR at the end of therapy are more likely to die or have moderate to severe impairment. Poor prognostic indicators are lethargy and severe hepatitis in disseminated disease, and prematurity and seizures in CNS disease.[127,128]

Mortality has been tremendously decreased with high-dose acyclovir and is now 29% for disseminated disease; 4% for CNS disease; and 0% for SEM disease.[127,128] Although the percentage of survivors with normal development (31%) has not changed for CNS disease, normal development among survivors of disseminated disease is now 83%, and for SEM disease is greater than 98% (Figs. 50.1 and 50.2).[127,128] Neonates with SEM disease with neurodevelopmental abnormalities on follow-up may represent undetected CNS disease, adverse effects of inflammation secondary to disease, or seeding from recurrent skin lesions. In a study of 77 neonates with culture-proven HSV disease, CSF PCR detected HSV DNA in 7 of 29 infants who had been classified as having SEM disease, 13 of 14 classified as having disseminated disease, and 26 of 34 who had been classified as having CNS disease. HSV DNA remains in CSF for an average of 10 days after the onset of CNS disease.[126] It has also been shown that infants with fewer than 100 copies of HSV DNA per microliter of CSF after 4 days of treatment had improved survival and neurologic outcome.[68] To improve outcome, earlier recognition and treatment of infection are needed. Initiation of therapy in the high-dose acyclovir trial usually began 4-5 days after onset of symptoms, which is no better than that in the low-dose trial.[127] Topical ophthalmic antiviral drugs should be given to infants with ocular involvement in addition to parenteral therapy. This may include 1% trifluridine, 0.1% iododeoxyuridine, or 3% ganciclovir. All other therapy is supportive. Early data indicate that quantitative PCR for HSV DNA in blood may be useful in determining outcome and treatment, but there are not enough data to recommend this currently. Infants with disseminated disease have higher viral loads compared with infants with CNS disease and infants with SEM disease.[132] The viral load is also higher in those infants who die than in those who survive with neurologic disease or those who survive without neurologic disease.

Oral suppressive acyclovir therapy for 6 months after completion of treatment has been used to decrease recurrences in infants,[122] which occurred in 50% of infants within 1-2 weeks of stopping the initial acyclovir course. There is a significant reduction in the recurrence of skin lesions in infants with any of the three disease classifications and improved neurodevelopmental outcomes with CNS HSV disease.[27,130,235] Infants are treated with three doses per day at 300 mg/m^2/dose, and the neutrophil counts need to be checked at 2 and 4 weeks and then monthly during therapy.

Resistance to acyclovir is a concern and has been seen in mothers who have had multiple recurrences treated with suppressive acyclovir, mothers who have taken oral acyclovir for suppression in the later part of pregnancy, and even in a few infants on suppressive therapy for the 6 months after the end of treatment.

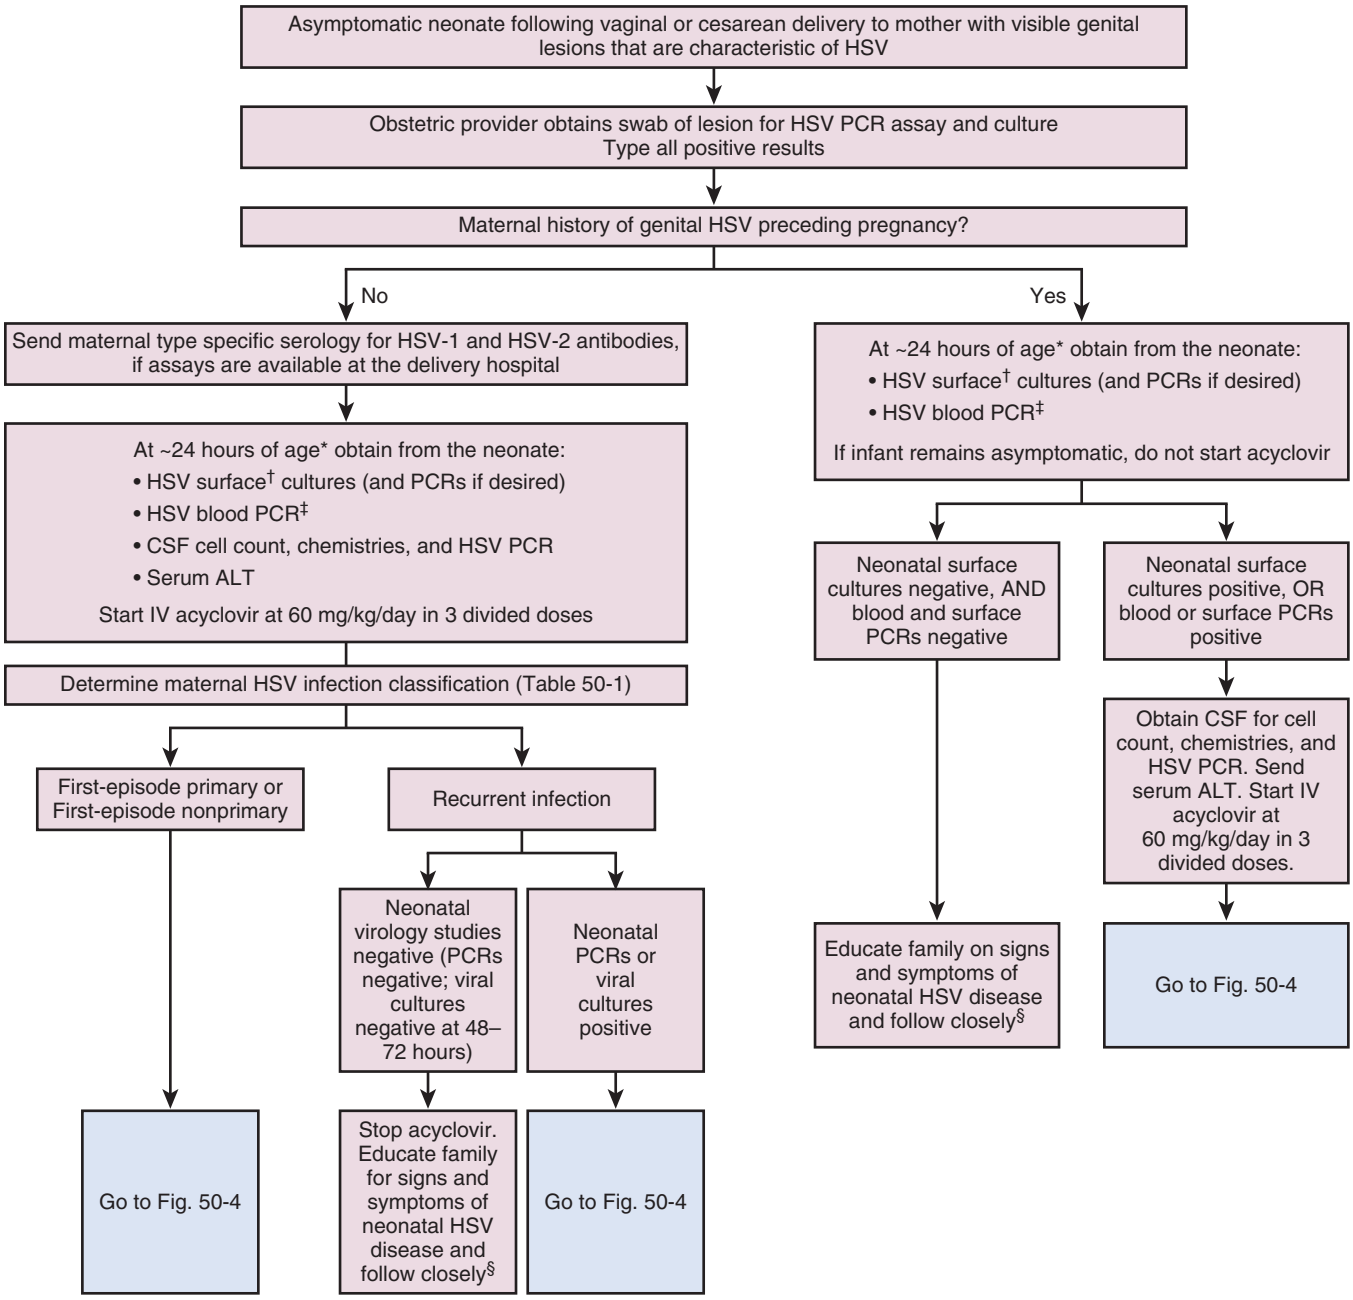
Prevention

In 1999, the American College of Obstetrics and Gynecology recommended that cesarean delivery be performed if a mother has HSV genital lesions or prodromal symptoms at the time of delivery. Seventy percent of mothers of infants with neonatal disease do not have a history or symptoms of HSV infection, however, and their partners do not have a history of HSV infection, and neonatal infection may still occur even if a cesarean delivery is performed. Repetitive cervical cultures do not predict whether a mother will be shedding virus at delivery. Mothers should be counseled regarding the signs and symptoms of disease, and some may then recognize infection. If rupture of membranes has been present longer than 6 hours, some experts still recommend cesarean delivery in the face of genital lesions, but data are lacking, and controversy exists. Scalp electrodes should be avoided. There is also no consensus about treatment when a mother has genital lesions and ruptured membranes, except in the case of a very immature fetus.

If an infant is delivered vaginally to a mother with recurrent genital lesions (5% risk of infection), most experts do not recommend treating the infant. The infant does not need contact precautions. Cultures and PCR of the neonate should be obtained at 24 hours of life, and the infant should be observed carefully. Circumcision should be delayed until cultures are known to be negative. Hand washing should be emphasized. The infant should be managed with contact precautions. If the mother has an active herpes labialis or stomatitis, she should wear a disposable surgical mask while handling her infant until the lesions have crusted and dried. She should not kiss the infant. Breastfeeding may be allowed if there are no lesions on the breast. The mother needs to be taught the signs and symptoms of neonatal disease because culture does not always detect neonatal disease.

Whenever a mother has active genital lesions at the time of delivery, and she has no history of prior herpetic infection, both herpes culture and PCR need to be performed, regardless of whether the birth is via cesarean section or vaginal delivery (Figs. 50.3 and 50.4).[131] Type-specific serology can be used to determine if this is a recurrent infection or is a first episode infection (Table 50.1). Because the risk of infection to the newborn is greater than 50% in a primary, first-episode infection and 25% in a nonprimary, first-episode infection in the mother, these infants should have surface cultures and blood and surface PCR for HSV, serum alanine aminotransferase (ALT) and CSF cell count, chemistries, and PCR for HSV performed at 24 hours of life, and earlier if the baby is ill or premature or there was prolonged rupture of membranes. Acyclovir should be started after the evaluation. If it is a recurrent infection, the acyclovir may be discontinued after a negative evaluation. Empiric acyclovir treatment should be considered for 10 days for any first-episode infection, whether primary or nonprimary, even if the baby's evaluation is negative. If a CSF infection is suspected, treatment should be continued for 21 days, after which a repeat CSF PCR needs to be sent. Acyclovir should be given for another 7 days whenever the PCR is positive for HSV.



There is also considerable controversy concerning the prevention of a primary HSV genital infection in a seronegative pregnant woman. Some authorities advocate for type-specific serologic screening for HSV in all pregnant women, arguing that many mothers want the information; that they may be counseled against oral or unprotected sex; and that strategies may be devised from the data that are collected. However, others argue against testing, stating that it is not cost effective, that there is no recommended intervention, and that the unexpected positive test result can cause significant psychological and social distress. Targeting

TABLE 50.1 Maternal Infection Classification by Genital HSV Viral Type and Maternal Serology*

Classification of Maternal Infection	PCR/Culture From Genital Lesion	Maternal HSV-1 and HSV-2 IgG Antibody Status
Documented first-episode primary infection	Positive, either virus	Both negative
Documented first-episode nonprimary infection	Positive for HSV-1 Positive for HSV-2	Positive for HSV-2 AND negative for HSV-1 Positive for HSV-1 AND negative for HSV-2
Assume first-episode (primary or nonprimary) infection	Positive for HSV-1 OR HSV-2 Negative OR not available†	Not available Negative for HSV-1 and/or HSV-2 OR not available
Recurrent infection	Positive for HSV-1 Positive for HSV-2	Positive for HSV-1 Positive for HSV-2

*To be used for women without a clinical history of genital herpes.
†When a genital lesion is strongly suspicious for HSV, clinical judgment should supersede the virologic test results for the conservative purposes of this neonatal management algorithm. Conversely, if in retrospect, the genital lesion was not likely to be caused by HSV and the PCR assay result or culture is negative, departure from the evaluation and management in this conservative algorithm may be warranted.
From Kimberlin DW, et al. Guidance on management of asymptomatic neonates born to women with active genital herpes lesions. *Pediatrics*. 2013;131:e635.

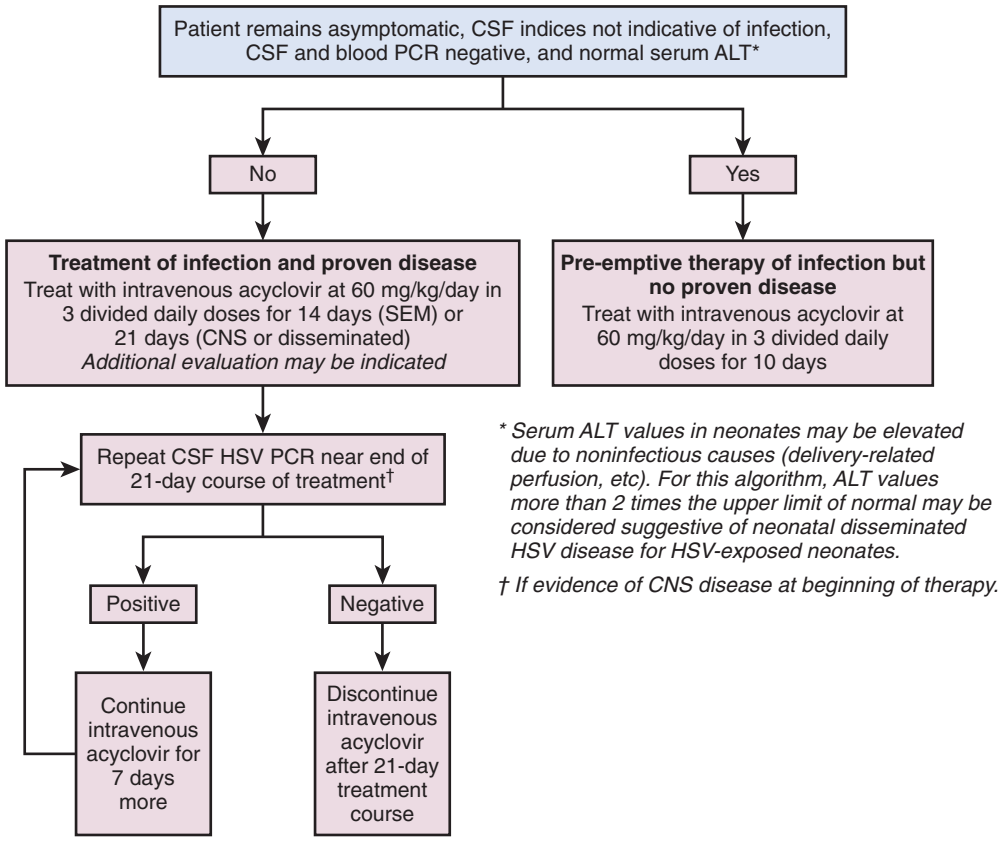
¶ This algorithm should be applied only in facilities where access to PCR and type-specific serologic testing is readily available and turnaround time for test results is appropriately short. In situations where this is not possible, the approach detailed in the algorithm will have limited, and perhaps no, applicability.

** Evaluation and treatment is indicated prior to 24 hours of age if the infant develops signs and symptoms of neonatal HSV disease. In addition, immediate evaluation and treatment may be considered if:*

- *There is prolonged rupture of membranes (>4–6 hours)*
- *The infant is premature (≤37 weeks' gestation)*



† Conjunctivae, mouth, nasopharynx, and rectum, and scalp electrode site, if present.

‡ HSV blood PCR is not utilized for assignment of disease classification.

§ Discharge after 48 hours of negative HSV cultures (and negative PCRs) is acceptable if other discharge criteria have been met, there is ready access to medical care, and a person who is able to comply fully with instructions for home observation will be present. If any of these conditions is not met, the infant should be observed in the hospital until HSV cultures are finalized as negative or are negative for 96 hours after being set up in cell culture, whichever is shorter.

• **Fig. 50.4** Algorithm for the *treatment* of asymptomatic neonates after vaginal or cesarean delivery to women with active genital herpes lesions. ALT, Alanine aminotransferase; CNS, central nervous system; CSF, cerebral spinal fluid; SEM, skin, eyes, mouth. (Adapted from Kimberlin DW, et al. Guidance on management of asymptomatic neonates born to women with active genital herpes lesions. *Pediatrics*. 2013;131:e635.)

for testing only women who are at high risk for infection misses too many seronegative women. Some treatment strategies do exist, however. It has been shown that the use of condoms in at least 70% of sexual intercourse between a woman seronegative for HSV and a man seropositive for HSV reduced transmission by greater than 60%.[123] Antiviral suppression with valacyclovir for 8 months in seropositive male partners reduced the transmission of HSV-2 infection to pregnant women by 48% and symptomatic infection by 75%.[54]

Obstetricians now recommend antiviral prophylaxis (usually valacyclovir or acyclovir) from 36 weeks of pregnancy onward to suppress viral recurrences. No major malformations have been associated to date with the use of acyclovir in pregnancy. In a Cochrane Database meta-analysis of third-trimester antiviral prophylaxis, women were less likely to have recurrence at delivery (relative risk 0.28), cesarean delivery for genital lesions (relative risk 0.30), and HSV detected at delivery (relative risk 0.14).[106] Although there were no cases of neonatal disease among the infants, there were too few patients to draw a conclusion about neonatal risk. Neonatal infection may occur because viral shedding still does occur. There has been some success in vaccine development for women who are seronegative for HSV-1 and HSV-2, but the trials still need to be performed.

Cytomegalovirus (Human Herpesvirus 5)

CMVs are the largest viruses in the Herpesvirus family and are noted for their worldwide distribution among humans and animals. The virus is highly species specific, and humans are the only known reservoir for disease. Infection occurs throughout the year. After primary infection, the virus enters a latent state, and reactivation may frequently occur. Reinfection may also result from any of the thousands of human strains, which are homologous, but not identical. The differing antigenic makeup of the various strains may make it possible to identify the source of the viral infection. It also allows re-infection to occur with other strains in an already seropositive individual.

The virus has a double-stranded DNA core surrounded by an icosahedral, or 20-sided, capsid. This capsid is surrounded by amorphous material, which, in turn, is surrounded by a lipid envelope, probably acquired during budding through the nuclear membrane. The virus is named for the intranuclear and paranuclear inclusions seen with symptomatic disease—cytomegalic inclusion disease. These inclusion bodies often yield an "owl's eye" appearance to the cells. The virus does not code its own thymidine kinase or DNA polymerase, which is important when considering treatment. The virus is cultured in the laboratory only in

human fibroblasts, although it replicates in vivo primarily in epithelial cells.

Epidemiology and Transmission

CMV is currently the most common intrauterine infection. CMV is responsible for congenital infection in 0.15%-2% of newborns, and it is the leading cause of nongenetic deafness and learning disability. Infection is more prevalent in underdeveloped countries and among lower socioeconomic groups in developed countries, where crowding and poor hygiene are more common. Each year, 2% of middle- to high-socioeconomic-class women of childbearing age seroconvert compared with 6% of women from lower socioeconomic groups. Seropositivity also increases with age, breastfeeding for longer than 6 months, non-white race, number of sexual contacts, and parity. A study of US national death certificate and census data from 1990-2006 documented that African Americans and Mexican Americans were at increased risk for congenital CMV infection and that African Americans and Native Americans had a much greater rate of mortality among infants under age 1 year because of congenital CMV.[30] Of note, the highest rate of congenital CMV infections occurs in populations with the highest rates of maternal seroprevalence rather than in countries with only moderate seroprevalence among pregnant women, as in the United States. Primary and nonprimary maternal infections may contribute differently to the development of congenital CMV in different populations.

Transmission of CMV requires close contact with contaminated secretions because the virus is not very contagious. The virus can be cultured from urine, cervical secretions, saliva, semen, breast milk, blood, and transplanted organs, and all these sites intermittently excrete virus. Viral excretion is particularly prolonged after primary infection, but it also occurs with reactivation of infection or re-infection with a different strain. Congenitally infected infants may shed the virus for years and serve as a large reservoir for spreading infection to others. Toddlers also may shed the virus for prolonged periods compared with adults, in whom the humoral and cellular defense mechanisms lead to a latent state within a few months.

Transplacental transmission is responsible for congenital infection in 1% of newborns, and intrauterine fetal death is more likely. Primary maternal infection during pregnancy is more likely to result in maternal-to-fetal transmission, but fetal infection may also result in women with pre-existing antibody to CMV. This may occur via reactivation of a prior maternal infection, or infection with a newly acquired strain. Roughly two thirds of infants with congenital CMV worldwide are born to mothers with pre-existing antibody to CMV because of the high prevalence of CMV in the population.[273] Overall, only 5%-10% of congenital infections are symptomatic, and these are more likely after a primary maternal infection, although symptomatic infections have been reported in women with pre-existing antibody. Symptomatic infants have a mortality of 20%-30%, and two thirds of survivors may have sequelae. The 90% of infants with asymptomatic infection at birth, however, also have a 5%-15% risk of later sequelae.

Even with primary maternal CMV infection during pregnancy, transplacental infection occurs in only 30%-40% of the fetuses, and only 10%-15% of these infected fetuses develop symptomatic disease. With recurrent maternal CMV infection or re-infection with a new strain during gestation, only 1%-3% of fetuses are infected. Although the risk of transmission seems to be increased in the third trimester, the risk of malformations (which occur during the period of organogenesis) and developmental disabilities lessens. The fetus may be infected throughout gestation. The rate of intrauterine transmission was 9% preconceptually, and 31%, 34%, and 40% in the first, second, and third trimesters, respectively.[208] Maternal IgG crosses the placenta and provides passive immunity for the fetus but may also facilitate transport of CMV across the placenta, as IgG-virion complexes use the fetal F_C receptor on the syncytiotrophoblast for transcytosis. Villus core macrophages can neutralize complexes formed with high-avidity antibodies, but low-avidity antibody allows the virus to escape[48] and seems to be more significant in the first half of pregnancy when the virus has considerable teratogenic potential. Neurons migrate from the periventricular germinal matrix to the cortex between 12 and 24 weeks of gestation. This process may be interrupted by infection, resulting in CNS malformations. In the second half of pregnancy, during the period of myelination, white matter lesions may develop, as seen on MRI.[153]

Perinatal infection is responsible currently for an additional 3%-5% of infections among newborns, resulting from exposure to cervical secretions and blood during delivery or via breast milk.[182] Transmission in early childhood may occur from child to child and from child to other family members. There is also an implication that infection may occur via fomites because virus may survive in urine for hours on plastic surfaces and has been cultured from toys in daycare centers. Nearly half of mothers of premature infants infected in the nursery seroconvert within 1 year, and the same proportion of susceptible family members seroconvert when a single family member is infected.

Daycare compounds the problem. There is a 15% rate of infection among parents of children in daycare, particularly if the child is younger than 18 months. Mothers of children in daycare, particularly if they are of middle socioeconomic status and previously seronegative, are at significant risk of developing a primary CMV infection in a subsequent pregnancy; this may account for 25% of symptomatic congenital infections. Seronegative women who work at daycare centers have an 11% seroconversion rate per year, well above any predictable rate, and are at considerable occupational risk. Among children attending daycare, 30%-70% excrete the virus.

Similar concern has been expressed about female health care workers and their occupational risk. Early data did not support an increased risk of transmission of the virus, but current infection control measures and diagnostic

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

methodologies did not exist at that time, so the risk is not really known.

After early childhood, viral transmission seems to be minimal until puberty, when sexual activity begins. Infection rates are highest among adults with multiple sexual partners. An additional risk of infection occurs with blood transfusions and organ transplantation, as the virus is present within the leukocytes and tissues. Transmission may be prevented by mandating that all blood products come from seronegative donors. Alternatively, the white blood cells carrying the virus may be removed by using frozen, deglycerolized red blood cell transfusions or by using filters to remove the leukocytes. However, neither the use of only seronegative blood nor the use of filters completely protects against transmission of virus. Thus, some recommend using both mechanisms.

CMV transmission via human breast milk feeding has been reported to result in infection in premature infants (<32 weeks' gestation), resulting in a sepsis-like infection. The virus is found in the whey portion of the milk, and mothers may excrete virus in their milk when they are not excreting the virus elsewhere, such as in urine or saliva. The long-term outcome has not yet been determined, but in a report of 40 preterm infants who developed viruria in the nursery, most likely from breast milk feedings, neonatal outcome was not different from that in control infants. The infants exhibited cholestasis, elevation of C-reactive protein, mild neutropenia, and thrombocytopenia, but these symptoms resolved.[183] There is still debate as to whether the virus contributes to bronchopulmonary dysplasia or whether the most immature infants will develop hearing, neurologic, or developmental abnormalities.

Maternal Clinical Manifestations

Most women are asymptomatic during primary infection and even more so with re-infection or recurrent infection, and pregnancy does not alter the clinical picture. A mononucleosis-like illness, which is heterophil negative, may develop in 5%-10% of women. Other manifestations are rare.

CMV frequently infects the decidua of the placenta, causing fibrosis and edema that result in intrauterine hypoxia and the release of cytokines further stimulating the placenta. This placental injury and hypoxia can cause fetal intrauterine growth restriction (IUGR), even without transmission of the virus to the fetus.

Asymptomatic Congenital Infection

Although 85%-90% of all infants with congenital CMV are asymptomatic at birth, 15% may be at risk for later sequelae. The results of follow-up of 330 infants with asymptomatic infection who were mostly of low socioeconomic status are shown in Table 50.2. The most important sequela seems to be sensorineural hearing loss, which is often bilateral and may be moderate to profound. The presence of periventricular radiolucencies or calcifications on CT is highly correlated with hearing loss. The hearing loss may be present at birth or may appear only after the first year of life and is frequently progressive as a result of continued growth of the virus in the inner ear. There is a very low risk of chorioretinitis, which may not be present at birth but may develop later secondary to continued growth of the virus. A further finding may be a defect of tooth enamel in the primary dentition, leading to increased caries. Neurologic handicap may occur but is uncommon. Premature infants are most at risk.

TABLE 50.2 Sequelae in Children After Congenital Cytomegalovirus Infection

Sequelae	Symptomatic Infection (%)	Asymptomatic Infection (%)
Sensorineural hearing loss	58	7.4
Bilateral hearing loss	37	2.7
Speech threshold, moderate to profound	27	1.7
Chorioretinitis	20.4	2.5
IQ ≤70	55	3.7
Microcephaly, seizures, or paresis/paralysis	51.9	2.7
Microcephaly	37.5	1.8
Seizures	23.1	0.9
Paresis/paralysis	12.5	0
Death	5.8	0.3

Data from Stagno S. Cytomegalovirus. In: Remington JS, et al., eds. *Infectious diseases of the fetus and newborn infant*. 5th ed. Philadelphia: Saunders; 2001:408.

Symptomatic Congenital Infection

Cytomegalic inclusion disease occurs in only 10%-15% of infected infants and results in multiorgan involvement, particularly of the reticuloendothelial system and the CNS. Death may occur at birth or months later, resulting in an overall mortality of 20%-30%, usually from DIC, bleeding, hepatic failure, or bacterial infection.

CNS involvement may be diffuse. Infants may be microcephalic, exhibit poor feeding and lethargy, and be hyper- or hypotonic. Intracranial calcifications of the basal ganglia and cortical and subcortical regions, ventricular enlargement, cortical atrophy, or periventricular leukomalacia may also be present. Most commonly, an infant who is small for gestational age or premature has hepatosplenomegaly and abnormal liver function tests. Hyperbilirubinemia, which occurs in more than half of the infants, may be transient but is more likely to be persistent, with a gradual increase in the direct component. Petechiae, purpura, and thrombocytopenia (direct suppression of megakaryocytes in bone

marrow) usually develop after birth and may persist for weeks. Approximately one third of infants with congenital infection have thrombocytopenia, and one third of those have severe thrombocytopenia, with platelet counts less than 10,000/dL. There may also be a Coombs-negative hemolytic anemia. Diffuse interstitial or peribronchial pneumonitis is possible, but less common than with perinatally acquired disease. Table 50.3 lists the clinical findings in 24 newborns with symptomatic CMV infection. Persistent CMV may be responsible for a severe necrotizing pneumonitis in preterm infants and is hypothesized to result in a greater severity of bronchopulmonary dysplasia.

TABLE 50.3 Clinical Findings in the First Month of Life in 24 Newborns With Symptomatic Cytomegalovirus Infection After Primary Maternal Infection

Finding	No. (%)
Jaundice	15 (62)
Petechiae	14 (58)
Hepatosplenomegaly	12 (50)
Intrauterine growth restriction	8 (33)
Preterm birth	6 (25)
Microcephaly	5 (21)
Hydranencephaly	1 (4)
Death	1 (4)

Prognosis

Fowler et al.[85] showed that although maternal antibody may not prevent congenital CMV infection, it lessens the severity (Table 50.4). Sequelae were found in 25% of infants after primary infection, but in only 8% after recurrent infection. Likewise, mental impairment (intelligence quotient [IQ] <70), sensorineural hearing loss, and bilateral hearing loss were found in 13%, 15%, and 8% of infants, respectively, after primary maternal infection, but only 5% of infants born after recurrent maternal infection had sensorineural hearing loss, and none had mental impairment or bilateral hearing loss. These infants also showed the progressive nature of sequelae after primary and recurrent infection (Fig. 50.5).

Ramsay et al.[220] looked at the 4-year outcome of 65 neonates with symptomatic congenital CMV in the United Kingdom and found a better prognosis than previously reported from the United States (Table 50.5). Overall, the rate of neurologic abnormalities was 45%. Infants who presented with abnormal neurologic findings other than microcephaly had the worst prognosis, with a 73% rate of gross motor and psychomotor abnormalities compared with a 30% rate among children who did not present with neurologic findings. A Japanese study of 33 congenitally infected infants found that abnormal abdominal findings (ascites or hepatosplenomegaly) on fetal ultrasonography were associated with liver dysfunction and a 53-fold increase in mortality; infants who had no abdominal findings survived.[158] Evidence is also accumulating that neonatal viral blood load (>1000 copies per 10^5 polymorphonuclear leukocytes

TABLE 50.4 Sequelae in Children With Congenital Cytomegalovirus Infection According to Type of Maternal Infection

Sequelae	Primary Infection*	Recurrent Infection*	*P* Value
Sensorineural hearing loss	15 (18/120)	5 (3/56)	0.05

[PMNLs] via quantitative PCR) may also predict infants who will develop sequelae, regardless of whether the infants were symptomatic or asymptomatic after birth.[138] Chorioretinitis, periventricular calcifications, and microcephaly remain standard predictors of poor cognitive outcome. In contrast, children who have normal development and no hearing loss at 1 year of age are unlikely to develop neurodevelopmental handicaps.

Perinatal Infection

Mothers with recurrent CMV infection or re-infection usually transfer significant antibody to the infant in utero. Even if this antibody transfer does not occur, a term infant who acquires infection after birth, denoting a perinatal infection, is usually asymptomatic. Transmission may occur in passage through the birth canal, via breast milk, or secondary to blood transfusion. Breastfeeding infants largely seroconvert. The incubation period is 4-12 weeks. Term infants may develop pneumonitis secondary to CMV and present with cough, tachypnea, congestion, wheezing, and apnea. Few infants require hospitalization, and there is spontaneous resolution in most term infants. In contrast, premature infants, often infected through blood transfusion, have a high rate of serious or fatal illness. They also may develop pneumonitis, but with a picture of overwhelming sepsis, hepatosplenomegaly, thrombocytopenia, and neutropenia. There may be an increased risk in these infants of neuromuscular handicaps, although there does not seem to be a higher rate of sensorineural hearing loss, microcephaly, or chorioretinitis. Transmission via blood transfusion can now be largely eliminated, indicating that most infants are infected postnatally by maternal breast milk.

Neurologic Impairment

Not all infants with symptomatic disease at birth have neurologic impairment. One third of these infants may have a normal neurologic outcome, and none of 45 infants with normal ultrasonography results had long-term sequelae (Table 50.6).[10] However, 5%-15% of asymptomatic infants may have sequelae.

Initially, CT was considered the gold standard to diagnose cerebral involvement in congenital CMV infection, and 90% of symptomatic infants with abnormal CT findings had neurodevelopmental or neurosensory sequelae. However, MRI is much more sensitive in diagnosing white matter and migrational abnormalities. Cranial ultrasonography is more sensitive in diagnosing lenticulostriate vasculopathy and germinolytic cysts, which are especially found in the anterior temporal region along with ventriculomegaly and ventricular septations. Infection in the first trimester may result in abnormal CNS development, which, in turn, may cause abnormal neuronal migration and cerebellar hypoplasia. Infection occurring between 16 and 18 weeks' gestation may result in lissencephaly, whereas infection occurring between 18 and 24 weeks' gestation is related to the development of polymicrogyria. Migrational disorders correlate with poor neurodevelopment and sensorineural hearing loss, and polymicrogyria correlates with cognitive

and motor delay and epilepsy. Periventricular calcifications are also a poor prognostic indicator of developmental delay.

Abnormalities in balance and posture causing delays in walking, abnormalities in gross motor function, and cerebral palsy are now being seen in children with sensorineural hearing loss. These may reflect abnormal vestibular function in the ear and/or cerebellar lesions. A few reports have noted an increase in autism spectrum disorders, but this is not universal. In contrast, a normal fetal brain MRI result generally indicates a good clinical outcome, although there may still be some cases of mild hearing loss.

Hearing and Visual Impairment

Congenital CMV is the most significant cause of nongenetic sensorineural hearing loss in childhood: 10%-15% of all infants experience hearing loss, but it may also be detected in 30%-65% of symptomatic infants.[153] One fourth of hearing loss detected by 4 years of life is secondary to congenital CMV infection. The hearing loss tends to be more severe and to occur earlier in infants with symptomatic infection. These children also tend to have bilateral loss, whereas infants with asymptomatic infection are more likely to have unilateral loss of hearing. The loss can be progressive or fluctuate and may be delayed by years. Less than half of all sensorineural hearing loss secondary to CMV is detected by newborn screening. Increased blood and urine viral load with more prolonged urinary excretion at an earlier age is associated with a higher risk of sensorineural hearing loss in both symptomatic and asymptomatic infants. These children often shed virus for greater than 4 years. The cause of this continued and fluctuating hearing loss is not well understood. It has been variably attributed to a direct cytopathic effect of the virus, to the host's immune response, and to injury to the endolymphatic structures. Rehabilitation with hearing aids or cochlear implants can provide useful speech comprehension, even if language development is not as advanced as in uninfected children who do not have other neurologic handicaps.

Chorioretinitis may be found in 15%-30% of symptomatic newborns. Children often have impairment or strabismus secondary to chorioretinitis, optic atrophy, or central cortical lesions and to macular scarring. Chorioretinal scars, resulting in visual impairment, are frequent in children receiving cochlear implants.[76]

Antenatal Diagnosis

Because most women with CMV infection remain asymptomatic, screening for primary infection is necessary to determine risk. Detecting CMV IgG, which has high sensitivity and specificity, in a woman known previously to be seronegative reliably diagnoses primary infection. Few European or American countries routinely screen for seroconversion, however, because there is no consensus for treatment of either a newly infected pregnant woman or her infant. Detection of CMV IgM may indicate a recent infection, but IgM also increases with reactivation of latent infection or re-infection. CMV IgG avidity testing may be helpful: The binding capacity or avidity of IgG is low just after an infection and remains low for 18-20 weeks after infection and then increases with time. Also, the synthesis of IgG antibodies against glycoprotein B (gB) is delayed in a primary infection, so the absence of these antibodies in an immunoblot test is a marker for recent infection. Finally, CMV DNA may be detected during acute infection from the peripheral blood.

If a primary maternal infection is suspected, or ultrasonography shows abdominal or cerebral findings or IUGR, fetal diagnosis may be undertaken. Cordocentesis is unnecessary because the sensitivity is lower and the risks are greater than with amniocentesis. CMV may be detected in the amniotic fluid by viral culture or by PCR for CMV DNA. The amniotic fluid should only be sampled at least 6 weeks after the onset of maternal infection to allow for delayed passage of virus across the placenta and at 21-23 weeks' gestation to allow for fetal renal maturity to be able to excrete the virus.[141] A high viral load was initially

correlated with the development of a symptomatic infection and neurodevelopmental sequelae, but this was not confirmed in subsequent studies.

Neonatal Diagnosis

CMV must be identified in an infant by 21 days of age to be certain it is a congenital infection rather than a perinatal infection. Urine culture for CMV, either by routine viral culture or by rapid shell vial culture, was the gold standard for the diagnosis of CMV infection for years. More recently, it has been replaced by PCR amplification testing of urine, saliva, or blood. PCR testing performs as well as or better than rapid culture.[230] PCR offers more rapid turn-around, is not as affected by storage and transport conditions, costs less, and is better for high throughput than culture.[230] It performs well in targeted testing and large volume screening testing. Both saliva and urine are acceptable in large-volume screening programs, but saliva is easier to collect and comparable in reliability.[230] In a study in the United Kingdom, 98% of salivary swabs collected by parents from newborns who failed the routine hearing screen were successfully tested before 21 days of life for CMV.[286] Cost benefit analyses of this program[285] and a similar program in the United States[19] compared well with other screening programs, suggesting a potential for targeted screening of at-risk infants who might benefit from treatment. Screening of pregnant women in general is not recommended in the United States or in many European countries because of the lack of a successful treatment modality. However, it has been suggested that screening of women undergoing assisted reproduction might identify those recently infected and should, therefore, delay their efforts. In addition, dried blood spots, as collected on the Guthrie cards in newborn screening programs, can be used to retrospectively diagnose a congenital infection in an older infant. The sensitivity of PCR testing of dried blood spots is slightly lower, making them less suitable for screening programs. Finally, the diagnosis may be made by determining a fourfold increase in specific IgG titers or presumptively by detecting anti-CMV IgM because IgM does not cross the placenta. However, there are false-positive and false-negative results with IgM, rendering it less useful.

Treatment

Ganciclovir (GCV) and its oral prodrug valganciclovir (VGCV) are used to treat the newborn with symptomatic congenital infection. GCV is an acyclic deoxyguanosine nucleoside analogue, which acts as a chain terminator during elongation of the CMV DNA.

Kimberlin et al.[129] randomly assigned neonates with symptomatic CNS disease to receive 6 weeks of therapy with ganciclovir, at 6 mg/kg/dose given every 12 hours versus no treatment and monitored hearing with brainstem auditory evoked response. When tested at 6 months, in 84% of treated infants, normal hearing was maintained or hearing was improved, in contrast to 59% of control infants. None of the treated infants had worsening of hearing at 6 months compared with 41% of untreated infants. When tested at 1 year, 21% of treated infants and 68% of control infants exhibited worsening of hearing. Neutropenia was three times more common (63%) in treated infants than in untreated infants. Maintenance of IV access was also an issue. Viral excretion in urine returned to pretreatment levels within 2 weeks after GCV was discontinued, as did the viral load.[189] In addition, the Denver Developmental Screening Test was also performed at 6 weeks, 6 months, and 1 year of age.[189] Infants who were treated with GCV had fewer developmental delays at 6 months and at 1 year of age.

Subsequently, it was determined that oral administration of VGCV given twice daily at 16 mg/kg/dose provided comparable systemic coverage.[124] A second randomized, placebo-controlled trial comparing 6 weeks of oral VGCV treatment to 6 months of oral VGCV in infants with symptomatic congenital infection was begun.[125] Although no difference in best ear hearing as determined by brainstem auditory evoked response was seen at 6 months' follow-up, there was a small, but significant improvement in hearing at 12 and 24 months among the infants treated for 6 months. The infants treated for 6 months also performed better on the Bayley Scales of Infant and Toddler Development (3rd edition) at 24 months. Of note, neutropenia was comparable between the two groups and lower than in the GCV trial. Therefore, it is recommended that infants with symptomatic congenital disease in their first month of life be treated with 6 months of oral VGCV after counseling the parents regarding the 20% risk of neutropenia. Carcinogenicity and gonadotoxicity have been seen in animal models, but not in humans. Infants with asymptomatic congenital disease should not be treated. Recently, a small study of 54 infants with symptomatic infection and hearing impairment at birth were treated with 12 months of GCV/VGCV.[22] Hearing improved in 65%, with return to normal hearing in most. There was no control group, and hearing was not reported beyond a year of life.

Prevention

Pasteurization can be used to inactivate CMV in human milk, and freezing of the milk decreases, but does not eliminate, the virus. If a mother is known to be CMV seronegative and her infant must receive donated, fresh human milk, the use of a seronegative donor would be beneficial.

The development of a vaccine against CMV is a public health priority. Several live-attenuated vaccines have been developed, but trials have not demonstrated sufficient protection, and none of the vaccines has been licensed for use. In addition, it is now understood that natural immunity does not prevent transmission of the virus to the fetus and that a significant proportion of congenital infections result from nonprimary infections during pregnancy. Clinical isolates of CMV strains show significant genetic variation and recombination into a tremendous number of strains, implying that multivalent vaccines may be needed. These vaccines

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

may need to target both the cellular and humoral immune responses to the virus to be effective. There is some promise in recombinant live-attenuated vaccines, which delete the genes responsible for immune evasion.

However, prevention remains the most important available means to avoid infection. CMV may be transferred to human hands by contact with mucosal surfaces, saliva, urine, or stool from small children shedding the virus or from surfaces contaminated by those children. The human skin maintains an acidic microenvironment, so the virus does not survive on human hands as long as it does on other surfaces. Nevertheless, it can be transferred from the hands to mucosal membranes, potentially resulting in infection. Hand washing with soap, antibacterial soap, or even just water removes much of the virus, and hand sanitizers and, to a lesser extent, diaper wipes can inactivate the virus. Female childcare workers, especially when their children are younger than 2 years of age, need to be counseled about the risks of CMV in pregnancy and taught good hand washing procedures, as do women health care workers, particularly in nurseries. The US Centers for Disease Control and Prevention (CDC) has developed a set of hygiene practices to reduce the risk of CMV infection for women who are pregnant or planning to become pregnant. These include thoroughly washing hands with soap and warm water after changing diapers, feeding or bathing a child, wiping the nose or drool, or handling the child's toys. The pregnant woman should not share food, drinks, eating utensils, or toothbrushes with a young child or put a pacifier in her own mouth. She should avoid saliva when kissing a young child, and she should clean toys, countertops, and other surfaces in contact with either saliva or urine. There was an 84% reduction in seroconversion among seronegative pregnant women in high-risk occupations when they were educated about CMV and hygiene in comparison with those who did not receive counseling.[226]

Transmission of CMV via blood transfusions may be largely eliminated by using blood from antibody-negative donors, by using frozen, deglycerolized red blood cells, or by using leukocyte-depletion filters. Because both methods have a small failure rate, some recommend using both antibody-negative donors and leukocyte depletion filters.

When a pregnant woman has been infected with CMV and her fetus has been diagnosed with infection, few options are available other than abortion. The use of passive immunization with CMV-specific hyperimmune globulin (HIG), primarily given intravenously, initially suggested a lower rate of transmission of the virus to the fetus,[186] but a subsequent randomized double-blind trial of HIG in 124 women found a fetal transmission rate of 30% in treated women with a primary infection, and 44% in control women, which did not reach statistical significance.[225] There was also a higher rate of obstetric complications among treated women, so the use of HIG is not routinely advised. A large scale trial in the United States is currently in progress.

Varicella-Zoster Virus (or Human Herpesvirus 3)

Varicella (chickenpox) is one of the most highly communicable human diseases. It is the result of a primary infection with varicella-zoster virus (VZV), which is one of the human DNA herpesviruses. After infection, latent virus persists in the dorsal root ganglia. The localized rash of herpes zoster results from a reactivation of infection, in which the virus begins to multiply within the ganglia and propagate down the sensory nerves to its dermatomes.

Epidemiology and Transmission

Humans are the only known reservoir of VZV. Immunity is lifelong and widespread. Of young adults, 70%-80% have a history of chickenpox, and this has been found to be quite reliable. Conversely, only 10%-20% of individuals lacking a history of chickenpox have been found to be seronegative, even though asymptomatic infection is believed to be unusual. Chickenpox rarely occurs in immunocompetent, seropositive individuals, although it has been reported to occur among pregnant women. Most reinfections are mild. Because of the implementation of universal immunization in the United States in 1995, as well as the recommendation of a second vaccine dose in 2006, varicella infections have decreased by greater than 90%. Primary varicella infection in pregnancy now only amounts to roughly 2-3/1000 pregnancies/year.

The initial protection against VZV depends on IgG. Neonates become ill because they are exposed to high titers of the virus from the mother and yet antibody is absent. In contrast, limitation of the severity of the infection and recovery from infection largely depend on cellular immunity, or T cells. Pregnant women and others who are immunosuppressed have decreased T-cell immunity, so disease can be very severe. Severe disease may also develop when the individual is receiving high doses of steroids.

Chickenpox is seen year round, with some increase in winter months, and is worldwide in distribution. In household contacts, 90% of susceptible individuals are infected. Transmission of the virus occurs via air-borne droplet spread or via contact with the virus in the vesicular lesions of either varicella or, rarely, zoster. Although it is well documented that susceptible individuals may develop varicella after exposure to zoster lesions, varicella-zoster does not develop after exposure to chickenpox. Transmission may occur 1-2 days before the onset of the rash until all vesicular lesions are dried and crusted, at least 6 days after onset of the rash. The incubation period is 10-21 days after exposure, unless the individual has been given varicella-zoster immunoglobulin, which may delay the onset of the infection for 28 days. When the mother has varicella around the time of delivery, the onset of the rash in the newborn is usually 9-15 days after the onset of the rash in the mother.

After replication of the virus within the nasopharynx and invasion of the local lymph nodes, there is transient viremia,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

which seeds the viscera. Viral multiplication continues, causing a greater viremia and widespread cutaneous involvement. Subsequent viremias result in crops of vesicles, followed by the development of latency within the dorsal root ganglia.

Clinical Manifestations

After a short prodrome of fever, headache, and malaise, there is generalized exanthema, which begins on the face and trunk and proceeds centripetally. Recurrent crops of vesicles appear for 2-5 days and then crust and scab, usually healing without scarring. Secondary bacterial infection of the cutaneous lesions is the most common complication and may lead to sepsis, pneumonia, and meningitis. Most other complications are rare, including encephalitis, hepatitis, myocarditis, arthritis, and glomerulonephritis. Reye syndrome, which sometimes occurred after chicken pox, has almost disappeared now that it is recommended not to use salicylate-containing products with chicken pox.

Varicella pneumonia is the most common cause of mortality. The onset of fever and cough usually occurs within 2-4 days after the development of the rash but may occur later. Radiographic changes consist of diffuse, nodular lesions with perihilar prominence. Dyspnea, cyanosis, rales, and chest pain may be severe, and there may be hemoptysis. Although only 15% of adults develop pneumonia, 90% of all cases of chickenpox pneumonia occur among adults. Immunocompromised individuals are also at increased risk.

Shingles, or varicella zoster, is characterized by clusters of vesicles in 1-3 sensory dermatomes as a result of VZV reactivating from the latent state in the sensory ganglia where it had resided. These vesicles are pruritic and painful and, occasionally, result in postherpetic neuralgia, which can last a few days to months. Occasionally, there can be reactivation of VZV viscerally without any skin lesions.

Varicella in Pregnancy

There does not seem to be an increased risk of spontaneous abortion or prematurity as a result of maternal chickenpox, although prematurity and IUGR are common among infants with congenital varicella syndrome. Mortality of 40% with chickenpox pneumonia has been reported among pregnant women who did not receive antiviral therapy. Some experts recommend oral acyclovir or valacyclovir for pregnant women with varicella, especially during the second and third trimesters, when the risk of severe infection is greatest. IV acyclovir is recommended in the presence of varicella complications.

Because of the potential for increased mortality, varicella-zoster immunoglobulin (VZIG) may be useful for passive immunization of a susceptible pregnant woman after significant exposure to varicella. Controlled trials are, however, still unavailable. VZIG needs to be administered within 96 hours of exposure and, preferably, after susceptibility has been confirmed serologically. VZIG, or Varizig, is approved by the US Food and Drug Administration (FDA) for use in newborns, premature infants, children less than 1 year of age, and pregnant women. Uncertainty continues regarding its effect on the fetus. VZIG may not protect the fetus from infection. Likewise, the absence of signs of maternal chickenpox after the use of VZIG does not indicate that the fetus is protected, and there is at least one report of congenital varicella syndrome when the mother received VZIG 4 days after exposure.[233] Ultrasonography revealing a wasted limb may assist in the diagnosis of infection of the fetus, although this is, of necessity, a late diagnosis, which rules out the option of an abortion.

Congenital Varicella Syndrome

Intrauterine infection occurs as a result of hematogenous dissemination across the placenta and can occur even with mild maternal infection.[73,200] The lowest risk of congenital varicella syndrome (CVS) occurs with maternal infection before 12 weeks of pregnancy (0.55%) and rises to 1.4% between 13 and 20 weeks, giving an overall risk of 0.91% in the first 20 weeks of pregnancy[277] (Table 50.7). Only a couple of cases of CVS have been described between 20 and 28 weeks' gestation. A few infants (1.1%) may develop herpes zoster in the first 2 years of life when the mother had had varicella in the late second or third trimester of pregnancy. A later maternal infection is more likely to result in less severe fetal manifestations. Although portions of the congenital syndrome have been seen after maternal zoster, the full syndrome has not been seen, presumably because viremia is uncommon with zoster, and some pre-existing immunity is present. Theoretically, the fetal lesions result from the occurrence of zoster in utero.

Typical features of the congenital syndrome include cicatricial cutaneous lesions, often in a zigzag shape, with limb involvement, ocular abnormalities, and severe mental retardation. The condition may progress to an early death. Skin lesions usually occur over an involved limb, sometimes over the contralateral limb, and are often depressed

and pigmented in a dermatomal distribution. Cataracts, microphthalmia, chorioretinitis, cerebral atrophy, seizures, and mental retardation may occur; sometimes bowel and bladder dysfunction also may occur. Hypoplasia of the bone and muscle of a limb is prominent.

Maternal counseling is difficult because the incidence of the syndrome is so low as to preclude routinely recommending abortion. Maternal infection may have a 25% incidence of fetal varicella, but this does not indicate that the fetus will develop congenital varicella syndrome. Similarly, chorionic villus sampling with PCR to show virus and cordocentesis to show fetal VZV IgM indicate only fetal infection, not the development of the congenital syndrome.

The most helpful prenatal test is fetal ultrasonography. Unfortunately, the abnormalities may occur late, thus precluding elective abortion. Limb abnormalities carry a 50% risk of mental retardation and early death. Hydrocephalus, liver calcifications, hydrops fetalis, and polyhydramnios may also be seen.

Perinatal Chickenpox

Chickenpox is considered congenital when it occurs within the first 10 days of life, and it results from transplacental transmission of the virus from mother to fetus. Maternal varicella, particularly occurring from 5 days before delivery until 2 days after delivery, results in a higher neonatal mortality (20%-30%) because there has not been enough time for maternal antibody to develop and transfer across the placenta to the fetus. The fetal attack rate is 24%-50%. The incubation period is shorter—9-15 days from the onset of the maternal rash to the development of fetal or neonatal disease. Infants may have a very mild infection with few lesions or may have severe disease, with widespread cutaneous and visceral involvement, including encephalitis and hepatitis. Death most often occurs secondary to pneumonia. Zoster may also occur and represents an intrauterine infection.

Dried blood spots from the Guthrie cards of greater than 400 children with cerebral palsy were compared with case controls for the presence of neurotrophic viruses as determined by PCR.[92] Although seroprevalence was high even in control infants (nearly 40%), the presence of VZV DNA nearly doubled the risk of cerebral palsy.

Postnatally acquired chickenpox occurs between 10 and 28 days of life. The infection is usually mild and is unlikely to result in death. An outbreak may occur within the neonatal intensive care unit (NICU) but is much less common than in pediatric units.

Laboratory Diagnosis

PCR of vesicular fluid or a scab, or even saliva during the acute infection, is now the preferred method for diagnosis. Culture and direct fluorescent antibody (DFA) testing are less reliable. Serologic testing for IgG can detect an increase in antibody titer and document infection retrospectively. The presence of specific IgM usually indicates recent infection but is an unreliable indicator.

Therapy and Prevention

The primary approach to varicella should be preventive. The vaccine seems to protect 85% of individuals vaccinated. Pregnancy should be avoided for at least 1 month after vaccination, but there have been no cases reported of fetal malformations in inadvertently immunized pregnant women. Nursing mothers may be immunized as the vaccine strain has not been detected in breast milk. Healthy children should be vaccinated promptly, according to the immunization schedule, at ages 12-15 months and 4-6 years. Parents should be counseled about the possibility of a febrile seizure resulting after vaccination. There should be at least 3 months between doses when catch-up vaccination is being given. There are separate recommendations for children with chronic disease or immunodeficiency or those who are receiving steroids. The vaccine should also be given to an otherwise healthy child at least 12 months of age within 3-5 days of exposure and repeated at the appropriate age.

VZIG should preferably be given within 96 hours after exposure. It modifies the course of infection but does not prevent it. Passive immunization should be administered to any infant born to a mother who develops varicella 5 days before delivery to 2 days after delivery. Because a high dose would be needed, it is not recommended that the mother be given VZIG before delivery for passive immunization of the infant.

Acyclovir is the antiviral drug of choice for any infant with severe or potentially severe chickenpox, whether congenital or postnatal in origin. No acute toxicity has been shown after acyclovir use for neonatal HSV infections, although the dosage for neonatal chickenpox is much higher, and long-term toxicity is unknown.

Although nosocomial cases of chickenpox are uncommon in the nursery, they may occur. Strict respiratory droplet isolation of any patients with active lesions or in the incubation period needs to be implemented, and only visitors and staff with prior immunity should be allowed in the room. Strict hand washing and contact precautions are a necessary. Postnatal exposure of a term infant 2-7 days of age should carry little additional risk. Infants with low birth weight or preterm infants may be at considerable risk, however, because they were born before the transfer of maternal antibody across the placenta. All hospitalized exposed preterm infants with birth weight 1000 g or less or gestational age less than 28 weeks should receive VZIG or IV acyclovir, regardless of the maternal immune status. Hospitalized, exposed preterm infants (≥28 weeks' gestation) should receive VZIG or IV acyclovir if the mother lacks a reliable history of chickenpox or serologic evidence of immunity. VZIG cannot be used to control the spread of varicella in a nursery because it only modifies, but does not prevent, the course of chickenpox. Infants with congenital varicella syndrome do not need to be isolated if all the skin lesions have healed.

Strict preventive measures are also necessary in the delivery and nursery services. If the mother has active lesions

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

of chickenpox at the time of delivery, she must be isolated from other patients and the staff. If the maternal lesions appear within 5 days before delivery and 2 days after delivery, the infant should be protected further with VZIG. If the mother had chickenpox before delivery and her lesions have healed, she need not be isolated, but the infant should be, preferably in the mother's room, during the incubation period. An infant with congenital chickenpox also needs isolation and treatment but may remain with the mother. If the mother was exposed to chickenpox 6-20 days before delivery and she has no history of chickenpox, she and her infant need to be isolated while her susceptibility is being confirmed via serology, and VZIG should be given to the infant if the mother develops lesions within 48 hours of delivery. The mother and the infant may be discharged home together. If the mother develops the varicella rash postnatally, the infant has already been heavily exposed, and transplacental transfer of maternal anti-VZV IgG and breast milk antibodies may decrease the severity of the infant's infection.

Epstein-Barr Virus (Human Herpesvirus 4)

EBV, a B-lymphotropic herpesvirus, is among the most prevalent of human viruses. Greater than 95% of pregnant women are seropositive. When EBV infects adolescents, it may cause infectious mononucleosis, but most infections are asymptomatic. The development of a rash is more common when infection is treated with ampicillin or other penicillins. CNS and hematologic symptoms and, rarely, disseminated disease, which is usually fatal, may occur. Lymphoproliferative disorders may also result from infection. The virus has been associated with a few malignancies, most often in Africa and Asia. A case-control study of more than 400 children with acute lymphoblastic leukemia (ALL) showed an association of maternal infection with EBV at 12-14 weeks' gestation.[145] Further study indicated reactivation may also be associated with non-acute lymphoblastic childhood leukemia.[257] However, the Guthrie cards of 54 children with ALL failed to show any DNA of EBV via PCR testing.[96] Findings from this and other studies have left the matter open to question. Finally, using quantitative real-time PCR to detect viruses in the tissue of infants who died as a result of sudden infant death syndrome compared with controls, there was a statistical association with EBV and HHV-6[9] and sudden infant death syndrome.[9]

Humans are the only natural hosts for the virus; as is typical of herpesviruses, the virus is excreted intermittently during reactivations for the remainder of the individual's life. Transmission, via saliva, seems to require close, personal contact. Fomites are not believed to transmit infection, even though virus may be viable for hours in saliva outside the body. Infection is endemic year round. Blood transfusion has also been documented to transmit virus occasionally.

Primary infection is rare during pregnancy because nearly all pregnant women are immune. The virus can be detected in cervical secretions by DNA hybridization. IgG and IgM to the viral capsid antigen can be detected in the acute infection, whereas IgG to the EBV nuclear antigen is detectable during latent infection.

Several studies have associated the occurrence of a primary infection in the first trimester of pregnancy with an adverse outcome, including prematurity and pregnancy-induced hypertensive diseases, although these associations remain unproven. EBV can cross the placenta and has been shown to cause placental infection, but the pregnancy outcome seems to be normal. There do not appear to be any congenital anomalies.

There is a report associating the presence of CMV and EBV viral DNA (rarely found in the blood of the newborn screening cards) with the development of cerebral palsy. The viruses were not found in the blood of the case controls.[161]

Human Herpesvirus 6 and 7

The role of the T-lymphotropic viruses HHV-6 and HHV-7 in human infection is just being recognized because HHV-6 was identified only in 1986, and HHV-7 was identified even later. They are double-stranded DNA members of the herpesvirus family, and are closely related to CMV. Like all herpes viruses, they cause persistent and lifelong infection. They are present worldwide, and humans are the only known hosts. There is only one variant of HHV-7, but two variants of HHV-6—A and B. Reflecting the high seroprevalence in adults, most infants have maternally acquired HHV-6 and HHV-7 IgG antibody, which wanes over the first 6 months of life, at which time these infants become seronegative and more susceptible to infection. HHV-6B infection is common in infants 6-12 months of age, and most children are seropositive by age 2 years. HHV-7 is acquired later than HHV-6 but is usually acquired by age 5-6 years. After infection, the virus persists for life and is shed in saliva, which is recognized as the major source of transmission. The mean incubation period is 9-10 days for HHV-6 and not known for HHV-7.

Many infants with primary HHV-6 infection are afebrile, although infants infected at younger than 6 months of age were more likely to be febrile than infants infected after 6 months.[292] Symptoms were present, however, in greater than 90% of cases of primary infection. These may include high fever without rash and sometimes cervical or postoccipital lymphadenopathy, otitis media, and respiratory or gastrointestinal disease. There may rarely be hepatitis or a mononucleosis syndrome. One fourth of the infants were diagnosed with infantum subitum (roseola), which causes an erythematous maculopapular rash when the fever resolves. Persistent and reactivated infection has not been shown to cause illness but does persist in the brain, and HHV-6 has been implicated in some cases of meningitis and encephalitis in infants and children younger than 2 years of age. It is also associated with febrile seizures in 10% of these febrile infants, and some of these infants develop

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

status epilepticus. HHV-7 infections are usually asymptomatic, but a few may cause roseola and may be responsible for recurrent cases of roseola, in which case it remains unclear whether they are the primary cause or simply able to reactivate HHV-6. HHV-7 is also responsible for febrile illness and cases of febrile seizures. Again, whether the seizures are caused by the HHV-7 infection or by reactivation of HHV-6 is still being debated.

HHV-6 is the only herpesvirus that can integrate its genome into the human chromosome, and many authors have hypothesized that HHV-6 congenital infection is inherited chromosomally and not transferred across the placenta.[256] There are no cases of congenital HHV-7, which cannot integrate into the chromosome.[98] About one third of congenital HHV-6 infections are caused by HHV-6A. The remaining two thirds are caused by HHV-6B. All cases seem to be asymptomatic.[98] This is in contrast to HHV-6 infections later in infancy, all of which are caused by HHV-6B. Although HHV-6 can be transmitted transplacentally from mother to fetus with maternal re-infection or reactivation of infection, congenital HHV-6 infections can be inherited from the chromosomes of either or both parents. Congenital infection was found in 1% of US infants, a rate similar to those in other western European countries,[98] and is not known to cause any clinical disease. However, there is one report of 57 newborns with HHV-6 congenital infection and 242 control newborns without infection showing significantly lower developmental scores on the Bayley-II Mental Index at 12 months of age compared with the scores in the controls. There were no effects on the visual or hearing screens.[39] HHV-7, but not HHV-6, has been found in human milk.

Diagnosis remains difficult. Few assays are commercially available. Indirect immunofluorescence can be used to distinguish HHV-6 from HHV-7 IgG antibody and can be followed for a fourfold rise in serial titers, but IgM antibodies cannot always be detected in young children with primary infections. Also, antigen detection can be used to determine active HHV-6 and HHV-7 infections, but the assays are not sensitive in young children. Of note, confirmation of infection does not change the management of the infant in the majority of cases.

Paramyxoviruses Family

Paramyxoviruses are being increasingly noted as significant causes of human disease. Their spectrum has been greatly expanded with the discovery of human metapneumovirus (hMPV). They are single-stranded, RNA viruses with a lipid envelope. Among the human pathogens, there are two subfamilies. The Paramyxoviridae subfamily includes the parainfluenza viruses (PIVs) and the mumps and measles viruses. hMPV, along with the related respiratory syncytial virus (RSV), belongs to the other subfamily, the Pneumovirinae.

Parainfluenza Virus

PIVs are enveloped, single-stranded, negative-sense RNA viruses in the Paramyxoviridae family. The four antigenic types (1-4) belong to the same subfamily as the mumps and measles (rubeola) viruses. Spread occurs through direct contact with infected respiratory secretions, via either respiratory droplets or contact with contaminated secretions on fomites. PIV-3 has been shown to survive for at least 10 hours on nonabsorptive surfaces (countertops) and 4 hours on absorptive surfaces, such as hospital coats, but die within minutes on finger pads.[12,26] Infection may occur year round, but seasonal or nosocomial outbreaks also occur. PIV-1 and PIV-2 outbreaks of croup or other respiratory illnesses tend to occur in the fall season, whereas PIV-3 outbreaks, which are associated with bronchiolitis and pneumonia in infants, are more likely to occur in spring and summer. Parainfluenza may also exacerbate symptoms of chronic lung disease.

Nearly everyone is infected with all PIV types by 5 years of age. PIV-3, the most common cause of respiratory illnesses of all the serotypes, is also the most common type in infants younger than 12 months of age, infecting about half of them in that first year.[279] PIV-3 seems to spare infants in the first 4 months of life because of the presence of transplacentally acquired neutralizing antibodies, but it is the usual source of nosocomial nursery outbreaks, spread via health care workers,[93,163,177] often in the presence of overcrowding. Older, convalescing preterm infants seem to be at increased risk of severe disease in nursery outbreaks, consistent with waning levels of maternally acquired antibody,[177] and this may result in a high mortality rate among chronically ill infants. The incubation period is 2-6 days, and virus may be shed for 3 weeks or longer by infected infants. Immunity is incomplete, so re-infections may occur with all of the serotypes, but they mostly cause only mild upper respiratory infections.

PIVs have been regarded as second in frequency to RSV as a cause of respiratory infections. Rhinovirus seems to be more common in respiratory infections, however, and the more recently discovered hMPV is also probably more common than PIV. As a group, PIVs are responsible for upper respiratory infections, laryngotracheitis (croup), bronchiolitis, and pneumonia. PIVs may also exacerbate asthma symptoms. PIV-1 and PIV-2 are more likely to cause croup, whereas PIV-3 is highly associated with bronchiolitis and pneumonia, particularly in infants and young children. Respiratory infections from PIVs may be difficult to differentiate clinically from infections caused by RSV. In young children and infants, these infections tend to be mild with a very low mortality rate. Infected children may require supplemental oxygen but rarely need ventilatory support. A few infants are asymptomatic. PIVs have been identified as a cause of 13% of community-acquired pneumonia in infants.[144] Co-infection with other respiratory viruses may occur in 20%-60% of infants and may increase the severity of the infection.[50] In newborns, the infection is more similar

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

to a severe RSV infection. Infants may have apnea, bradycardia, and pneumonia, and there may be worsening of chronic lung disease.[93,163,177,279]

PIV infection may be diagnosed by isolating the virus from nasopharyngeal secretions or by rapid antigen detection techniques, such as immunofluorescence and by PCR antigen detection. Serologic detection is not helpful. Prevention of nosocomial infections requires strict adherence to contact and respiratory precautions and strict hand washing. Treatment is largely supportive. Severely ill infants must be monitored closely for need for oxygenation and ventilation. Severe laryngotracheobronchitis has been treated with racemic epinephrine and parenteral corticosteroids, which decrease symptom severity and duration of hospitalization. Antibiotics may be used if there is bacterial superinfection. The usefulness of ribavirin or IVIG remains unproven.

Mumps

The mumps virus is an RNA virus in the paramyxovirus family, and humans are the only natural hosts. The virus is transmitted via respiratory droplets, saliva, and fomites. The incubation period ranges from 7-23 days, but is generally 14-18 days. The virus is readily isolated from saliva, urine, and CSF but is usually identified by reverse transcriptase PCR (RT-PCR) of buccal swabs. Diagnosis can also be made by observing an increasing antibody titer. Treatment is supportive. Respiratory droplet precautions should be taken for any individual within the incubation period or with active mumps.

The mumps vaccine was licensed in 1967 and recommended for routine childhood vaccination in 1977. A two-dose routine was begun in 1989. Since then, the incidence has declined to 0.1/100,000. Because of the high immunization coverage in the United States, there have been a couple of outbreaks of mumps since 2006, primarily among college students who received two doses of the vaccine. Two doses of the vaccine are considered 88% effective in preventing infection. Symptoms in breakthrough disease are usually mild.

Clinically, the virus causes a prodrome of fever, malaise, and myalgia, usually followed by salivary gland swelling within 24 hours and then resolving within 1 week. The parotitis is usually bilateral and more often involves the parotid glands than the submaxillary glands; the sublingual glands are involved only rarely. Orchitis may rarely develop in infancy, but is usually found only in postpubertal boys, and rarely causes sterility. Likewise, aseptic meningitis and pancreatitis are uncommon complications usually found in older children. CSF pleocytosis is common, even without CNS symptoms. Finally, infection may be asymptomatic or limited to respiratory symptoms. Therapy is nonspecific and supportive.

There is no evidence that mumps is either more common or more severe among pregnant women compared with nonpregnant women. Deaths are exceedingly rare. Siegel and Fuerst[241] found no significant increase in risk of low birth weight among infants born to mothers with mumps when studied prospectively. In contrast, there is a considerable increase in the risk of a first-trimester (but not a second- or third-trimester) abortion; the risk can be 27% among women with first-trimester mumps compared with a risk of 13% for uninfected, controls.

Although there have been multiple reports of birth anomalies after mumps in pregnancy, there is lack of proof of association, and studies using controls have failed to find any increase in congenital malformations. There has been considerable discussion about a possible association between gestational mumps and endocardial fibroelastosis in infants. Statistical evidence is, however, lacking, and the issue remains debatable. Pregnancy should be avoided for 28 days after the live-virus mumps vaccine has been given, although there are no reports of malformations in the infants of pregnant women who were inadvertently vaccinated.

Congenital and postnatal cases of mumps are exceedingly rare and nearly always subclinical or very mild. Mumps as a cause of parotitis or aseptic meningitis is rare; even mothers with active mumps rarely infect their infants. There have been a few reports of mumps pneumonia causing severe respiratory distress and death in infants. There have been no reports of nosocomial epidemics of mumps in the nursery; transmission within the hospital is possible, but rare.

Rubeola (Measles)

The measles virus, which is also a paramyxovirus, has an RNA core and a lipid envelope. Humans are the only natural hosts. There is only one serotype.

Transmission

Rubeola is the most infectious of the childhood viral illnesses. It is most commonly found in late winter and in spring in temperate climates. The virus is usually transmitted via respiratory droplets but may be airborne. Individuals are infectious from the onset of the prodrome (3-5 days before onset of the rash) until 4 days after the onset of exanthema. The incubation period is usually 10-12 days with a range of 7-21 days, but it is difficult to recognize the time of exposure because patients are infectious during the prodrome. There is a 5% primary vaccine failure rate in individuals who receive only a single dose of the vaccine; therefore, a two-dose vaccine schedule is now routinely recommended. Most cases and outbreaks of measles in the United States continue to occur in nonvaccinated individuals from other countries, and the virus is no longer considered endemic in the United States. However, there continue to be cases among infants less than 12 months of age and in women with waning immunity. This is of concern as the age of childbearing has increased during recent years.

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

There have also been calls for the development of a better vaccine.[212]

Transplacental, hematogenous transmission may also occur. In this instance, the fetus may have onset of disease virtually simultaneously with the mother, implying a large enough initial viral titer so as not to require further viral replication and viremia in the fetus.

Laboratory Diagnosis

Although the virus may be cultured from nasopharyngeal secretions, blood, urine, or other specimens, it is difficult to isolate, so most diagnoses are made through serology. A significant increase in IgG antibody concentration can be used if acute and convalescent sera are obtained, but most commonly, serum IgM titers are used. IgM may remain elevated for at least 1 month after the onset of the rash. RT-PCR can identify viral RNA in nasopharyngeal, blood, urine, and throat specimens. Measles is required to be reported to the CDC within 24 hours of suspicion of infection. Also, it is recommended that specimens be tested for rubella in any instances in which there is a suspicious rash with a negative IgM for measles.

Clinical Manifestations

Clinically, the prodrome of measles begins with fever, cough, coryza, and conjunctivitis (with photophobia) and ends with the development of myriad Koplik spots, tiny, red-ringed white spots on the buccal mucosa. The maculopapular exanthema then begins over the head and neck, spreading to the trunk and upper extremities, then to the lower extremities, and finally fading in the same order over 7-10 days.

Measles pneumonia, often complicated by bacterial superinfection, is the most serious complication and is the usual cause of death in children younger than 1 year of age. The mortality rate in the United States is, however, only 0.1%. Measles encephalitis, leading to drowsiness, seizures, and coma is uncommon but may occur in newborns and has a mortality rate of 11% and the potential for significant morbidity. Otitis, croup, purpura, myocarditis, pneumonia, diarrhea, and subacute sclerosing panencephalitis (SSPE) may also occur. SSPE is rarely seen now that there is widespread measles immunization. It is a degenerative CNS disease occurring 7-11 years after wild-type measles infection and leading to behavioral and intellectual deterioration and death.

Effects on the Pregnant Woman

The clinical course of rubeola in either a pregnant or postpartum woman is the same as in a nonpregnant woman. The earliest reports of overwhelming pneumonia (often associated with congestive heart failure) caused by infection during pregnancy were tempered by many others in which maternal morbidity and mortality rates were not increased. In the measles epidemic in the United States from 1988-1991, infection during pregnancy was again associated with more serious complications, such as pneumonia and hepatitis. The mortality rate was 3%-8%.

Effects on the Fetus

Measles during pregnancy does not seem to be teratogenic because few to no malformations have been reported among infants born to mothers infected during epidemics. There are reports of fetal losses with infection during pregnancy. Measles also seems to be responsible for premature delivery, and these deliveries occur during or shortly after the acute illness. Some infants have experienced growth restriction.

Perinatal Measles

Perinatal measles includes infections acquired transplacentally and infections acquired postnatally. Infection is assumed to be transplacental in origin if it occurs before 10 days of life. Most infants born to mothers with measles at or just before delivery remain uninfected, however, and become susceptible to disease later on. The disease itself may be mild but may also be fatal and is often associated with pneumonia, particularly among infants born prematurely. Postnatally acquired rubeola is usually mild with minimal mortality because the infants still have good levels of maternally derived antibody. Of great concern are reports of infants who were infected with measles before 2 years of age and went on to develop subacute sclerosing panencephalitis without the prolonged incubation period normally seen. They become ill with rapidly progressive disease before age 5 years.[60]

Therapy and Prevention

The therapy for measles is usually symptomatic. No specific antiviral therapy is available. Ribavirin is not licensed for use in the treatment of measles. Vitamin A is now recommended for all children with measles, regardless of where they live, because it is known that some infants and children in the United States have vitamin A deficiencies. Infected patients should be isolated, and the isolation should include precautions against air-borne transmission. Exposed, unimmunized individuals may be given measles vaccine within 72 hours of exposure because vaccination sometimes affords protection.

Nonimmunized pregnant women and newborns who have no history of rubeola and who are exposed should be given immunoglobulin, 0.25 mL/kg, preferably within 72 hours of exposure. The live attenuated measles vaccine should be administered to infants at 12-15 months of age, when maternally transferred antibodies are beginning to wane. The dose should be repeated at the time of school entry to ensure that individuals with waning immunity are protected. Vaccination given before a child reaches 12 months of age should not be counted toward the two doses. The dose should be repeated at age 12-15 months. The vaccine is contraindicated in pregnancy, and a vaccinated woman should be counseled not to become pregnant for 28 days. Susceptible women who deliver during the incubation period or with rubeola need to be isolated from their infants

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

if the infant is not born with a rash. Only immune staff and visitors may be allowed in the room. Immunoglobulin should be given to the mother and infant, preferably within 72 hours of exposure or immediately after delivery if no rash is present. If siblings at home have measles when a susceptible mother and infant are discharged, the mother and infant should receive immunoglobulin.

True prevention of rubeola lies in maintaining high immunity in the population. This maintenance of immunity necessitates second vaccine doses to young adults, and this is particularly important now that women are becoming pregnant at an older age, at which time their immunity may be waning, especially if they had received only a single vaccine in their childhood. It has also been shown that preterm infants born before 32 weeks' gestation have very low levels of transplacentally transferred antibody and are susceptible to infection by 6 months postnatally. Extremely preterm infants vaccinated at age 15 months, however, show an antibody response that is similar to that of term infants. It is particularly important that pediatricians continue to emphasize to their patients' families that MMR (mumps-measles-rubella) vaccination has *never* been shown to have a causal relationship to autism in numerous very large studies.

Respiratory Syncytial Virus

RSV is now recognized to be the most common respiratory pathogen in infants and children, infecting nearly all children by age 2 years and re-infecting about 50% of children each year. In the United States, about 2%-3% of infants younger than 1 year of age are admitted to the hospital with bronchiolitis. Most of the hospitalizations for RSV actually occur in the first 3 months of life. The mortality rate is roughly 2 per 100,000 infants. In infants who acquire the virus nosocomially, the mortality rate appears to be high, possibly because of underlying, pre-existing pulmonary disease.[280] RSV usually causes a mild upper respiratory infection but may be responsible for severe pneumonia and bronchiolitis, especially in high-risk populations. RSV usually occurs in the winter to early spring months in temperate climates, with a few relatively isolated infections during the rest of the year. This season overlaps that of other respiratory viral pathogens, so co-infections are common (≈20%). It is unclear how this affects disease severity. hMPV has roughly the same season as RSV and is increasingly being found to cause co-infection with RSV, now that it can be identified, but rhinovirus and adenovirus are also commonly found with RSV; influenza, parainfluenza, and newer coronaviruses (CoVs) are found less commonly. Infection is predominant in tropical climates during the rainy season.

RSV is a single-stranded, enveloped RNA paramyxovirus that can be divided into A and B types and divided further into subtypes. Both types may be present during epidemics, although one type is usually predominant. Although viral load seems to correlate with severity of infection, the subtype may also correlate with severity, clinical course, and outcome. Because there is a 50% sequence divergence between type A and type B, infection with one type does not protect against infection with the other. Also, immunity is incomplete, and re-infection commonly occurs among infants, children, and adults. The viral genome encodes for 10 different proteins. Two surface proteins are particularly important. The fusion (F) protein is similar in all strains. It is responsible for the cell fusion, or syncytium, for which the virus is named. The G glycoprotein is an attachment protein, and it is responsible for the strain differences. There is no neuraminidase or hemagglutinin activity.

A few infants are infected with RSV during the first 3 weeks of life when levels of transferred maternal neutralizing antibody are at their highest. Infants with the highest antibody concentrations may have less severe infections. The effect of antibody in breast milk is inconsistent.

Transmission

Transmission of RSV most commonly occurs by direct contact with infected secretions from the hands to the nose or the eye. Humans are the only source of the virus. Hospital staff members play a major role in the nosocomial spread of RSV via this mechanism, but this can be addressed effectively with good hand washing. Transmission may also occur via large droplets for less than 3 feet or via fomites because live virus may be isolated for a half hour from skin, 2 hours from gowns and gloves, and 1 day from glass or plastic. Viral shedding usually occurs over 3-8 days, but may last for weeks in high-risk or immunocompromised children. Incubation may be 2-8 days. Nursery epidemics of RSV bronchiolitis and pneumonia have been described, and some have occurred simultaneously with parainfluenza and rhinovirus. In such epidemics, one third of the nursery staff may be infected, and this may be the cause of much of the spread within the nursery.

Clinical Manifestations

Children in high-risk groups, particularly children who have pulmonary hypertension, heart disease, and lung disease, have a greater likelihood of severe disease, hospitalization, and mortality. Premature infants are particularly likely to require hospitalization if they have bronchopulmonary dysplasia but are still 10 times more likely to be rehospitalized compared with term infants with RSV, even if the premature infants do not have chronic lung disease. They are also more likely to be rehospitalized with RSV disease if they are born just before or during the RSV season or are discharged between September and December. Children with cyanotic or complex congenital heart disease or those who have Down syndrome are noted to have a higher mortality, and children who are immunocompromised or have cystic fibrosis are more likely to have severe disease, higher rates of mortality, and pneumonia. Long-term corticosteroid therapy seems to prolong the duration of viral shedding, and has not been shown to decrease the severity of disease. Finally, healthy infants younger than 6 weeks of age

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

are more likely to develop lower respiratory tract infection and require prolonged hospitalization and intensive care. More recently, it has been shown that infants with vitamin D deficiency at birth are more likely to be infected with RSV during infancy.[17]

There have been numerous studies to determine risk factors for infection, with a fair amount of variation in results. Because 3%-5% of all infected infants are born at 33-35 weeks' gestation, the cost of administering palivizumab to all is prohibitive, so treatment with palivizumab is usually limited to infants at higher risk. High-risk factors include preterm birth, chronic lung disease of prematurity, postnatal age less than 6-10 weeks at the onset of the RSV season, cyanotic and complex congenital heart disease, pulmonary hypertension, neurologic disease, and immunodeficiency. Most studies report increased risk from other children, but this is variously documented as having two or more siblings, having school-age siblings or preschool-age siblings, or attending daycare.

Some reports find disease associated with the adverse effects of maternal prenatal smoking on lung growth and development in the fetus, whereas others indicate a worse effect secondary to smoking within the home. In the United States, Hispanic infants and Native American and Alaskan infants are more likely to be hospitalized compared with infants in the general population. Other reported risk factors include small for gestational age (<10% birth weight), male gender, multiple birth, cystic fibrosis, and family history of eczema. Reports vary concerning a family history of asthma or the effects of breastfeeding.[25,81,217,231,232] Single-nucleotide polymorphisms, such as those in the promoter region of the gene for interleukin-8 (IL-8), have also been associated with chronic pulmonary morbidity after RSV infection in term infants.

Young infants with infection may be asymptomatic. When symptoms occur, they are often nonspecific or are mild upper respiratory symptoms, such as a clear nasal discharge, cough, and coryza. Some infants have presented with respiratory arrest secondary to apnea. Others have simply developed bradycardia. Dyspnea, cyanosis, pulmonary infiltrates on the chest radiograph, wheezing, respiratory decompensation, and fever all are well described. About two thirds of young children develop bronchiolitis, and one third develops pneumonia. Very premature infants may have minimal respiratory symptoms at first and may simply present with poor feeding, irritability or lethargy, and apnea. Fifty percent of infants may also have otitis media.

Although most febrile infants with bronchiolitis have a low risk of concurrent bacterial infection, the risk is significantly higher in preterm infants. Resch et al.[223] reported that 9.5% of infants born at less than 37 weeks' gestation had concurrent bacterial infections compared with 3.1% of term infants. Length of hospital stay was more than doubled. Infections tend to occur in the urinary tract and in the tracheal aspirate, and some occur in the bloodstream.

The diagnosis is usually made rapidly from anterior nasopharyngeal or nasal swabs by using immunofluorescence and enzyme immunoassay techniques, which have variable sensitivity, depending on the assay used and the amount of virus being shed. Culture of secretions is possible but results in delayed diagnosis and may miss co-infection with another virus. Infections with parainfluenza, rhinovirus, adenovirus, and hMPV may mimic RSV infection in an infant. Serologic testing is of limited value, particularly in young infants. PCR may also be used to detect antigen, but it detects RNA rather than DNA. The RNA may persist for weeks after the infection has subsided. Infections with parainfluenza, rhinovirus, adenovirus, and hMPV may mimic RSV infection in an infant.

Subsequent Respiratory Morbidity

Infection with RSV in term infants, particularly in the first year of life, is associated with chronic respiratory sequelae; this has been documented consistently in all clinical studies.[249,290] Term infants hospitalized for RSV bronchiolitis are three times as likely to have recurrent wheezing and 10 times more likely to need bronchodilators at age 10 years.[187] Likewise, the prevalence of asthma at 7½ years of age was 30% among infants hospitalized for RSV bronchiolitis, but only 3% in controls.[242] In contrast, the incidence of asthma was significantly less (50%) among 7-year-olds who had two or more uncomplicated upper respiratory infections, or "colds," before age 1 year.[109,134,249] RSV bronchiolitis in the first year of life increases the likelihood of recurrent wheezing but may or may not increase atopy.[102] The incidence of recurrent wheezing seemed to decrease in studies of longer duration, but there may be some abnormalities in pulmonary function even in adults. It is unclear why these infants are more predisposed to recurrent wheezing. Severe infection may be a marker for a genetic predisposition,[248] or RSV bronchiolitis may induce long-term changes in the lungs when infection occurs at a certain developmental stage.[134]

Preterm infants are more likely to be infected with RSV and develop more severe lower respiratory tract disease compared with term infants. Preterm infants, particularly if they develop chronic lung disease of prematurity, have smaller airways, which are more likely to become obstructed with mucus, necrotic tissue, and edema. They are also more likely to have immature immunity and lack significant maternal transfer of antibodies. Likewise, term infants with abnormal pulmonary function resulting in smaller-size airways are predisposed to developing severe lower respiratory tract infection with RSV. Similarly, Broughton et al.[32] showed that symptomatic RSV infections were more likely to develop in preterm infants with increased respiratory resistance at discharge from the NICU at 36 weeks' corrected gestational age. On follow-up at 1 year of age, preterm infants who had RSV infections have significantly higher airway resistance, but similar lung volume, as in controls.[33] Finally, preterm infants treated with palivizumab who were not hospitalized for RSV were less likely to develop recurrent wheezing (13%) compared with all preterm infants who did not receive palivizumab (26%) and compared with

untreated preterm infants who were also not hospitalized for RSV (23%).[244]

Prophylaxis and Therapy

The primary treatment for RSV infection is supportive care and includes oxygen therapy to correct hypoxemia and hydration. Care must be taken to prevent hyponatremia because infants with bronchiolitis have elevated levels of antidiuretic hormone. Bronchodilators have frequently been used but are not recommended because they do not improve oxygenation or reduce the need for hospital admission, the time to disease resolution, or the length of hospital stay. Likewise, nebulized epinephrine has not been shown to be beneficial. Corticosteroids are not recommended for bronchiolitis in infants and may cause prolonged shedding of virus. Palivizumab is also not recommended for treatment of infection because it has not shown any efficacy. Nebulized hypertonic saline may be of benefit. Antimicrobial therapy is not indicated for bronchiolitis or pneumonia caused by RSV unless there is a concurrent bacterial infection. They may be considered for otitis media. Chest physiotherapy has not been shown to be of benefit either. Nasal continuous positive airway pressure (CPAP) may improve ventilation and oxygenation, as may high flow nasal cannula therapy with heated humidified air. Intubation may be needed for the most severe respiratory failure.

A Cochrane review of 12 trials lacked the power to provide firm conclusions regarding the use of ribavirin.[267] Ribavirin may cause a small improvement in oxygenation, but the evidence does not support a decrease in intensive care unit (ICU) admission or length of stay or the need for ventilation. Weighing against these findings are the cost of treatment and potential toxic risks to the patient and staff, particularly because it is given as an aerosol, so ribavirin use is extremely limited or not used at all. Inhaled nitric oxide and extracorporeal membrane oxygenation have been used for respiratory failure. Most infants do not need antibiotic coverage; possible exceptions are infants needing intensive care and preterm infants.

Infected infants should be isolated with contact precautions. Use of gowns and gloves in addition to masks and goggles has decreased hospital spread. Staff members should not care for infected and uninfected infants simultaneously. Education of staff and family must include hand washing before and after patient care. Staff and family should not be in the hospital when they have respiratory infections. During the RSV season, sibling visitation should be eliminated. In the event of an epidemic, there should be laboratory screening for RSV infection and segregation of infected and uninfected patients and staff. There are no data on the use of RSV immunoglobulin in an epidemic, although there are many anecdotal reports of its use in NICU epidemics. Antibiotics are not routinely needed, except in cases of bacterial co-infections or, sometimes, concomitant otitis.

The primary defense against RSV infection should be avoidance of high-risk settings. The families of all high-risk infants should be instructed in avoidance behavior and careful hand washing. Whenever possible, high-risk infants should not be placed in high-risk situations, such as daycare or other situations where infected children are likely to be present. Infants should never be exposed to tobacco smoke. This is in the control of the family and is much less costly than palivizumab.

RSV IVIG made from donors with high serum titers of neutralizing antibody to RSV was licensed in 1996 by the FDA for prophylaxis of severe lower respiratory tract disease in children younger than 2 years of age at high risk because of bronchopulmonary dysplasia or preterm birth at 35 weeks' gestation or less. It has been replaced by palivizumab and is no longer available.

Palivizumab, a humanized mouse monoclonal IgG_1 antibody, was licensed by the FDA in 1998. The product consists of 95% human amino acids and 5% mouse amino acids. The mouse sequence for antigen binding was grafted to gene segments coding for human IgG; this prevents an antimouse reaction on repeated use. It is active against the A and B viral strains. The antibody binds to the F protein of the virus, preventing its conformational change on the viral surface and, thus, preventing the fusion of the RSV viral envelope with the plasma membrane of the respiratory tract epithelial cell, rendering the virus incapable of entering the cell to replicate. It is given intramuscularly every 30 days for a total of five doses at a dose of 15 mg/kg. The first dose should be given at the onset of the RSV season. Five doses in a season provide adequate serum concentration to cover 6 months in a season. Efficacy is similar to that of RSV IVIG (a 55% reduction in hospitalizations because of RSV in high-risk infants),[110] but it does not prevent otitis media or hospitalizations for other respiratory viruses. It is much easier to administer.[95] Home-based programs for administration seem to improve compliance with regular, 30-day administration and decrease the risk of other exposures in the doctor's office or clinic. No increase in adverse effects has been observed in comparison with controls. Also, palivizumab does not interfere with other vaccinations. It may cause an allergic reaction. If so, no further doses should be given. It is not effective and not approved for the treatment of RSV infections. A follow-up study of preterm infants in their second year of life who had received palivizumab in their first year of life and had not been hospitalized with an RSV lower respiratory tract infection showed a low rate of airway morbidity, recurrent wheezing, and RSV hospitalization in their second season.[77] The AAP Committee on Infectious Diseases in 2014 analyzed the cost-benefit data and concluded that the small decrease in wheezing provided by palivizumab did not justify the costs of the program and severely curtailed the recommended indications for its use.[52] This issue remains extremely controversial.[290]

A trial of palivizumab for infants with acyanotic and cyanotic congenital heart disease showed a 45% reduction in RSV hospitalizations (9.7% versus 5.3%) with the larger decrease in infants with acyanotic lesions.[78] Adverse events and deaths were similar in treated infants and in infants who received a placebo. Also, a 58% reduction in palivizumab

serum concentration was noted after cardiopulmonary bypass, so the antibody needs to be given when off bypass.

Among infants with less than 33 weeks' gestation, the rate of rehospitalization was at least 13.4% for lower respiratory disease because of RSV when the infants did not receive any RSV prophylaxis. In addition, 11% of the infants were rehospitalized twice in 1 year for RSV.

Current recommendations of the AAP Committee on Infectious Diseases for the use of palivizumab for prophylaxis[52] are as follows:

Eligibility Criteria for Prophylaxis With Palivizumab

A. *Infants with chronic lung disease (CLD) of prematurity*
   1. Preterm infants with a gestational age less than 32 weeks, 0 days, who need greater than 21% oxygen for at least the first 28 days of life during the RSV season in their first year of life.
   2. These preterm infants may continue to receive prophylaxis during their second year of life if they continue to require medical support (steroid therapy, diuretic therapy, or supplemental oxygen) during the 6 months prior to the onset of the RSV season.

B. *Infants with congenital heart disease (CHD)*
   1. Children with hemodynamically significant disease who are receiving medication to control congestive heart failure and will require cardiac surgery, and children with moderate to severe pulmonary hypertension who are in the first year of life and within 12 months of the onset of the RSV season.
   2. Infants with cyanotic heart disease in the first year of life have an unknown benefit from palivizumab, and the decision to administer prophylaxis needs to be made in consultation with the pediatric cardiologist.
   3. Infants younger than 2 years who undergo cardiac transplantation during the RSV season.
   4. Children receiving prophylaxis with palivizumab and who continue to receive prophylaxis after a surgical procedure involving cardiopulmonary bypass, or who are at the conclusion of extracorporeal membrane oxygenation (ECMO), should receive a postoperative dose of 15 mg/kg palivizumab because the procedure causes a mean decrease of serum concentration of 58%.
   5. Infants who do not qualify for palivizumab prophylaxis include:
      a. Infants and children with hemodynamically insignificant heart disease (secundum atrial septal defect [ASD], small ventricular septal defect [VSD], pulmonic stenosis, uncomplicated aortic stenosis, mild coarctation of the aorta, and patent ductus arteriosus [PDA]).
      b. Infants with lesions corrected by surgery, unless they continue to need medication for congestive heart failure.
      c. Infants with mild cardiomyopathy not receiving medical therapy for the condition.

C. *Preterm infants without CLD or CHD*
   1. Preterm infants born before 29 weeks, 0 days, who are less than 12 months of age at the onset of the RSV season.
   2. Preterm infants born before 29 weeks, 0 days, who are born during the RSV season need less than the full 5-monthly doses.
   3. Infants born after 29 weeks, 0 days, may qualify to receive prophylaxis on the basis of CHD or CLD or other condition.

D. *Children with anatomic pulmonary abnormalities or neuromuscular disorder*
   1. No prospective data for risk are available.
   2. Infants with neuromuscular disease or congenital anomaly that impairs the ability to clear secretions from the upper airway because of ineffective cough do have increased risk of prolonged hospitalization for lower respiratory tract infection and may be considered for prophylaxis in the first year of life.

E. *Immunocompromised children*
   1. No prospective data regarding efficacy of prophylaxis for RSV exist, but children receiving chemotherapy or who are immunocompromised may develop severe or fatal RSV disease.
   2. Prophylaxis may be considered for immunocompromised children during the first 24 months of life.

F. *Children with Down syndrome*
   1. There appears to be a slight increase in hospitalization rates in children with Down syndrome, but not enough to justify prophylaxis on the basis of Down syndrome alone.
   2. Prophylaxis may be given if there is qualifying CHD, CLD, airway clearance issues, or prematurity less than 29 weeks, 0 days.

G. *Children with cystic fibrosis*
   1. Children with cystic fibrosis with clinical evidence of CLD and/or nutritional compromise in the first year of life.
   2. Children with cystic fibrosis in the second year of life with manifestations of severe lung disease or weight for length less than the 10th percentile.

H. *Breakthrough RSV hospitalization*
   1. Palivizumab prophylaxis should be discontinued in a child who experiences a breakthrough RSV hospitalization because the likelihood of a second RSV hospitalization is less than 0.5%.

Efforts toward development of a vaccine for active prevention of disease have been hampered by the results of the trial of the formalin-inactivated RSV vaccine, in which vaccinated infants had more severe disease and were more likely to die compared with nonvaccinated infants, possibly because the vaccine interfered with the secretory and neutralizing antibody response to the virus, allowing more active replication. Currently, there is significant interest in developing a maternal vaccine that would lead to transfer of antibody to the fetus. However, preterm infants would

miss the majority of antibody transfer and might not benefit.

Human Metapneumovirus

Discovered in Holland in 2001, hMPV is an enveloped, negative-sense RNA virus of the Paramyxoviridae family, in the same subfamily with and sharing many clinical characteristics of RSV. It is most closely related to RSV in that both viruses encode for three envelope glycoproteins—the F (fusion), G (attachment), and SH (short hydrophobic) proteins—and both viruses form a syncytium with infected cells. There are four major genotypes: A1, A2, B1, and B2. All four genotypes circulate simultaneously throughout the season, but in varying proportions. It is unclear what effect this simultaneous circulation has on immunity and whether certain genotypes are more virulent than others. hMPV is difficult to grow in the laboratory and has escaped detection but can now be identified through RT-PCR.

A large proportion of previously unidentifiable causes of respiratory tract disease in children and adults have been attributed to hMPV, and it is associated with upper and lower tract disease. Virtually all children are infected by age 5 years,[15] and infection may be recurrent throughout life. hMPV seems to be second only to RSV as a cause of bronchiolitis in children younger than 1-2 years of age.[37] Although RSV is most common in infants younger than 6 months of age, hMPV is more common in infants 6-12 months of age.[90,191] Protection against infection in the first 6 months may reflect the presence of maternal-specific antibody. hMPV occurs in epidemics, mostly in the winter and spring months, and overlaps seasonally with RSV. It may cause a co-infection with other respiratory viruses.[152] During epidemics, bronchiolitis may be caused by RSV or hMPV, alone or together, and infections by various other respiratory viral pathogens have been reported as co-infections. Under these circumstances, disease severity has variably been reported as more severe or unchanged. hMPV is also present in smaller numbers year round. The virus is worldwide in distribution. Humans are the only known source of infection. It is not clear whether the viral load correlates with severity of the disease.

In one study of nasal wash specimens obtained over a 25-year period from newborns to 5-year-olds, hMPV was responsible for 20% of previously virus-negative lower respiratory tract infections, suggesting that 12% of lower respiratory tract infections in these children (newborns to 5-year-olds) were caused by hMPV.[287] In this cohort, the mean age of infected children was 11.6 months. Three fourths of all infections occurred in the first year of life. Infection primarily occurred between December and April and resulted in a hospitalization rate of 2%.

Infection with hMPV seems to be slightly less severe than that with RSV. The disease spectrum has included upper respiratory tract infection (15%), bronchiolitis (59%), croup (18%), pneumonia (8%), and asthma exacerbation (14%). Asymptomatic infection may occur, particularly in healthy children or adults, and most healthy, symptomatic children have only mild or moderate infection. Others present with rhinitis, mild fever, a wet cough, or wheezing. Otitis has also been reported.[222] Increasingly, studies are indicating that severe prematurity (birth ≤32 weeks' gestational age) and chronic lung disease are significant risk factors for the need for hospitalization, ICU admission, and death among children under 5 years of age with lower respiratory tract infections. These children have higher clinical severity scores, need for supplemental oxygen, and a doubled duration of hospitalization.[72,173,194] Because formerly preterm infants often developed hypoxia and children with asthma did not have an increased length of hospitalization, it is hypothesized that this may have resulted from further alveolar damage rather than increased airway reactivity. Infection is believed to occur via contact with contaminated secretions, and the incubation period apparently is 3-5 days. The duration of viral shedding is unclear but may be prolonged in the face of immunodeficiency. Infection may be recurrent at all ages but is usually mild or asymptomatic. A few children may require hospitalization at a lower rate with hMPV infection compared with RSV infection, but similar to the hospitalization rates of influenza or parainfluenza.

Hospitalized patients should be isolated with contact precautions and an emphasis on careful hand washing. Covering the mouth and nose while coughing or sneezing is important. Treatment is supportive. Respiratory monitoring is important and may indicate a need for oxygen or mechanical ventilation. Bacterial superinfection seems to be unusual.

Human Immunodeficiency Virus

Epidemiology

Data from the CDC for the 2010-2014 period showed a decline in the rates of HIV in both male and female adolescents and adults in the United States. In 2015, 19% of all adults and adolescents diagnosed with HIV infection were women. Even though this represents a decline of 5% in this gender group, it is still a significant problem.[43] Most women newly diagnosed with HIV infection acquired it through heterosexual contact. Rates of HIV positivity are disproportionately high among women from minority populations. Despite a decline in the rates of newly diagnosed HIV infection in African American women (by 42% from 2005 to 2014), the rates are still high compared with those of other race groups. In 2015, the CDC reported that the incidence of new HIV infections in African American women was 26.2 per 100,000 compared with 5.3 and 1.6 per 100,000 in Hispanic and white women, respectively.[43] In 2015, according to CDC statistics, a total of 120 children younger than 13 years of age were diagnosed with HIV in the United States; of these cases, 86 had perinatally acquired infection.[43]

In contrast to most adult HIV infections in the United States, that in the developing world is contracted through

heterosexual means. The incidence is highest in east and central sub-Saharan Africa, Southeast Asia, and parts of South America. In these areas, most HIV-positive patients are middle-aged adults, with the prevalence among childbearing women in some urban centers exceeding 30%. The debilitation and fatality resulting from AIDS have led to the depletion of the vital workforce in tenuous economies and the orphaning of numerous uninfected offspring.

Currently, virtually all HIV-infected infants are found to have acquired the virus from an infected mother. Consequently, most mothers of infected infants in the United States fall into a high-risk category—IV drug use or sexual activity with a man at high risk (bisexuality or IV drug use). Infected children demonstrate a socioeconomic pattern nearly identical to that seen in HIV-1–infected women, and greater than 85% are from minority populations. Reflecting a medical success story of remarkable proportions, the incidence of perinatal HIV in the United States decreased by nearly 80% in the latter half of the 1990s. In the first decade of the 2000s, only 100-200 cases of perinatally acquired HIV infection per year were reported to the CDC. Much of this decline was the result of increased voluntary HIV testing during pregnancy and the widespread application of intragestational prophylaxis with antiretroviral (ARV) drugs. This success has extended to developing countries as well. The World Health Organization (WHO) reported a decline in perinatal HIV from 28% in 2009 to 14% in 2014 in 21 countries where a global plan of transmission reduction had been introduced.[196,263] The goal for the developing world, however, has not been reached, which is to achieve a transmission rate of 5% or less in breastfeeding populations and less than 2% in non-breastfeeding populations.[74]

Pathogenesis

HIV is an RNA-containing retrovirus with an approximately 9.7-kb genome. The virus infects cells contain the surface molecule CD4+, most notably helper T lymphocytes and macrophages. An infected adult initially exhibits a robust immune response to the virus, with the appearance of HIV-specific antibodies and CD8+ cytotoxic T lymphocytes. After an initial mononucleosis-like syndrome, adults experience a prolonged period of clinical latency, characterized by the establishment of stable, low-level plasma viral titers (referred to as the *set point*) and near-normal CD4+ T-lymphocyte counts. During this period, the number of target cells destroyed by HIV is balanced by CD4+ cell repletion. This state may last for years.

Despite the healthy appearance of patients with latent infection, HIV actively replicates in lymph nodes and circulating CD4+ cells and ultimately overwhelms the host, leading to increasing concentration of virus in plasma and tissues, clinical deterioration, and CD4+ cell depletion. This last phenomenon results in profound disruption of the immune system because CD4+ T cells coordinate many aspects of immunity. Thereafter, the host is placed at risk for acquiring infections with organisms that normally possess low pathogenicity (opportunistic infections) and AIDS-related cancers. The strongest predictor of progression of disease in adults is the concentration of plasma-borne virus, commonly referred to as the *viral load*. The viral load is measured by a quantitative RT-PCR test, which is widely available commercially. The number of CD4+ T cells also is an additional independent predictor of disease progression in adults.

Generally, untreated children with perinatal HIV-1 infection experience more rapidly progressive disease compared with adults. Similar to other intracellular pathogens, it is likely that HIV infection of the fetus early in gestation, when natural killer (NK) and T cells are low in number and immature in function, results in particularly severe disease. Even in a full-term newborn, however, T cells possess multiple functional deficiencies that render the host particularly susceptible to pathogens, such as HIV. Early HIV-specific cytotoxic T-cell lymphocyte responses, which are crucial for the initial control of HIV infection in adults, frequently are sluggish or absent in infected newborns. There is evidence that the fetal and newborn immune cells may provide better substrates for HIV infection or replication compared with mature cells because neonatal macrophages and memory T cells support HIV replication better than cells derived from adults. Consequently, infected newborns typically show very high plasma viral loads early in life, frequently registering hundreds of thousands to millions of viral RNA copies per millimeter of plasma by 4 weeks of age. Infants usually are unable to establish a set point, reflecting poor early control of viral replication, and, as a result, show unmoderated high viral loads throughout early childhood.[238]

As in adults, the strongest predictor of disease progression in perinatally acquired HIV-1 is the plasma-borne viral titer. High viral loads in infancy presage major manifestations of HIV and death early in life. Several factors other than viral load also have been associated with disease progression in perinatally acquired HIV-1. Thymic dysfunction, manifested by the early depletion of CD4 and CD8 T-cell populations, occurs in a small percentage of HIV-1–infected infants and is strongly associated with early severe disease. Co-infections with other pathogens in early life may detrimentally affect disease progression further. CMV in particular, long suspected of enhancing HIV-1 replication in adults through transactivating transcription factors, results in higher mean titers of HIV-1 and the early appearance of HIV-1–associated signs and symptoms and death in infants infected with CMV and HIV-1.

Mother-to-child transmission occurs in approximately 25%-30% of infants born to mothers who have not taken antiviral medications during their pregnancy. Intrauterine transmission has been shown directly by detection of virus in aborted fetal tissue. Most infants are negative for HIV immediately after birth, however, and become positive within the first several weeks after delivery, supporting the contention that most perinatal transmission occurs near the time of delivery or as the infant traverses the birth canal. Cervical secretions harbor HIV in concentrations

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

proportionate to concentrations in the bloodstream. Infection at or near the time of delivery, when the mucous membranes of the infant are exposed to infected maternal secretions and blood, is assumed to be the principal mode of perinatal acquisition of HIV.

The primary factor that places an infant at risk for perinatal HIV transmission seems to be the degree of maternal viremia during pregnancy and its correlates—severity of maternal clinical illness and CD4 cell depletion.[89] In several studies, the risk of transmission was proportionate to the maternal viral load. No level of maternal viremia is absolutely safe for the fetus, and transmission occasionally has been reported even when the maternal viral load has been undetectable. Nevertheless, vertical transmission rates approaching zero have been associated with viral loads smaller than 500-1000 HIV RNA copies per milliliter of plasma. Other risk factors for perinatal transmission are less well established. The presence of chorioamnionitis and the occurrence of premature rupture of membranes have been suggested as risks for perinatal HIV transmission. Instrumentation during delivery, with the associated exposure of the newborn to infected maternal blood and cervical secretions, also increases the risk of transmission. There also has been speculation that some viral genotypes may be more likely to cross from mother to child than others.

As transmission rates decline, a new population—the HIV-exposed but uninfected infant— has emerged. These infants have been found to have higher morbidity and mortality rates compared with the HIV-unexposed infants. Studies in developing countries have shown that lower respiratory tract infections and oral thrush are more common in this population group compared with their uninfected counterparts. Opportunistic infections, such as *Pneumocystis jiroveci* infection, which is rare in the non-immunocompromised populations, have also been more often described in these children.[74] Immunologically, these children have been found to differ from the rest of the population. CD4 and CD8 counts are lower, and cell-mediated immunity is altered, leading to hyper- or hypo-responses to specific antigens. Neutrophil counts are also decreased, and in the first few weeks of life, there is in innate cytokine production. However, vaccine responses are adequate and sustained in this population. It is hypothesized that exposure to the HIV virus in utero in addition to exposure to ARV drugs may lead to a "hyper-reactive" uterine environment that primes the immune system of these infants.[2]

HIV infection from mother to child also may occur though the ingestion of contaminated breast milk. Breast milk contains the virus in macrophages and in the cell free fraction, and the viral concentration in breast milk correlates with the concentration measured in the bloodstream. In the United States, where alternative infant nutrition is available, breastfeeding is contraindicated in HIV-infected mothers, even in those taking combination ARV therapy (ART). However, in the developing world, the high incidence of mother-to-child transmission of HIV attributable to breastfeeding is estimated to be 4%-22%. Although the risk of breast milk–related late postnatal transmission is highest in the first 6 months post partum, transmission occurs throughout the duration of breast milk exposure.

Breast milk–transmitted HIV is believed to enter the infant either through the gastrointestinal mucosa or possibly through tonsillar lymphoid tissue. Several factors that increase the risk of breast milk transmission, including the duration of breastfeeding, severity of infection in the mother, presence of breast lesions, and inflammation of the infant's gastrointestinal mucosa (particularly by *Candida* infection), have been identified. Several immunologic and chemical factors in breast milk have been found to inhibit HIV growth in vitro, and the relative concentrations of these factors in a particular specimen may influence the risk of transmission.

For resource-poor countries, where breastfeeding is the norm and formula feeding is not readily available, and possibly unsafe because of lack of clean water, the WHO has issued recommendations to prevent transmission to infants through breastfeeding.[288] It is a fact that children born to HIV-infected mothers have a higher risk of transmission through breastfeeding, but have a lower rate of hospitalizations for diarrheal illnesses and other infections in resource-poor areas.[133] Prospective studies have shown that the use of ART starting early in pregnancy is associated with lower transmission rates through breastfeeding as well as the use of ARV drugs (i.e., nevirapine) in the infant during the breastfeeding period in certain scenarios.[46,120,205] Mothers of uninfected infants in resource-poor countries who breastfeed are advised to not introduce any other form of feeding in the first 6 months so as to prevent gastrointestinal irritation from formula and possible transmission of the virus.[288]

Care of the Mother and Prevention of Vertical Transmission

Advanced HIV infection in the mother can adversely affect the outcome of the pregnancy, even if the infant is not infected. Studies performed in Africa have indicated that women with HIV infection bear infants who are smaller for gestational age and more premature compared with women without HIV infection. Perinatal mortality also is increased. Infants born to asymptomatically infected women have negligible effects. These data suggest that covariate factors in advanced HIV disease, particularly malnutrition, secondary and coexisting infections, and illicit drug and alcohol use, are the most important factors mediating the immediate health of the newborn and must be addressed appropriately during the obstetric care of the mother. All women should be placed on multivitamin supplements, which should be continued after gestation.

Care of the Mother and Infant in Developed Countries

Intragestational and postgestational administration of ARV drugs is extremely effective in preventing vertical transmission of HIV-1 and has become the standard of care in

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

the developed world.[175] In a landmark prospective, multicenter, randomized trial conducted in the early 1990s (PACTG 076), zidovudine prophylaxis resulted in reduction of vertical transmission, from 25.5%-8.3%.[53] The regimen employed in this study included three phases: (1) a maternal oral dose of 100 mg five times a day beginning between 14 and 34 weeks of gestation; (2) intrapartum IV zidovudine at 2 mg/kg of body weight over the first hour, followed by 1 mg/kg hourly until delivery; and (3) oral dosing of zidovudine at 2 mg/kg every 6 hours for 6 weeks for the infant. In response to the success of this study, the CDC recommended wide application of the PACTG 076 protocol to limit vertical transmission of HIV in the United States. Subsequent experience has indicated that in some populations, intrapartum and postpartum use of zidovudine could result in a 5% or less transmission rate.

Even as public health recommendations for this regimen were being established, significant changes in ARV strategies in HIV-infected adults were evolving and produced dramatic reductions in plasma-borne viral loads and AIDS-related deaths. These changes included the administration of multidrug regimens (rather than monotherapy) and the early institution of ARV medication based primarily on viral load rather than CD4-T cell depletion or the presence of symptoms. As a result, by the late 1990s, many women with HIV infection entering pregnancy already were taking multidrug regimens (formerly known as *highly active antiretroviral therapy* [HAART]) comprising various combinations of nucleoside reverse transcriptase inhibitors (sometimes, but not always, including zidovudine), non-nucleoside reverse transcriptase inhibitors, and protease inhibitors to maintain their own health.

The basic evaluation of pregnant women with HIV-infection should include, among others, the following:

1. Current and previous CD4 lymphocyte counts and HIV RNA viral load in copies/mL.
2. Documentation of any previous HIV-related illness to determine if the patient needs prophylaxis against opportunistic organisms.
3. Screening for co-infections, such as hepatitis B and C virus infections and tuberculosis, and for sexually transmitted diseases, such as gonorrhea and chlamydia. Review of immunization status, including tetanus, diphtheria, acellular pertussis (Tdap) immunization.
4. History of prior and current ART, resistance studies, and side effects of the regimens.

In addition, care of the pregnant patient with HIV infection ideally should be multidisciplinary, with constant communication between the primary caregiver for HIV treatment, the obstetrician, social workers, and other services to ensure patient adherence to the ARV regimen. It is also advisable to involve the pediatrician who will care for the infant to plan for prophylaxis for the infant and to ensure follow-up testing and evaluations.

In 2012, the results of a randomized trial studying three different regimens—zidovudine monotherapy for 6 weeks, 6 weeks zidovudine plus 3 doses of nevirapine in the first 8 days of life, and 6 weeks of zidovudine plus nelfinavir and lamivudine (3TC) for 2 weeks—in the prevention of HIV transmission to neonates whose mothers did not receive ARV during pregnancy were published. The trial (NICHD-HPTN 040/PACTG 043) showed that combination therapy was superior to monotherapy in preventing intrapartum HIV transmission.[185] Following the publication of this trial, the Department of Health and Human Services updated its recommendations to reflect the results of this and other important recent trials.[197]

As data emerge from clinical trials, guidelines are being updated regularly. Therefore, it is recommended that these guidelines be consulted for the most up-to-date information. The full text of these guidelines and updated information are available at http://AIDSinfo.nih.gov.

Some key points from these recommendations (last updated November 14, 2017) can be summarized as follows:

Maternal Antepartum/Intrapartum Care

1. All pregnant, HIV-infected women should receive combination ARV drugs ante partum, starting as early as possible during pregnancy *regardless* of their HIV RNA levels and CD4 T lymphocyte counts. A French cohort study, which looked at factors associated with mother-to-child transmission of HIV despite low viral load at the time of delivery, showed that women who transmitted the virus to their offspring were less likely to have had viral loads less than 500 copies/mL and were also less likely to have received ART at the time of becoming pregnant and early in the pregnancy.[261] It is also known that mother-to-child transmission is possible even with low RNA levels and in mothers on ART. There have been reports of discordance between the viral loads in blood and those in the genital tract; women with undetectable levels in blood have been found to shed the virus in the genital tract.[197,275]
2. Resistance testing is indicated in women whose RNA levels are above the resistance testing threshold (>500-1000 copies/mL) before starting or modifying ARV drug regimens in patients with known HIV infection and those diagnosed early in pregnancy. However, if HIV infection is diagnosed late in pregnancy, therapy should be started even if the results of resistance testing are not available. In all pregnant patients on ARV, the importance of strict adherence to the ARV regimen should be strongly emphasized.
3. IV zidovudine continuous infusion (2 mg/kg IV over 1 hour followed by continuous infusion of 1 mg/kg until delivery) is *recommended* for HIV-infected mothers with **viral loads greater than 1000 copies/mL** near delivery, those in whom viral loads are unavailable near the time of delivery, or in women who did not receive any antepartum ART regardless of the antepartum regimen or mode of delivery.

   Women who are on ART and have well-controlled **viral loads less than 50 copies/mL** consistently during late pregnancy and near delivery and in whom compliance

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

has not been a problem, *do not need* IV zidovudine and should continue their drug regimen orally on schedule as much as possible during labor and even before a scheduled cesarean section. This can be accomplished by taking the medication with small sips of water.

For women with **viral loads between 50-999 copies/mL**, the current available data are not sufficient to determine whether IV zidovudine offers additional protection to the infant. Some studies have shown lower maternal-to-fetal transmission in women with viral loads below 50 copies/mL as compared with those with 50-1000 copies/mL; 0.25 versus 2%.[181] Experts, therefore, recommend that IV zidovudine be *considered* in this group of patients, but this is left to the clinical judgment of the provider.

In women who are scheduled for a cesarean section and require IV zidovudine, it should be started 3 hours before the surgery (1-hour loading dose and 2-hour continuous infusion). For emergency cesarean section, the aim is to try to complete the 1-hour loading dose before proceeding with the cesarean section.

4. Expedited testing for HIV should be performed in all mothers without documentation of their HIV status unless they "opt out." Women who are considered to be at increased risk for acquiring HIV (partner with HIV infection, multiple sexual partners during pregnancy, illicit drug use, exchange of sex for money, or living in an area with high incidence of HIV infection in childbearing age) should also be tested at the time of labor, even if testing earlier in pregnancy yielded negative results. Testing should be done with HIV-1 and HIV-2 antigen/antibody combination immunoassay and an HIV RNA assay. These testing modalities should be available in institutions that offer maternity and neonatal intensive care and nursery services. For women who test positive, IV zidovudine should be started immediately.

Infant Management (Summarized in Table 50.8)

1. Depending on maternal risk, infants may receive prophylaxis, empiric HIV therapy, or HIV therapy:
   - *HIV prophylaxis:* This is defined as the administration of one or more ARV drugs to an infant without confirmed HIV to reduce the risk of maternal fetal transmission.
   - *HIV empirical therapy:* This refers to administration of three-drug combination ARV regimen to newborns with high risk of acquiring HIV. This serves as therapy

TABLE 50.8 Management of Neonates According to HIV Risk

Situation	• Mother received ART during pregnancy *and* • No compliance concerns *and* • Sustained viral suppression near delivery	• Mother did not receive antepartum or intrapartum ARV drugs • Mother received only intrapartum ARV drugs • Mothers with detectable viral loads near delivery despite receiving antepartum and intrapartum drugs (especially vaginal deliveries) • Mothers with acute HIV infection during pregnancy or breastfeeding	Presumed newborn HIV exposure: • Mother with unknown HIV status who tests positive at delivery or post-partum • Newborn with positive HIV antibody test	Newborn with confirmed HIV • Confirmed positive HIV virologic testing/NAT
Risk	Low risk of perinatal HIV transmission	Higher risk of perinatal transmission	Higher risk of perinatal transmission	Confirmed HIV
Newborn Management	Prophylaxis with 4 weeks of zidovudine	Combination prophylaxis with 6 weeks of ZDV plus 3 doses of NVP (at prophylactic dose) *Or* Empiric HIV therapy with ZDV, 3TC, and NVP (at treatment dose)	Combination prophylaxis with 6 weeks of ZDV plus 3 doses of NVP (at prophylactic dose) *Or* Empiric HIV therapy with ZDV, 3TC, and NVP (at treatment dose) Discontinue therapy if supplemental test confirm mother is not infected with HIV	3 drug combination ARV therapy: • Start therapy as soon as possible without delaying to wait for confirmatory NAT test result

ART, Antiretroviral therapy; ARV, antiretroviral; HIV, human immunodeficiency virus; NAT, nucleic acid test; NVP, nevirapine; ZDV, zidovudine.

for those who are later confirmed to be HIV infected and as prophylaxis for those exposed to the virus in utero, during delivery, or via breastfeeding but who do not acquire the virus.

- *HIV therapy:* This refers to administration of three-drug combination ART to newborns with confirmed HIV infection.

2. *Prophylaxis with zidovudine alone:* A 4-week course (as opposed to 6 weeks) can be considered *if* the mother received and absolutely adhered to standard combination ART with consistent viral load suppression during pregnancy and delivery. Data for this recommendation come from a 10-year observational cohort study performed in Ireland, where, since 1999, there was a countrywide adoption of a 4-week neonatal prophylaxis regimen for prevention of mother-to-child HIV transmission. Their regimen included monotherapy with zidovudine if the mother had received more than 4 weeks of ART, had achieved viral suppression, had been adherent to her therapy, and had rupture of membranes less than 12 hours before delivery. Otherwise, they would receive combination therapy with zidovudine, nevirapine (two doses), and lamivudine 3TC. In addition, all mothers received intrapartum zidovudine. In 916 children with known outcome (HIV PCR results known at ≥6 weeks), the vertical transmission rate was 1.09%, and if the analysis was restricted to those whose mothers received at least 4 weeks of ART, the vertical transmission rate was 0.4%.[79] The prophylaxis should be started within 6-12 hours of delivery at doses appropriate for gestational age (Table 50.9).
3. *Combination ARV prophylaxis:* Combination of zidovudine for 6 weeks started within 6-12 hours of delivery plus three doses of nevirapine (nevirapine first dose given within 48 hours of birth, second dose 48 hours after first dose, and third dose at 96 hours after second dose) at

TABLE 50.9 Dosing of Antiretroviral for the HIV-Exposed Infant by Gestational Age*

Antiretroviral	Dose†	Dose Adjustment	Duration
Zidovudine	<30 weeks' gestation at birth 2 mg/kg/dose orally twice daily‡ ≥30 to <35 weeks' gestation at birth 2 mg/kg/dose orally twice daily‡ ≥35 weeks gestation at birth 4 mg/kg/dose orally twice daily‡	Increase to 3 mg/kg/dose at age 4 weeks of life Increase to 3 mg/kg/dose orally at 2 weeks of life Continue same dose through week 4-6 of life	Birth-4 weeks for prophylaxis of infants born to mothers with low risk for maternal-fetal HIV transmission of HIV§ Birth-6 weeks for combination ARV prophylaxis or empiric HIV therapy of infants born to mothers higher risk for maternal-fetal transmission of HIV§
Lamivudine 3TC	>32 weeks' gestation at birth 2 mg/kg/dose orally twice daily	Increase dose to 4 mg/kg/dose orally twice daily at 4 weeks of life	Birth-6 weeks for combination ARV prophylaxis or empiric HIV therapy of infants born to mothers higher risk for maternal-fetal transmission of HIV§
Nevirapine	Prophylactic dose Birth weight 1.5-2 kg 8 mg/dose orally once daily Birth weight >2 kg: 12 mg/dose orally once daily (note: dose is *actual dose* and *not* in mg/kg	Prophylactic dose: needs no adjustment	Birth-6 weeks for combination ARV prophylaxis of infants born to mothers higher risk for maternal-fetal transmission of HIV§
	Empiric treatment dose 34 to <37 weeks' gestation at birth Birth-1 week: 4 mg/kg/dose orally twice daily	Increase dose to 6 mg/kg/dose orally twice daily at 1 week of life	Birth-6 weeks for empiric HIV therapy of infants born to mothers higher risk for maternal-fetal transmission of HIV§
	Empiric Treatment Dose >37 weeks' gestation at birth 6 mg/kg/dose orally twice daily	Continue same dose through week 6 of life	

*Please refer to text for full explanation of recommendations. Please refer to aidsinfo.nih.gov for the most up-to-date recommendations and dosing information as they are updated regularly.
†First dose started within 6-12 hours of birth.
‡If unable to tolerate orally, use 75% of the oral intravenously.
§If the diagnosis of HIV is established, consult with a pediatric HIV specialist.

weight-appropriate prophylactic dose (see Table 50.9) is recommended for infants at high risk of perinatal HIV acquisition. This includes:

- Infants born to mothers who did not receive antepartum or peripartum ARV drugs.
- Infants born to mothers who only received peripartum ARV drugs.
- Infants born to mothers who received antepartum and peripartum ARV drugs but did not attain virologic suppression near the time of delivery, especially if the delivery was vaginal.
- Infants born to mothers with acute or primary HIV infection during pregnancy.

The data from this recommendation come from a study of 1684 infants born to women with a diagnosis of peripartum HIV infection and who, therefore, had not received antepartum prophylaxis. The infants were randomized to three regimens: 6 weeks of zidovudine monotherapy, zidovudine for 6 weeks plus nevirapine × 3 doses, or zidovudine for 6 weeks plus nelfinavir and lamivudine (3TC) for 2 weeks.[185] Intrapartum transmission was higher in the zidovudine monotherapy group as compared to the 2- and 3-drug combination regimens (4.8% versus 2.2% and 2.4%, respectively). In the multivariate analysis, higher maternal viral loads, zidovudine monotherapy, and maternal use of illicit substances were associated with higher transmission rates.

4. *Empiric HIV therapy:* In the 2013 annual conference of retroviruses and opportunistic infections, a case of a baby who may have been cured of HIV infection by early initiation of ART was presented.[228] Also known as the "Mississippi baby," this child was born to an HIV-infected mother whose HIV status was unknown until after the delivery and hence did not receive ARVs antepartum or peripartum. The infant was born at 35 weeks' gestation, and two different tests confirmed the HIV infection (RNA and DNA PCR). At 30 hours of life, the infant was found to be HIV positive. The patient was started on AZT, 3TC, and nevirapine. The infant tested positive by DNA PCR at 6, 12, and 20 days, but the test done at 29 days was negative for HIV. The baby was treated with ART for 18 months, and at the 21-month follow-up, the child was still tested negative, but there was virologic rebound at age 4 years. In a similar case described shortly thereafter, very early administration of zidovudine, 3TC, and nevirapine at 30 hours of life resulted in a sustained period of "remission" with virologic rebound at age 4 years with discontinuation of ART.[36] Both cases illustrate that early treatment with a three-drug ARV regime may result in sustained periods of viral suppression. Several studies from Canada have also shown that early treatment within 30 hours of life with triple ARV regimens results in reduced levels of proviral HIV-1 DNA viral replication in CD4+ in newborns with perinatally acquired HIV.[36] These data have led the panel to recommend a three-drug regimen with zidovudine, 3TC, and nevirapine (at treatment dose) as an option for children at higher risk of HIV transmission. This approach is particularly favored by experts in the setting of acute HIV in pregnancy as the risk of in utero transmission is higher.
5. *HIV therapy:* Three-drug combination ART is recommended for infants with confirmed positive newborn HIV nucleic acid test (NAT). Most experts recommend starting therapy as soon as possible without waiting for a confirmatory NAT because false-positive HIV NAT tests are not common. The results of these tests are usually available during the first week of life. For term and preterm neonates, combination of zidovudine, 3TC, and nevirapine is recommended noting that this is the only regimen recommended for preterm infants at this time because safety and dosing data for other regimens are lacking. Combination of emcitarabine and raltegravir is another option that can be used starting at birth in term neonates. Lopinavir/ritonovir is recommended for term infants older than 2 weeks of age.
6. *Special situations:*
   - Newborns born to mothers with unknown HIV status at the time of delivery: In this situation, expedited testing should be performed on mothers and/or newborns as during labor or as soon after birth. Results should be available within 60 minutes. If testing positive, the infant should be started on combination ART or empiric HIV treatment without waiting for confirmatory tests. Mothers should be instructed to not breastfeed. If confirmatory tests are negative, then breastfeeding can be resumed and ART discontinued.
   - Newborns born to mothers with an ART-resistant HIV infection: Presently, there is no evidence that customized regimens for infants born to mothers with ARV drug–resistant HIV infection are superior to standard newborn prophylaxis. Consequently, in this scenario, it is advisable to consult with a pediatric HIV expert prior to delivery. For areas in which pediatric or adult HIV specialists are not available, the **National Perinatal HIV hotline (1-888-448-8765)** can provide guidance.
   - Mothers diagnosed with HIV infection while breastfeeding: In this circumstance, breastfeeding should be stopped until HIV infection is ruled out. Mothers can either pump and discard or pump and store the breast milk until the confirmatory results are available. Some experts recommend starting postexposure prophylaxis for 4-6 weeks after stopping breastfeeding. Consultation with a pediatric HIV expert is advised.

It is important to plan the discharge of babies on ARV carefully to maximize compliance. Because in many instances there is a delay in registering the infant for insurance and because liquid forms of ARV agents may be difficult to procure from community pharmacies, every effort should be made to supply the family with the infant's medications (not just a prescription) at discharge. In the United States and other resource-rich regions, mothers should be

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

counseled against breastfeeding, whether or not they are continuing ART after pregnancy. In addition, the risks of HIV transmission through premastication of food should be emphasized. In 2008, three cases of pediatric HIV were reported. In these children, the feeding of premasticated food by caregivers who had HIV infection was thought to be the method of transmission.[91] Transmission was presumed to be caused by the presence of blood in the caregiver's mouth. Therefore, the CDC recommends that mothers or caregivers with HIV infection should not premasticate food for uninfected infants because this may serve as a potential route of transmission.

Safety

The effectiveness of ART in the mother and intrapartum and postpartum prophylaxis in the infant in decreasing the incidence of vertical HIV transmission is incontrovertible. By the early 2000s, transmission rates after applying this strategy were less than 2%. Despite a broad experience, concerns remain, however, regarding the safety of deliberate exposure of the pregnant woman, the fetus, and the young infant to ARV drugs. The adverse effects of zidovudine exposure, as defined by the PACTG 076 trial, have been investigated through follow-up studies of mothers and children enrolled in this and similar trials. Mild and reversible anemia in infants occurs during the 6-week period of postnatal administration, but no further untoward effects have been consistently documented after years of observation.[174] Anemia may be more severe in an infant born to a mother who was receiving multiple ARV drugs during pregnancy. The current guidelines recommend a baseline complete blood count with differential (CBC/diff) on all newborns who will be started on zidovudine.[197] Some experts recommend repeating the CBC/diff at 4 weeks of age when the second HIV DNA PCR is performed, whereas others advocate repeating the CBC/diff only if the patient is symptomatic. However, the mild anemia that is associated with this regimen is usually reversible by age 12 weeks.

European investigators have raised some concern that a small percentage of children exposed in utero to zidovudine may have persistent defects in mitochondrial function, a subcellular target of zidovudine in vitro. Older children and adults receiving long-term nucleoside reverse transcriptase inhibitors, such as zidovudine, occasionally develop a high anion gap acidosis because of mitochondrial dysfunction. Studies of a large cohort of European children exposed as fetuses and infants to ART suggest that mitochondriopathies may occur in 0.26%, an incidence that is 20-fold greater than that expected in the general population. A retrospective evaluation of greater than 16,000 uninfected, exposed American children failed to reveal any subject with symptoms consistent with a mitochondrial disorder.[174]

The safety of non-zidovudine drugs when administered during and immediately after pregnancy is less well studied. The non-nucleoside reverse transcriptase inhibitor efavirenz is teratogenic in primates at serum concentrations routinely achieved after conventional dosing in humans.[174] Conversely, a recent meta-analysis looking at the safety of efavirenz in the first trimester of pregnancy found that the relative risk of defects in women on efavirenz-based regimens compared with those on efavirenz-sparing regimens was 0.85 (95% CI 0.61-1.20). In the study, in 39 of 1437 live births, the infants had birth defects of many kinds but only one neural tube defect.[82] Because the incidence of neural tube defects in fetuses exposed to efavirenz is not as high and because changing the regimen of a pregnant woman who sustained virologic response before conception may lead to uncontrolled viral load and hence higher risk for the baby, efavirenz should be continued in the first trimester in those mothers who were already on it at the time the pregnancy was diagnosed. Initial studies from Europe suggested that multidrug ART during pregnancy, especially protease inhibitors (PIs), predisposed to preterm delivery. This finding was not supported by data collected in an American cohort of 369 women receiving combination therapy without PIs and 137 additional women receiving combination therapy with PIs.[262] However, more recently, the Pediatric HIV/AIDS Cohort Study network's Surveillance Monitoring for ARV Toxicity study showed that the odds of preterm birth and spontaneous preterm birth were higher in mothers who used a protease inhibitor regimen during the first trimester.[276] When started later in pregnancy, there were no associated risks. The authors speculated that changes in immunologic and inflammatory mechanisms caused by the initiation of ARV therapy could interfere with cytokines involved in the maintenance of pregnancy, such as IL-10.

Studies examining the effectiveness of zidovudine/3TC and short courses of the non-nucleoside reverse transcriptase inhibitor nevirapine in preventing vertical transmission of HIV in developing countries likewise have not shown toxicity from these drugs either to the mother or to the infant, although the combination of zidovudine/3TC has been associated with a higher incidence of hematologic abnormalities (anemia and neutropenia). Therefore, CBC/diff should be checked at 4 weeks in infants receiving this combination.[113,206]

The use of some agents should prompt careful monitoring of the mother. Prolonged courses of nevirapine occasionally have been associated with significant hepatotoxicity in pregnant women, especially when the CD4+ counts exceed 250/mm^6; such dosing requires frequent, serial liver function tests. Nucleoside reverse transcriptase inhibitors, especially the combination of stavudine and didanosine, rarely may be associated with the development of lactic acidosis in the mother during pregnancy.

Lopinovir/ritonovir is not recommended for use in newborns younger than 14 days of age and premature infants because of the multiple side effects, including the potential for heart block, adrenal insufficiency, and electrolyte imbalances, among others.

For premature infants only zidovudine, 3TC and nevirapine are recommended at this time because of lack of

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

safety data. Consultation with a pediatric HIV specialist is strongly advised if other regimens are being considered.

Data regarding potential toxic effects of a wide range of other ARV drugs are being collected through long-term follow-up studies, and the clinician is encouraged to record all cases of ARV drug exposure with the Antiviral Pregnancy Registry.[263]

Prenatal Testing

The availability of effective prophylactic regimens against vertical transmission of HIV mandates routine prenatal HIV testing.[101] It currently is standard practice to add voluntary HIV testing to other prenatal screening tests. Most authorities recommend an "opt out" strategy for prenatal HIV testing; that is, the test is performed routinely unless the woman specifically requests that it be excluded, assuming such a strategy is consistent with state statute. For women with negative test results exhibiting high-risk behaviors or residing in high-incidence areas, the assay should be repeated during the third trimester. Problems still exist in reaching some populations of HIV-infected women, particularly women using illicit drugs, in a sufficiently timely fashion to prevent transmission to their offspring.

Cesarean Section Delivery

Multiple studies have documented the benefit of delivering infants born to HIV-infected mothers by cesarean section. A meta-analysis of 15 observational studies indicated consistent and significant reductions in vertical transmission when elective cesarean delivery is offered to these women. Nevertheless, the additional benefit gained by cesarean delivery is minimal in an adherent mother receiving ART with a very low or undetectable viral load late in pregnancy. Cesarean section may be most appropriate for the woman unable to administer ART to herself or to her newborn or in a mother who has a persistently high viral load (≥1000 copies/mL) despite receiving multidrug therapy. Operative delivery also should be considered in an infected woman when the viral load is unknown.

When elective cesarean section is indicated, it should be scheduled at 38 weeks of pregnancy and, if possible, should be performed while the membranes are intact. Premature rupture of the membranes decreases the benefit from cesarean delivery, but the duration of ruptured membranes beyond which operative delivery adds no benefit is unknown. IV zidovudine should be initiated at least 3 hours before surgery, and other ARV medications should be continued before and after delivery. Postpartum complication rates after elective cesarean section approximate the rates seen in noninfected women, although they are higher after emergent cesarean delivery and in women with advanced disease.

Clinical Manifestations

Virtually all infants born to an HIV-infected mother are asymptomatic at birth. Most HIV-infected offspring begin to show signs and symptoms within the first 1 or 2 years of life. A smaller proportion, termed *rapid progressors*, become symptomatic within 1 or 2 months after delivery. Infants with rapidly progressive disease have plasma viral loads early in life that are two or three times higher than the plasma viral loads in infants with more indolent infection.

With the exception of *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) pneumonia, most opportunistic infections occur late in the course of the child's illness. *P. jiroveci* pneumonia commonly manifests in the first months of life. In contrast to *P. jiroveci* pneumonia in adults, virtually all of whom have pre-existing immunity to *Pneumocystis* before acquisition of HIV infection, *P. jiroveci* pneumonia in infants is caused by primary infection in the absence of pre-existing immunity and results in severe, frequently overwhelming, bilateral pneumonia. Other characteristics of untreated or poorly controlled perinatal HIV infection are nonspecific. Recurrent bacterial infections are frequent in infants with HIV infection. Most of these are minor (e.g., otitis media), but some are severe (bacteremia, pneumonia, or meningitis). Other commonly encountered early manifestations include persistent mucocutaneous candidiasis, abdominal organomegaly, diffuse lymphadenopathy, chronic diarrhea, failure to grow, and developmental delay. Children also acquire a diffuse, interstitial pneumonia of uncertain origin, termed *lymphocytic interstitial pneumonia*. HIV-specific cancers, such as B-cell lymphomas, Kaposi sarcoma, and leiomyosarcomas, are unusual in children and generally occur late in the course of the illness.

Diagnosis and Care of Infants Exposed to Human Immunodeficiency Virus

All infants born to a mother with known HIV infection or to a mother who falls into a high-risk category should be longitudinally evaluated for HIV infection. The routine diagnostic HIV tests employed in adults (fourth-generation HIV-1/HIV-2 antigen/antibody combination and differentiation immunoassays) cannot be used to confirm infection in children. The sensitivity of the antigen is much lower than the NAT in the first months of life.[162,255] The antibodies cannot distinguish infant-derived IgG from that transplacentally acquired from a seropositive mother and are virtually always are positive in the newborn period whether the offspring is infected or not and are of little usefulness under 18 months of age.

The definitive diagnosis of HIV infection in a newborn requires the detection of virus with HIV DNA/RNA PCR. Virtually all untreated newborns have HIV viral loads well above the level of detection, and this test is greater than 90% sensitive and virtually 100% specific by 4 weeks of age. Viral load assays further give an estimation of the severity of the infection and a baseline for judging the success of ART. Virologic testing should be performed at 14-21 days of life, at 1-2 months, and again at 4-6 months. In infants who are at high risk for transmission, a test should be

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

obtained at birth, and because some studies have shown that the RNA PCR assay may be affected by combination ARV prophylaxis the test should be repeated 2-4 weeks after the ARV prophylaxis is discontinued.[35] To exclude HIV infection, two negative virologic test results are required, one obtained at 1 month of age or greater and another at 4 months of age or greater. Any positive result needs to be confirmed by a second specimen as soon as possible. Because maternal antibodies may persist for longer periods, some experts advocate a final HIV antibody test at 12-18 months in infants with prior negative results on virologic testing to document loss of maternal antibodies.

The CDC's updated guidelines recommend initiating ART for any infant diagnosed with HIV infection before age 12 months regardless of clinical status, CD4 percentages, or viral load.[195] Treatment of infants with multidrug regimens poses difficulties, and proper use of these complex and potentially toxic agents requires the advice of an expert with substantial experience in perinatal HIV infection.

Because *P. jiroveci* pneumonia is the major life-threatening complication during the first year of life of the HIV-infected infant's life, many experts recommend that prophylaxis for *P. jiroveci* pneumonia be administered beginning at 4-6 weeks and continuing for at least 1 year, or until HIV infection can be definitively excluded. The most effective prophylactic regimen is trimethoprim-sulfamethoxazole, 75 mg/m^2 per dose, twice a day, 3 days a week. The immunization schedule for the HIV-infected newborn includes recombinant hepatitis B vaccine at birth. The Bacillus-Calmette-Guerin (BCG) vaccine, which is administered to newborns in tuberculosis-endemic countries, is contraindicated in HIV-infected infants because of the risk of disseminated BCG vaccine. Preliminary data suggest that in the HIV-exposed child, the BCG vaccine may induce CD4 T-cell activation and may increase the risk of HIV infection through breastfeeding in these children.[103]

Prognosis

Before the introduction of ART, the median survival of children with HIV infection in the United States and Europe was 8-13 years. In the absence of ART, rapid progressors usually have multiple, life-threatening complications and die early in life. A few perinatally infected children have reached adolescence and remain symptom-free, with their immune systems intact, even without antiviral chemotherapy. The ultimate outcome of these unusual cases is unknown. As in adults, the survival of children in industrialized countries has markedly improved since the introduction of ART, reflecting the benefits of ARV regimens seen in adults. Longitudinal studies conducted in the late 1990s, the period during which HAART became standard in adults and children, documented a dramatic decline in yearly mortality rates among children with HIV infection. The reduction in mortality was experienced by all subgroups defined by age, gender, CD4 T-lymphocyte counts, and ethnicity.

Enteroviruses and Parechoviruses

Enteroviruses belong to the family Picornaviridae. The four traditional groups of enteroviruses are the polioviruses, echoviruses, coxsackie viruses, and enteroviruses. More than 100 types of non-polio enteroviruses have been described. Although these groupings are still widely employed, more recent molecular analyses have categorized enteroviruses into five genetically defined species and have indicated that some of the original members belong to non-enterovirus genera altogether. In particular, hepatitis A, initially designated an enterovirus, has been reclassified as a distinct and unique genus. Two additional former enteroviruses, echovirus 22 and 23, are sufficiently genetically and structurally different from the other enteroviruses to be assigned to a new genus name, *parechovirus*. Several new parechoviruses have been identified.

In fall 2014, the United States experienced an outbreak of a non-polio enterovirus that spread rapidly among children predominantly between ages 2 and 13 years—enterovirus D68 (EV-D68) (PMID 25552624). This virus shared the clinical features of other non-polio viruses, including upper and lower respiratory symptoms and neurologic manifestations, such as flaccid paralysis. During this outbreak, neonates and adults were, however, largely spared, suggesting that maternal immunity played a protective role in infants.[14,84,166,274]

Epidemiology and Transmission

Humans are the true hosts for the enteroviruses, but these viruses have been described in various animals, probably secondary to contamination by humans. These viruses are transmitted primarily by the fecal-oral route, but they have also been transmitted by the oral-oral route and have been isolated from swimming pools, from contaminated hands, and from flies. Typically, within a given geographically defined population, a narrow range of serotypes is responsible for most endemic disease. The community incidence of enteroviral disease peaks in temperate areas in summer and fall but occurs throughout the year in tropical areas. In addition to geographically confined organisms, occasional strains cause epidemics that can reach worldwide proportions. In all four enterovirus groups, there are far more subclinical, undiagnosed infections than recognized disease, but when disease occurs, it is particularly severe in the neonatal period.

Perinatal infection can occur before, during, or after parturition. Enteroviruses may be transmitted transplacentally, presumably during maternal viremia, and congenital infections have been most often described after a maternal infection in the third trimester; such infections can result in fetal death. Most infection in the neonatal period is, however, the result of exposure of the oral or respiratory tract mucosae to organisms harbored by the mother at the time of birth or from secretions from the mother or others shortly thereafter.

Epidemics of enteroviral diseases in the nursery have been described. The virus may be introduced by health care personnel, but more commonly, the infant index case has acquired the virus from his or her mother at the time of delivery. Risk factors for infection in the nursery include low birth weight, administration of antibiotics or blood, proximity to the index patient, care of the index patient by the same nurse within a nursing shift, and nasogastric feeding or intubation.

Infection During Pregnancy

Enterovirus infection during pregnancy is common, especially during peak periods of enteroviral disease in the community, with some surveys documenting an intragestational incidence of 9% or greater. Few data indicate any risk from either the polioviruses or the echoviruses for the development of congenital anomalies, but the situation is less clear for coxsackie viruses. Early investigations found an association of coxsackie viruses A9 and B2 to B4 with a higher rate of anomalies, particularly urogenital and cardiovascular anomalies, but others have found no such association. Reports of prematurity and stillbirth exist for all the enteroviral groups after infection late in pregnancy, but these effects seem to be uncommon. In most pregnant women, the infection is either asymptomatic or associated with mild, nonspecific illness. By contrast, mothers infected with echoviruses or coxsackie B viruses, the enteroviral groups most commonly associated with significant illness in newborns, frequently complain of fever and abdominal pain near the time of delivery.

The first case of EV-D68 in an adult occurred in a 35-year-old pregnant woman with a twin gestation. She presented at 33 weeks' gestation with cough, headache, dyspnea, and hypoxemia, which warranted her admission to the ICU. CT of the chest showed bilateral patchy infiltrates, and she tested positive for the virus on PCR testing. Her symptoms improved after 48 hours, at which time labor was induced because of a history of severe preeclampsia. She delivered healthy twins, who remained asymptomatic and were discharged home without at-home oxygen requirements.[274] No other reports of neonates exposed to this virus strain have been reported to date in the medical literature.

Neonatal Infection

The non-polio enteroviruses cause a wide spectrum of illnesses, and substantial data have been collected regarding specific types and strains. The severity of disease in a newborn is a function of the infecting strain, the titer of passively transferred specific antibody in the infant, and the timing of infection. Maternal infection just before delivery, before the mother can mount an antibody response, with high-titer viral transmission immediately before or during birth is associated with the most severe symptoms in the newborn.

Most neonatal enteroviral disease manifests as a nonspecific mild febrile illness. These infections probably are acquired postnatally. Signs and symptoms occur between the first and second weeks of life, usually after the infant has been discharged from the nursery, and consist of fever of 38° C to 39° C, irritability, vomiting or diarrhea, and poor feeding. These infants frequently are admitted to the hospital for a bacterial sepsis evaluation and discharged 3 days later when the bacterial cultures show negative results and the infant's symptoms have spontaneously improved. Occasionally, infants exhibit respiratory distress, rash, or aseptic meningitis. The course is self-limiting, and recovery without residual is the rule.[149] A history of an intercurrent viral-like illness in a family member can usually be elicited. Nosocomial infection, acquired horizontally after birth, also frequently has this relatively mild course.

A more fulminant, life-threatening illness occurs as a consequence of vertical transmission at the time of birth and before the development of significant serotype-specific antibodies in the mother. The risk of mortality is highest for echovirus-11, but other serotypes, particularly some coxsackie B viruses (especially Coxsackie B1) and several parechoviruses, also have been implicated.[121,270,284] Approximately one third to one half of infants with severe enteroviral disease are born prematurely.[3] In fulminant cases, onset of illness typically occurs within the first 2-5 days of life. Severe neonatal disease shares many characteristics of overwhelming bacterial infection, with extreme lethargy and hypoperfusion. Infants also present with fever, which may be greater than 39° C, poor feeding, and rash. The rash is usually macular or maculopapular, sometimes with petechiae. The most fulminant cases are complicated by hepatitis, first manifesting as hepatomegaly and jaundice. Such cases can progress to necrosis of the liver and fulminant hepatic failure with intractable coagulopathy and hemorrhage, as well as profound hepatocellular dysfunction. Mortality from enteroviral hepatitis and coagulopathy ranges from 30%-80%.[3]

Despite the life-threatening nature of the acute hepatic failure, recovery of hepatic function among survivors is the rule. Coincident with hepatitis, or sometimes separate from it, there may be myocarditis, characterized by respiratory distress, tachycardia, and arrhythmias, with mortality approaching 50%. As with hepatitis, if the infant survives acutely, full recovery over a long course is usual. Both these severe manifestations may occur coincidentally with meningoencephalitis. In these infants, CSF examination often is typical for viral CNS disease, but some serotypes produce CSF changes typical of bacterial meningitis, including marked hypoglycorrhachia, and still others result in no CSF pleocytosis at all. Although there are a few reports of neurologic sequelae among survivors of aseptic meningitis, development is normal in nearly all children. In contrast, neonatal encephalitis resulting from parechovirus may be severe, causing white matter injury and long-term sequelae in a significant proportion of affected infants.[269]

Enteroviral infection shortly after birth also has been implicated in a few cases of sudden infant death. Some infants have died within the first week of life. Mild prodromal symptoms usually precede the infant's death. Evidence of enterovirus has been found in the heart and respiratory tract at postmortem examination.

Laboratory Diagnosis

Traditionally, the diagnosis of enteroviral infection has been established by isolation of the virus in culture. Some serotypes of enterovirus are, however, very difficult to grow in vitro. More recently, PCR technology, using primers that flank a highly conserved region in the 5′ noncoding region of the genome present in nearly all serotypes, has become commercially available for the diagnosis of enterovirus. When applied to infection in newborns and young infants, PCR testing is more sensitive and much more rapid than viral culture. The widely used enteroviral PCR tests do not detect parechoviruses, however. Enterovirus can be identified by culture and PCR of serum, urine, CSF, nasopharynx, and stool. The usefulness of serology and antigen detection for diagnosis of enteroviral disease is precluded by the large number of non–cross-reacting serotypes.

Enterovirus D68, however, shares some biologic and molecular characteristics with human rhinovirus, particularly with human rhinovirus 87 and, therefore, PCR testing with real-time PCR will not distinguish between both viruses. Sequencing for this virus is available at the CDC.[160]

Therapy and Prevention

The most important measure in limiting the spread of enteroviral disease is strict hand washing. Access to the nursery should be limited to healthy personnel. Cohort nursing care during nursery epidemics may be effective in limiting spread. There is some evidence that passive immunization with immunoglobulin during a nursery outbreak may be beneficial in limiting new cases and decreasing the severity of illness in affected infants.

High-dose IVIG has been used in established neonatal disease, although there have been no controlled trials testing its effectiveness. It has also been used as prophylaxis for outbreaks in neonatology units.[88] Passive immunization has been shown to have a virologic effect in the infant only if the lot of immunoglobulin possesses very high titers against the offending serotype. The antiviral drug pleconaril, which is promising in the treatment of neonatal enteroviral infection, is still in development. This compound binds to sites on the enteroviral surface, prohibiting attachment to the target cell and subsequent uncoating. It has activity against numerous enteroviruses in vitro at concentrations that are readily achieved in the serum with human dosing. Preliminary experience, including data collected in neonates, indicates that the drug is highly bioavailable, has a large volume of distribution (including the CNS) and long half-life, and has few side effects. There have been numerous reports of pleconaril administration in infants with severe enteroviral disease, with recovery frequently occurring soon after drug initiation. The results of randomized controlled trials in neonatal infection have not been published, however, and in the absence of controlled studies, the effectiveness of pleconaril in severe newborn enteroviral disease remains uncertain. It is important to mention that pleconaril did not receive FDA approval and that the drug is no longer available for compassionate use. In 2015, the results of a randomized, double-blind, placebo-controlled trial of this drug for the treatment of neonates with severe enteroviral sepsis were published. Nineteen centers enrolled patients between the years 1999 and 2010, at which time the study was stopped because the drug was no longer available. Patients enrolled in both arms were allowed to receive other medications, including IVIG. The primary endpoint of the study was the reduction in the number of newborns with a positive viral culture from the oropharynx 5 days after initiating pleconaril, and some of the secondary endpoints were duration of positive cultures in all sites (oropharynx, rectum, urine, and serum), reduction in the duration of hospitalization, and lower mortality rates. Of the 61 patients enrolled, 43 tested positive for enterovirus (31 in the treatment arm and 12 in the placebo arm). The primary endpoint of the study was not met because a surprising number of newborns did not test positive on cultures from the oropharynx on day 1 (only 25% and 30% in the study and placebo group, respectively), and by day 5 no cultures tested positive in either group. However, time to negativity was shorter for samples from all culture sites in the pleconaril group compared with the placebo group, and the cumulative survival time over 2 months was greater in the treatment arm than in the placebo arm. In addition, the drug was safe and well tolerated. This study, therefore, highlights the need for further investigation of this drug and calls for the development of other treatments for this high mortality infection in newborns.[4,172]

Hepatitis Viruses

Hepatitis may result from various viral infections, including CMV, herpesvirus, rubella virus, EBV, VZV, and coxsackie virus. The disease usually occurs as part of a systemic infection. Primary infection of the liver, resulting in acute or chronic hepatitis, or both, may also be caused by specific hepatotropic viruses, as discussed in the following sections (see Chapter 91).

Hepatitis A Virus

Hepatitis A virus (HAV) is a spherical, single-stranded, positive-sense RNA particle in the picornavirus group. HAV is found worldwide. The infection is highly contagious and is spread most commonly by the fecal-oral route. Common-source outbreaks resulting from contaminated food, particularly raw shellfish culled from tainted waters, also occur. Rarely, HAV is transmitted via blood

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

transfusion or from mother to child. Fecal excretion of HAV begins 2-3 weeks before onset of the disease and may continue for 4-6 weeks. The average incubation period is 25-30 days.

HAV is a common infection in children, and children in daycare are at particular risk. Most pediatric infections are asymptomatic and anicteric. Children who do exhibit symptoms usually have a gastroenteritis-like syndrome and experience only mild hepatitis with virtually complete resolution. Adults are more likely to develop the typical signs and symptoms of hepatitis, with jaundice, abdominal pain, malaise, fever, acholic stools, dark urine, and vomiting. Fulminant disease is uncommon, and the mortality rate is less than 1%. The carrier state does not occur. The diagnosis is made by detecting anti-HAV IgM antibodies in the serum, which appear with the onset of disease and persist for several months. Detection of anti-HAV IgG, which persists throughout life, may indicate either recent or distant infection.

Acute HAV in pregnancy does not seem to increase the risk of congenital malformations, stillbirths, IUGR, or spontaneous abortion. The risk of perinatal transmission is minimal, even when the mother develops acute disease within the last weeks of pregnancy.[259] Perinatal transmission can rarely occur, however, and spread in special care nurseries has been reported. In most instances, neonatal disease is asymptomatic or mild and is self-limiting. Occasional reports suggest that maternal disease with HAV during pregnancy can result in meconium peritonitis in the fetus.[47,61]

Although vertical transmission of HAV is unusual, some authorities recommend treating the infant with 0.02 mL/kg of serum immunoglobulin intramuscularly if maternal symptoms develop 2 weeks before to 1 week after delivery. Even though the virus can be detected in breast milk, maternal immunoglobulins likely play a protective role, and therefore, breastfeeding should not be discouraged.[47,61]

Any unusual nursery outbreak of HAV should be managed with the administration of prophylactic immunoglobulin to susceptible staff and infants and with emphasis on good hand washing. Two formalin-inactivated HAV vaccines are available in the United States and are highly protective but are not yet licensed for children younger than 12 months of age.

Hepatitis B Virus

Hepatitis B virus (HBV) is the prototype of the family of viruses known as *hepadna viruses* (hepatotropic DNA viruses). The complete infectious virion is a 42-nm sphere. Hepatitis B surface antigen (HBsAg) is found in the viral envelope and is produced in excess during infection, resulting in circulating, free spherical and tubular particles. It is detected (usually with radioimmunoassay [RIA] or enzyme-linked immunosorbent assay [ELISA]) in acute and chronic infection. Subdeterminants of the surface antigen define four major serotypes. All four share an epitope designated "a"; antibody to HBsAg (anti-HBsAg) is directed against this common epitope and confers some protection against all four serotypes.

The viral inner core nucleocapsid contains hepatitis B core antigen (HBcAg), DNA polymerase, and partially double-stranded DNA. Hepatitis B core antigen is expressed on the surface of the infected hepatocyte but does not circulate and cannot be detected by routine assays. Anti-HBcAg, total and IgM specific, can be detected with RIA or ELISA. HBeAg, a soluble polypeptide encoded within the same open reading frame as the core antigen, is detectable when HBV replication is rapid. Its appearance usually indicates a high concentration of HBV. HBeAg-negative individuals are infectious, but transmission of disease occurs at a lower rate. HBeAg and anti-HBe also can be detected with either RIA or ELISA. Several genotypes of HBV have been defined and designated types A through H. Hepatitis B virus DNA initially is transcribed into RNA intermediates, which serve as messages for viral proteins or as a template for progeny viral genomic DNA through reverse transcription by the viral polymerase.

Clinical Manifestations and Hepatitis B Virus Blood Tests

HBV infection is most often contracted via injection drug use but may be transmitted through intimate physical contact or vertically from mother to infant. Blood products are routinely screened for HBV, and transfusion, previously the most common source of HBV infection, is now only rarely implicated. The incubation period is 50-180 days. HBsAg usually is present 1-3 months after exposure and appears before the onset of symptoms. Elevation of hepatocellular enzymes in the serum may be found 2 weeks to 2 months after HBsAg is detected. This period in adults frequently is characterized by a prodrome of nausea, vomiting, headache, and malaise, which progresses to jaundice.

Within 1-2 weeks of the onset of jaundice, HBsAg usually is cleared from the serum. With self-limiting disease, there is often a window period between the disappearance of HBsAg and the development of anti-HBsAg, so both tests yield negative results. The appearance of anti-HBsAg is a marker of recovery and immunity against future reinfection. The IgM antibody response to HBcAg begins before the disappearance of HBsAg and persists through the window period. Testing for HBsAg and IgM anti-HBcAg is the most reliable strategy to document recent HBV infection. IgM anti-HBcAg disappears by 6 months, but the later-appearing IgG anti-HBcAg may persist for life. HBeAg is variably expressed in HBV disease and denotes actively replicating, high-titer infection. The development of anti-HBeAg signals improved control of viral replication, but not eradication. HBV vaccines are composed of recombinant HBsAg; recipients of vaccine test positive for anti-HBsAg. Vaccine recipients can be distinguished from hosts who have recovered from wild-type infection by the absence of antibody to other viral components, particularly anti-HBcAg.

Most adults with HBV infection have a self-limiting disease and become noncontagious. Less than 1% develop fulminant hepatic failure, but many of these patients die. The virus is not cytopathic for the infected hepatocyte, and hepatic damage and subsequent viral clearance are the results of the host's immune response. Chronic active or persistent hepatitis, which may develop in 30% of chronic carriers, is characterized by persistent serum HBeAg in the absence of anti-HBsAg and is particularly common in patients superinfected with the hepatitis D virus.

Infants born to antigen-positive mothers or mothers with acute hepatitis have a 35% incidence of prematurity and are more likely to be of low birth weight. The risk of preterm birth seems to be related to degree of maternal illness. Fulminant fatal cases of neonatal hepatitis secondary to vertically transmitted HBV are uncommon, but do occur (1%-2% of all cases) and may be recurrent in successive pregnancies. More typically, infants infected with HBV develop a less robust immune response to the HBV-infected hepatocyte compared with adults and establish asymptomatic chronic infection ("chronic carriage"). The development of chronic carriage is strongly correlated with age: 95% of infants become chronic carriers compared with 30% of toddlers and 5% of adults.[108]

The consequences of chronic HBV carriage established in the newborn are not encountered until early adulthood, at which time the patient has a gradual onset of hepatic fibrosis and insufficiency. Carriers also may develop hepatocellular carcinoma after the initial infection. Hepatocellular carcinoma is most common in populations affected by a high incidence of vertically transmitted HBV and in populations with high cross-sectional prevalence of HBV surface and HBe antigenemia.[252] HBV itself is not oncogenic; the formation of tumor is probably the result of years of low-grade inflammation and repeated hepatocellular regeneration.

Perinatal Transmission

Multiple studies have shown that vertical transmission of HBV is strongly associated with high-grade maternal HBe antigenemia and that almost all infants born to HBeAg-positive mothers are infected in the first year of life, with 85%-90% developing chronic viral infection. The risk of vertical transmission of HBV from an asymptomatic carrier mother to her infant increases from 10%-85% when the mother is HBeAg positive. Mothers may transmit HBV vertically in sequential pregnancies. The risk of vertical transmission of HBsAg from mother to infant at birth is higher in Asia than in Western industrialized countries.

Transmission occurs significantly more often at birth or in the postpartum period than transplacentally. Cord blood samples frequently are HBsAg negative in infants who subsequently become infected. Peripartum transmission is implied further by observations made in mothers who acquire acute hepatitis B infection during pregnancy. The risk is very low with infection during the first two trimesters, but increases to 50%-75% with hepatitis late in pregnancy or in the early postpartum period. Entry of virus through the infant's gastrointestinal tract is suggested by the finding that 95% of the gastric contents of infants born to carrier mothers are HBsAg positive after birth.

Although HBsAg can be found in the breast milk of 70% of carrier mothers, studies have not shown an increased risk with breastfeeding, indicating that mothers who desire to breastfeed may do so with little risk. American studies indicate further that breastfeeding carries no detectable risk of vertical HBV transmission in an infant who has received appropriate immunoprophylaxis at birth.[104]

There is also risk of transmission of HBV to family contacts of HBsAg carriers as a result of close contact over long periods. The risk is higher from sibling carriers than from either parent and is increased when the family member has evidence of liver disease. In the developing world, a significant proportion of infant infection is the result of horizontal transmission from the mother or other family members during the child's early life, rather than infection at the time of birth.

Prevention

Approximately 0.8% of pregnant women in the United States are HBsAg positive. Active and passive immunization can prevent vertical transmission of HBV in 85%-95% of cases, even in high-risk situations. The institution of immunoprophylaxis has had a profound impact on the incidence of newborn-acquired acute and chronic HBV infection and the associated hepatocellular carcinoma, particularly among high-prevalence populations in the United States (e.g., Alaskan Natives) and in areas of high endemicity in the developing world.[45,143]

Less than 50% of HBV-infected women in the United States have risk factors for HBV infection. Consequently, present recommendations mandate routine, universal screening of all pregnant women for HBV and universal vaccination of all infants. Current guidelines recommend that all pregnant women be tested for the presence of HBsAg early in pregnancy. Women at high risk for acquiring HBV, such as IV drug users or women with clinical hepatitis, should be tested again shortly before parturition. Hospitals are advised to develop systems that ensure the results of HBV screening tests are available to the pediatrician at the time of delivery. In everyday practice, some women without identified risks may acquire infection after the initial screening test, and others fail to be rescreened, and it may be impossible to transmit every woman's HBV status to the pediatrician in a timely fashion. In large centers that can perform HBV testing daily, screening at the time of delivery may overcome both of these potential problems.

Treatment of the infant varies, depending on whether the mother is HBsAg positive, HBsAg negative, or of unknown status at delivery. Infants of HBsAg-negative mothers do not need treatment with hepatitis B immunoglobulin (HBIG). They should be vaccinated before leaving the hospital with either Recombivax HB (5 μg in 0.5 mL)

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

or Engerix-B (10 μg in 0.5 mL). Both must be given intramuscularly. Subsequent doses should be given at 1-2 months (with a minimal interval of 4 weeks between dose 1 and dose 2) and 6 months of age (with a minimal interval of 8 weeks between dose 2 and dose 3), although the last dose may be given up to age 18 months. Combination vaccines that are currently available include HBV antigen and other childhood vaccines in the same vial. Only the monovalent preparation of hepatitis B vaccine should be used for the first dose, however, assuming it is administered at age less than 6 weeks.

Infants of HBsAg-positive mothers should be passively immunized with HBIG (0.5 mL given intramuscularly) and hepatitis B vaccine at a different anatomic site within 12 hours of birth, although some benefit can be obtained even if given 48 hours after birth. The vaccination schedule should be completed by 6 months to ensure rapid protection of the infant. In contrast with infants born to HBsAg-negative mothers, infants born to mothers with HBV infection should be tested for HBsAg and anti-HBsAg after the vaccine schedule has been completed (at age 9-15 months, to allow clearance of HBIG from the infant's bloodstream) to detect failure of seroconversion or vertical transmission despite vaccination.

If the mother's serologic status is unknown, maternal HBsAg should be tested at delivery, and the first dose of the vaccine should be given to the infant within 12 hours of birth. If the mother proves to be positive for HBsAg, HBIG should be administered to the infant as soon as possible, but certainly within the first 7 days of life.

Early studies examining hepatitis B vaccine response in preterm infants indicated a lower seroconversion rate among infants with very low birth weight born to HBsAg-negative mothers compared with infants weighing more than 2000 g. Subsequent studies have determined that medically stable preterm infants immunized at 30 days of age have an antibody response similar to full-term infants regardless of gestational age or birth weight. In a preterm infant born to a mother who is HBsAg negative, the first dose of HBV vaccine should be given at 30 days of life or when the infant's weight reaches 2000 g, before hospital discharge. In preterm infants born to HBsAg-positive mothers, HBV vaccine should be given within 12 hours of birth along with HBIG, but the full three-dose vaccine schedule should be initiated at 30 days of age (i.e., the infant should receive a total of four vaccine doses).

If a preterm infant is born to a mother with uncertain HBV status and her status cannot be determined within 12 hours after delivery, HBIG should be administered to the infant immediately because suboptimal immune response to vaccine alone precludes its use as a single intervention in the event that the mother proves to be HBV positive. If the mother's HBV tests ultimately show negative results, the vaccine schedule can proceed using the same schedule for mothers known to be HBsAg negative at delivery. Breastfeeding is not contraindicated and should be encouraged.

After nearly 20 years of widespread newborn vaccination, the hepatitis B vaccine seems to be exceedingly safe when given during infancy.[147] The original hepatitis B vaccine preparations contained the preservative thimerosal, a derivative of mercury. Concerns regarding the potential, albeit unproven, toxicity of thimerosal prompted a brief suspension of perinatal hepatitis B vaccination in the late 1990s and a mandate to develop vaccine formulations that did not contain this preservative. By 2001, all vaccines included in the childhood schedules were either thimerosal-free (including hepatitis B) or contained only trace amounts.

There are situations during pregnancy in which treatment of hepatitis B should be considered to prevent mother-to-child transmission of the virus. The American Association for the Study of Liver Diseases recommends that treatment should be considered, after carefully weighing risks and benefits, in mothers with HBV DNA viral loads greater than 200,000 IU/mL. Tenofovir, lamivudine, and telbivudine are the only drugs that have been studied during pregnancy, with tenofovir being preferred because of its safety profile (Category B). Treatment is started between 28 and 32 weeks' gestation and continued up to 3 months after delivery. Infants born to mothers who have received treatment should still receive the HBIG and hepatitis B vaccines, as described previously.

Even though these drugs are not secreted in largely through breast milk, the effects of these drugs in breastfeeding children have not been well studied. At present time, there is no contraindication to breastfeeding; however, risks and benefits should be discussed with the mother.[258]

All children born to mothers with hepatitis B infection should have post-vaccine serologies performed between 9 and 12 months, or 1-2 months after completion of the last hepatitis B vaccine series dose. The purpose of testing is mainly to identify those who may have been incubating the virus and whose transmission was not prevented through vaccination.[272]

Hepatitis C Virus

Hepatitis C virus (HCV) is a single-stranded RNA virus of the family Flaviviridae. HCV is composed of six genotypes and multiple subtypes. The severity of the infection corresponds to the HCV strain, with genotype 1 causing the most aggressive course. HCV is the most common chronic blood-borne infection in the United States and the most frequent condition requiring liver transplantation. The seroprevalence among volunteer blood donors in the United States is approximately 1%-2%. At present, IV drug use is the most prominent risk factor for acquisition of HCV. Health care workers experiencing a needle-stick injury or mucous membrane exposure to blood products also are at risk. Sexual transmission of HCV is uncommon, and household contact results in viral transmission only rarely, if at all.

Historically, transmission occurred most frequently after exposure to blood or blood products, including sporadic

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

lots of intravenous immunoglobulin. The practice of administering multiple small-volume transfusions to ill neonates during the 1960s and 1970s resulted in inadvertent HCV infection in a substantial proportion of the recipients. The screening of potential blood donors with newer-generation antibody tests for HCV, however, has greatly reduced the incidence of transfusion-acquired infection in adults and children. Since the implementation of these screening programs, vertical transmission has become the most common mechanism of HCV infection in children.

HCV infection has a 30- to 60-day incubation period. In unusual circumstances, infection results in acute hepatitis with symptoms similar to those caused by other hepatotropic viruses—abdominal pain, jaundice, nausea, vomiting, fever, and malaise. Most acute infections in adults, however, are asymptomatic. More than half of all adults with HCV infection develop chronic hepatitis, which may resolve or may progress in one fourth of patients to cirrhosis and eventually to hepatic failure.[224] As with chronic HBV infection, chronic HCV infection is a significant risk factor for hepatocellular carcinoma. However, in 2011, the introduction of highly effective anti-HCV protease inhibitors changed the hepatitis landscape. The infection is now treatable with shorter courses, as short as 8-12 weeks and with high sustained virologic responses.[1] Notwithstanding, these newer agents are not recommended during pregnancy and antiviral therapy should be considered prior to pregnancy, if feasible. (AASLD-IDSA. Recommendations for testing, managing, and treating hepatitis C. http://www.hcvguidelines.org.)

Although HCV infection is relatively prevalent among young adults, almost every expert recommends against screening for HCV during pregnancy, unless the woman possesses known risk factors for infection, such as transfusion or organ transplantation before 1992 or infusion of clotting factor concentrates before 1987; IV drug abuse; presence of a tattoo or body piercing that was placed unprofessionally; or HIV infection. Pregnancy does not seem to worsen the severity of HCV infection, and HCV infection does not seem to increase maternal or fetal morbidity and mortality beyond that conferred by concomitant maternal drug use. As in nonpregnant adults, most pregnant women infected by HCV are asymptomatic with only mildly abnormal liver function tests.

The incidence of mother-to-child transmission in women not co-infected with HIV is approximately 5%.[159] HIV co-infection in the mother increases the risk of vertical transmission of HCV twofold to fivefold. More recent data, however, suggest that effective multidrug therapies for HIV during pregnancy may reduce the risk of transmission of HCV as well. Maternal illicit drug use also increases the risk of vertical transmission of HCV to the newborn. Transmission seems to be a function of the degree of maternal viremia. If the mother's serum is HCV negative, as shown by PCR, the rate of transmission to the newborn approaches zero.[80] Conversely, studies have indicated that transmission rates are roughly proportional to maternal HCV plasma load.[111] However, no minimal level of viremia, below which the infant is safe, has been established.

Most infants probably are infected at or near delivery, and several investigators have documented that the risk of vertical transmission is increased by prolonged rupture of the membranes and invasive fetal monitoring, both of which heighten the exposure of the newborn to maternal blood.[159] Most series have been unable to document protection from HCV vertical transmission through cesarean section.[111] Some samples of colostrum and breast milk contain detectable HCV RNA, but studies indicate no increased risk of mother-to-child transmission attributable to breastfeeding as long as the nipples are not damaged or bleeding.[254] Administration of immunoglobulin to a newborn has no role in preventing vertical transmission because donors for commercial immunoglobulin preparations are screened and rejected for the presence of HCV antibodies.

Infants born to mothers infected by HCV are virtually all asymptomatic at birth and remain so for years.[260] There are few long-term longitudinal studies of these infants. Progression of disease seems to be slower in children than in adults, and most children experience only mild to moderate intermittent elevations of serum liver transaminase levels through at least the first two decades of life. Liver histologic changes tend to be mild as well. It is uncertain how many of these children progress to cirrhosis or hepatocellular carcinoma later in life. In a small proportion of children with vertically transmitted HCV, the infection clears spontaneously over the first few years of life. Maternal HCV antibodies may be detectable in the infant for 18 months and cannot be used for diagnosis unless they persist beyond this time. HCV-specific RNA can be detected in the serum with PCR. Most infants born to a mother infected with HCV have negative HCV PCR at birth, but with infection, PCR becomes positive after the first 1 or 2 months. Thereafter, the test is variably positive throughout life, reflecting intermittent episodes of viremia.

Hepatitis D Virus

Hepatitis D virus (HDV), formerly known as the δ agent, is a defective RNA virus that uses HBsAg as its surface coat and requires co-infection with HBV. Its epidemiology is the same as that of HBV. HDV is transmitted parenterally, and in the United States, it is most commonly found in drug addicts and those with hemophilia. HDV is worldwide in distribution. Perinatal transmission, which is rare, occurs only with HBV transmission and can be interrupted by interrupting HBV perinatal transmission.

Hepatitis E Virus

Hepatitis E virus (HEV) is a single-stranded, positive-sense, non-enveloped RNA virus unrelated to the other hepatitis agents. HEV disease has been identified in Asia, Africa, the Middle East, and Central America.[246] Occasionally, a case is diagnosed in an immigrant in the United States or

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Europe. In endemic areas, HEV occurs sporadically, but several instances of large outbreaks have been reported, typically affecting thousands of people. Infection is transmitted through contaminated water supplies sullied by sewage; person-to-person spread is uncommon. The diagnosis can be made through identification of viral particles in the stool, Western blot assays for anti-HEV IgM and IgG, and detection of circulating viral RNA by using PCR, but these tests are not routinely available in most hospitals in the United States. In nonpregnant women, infection with HEV is similar to that caused by HAV. Most cases are characterized by self-limiting icteric hepatitis and full recovery. Subclinical and anicteric infections also occur. Fulminant hepatitis results from a small fraction of infections. HEV infection does not lead to chronic hepatitis.

There is a striking association between pregnancy and the development of overwhelming HEV-related hepatitis, particularly in women from the Asian subcontinent. In some endemic areas, HEV is the most common identifiable cause of clinically apparent hepatitis in pregnant women, even when the prevalence of HEV in the general population is lower compared with other hepatotropic pathogens. Massive hepatic necrosis is particularly prominent during the third trimester of pregnancy, when the mortality rate can exceed 20%.[6] The reasons for this predilection are unknown, but some data suggest that hormonal elevations during pregnancy promote viral replication.[117]

Mild HEV disease during pregnancy can result in abortion, intrauterine death, stillbirth, or preterm delivery.[201] Reports studying a few subjects have documented vertical transmission of HEV in more than half of infants born to mothers who were viremic during pregnancy. Blood-borne virus can be detected soon after birth, suggesting intrauterine transmission. All the affected infants had abnormalities of liver function tests, and approximately 20%-25% died; one of these was found to have hepatic necrosis at autopsy. Liver function returned to normal in survivors after 2-3 months.

In 2011, a recombinant HEV vaccine was licensed in China for use in patients 16 years of age and older.[176,199] The vaccine has been shown in clinical trials to have an efficacy close to 87%, especially against HEV genotype 4. In addition, the protective effects of the vaccine last up to 5 years.[293] Unfortunately, this vaccine is not available in the rest of the world at this time.

Hepatitis G Virus and GB Virus Type C

Hepatitis G virus (HGV) and GB virus type C (GBV-C) were isolated independently, but subsequently, they proved to be nearly identical flaviviruses based on genetic sequence. HGV/GBV-C has a genomic organization similar to that of HCV. In adults, infection by HGV/GBV-C results in viremia that lasts for months to years, but the virus eventually is cleared by the appearance of antibody against the viral protein E2. Although initial studies suggested that HGV/GBV-C was a cause of hepatitis, subsequent surveys have failed to establish that HGV/GBV-C infection produces liver disease or any disease at all. This observation, along with data that suggest that HGV/GBV-C primarily infects lymphocytes rather than hepatocytes, has prompted some experts to recommend that the name "hepatitis G virus" be discontinued.

HGV/GBV-C is transmitted through the same routes as HIV and HCV—transfusion, injection drug use, sexual activity, and vertical transmission from mother to infant. Occasional patients with HGV/GBV-C infection have none of these risk factors, suggesting that other modes of acquisition occur as well. Prevalence studies have documented that active infection, defined by the detection of circulating HGV/GBV-C RNA, and past infection, defined by the presence of antibody to HGV/GBV-C, are extraordinarily common in healthy individuals and patients with underlying conditions. Approximately 2% of blood donors have evidence of active HGV/GBV-C infection, and an additional 15%-18% have evidence of past infection. Coinfection with HGV/GBV-C occurs in greater than 20% of subjects with HCV infection. Ongoing or past infection by HGV/GBV-C is detected in two thirds or more of IV drug users and patients with HIV. Although no clinically apparent disease has been identified in individuals infected with HGV/GBV-C, interest in this virus has been rejuvenated by studies suggesting that active HGV/GBV-C replication in HIV-infected patients may slow the progression of HIV disease. The mechanism of this putative protective effect in HIV-infected hosts is uncertain.

HGV/GBV-C is efficiently transmitted from mother to child. Studies that have included healthy women and mothers co-infected with HCV or HIV have documented HGV/GBV-C transmission to more than one half of their offspring. Typically, an infant becomes positive for HGV/GBV-C RNA by 3 months of age, and, similar to adults, active infection lasts for months. Most studies have failed to detect an independent association between HGV/GBV-C infection in vertically infected newborns and subclinical or clinically apparent liver disease. To date, no other clinical consequences have been identified in infected infants.[278]

Rotavirus

Rotavirus is the predominant cause of acute viral gastroenteritis in infants and young children. It is a double-stranded RNA virus containing 11 genomic segments. The virus is composed of three concentric capsid shells. Strains are characterized by the electrophoresis migration patterns of the RNA segments and by structural differences of the capsid proteins VP6, VP7, and VP4. VP6 serotype A accounts for most of the rotaviruses that are pathogenic in humans. The virus replicates primarily in enterocytes in the proximal small intestine, where infection leads to denuding of the villus tips and mononuclear cell infiltration of the underlying lamina propria. The virus seems to remain localized to the intestine. It has not been identified in breast milk.

Epidemiology and Transmission

The distribution of rotavirus is widespread throughout the industrialized countries as well as the developing world. The virus causes an estimated 150 million diarrheal episodes in infants and young children each year, and approximately 0.5 million deaths. Rotavirus infections are usually prevalent in temperate climates during the winter months, whereas in tropical areas, infection is endemic year round. In some nurseries endemic infection rates reflect the incidence in the community, but in others, the incidence of disease is relatively constant. Rotavirus infection in neonatal units may also occur in the context of a clinically apparent outbreak. The distinction between endemic and epidemic rotavirus disease in the nursery, however, is blurred. Longitudinal prevalence surveys conducted in geographically diverse nurseries during periods without outbreaks indicate that 10%-70% of infants admitted in hospital for longer than 1 week excrete rotavirus at some time before discharge, often asymptomatically, and that typically only one or two strains account for all the infections over many months.

Epidemiologic aspects of rotavirus potentiate its spread in a confined environment, such as a nursery. The stool of infected individuals contains high titers of virus, and infection can be transmitted by very small inocula. Additionally, the virus survives on inanimate surfaces and is resistant to many commercial disinfectants. Rotavirus likely is introduced into the unit by a newborn who acquires infection during delivery after exposure to maternal stool, or by an infant or a staff member who imports the virus from the community. Thereafter, most infection is nosocomial, transmitted via the hands of personnel. Viral excretion in the stool begins 1-2 days before the onset of diarrhea, is highest after 3-4 days of diarrhea, and then wanes 1-2 weeks later. Outbreaks may spread rapidly through the nursery, where the most important factors determining spread seem to be the frequency of handling the infants and the closeness of the bed spaces.

Clinical Manifestations

Nearly all reports indicate that rotavirus infection frequently is asymptomatic or mildly symptomatic in newborns. Some data suggest that maternally derived serum and intestinal antibodies and possibly breast milk antibodies may be responsible for preventing or alleviating infection early in life. Additionally, a high proportion of nursery infections are caused by the VP4-serotype designated P[6].[150] This serotype is not usually isolated from older children with community-acquired symptomatic infection. The reasons underlying the predilection of newborns for P[6] strains are unknown, but this observation suggests that the relatively mild disease in infants may partially be the result of the intrinsic properties of the infecting virus.

Symptomatic infants develop irritability and poor feeding, followed by watery or mucous stools that are sometimes bloody and frequently contain increased reducing substances.[219] Occasionally, infants develop severe diarrhea and dehydration, but fatalities are rare. There has been speculation that rotaviral infection may predispose to necrotizing enterocolitis, but such an association has not been clearly established.

The diagnosis is usually made by detection of viral antigen in stools by using ELISA. The rate of false-positive results may be 1%-4%. Hand washing remains the most effective prophylactic measure. Hard surfaces should be washed with alcohol-containing disinfectants because quaternary ammonia–containing compounds are not active against the virus. Therapy consists of rehydration and maintenance of fluids and electrolytes. Some investigators have found that breastfeeding prevents infection or lessens the severity of the illness.

A tetravalent vaccine approved by the FDA in 1998 was removed from the market in 1999 because postmarketing surveillance indicated a rare association with intussusception. Two additional oral rotavirus vaccines were introduced in the mid-2000s: a pentavalent product composed of five re-assorted strains derived from human and bovine rotaviruses (RV5) and a monovalent vaccine composed of an attenuated human strain (RV1). Data for intussusceptions from the Vaccine Adverse Event Reporting System (VAERS) from 2006 through 2012 were recently published. The VAERS received 584 reports of confirmed intussusception cases after the administration of RV5 and 52 after RV1.[97] Most intussusceptions after RV5 occurred 3-6 days after the administration of the first dose. The overall risk after three doses of the vaccine was estimated at 0.79/100,000 cases, implying a slight increase in risk for intussusception. The CDC and the AAP continue to recommend the vaccine for infants in the United States because the benefits of the vaccine far outweigh the risks. So far, the vaccine has been shown to have prevented more than 382,000 hospitalizations from rotavirus-related illness, translating into approximately 1.2 billion dollars in savings in medical cost related to rotavirus morbidity.[146] The first dose of each vaccine is preferentially administered at 2 months, although both may be given at 6 weeks. Immunization of preterm neonates is recommended at the same postnatal age if the infant is otherwise stable and he or she has been discharged from the hospital. The vaccine should be avoided in infants suspected of having severe combined immunodeficiency syndrome (SCIDS) and in those with a history of allergy to any component of the vaccine and in those with a previous history of intussusception.[42] On the contrary, in the HIV exposed/infected infant the CDC supports the administration of the vaccine because the diagnosis of HIV may not be confirmed in infants at the time they receive the vaccine; and because the vaccine strain is attenuated, it is less risky for the infant to develop rotavirus from the vaccine strain than from the wild type. Studies of this vaccine in South Africa have shown that it is immunogenic and safe in this population.[247]

Parvovirus B19

Parvoviruses are small (23-25 nm), single-stranded DNA viruses of the family Parvoviridae (genus *Erythrovirus*) that lack an envelope, but form capsids (*Parvum* is the Latin word meaning "small"). The viral genome consists of approximately 5600 nucleotides and encodes for only three proteins—a nonstructural protein, NS1, which functions in replication and is responsible for the destruction of the erythroid progenitors, and two structural proteins, viral protein 1 (VP1) and viral protein 2 (VP2).[291] Viral protein 1 differs from VP2 only in that it has 226 additional amino acids at its amino terminal. Although most of the capsid consists of VP2, which may assist in the entry of the virus into the cell, the additional 226 amino acids of VP1 form loops that are external to the capsid and contain the epitopes recognized by neutralizing antibodies. Immunity to parvovirus occurs primarily through the antibody response, and IgG confers lasting immunity.

Parvoviruses are animal viruses, which seem to be species specific. Parvovirus B19 replicates only in human erythroid precursors and is the only virus in the family definitely known to be pathogenic in humans. Parvovirus B19 was identified in 1975 in the sera of blood being screened for hepatitis B, and its name signifies the well in which it was identified. Parvovirus B19 is distributed worldwide, and infection occurs sporadically throughout the year, although there are seasonal increases in temperate zones, particularly in spring, and epidemics occur every 4 years.

Transmission of infection occurs mainly through contact with respiratory secretions or droplets but also occurs vertically from mother to fetus and via blood or blood products. IgG antibodies to parvovirus B19 are believed to confer lifelong immunity, and vertical transmission has not been documented in women with immunity before pregnancy. Secondary infection rates among nonimmune household contacts approach 50%, and child care personnel and teachers have an occupational risk of approximately 20%-30%. Although seroprevalence is found in only 5%-10% of young children, it increases to approximately 50% in young adults and is nearly 90% in older adults. The annual seroconversion rate of women of childbearing age is estimated to be 1.5%. The risk seems to be greatest in homes with multiple children, especially between ages 3 and 10 years. The incubation period usually is 4-14 days but can be 21 days. Rash and joint symptoms appear 2-3 weeks after infection. Individuals are most infectious before the onset of the rash, but are no longer so after the appearance of the rash, so school attendance with rash is not of concern. Hospitalized patients with aplastic crisis may remain contagious for a week after the onset of symptoms.

Clinical Manifestations

In most instances, infection with parvovirus B19 is asymptomatic and remains unrecognized. The most common illness is erythema infectiosum, or fifth disease. These individuals usually have a syndrome of malaise, headache, and low-grade fever, followed 7-10 days later by the development of an erythematous, "slapped cheek" rash, sparing the nasal bridge and circumoral region, followed by a blotchy, maculopapular rash of the trunk and then the extremities, particularly the thighs. These areas develop central clearing, resulting in a reticular or lacey pattern. This rash may recur over weeks to months later with heat or cold exposure. Individuals shed virus during the prodrome and are unlikely to be infectious by the time the rash aspect of the illness occurs. Another manifestation that is less common in children is a symmetric arthralgia or arthritis, particularly of the hands, wrists, and knees, which is usually self-limited. Both manifestations, rash and arthropathy, seem to be immune mediated. A few individuals develop a mild respiratory illness with no rash and, rarely, some develop a papular, purpuric "gloves and socks" syndrome, with painful, purpuric papules over the hands and feet.

Because the virus causes lysis of red blood cell precursors, it may cause a transient red blood cell aplasia, which is rarely significant in healthy individuals. Aplastic crises may result, however, in the presence of hematopoietic disease, such as sickle cell disease or thalassemia. Occasionally, parvovirus B19 will also cause thrombocytopenia, neutropenia, and lymphocytopenia. Chronic infection and anemia may result in patients with immunodeficiency disorders. Other reports suggest an association of the virus with myocarditis,[198] peripheral nerve abnormalities, or vasculitis.

Fetal Infection

Fifty percent of pregnant women are susceptible to parvovirus. When infection occurs, transplacental transmission of parvovirus is estimated to be 30%-50% and is less frequent with advancing gestational age. Spontaneous abortion has been seen in up to 30% of first-trimester infections, nonimmune fetal hydrops and/or fetal death in 12% of cases in the second-trimester, and fetal death in 7% of third-trimester cases.[31,216] Most pregnancies result in apparently normal newborns despite proven fetal infection,[135] although there may be an increase in the number of infants who are small for gestational age. Although there have been a few reports of congenital anomalies, most case series have not found an increased incidence of anomalies. In studies of viral causes of intrauterine fetal deaths, parvovirus was found in 13% of fetuses and was highly associated with chronic villitis and hydrops fetalis.[251] Parvovirus B19 attaches to the globoside glycolipid cellular receptor found on erythroid precursor cells (erythroblasts and megakaryocytes), erythrocytes, placental syncytiotrophoblasts, fetal myocardium, and endothelial cells, but replication occurs only in the erythroid progenitor cells.[291] The apoptosis of the red blood cells appears to be caspase mediated.

The most common adverse fetal outcome reported in infected fetuses is hydrops fetalis; parvovirus B19 may

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

be responsible for 20%-30% of the cases of nonimmune hydrops, particularly during epidemics. Irrespective of when maternal infection occurs, fetal nonimmune hydrops most commonly occurs between 17 and 23 weeks' gestation, when hematopoiesis is occurring most rapidly and is located in the liver, and when the placental trophoblasts have the highest concentration of the P antigen, the B19 cell receptor.[24] The virus infects the erythroid progenitor, causing a maturation arrest at a time when the fetus is expanding its red blood cell volume and has a shortened red blood cell life span, resulting in severe fetal anemia in most, but not all, instances. Fetal anemia results in congestive heart failure, a known cause of hydropic changes, such as generalized edema, ascites, and pleural effusions. However, fetal hydrops has occurred in the third trimester and as late as 12 weeks after maternal infection, so follow-up with fetal ultrasonography must be continued with diligence.

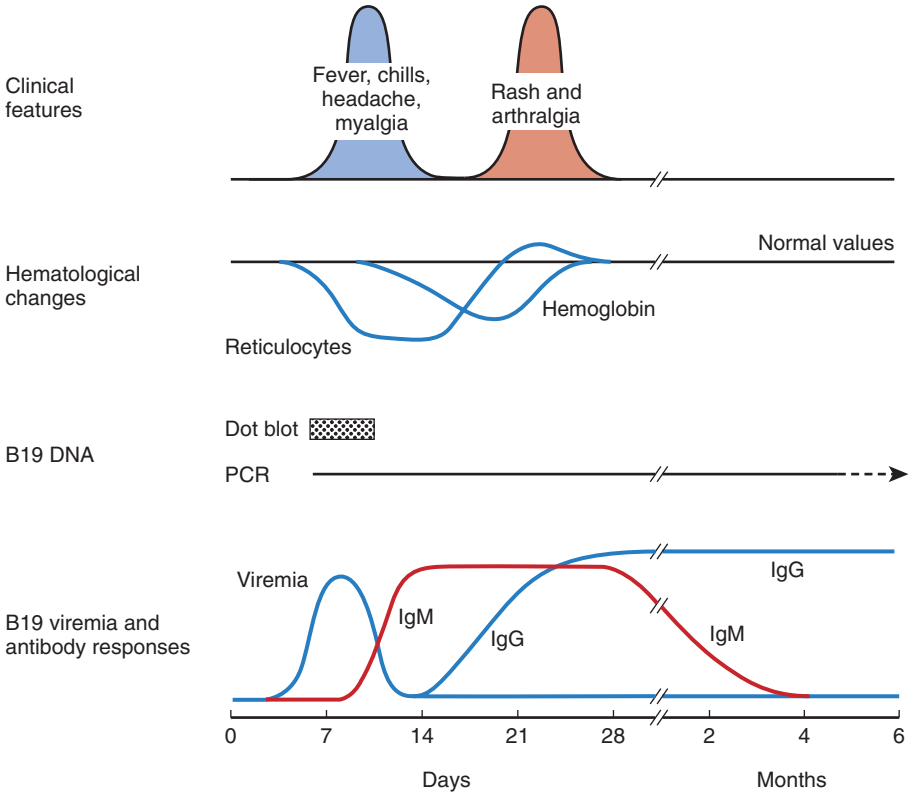
The virus may also cause myocarditis, after attachment to the globoside receptors in the myocardial cell, which also results in hydrops. Some fetuses develop thrombocytopenia and hepatic damage. Meconium peritonitis has resulted from small bowel obstruction and perforation. Placental damage, resulting in leakage of α-fetoprotein, is often linked to poor outcome. The mother may also become ill with "mirror syndrome," which consists of a preeclampsia-like state, with anemia, hypertension, proteinuria, and edematous legs, mirroring the fetal infection.[56] The mirror syndrome is believed to be secondary to perfusion abnormalities of the placenta.

There are too few cases of hydrops secondary to parvovirus B19 to conduct a controlled trial, and most clinicians advocate intrauterine transfusion. Although untreated fetuses may also survive hydrops, survival in small case series appears to be lower (55%) than among the transfused fetuses. Measurement of the middle cerebral artery peak systolic velocity on fetal ultrasonography to determine severe anemia and high cardiac output can be used as an indicator of the need for fetal transfusion. When transfusion has been used, survival of the fetus has been 85%. Platelets should also be available for transfusion because the severely anemic fetus may also have thrombocytopenia. Most fetuses who survived intrauterine transfusion demonstrated a good neurodevelopmental outcome on follow-up.[63] However, a study of 28 infants indicated that 11% had neurodevelopmental impairment.[57] Digitalization has also been used for fetuses with myocarditis. Surviving fetuses do not seem to have heart disease. A few cases have also been reported of encephalitis, meningitis, perivascular calcifications, and intrauterine stroke. In these cases, virus seems to infect the immature endothelial cells.

Diagnosis

Because parvovirus B19 is too fastidious to grow in the laboratory, serology remains the best means of diagnosis, with the measurement of specific IgM or an increase in titer of specific IgG. IgM antibodies appear 7-14 days after infection and are often present for at least 2-3 months. IgG antibodies appear within days and persist for the life of the patient (Fig. 50.6).[67] Currently assays for parvovirus B19 IgM detect slightly greater than 90% of acute infections, and detection of viral DNA by PCR detects greater than 95% of infections. Acute maternal infection can best be diagnosed by using combination parvovirus B19 IgM serology and parvovirus B19 DNA detection by using PCR.[24] Not all fetuses make parvovirus B19 IgM, so viral DNA needs to be detected. Parvovirus B19 DNA may be detected in maternal serum, amniotic fluid, or fetal blood by using PCR, but the presence of the antigen does not always indicate recent infection because small levels of DNA may be detected for several months after acute infection. Placental infection has been documented at 14-16 weeks' gestation, but it is rare for the amniotic fluid to be infected before 21 weeks' gestation, and detection of amniotic fluid infection usually requires a delay of at least several weeks after the maternal infection. Placental infection does not invariably result in fetal infection.

Isolation



Contact isolation with use of gown, gloves, and mask is indicated for hospitalized patients with aplastic crisis. Pregnant health care personnel should be aware of their risks, although the magnitude of this risk is uncertain. Serologic testing and the option not to care for a patient with an aplastic crisis may be offered. Patients with only the rash of erythema infectiosum are not contagious.

Although pregnant childcare and health care workers are at increased risk of infection, they are also at risk of infection within the community and within their own homes, and the fetus, if infected, has a low risk of adverse outcome. Therefore, it is not recommended that these pregnant workers be kept away from their workplaces. They do, however, need counseling regarding hygiene.

Influenza A and B

The influenza viruses are RNA viruses of the family Orthomyxoviridae. Although there are three antigenic types (A-C), type C is only responsible for mild flulike symptoms, or coryza, in children. Its antigens are not included in the influenza vaccines. Types A and B are both responsible for epidemics, and their antigens are both included in the influenza vaccines. Type A virus is further classified by the presence of two distinct glycoprotein surface antigens, the hemagglutinin (H) and neuraminidase (N) antigens. Hemagglutinin is responsible for viral binding to cell receptors, and neuraminidase is responsible for the release of virus duplicated from the cell after replication. The H1, H2, and H3 hemagglutinin subtypes are particularly important in epidemics because immunity is largely caused by the production of antibodies to these antigens. "Drifts," or minor changes in the antigens, occur in both the influenza A

• **Fig. 50.6** Course over time for clinical, serologic, and virologic characteristics of B19V infection in pregnancy. (Adapted from Dijkmans AC, et al. Parvovirus B19 in pregnancy: prenatal diagnosis and management of fetal complications. *Curr Opin Obstet Gynecol*. 2012;24:95.)

subtypes and in influenza B over time, requiring changes in the immune response to the virus.

An antigenic "shift," with the development of a new hemagglutinin or neuraminidase antigen, results in pandemic infection at infrequent intervals. When an antigenic shift occurs, the new antigenic viral strain almost completely replaces the prior seasonal strain. Therefore, the 2009 pandemic influenza A (H1N1) replaced the prior seasonal influenza A (H1N1). The virus type that predominates in a season alters the morbidity (hospitalizations) and mortality for that season.

Influenza A (H3N2) has nearly three times the average mortality, whereas influenza A (H1N1), which predominated in the 2009 pandemic, had four times the average mortality in children, because of a prior lack of exposure and immunity and because of its particular virulence in children. In one 10-year study of 209 infants in the first year of life, influenza A (H3N2) occurred most commonly, followed by influenza B and influenza A (H1N1), with infections in 178, 96, and 26 infants, respectively.[94]

Both swine influenza and avian influenza can occasionally cause infection with the typical influenza symptoms in humans. Swine influenza is usually associated with attendance at agricultural fairs and does not result in significant human-to-human transmission. Avian influenza is associated with contact with domestic or wild birds. Two avian influenza viruses have been responsible for severe disease and mortality in humans: influenza A (H5N1) has been reported in Asia, Africa, the Middle East, and Europe in 1997, and influenza A (H7N9) has occurred endemically in China since 2013.

The onset of influenza is characterized by the sudden onset of fever and chills, with associated malaise and headache, myalgia, sore throat, conjunctivitis and rhinitis, and sometimes vomiting and diarrhea, often resulting in otitis media. Full recovery occurs in most otherwise healthy children by 3-5 days. Occasionally, a previously healthy child may develop myocarditis, a lower respiratory tract infection (pneumonia or bronchiolitis), or CNS disease, ranging from febrile seizures to encephalitis. Secondary bacterial infections may be significant and may result in death. Aspirin or aspirin-containing products should never be given to any child suspected of having influenza infection to prevent the now-rare Reye syndrome.[100]

Most influenza infections in neonates are asymptomatic. Infection is less common in the first 6 months of life and usually less symptomatic, probably reflecting the transplacental transference of maternal antibody during pregnancy, which may protect the infant for the first 6 months, and antibody transferred via breast milk. Infants may, however, present with high fever and an upper respiratory tract infection, and the infection may be indistinguishable from bacterial sepsis. The highest mortality has been reported in infants younger than 6 months of age. In the 2003-2004

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

influenza season, the mortality rate among infants younger than 6 months of age was 0.88 per 100,000 children. One third of the infants died at home, and one fourth had co-infections with bacteria, particularly pneumococcal or staphylococcal pneumonia. Chronic neurologic and neuromuscular conditions not previously recognized as at-risk conditions were present in one third of the children.[20] However, almost half of all deaths resulting from influenza occur in children with no underlying chronic conditions, such as pulmonary or cardiovascular disease or immunosuppression putting the child at risk.

Bronchiolitis, pneumonia or croup, fever, rhinorrhea, apnea, irritability, and feeding difficulties all may be primary symptoms. In a prospective study of the first year of life, one third of the infants were infected, but only 40% of the infants were infected in the first 6 months of life, and most lower respiratory tract disease and otitis media occurred in the latter 6 months, when the transferred maternal antibody would be expected to have waned.[94] There was also a very significant increase in risk of infection with increasing numbers of siblings, ranging from a 20% infection rate with no siblings to a 59% rate with three or more siblings. Lower respiratory tract disease was, however, far less common than with RSV or PIVs. One third of infants presenting to the emergency department during influenza epidemics had influenza infection, although they frequently had no respiratory symptoms. In contrast, one third of the infants presenting with a community-acquired pneumonia were also infected with influenza.[139,211]

Several influenza A and a few influenza B epidemics have been reported in NICUs. Low rates of immunization among staff members played a significant role in these epidemics. Prematurity and pulmonary disease, particularly bronchopulmonary dysplasia, seem to be risk factors.

Pregnant women infected with H1N1 influenza virus in 2009 had higher rates of hospitalization and death, accounting for 6% of such deaths in the United States. Risk factors for severe disease include obesity, asthma, multiparity, and multiple births. Pregnant women should be vaccinated during prenatal visits and may receive both seasonal flu vaccine and H1N1 flu vaccine at the same time in different body sites (one in each arm), when both viruses are in season. Vaccination of the pregnant woman may offer some protection to her newborn infant, which is particularly important, as the vaccine is not licensed for infants less than 6 months of age. Certainly, all caregivers of infants less than 6 months of age should also be vaccinated in an effort to prevent them from bringing influenza to the infant. Pregnant women should receive the injectable, inactivated vaccine. Breastfeeding is likewise compatible with vaccination and may offer some antibody protection to the infant.

To date, the virus has not been shown to cross the placenta, but the newborn may be exposed to contaminated secretions at birth. Thus, the newborn should be considered exposed, rather than infected, and should be carefully observed. The baby may be separated from the mother and kept in an incubator in the same room, or the baby may be put in a separate room until the mother has been treated with antivirals for at least 48 hours, has been free of fever while off antipyretics for at least 24 hours, and can control her cough and respiratory secretions. Breastfeeding should be supported, and expressed breast milk should be used to feed the newborn. In the 2009 pandemic, more than 50% of nurseries restricted breastfeeding by the mother while she was ill. When able to see her infant, the mother should wear a face mask, wash her hands with soap and water, and follow respiratory hygiene and cough etiquette guidelines for at least 7 days after symptom onset or 24 hours after resolution of symptoms, whichever is longer.

In past pandemics, secondary bacterial infections, particularly caused by *Streptococcus pneumoniae* (*Pneumococcus*), have also been the cause of increased morbidity and mortality. Continued pneumococcal vaccination is important.

Influenza is rapidly and easily spread person to person by aerosol droplet or by contact with contaminated secretions. The particles only travel a short distance (<6 feet) because of their size. Viral shedding and infectiousness are greatest in the 24 hours before onset of symptoms and at the peak of symptoms. Individuals should cover their noses when coughing or sneezing and should avoid touching their mouths, noses, or eyes with their hands. The virus may survive in the environment for 2-8 hours, although the role of fomites in transmitting infection is unclear. The virus can be destroyed by heat (75-100° C) or by numerous chemical germicides or household disinfectants. The incubation period is 1-3 days. Individuals are contagious the day prior to developing symptoms. Winter outbreaks are more common in temperate climates. School-age children have the highest attack rate and serve as a source of spread to adults and younger children. Hand washing with soap and water or alcohol-based hand cleansers and cohorting are the most effective means to interrupt epidemics within the NICU. Cohorting requires rapid diagnosis. PCR detection of influenza RNA is the most rapid and sensitive means of diagnosis. In addition, staff members should not work when ill, and family members should be carefully screened, particularly during the influenza season, for viral illness before admission to the NICU. The infection is *not* spread by eating any particular food, such as pork or pork products.

Infants who are born to pregnant women with influenza have an increased risk of preterm birth, low birth weight, and small size for gestational age, especially when the mother is severely ill. The decreased tidal volume and increased cardiac output, as well as the immunologic changes of pregnancy, put the pregnant woman at higher risk of severe illness requiring hospitalization. All women who may be pregnant during an influenza season should receive inactivated vaccine. The vaccine is safe throughout pregnancy and breastfeeding. Administration of the vaccine to the mother during the pregnancy is not associated with fetal death, preterm birth, or congenital malformations. Additionally, the neonatal antibody level is much higher and the infant is much less likely to develop influenza in the first 6 months of life. The vaccine may be given in any

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

trimester. Staff members in the NICU should also be encouraged to be vaccinated; compliance has traditionally been low, although now most hospital programs require staff to either receive the vaccine or wear a clean mask before each patient contact throughout the influenza season. Also, inactivated vaccine should be given to family members of high-risk infants. Little is known about the safety and efficacy of antiviral prophylaxis in staff members and parents during epidemics in the NICU, although it has been used.[100]

Treatment should not be withheld while awaiting laboratory test results in a high-risk individual. The tests of choice include RT-PCR, viral culture, and rapid molecular assays, which are widely available and have high sensitivity and specificity.

Oseltamivir, a neuraminidase inhibitor, has been used in several nurseries during outbreaks, particularly during the 2009-2010 pandemic. The most commonly reported side effects include vomiting and diarrhea. The FDA licensed oseltamivir for use in children as young as 2 weeks of age. However, it is being used to treat both preterm and term infants at birth because the benefits appear to outweigh the risks. Fever needs to be controlled, most often using acetaminophen, but aspirin-containing products should never be given to individuals suspected of having influenza infection.

Recommendations for prophylaxis and/or treatment of influenza may be found online (www.cdc.gov/flu/professionals/antivirals/index.htm). Treatment is most effective if begun within 48 hours of onset of disease but can still be effective even if started later. Children should be evaluated for bacterial co-infections and, if infection is suspected, treated with antimicrobials. Siblings of infected children, particularly if they are less than 6 months of age or have other high risk, chronic conditions, may need prophylaxis or treatment. The inactivated vaccine should be given to children 6 months of age and older. Prior to 6 months of age, antibody response is inadequate. The vaccine contains no live virus. Both the trivalent and quadrivalent inactivated vaccines may be used. Live attenuated vaccine is *not* recommended. A dosing algorithm may be found in the annual AAP influenza policy statement published each year in the September issue of *Pediatrics*, or online (https://www.aap.org/en-us/advocacy-and-policy/aap-health-initiatives/Children-and-Disasters/Documents/Special-Considerations-to-Treat-and-Prevent-Flu-in-Newborns_FINAL.pdf). Children 6 months to 8 years of age who have not previously been vaccinated require two doses of vaccine given at least 4 weeks apart for protective titers to develop. All people should be vaccinated annually. The vaccine may be given with other live or inactivated viruses. Egg allergy does not preclude the use of the vaccine. Vaccination should be the mainstay of prevention of influenza.

Rubella Virus

Rubella virus is an RNA virus in the Togaviridae family. It is surrounded by a lipid-containing envelope, which is responsible for its infectivity. Only one immunologic strain has been identified; the epidemics that have occurred seem to be secondary to changes in the susceptibility of the population, rather than changes in the virulence of a strain.

Rubella produces a very mild but extremely contagious disease, sometimes referred to as *German measles*. The incubation period is 14-23 days. It primarily manifests in adults with a maculopapular rash that can last 3 days and spreads from the face to the trunk and extremities, and with postauricular, suboccipital, and posterior cervical lymph node enlargement. There may be conjunctivitis, headache, sore throat, and cough. Although arthralgia may occur, recovery is nearly always rapid and complete. Fever is slight. Thrombocytopenia and encephalitis are rare. Half of all infections may be asymptomatic.

Epidemiology and Transmission

Rubella virus exclusively infects humans and is spread via respiratory droplet contact. Infections are worldwide in distribution but tend to peak in late winter and early spring. Presumably, the viral reservoir is maintained by mild or asymptomatic infections that occur constantly throughout the year and by prolonged viral shedding (possibly ≥1 year) from congenitally infected infants. Most individuals shed virus from 7 days before the onset of the rash until 14 days afterward. In the pre-vaccine era (before 1969), epidemics occurred every 6-9 years. The last major epidemic in the United States was in 1965. The goal of routine rubella vaccination in the United States, which was initiated in 1969, was to eliminate congenital rubella syndrome. From 2001-2006, there were only four cases of congenital rubella syndrome in the United States. Three of the mothers were born outside of the United States.[164] In 2004, the CDC declared that rubella was no longer endemic in the United States. Rubella continues to occur among immigrants, however, and it is important that pediatricians continue to administer the vaccine. The current goal is global elimination.

Most cases of congenital rubella syndrome occur after a primary maternal infection that causes viremia and intrauterine transmission. A few cases have occurred after maternal re-infection with rubella, but these are very rare. Accidental vaccination with RA27/3 vaccine in pregnancy may result in fetal infection (2%), but congenital defects or congenital rubella syndromes have not been seen.

After a primary maternal infection in the first trimester, there may be fetal loss, stillbirth, placental infection, or congenital rubella syndrome, or the fetus may remain totally uninfected. Not all infected fetuses develop congenital rubella syndrome. The virus may cause persistent placental infection with or without persistent fetal infection. The placenta is a relatively effective barrier to fetal infection from 12-28 weeks' gestation, but it is not so effective in the first and third trimesters, particularly in the last month of pregnancy.

Gestational age at the time of maternal infection is the most important determinant of fetal infection and of the development of congenital defects, although fetal infection may occur at any point in gestation. Among 273 infants delivered after maternal rubella infection, Miller et al.[168] reported that fetal infection occurred in 90% of infants after maternal infection before 11 weeks' gestation, in 67% of infants at 13-14 weeks' gestation, and in 25% of infants at 23-26 weeks' gestation. Infection increased to 53% of infants after maternal infection in the third trimester, however, and reached 100% in the last month of pregnancy.

In addition, the risk of fetal damage with fetal infection decreases with increasing gestational age. Peckham[204] followed up 218 congenitally infected infants for 2 years and found that fetal damage occurred in 52% of infants infected before 8 weeks' gestation, in 36% of infants infected at 9-12 weeks' gestation, and in 10% of infants infected at 13-20 weeks' gestation. No fetal damage was shown after infection beyond 20 weeks' gestation. Rubella results in chronic infection of the fetal tissues, however, causing an inhibition of fetal cell multiplication. Many infants who show no apparent involvement at birth experience consequences years later. In concordance with the chronicity of the disease, Peckham[204] later noted that at 6-8 years of age, these same infants had an 82% risk of sequelae after infection in the first trimester. The risk of fetal damage reported by Miller et al.[168] was even higher, with sequelae shown in 90% of infants infected before 11 weeks' gestation, 33% infected at 11-12 weeks' gestation, 11% infected at 13-14 weeks' gestation, and 24% infected at 15-16 weeks' gestation.

Congenital Rubella Syndrome

Congenital rubella is not a static disease. Nearly three fourths of infected infants show no apparent involvement at birth, but develop consequences years later. Greater than 50% of infants with expanded congenital rubella syndrome have IUGR (birth weight is often <1500 g) and fail to thrive postnatally. These infants often have myriad transient symptoms, including thrombocytopenia, petechiae and purpura, hemolytic anemia, hepatitis, jaundice, and hepatosplenomegaly. Nearly half the infants show "blueberry muffin" spots on the head, neck, and trunk, which represent dermal extramedullary hematopoiesis. Infants may also show myocarditis, cloudy cornea, long bone radiolucencies, interstitial pneumonia, and meningoencephalitis, manifesting as an elevated CSF protein level and pleocytosis. Although most of these symptoms are transient, they may also indicate severity of infection. Fulminant hepatitis or pneumonia, myocarditis with congestive heart failure, meningoencephalitis, thrombocytopenia, and bony lesions all are associated with a higher mortality.

Congenital rubella is best known for causing deafness and defects of the eye, CNS, and heart. Three fourths of infants develop sensorineural deafness, usually bilateral. Deafness may be the only sequela of congenital infection and may occur with maternal infection up to 20 weeks' gestation.

Congenital heart disease occurs only when the fetus is infected during the first 8 weeks of gestation, the period during which organogenesis occurs but is quite common with infection during that period. PDA, the most common lesion, may occur alone or in conjunction with pulmonary artery or valvular stenosis, or there may be stenoses of other vessels.

Microcephaly and neuropsychiatric problems are also common. Studies of long-term outcome show that 26% of children with congenital rubella syndrome had severe mental retardation, 12% had neurologic problems, 18% had behavioral abnormalities, and 6% had autism. Most rubella survivors without mental retardation had learning disorders, behavioral problems, difficulties with balance, and muscle weakness.

Ophthalmologic abnormalities may include cataracts in one third of children, often bilateral and occasionally accompanied by glaucoma. Other children may have microphthalmos or characteristic "salt and pepper" chorioretinitis. Rubella RNA can be detected and quantified in the lens of affected infants.

Attention has focused more recently on the effects of HLA haplotypes, immune complexes, and autoantibodies in predisposing congenital rubella survivors to autoimmune conditions. In a 60-year follow-up of congenital rubella survivors, Forrest et al.[83] reported that 20% had died (mostly of cardiovascular disease and malignancy); 68% had mild aortic valve stenosis, 22% had diabetes mellitus, 19% had thyroid disease, 73% had early menopause, and 13% had osteoporosis. HLA-A1 and HLA-B8 antigens were increased in frequency.

Diagnosis

Diagnosis of maternal rubella on the basis of clinical findings is unreliable, and serologic testing must be performed. If the maternal immune status is unknown at the time of rash illness, acute-phase titers should be obtained within 7 days of the illness; seropositivity usually indicates prior immunity with very little risk of current infection. Women with very low titers may be re-infected, which can result in a small risk of fetal infection. Latex agglutination, enzyme immunoassay tests, and immunofluorescence are now more commonly used than passive hemagglutination techniques.

Rubella-specific IgM may be determined 7-14 days after the illness. A high or moderate IgM titer is very helpful, but false-positive results may occur, and low IgM titers may be found in patients with subclinical reinfection. Rubella-specific IgM may be high with re-infection or post-vaccination, or it can be high as a false positive. Testing IgG avidity can help differentiate acute infection from these situations.

Traditionally, an increase in serum antibody titers obtained initially in the acute phase, preferably within 7 days of illness and repeated in the convalescent phase 10-14

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

days later, is used to diagnose acute infection. The titers need to be run simultaneously in the same laboratory. If antibody is still not present 4 weeks after exposure, another serum sample should be tested at 6 weeks for certainty. Acute-phase titers may be obtained, with less accuracy, 28 days after illness, but are not interpretable thereafter.

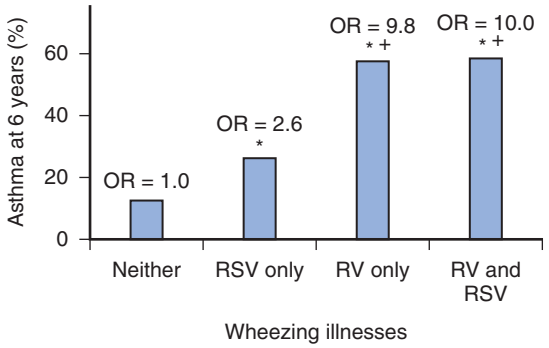
The antenatal diagnosis of fetal rubella infection has been made with rubella cultures or detection of rubella-specific IgM or rubella-specific antigen or RNA by RT-PCR from amniotic fluid or percutaneous umbilical blood sampling. Chorionic villus sampling has also been used, but less is known of its reliability.

Any infant born to a mother suspected of having had a rubella infection during pregnancy or any infant born with clinical signs and symptoms consistent with congenital rubella syndrome should have a complete evaluation and diagnostic workup. Isolation of rubella virus from a newborn provides an absolute diagnosis. The virus is most often isolated from the nasopharynx but has been grown in blood, CSF, and urine or even from the lens of the eye or CSF years later. The diagnosis may also be made by detecting rubella-specific IgM in cord or infant blood or by detecting stable or increasing concentrations of rubella-specific IgG in the infant's serum over several months, although infants with hypogammaglobulinemia may fail to produce antibody. More recently, oral fluid testing for rubella-specific IgM or RT-PCR for rubella antigen has been very helpful.

Prevention and Therapy

All children with postnatally acquired rubella should be isolated for 7 days after the rash appears. In contrast, children with congenitally acquired rubella should be considered contagious for at least 1 year, unless repeated urine and blood cultures are negative. In addition, the families of these infants should be counseled regarding the risks to pregnant women.

Susceptible pregnant women exposed to rash illnesses should have a laboratory workup performed for diagnosis, as should the individual who is the origin of the illness. Immunoglobulin is not recommended for prophylaxis in an exposed pregnant woman because congenital rubella has occurred despite the lack of symptoms in women given immunoglobulin. Also, vaccination after exposure does not prevent infection from the current exposure but might prevent exposure and infection in the future.



The goal in the United States is to eliminate rubella with vaccination. The RA 27/3 rubella virus vaccine is exclusively used in the United States and is highly effective. Infants should be vaccinated at 12-15 months of age and again at school entry. Preterm infants seem to lose maternal antibody to rubella at a much earlier age compared with term infants because the antibody is transferred primarily during the third trimester. The antibody response to vaccination is, however, similar to that of term infants. Postpartum and postpubertal women should be vaccinated unless contraindication exists. Breastfeeding is not contraindicated. Women should not be vaccinated during pregnancy because 3% of fetuses may be subclinically infected, but birth defects have not been reported after vaccination of pregnant women, even if the fetus is infected. The theoretical risk to the fetus is not greater than 1.3%. It is acceptable to vaccinate children of pregnant women because there is no evidence of transmission of virus after vaccination. Some parents continue to believe that the MMR vaccine may cause autism, even though numerous data and studies have shown that there is no association. The Immunization Safety Review Committee of the Institute of Medicine rejects any causal association.

Rhinovirus

Rhinoviruses are the most prevalent of human pathogens and are well known to cause the "common cold." Infection, which may persist for up to 2 weeks, usually begins with a sore throat and clear, watery rhinorrhea, which gradually becomes mucopurulent. Symptoms may include malaise and myalgia, fever, cough, sneezing, and headache. Rhinoviruses are small, non-enveloped, simple, positive-stranded RNA viruses classified as picornaviruses. There are three large groups of human pathogens among the Picornaviridae family: enteroviruses (enteroviruses, polioviruses, coxsackie viruses, and echoviruses), hepatoviruses (hepatovirus A), and rhinoviruses. There are more than 100 rhinovirus serotypes, and even more serotypes are being described with improved methodology. Immunity to one serotype offers little immunity to another, and immunity is of variable and brief duration and specific to a serotype. The rhinoviruses are usually spread from person to person via contaminated hands and self-inoculation of the nasopharynx but may also be spread via aerosol droplets. Infection may occur year round but may be epidemic in fall and spring in temperate climates; the incubation period lasts 2-7 days. Shedding has been documented for up to 6 weeks. Many strains will not grow in cell culture of the nasopharynx, and serology is confounded by the many strains. PCR is used to identify the virus and shows the prevalence and importance of this virus, particularly in infancy and early childhood.

A series of reports on 285 infants who were at high risk of developing asthma and were followed up to age 6 years emphasized the important role that rhinovirus infections play in the first year of life.[112] Human rhinovirus was found to be the most common etiology of upper respiratory tract infection (48%) and occurred early and repetitively in these high-risk infants. Co-infection with other viruses generally resulted in more severe upper respiratory tract infections.[114] Higher rates of infection were found in children enrolled in daycare or who had siblings in the home. A wheezing illness caused by rhinovirus at any point in the first 3 years of life in these high-risk infants resulted in a 10-fold increase in risk of asthma at 6 years of age—much more of a risk than found with RSV wheezing illness in early childhood (Fig. 50.7).[112] Yet it still remains unclear whether bronchiolitis or respiratory viral infections in the early years of life cause

• **Fig. 50.7** Risk of asthma at age 6 years in children who wheezed during the first 3 years of life with rhinovirus (RV), respiratory syncytial virus (RSV), or both (*P = 0.05 versus neither; ^{+}P = 0.05 versus RSV only). OR, Odds ratio. (From Jackson DJ, et al. Wheezing rhinovirus illnesses in early life predict asthma development in high-risk children. *Am J Resp Crit Care Med*. 2008;178:667.)

chronic respiratory disease—in particular, asthma—or are simply markers for children who have a genetic predisposition to asthma.

Rhinovirus is responsible for five hospitalizations per 1000 children younger than 5 years of age each year, which is far more significant than has been found for RSV.[137,169] Because rhinovirus is now known to cause lower respiratory tract disease, it has been argued that it may enhance susceptibility to asthma.[167] Infants with decreased pulmonary function, in particular higher airway resistance, are more likely to develop severe infection and to require hospitalization.[69,266] The virus is also responsible for many of the exacerbations of asthma.

Rhinoviruses have also been shown to be the etiology of sporadic, individual infections, or outbreaks, in the NICU. Infants may present with apnea, feeding difficulties, cough or rhinitis, and fever. They may also require increased oxygen or increased ventilatory support. Signs and symptoms may be indistinguishable from RSV. Infants who are not breastfed may also have a higher risk of severe infection owing to rhinovirus.[170] Preterm infants, particularly those with bronchopulmonary dysplasia, seem to be particularly susceptible to rhinovirus. In them, rhinovirus may be more common than RSV and is responsible for bronchiolitis and lower respiratory tract disease. The virus may cause significant worsening of the pulmonary status, necessitating prolonged increases in care in infants with bronchopulmonary dysplasia. In addition to rhinovirus, RSV, hMPV, and PIV are significant causes of lower respiratory tract infections requiring re-admission to the hospital and/or ICU in extremely preterm infants (≤32 weeks' gestational age). The role of human bocavirus remains controversial.

There is no effective treatment, and the only prophylaxis is use of infection control measures, such as contact precautions and hand washing, as well as respiratory droplet precautions. It is strongly urged by the FDA that cold medications available over the counter not be used in children less than 4 years of age, because of both safety and efficacy issues. Antibiotics are not of benefit and do not prevent bacterial superinfection. Rather, they may encourage antimicrobial resistance.

Coronavirus: Severe Acute Respiratory Syndrome and Middle East Respiratory Syndrome

Most human CoVs cause the "common cold", a limited upper respiratory infection resulting in malaise, fever, sore throat, sneezing, and cough. Occasionally, the virus is responsible for bronchiolitis, pneumonia, and croup. These lower respiratory tract infections are usually seen in infants or the immunocompromised. The CoV is a non-enveloped, single stranded, positive-sense RNA virus with crown-like projections seen on their surface on electron microscopy. CoVs are host specific. They can infect humans and other animals.

In 2002-2003, an epidemic of severe acute respiratory syndrome (SARS) occurred in China, Hong Kong, Vietnam, and Canada and was eventually reported in 16 countries, including the United States. A novel CoV, unrelated to other known human and animal CoVs, has been shown to be the cause of the outbreak. The horseshoe bats of southern China were found to be the natural reservoir of this enveloped RNA virus, which probably spread to the civet cat and then to humans in the marketplace. There have been no worldwide epidemics since 2004.[23] Severe disease caused by SARS-CoV primarily occurred in adults, although even among adults, infection ranged from asymptomatic to mild to severe. Patients developed the usual symptoms of the "common cold," but then worsened to a nonproductive cough and dyspnea 5-7 days later. Twenty percent required mechanical ventilation. Mortality occurred in 10% but rose to 50% in those older than 60 years of age. One fourth also had significant diarrhea.

A second CoV which can also cause severe disease has emerged—the MERS-CoV—which is responsible for the Middle East respiratory syndrome. As with SARS, disease can be asymptomatic, mild, or severe and fever, dyspnea, cough, and some vomiting and diarrhea can occur, with rapid worsening, chest infiltrates, need for mechanical ventilation, and a 50% mortality rate. As yet, infections have been limited to adults, usually male, who have other chronic diseases.

Virtually all cases of SARS in children have occurred via contact with infected adults, either in the home or in a health care setting. Co-infection may occur with other viral pathogens. Less than 10% of infections have occurred in children. The virus causes a mild, nonspecific respiratory illness in younger children, in contrast with the very serious, life-threatening infection in adults and teenagers older than 12 years. Most children present with fever but may have rhinorrhea, cough, coryza, myalgia, malaise, chills, or diarrhea.[148]

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

In young children, the physical examination is normal, and the course is shorter and milder. As a group, young children apparently do not develop significant respiratory distress or require oxygen, and they make a complete recovery. Chest auscultation is unimpressive. Chest radiography shows mild focal alveolar infiltrates. (In some cases, high-resolution CT showed airspace disease, even though the chest radiography result was negative.) Less than 1% of children require mechanical ventilation.[148] Similar to adults, children have multiple laboratory findings, including lymphopenia from destruction of the CD4+ and CD8+ lymphocytes, thrombocytopenia, and mild DIC. Lactic dehydrogenase is also elevated in most cases. No deaths have occurred in young children, who become asymptomatic within 6 months. Most reports of infections in children begin with infants a few months old. One premature infant presented at 56 days of life, at a corrected age of 38 weeks. His illness was comparable with that of adults and required oxygen, CPAP, and NICU admission, although he made a complete recovery.[245]

No infants born to mothers infected with SARS-CoV have shown any evidence of transplacental or congenital infection. Pregnant women may be more severely affected, with a mortality rate of 25%. Only one infant survived of seven pregnancies in women infected in the first trimester in Hong Kong, but two less severely affected women in the United States had infants with normal outcomes. Infants born to mothers infected in the second or third trimester seem to survive, whether born via cesarean section prematurely because of the mother's deteriorating condition or vaginally at term to a convalescent mother. None of the infants had evidence of infection. Infants born soon after the mother was infected tend to be appropriately grown, whereas infants born later have IUGR and oligohydramnios[148]; this could be secondary to ribavirin or steroids used to treat the mother's illness or because of the mother's illness itself. Infants born prematurely had a high incidence of necrotizing enterocolitis and jejunal perforation. Extensive fetal thrombotic vasculopathy with zones of avascular villi was noted in the placentae of two infants who survived maternal SARS infection.[183]

Diagnosis may cautiously be made using RT-PCR, but false-positive results occur often. Serology is helpful, but not widely available. The Public Health Department should be consulted prior to making the diagnosis.

Diagnosis of disease in children may be based on the WHO definition of probable SARS (radiographic evidence and epidemiologic linkage) or the CDC definition of suspected SARS (radiographic evidence is unnecessary). Children seem more likely to have negative RT-PCR and viral culture results, possibly because of a lower viral titer in the upper airway.

Infected individuals should be quarantined, and there should be strict adherence to infection control principles to prevent spread via aerosol, droplet, or fomites. There is only one documented case of transmission of infection from children to adults, but there have been cases of not yet symptomatic parents infecting health care workers.[250] This situation may represent the lower viral titers in children.

Treatment is primarily supportive. Many agents have been used in a noncontrolled fashion to treat severe disease without evidence of efficacy.

West Nile Virus

West Nile virus (WNV) is an enveloped single-stranded, positive-sense RNA flavivirus that is part of the Japanese encephalitis virus complex, and is transmitted to humans by the bites of infected mosquitoes. This arbovirus (arthropod-borne) survives in nature in a cycle that goes from mosquito to bird to mosquito, and primarily involves the *Culex* species of mosquitoes. Birds, especially crows, serve as amplifying hosts because of their high-titer viremia and are responsible for the spread of the virus over distances, whereas mosquitoes serve as vectors of the virus to humans who are accidentally infected when bitten. Infected humans are generally regarded as a dead end, but infected donors may transmit disease via blood transfusion or organ transplantation. Indigenous to Africa, Asia, Europe, and Australia, WNV was first reported in the Western Hemisphere in 1999 in an epizootic in New York City. Since then, it has rapidly spread throughout eastern and midwestern parts of the United States, northward to Canada, and southward to the Central and South Americas. Human infection may be asymptomatic (80%) or result in simple West Nile fever (20%). It may also result in neuroinvasive disease causing encephalitis, meningitis, or a flaccid paralysis resembling polio. Children, who develop symptomatic disease less frequently compared with adults, have milder symptoms and usually experience complete recovery, although there are rare cases of death. Children represent only 2% to 5% of all cases of neuroinvasive disease.[16] The incubation period ranges from 2-14 days, but disease usually occurs in 2-6 days. Most infections occur in summer or early fall after expansion of the viral and mosquito populations in spring and early summer. Diagnosis is made by testing serum and CSF for WNV-specific IgM. Positive tests need to be confirmed by a neutralization assay or the detection of WNV RNA in plasma, CSF, or urine. There is no specific treatment for infection or vaccine to prevent infection. Treatment is supportive. A controlled trial of WNV hyperimmunoglobulin failed to show benefit. Preventive measures are the only defense and involve mosquito control and education of the public, including pregnant women, to wear protective clothing, use insect repellent on the skin and clothing when outdoors, and avoid the outdoors during peak mosquito hours (dusk to dawn).

There have been few reports of WNV infections in children younger than 1 year of age. Breastfeeding was implicated in a report from Michigan in 2002, when an infant was found to have WNV-specific serum IgM after breastfeeding for 17 days. The mother developed WNV meningoencephalitis

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

9 days after receiving an infected transfusion, which had been given after the birth of the infant. WNV genetic material was detected transiently in the breast milk. The infant remained well.[105] However, although WNV-specific IgM and WNV RNA have been detected in the breast milk of infected mothers, transmission to the infant appears to be rare.[16] The CDC reported that five of six infants who were being breastfed during maternal disease presentation remained healthy; viral RNA and WNV-specific antibody were not detected in their sera.[16] The sixth infant developed a rash but was not tested. WNV-specific IgA was detected for a short time in the milk of one mother, but all other samples were negative for WNV RNA, IgA, IgM, and IgG. The breast milk was also tested in nine other seropositive mothers in Colorado. Two samples tested positive for WNV-specific IgM and neutralizing antibodies.[16] The CDC continues to recommend breastfeeding because the established benefits outweigh the risks.

Intrauterine infection was probably documented in 2002 in the fetus of a mother who developed paraplegia secondary to WNV during the second trimester of her pregnancy.[8] The infant appeared well at term and had normal physical examination results, including head circumference. Ophthalmologic examination revealed marked chorioretinal scarring, however, and MRI of the brain showed generalized lissencephaly and marked white matter loss. In a survey in Colorado during an epidemic, 549 cord blood samples were screened for WNV-specific IgG and IgM. Of the cord samples, 4% were positive for IgG, indicating maternal infection, but none was positive for IgM, and all infants had normal growth and outcome.[192] Likewise, the CDC followed the outcome of 77 pregnancies where the mothers had been infected with WNV. There were four miscarriages and two elective abortions. Of the 72 liveborn infants, none had conclusive evidence of congenital infection, although three infants developed infections that might have been congenitally acquired. Seven infants had major malformations, but only three of these could have been related to infection, and none of these infants had evidence of infection.[190]

Eighty-three pregnant women with WNV infection were registered with the CDC in 2003 and 2004; 77 were followed up.[213] There were equal proportions of infection in all three trimesters. The spontaneous abortion rate was similar to that of the general population, but there were more malformations (5.5%) than expected. The malformations, however, appeared to be unlikely to be caused by WNV infection. There were three possible intrauterine infections. One breastfed infant developed WNV meningitis at 10 days of life. The mother had had WNV neuroinvasive disease 6 days prior to delivery. A second breastfed infant had a rash and coarctation of the aorta at birth. The mother had had WNV fever at delivery. A third formula-fed infant died as a result of WNV encephalitis and lissencephaly. The mother had had WNV fever 3 weeks prior to delivery. The first two infants survived and had normal development at age 1 year on the Bayley-III Scales of Infant and Toddler Development. Eleven of the original 77 infants were followed up at age 3 years.[236] The ophthalmologic examinations were normal, and there were no global delays on the Bayley-III Scales of Infant and Toddler Development.

The CDC has developed guidelines for the evaluation of infants born to mothers infected by WNV during pregnancy and a registry for pregnancy outcome.[264] Screening for WNV in asymptomatic, pregnant women is not recommended because there is no therapeutic intervention, and the outcome is currently unknown. A detailed ultrasound examination of the fetus should be obtained no earlier than 2-4 weeks after the onset of symptoms in an infected pregnant woman. Amniotic fluid, chorionic villi, and fetal serum may be tested for infection; in the event of a miscarriage or abortion, all products of conception should also be tested. Infants born to women known to be infected during the pregnancy should have a thorough physical examination, including measurements of head circumference, length, and weight; a neurologic examination; and evaluation for dysmorphic features, any dermatologic lesions, or hepatosplenomegaly. The infant's serum should be tested for IgG and IgM specific for WNV, and the infant should undergo evoked otoacoustic emission testing or auditory brainstem response testing. The placenta should also be examined by a pathologist.

An infant suspected to have WNV infection should undergo an extensive workup, including ultrasonography of the head and an ophthalmologic examination. The infant should also undergo CBC and liver function tests. Examination of the CSF should be considered and should include an IgM for WNV. The IgM may persist for more than 1 year, and it may cross-react with other flaviviruses. Acute and convalescent sera showing at least a fourfold rise in virus-specific neutralizing antibodies can differentiate the WNV infection. The infant should be examined by a dysmorphologist, and developmental milestones and growth measurements should be monitored for the first year of life. At age 6 months, the infant should undergo additional hearing screening and determination of WNV IgG and IgM.

Adenovirus

Adenoviruses are double-stranded, non-enveloped DNA viruses that do not show the seasonal distribution of most respiratory viruses but are present through the entire year. Disease may be endemic, epidemic, or sporadic. The seven species (A-G) have multiple (at least 55) distinct serotypes, and the different serotypes cause different kinds of illness. The virus is most commonly found in the upper respiratory tract, and infection usually spreads via respiratory tract secretions. The virus is viable in the secretions for long periods, so fomites contaminated with secretions may transmit infection, in addition to aerosolized droplets and person-to-person contact. Viral shedding may occur intermittently for months after infection. Individuals may be re-infected and have asymptomatic infection. Health care workers and equipment, particularly ophthalmologic

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

equipment, have been implicated as sources of infection, so control requires careful hand washing and contact and droplet precautions. Health care workers with conjunctivitis should not participate in direct patient care for 2 weeks after onset and should use gloves in addition to strict hand washing. Ophthalmologic medications should be single-dose in nature, and equipment needs careful sterilization. The CDC recommends frequent hand washing with soap and water; not touching the eyes, nose, or mouth; covering the nose and mouth while sneezing or coughing; and avoiding sick contacts. Daycare centers for young infants and children is another frequent source of infection, and there are few effective control measures other than careful hygiene because the virus is also shed in the stool.

Greater than 80% of adenoviral infections occur in children younger than 4 years of age. Immunocompetent older children and adults usually develop acute, self-limiting infections, resulting in respiratory and gastrointestinal disease.

Adenovirus is most often associated with the "common cold," pharyngitis, otitis media, or pharyngoconjunctival fever. Adenovirus may also cause pneumonia, bronchiolitis, croup, and a pertussis-like infection. Respiratory infections are most common in late winter to early summer. Enteric strains cause gastroenteritis, more often in young infants and children, and occur year round. Epidemic keratoconjunctivitis can be spread from contaminated water in inadequately chlorinated swimming pools in summer or from ophthalmologic equipment.

Infants and young children, similar to immunocompromised individuals, may develop disseminated infections, pneumonia, bronchiolitis, or meningoencephalitis. Infection may be confused with invasive bacterial disease and treated with antibiotics. Prolonged fever of 1-7 days' duration may be seen. The degree of inflammation is indicated by the considerable elevation of C-reactive protein, which, in turn, may be related to viral load and disease severity. These infants are usually infected with subgroup B viruses (serotypes 3, 7, 21, and 35) and, less commonly, with subgroup D viruses (serotypes 2 and 32), but recent reports have also noted outbreaks of subgroup C. These infants may develop pancytopenia, DIC, pleural effusion, wheezing, and hepatitis. Pneumonia may be fatal and, if the infant survives, may result in significant lung damage, necessitating increased respiratory support for months.

In Dallas, 26 neonates were hospitalized with adenoviral infections over 17 years (1995-2012): 88% had respiratory signs, and 65% temperature instability.[229] The infants presented at a mean age of 16 days. Fifty-eight percent had had ill contacts. Four neonates developed disseminated infections, and the mortality rate was 80%. None of the infants with localized infection died. Disease ranged from upper respiratory tract infection to fulminant disease, including hypotension, apnea, hepatitis, and pneumonia.[229] In contrast to other reports in the literature, all but one of these infants were full term. These authors found reports of 72 additional neonates with adenovirus infection. Forty-seven percent of these infants were born prematurely. The mortality was similar (67%) among the 30 infants with disseminated disease, but 31% among the 42 infants with localized infections. Combining both groups, respiratory signs (76%) were the most common presentations. With pneumonia, seen in 50%, the mortality rate was 71%. Two thirds of the infants received mechanical ventilation, and eight received ECMO. Of note, 30% of all the reported neonates presented within the first 3 days of life, and 41% of those infants presented at birth. Presentation within the first 3 days of life was associated with disseminated disease (66%), prolonged rupture of membranes for 18 hours or longer, and maternal flulike illness during pregnancy or at delivery. The authors noted that with an incubation period as short as 2-3 days, presentation under 3 days of life suggested in utero transmission.

Evidence for congenital infection is accumulating.[49] Virus has been identified by using PCR in the amniotic fluid and in stillborn infants and those with hydrops. There are other reports of intrauterine or postnatal myocarditis caused by adenovirus. These infants tend to be small for gestational age and die as a result of disseminated disease. The serotypes found in young children are not as commonly found in infants younger than 6 months of age, suggesting that transplacental maternal antibody may be protective.[209]

Several reports have documented outbreaks of epidemic keratoconjunctivitis secondary to serotype 8 in NICUs.[44,210] Affected infants have lid edema, erythema, fever, and, less commonly, conjunctivitis. They also develop acute and chronic respiratory manifestations.

Adenovirus type 30 has been identified as the source of an outbreak in the NICU affecting 21 infants.[75,209] Type 30 is a group D adenovirus not previously identified in NICU outbreaks, although group D adenoviruses have been known to cause gastrointestinal infections and keratoconjunctivitis. Eight infants developed pneumonia (of whom seven died), and eight infants developed conjunctivitis. In five asymptomatic infants, infection was detected only through surveillance cultures. Several items of importance were noted in this report. The ophthalmologists, who had upper respiratory infections but continued to work and did not completely follow the American Academy of Ophthalmology infection control best practices, seemed to have played a major role in this outbreak. Infection control measures were successful but were discontinued too soon, before all of the infants had stopped shedding the virus, and the outbreak began again. Steroid use in the infants with pneumonia was recognized to have a high association with mortality.[75,209]

Although diagnosis of adenoviral infection can be made via tissue culture, shell vial technique, or antigen detection via immunofluorescence in the pharynx, eye, body fluids, or stool, PCR is the most sensitive and specific test and is the diagnostic method of choice.

Treatment is supportive. Children with pneumonia or disseminated disease, particularly neonates, often require mechanical ventilation. Support has also expanded to include ECMO. In a review of the ECMO Life Support Organization (ELSO) Registry from 1988 through 1994,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

children with adenoviral infections represented one third of the children being supported by ECMO for viral infections and had the poorest survival (25%).[165] In a more recent review of the ELSO Registry (1998-2009), children requiring ECMO support for adenovirus infection had a 38% survival at hospital discharge, but survival was only 11% among the neonates younger than 31 days of age.[215] Mortality was associated with neonatal presentation, degree of acidosis, sepsis and increased peak inspiratory pressure on the ventilator. ECMO complications of pneumothorax and intracranial hemorrhage also increased the risk of mortality.

Human Papillomavirus

Human papillomavirus (HPV) is a double-stranded, nonenveloped DNA virus. The organism cannot be propagated in cell culture, and its presence is detected by the identification of viral DNA from tissue samples. Infection by HPV usually is asymptomatic. A few infected adults develop mucocutaneous lesions, most commonly cutaneous and genital warts and neoplasms of epithelial surfaces, especially the uterine cervix. HPV can be typed according to DNA sequence, and greater than 100 genotypes have been identified. The different types can be distinguished by their propensity to cause low-grade warts (particularly types 6 and 11) versus high-grade, carcinomatous lesions (particularly types 16 and 18). Genital HPV infection in adults is usually transmitted via sexual contact. Nonsexual modes of acquisition, such as autoinoculation and heteroinoculation, are, however, suspected.

HPV transmission to the newborn presumably can occur in three periods; around the time of conception, during gestation (prenatal), or during or immediately after birth (perinatal). The virus has been detected in sperm cells, oocytes, amniotic fluid, placenta, and umbilical cord serving as evidence that vertical transmission occurs. Although some studies suggest vertical transmission occurs in more than half the pregnancies involving women with known HPV-related genital lesions, the results of studies have been variable and, therefore, rates not well defined.[87] HPV isolated from the pharynx or genital tract of the infant soon after birth frequently is discordant from HPV found in the mother, suggesting at least some neonatal acquisition by horizontal routes. HPV detected soon after delivery usually causes no clinically detectable disease, and evidence of infection disappears within a few months[154]; seroconversion to the initially detected virus is unusual.

The childhood disease most strongly associated with vertically transmitted HPV is juvenile-onset recurrent respiratory papillomatosis (JORRP). This illness, which usually becomes clinically apparent by age 2-3 years, is characterized by the development of multiple benign laryngeal papillomas. These lesions require repeated surgical excision to avoid airway obstruction. Occasionally, papillomas spread to the lower respiratory tract. JORRP is most strongly associated with HPV types 6 and 11, and often there is a history of condylomatous lesions in the mother caused by HPV of the same type.[243] The prevalence of JORRP is approximately 2 per 100,000 persons younger than 18 years of age, far lower than the prevalence of genital warts in pregnant women, suggesting that most infants exposed to HPV types 6 and 11 during birth remain unaffected.

Some, but not all, studies suggest a lower risk of JORRP if the infant is delivered by cesarean section, but operative delivery is not always protective, and it is not routinely recommended in a pregnant woman with genital warts. It is suspected that vertically transmitted HPV also can result in the development of anogenital warts in the child within the first several years of his or her life, presenting a dilemma to the child's caregivers because identical lesions can be associated with sexual abuse.

Three FDA-licensed HPV vaccines are available in the United States. The bivalent vaccine (2vHPV) contains the major capsid proteins of HPV types 6 and 18; the quadrivalent (4vHPV), in addition to 16 and 18, also protects against types 6 and 11; the 9-valent (9vHPV), licensed in 2014, protects against types 6, 11, 16, 18, 31, 33, 45, 52, and 58.

Since 2016, only 9vHPV is being administered in the United States and is recommended for males and females starting at age 9 years through age 26 years.[207]

Because laryngeal and anogenital disease in newborns are caused primarily by HPV types 6 and 11, the broad application of 9vHPV has the potential to reduce significantly mother-to-child transmission of HPV infection.[237] Transmission dynamics models suggest that the herd immunity effect of vaccinating only girls is robust, even when coverage rates are low and that the potential for elimination of HPV types 6, 11, 16, and 18 exists if coverage of 80% were to be achieved in girls and boys and maintained overtime.[29] Data already attest to the efficacy of the HPV vaccines in general, showing that after 4 years on the immunization schedule, the incidence of HPV in women 14-19 years of age has decreased by 56% despite low vaccination rates, implying that vaccine effectiveness, in addition to herd immunity, may also play a role in the decline in incidence rates.[155] Another benefit of the vaccine may be the reduction of premature births. A recent study from New Zealand showed that having received the quadrivalent HPV vaccine was associated with a reduction of preterm births by 13%.[140] The HPV vaccine is recommended for women of childbearing age; therefore, some patients may receive a dose of the vaccine inadvertently while pregnant. In this situation, the CDC recommends postponing the series until the pregnancy is complete.[41] So far, no adverse events to the developing fetus have been reported. In a retrospective cohort study looking at outcomes of pregnancies of mothers who received the quadrivalent HPV vaccine during the periconceptual period or during pregnancy, there was no association between vaccination and adverse pregnancy or birth outcomes.[151] However, the vaccine is not recommended for pregnant women at this time. The vaccine, conversely, can be administered to lactating women.

Emerging Viruses

Zika Virus

Epidemiology

Zika virus belongs to the Flaviviridae family along with other viruses, such as Dengue virus, yellow fever virus, WNV, and Japanese encephalitis virus.[70,136] They are single-stranded, positive-sense, enveloped RNA viruses transmitted by arthropods (predominately mosquitoes and ticks). Zika virus was first described in 1947 when it was isolated from a Rhesus monkey in the Zika forest of Uganda.[65,66] Sporadic human cases were described until 2007 when an outbreak occurred in the Yap Island of Micronesia.[70] More than 900 residents of the island were infected and experienced a mild self-limiting illness with rash, conjunctivitis, and arthralgia. In October of 2015, the Brazilian Ministry of Health issued a health warning after the state of Pernambuco, Brazil, experienced an increase in the number of cases of microcephaly from an average of 10 cases per year to 144 cases in 11 months. At the time, Zika virus had been reported to be circulating in the country, and the association was presumed.[180,193] Thereafter, the virus became widespread in the Latin American countries. In the United States, the first local transmissions were detected by July 2016 when 14 cases in Florida were confirmed by the Florida Department of Health.[240] As of November of 2017, the CDC reported 2311 pregnancies with laboratory evidence of possible Zika virus infection in the United States and in the District of Columbia. However, the number of cases since the peak of 2016 has sharply declined in Latin America and the Caribbean islands, reflecting widespread population immunity. It is unclear when the virus will resurge, but it is likely that cases at a lower scale will continue to occur.[51]

The vector for Zika virus is the *Aedes* mosquito. In Latin America, *Aedes aegypti* is the most commonly implicated. *Aedes albopictus*, which predominates in the United States, is a less common transmitter of the virus because this species feeds more frequently on animals than on humans. Nonetheless, mosquitoes from this species have also tested positive for the virus.[119] The incubation period ranges from 3-10 days. However, the virus can persists in body fluids for a prolonged period and, therefore, can be transmitted in other ways, such as through organ donation, blood transfusions, needle-stick injuries, sexual contact, and vertical transmission.[64,221,239] A study by Paz-Bailey et al. evaluated the persistence of the Zika virus RNA in different body fluids, namely, semen, vaginal secretions, urine, saliva, and serum and found that the virus remained detectable in urine, serum, and semen for 39, 54, and 81 days, respectively.[203]

The clinical manifestations of Zika in the general population overlap with those of other arboviral infections and range from being completely asymptomatic in 80% of the population to a clinical syndrome characterized by fever, maculopapular rash, arthralgia, and conjunctivitis. Conversely, in those acquiring the infections in utero, microcephaly is the hallmark.[55,239]

Through sequencing studies, two main Zika strains have been identified—the African lineage and the Asian lineage. The Zika virus strains that have been isolated in patients in Brazil are closely related to the Asian lineage, which has been associated with brain developmental defects.[64]

Congenital Zika Syndrome

There is now sufficient data to more definitively establish the teratogenic potential of Zika virus in humans, especially the tropism for the CNS of the developing fetal brain. One of the first reports suggesting such association was published in the *New England Journal of Medicine* in March of 2016.[171] A 25-year-old Slovenian woman, who had worked as a volunteer in a northern state in Brazil, returned to her native country where she terminated her 32-week pregnancy after multiple fetal structural abnormalities were identified, mainly confined to the CNS. These included IUGR, accompanied by microcephaly, ventriculomegaly, and numerous calcifications in various parts of the brain. Real-time RT-PCR was used to detect Zika viral RNA in several tissues, including brain tissue. The virus was only detected in the fetal brain tissue, and complete sequencing of the virus showed a high similarity with the Asian lineage strains, including strains that had been isolated in Brazil the previous year. More recently, a prospective, multicenter, case-control study from Brazil confirmed the association between Zika virus infection in utero and microcephaly. In this study, de Araujo et al. matched 91 infants born with microcephaly to 173 controls during an 11-month period in 2016.[55] In the microcephaly group, 35% tested positive for Zika virus by quantitative RT-PCR (qRT-PCR) in CSF or serum, whereas none of the controls tested positive. No child in the study tested positive for CMV infection, toxoplasmosis, or rubella. The overall matched odds ratio for microcephaly and Zika infection was 73.1 (95% confidence interval [CI] 13.0-∞). CT results as well as Zika virus test results were available in 79 children in the microcephaly group. Abnormalities (calcifications, ventriculomegaly, and cortical development malformations) were more common among infants who tested positive for Zika virus compared with those who tested negative (43% versus 10%; $P = 0.029$).

The mechanisms of neurologic injury caused by Zika virus are still not fully understood. In the 1970s, Bell et al. conducted experiments on mice and found that Zika virus infected neurons and astroglial cells.[18,202] When these cells were infected, the virus appropriated their mechanism of defense against viruses by producing inclusion bodies in the endoplasmic reticulum and mitochondria. These inclusion bodies served as viral replication factories. Autophagy (a mechanism of cell protection that involves lysosomal degradation) and cell division stability in the dividing cells were affected, resulting in delayed mitosis, earlier neural differentiation, and increased rates of apoptosis, all playing a role in the development of microcephaly in mice.[18,202]

Studies in murine and rhesus monkeys suggest that the mechanisms of congenital Zika syndrome (CZS) is through vertical transmission via placental infection and subsequent fetal brain tissue injury.[21,116,184,202,203] Several mouse models have shown that mice infected early in pregnancy develop placental and brain infections, resulting in IUGR and fetal demise in many. In a study performed on eight infants who had clinical and epidemiologic evidence of Zika virus–related microcephaly and had died and on 44 women who were suspected to have contracted the virus during pregnancy, replicative Zika virus RNA in situ hybridization was found in the brain tissue of seven infants and in the placenta of the mothers who had suffered fetal losses in the first and second trimesters. This study demonstrated that the virus replicated and persisted in the placenta and brains of infected patients.[21] Placental macrophages (also known as *Hofbauer cells*) are the primary sites for the replication of Zika virus. These cells can reach fetal blood cells and are the likely mode of dissemination of the virus into fetal tissues.[21,116] During the first trimester, when placental macrophages are proliferating, the virus may target them, increasing infection in the placental basal decidua and chorionic villi and allowing transplacental transmission.[253] Epidemiologic studies have shown that infections in the first and second trimesters more commonly result in microcephaly compared with those occurring later in pregnancy, although CNS abnormalities have been described as occurring during all trimesters.[28,107,188,239]

The distinctive features of CZS are the result of direct damage caused by the virus in the developing fetal brain, resulting in volume loss. Severe microcephaly with features reminiscent of fetal brain disruption sequence may be observed in some infants. These include overlapping sutures, prominent occipital bone, redundant scalp skin, craniofacial disproportion, and severe neurologic impairment.[55,86,156,171,234,240] Radiologic features include subcortical calcifications, ventriculomegaly, thinning cortex, corpus callosum agenesis, and cisterna magna enlargement, among others. Nonetheless, radiologic features of CZS have been identified in normocephalic infants, and in some infants microcephaly develops after birth.[13,178,265] From a functional standpoint, hypertonia, hyper-reflexia, arthrogryposis, seizures, irritability, and dysphagia have been described.[55,86,118,156,171,234,239,240]

Similar to other congenital viral syndromes, ocular manifestations and sensory neural hearing loss may occur.[38,58,59,142,289] The presumed pathogenesis of eye involvement relates to the capacity of the virus to cross barriers. After infecting stromal placenta cell macrophages, Zika virus is thought to subsequently invade the blood-brain barrier infecting neuronal progenitor cells, including bypassing the retinal barrier.[38] From there, the virus provokes angiogenesis and inflammatory cytokine–related responses that lead to damage. This is supported by the findings of the viral RNA in endothelial cells and pericytes of the inner blood-retinal barrier and in retinal pigment epithelial cells. Infections occurring in the first trimester are more likely to result in eye alterations compared with those occurring later in pregnancy. In a study from Brazil of 29 infant with Zika virus–presumed microcephaly, 34% had ocular manifestations.[58] In another study, ocular findings were more common in infants born to mothers who had symptoms of Zika virus infection in the first trimester compared with infants of those who had symptoms later in pregnancy. Ocular findings were also more prevalent in infants with severe microcephaly.[268] Most commonly described funduscopic findings are chorioretinal abnormalities, including macular atrophy, focal pigmentary changes in the macular region, and optic nerve abnormalities, such as optic disc hypoplasia. These manifestations are usually bilateral.

Hearing loss, a common finding in other congenital infections, has also been described in infants infected with Zika virus in utero. Leal et al. studied 70 children from the State of Pernambuco in Brazil with microcephaly and confirmed Zika virus infection and evaluated them for hearing loss. Auditory evaluations were performed with auditory brainstem response testing. These authors found that 7.1% of the infants had sensorineural hearing loss, which varied in laterality and severity among the affected infants.[142] At this time, it is unknown if sensorineural hearing loss progresses over time, and hence the importance of follow-up testing in these children.

According to data gathered by the CDC through the US Zika Pregnancy Registry established in 2016, of 972 completed pregnancies of mothers with possible recent Zika virus infection during pregnancy, 5% of the infants developed birth defects. The percentage was higher in cases of confirmed Zika virus infection, with rates of 10%.[227] Other studies have shown similar rates.[28,107] Most recent US population health surveillance data on birth defects from the CDC revealed a rate of birth defects potentially related to Zika virus infection of 3 per 1000 live births (95% CI 2.9-3.2).[62]

Diagnosis

Zika virus detection can be accomplished by molecular (RT-PCR) or serologic methods (IgG and IgM). When a patient is infected by the virus, the RNA becomes detectable in serum at onset of symptoms and then declines as IgM antibodies rise in peripheral blood. Detection of viremia via Zika virus NAT is most useful in the first 6 weeks of infection, with the yield increasing when both urine and serum are tested. NAT can also be performed in other bodily fluids, with varying durations.[5,179,218,240]

Zika virus IgM antibodies are detected by using ELISA in the first 12 weeks, starting at approximately 1 week after onset of symptoms, which may persist for longer periods. Because the majority of infections are asymptomatic, determining if an infection occurred during pregnancy or earlier is challenging.[5,218] In addition, the close genetic relatedness between Zika virus and Dengue virus leads to immunologic cross-reactivity[214] and the possibility of false-positive test results. Positive and equivocal tests should be confirmed with plaque reduction neutralizing tests (PRNT). This assay

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

measures neutralizing antibodies (which are mainly IgG) that form shortly after the IgM and remain positive lifelong. This assay also may encounter problems with cross-reactivity because patients who have experienced a previous flavivirus infection or those who have been vaccinated with the yellow fever vaccine will develop high titers of neutralizing antibodies, making it difficult to distinguish the virus responsible for the current infection. In addition, PRNT is labor intensive and only offered at specialized centers (CDC).[218] It is important to point out that as the number of cases decline, the rate of false-positive results will increase; therefore, the CDC has issued new recommendations for testing in the setting of low prevalence. CDC recommendations for testing pregnant women are summarized in Table 50.10.[11] These guidelines are updated on a regular basis and should be consulted for the most up-to-date and complete information.

Placenta, umbilical cord, fetal organs, and other products of conception can be sent for testing in cases of fetal loss, stillbirth, or infant death. The samples are processed at the CDC and require local health department notification and preapproval by the CDC. For preapprovals, the CDC can be contacted through email at pathology@cdc.gov. The role of amniocentesis in the evaluation of CZS is unknown, but if obtained, NAT testing should be considered.

Results should be interpreted with caution, taking into consideration the timing of pregnancy, the expected outcomes, and the patient's values, among others, and therefore, consultation with an infectious disease specialist is recommended. The CDC also offers assistance to health

TABLE 50.10 Summary of Zika Virus Testing Guidance According to Centers for Disease Control and Prevention Recommendations

	Pregnant *With* Symptoms of Zika Virus Disease *and* Possible Zika Virus Exposure		Pregnant *Without* Symptoms of Zika Virus Disease *and* Possible Zika Virus Exposure	
Whom to test	• Pregnant women who report possibly being exposed to ZV during the current pregnancy and have symptoms • Pregnant women who report possibly being exposed to ZV during the current pregnancy and have a fetus with US findings concerning for congenital Zika syndrome		• Asymptomatic pregnant women with *ongoing* (live or frequently travel to an area with documented risk of Zika transmission) possible ZV exposure • Not indicated but should consider in asymptomatic pregnant women without ongoing exposure*	
Timing	As soon as possible through 12 weeks after onset of symptoms		First test with onset of prenatal care in women without a diagnosis of ZV If initial test is negative, repeat testing two additional times during pregnancy	
Type of test	ZV NAT in serum *and* urine *and* ZV IgM serology in serum. Test concomitantly for Dengue with Dengue virus IgM		ZV NAT in serum *and* urine	
	Results	**Interpretation**	**Results†**	**Interpretation**
	ZV NAT positive and ZV IgM positive	Acute Zika virus infection	Positive NAT in serum ***and*** urine	Acute Zika virus infection
	ZV NAT negative and ZV IgM negative	No evidence of Zika virus infection		
	ZV NAT negative and **non**-negative ZV IgM (non-negative: positive or equivocal, possibly or presumably positive)	Send sample for plaque reduction neutralization test (PRNT)‡	Negative NAT in serum and urine	No Zika RNA detected, However, Zika virus infection cannot be ruled out§

ZV, Zika virus; NAT, nucleic acid test.
*If testing is considered, a discussion between the patient and the physician should weigh risks and benefits of testing taking into consideration the patient's values, clinical judgment, and expected outcome, among other issues.
†If NAT is only positive on serum or urine, the test should be repeated on the original NAT positive test. If results are still positive, the patient should be considered as having acute Zika infection. If the repeat NAT result is negative, consultation with an infectious disease specialist is recommended (author's recommendation), and the IgM test should be repeated 2 weeks after the original sample was tested.
‡Consultation with an infectious diseases specialist is recommended (author's recommendation).
§Because Zika virus RNA declines over time, the presence of the virus in urine and serum will differ among patients. Therefore, testing at only one point in time does not completely exclude infection. Consultation with an infectious diseases specialist is recommended to discuss IgM testing with patient (author's recommendation).
Adapted from CDC testing algorithms. For the most up to date guidance and complete information, refer to https://www.cdc.gov/zika/laboratories/lab-guidance.html. Accessed January 27, 2018.

care providers with regard to sample submission and clinical questions through email at ZikaMCH@cdc.gov.

Infants born to mothers with possible or confirmed Zika virus infection and those with clinical features consistent with CZS should undergo testing as soon as possible after birth. Testing consists of NAT in serum and urine and possibly CSF and serum IgM. A positive NAT result from either sample (infant urine, serum, or CSF) regardless of the IgM result, confirms the diagnosis of CZS. However, testing beyond the immediate neonatal period may not allow for distinction between congenital infection and that acquired postnatally in areas with ongoing transmission. Conversely, negative results of NAT and IgM performed soon after pregnancy should be interpreted as congenital infection being unlikely. A negative NAT result in combination with a non-negative IgM result, defined as any test result other than a negative result, such as a positive, equivocal, presumptive positive, or possible positive result, should be confirmed with PRNT, as a false-positive IgM result is possible.[5] Cord blood may be contaminated with maternal blood and, therefore, should not be used for neonatal assessment.[294] In addition to testing for Zika virus NAT in serum and urine and IgM testing in serum shortly after birth, infants should undergo standard evaluations which includes:

- Thorough physical examination, including growth parameters.
- Vision screening as recommended by the AAP.
- Hearing screen at birth—automated auditory brainstem responses are the preferred method.
- Monitoring and screening of child development by utilizing AAP validated tools.

Additionally, head ultrasonography and a comprehensive ophthalmologic examination should be performed. The CDC recommendations are summarized in Table 50.11. If findings suggestive of CZS are identified at any time, referral to specialist to evaluate for congenital Zika virus infection is indicated.[5,13,227]

Infant Follow-Up

Infants diagnosed with congenital Zika virus infection require a multidisciplinary approach.[5,227] Special needs should be anticipated and early interventions instituted. Social services may be very useful providing families with coordination of care and supportive services. An infectious disease specialist should be consulted because other congenital infections may need to be excluded, and the specialists will assist with the interpretation of tests, especially when the results are non-negative. A geneticist may need to evaluate for other causes of microcephaly and congenital abnormalities. A neurologist and an ophthalmologist should evaluate these patients by 1 month of age and follow up closely thereafter because these infants may require electroencephalography (EEG) or advanced imaging. Infants identified with hearing loss need to be monitored frequently because, unlike in CMV infection, the progression of hearing loss with Zika virus infection is unknown at this time. An endocrinologist, an orthopedic specialist, a pulmonologist, and an occupational therapist may also need to be involved. Most importantly, compliance with routine general pediatric follow-up visits should be emphasized. Knowledge about CZS is still being accumulated, and it is likely that as these children grow older, previously undescribed conditions will emerge and, therefore, regular follow-up is pivotal.[5,227]

Prevention

Vector control, avoidance of exposure to mosquito bites, and epidemiologic surveillance are the current prevention strategies to prevent Zika virus infection in pregnant women. At the height of the epidemic in 2016, travel warnings for pregnant women or for those trying to become pregnant were issued, as well as recommendations for avoidance of unprotected sexual intercourse during pregnancy with anyone who may have been exposed to the virus and even postponement of pregnancy plans in areas of widespread transmission.[203,221,239,294] The Zika virus infection landscape, however, has changed, and very few to no cases have been reported in the past several months, so recommendations will likely change.[51] Therefore, epidemiologic surveillance and keeping up to date with the information provided by such agencies as the CDC and the WHO are important.

More than 40 vaccine candidates against Zika virus are being studied at this time. However, none is currently available.[71] Moreover, several factors that can delay the development of these vaccines have emerged. One is the decline in the number of worldwide cases, and the other is the safety concerns that have emerged following the results of the Dengue virus vaccine trials, in which the vaccine has been observed to provoke antibody-dependent enhancement (ADE).[157] Studies have now shown that in Dengue-endemic areas, pre-existing immunity to Dengue virus may affect an individual's immunologic response to Zika virus[214] and concerns regarding the risk of ADE with a Zika vaccine have been raised.[71,214] The epidemiology of the virus in the years to come will likely determine the availability of such vaccines.

TABLE 50.11 Summary of Evaluation for Infants With Possible Congenital Zika Virus Infection According to Centers for Disease Control and Prevention Recommendations

Scenario	Possible Zika Exposure *and* Clinical Findings Consistent With CZS	Possible Zika Exposure *and* Infant *Without* Findings Consistent With CZS *and* Maternal Laboratory Evidence of Zika During Pregnancy	Possible Zika Exposure *and* Infant *Without* Findings Consistent With CZS *and* No Maternal Laboratory Evidence of Zika During Pregnancy
Initial Evaluation	• Standard evaluation* • ZV NAT (serum and urine) within a few days after birth • ZV IgM (serum) within a few days after birth • Consider ZV NAT and IgM on CSF • Head US by 1 month age • ABR by 1 month of age • Eye exam by ophthalmology by 1 month of age • Test for other diseases associated with congenital abnormalities • Referral to specialists and early intervention (See Table 50.3.)	• Standard evaluation* • ZV NAT (serum and urine) within a few days after birth • ZV IgM (serum) within a few days after birth • Head US by 1 month age • ABR by 1 month of age • Eye examination by ophthalmology by 1 month of age	• No further testing required • If findings of CZS are identified at any time refer to specialist and follow recommendations for clinical findings consistent with CZS
		Initial Evaluation	
		Normal	**Abnormal**
		• Infant with laboratory evidence of CZS†: follow recommendations for clinical findings consistent with CZS • Infant with no laboratory evidence of CZS: congenital infection unlikely.	Follow recommendations for clinical findings consistent with CZS syndrome
		Routine follow up	

ABR, Automated auditory brainstem response; CSF, cerebral spinal fluid; CZS, congenital Zika syndrome; NAT, nucleic acid test; US, ultrasonography; ZV, Zika virus.

*__Standard Evaluation:__ Thorough physical examination including growth parameters; vision screening as recommended by the American Academy of Pediatrics (AAP); hearing screen at birth (automated auditory brainstem response is preferred method).

Developmental monitoring and screening utilizing AAP validated tools.

†__Confirmed Congenital Zika Infection__: NAT positive *and* IgM positive/negative or non-negative (or equivocal, possibly or presumably positive).

__Probable Congenital Zika Infection__: NAT negative *and* IgM non-negative (positive or equivocal, possibly or presumably positive) Need to confirm with plaque reduction neutralization assay and consultation with expert recommended.

__Congenital Zika Infection unlikely:__ NAT negative and IgM negative.

Adapted from CDC testing algorithms. For the most up-to-date guidance and complete information, refer to https://www.cdc.gov/pregnancy/zika/testing-follow-up/follow-up-care.html. Accessed January 27, 2018.

Key Points

- Many viruses are well known, and many new viruses that have devastating effects on the fetus and newborn are continually being discovered. Known therapeutic measures are frequently of little efficacy, leaving prevention as the primary means of protection for the fetus and the newborn.
- Mother-to-child transmission of HIV is now the most common source of HIV infection among infants and children. In high-economy countries, including the United States, this source of transmission is nearly completely eliminated with the universal use of antenatal HIV testing, combination ART during pregnancy, elective cesarean section, and prohibition of breastfeeding by infected mothers.
- Most women of childbearing years in high-economy countries are immune to measles, mumps, and rubella, as a result of MMR vaccination, limiting risk to the fetus and the newborn with the risk of maternal infection virtually eliminated. Similarly, the use of the varicella vaccine, coupled with acyclovir and VZIG treatment, has greatly decreased the incidence of varicella infection in pregnant women.
- The implementation of the hepatitis B vaccine and HBIG for prevention of mother-to-infant transmission is quite effective, and yet compliance remains an issue.
- Poliomyelitis has been virtually eliminated with universal vaccination, but there are, as yet, no vaccines and no specific therapies available for other enteroviruses that can cause severe, devastating infections in the neonate.
- Congenital CMV infection remains the largest source of nongenetic hearing loss and developmental disorders in children, and yet no vaccine has been approved for use as yet; therapy with ganciclovir/valganciclovir has limited efficacy.
- Neonatal HSV infection remains life-threatening and may have devastating consequences for the fetus and the newborn. There is no available vaccine, and therapy with acyclovir, particularly if infection is not promptly recognized and therapy is delayed, may still result in death or severe handicap in the infant.
- There are no effective therapies for viruses causing respiratory infections in the newborn. Prevention remains key. The use of palivizumab for prevention of RSV continues to be controversial.

Normal and Abnormal Brain Development

PIERRE GRESSENS, SANDRINE PASSEMARD, AND PETRA S. HÜPPI

Normal development of the human central nervous system (CNS) encompasses several steps, including neuroectoderm induction, neurulation, cell proliferation and migration, programmed cell death, neurogenesis and elimination of excess neurons, synaptogenesis, stabilization and elimination of synapses, gliogenesis, and myelination (Table 51.1).

These different steps of brain development and maturation are controlled by the interaction between genes and the environment. Numerous genes involved in brain development have been identified: genes controlling neurulation, neuronal proliferation, neuronal size and shape, programmed cell death, neuronal–glial interactions, and synaptic stabilization.[104] However, it seems unlikely that the 30,000 genes in humans can totally control the organization of 100 billion neurons and trillions of synapses. A normal pattern of expression of these genes requires an adequate environment. Interactions with the intrauterine milieu (factors coming from the mother, placenta, or amniotic fluid) and with the postnatal environment critically modulate gene expression through reciprocal action with neurotransmitters, trophic factors, and hormones and their machinery. Accordingly, brain malformations can be due to environmental factors, genetic factors, or an interaction of both (Boxes 51.1 through 51.4).

This part of the chapter focuses primarily on the development of the neocortex. Detailed descriptions of the development of other CNS structures, such as the cerebellum, can be found in texts by ten Donkelaar et al.[110] and Wang and Zoghbi.[120]

Neural Induction and Neurulation

During the early stages of gastrulation, organizing centers produce inductive molecules that initiate genetic programs leading to the differentiation of the neural tissues from surrounding tissues.[107] Grafting experiments in amphibians have shown that the appearance of neural tissue depends on signals coming from mesodermic cells of the dorsal marginal zone (the Speeman organizing center) and that other signals deriving from this zone also allow regionalization of the neuroectoderm along the rostrocaudal axis. Studies have identified some of the factors implicated in neural induction, including follistatin, noggin, Notch, dorsalin1, Wnt1, and Hedgehog.

Neurulation is the process by which neuroectodermal cells transform into a neural tube, which will differentiate into the brain and the spinal cord. Neurulation can be divided into four steps that overlap both in time and space: (1) neural plate formation, (2) neural plate modeling, (3) neural groove formation, and (4) closure of the neural groove to form the neural tube. In humans, the neural plate appears at the beginning of the third gestational week in the mediodorsal zone of the embryo, just ahead (in the rostrocaudal axis) of the Hensen node. The neural groove appears during the third gestational week. Neural tube closure starts at the beginning of the fourth gestational week, with the formation of the neural crests (which will give rise to dorsal root ganglia, Schwann cells, and cells of the pia and arachnoid). Neural tube closure begins in the region of the lower medulla and proceeds both rostrally and caudally.

The anterior neuropore closes at approximately 24 gestational days and the posterior neuropore closes at approximately 26 gestational days. This posterior site of closure is located around the lumbosacral level, and more caudal spinal cord is formed secondarily by a separate process involving canalization (4 to 7 gestational weeks) and retrogressive differentiation (seventh gestational week to after birth; giving rise to the ventriculus terminalis and the filum terminale). The neural tube is initially a straight structure. Before the closure of the posterior neuropore, the anterior part of the neural tube is shaped into three primary vesicles: the prosencephalon, the mesencephalon, and the rhombencephalon. The prosencephalic phase and the formation of the hemisphere take place between 5 and 10 gestational weeks in humans.

CNS regionalization results from the combination of two mechanisms. Rostrocaudal regionalization creates

Abstract

Normal development of the human central nervous system (CNS) is a dynamic process with several steps. These different steps of brain development and maturation are controlled by genes. However, it seems unlikely that the 30,000 genes in humans can totally control the organization of 100 billion neurons and trillions of synapses. A normal pattern of expression of these genes requires an adequate environment. Interactions with the intrauterine milieu (factors coming from the mother, placenta, or amniotic fluid) and with the postnatal environment critically modulate gene expression but also endogenous activity and environmental stimuli can modify brain development. Accordingly, brain malformations can be due to environmental factors, genetic factors, or an interaction of both. This part of the chapter focuses primarily on the development of the neocortex.

• BOX 51.1 Environmental Factors and Maternal Conditions With Potential Impact on the Developing Brain

Therapeutic Drugs

- Retinoic acid
- Antithyroid drugs
- Estroprogestative hormones, testosterone, and derivatives
- Antimitotic drugs
- Lithium and psychotropic drugs
- Benzodiazepines and antiepileptic drugs

Addiction Drugs

- Tobacco
- Caffeine
- Ethanol
- Cocaine
- Opiates
- Cannabis

Physical and Chemical Agents

- Dioxins and heavy metals
- Organic solvents
- Ionizing radiation
- Head trauma
- Repeated shaking

Maternal Factors and Status

- Sex hormones
- Catecholamines
- Thyroid hormones
- Diabetes mellitus
- Peptides (vasoactive intestinal peptide)
- Placenta and decidual hormones
- Oxygen and hypoxia–ischemia
- Hyperthermia

Infectious Agents

- Herpes simplex virus I and II
- Herpes zoster virus
- Cytomegalovirus
- Rubella virus
- Parvovirus B19
- Coxsackie virus, B group
- Human immunodeficiency virus
- Influenza virus
- Benign lymphocytic meningitis virus
- *Toxoplasma gondii*
- *Listeria monocytogenes*
- *Treponema pallidum*

• BOX 51.2 Major Etiologies of Human Holoprosencephaly

Chromosomal Holoprosencephaly

- Chromosome 13: trisomy, deletion or duplication of 13q, ring
- Deletion 2p, duplication 3p, deletion 7q, deletion 21q
- Triploidy

Syndromal Holoprosencephaly

- Meckel syndrome
- Varadi-Papp syndrome
- Pallister-Hall syndrome
- Smith-Lemli-Opitz syndrome
- Velo-cardio-facial syndrome

Nonsyndromal Genetic Holoprosencephaly (Sporadic or Mendelian Inheritance)

- SIX3: HPE2 locus on chromosome 2p21
- SHH: HPE3 locus on chromosome 7q36
- TGIF: HPE4 locus on chromosome 18p11.3
- ZIC2: HPE5 locus on chromosome 13q32

Environmental Holoprosencephaly

- Hypocholesterolemia
- Retinoic acid exposure
- Ethanol exposure

TABLE 51.1 Schematic Chronology of the Major Events During Human Neocortical Development

Neuroectoderm induction	3rd GW
Neurulation	3rd to end of 4th GW
Prosencephalic and hemispheric formation	5th to 10th GW
Neuronal proliferation	10th to 20th GW (?10th to end of gestation for interneurons)
Neuronal migration	12th to 24th GW (?10th to 41st GW for interneurons)
Programmed neuronal cell death	28th to 41st GW
Synaptogenesis	20th GW to puberty
Gliogenesis	20th to 24th GW to ?postnatal years
Myelination	36th to 38th GW to 2 to 3 postnatal years
Angiogenesis	5th to 10th GW to ?postnatal years

GW, Gestational week.

transverse domains with distinct competences in the neural plate and tube,[54,105,122] whereas dorsoventral regionalization creates longitudinally aligned domains.[102] The combination of these two axes yields a grid-shaped pattern or regionalization.[100] Different genes involved in this regionalization have been identified. These include the *BMP* (bone morphogenetic proteins), *PAX* (paired box genes), and *SHH* (sonic hedgehog) genes for the dorsoventral axis, and the *HOX* (clustered homeobox-containing genes), *KROX20*, *FGF8* (fibroblast growth factor-8), *EN* (engrailed genes), *WNT*, *OTX* (homeobox genes homologous of the *Drosophila* orthodenticle gene), *EMX* (related to the "empty spiracles" gene expressed in the developing *Drosophila* head), and *DLX* (homeobox genes homologous to the distal-less genes of *Drosophila*) genes for the rostrocaudal axis (Fig. 51.1).

• BOX 51.3 Classification of Human Congenital Microcephaly

Primary Genetic Microcephaly

Microcephaly Primary Hereditary (MCPH): Autosomal Recessive Inheritance, Except for MCPH18

- *MCPH1* (Microcephaly), *WDR62* (MCPH2), *CDK5RAP2* (MCPH3), *CASC5* (MCPH4), *ASPM* (MCPH5), *CENPJ* (MCPH6), *STIL* (MCPH7), *CEP135* (MCPH8), *CEP152* (MCPH9), *ZNF335* (MCPH10), PHC1 (MCPH11), *CDK6* (MCPH12), *CENPE* (MCPH13), *SASS6* (MCPH14), *MFSD2A* (MCPH15), *ANKLE2* (MCPH16), *CIT* (MCPH17), *WDFY3* (MCPH18).

Primary Microcephaly With Dwarfism (Autosomal Recessive)

- Seckel syndrome: *ATR* (SCKL1), *RBBP8* (SCKL2), *CENPJ* (SCKL4), *CEP152* (SCKL5), *CEP63* (SCKL6), *NIN* (SCKL7), *DNA2* (SCKL8), *TRAIP* (SCKL9), *NSMCE2* (SCKL10),
- Microcephalic osteodysplastic primordial dwarfism: *PCNT*
- Meier Gorlin syndrome: *ORC1* (MGORS1), *ORC4* (MGORS2), *ORC6* (MGORS3), *CDT1* (MGORS4), *CDC6* (MGORS5), *GMNN* (MGORS6), *CDC45L* (MGORS7), *MCM5* (MGORS8).

Microcephaly With Simplified Gyral Pattern (Autosomal Recessive)

- Normal or thin corpus callosum
- Agenesis of the corpus callosum

Microlissencephaly, MLIS (Autosomal Recessive)

- With thin cortex: *RELN* (MILIS1 or Norman Roberts syndrome)
- With thin cortex, brainstem and cerebellar hypoplasia (MLIS2 or Barth syndrome)
- With intermediate cortex (MLIS3)
- With mildly to moderately thin cortex (MLIS4)

Microcephaly Associated With Other Brain Malformations

Microcephaly as Part of a Syndrome

- Neu-Laxova syndrome (autosomal recessive)
- *PHGDH* (NLS1), *PSAT1* (NLS2)
- Rubinstein-Taybi syndrome (autosomal dominant)
- *CREBBP* (RSTS1), *EP300* (RSTS2)
- Cornelia de Lange syndrome (autosomal dominant except for CDLS X-linked)
- *NIPBL* (CDLS1), *SMC1A* (CDLS2), *SMC3* (CDLS3), *RAD21* (CDLS4), *HDAC8* (CDLS5).

Microcephaly Associated With Biochemical Disorders

Microcephaly Secondary to Environmental Factors

- Hypoxia–ischemia
- Severe malnutrition
- Maternal hyperphenylalaninemia and phenylketonuria
- Ionizing radiation
- Ethanol exposure
- Infections (cytomegalovirus, benign lymphocytic meningitis virus, *Toxoplasma gondii*, Rubella virus, Zika virus)

• BOX 51.4 Genes and Environmental Factors Identified in Human Neuronal Migration Disorders

Periventricular Heterotopia

- *FLNA* (X-linked)
- With microcephaly: *ARFGEF2* (autosomal recessive)

Classic Lissencephalies

- *LIS1* (autosomal dominant)
- *DCX* (X-linked)
- *TUBA3* (autosomal dominant)
- *ARX* (X-linked)

Cobblestone Lissencephalies (Autosomal Recessive)

- *POMT1*
- *POMT2*
- *FCMD (FKTN)*
- *FKRP*
- *POMGNT1*
- *POMGNT2*
- *DAG1*
- *ISPD*
- *LAMB1*
- *POMK*
- *RXYLT1*

Lissencephaly With Cerebellar Hypoplasia

- *RELN* (autosomal recessive)

Peroxysome Biogenesis Disorders

- Zellweger syndrome, autosomal recessive: *PEX1* (PBD1), *PEX12* (PBD3), *PEX6* (PBD4), *PEX10* (PBD6),

Environmental Factors

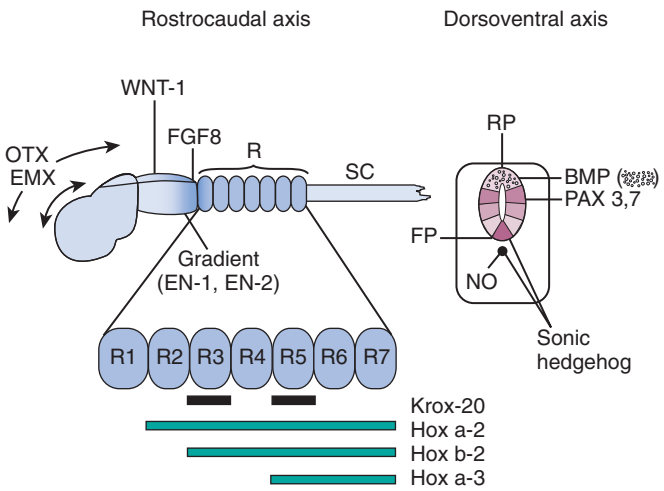
- Ethanol exposure
- Cocaine exposure
- Cytomegalovirus
- *Toxoplasma gondii*
- Ionizing radiation

Neuronal Proliferation

There are no precise data concerning the number of neurons present in the brains of different mammalian species. In the human adult brain, estimates range from 3 billion to 100 billion neurons. Similarly, the precise proportion of glial cells is unknown, with a neuron-to-glia ratio estimated at between 1:1 and 1:10.

In some regions of the CNS, neuron production continues for the entire life span. This late neurogenesis is apparent in the olfactory bulb and the dentate gyrus. Its importance at the level of the neocortex, especially in physiologic conditions, remains to be demonstrated. In this context, production of neurons for the human neocortex is generally considered to be a phenomenon occurring during the first half of gestation.

The neocortex is composed of vertical units (neuronal columns): the number of neurons in a given unit seems stable throughout studied mammals and is constant throughout the different cortical areas (with the exception of the visual cortex). In contrast, the time necessary to produce the neocortical neurons of a given column progressively increases with increasing mammalian evolutionary



Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

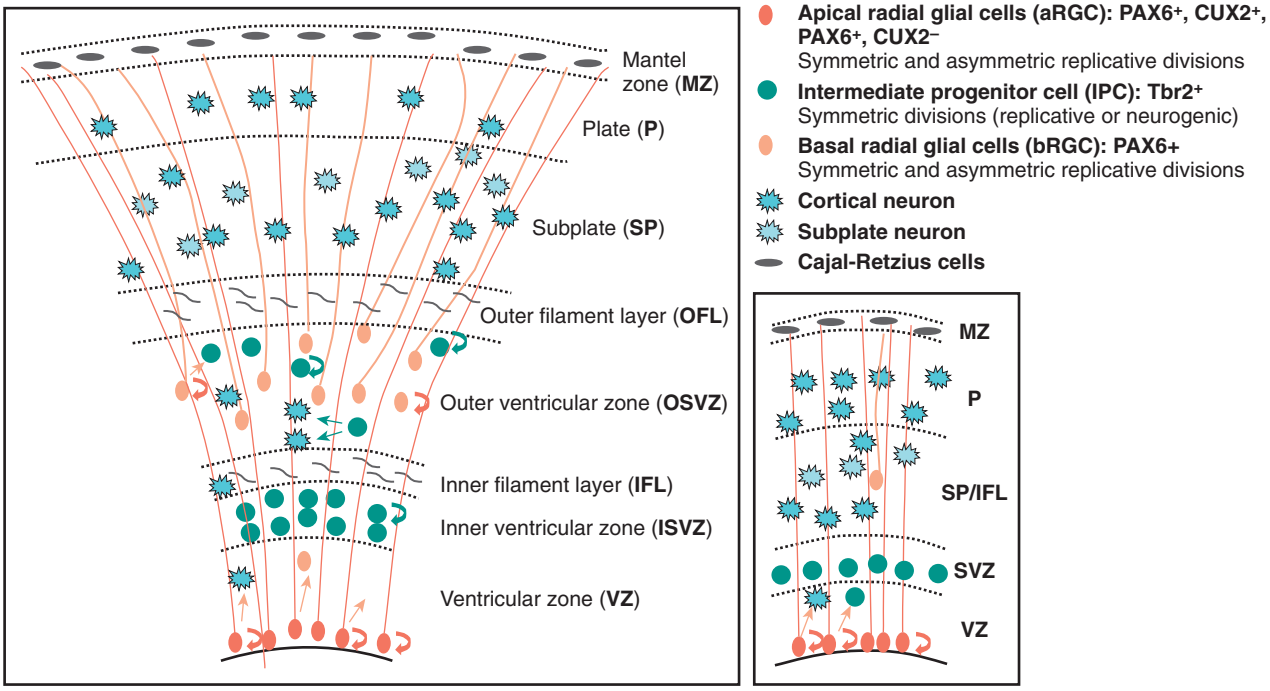
complexity. Indeed, the period of neurogenesis neurons takes 6 days in mice, whereas it takes approximately 10 weeks in humans. Glutamatergic neurons of the neocortex are generated in the ventricular zone (VZ) and the subventricular zone (SVZ) of the lateral ventricles, whereas a large proportion of GABAergic neurons of the neocortex are generated in the ganglionic eminence (which also produces thalamic neurons).



The cerebral cortex has evolved in size by expansion of the surface area, without a comparable increase in its thickness, thus imposing folding constraints and convolutions. Recent comparative studies performed during the development of the neocortex in lissencephalic and gyrencephalic models support that the increased capacity of the progenitors to proliferate, with subsequent amplification of cortical neuron populations, is largely involved in this evolution.

In mice, two main types of progenitors, radial glial cells (RGCs) and intermediate progenitor cells (IPCs), also called *basal progenitors*, have been described (Fig. 51.2).[71,74] RGCs occupy the VZ and are characterized by the expression of Pax6. They are highly polarized cells, with their apical pole connected to the ventricle luminal border and their basal pole to the pial surface. They thus extend their cellular process through the entire cortical wall and play a major role in guiding young neurons' migration into a specific layer. RGCs have the ability to self-renew either by autoreplicative symmetric divisions or by asymmetric division, which generates a further RGC and either an IPC or a neuron (neurogenic division).

Autoreplicative symmetric divisions are prominent in the mouse VZ until embryonic day 13, when the production of neurons becomes amplified through asymmetric neurogenic

• **Fig. 51.1** Schematic representation of some genes involved in the patterning of the rostrocaudal and dorsoventral axis of the central nervous system. FP, floor plate; NO, notochord; R, rhombomeres; RF, roof plate; SC, spinal cord. (From Lagercrantz H, Ringstedt T. Organization of the neuronal circuits in the central nervous system during development. *Acta Paediatr.* 2001;90:707, with permission.)

• **Fig. 51.2** Comparison of cortical development in mice and humans. In mice, cortical neurons arise mainly from two subsets of progenitors: radial glial cells (RGCs) in the ventricular zone (VZ), which generate intermediate basal progenitors (IPCs) migrating into the subventricular zone (SVZ). In humans, the lineage of RGCs is more complex. The SVZ is split into an inner (ISVZ) and outer (OSVZ) domain. IPCs occupy both areas, whereas another type of progenitors, basal RGCs (bRGC), is largely represented in the OSVZ.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

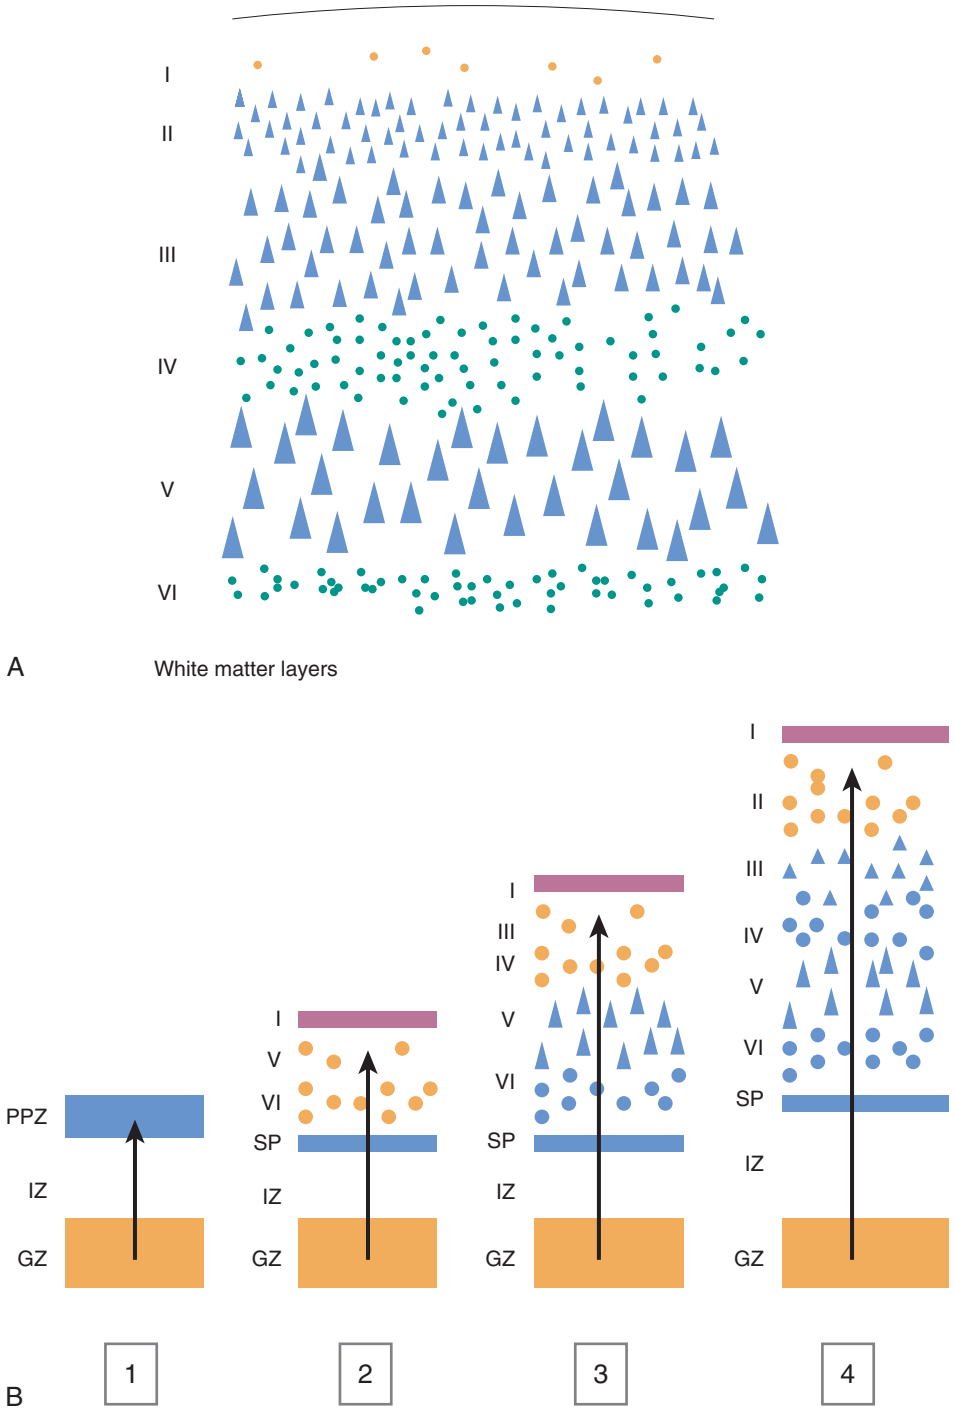
divisions. Notch activity is required to maintain the basal process and the RGC identity, but the pathways promoting asymmetric versus symmetric divisions remain to be determined. All RGCs give rise to IPCs, which settle in the SVZ. IPCs express Tbr2, divide symmetrically to self-renew or to give birth to two neurons, and are not polarized. They are limited to one or two further rounds of division in rodents.

In humans, the situation is much more complex (see Fig. 51.2).[71,74] Whereas RGCs remain the major cell type in the VZ, the SVZ is drastically enlarged and subdivided into the inner (ISVZ) and outer (OSVZ) parts (see Fig. 51.2). The ISVZ is mainly composed of IPCs, whereas OSVZ includes IPCs and another type of RGCs, which are not attached at their apical side to the ventricle but maintain the basal process connected to the pial neocortical surface. These SVZ basal RGCs (bRGCs) express Pax6, similarly to ventricular apical RGCs (aRGCs). Like their apical counterparts, bRGCs can undergo symmetric division to self-renew, and asymmetric divisions to self-renew and generate either IPCs or neurons. Remarkably, both IPCs and bRGCs are endowed with a high ability to proliferate. Their pools are thus largely amplified in humans, between the 11th and 17th gestational weeks, as well as in other gyrencephalic species. Amplification of IPCs and bRGCs is obviously an important process that strongly impacts the extent of neurogenesis and appears to be a major process for cortical expansion.

Neuronal Migration and Cortical Lamination

Neocortical neurons derive from the primitive neuroepithelium and migrate to their appropriate position in the cerebral mantle. In humans, migration of neocortical neurons occurs mostly between the 12th and the 24th weeks of gestation.[103] The first postmitotic neurons produced in the VZ migrate to form a subpial preplate or primitive plexiform zone (Fig. 51.3). Subsequently produced neurons, which will form the cortical plate, migrate into the preplate and split it into the superficial molecular layer (layer I or marginal zone containing Cajal-Retzius neurons) and the deep subplate. Schematically, the successive waves of migratory neurons pass the subplate neurons and end their migratory pathway below layer I, forming successively (but with substantial overlap) cortical layers VI, V, IV, III, and II (an inside-out pattern).

Neocortical migrating neurons can adopt different types of trajectories (Fig. 51.4)[39,97]:



1. A large proportion of neurons migrate radially, along radial glial guides, from the germinative zone to the cortical plate. Radial glia are specialized glial cells present in the neocortex during neuronal migration; these cells display a radial shape with a nucleus located in the germinative zone, a basal process attached on the ventricular surface, and a radial apical process reaching the pial surface (Fig. 51.5). Rakic[96] postulated that these radially arranged glial guides keep a topographic correspondence between a hypothesized protomap present in the germinative zone (ventricular and SVZs) and the cortical areas.
2. An important group of neuronal precursors initially adopt a tangential trajectory at the level of the ventricular or subventricular germinative zones before adopting a classic radial migrating pathway along radial glia. This tangential migration could permit some dispersion at the level of the cortical plate of neurons originating from a single clone in the germinative neuroepithelium, increasing the clonal heterogeneity within a given cortical area.
3. Tangentially migrating neurons have also been described at the level of the intermediate zone (prospective white matter). Most of these neuronal cells displaying a migrating pathway orthogonal to radial glia originate in the ganglia eminence. Most gamma-aminobutyric acid (GABA)–expressing interneurons seem to be produced by this mechanism.

Studies over the last decade have identified several molecules involved in the control of neuronal migration and in targeting neurons to specific brain regions.[59,81,87]

These molecules can be divided into four categories (Fig. 51.6):

1. Molecules of the cytoskeleton that play an important role in the initiation and progression (extension of the leading process and nucleokinesis) of neuronal movement. Initiation controlling molecules include Filamin-A (an actin-binding protein involved in periventricular nodular heterotopia) and Arfgef2 (adenosine diphosphate [ADP]-ribosylation factor GEF2, which plays a role in vesicle trafficking and is involved in periventricular heterotopia combined with microcephaly). Progression controlling molecules include doublecortin (Dcx, a microtubule-associated protein [MAP] involved in double cortex and lissencephaly), Lis1 (a MAP and dynein regulator involved in isolated type 1 lissencephaly and Miller-Dieker syndrome), alpha-tubulin (involved in the formation of tubulin heterodimers), and other molecules that are associated with migration defects in transgenic mice but that have not yet been associated with human disorders (phosphatase inhibitor 14-3-3epsilon, MAP1B, MAP2, and tau).
2. Signaling molecules, which play a role in lamination. These molecules include the glycoprotein Reelin (involved in lissencephaly and cerebellar hypoplasia in humans and in the Reeler mouse mutant characterized by an inverted cortex) and other proteins generally associated with inverted cortex in transgenic or mutant mice but which have not yet been associated with human disorders, such as adaptor protein Disabled-1 (Dab1), ApoE receptor 2 (Apoer2), very low density lipoprotein receptor (Vldlr), two Reelin receptors, serine-threonine kinase Cdk5 (cyclin-dependent kinase 5), activator of Cdk5 p35, Brn1/Brn2, and transcriptional activators of Cdk5 and Dab-1.
3. Molecules modulating glycosylation that seem to provide stop signals for migrating neurons. These molecules

include POMT1 (protein *O*-mannosyltransferase associated with Walker-Warburg syndrome), POMGnT1 (protein *O*-mannose beta-1,2-N-acetylglucosaminyltransferase involved in muscle-eye-brain disease), Fukutin (a putative glycosyltransferase involved in Fukuyama muscular dystrophy), and focal-adhesion kinase (Fak involved in migration disorder in transgenic mice). These three human diseases comprise type 2 lissencephaly (cobblestone lissencephaly).

4. In addition to these three major groups of molecules, other factors have been shown to modulate neuronal migration, including neurotransmitters (glutamate and GABA),[8,9,76] trophic factors (brain-derived neurotrophic factor BDNF and thyroid hormones),[12] molecules

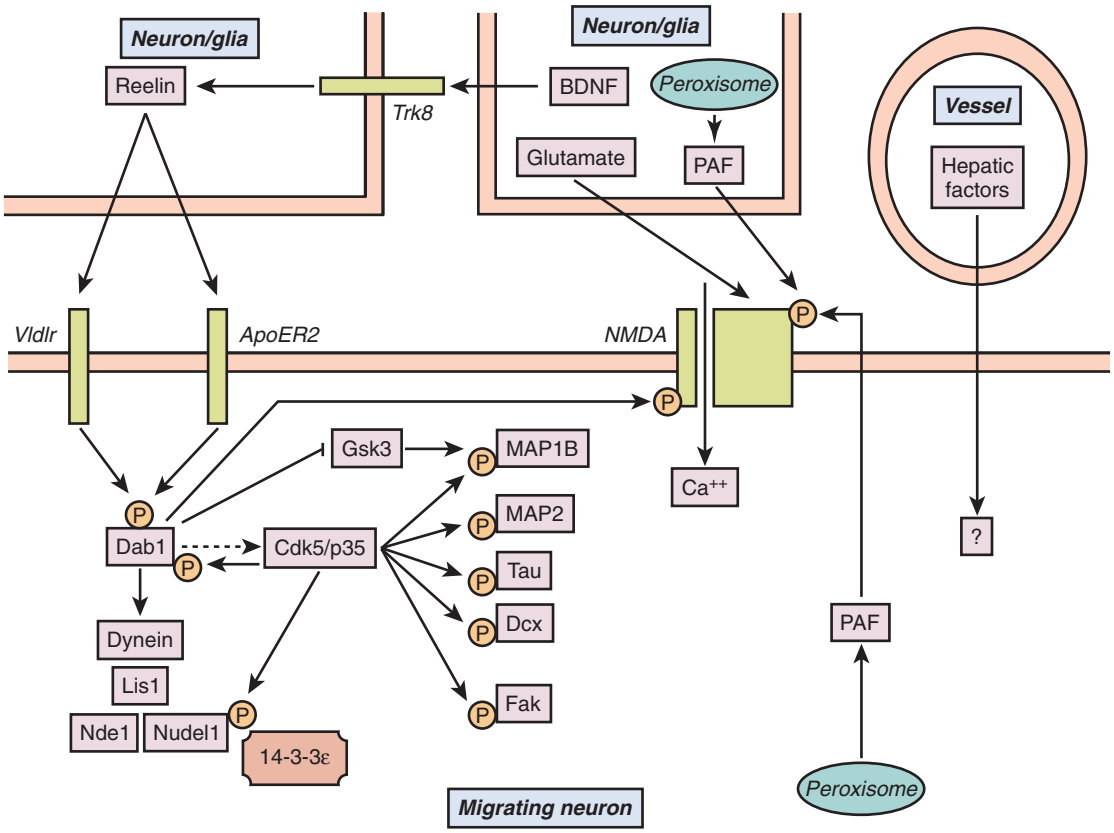
deriving from peroxisomal metabolism, and environmental factors (ethanol and cocaine).



The application of diffusion-weighted magnetic resonance imaging (MRI) or diffusion tensor MRI to the evaluation of developing brain has opened up the possibility to study some of these developmental events in vivo. Quantitative indices derived from the diffusion tensor allow measurement of apparent diffusion and diffusion anisotropy, ultimately depending on microstructural tissue development. Several different diffusion tensor imaging (DTI) parameters are available in this assessment. These include the three diffusion tensor eigenvalues (l1, l2, l3, which represent diffusion along the three tensor principal axes), the mean diffusivity (D_{av}) or apparent diffusion constant (ADC), and a mathematical measure of anisotropy, and this describes the degree to which water diffusion is restricted in one direction relative to all others. Diffusion tensor MRI was used to study cortical development in human infants ranging from 26-41 weeks' gestational age; apparent diffusion of water in cortex was maximally anisotropic at 26 weeks' gestational age and declined to zero by 36 weeks' gestational age.[77] During this period, the major eigenvector of the diffusion tensor in cerebral cortex is oriented radially across the cortical plate. Vector maps illustrate diffusion anisotropy and direction of the major diffusion eigenvector. In the case of cortical gray matter, the vectors are oriented radially, consistent with the orientation of the radial glial fibers (Fig. 51.7).[77] Anisotropy changes are different in early intracortical maturation, where changes in fraction anisotropy (FA) are mainly due to changes in l1[20] confirmed also by studies in the developing rat brain.[48,106] One study on

human fetal brain has shown that cortical anisotropy increases from 15 weeks' gestation to approximately 26 weeks' gestation and then shows a gradual decline to 32 weeks' gestation.[43] The increase of anisotropy in this period coincides with active neuronal migration along the radial glial scaffolding, whereas the decrease coincides with the phase of neocortical maturation with transformation of the radial glia into the more complex astrocytic neuropil. Neurite orientation dispersion diffusion imaging (NODDI) has been used to characterize both white matter and gray

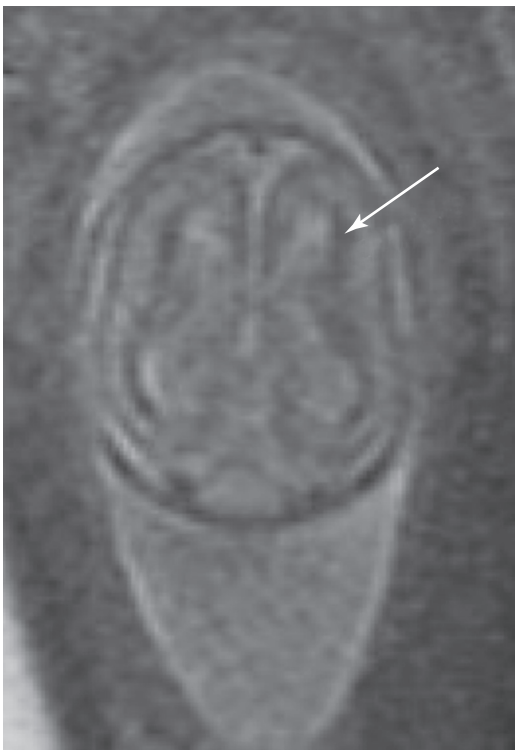
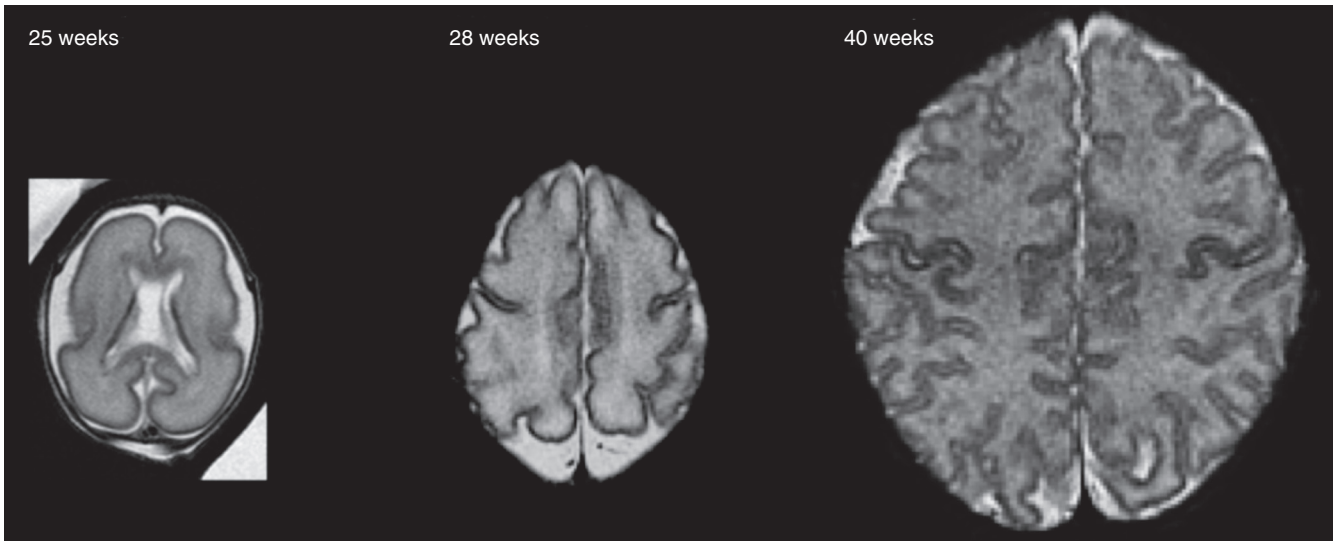
matter development in studies characterizing further the ongoing microstructural development in the newborn period.[28,69]



The use of new, ultrafast MRI sequences, such as multiplanar, single-shot, fast spin-echo T2-weighted images, helps obtain high-resolution images of the fetus in utero with imaging times of less than 1 minute.[2] The normal MRI pattern of fetal brain maturation from 13 weeks' gestation has been described, with documentation of the presence of the primary sulci and the insula by 15 weeks' gestation. Operculization of the insula begins by 20 weeks' gestation and all the main sulci, except the occipital sulci, are present by 28 weeks' gestation.[2] From 28 weeks' gestation, there is mainly an increase in secondary and tertiary sulcal formation. From 23-28 weeks in vivo[37] and from 15 weeks in vitro,[11,18] the typical multilayer pattern of the cerebral parenchyma can be observed with the innermost hyperintense signal (T1-weighted MRI) of the germinal matrix (Fig. 51.8). The five-layer pattern of the fetal forebrain, including the layers of neuroblast formation and migration, could be identified at 16-18 weeks' gestation in postmortem fetal brains.[18] During the last trimester, the gyri and sulci already formed become more prominent and more deeply infolded, with subsequent development of secondary and tertiary gyri at gestational age 40-44 weeks (Fig. 51.9).

Central Nervous System Organization



Subplate Neurons

As mentioned previously, subplate neurons constitute a distinct structure during neocortical development.[64] Neurons of the subplate are generated at approximately the seventh week of gestation, and the subplate is generated from the preplate at approximately 10 gestational weeks. This structure localized beneath the neocortical plate reaches its maximal thickness between 22 and 36 gestational weeks. The subplate is present in preterm neonates but has disappeared in full-term neonates. Some authors have suggested that these neurons disappear by apoptosis, whereas others have suggested that they are incorporated into layer VI of the mature neocortex.

Subplate neurons express different neurotransmitters, neuropeptides, and growth factors; receive synapses; and

make connections with cortical and subcortical structures. These neurons play several important roles during brain development: (1) They produce axons for the internal capsule that will serve as guiding axons for axons originating from neurons in layers V and VI; (2) between 25 and 32 gestational weeks, they produce axons for the corpus callosum; and (3) they act as a waiting zone for thalamocortical axons (with which they establish synapses) before they invade the cortical plate and reach layer IV. This waiting zone is necessary for appropriate target selection by thalamocortical afferents.

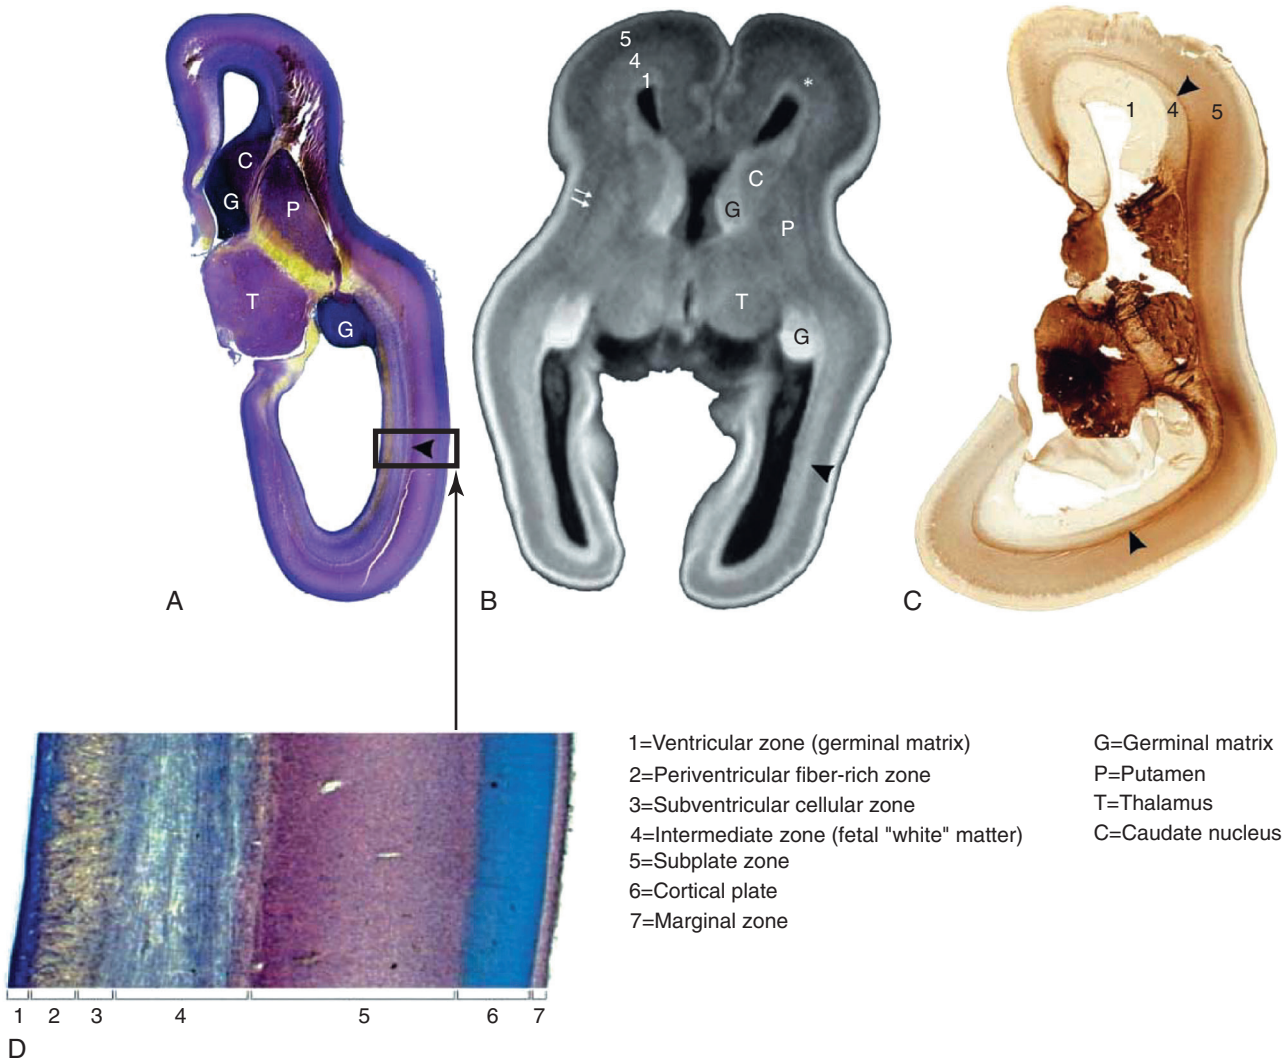
The subplate neurons can be lesioned or destroyed in preterm neonates with periventricular white matter lesions.[101] These data have been substantiated in animal models of periventricular white matter damage (see Chapter 52).[78]

MRI has been used to visualize the developmental evolution of the subplate zone and other laminar compartments of the fetal cerebral wall between 15 and 36 weeks' gestation. The combination of MRI and histochemical staining of the extracellular matrix enabled selective visualization of the subplate zone in the developing human brain.[63,116] The tissue elements of the subplate zone are embedded in an abundant, highly hydrophilic, and transient extracellular matrix that is most likely responsible for the low signal intensity on T1-weighted MRI in Fig. 51.10 and the slightly higher signal intensity on T2-weighted MRI as seen in vivo at 26 weeks (Fig. 51.11).

Axonal and Dendritic Growth

When neurons near their final destination, they start to produce axons and dendrites, allowing connection with distant cerebral structures. This ontogenic step occurs largely, but not exclusively, during the second half of gestation and extends into the postnatal period. For example, evoked visual potentials can be produced as early as 24-27 gestational weeks in human neonates, confirming the existence of an established wiring at this early developmental stage.

Growing axons have to find their path through developing structures to reach their target. In this process, growing axons and, in particular, their distal tip, called the *growth cone*, are helped by several mechanisms:



1. The transcriptome of each neuron contains information determining the types of connections that this neuron can establish.
2. Target neurons or neurons on the pathway of growing axons secrete or express on their membranes chemoattraction or chemorepulsion factors that interact with receptors present on growth cones, resulting in attraction or repulsion of these axonal growth cones. Several ligand-receptor families have been described, including netrin, slit, comm, robo, semaphorin, cadherin, and ephrin receptors.[70] The interaction between these different ligands and receptors leads to changes in calcium levels in the growth cones, which seem to play a key role in the resulting behavior of the growth cone.
3. Neurotransmitters and trophic factors are liberated that will favor or inhibit the extension of the growing axons expressing the corresponding receptor.
4. Growth cones can interact with various glycoproteins of the extracellular matrix that act as guiding cues.
5. At early stages of brain development, distances separating structures are rather small, facilitating the navigation of growth cones. These first-produced axons, called *pioneer axons*, serve as guides for later-produced axons, when distances between structures are significantly larger.

As for neuronal production, some axonal projections are produced in excess, connecting too many structures or neurons. This initial phase is followed by a regressive phase where redundant or misconnected axons are eliminated or retracted, allowing the emergence of adequate and functional connections. This balance between the maintenance and the elimination of axons is regulated by different mechanisms. Obviously, the survival of the neuron is determinant in this decision. Furthermore, competition for available trophic factors interacts with the genome to modulate this balance.[13] Also, electrical activity is a key determinant for the maintenance of axons. Accordingly, in utero and especially postnatal stimuli and experiences significantly shape the developing brain by modulating the maintenance or elimination of some axons.[15]

Some callosal connections, some "feedback" intracortical connections, and some corticofugal projections (e.g., the motor pathway) seem to be examples of connections largely under the control of this "overproduction–elimination" principle and, therefore, are highly dependent on the environment.[53] In contrast, some "feedforward" intracortical connections seem to be more genetically predetermined and, therefore, less susceptible to environmental cues.[94]

Studying white matter development with in vivo imaging was largely impossible before the advent of advanced MRI techniques, with diffusion imaging being of particular interest in the assessment of the white matter microstructure. Diffusion characteristics differ between pediatric and adult human brains in two primary ways. First, ADC values are higher for the pediatric brain than for the adult brain. Second, ADC maps of the pediatric brain show contrast between white and gray matter, with the ADC values for white matter being higher than those for gray matter. The precise cause of the decrease in ADC with increasing age is not known, although it has been postulated that the rapid decrease observed between early gestation and term is due to the concomitant decrease in overall water content. Brain water content decreases dramatically with increasing gestational age. As it does, structures that hinder water motion (e.g., cell and axonal membranes) become more densely packed, which further restricts the motion of the remaining water. The use of diffusion tensor MRI has allowed visualization of early white matter connectivity (Fig. 51.12) with demonstration of interhemispheric callosal fibers in the nonmyelinated stage at 28 weeks of gestation. During white matter development, decreases in diffusion are observed principally in l2 and l3 (and much less in l1), which reflect

• **Fig. 51.10** The cerebral wall displays five laminar compartments of varying magnetic resonance imaging (MRI) signal intensity **(B)**, which partly correspond to laminar compartments delineated on Nissl-stained **(A)** and histochemical **(C)** sections. Starting from the ventricular surface, these laminar compartments are as follows: The ventricular zone (germinal matrix) of high MRI signal intensity, which corresponds to the highly cellular ventricular zone in Nissl-stained sections and, therefore, is marked with number 1 (1 in **D**). The periventricular zone of low MRI signal intensity, which largely corresponds to the periventricular fiber-rich zone (2 in **D**). The intermediate zone of moderate MRI signal intensity, which encompasses both the subventricular cellular zone and the fetal white matter (3 and 4 in **D**). The subplate zone of low MRI signal intensity, which closely corresponds to the compartment marked with 5 in Nissl-stained section (5 in **D**) and acetylcholinesterase-stained section (5 in **C**); therefore, it is marked with 5 on MR images (5 in **B**). The cortical plate of high MRI signal intensity, which closely corresponds to the compartment marked with 6 on Nissl-stained sections (6 in **D**) but on MR images cannot be separated from the marginal zone (7 in **D**); therefore it is always described on MR images as a band of high signal intensity situated above the subplate zone. (From Kostovic I, et al. Laminar organization of the human fetal cerebrum revealed by histochemical markers and magnetic resonance imaging. *Cereb Cortex.* 2002;12:536, with permission.)

changes in water diffusion perpendicular to white matter fibers and may indicate changes due to premyelination (change of axonal width) and myelination.[36,83,88]

Relative anisotropy values for white matter areas are relatively low in newborns and increase steadily with increasing age.[82] They are particularly low for preterm infants.[51] This increase has been attributed to changes in white matter microstructure that accompany the "premyelinating state."[121] This state is characterized by a number of histologic changes, including an increase in the number of microtubule-associated proteins in axons, an axon caliber change, and a significant increase in the number of oligodendrocytes. It is also associated with changes in the axonal membrane, such as an increase in conduction velocity and changes in Na^+/K^+–adenosine triphosphatase (ATP) activity. Myelination then further increases relative anisotropy values. Although myelin accounts for much of the change in relative anisotropy, diffusion anisotropy is present under

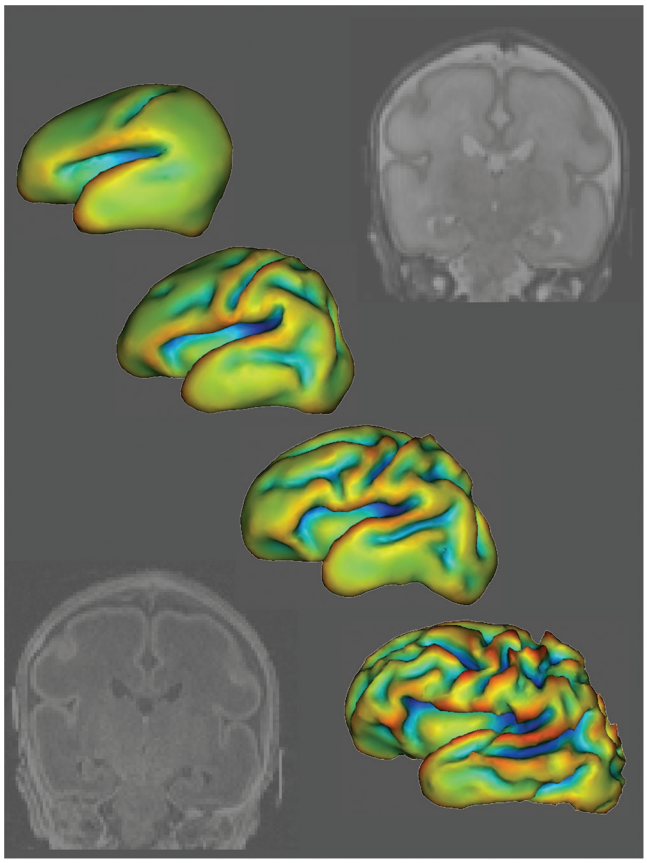
any circumstance in which the cytoarchitecture of the tissue is arranged in such a way as to lead to greater hindrance of water motion in one direction compared with others.

Making proper connections through white matter structures is probably one of the determining factors for further cortical organization. One major hypothesis for the morphogenetic mechanism of cortical folding is based on mechanical tension along axons in white matter.[114] A striking increase in cerebral cortical volume accompanies the axonal and dendritic growth described above. That this growth is particularly rapid between approximately 28 and 40 weeks' gestational age has been shown by quantitative three-dimensional MRI techniques with use of postacquisition image analysis. Volumetric analysis of MRI data sets is achieved by segmentation of the imaged volume into tissue types, depending on differences in signal intensity, followed by three-dimensional renderings.[42] Overall brain volume more than doubles between 28 and 40 weeks' gestation, and cortical gray matter volume increases fourfold in the same period.[52] This increase is thought to relate primarily to neuronal differentiation rather than to an increase in the total number of neurons. Cortical surface, changing from smooth and lissencephalic to highly convoluted, increases fivefold between 28 and 40 weeks' gestation (Fig. 51.13).[25]

So far, several hypotheses have been put forward on the mechanisms that underlie the folding process during development, but the potential influence of genetic, epigenetic, and environmental factors is still poorly understood. According to postmortem observations of fetal brains,[31] the primary folds would form in a relatively stable spatiotemporal way during intrauterine life, depending on physical constraints and mechanical factors.[98] An attractive theory suggests that the specific location and shape of sulci are determined by the global minimization over the brain of the viscoelastic tensions from white matter fibers connecting cortical areas.[45,46] This may explain why specific abnormalities in the sulcal pattern are observed in certain brain developmental disorders that are the result of subtle impairments in the neuronal migration and the setup of corticocortical



• **Fig. 51.11** T2-weighted magnetic resonance imaging (MRI) (axial plane) of a preterm infant at 26 weeks' gestation, with *arrows* indicating subcortical zone of higher signal intensity corresponding to the autopsy description of highly hydrophilic extracellular matrix in the subplate zone.

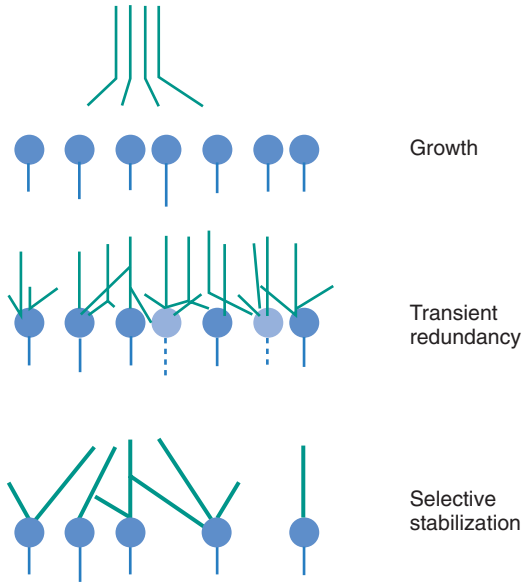
Mapping the early cortical folding process in the preterm newborn brain. *Cereb Cortex*. 2008;18:1444.)

connections.[95,115] The emergence of the cortical foldings in the preterm newborn brain was studied by applying dedicated postprocessing tools to high-quality MRI scans acquired shortly after birth over a developmental period critical for the human cortex development.[25,44] Through the three-dimensional reconstruction of the developing inner cortical surface, a sulcation index was derived and allowed for measurement of variations with age, gender, and presence of brain lesions and mapped the individual sulci appearance, highlighting early interhemispheric structural asymmetries that may be related to the cortical functional specialization of the brain. Females have lower cortical surface and smaller volumes of cortex and white matter compared with males, but equivalent sulcation. The highest sulcal index is found in the central region, followed by the temporo-parieto-occipital region, with the lowest sulcation index in the frontal region, which confirms that the medial surface folds before the lateral surface and that the morphologic differentiation of sulci begins in the central region and progresses in an occipitorostral direction. Such spatiotemporal differences in brain maturation have been described in detail in older children through analyses of cortical volume and thickness changes.[34] In particular, occipital regions grow much faster than prefrontal regions in newborns born at term,[35] and higher-order association cortices mature only after lower-order somatosensory and heterotopia visual cortices.[108]



The right hemisphere presents gyral complexity earlier compared with the left hemisphere, and this is particularly evident at the level of the superior temporal sulcus, which parallels early functional competence in response to auditory stimuli in newborns.[26] Preterm birth may be responsible for the delay that was observed in the appearance of sulci in comparison with that in postmortem and fetal studies, in that both cortical volume[55] and surface area[1] of extremely preterm infants imaged at term equivalent age are decreased and less complex than in normal infants; this impairment seems to increase with decreasing gestational age at birth.[58] Furthermore, preterm infants with intrauterine growth restriction had more pronounced reduction of volume in relation to surface area and increased sulcation with resultant changes in cortical thickness, which correlated with impaired behavioral functions.[24] In more recent studies, three distinct waves of cortical folding patterns could be described, representing primary secondary and tertiary cortical folding, and preterm infants at term equivalent age had altered sulcal pattern compared with full-term newborns, again indicating the disruption of normal cortical development by prematurity.[27,72]

Synaptogenesis

The concept of synaptic stabilization (with the elimination of nonstabilized synapses) has been proposed.[16,29] During brain development, there are successive waves of overproduction of labile synapses, inducing redundant connections produced in a relatively random manner (Fig. 51.14). This step is under tight genetic control. Each wave of overproduction is followed by a period of stabilization of synapses that have a functional meaning and elimination of redundant or meaningless synapses. This period of stabilization and elimination is highly influenced by environmental stimuli and experience. In this model, a moderate increase in the number of genes would induce a richer substrate on which the environment could produce a more complex network. Neuronal activity–mediated glutamate release induces a postsynaptic calcium influx at the level of N-methyl-D-aspartate (NMDA) receptors. Calcium changes lead to production of trophic factors, such as brain-derived neurotrophic factor, which stabilize labile synapses, protecting them against elimination. Nitric oxide, which is rapidly produced after glutamate binding to its NMDA receptor, is another key player in synaptic stabilization and plasticity. This model of synaptic stabilization and elimination does not exclude the existence of an instructive process where synaptic connections are adequately established right away.

Studies have demonstrated a key role of quiescent microglia in synaptic elimination. In the normal developing brain, quiescent microglia continuously extend and retract motile

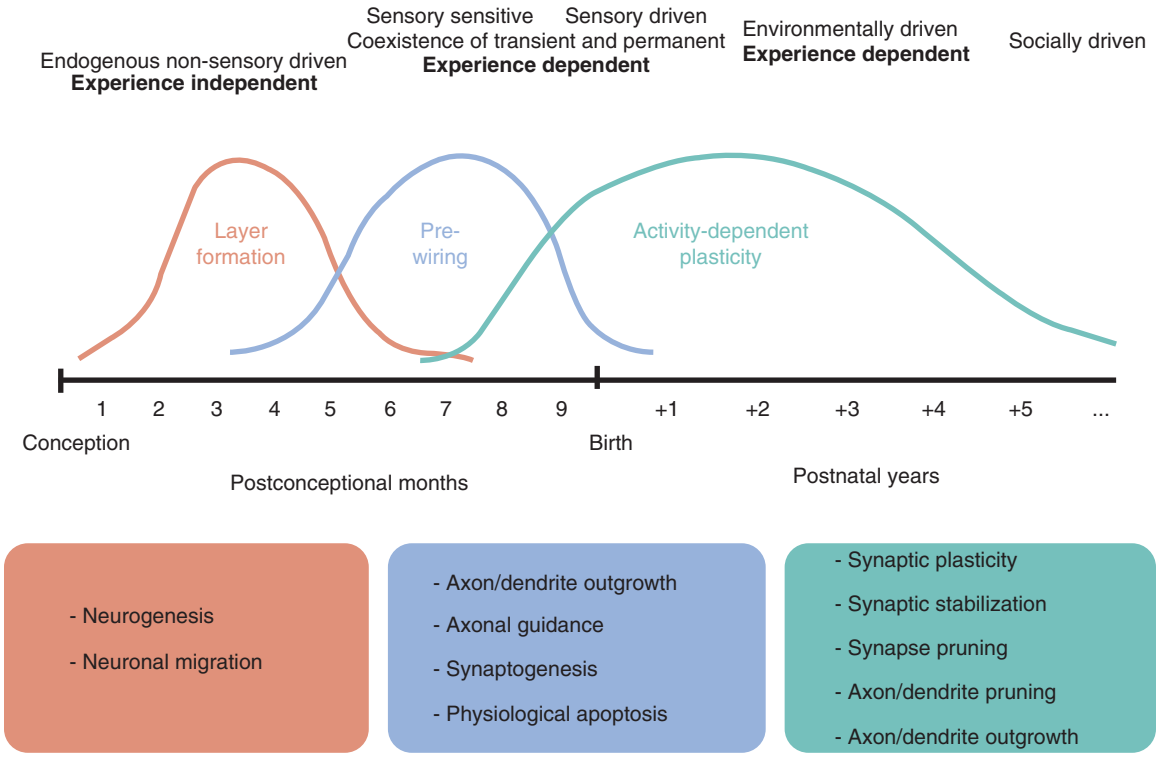
• **Fig. 51.14** Schematic representation of the epigenetic hypothesis based on selective stabilization of synapses. Spontaneous or evoked activity of developing neuronal networks controls the selective elimination of redundant synapses formed during the transient phase of synaptic redundancy. (Adapted from Changeux JP, Danchin A. Selective stabilisation of developing synapses as a mechanism for the specification of neuronal networks. *Nature.* 1976;264:705.)

processes. These processes interact with synapses, leading to the elimination of synapses by mechanisms that include the phagocytosis of axon terminals and dendritic spines.[112]

In monkey occipital neocortex, five successive waves of synaptogenesis have been described.[10] Based on data obtained in human occipital cortex,[70] the following timetable for humans is proposed (Fig. 51.15): (1) the first phase starting approximately 6-8 weeks of gestation and limited to lower structures like the subplate; (2) the second phase starting after 12-17 weeks with relatively few synapses produced in the cortex (contacts on the dendritic shafts); (3) the third phase starting around midgestation and ending approximately 8 months after birth; this phase is characterized by an estimated rate of 40,000 new synapses per second in the monkey; (4) the fourth phase lasting until puberty and also characterized by a high rate of synapse production; and (5) the last phase extending until late adulthood but somewhat hidden by the intense loss of synapses characterizing these ages. Experimentally, the first two phases are not affected by lack of sensory stimuli. The third phase partially depends on this sensory input, whereas the fourth phase is highly dependent on sensory input and experience (Fig. 51.16).

Current understanding of the mechanisms of synaptogenesis and of synaptic stabilization raises numerous questions in neonatal medicine and pediatric neurology. Very preterm infants are a typical example of such an issue:

- What are the effects of environmental modifications of preterm birth on synaptic stabilization?
- What are the influences (positive or negative) of too early sensory stimuli for synaptogenesis?



• **Fig. 51.15** Schematic representation of the synaptic density in the visual cortex of the macaque monkey. (From Bourgeois JP. Synaptogenesis, heterochrony and epigenesis in the mammalian neocortex. *Acta Paediatr Suppl.* 1997;422:27.)

- What are the effects on the synaptic equipment of drugs that interfere with the glutamatergic or the nitric oxide system?

Programmed Cell Death

Depending on brain area, between 15% and 50% of the initially formed neurons will be eliminated by a physiologic process called *programmed cell death*, or *apoptosis*. Approximately 70% of these neurons that are destined to disappear seem to die between 28 and 41 gestational weeks.

• **Fig. 51.16** Schematic time dependent representation of major brain developmental events in the fetal, neonatal, and infant periods. Of note, the gradual switch from activity and experience independent to activity and experience dependent, environmentally driven plasticity. (Adapted from Kiss JZ, Vasung L, Petrenko V. Process of cortical network formation and impact of early brain damage. *Curr Opin Neurol.* 2014;27:133-141.)

Programmed cell death is a complex mechanism that involves a balance between death and trophic signals, death and survival genetic programs, and effectors and inhibitors of cell death (Fig. 51.17).[79,117] Under the influence of a combination of exogenous and endogenous factors, genetic programs are activated (hence the name, "programmed cell death") that are able to overcome the natural defenses of the neuron. The cell eventually dies and is rapidly removed by phagocytosis performed by neighboring glial cells. In this process, activation of the cascade of caspases (proteolytic enzymes) is a key step leading to DNA fragmentation and neuronal cell death. The caspase pathway can be activated by intrinsic and extrinsic mechanisms. The intrinsic mechanism or mitochondrial-dependent pathway is triggered by cytochrome C release by mitochondria and is controlled by members of the Bcl-2 family, whereas the extrinsic pathway is triggered by activation of death receptors, a subgroup of the tumor necrosis factor receptor superfamily. Neuronal apoptosis can be also triggered by a caspase-independent pathway involving apoptosis-inducing factor (AIF) release from mitochondria.

Electrical activity seems to be a critical factor for neuronal survival. During the period of brain growth spurt in rodents, administration of drugs that block electrical activity leads to a dramatic exacerbation of neuronal cell death in different brain areas. These drugs include NMDA receptor

• **Fig. 51.17** Schematic representation of the molecular cascade leading to neuronal apoptosis and showing the balance between pro-survival (*left side*) and prodeath (*right side*) factors.

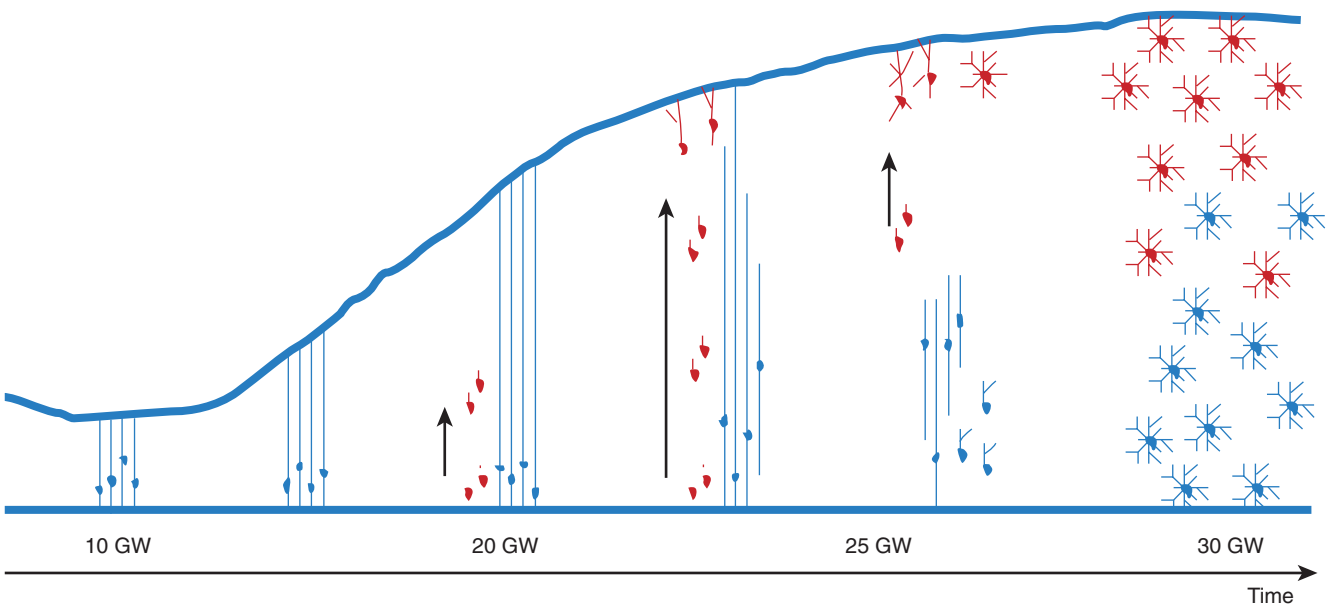
blockers (MK-801 or ketamine), GABA-A receptor agonists, such as classic antiepileptic drugs (phenytoin, phenobarbital, diazepam, clonazepam, vigabatrin, or valproic acid) and anesthetics (combination of midazolam, nitrous oxide, and isoflurane).[86] These effects on neuronal cell death are mimicked by acute administration of ethanol, which blocks NMDA receptors and activates GABA-A receptors. Although the mechanism is unknown, the systemic injection of a combination of sulfites (which are present in the excipient of some commercially available preparations of injectable glucocorticoids and vasoactive amines) and dexamethasone to newborn mouse pups led to an exacerbation of programmed neural cell death both in the neocortex and basal ganglia.[7,102]

Postnatal systemic steroid therapy had been widely used for chronic lung disease in the preterm infant until follow-up studies indicated higher rates of cerebral palsy and of subnormal (<70) cognitive function in steroid-treated infants. Quantitative MRI studies have indicated a possible origin of these functional deficits by showing marked reduction of cortical gray matter volume after repetitive antenatal and postnatal steroid treatments.[80,84] Different roles have been attributed to programmed cell death, although final proofs are still lacking. These comprise elimination of "sick" neurons; increase of neuronal diversity by eliminating redundant neurons; and competition for trophic factors with elimination of neurons that have lower access to these trophic factors. Consequences of cortical neuronal apoptosis may be widespread and include effects on cortical layering as well as distant effects on brain connectivity.[90]

Glial Proliferation, Glial Differentiation, and Myelination



Glia comprise three types of cells: astrocytes, oligodendrocytes, and microglia (brain macrophages).

Astrocytes

Neocortical astrocytes have a dual origin (Fig. 51.18).[41] After the end of neuronal migration, radial glial cells (which are glial cells specialized in the guidance of migrating neurons) transform into astrocytes, which are found mainly in the deep cortical layers and underlying white matter. In addition, the periventricular germinative zone produces, after the end of neuronal production, astrocytic precursors that will migrate mostly into the superficial neocortical layers.

The presence of low-intensity periventricular bands in white matter on T2-weighted MRI has been recorded in studies of premature infants, predominantly less than 30 weeks' gestational age. These bands are thought to represent populations of migrating radial glial cells based on their position and on correlative neuropathologic data.[6,17] The presence of these bands on T2-weighted MRI is, therefore, thought to be a marker of normal brain development.

Transformation of radial glia into astrocytes involves an autophagic digestion of apical processes and a nuclear translocation from the germinative neuroepithelium toward white matter. Molecular mechanisms controlling this transformation remain unknown. In vitro, it was shown that neurons are necessary to maintain the radial phenotype of these glial cells.

• **Fig. 51.18** Schematic representation of the dual origin of neocortical astrocytes in human fetuses. Astrocytes destined to white matter and deep cortical layers derive from the progressive transformation of radial glial cells (*blue cells*), whereas most astrocytes destined to the more superficial cortical layers derive from precursors that migrate from the germinative neuroepithelium (*red cells*). GW, gestational weeks. *Arrows* indicate migrating astrocytes.

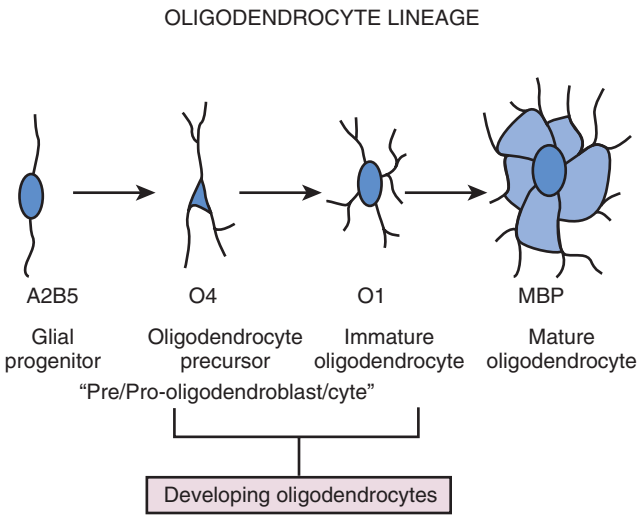
In the human neocortex, this astrocytic proliferation probably starts at approximately 24 weeks of gestation, with a peak at approximately 26-28 weeks. The final stage of astrocyte production is not known, but one might assume that the bulk of astrocyte production is completed by the end of normal gestation. However, it is important to remember that astrocytes retain the capability to divide throughout their life span. This peak of astrocyte production at approximately 26-28 weeks might be particularly important for preterm neonates. Indeed, astrocytes play several important roles during brain development, including axonal guidance, stimulation of neuron growth, synaptic formation, transfer of metabolites between blood vessels and neurons (magnetic resonance spectroscopy [MRS] results), establishment of scaffolding structures, production of extracellular matrix components, production of trophic factors, neuronal survival, myelination, and participation in the blood-brain barrier. For example, experimental transient blockade of astrocyte production in the rodent neocortex leads to increased neuronal programmed cell death and long-term changes in neocortical synaptic equipment.[124]

One of the essential contributors to progress in the noninvasive detection of tissue metabolism and in vivo biochemistry has been proton MRS (^{1}H-MRS), which gives specific chemical information on the biochemistry of numerous intracellular metabolites (Fig. 51.19). Neurochemistry has particularly benefited from this technique in that there is the possibility of detecting cerebral metabolites in vivo in otherwise inaccessible tissues. Astrocytes play a variety of complex nutritive and supportive roles in relation to neuronal metabolic homeostasis. For example, astrocytes take up glutamate and convert it to glutamine; removal of glutamate from the extracellular space protects surrounding cells from glutamate-induced excitotoxicity. Glutamate and glutamine are amino acids that are measured in ^{1}H-MRS when using short echo times. Alternatively, glutamate in the astrocyte can stimulate glycolysis with lactate production. Lactate is then released into the extracellular space and can also be taken up by neurons and used for energy generation.[89] In the immature brain, especially in the immature white matter, lactate is present in higher concentrations.[14,50]

Osmoregulation is another major metabolic task fulfilled by astroglia. Osmolytes synthesized by astrocytes or present in astroglia include taurine, hypotaurine, and myoinositol. Developmental changes in myoinositol have been described by Kreis et al.,[65,88] who found a decrease of myoinositol during the first year of life and a marked reduction of myoinositol in the first weeks after birth regardless of the gestational age at birth. Studies indicate that astroglial cells are also able to synthesize creatine from glycine, which will need to be considered in interpreting creatine concentrations in the brain[8,23] and the role of creatine as a neuroprotective agent.

Oligodendrocytes and Myelination

Oligodendrocytes, which produce myelin, can be divided into four cell types according to their stage of maturation: oligodendrocyte progenitor (NG2+), preoligodendrocyte (O4+, O1−), immature oligodendrocyte (O4+, O1+), and mature myelinating oligodendrocyte (O4+, O1+, MBP+, PLP+).



• **Fig. 51.19** Averaged in vivo proton magnetic resonance spectroscopy (^{1}H-MRS) spectra during human development in function of different regions of the brain: WM, white matter; GM, gray matter; Tha, thalamus. Metabolites identified are Lac, lactate; NA, N-acetyl-aspartate; glx, glutamine and glutamate; Cr, creatine and phosphocreatine; Cho, choline; ml, myoinositol. Spectra are scaled identically. Developmental changes in metabolite concentrations are illustrated by different peak heights comparing spectra from preterm and full-term newborns. (Spectra analyzed by Roland Kreis, MR Center, Inselspital, University of Berne, Switzerland.)

The progenitors originate from the proliferative SVZ and are bipolar and mitotically active. They are produced during the last months of gestation and in the early postnatal period. During migration in white matter, differentiation into preoligodendrocytes occurs, which are multipolar cells retaining a proliferative capacity. This second cell type is the dominant one in the second half of gestation in periventricular white matter. The immature oligodendrocyte is a multipolar cell that starts in the third trimester to ensheath the axons in preparation for myelination. The last stage is differentiation into the mature, myelinating, highly multipolar cell. Each stage of differentiation can be marked by specific monoclonal antibodies (Fig. 51.20).[3]

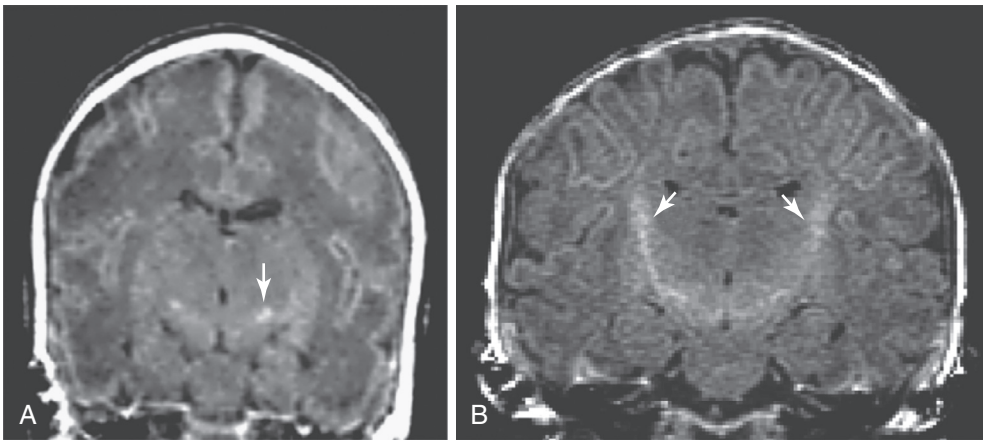
Growth factors, hormones, and cytokines (basic fibroblast growth factor, neurotrophin-3, platelet-derived growth factor, insulin-like growth factor type 1, interleukin-6, thyroid hormone) are implicated in oligodendrocyte maturation, but up to 50% of oligodendrocytes undergo programmed cell death (apoptosis) during development.[118] Preoligodendrocyte progenitors are highly vulnerable to oxidative stress, excitotoxic cascade (through a-3-amino-hydrox y-5-methyl-4-isoxazole propionic acid [AMPA]-kainate and NMDA receptors), and hypoxic-ischemic insults.[118]

^{1}H-MRS as an in vivo technique to assess metabolic composition of brain tissue can help in characterizing integrity of developing white matter. N-acetylaspartate (NAA), an amino acid specific to the CNS, has been shown to be uniquely localized in neuronal tissue of the adult brain, whereas during development it is also found in oligodendrocyte type 2 astrocyte progenitor cells and immature oligodendrocytes.[113] NAA has been shown to be an acetyl group source in the nervous system.[79] The major requirement for acetyl groups is lipid synthesis, which takes place immediately before myelin deposition in the developing brain. A marked increase of NAA shown in several studies[49] in the period from 32-40 weeks of gestation, just before the initiation of myelination, supports the importance of NAA in lipid synthesis (see Fig. 51.19). Regional differences in age-dependent changes of NAA concentrations during early brain development show stable concentrations in perithalamic voxels,[14] where myelination is already initiated at 32 weeks, and a marked increase in central cerebral white matter[66] between 32 and 40 weeks of gestation (see Fig. 51.19).

• **Fig. 51.20** Schematic representation of the oligodendrocyte development showing their morphology and some major immunohistochemical markers (A2B5, 04, O1, and MBP [myelin basic protein]). (Adapted from Back SA, et al. Immunocytochemical characterization of oligodendrocyte development in human cerebral white matter. *Soc Neurosci Abst.* 1996;20:1722.)

Myelination occurs over a protracted period, ending long after birth (Table 51.2). The chronology and rate of myelination vary with the brain structure. Structures that function first tend to be myelinated first. However, although myelination leads to a marked acceleration in nerve conduction, human and experimental studies have reported several examples of dissociation between the degree of myelination and the maturation of a given function. Myelination starts in the cerebral hemispheres around birth and is largely complete by age 2-3 years. There is no detectable myelination in the forebrain before the seventh gestational month, and this process continues in some parts until the years of maturity. Myelination is most intense in the telencephalon during the third trimester and postnatally. Pathways of the olfactory, optic, acoustic, and sensorimotor cortex are the first to be myelinated, whereas projection and association pathways are the last. Projection fibers begin myelination before association fibers. The myelination of association fibers lasts until adulthood. Recent experimental studies further support the idea that myelination is directly linked to neuronal activity, and this underlines the role of environmental stimuli in the maturation of the developing brain.[33]

Imaging Characteristics of Myelination



On histologic examination, mature myelin is present at 37-40 postconceptional weeks in the posterior limb of the internal capsule and in the lateral cerebellar white matter (see Table 51.2). Myelination advances at differing rates in different regions of the brain. Myelination occurs in an orderly and predictable fashion, proceeding cephalad from the brainstem at 29 weeks to reach the centrum semiovale by 42 weeks. Myelination advances at differing rates in different regions of the brain and is visible at different times on T1-weighted (lipid: high signal) and T2-weighted (water: high signal) MRI, the classic imaging sequences on conventional MRI.[5,6] The exact reasons for these differences are not clear. However, it is known that the T1 shortening correlates temporally with the increase in cholesterol and glycolipids that accompany the formation of myelin from oligodendrocytes.[92] Furthermore, the T2 shortening correlates temporally with the tightening of the spiral of myelin around the axon, the conformational changes in the myelin proteins, and saturation of polyunsaturated fatty acids in the myelin membranes. Portions of the proteins, cholesterol, and glycolipids that compose myelin are hydrophilic and form

TABLE 51.2 Sequence of Myelination Based on Histologic Analysis and Magnetic Resonance Imaging (MRI)

Anatomic Region	Median Age for Detection of Myelin: Histology[123]	Age for Detection of Myelin: MRI[37]	
		T1-Weighted Images	T2-Weighted Images
Ventrolateral thalamus		28–30 wk	3234 wk
Posterior limb of internal capsule	38/44 wk*	38–40 wk	Posterior portion: 40–48 wk Anterior portion: 56–70 wk
Anterior limb of internal capsule	50/87 wk	48–53 wk	70–90 wk
Central corona radiata	37/52 wk	38–56 wk	52–65 wk
Genu corpus callosum	50/53 wk	56–64 wk	64–72 wk
Splenium corpus callosum	54/65 wk	52–56 wk	56–64 wk
Occipital white matter			
Central	47/87 wk	52–60 wk	76–96 wk
Peripheral	56/122 wk	56–70 wk	90–102 wk
Frontal white matter			
Central	50/119 wk	52–64 wk	90–106 wk
Peripheral	72/119 wk	70–90 wk	96–114 wk

*The first number corresponds to earliest identification of some myelin tubules by microscopic examination of hematoxylin and eosin (H&E) stained sections. The second number corresponds to mature myelin stained with blue dye by eye observation.
wk, Week.

• **Fig. 51.21** T1-weighted magnetic resonance (MR) images illustrating progress of myelination. **A,** At 28 weeks' gestation, distinct T1 shortening (high signal) is seen only in a small perithalamic region (*arrow*). **B,** At 40 weeks, distinct T1 shortening (high signal) is seen throughout the internal capsule reaching the central cortex (*arrows*).

hydrogen bonds more strongly with water molecules. With an increase in bound water to the myelin building blocks, there is a consequent decrease in free water and an increase in T1 shortening times. This reduction in free water accompanying the preparation for myelination may explain the pattern of T1-weighted MRI changes preceding anatomic myelination by histologic analysis (see Table 51.2). Sensory pathways are the first to myelinate: Vestibular, acoustic, tactile, and proprioceptive senses are myelinated at term birth. A shortened T2 relaxation time and, therefore, a T2 hypointense signal is observed in the ventro-postero-lateral nuclei of the thalamus as early as 28 weeks' gestation, in the posterior limb of the internal capsule as early as 36 weeks' gestation, and in the corona radiata and the sensorimotor cortex at term. The signal alteration in the sensory motor cortex might also be due to a more advanced organization of cortical neurons, oligo-dendro-glial cells, synaptic density, and dendrite formation, which would cause decreased interstitial water and a shortening of the T2 relaxation time (Fig. 51.21).[62] Phylogenetically older structures, such as the inferior and superior cerebellar pedunculi and vermis, are myelinated before term, whereas the cerebellar hemispheres

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

are myelinated much later.[109] Similarly, the amygdala and hippocampus are partly myelinated at term.

Changes in the volume of myelinated white matter have also been determined by volumetric MRI studies, with myelin comprising less than 5% of total brain volume at 34 weeks' gestation and showing a rapid increase thereafter.[52] The dramatic fivefold increase in myelinated white matter after 34 weeks is of major interest for the understanding of brain injury during this period. This increase in myelin is presumed to be the result of the maturation of oligodendrocytes that have been actively differentiating during the immediately preceding period.

New methods based on "multicomponent relaxation" (MCR) analyses have introduced models that aim to distinguish different pools of water molecules from measured MRI signals, on the basis of the characterization of different T1 and/or T2 properties and of relationships through exchange processes. This approach applied to the developing white matter has recently provided quantitative reports of the spatiotemporal pattern of the myelination progression from the newborn period to childhood.[21]

Microglia and Brain Macrophages

Microglia constitute 5%-15% of the total cerebral cellular population. The prevailing view is that microglial cells are derived from circulating precursor in the blood that originates from bone marrow.[73] During the first trimester of human gestation, penetrating cells have ameboid morphology, with large ovoid cell bodies and no or few short processes, and express macrophage antigenic characteristics, depending on their location and activation state. This macrophage-like morphology evolves into an intermediate and a mature phenotype with a smaller cell body and longer processes. At midgestation, macrophage–microglia populations are mostly detected in white matter pathways, such as the external and internal capsules and corpus callosum. As suggested by rodent studies, these cells could contribute to physiologic developmental remodeling through phagocytosis of cellular fragments produced by neurodevelopmental apoptosis and elimination of exuberant axons and dendrites, as well as synaptic elimination.[75]

In the case of a cerebral lesion, experimental data support a neurotoxic role for the cerebral macrophage through the production of free radicals and nitric oxide. Under pathologic conditions, microglial cells can be transformed into functional brain macrophages with the reappearance of specific cell surface markers.

After development, mature microglia constitute a quiescent cellular population with small cell bodies, numerous long, thin processes, and a possible role in the regulation of the extracellular environment and immune protection of the brain.

Brain Vascular Development

Despite its major role in brain development and functioning, the ontogeny of the brain vasculature has not been the focus of numerous studies. Precise description of the successive steps of brain vessel development and its chronology is still lacking, and little information is available on the molecular mechanisms controlling the development and patterning of brain vessels. Accordingly, the exact timing of the switch from a neuronal anaerobic metabolism to an aerobic one is unknown, although this information might be critically important in understanding the potential consequences of hypoxia or ischemia at successive stages of brain development.

As soon as the neural tube is formed, blood vessels penetrate the primitive neuroepithelium. During migration of neocortical neurons, the density of blood vessels is rather low, with significant distances separating migrating cells from blood vessels. Penetration of vessels in the cerebral mantle is radial and ventriculopetal, starting from the leptomeningeal plexus and directed toward the ventricle.[68,85] No transventricular, paraventricular, or recurrent arteries ending in deep white matter have been identified. Horizontal collaterals progressively appear with a ventriculofugal gradient that reaches white matter at approximately 20 gestational weeks in the human fetus. The chronology of the horizontal ramification of vessels starts at approximately 20 weeks of gestation in the subplate and deep cortical layers, reaches layer III approximately at birth, and is completed (layers II and I) in the postnatal period.

Most neopallial vessels remain devoid of apparent muscularis until the final weeks of gestation.[67] Muscularis development follows a ventriculopetal gradient. The lack of muscular layers around neopallial arteries and the gradient of muscularization of these vessels could explain the high susceptibility of immature arteries to deep white matter and germinal matrix hemorrhages and the lack of vasomotor autoregulation in periventricular areas during a large part of the second half of gestation or the corresponding period in the preterm infant.

Abnormal Brain Development and Disorders

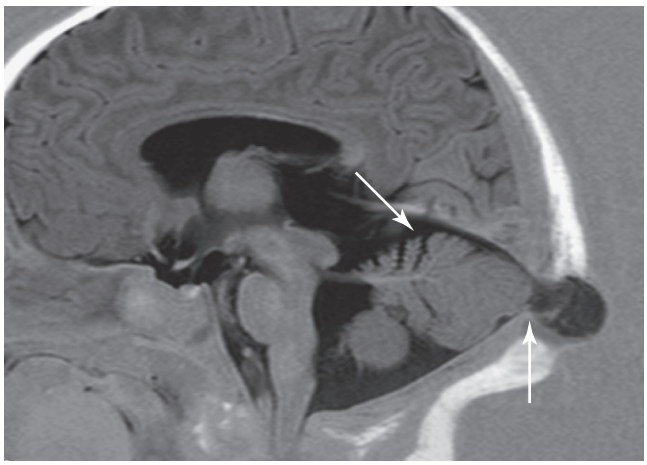
Generally, the different categories of congenital malformations of the CNS reflect the time at which a noxious event disrupted the normal sequence of CNS development rather than the nature of the noxious event itself. Therefore, in this section, the congenital CNS disorders are arranged according to time of onset of the morphologic alteration.

Disorders of Neural Tube Formation and Prosencephalic Development

Craniorachischisis Totalis, Anencephaly, Myeloschisis, Encephalocele, Myelomeningocele, and Occult Dysraphic States

Craniorachischisis totalis is secondary to total failure of neurulation with the formation of a neural platelike structure without overlying tissue. The onset of this malformation is

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.



no later than 20-22 days of gestation and most cases are aborted spontaneously during embryonic life.

Anencephaly results from failure of anterior neural tube closure and occurs before 24 days of gestation. It is often associated with polyhydramnios. Approximately three fourths of these infants are stillborn, and the rest die in the neonatal period.

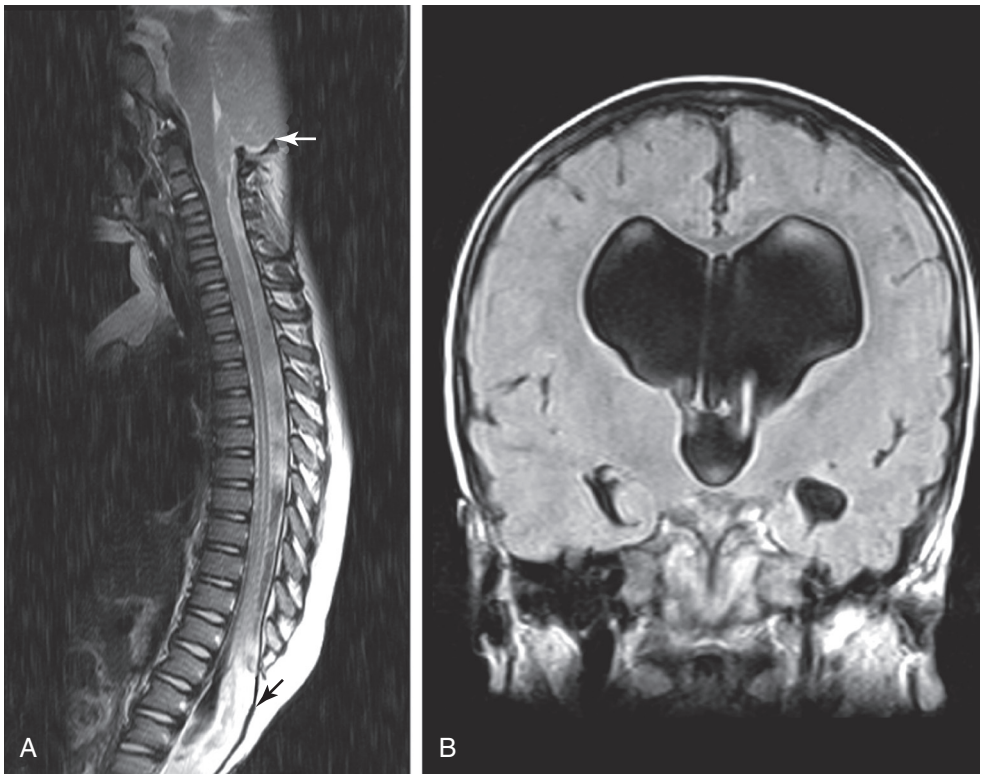
Myeloschisis results from failure of posterior neural tube closure and occurs before 24 days of gestation. A neural platelike structure without overlying tissue replaces large parts of the spinal cord. Most of these infants are stillborn.

Encephalocele is usually considered to be a restricted disorder of anterior neural tube closure, although its precise mechanisms remain unknown. It occurs before 26 days of gestation. Encephalocele is occipital in three fourths of cases, sometimes frontal (where it may protrude into the nasal cavities), and rarely temporal or parietal. Neural tissue (most often from the occipital lobe) in the encephalocele usually displays a normal gyration and underlying white matter and is connected to the brain through a narrow neck (Fig. 51.22). Hydrocephalus is present in approximately half the cases. In cases in which the encephalocele is located in the lower occipital region or upper cervical area, the cerebellum is usually present in the encephalocele, occipital tissue is present in approximately half the cases, and Chiari II malformation is associated (producing Chiari III malformation). Corpus callosum agenesis and anomalies of venous drainage are frequently associated. Encephaloceles are observed in a variety of chromosomal disorders (e.g., trisomies 13 and 18) and syndromes (e.g., Walker-Warburg, Meckel-Gruber, Dandy-Walker, Joubert, Goldenhar-Gorlin, Knobloch, and Robert syndromes).

Myelomeningocele is a restricted disorder of posterior neural tube closure that occurs before 26 days of gestation. (See also Chapter 13 for in utero diagnosis and treatment.) It involves all layers, including the spinal cord, nerve roots, meninges, vertebral bodies, and skin. Approximately three fourths of myelomeningoceles have a lumbar localization (thoracolumbar, lumbar, or lumbosacral). Hydrocephalus is present in 70% of cases, especially when the lumbar region is involved. Chiari II malformation is almost always present in lumbar myelomeningoceles (Fig. 51.23). Location and extent of the lesion determine the clinical symptoms. Thoracic myelomeningoceles have a generally poor prognosis. Varying degrees of paresis (often severe) of the legs and sphincter dysfunction are the major clinical signs. Although myelomeningocele can be observed in chromosomal abnormalities and in single-gene disorders, the vast majority of isolated nonsyndromal cases are thought to be caused by interaction of genetic susceptibility (e.g., specific mutations in the methylenetetrahydrofolate reductase gene) with environmental factors (e.g., valproate exposure or maternal type 1 diabetes mellitus).

• **Fig. 51.22** Occipital encephalocele (*right arrow*) with moderate displacement of the cerebellum (*left arrow*) and dilation of ventricular system, particularly the fourth ventricle. (Image courtesy of J. Delavelle, Department of Radiology, University Hospitals of Geneva, Geneva, Switzerland.)

In the case of a newborn with a myelomeningocele, the clinician is faced with difficult decisions about what to tell the parents and whether to close the spinal defect surgically. Surgery should be undertaken within the first 24 hours after birth to prevent further deterioration of the spinal cord and nerve roots and to prevent infection (meningitis). Fetal and neonatal therapies of myelomeningocele are discussed in Chapters 13 and 58.



Factors that influence the decision for surgical closure include size and location of the lesion, the technical feasibility of closure, the prognosis for ambulation, the presence or absence of associated abnormalities (hydrocephalus, kyphosis, or other major structural abnormalities), the availability of personnel and a facility to provide adequate care for the infant, and the structure of the infant's family and the attitudes of family members toward the defect and its consequences. The usual decision is to proceed with early surgical closure of the spinal defect, followed by placement of a ventriculoperitoneal shunt if hydrocephalus is present (see Chapter 58). Thereafter, the infant requires long-term neurosurgical, orthopedic, and urologic follow-up to maintain shunt stability; promote ambulation, if possible; and minimize the untoward effects of multiple urinary tract infections.

Occult spinal dysraphisms are considered to be disorders of caudal neural tube formation (secondary neurulation) and include distortion of the spinal cord or roots by fibrous bands and adhesions, intraspinal lipomas, epidermoid cysts, fibrolipomas, subcutaneous lipomas, tethered cord (the most common condition), and diastematomyelia. Clinical symptoms are variable (absent, minimal, moderate, or severe), depending on the degree of neural tissue involvement. Clinical signs include motor and sensory deficits in the lower and sometimes upper (when posterior fossa or cervical cord malformations are associated) limbs, bowel and bladder dysfunction, and ophthalmologic complications (when hydrocephalus is present).

Holoprosencephaly and Agenesis of the Corpus Callosum

(See also Chapter 57.)

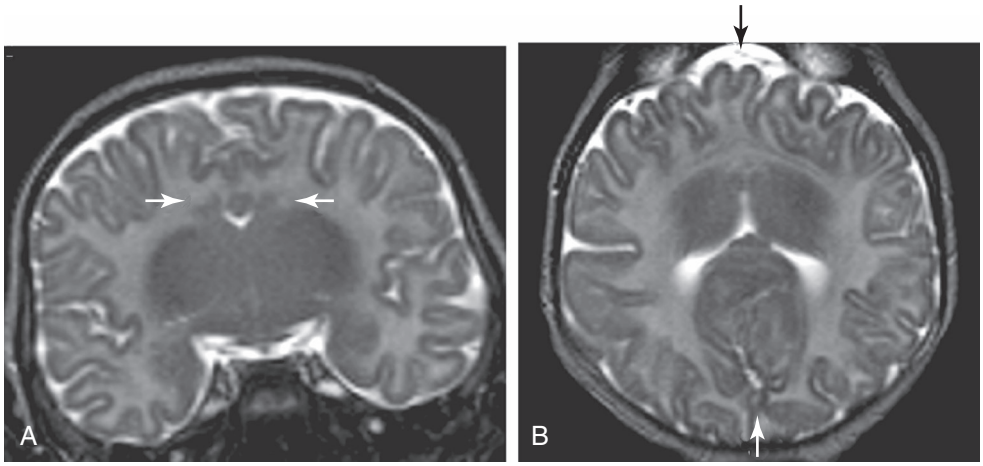
• **Fig. 51.23** **A,** Lumbar myelomeningocele (*black arrow*) with distal displacement of medulla and cerebellum (*white arrow*) (Chiari malformation) with associated hydrocephalus **(B)**. (Image courtesy of J. Delavelle, Department of Radiology, University Hospitals of Geneva, Geneva, Switzerland.)

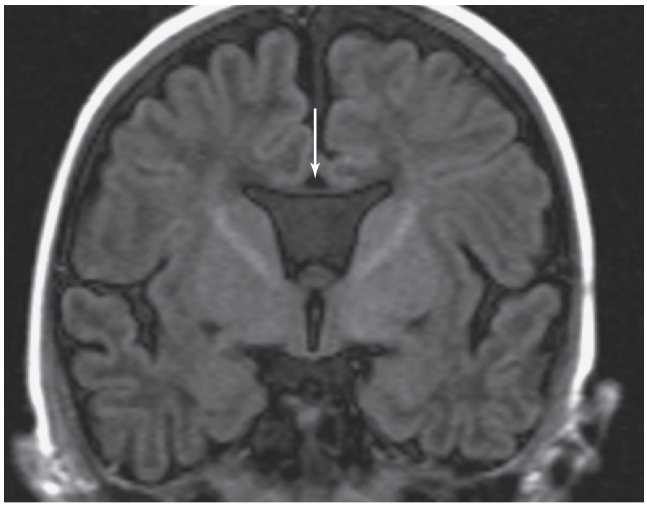
Holoprosencephaly refers to a large spectrum of brain malformations sharing a common embryologic origin. The frequency of holoprosencephaly is approximately 1 per 10,000 births, including miscarriages and terminations beyond 20 weeks of gestation, although it reaches approximately 40 per 10,000 if embryos are included, suggesting that holoprosencephaly is often accompanied by early embryonic loss.

Holoprosencephaly results from a defect in the cleavage of the prosencephalon in the rostrocaudal axis (between the diencephalon and the telencephalon) and in the transversal axis (division into two hemispheres). Holoprosencephaly can be divided into alobar variants (absence of interhemispheric fissure, corpus callosum, and third ventricle; unique ventricle; fusion of thalami), semilobar variants (presence of the interhemispheric fissure in the caudal part), and lobar variants (presence of a third ventricle; frontal horns partially formed; presence of the corpus callosum; hypoplastic frontal lobes) according to the severity of the malformation (Fig. 51.24). There seems to be a continuum between lobar holoprosencephaly and septo-optic dysplasia (Fig. 51.25). In all forms of holoprosencephaly, the septum pellucidum and the trigone are missing, whereas the olfactory bulbs and tracts are usually hypoplastic or absent (arhinencephaly).



The most severe forms of dysmorphic facies are usually found in alobar holoprosencephalies; however, this is not a general rule, and facial anomalies do not always reflect the severity of the brain malformations. Malformations affecting mainly the cardiac, skeletal, genitourinary, and gastrointestinal organs are frequent. In the most severe cases, neurologic signs are already present in the neonatal period and include apneas, seizures, tonic spasms, lack of neurologic development, and death.

Causes of holoprosencephaly are variable, with genetic, chromosomal, syndromic, and environmental etiologies (see Box 51.2). Most cases are sporadic, although some familial cases have been reported. Several maternal factors, such as maternal diabetes or ethanol consumption, have been associated with holoprosencephaly. Holoprosencephaly is also observed in several syndromes, including the Smith-Lemli-Opitz syndrome, which is characterized by abnormalities in cholesterol metabolism.



Approximately 12 loci, located on 11 chromosomes, have been identified for holoprosencephaly (HPE1 through HPE12). The genes *SIX3* (coding for a homeoprotein), *SHH* (transduction factor; see earlier), *ZIC2* (zinc finger transcription factor), and *TGIF* (TG-interacting factor, interacting with Smad2) have been identified as corresponding to loci HPE2, HPE3, HPE5, and HPE4, respectively. Among these genes, *SHH* is considered the most important one. Interestingly, abnormalities affecting genes located downstream to *SHH* in the *SHH* pathway also induce holoprosencephaly.

Agenesis of the corpus callosum is a relatively frequent malformation. Its prevalence in the general population is unknown because it might occur in a totally asymptomatic manner. Its prevalence in a population with mental

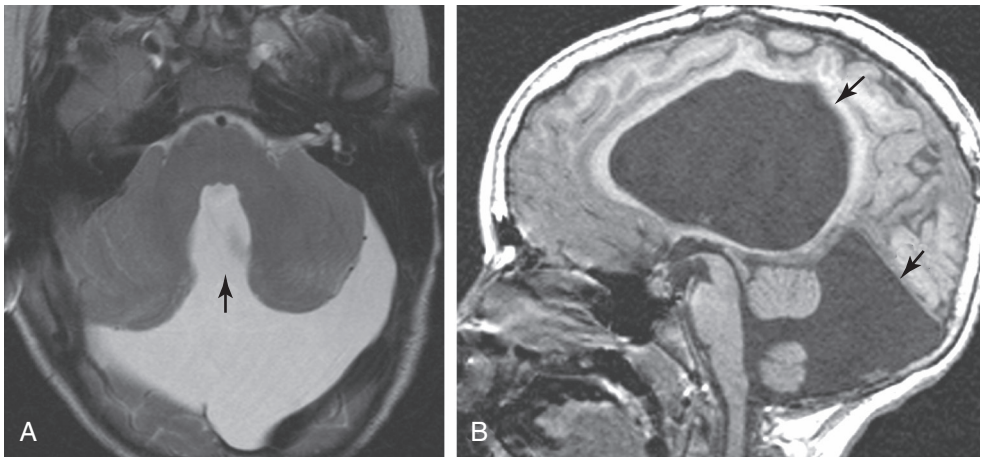
• **Fig. 51.25** Septo-optic dysplasia with agenesis of the corpus callosum and septum pellucidum (*arrow*). (Image courtesy of J. Delavelle, Department of Radiology, University Hospitals of Geneva, Geneva, Switzerland.)

retardation reaches 2%-3%. Agenesis of the corpus callosum represents approximately 50% of the malformations of the midline.

Agenesis of the corpus callosum can be partial (affecting in most cases the posterior portion, except when it is associated with holoprosencephaly) or complete. The lateral ventricles are deformed by the fibers of the cerebral hemispheres that were destined to form the corpus callosum and that form the Probst bundles running longitudinally along the lateral ventricles. The Probst bundles are inconsistently present, and their presence has been considered a sign of better prognosis.

Corpus callosum agenesis can be associated with other brain malformations (e.g., neuronal migration disorders) or with extracerebral malformations. In the presence of associated malformations, the prognosis in agenesis of the corpus callosum is considered poor in most cases. In contrast, the prognosis in isolated agenesis of the corpus callosum (partial or complete) is much more variable, with some cases having a totally normal or near-normal neurologic outcome, some cases with moderate or severe neurologic handicap, and some cases evolving toward death within the first days or months after birth. Because of the relatively low number of reported cases and the relatively short follow-up in many of these cases, providing reliable figures for the neurologic outcome of the isolated malformation remains difficult.



Dandy-Walker Malformation

Although it does not primarily affect the cerebral hemispheres, Dandy-Walker malformation is included in this chapter because it is frequently associated with malformations of the cerebral hemispheres (important for differential diagnosis and for determination of the outcome), it often has neonatal signs, and it is the prototype of cerebellar malformations observed in the neonatal period.

Dandy-Walker malformation results from abnormal development of the rhombencephalon, probably occurring between the 7th and the 10th gestational weeks. Dandy-Walker malformation is observed in approximately 1 per 25,000-30,000 births. This malformation is usually sporadic, with a few reported familial cases. Its etiology is unknown, and environmental factors (e.g., ethanol, warfarin sodium, viral infection) have been reported in a few cases.

Dandy-Walker malformation classically consists of three major abnormalities: (1) enlargement of the posterior fossa and elevation of the tentorium; (2) cystic dilation of the fourth ventricle; and (3) partial or complete agenesis of the corpus callosum. Hydrocephalus is often present but may appear late during pregnancy or even after birth. Other brain malformations (in particular, abnormalities of the midline and neuronal migration disorders) are observed in up to 70% of cases (Fig. 51.26). Extraneurologic malformations involving the heart, kidneys, limbs, and face also occur

• **Fig. 51.26** Dandy-Walker malformation with enlargement of posterior fossa. **A,** Axial T2-weighted magnetic resonance imaging (MRI) with absence of cerebellar vermis (*arrow*). **B,** Sagittal T1-weighted MRI with elevation of the tentorium (*bottom arrow*) and hydrocephalus (*top arrow*). (Image courtesy of J. Delavelle, Department of Radiology, University Hospitals of Geneva, Geneva, Switzerland.)

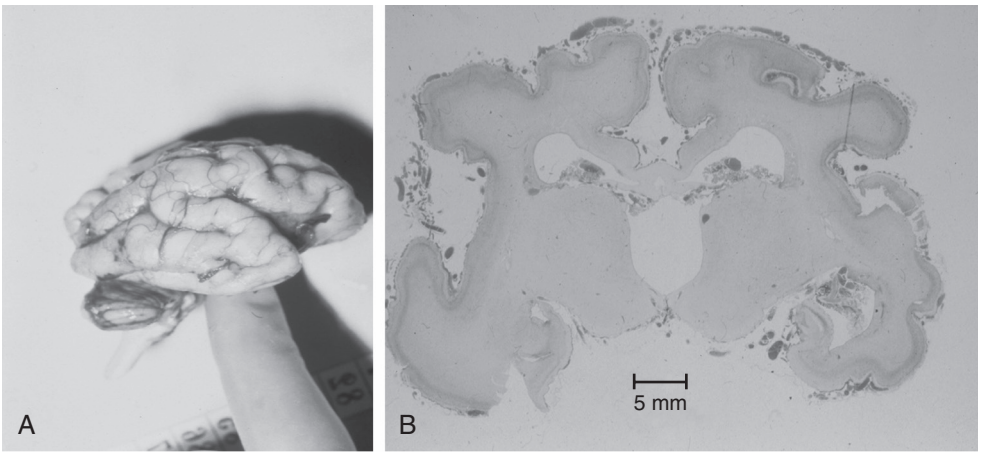
frequently. The associated neurologic and extraneurologic abnormalities have a major impact on the prognosis of Dandy-Walker malformation, with better prognosis often (but not always) associated with cases of isolated Dandy-Walker malformation.

As reviewed by Volpe,[119] a prominent posterior fossa cerebrospinal fluid collection can be divided into three categories: (1) enlargement of the fourth ventricle (including Dandy-Walker malformation, other disorders with agenesis of the cerebellar vermis, such as Joubert syndrome and other familial vermian ageneses, and trapped fourth ventricle); (2) enlarged cisterna magna; and (3) arachnoid cyst.

Abnormalities of Neuronal Proliferation

Microcephaly

(See also Chapter 57.)



Microcephaly is defined by an occipitofrontal circumference below −2 standard deviations (SD) for age and gender. Severe microcephaly refers to a circumference below −3 SD. Skull growth is determined by brain expansion, which takes place during the normal growth of the brain during pregnancy and infancy. Microcephaly most often occurs because of failure of the brain to grow at a normal rate. Any condition that affects brain growth can cause microcephaly. Primary microcephaly is distinguished from secondarily acquired microcephaly, in which the brain attains the expected size during pregnancy but subsequently fails to grow normally. Microcephaly can be divided into acquired etiologies (e.g., anoxic/ischemic brain damage, severe malnutrition, fetal alcohol syndrome, intrauterine infection, maternal hyperphenylalaninemia and phenylketonuria, anticonvulsant drugs, irradiation) and primary developmental microcephaly (see Box 51.3). The latter can be divided into (1) isolated primary microcephaly; (2) primary microcephaly associated with dwarfism; (3) microcephaly associated with other brain malformations; (4) microcephaly associated with chromosome disorders; (5) microcephaly as part of a syndrome with multiple congenital anomalies (e.g., Neu-Laxova, Rubinstein-Taybi, and Cornelia de Lange syndromes); and (6) microcephaly associated with biochemical disorders.

Primary Microcephalies

Primary microcephalies are a rare (<1/10,000), genetically and clinically heterogeneous group of autosomal recessive disorders that result from insufficient production of mature neurons during neurogenesis (Fig. 51.27). Known causal genes are involved in cell-cycle control (verification of DNA integrity, DNA replication, centrosome duplication, and spindle pole organization). The common pathophysiologic endpoint of these processes is an alteration in the cell-cycle timing and fate determination of neuronal progenitors. This may result in premature neuronal differentiation and a reduced number of neurons, although the exact mechanisms remain unclear for most primary microcephalies studied so far. Alterations to these processes may lead to isolated primary microcephaly (MCPH) or primary microcephaly with dwarfism (Seckel syndrome [SCKL], microcephalic osteodysplastic primordial dwarfism type 2 [MOPD2], and Meier-Gorlin syndrome [MGS]). Causal genes are currently known in about 30% to 50% of patients.

Primary microcephalies are characterized by an occipitofrontal circumference at birth of greater than 2 SD below the mean for gender, age, and ethnicity, and at least 3 SD below the mean at age 6 months. Patients usually exhibit no neurologic anomalies except seizures, mild pyramidal syndrome, and behavioral disturbances. Cognitive impairment ranges from borderline to severe. The reduced brain volume of these patients is usually associated with a simplified gyral pattern, but not with cortical dysgenesis or infratentorial abnormalities. However, some patients exhibit migration or cortical organization defects. The recent discovery of several new genes with mutations causing primary microcephaly has changed the diagnostic approach and highlighted new ways to understand the mechanisms involved in brain growth[57,111]:

• **Fig. 51.27** Primary microcephaly. **A,** Gross specimen. **B,** Microscopic section. (From Barkovich AJ, et al. Formation, maturation, and disorders of brain neocortex. *AJNR Am J Neuroradiol.* 1992;13:423, with permission.)

1) MCPH can result from mutations in at least nine genes—*MCPH1* (locus MCPH1), *WDR62* (MCPH2), *CDK5RAP2* (MCPH3), *CASC5* (MCPH4), *ASPM* (MCPH5), *CENPJ* (MCPH6/SCKL4), *STIL* (MCPH7), *CEP135* (MCPH8) and *CEP152* (MCPH9/SCKL5).

2) SCKS is caused by mutations in seven genes—*ATR* (SCKL1), *RBBP8* (SCKL2), *CENPJ* (SCKL4/ MCPH6), *CEP152* (SCKL5/ MCPH9), *CEP63* (SCKL6), *NIN* (SCKL7) and *ATRIP* (SCKL8).

3) *PCNT* is the only known *MOPD2* gene.

4) MGS is caused by *ORC1* (MGS1), *ORC4* (MGS2), *ORC6* (MGS3), *CDT1* (MGS4), and *CDC6* (MGS5) mutations. Although MGS has been defined as a syndromal form of primary microcephaly (because of ear and patellar anomalies), some patients have a phenotype that cannot be differentiated from MCPH or SCKS.

Microcephaly With Simplified Gyral Pattern

Microcephaly with simplified gyral pattern are disorders characterized by congenital severe microcephaly, reduced number and shallow appearance of gyri, and normal to thin cortex. Two clinical variants are delineated, one with a normal or thin corpus callosum and one with agenesis of the corpus callosum. Inheritance is autosomal recessive. Primary microcephaly and microcephaly with simplified gyral pattern are likely part of a continuous phenotype, with mild microcephaly with simplified gyral pattern being seen in some patients from families with typical primary microcephaly.[99]

Beyond the three genes described previously, several other loci have been mapped for microcephaly vera or microcephaly with simplified gyral pattern. Approximately 20% of families are still unlinked.

Microlissencephaly

Microlissencephaly disorders have simplified gyri but are distinguished from microcephaly with simplified gyral pattern by a cortex that is thicker than in normal brains. At least four different types have been identified on imaging and clinical grounds: (1) microlissencephaly with thick cortex (MLIS1, or Norman-Roberts syndrome); (2) microlissencephaly with thick cortex, severe brainstem, and cerebellar hypoplasia (MLIS2, or Barth syndrome); (3) microlissencephaly with intermediate cortex and abrupt anteroposterior gradient; and (4) microlissencephaly with mildly to moderately thick (6–8 mm) cortex. Inheritance is autosomal recessive. No gene has been mapped.

Megalencephaly

(See also Chapter 57.)

Megalencephaly (or macrocephaly) corresponds to an excess increase of the brain volume. It can affect one (hemimegalencephaly) or both hemispheres (symmetric megalencephaly).

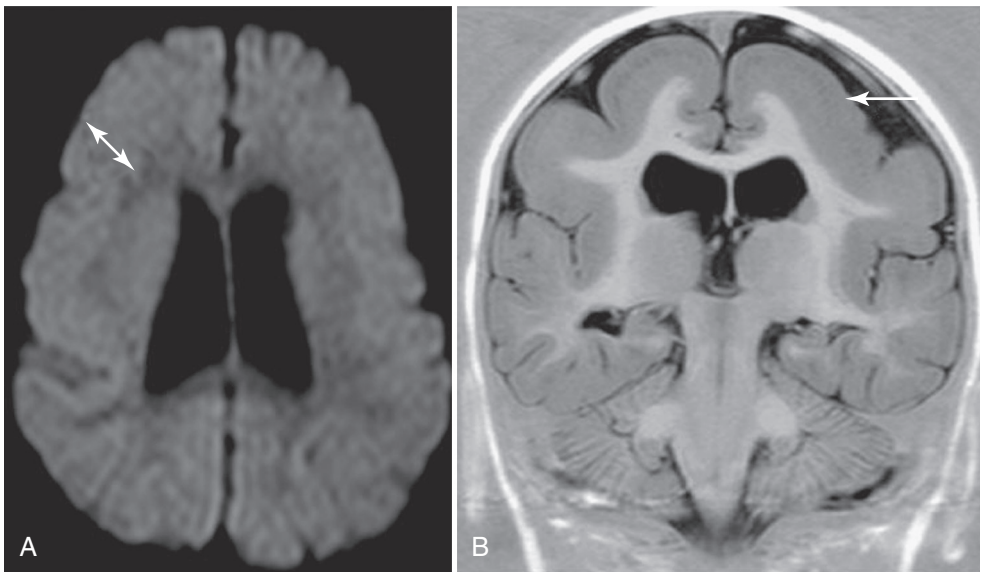
Symmetric megalencephaly can be associated with other brain malformations, including hydrocephaly, tumors, or gyration abnormalities (e.g., pachygyria). Some cases of symmetric megalencephaly have a familial transmission with different modes of inheritance. Some of these transmissible forms are accompanied by familial mental retardation. Megalencephaly can also be part of a syndrome, such as Weaver and Proteus syndromes. In the absence of associated malformation or familial history, the prognosis of isolated symmetric megalencephaly is difficult to determine because some cases have a normal evolution, whereas mental retardation can be observed in other cases. Symmetric megalencephaly must be differentiated from congenital macrocrania with normal brain volume but increased pericerebral spaces. This entity, sometimes called *external hydrocephaly*, can have a familial transmission (usually autosomal dominant) and often has an excellent neurologic prognosis.

Hemimegalencephaly is characterized by increased growth of one hemisphere or a part of it. This hemisphere is abnormal, with foci of pachygyria, polymicrogyria, heterotopias, and white matter gliosis. The brainstem and the cerebellum can also be affected. Hemimegalencephaly can

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

be isolated or associated with hemihypertrophy (as part of a syndrome, such as Protée syndrome, Klippel-Trenaunay-Weber syndrome, or Ito hypomelanosis) or, in some cases, with other malformations as part of Bourneville sclerosis. Hemimegalencephaly is usually sporadic. Its pathophysiologic process remains unclear but could involve genes implicated in brain symmetry, such as *LEFTY1*, *LEFTY2*, or *ZIC3*. Patients with hemimegalencephaly usually display a macrocrania, hemiplegia, severe or intractable epilepsy, and developmental delay that can be severe and exacerbated by the epilepsy.

Disorders of Neuronal Migration



Abnormalities of neuronal migration have been described in a large variety of syndromic, genetic, and environmental conditions (see Box 51.4).

Classic Lissencephalies (Type I Lissencephalies)

Classic lissencephalies form a genetically heterogeneous group with highly variable neuroradiologic signs. Complete agyria (lack of gyration) has to be distinguished from pachygyria (incomplete gyration with a reduced number of flat and broad gyri separated by shallow sulci).[4] The shallow sylvian fissures result in a figure-of-eight appearance of the axial brain sections. Aspect and severity can vary according to the cortical area and generally follow a rostrocaudal gradient. Hippocampus and temporal cortex are often less affected. Dobyns and Truwit have proposed a radiologic score of severity based on the presence and location of agyria, pachygyria, and subcortical band heterotopias.[22] On MRI, the cortex appears more thickened (5–20 mm) in comparison with the normal thickness (2.5–4 mm). The microscopic cytoarchitecture is abnormal (reduction of the number of cortical layers and abnormal neuronal densities), yielding a neuropathologic pattern that is specific for each molecular abnormality described thus far. Lateral ventricles can be enlarged in their posterior portion (colpocephaly). Lissencephaly variants are characterized by major abnormalities of the corpus callosum and of the cerebellum. By definition, head circumference is greater than −3 SD in classic lissencephalies and is less than −3 SD in microlissencephalies (see earlier). The incidence of classic lissencephaly is estimated to be 1.2 cases per 100,000 live births.

LIS1 Mutations (Isolated Lissencephaly and Miller-Dieker Syndrome)

Abnormalities of the *LIS1* gene (platelet-activating factor acetylhydrolase isoform 1B alpha subunit gene, *PAFAH1B1*), which encodes the LIS1 (PAFAH1B1) protein, account for the pathology seen in 40% of patients with lissencephaly. Deletions and nonsense mutations of *LIS1* induce an agyri–pachygyric phenotype with a posteroanterior gradient (posterior being more severe; grade 2–3, according to Dobyns[22]). Missense mutations can induce less severe phenotypes (grade 4, according to Dobyns[22]). The cortex is thickened (10–20 mm), disorganized, and generally composed of four layers: a large molecular layer, a layer of superficial neurons, a paucicellular layer containing myelinated fibers, and a deep layer containing neurons that failed to reach their final target. The 17p13 deletion, which contains the *LIS1* gene, is responsible for Miller-Dieker syndrome, which combines a grade 1 lissencephaly and dysmorphic features (prominent forehead, bitemporal hollowing, micrognathia, malpositioned and/or malformed ears, short nose with upturned nares and low nasal bridge, long and thin upper lip, and late tooth eruption) (Fig. 51.28). Septum calcifications are sometimes observed.

• **Fig. 51.28** Type 1 lissencephaly, or Miller-Dieker syndrome, with **(A)** pachygyric "four-layered" thickened cortex (*arrow*). **B,** Axial diffusion weighted image also characterizes thickened cortex compared with underlying white matter (*arrow*). DCX Mutations

The *DCX*, or *XLIS*, gene, encoding doublecortin or DCX and located on the X chromosome, is responsible for the disease in about 40% of patients with lissencephaly and in 85% of patients with subcortical laminar heterotopia.[19,38,91] In boys, mutations induce a classic lissencephaly (grade 1 to grade 4) with a thickened cortex (10–20 mm) and a rostrocaudal gradient (i.e., a gradient reverse to that observed in patients with *LIS1* mutations). Heterozygous girls display a subcortical laminar heterotopia, which consists of a gray matter layer of variable thickness and located between the normally located superficial cortical gray matter and the lateral ventricle ("double cortex"). This double cortex can be limited to the anterior part of the hemispheres. The clinical phenotype in females is variable and ranges from a complete lack of neurologic signs to mental retardation and epilepsy. Female carriers do not have a preferential X chromosome inactivation, and therefore a normal MRI finding does not exclude the presence of a carrier status. Results of neuropathologic studies have shown that brains from patients with *LIS1* mutations exhibited the classic inverted four-layer lissencephalic architecture and unique cytoarchitectural findings, including a roughly ordered six-layer lamination in male patients with *DCX* mutations and lissencephaly.

Tubulin Mutations

Mutations of the alpha 3 tubulin gene *TUBA3* have been described[60] in one male patient and in one female patient. The first patient presented with a classic lissencephaly with a thick disorganized cortex and, clinically, with severe epilepsy, mental retardation, and motor deficits. The second patient exhibited less severe cortical abnormalities with temporal and rolandic pachygyria and abnormal organization of the hippocampus. Both patients had corpus callosum agenesis, inferior vermis abnormalities, and brainstem hypoplasia. The *TUBA3* gene is the human homologue of the murine *Tuba1*, which is expressed during early embryonic development. *Tuba1* mutations impair the ability of the protein to bind guanosine triphosphate (GTP) and to form native heterodimers with b-tubulin, which is very important for microtubule function. Mutations in murine *Tuba1* induce abnormal neuronal migration with disturbances in layers II/III and IV of the visual, auditory, and somatosensory cortices. Mutations in *TUBB2B* and *TUBA1A* genes have been described in patients with lissencephalies.

ARX Mutations

Mutations in the *ARX* (Aristales-related homeobox) gene cause a particular classic X-linked lissencephaly with or without corpus callosum agenesis. The cortex in three layers of *ARX* lissencephalies is less thick (5–10 mm) than in the other classic lissencephalies and the cortical abnormality displays a rostrocaudal gradient (frontal regions being more affected). Female carriers can have isolated or combined corpus callosum agenesis, epilepsy, and/or mental retardation.

X-linked lissencephaly with ambiguous genitalia (XLAG) syndrome is also associated with mutations of the *ARX* gene. Affected boys have lissencephaly, corpus callosum agenesis, facial dysmorphic features, ambiguous genitalia, thermoregulation troubles, and severe epilepsy, which can begin prenatally. *ARX* gene mutations are implicated in a wide spectrum of X-linked disorders, ranging from mild forms of X-linked mental retardation without apparent brain abnormalities to severe lissencephaly. Phenotypes include corpus callosum agenesis with mental retardation, X-linked West syndrome, and Partington syndrome (hand dystony). A phenotype–genotype correlation has not been established.

The *ARX* gene is expressed mainly in telencephalic structures. In adults, *ARX* gene expression becomes restricted to a population of GABAergic neurons.[93] *ARX* seems to be implicated in interneuron migration from the ganglionic eminence (future thalamus); however, its role in cell differentiation and neuronal migration needs to be further clarified.

Lissencephaly With Cerebellar Hypoplasia

Lissencephaly with cerebellar hypoplasia (LCH) is a heterogeneous group of lissencephalies associated with a cerebellar hypoplasia, preferentially of the vermis and hemispheres that display sulci. A temporary classification comprising eight subtypes has been proposed. Although the phenotype of type A LCH is caused by *LIS1* or *DCX* gene mutations, patients with type B LCH have or display *RELN* gene mutations.[47] The latter lissencephaly is more severe than type A LCH but has a rostrocaudal gradient similar to that seen in patients with *DCX* gene mutations. The cortex is quite thick (5–10 mm), and the cerebellum is hypoplastic and smooth.

Other genes responsible for other forms of LCH are unknown. Type C LCH patients usually have a cleft palate. Patients with type D LCH (patients with Barth syndrome) display a neuropathology that includes massive brain and cerebellum and corticospinal tract hypoplasia; their cortex is thick (10–20 mm). Type E LCH is closely similar to type A LCH, but has a marked gradient from frontal agyria to occipital pachygyria. Type F LCH includes a corpus callosum agenesis. Moreover, two new types of LHC have been reported: (1) LCH with corpus callosum agenesis and cerebellar dysplasia and (2) a subtype with cerebellar hypoplasia, Dandy-Walker malformation, and myoclonic epilepsy.

Syndromic Lissencephaly

Two types of lissencephalies are included in the group of syndromic lissencephalies: (1) lissencephalies associated with other neurologic abnormalities (e.g., lissencephaly/pachygyria associated with peripheral demyelinating axonopathy) and (2) lissencephalies observed in syndromes of multiple malformations (in which lissencephaly is generally inconstant and not necessary for diagnosis). Among these syndromes, craniotelencephalic dysplasia (extensive craniosynostosis, microphthalmy, encephalocele), Warburg microsyndrome (corpus callosum agenesis, microphthalmy, microcephaly, cataract, dysmorphic features), Goldenhar

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

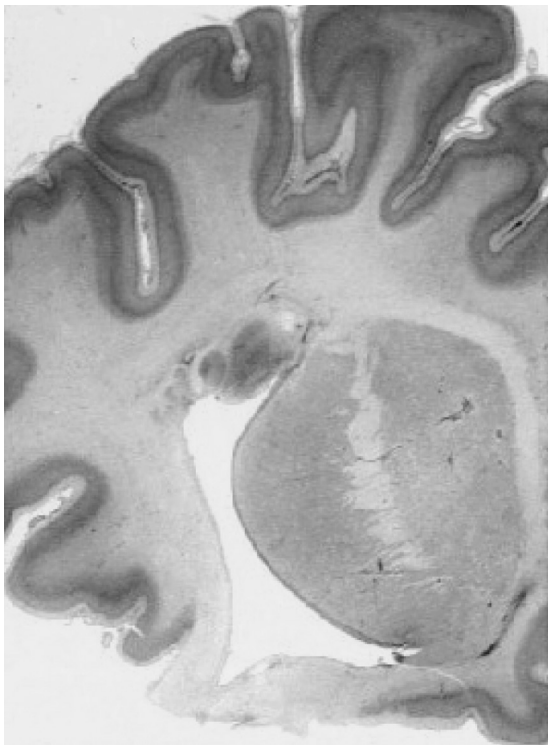
syndrome (hemifacial microsomia, branchial arch development abnormalities, hemifacial microsomia, microtia), and Baraitser-Winter syndrome (hyperthelorism, ptosis, coloboma, pachygyria/lissencephaly with a frontal predominance) have been reported.

Cobblestone Lissencephalies (Type II Lissencephalies)

Cobblestone lissencephalies are characterized by a pachygyric or granular brain appearance with shallow sulci and hypomyelination with subcortical cystic cavitations. Lateral and third ventricle dilation, which can be severe; vermis hypoplasia; or general cerebellar and brainstem hypoplasia with small pyramids can be observed. Additional brain anomalies, such as hypoplasia/agenesis of corpus callosum, occipital encephalocele, and Dandy-Walker malformation, have been described. Hemispheres can be merged on the median line by gliosis. The cortex is thickened (7–10 mm), disorganized, and invaded by gliovascular fascicles. White matter contains many heterotopic neurons. Typically, the brain is surrounded by a neurofibroglial envelope, which is not observed in classic lissencephalies and which induces a bumpy aspect (hence "cobblestone") rather than smooth aspect to the cortical surface. The cortical development defect occurs most likely between 6 and 24 weeks of gestation. Many neurons migrate too far through a defective glial-limiting membrane into the subpial space, that is, beyond the cortical plate. Cobblestone lissencephalies are linked to abnormal O-glycosylation of alpha dextroglycan. The *POMT1* (9q34 locus) and *POMT2* genes encode the two O-mannosyltransferases proteins 1 and 2 (POMT1, POMT2). POMGnT1 encodes an O-mannosyl-beta-1,2-N-acetylglucosaminyltransferase. The *FCMD* gene on chromosome 9q31 (FKTN) encodes the fukutin protein.

Clinically, cobblestone lissencephalies are observed in three autosomal recessive syndromes that have been shown to display a significant overlap, as indicated by molecular genetic discoveries. The incidence of cobblestone lissencephalies is not known but is most likely around 1 case in 100,000 live births.

Walker-Warburg syndrome is the most common and the most severe form of cobblestone lissencephaly. It is characterized by the combination of brain malformations, such as hydrocephalus, agyria, retinal dysplasia, and sometimes occipital encephalocele (HARD+/−E syndrome) with structural eye abnormalities and muscular dystrophy. Newborns die within the first postnatal months. Eye abnormalities include cataracts, microcornea, and microphthalmia, retinal dysplasia, hypoplasia or atrophy of the optic nerve, and glaucoma. In 30% of the patients, this phenotype is linked to *POMT1* or *POMT2* mutations.



The severity of the brain involvement in Fukuyama syndrome is milder than that in Walker-Warburg syndrome and muscle-eye-brain (MEB) syndrome, and the eyes are only occasionally affected severely. MEB syndrome is characterized by eye involvement (congenital myopia and glaucoma and retinal hypoplasia), mental retardation, and structural brain involvement (pachygyria, flat brainstem, and cerebellar hypoplasia). Fukuyama disease is linked to mutations of the *FCDM* gene. MEB syndrome is linked to *POMGnT1* gene mutations.

Type III Lissencephaly

Type III lissencephaly is characterized by severe microcephaly, agyria, corpus callosum agenesis, cerebellar, basal ganglia hypoplasia, a thin six-layered cortex, and blurred white matter borders. This lissencephaly has been reported in three autosomal recessive syndromes: Neu-Laxova syndrome, Enchara-Razavi-Larroche lissencephaly (microcephaly, corpus callosum agenesis, cystic cerebellum, brain stem hypoplasia, fetal akinesia),[30] and a syndrome reported with lissencephaly, severe microcephaly, corpus callosum agenesia, cerebellar hypoplasia, dysmorphic features, and punctuate epiphysis. Neuropathologic findings are similar in these three entities and thereby suggest that they are either allelic diseases or linked to genes implicated in the same function or pathway.

X-Linked Periventricular Heterotopia

Human X-linked dominant periventricular heterotopia is characterized by neuronal nodules lining the ventricular surface (Fig. 51.29). Hemizygously affected males die within the embryonic period, and affected females have epilepsy, which can be accompanied by other manifestations, such as patent ductus arteriosus and coagulopathy. The gene responsible for this disease, Filamin A gene *FLNA*,[32] encodes an actin-cross-linking phosphoprotein, which transduces

• **Fig. 51.29** Periventricular nodular heterotopias. (From Barkovich AJ, et al. Formation, maturation, and disorders of brain neocortex. *AJNR Am J Neuroradiol.* 1992;13:423, with permission.)

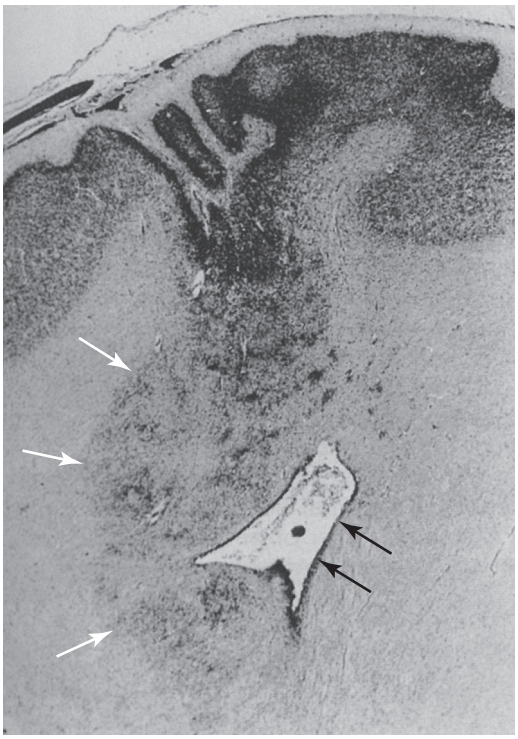
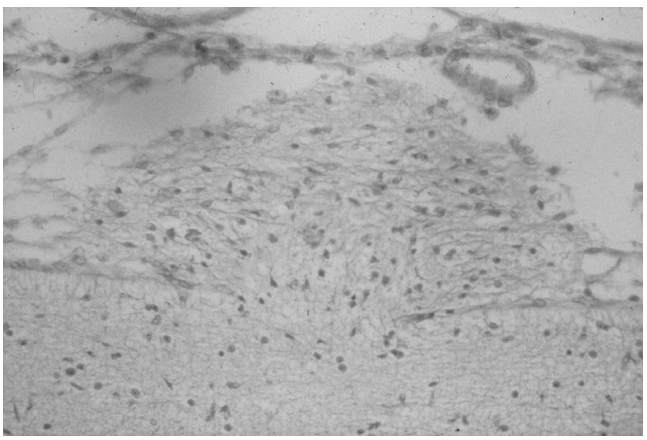
ligand-receptor binding into actin reorganization. Filamin A is necessary for locomotion of several cell types and is present at high levels in the developing neocortex.

Null mutations in the *FLNA* gene induce, through a loss-of-function mechanism, X-linked periventricular heterotopias and extraneural abnormalities (cardiac valvular anomalies, propensity to premature stroke, small joint hyperextensibility, gut dysmotility, and persistent ductus arteriosus).



Zellweger Syndrome

Zellweger cerebro-hepato-renal syndrome is a fatal autosomal recessive disease caused by an absence of functional peroxisomes. One hallmark of this human disease is the presence of heterotopic neurons in the neocortex, the cerebellum, and the inferior olivary complex. Patients display severely retarded and/or rapid regression of psychomotor development, facial dysmorphisms, and severe muscular hypotonia; they usually die within the first postnatal months.



Animal models of this human disease have been produced by inactivation of a gene critically involved in peroxisomal assembly.[40] The analysis of these models showed that (1) the migration defect was partially caused by altered NMDA glutamate receptor-mediated calcium mobilization; (2) this NMDA receptor dysfunction was linked to a deficit in platelet-activating factor (PAF) synthesis; and (3) normal neocortex development requires normal peroxisomal metabolism in the brain and in the liver.

Effects of Environmental Factors on Neuronal Migration

Neuronal migration disorders have been described in humans or in animal models after in utero exposure to several environmental factors, including cytomegalovirus infection or toxoplasmosis (Fig. 51.30) and exposure to ethanol (Fig. 51.31), cocaine, or ionizing radiation.[39] In most cases, the mechanisms by which these factors disturb neuronal migration remain unclear. Cocaine exposure during gestation has been shown to disturb neuronal migration and cortical addressing both in mice and monkeys. Cocaine exposure in mice was also shown to specifically decrease GABA neuron migration from the ganglionic eminence to the cerebral cortex but not to the olfactory bulbs, suggesting a degree of specificity in the effects of cocaine on neuronal migration. In human fetal alcohol syndrome, neuronal molecular ectopias have been described in several cases, although this sign is not restricted to this syndrome (see also Chapter 14). Animal studies have identified abnormalities of radial glia and disturbances of transformation of radial glia into astrocytes.

Disorders of Central Nervous System Organization and Maturation

Disorders involving subplate neurons, axonal and dendritic growth, synaptogenesis and synaptic stabilization, programmed cell death, and glial proliferation and differentiation are likely to have a major impact on brain functions. Unfortunately, little is known about these disorders, largely because the tools for adequate investigation of these steps are usually not available, even with postmortem tissues. The clinical consequences are rarely obvious in the neonatal period and usually occur later in life. These disorders can be schematically classified into primary (e.g., idiopathic mental retardation, Down syndrome, fragile X syndrome,

Angelman syndrome, Rett syndrome, neurofibromatosis type I, tuberous sclerosis (Bourneville disease), Coffin-Lowry syndrome, Rubinstein-Taybi syndrome, Duchenne muscular dystrophy, thyroid deficiency, and autism) or potentially acquired (e.g., malnutrition deficiencies or effects of prematurity and related environmental factors, including therapeutic drugs and illicit drugs [e.g., cocaine], acting on the CNS and inducing organizational disorders).[56,119] In most of these disorders, several steps of brain development, such as cortical lamination, dendritic branching and arborization, synaptic contacts, axonal development, and myelination, are affected. For example, in tuberous sclerosis, neuronal proliferation and later glial differentiation and proliferation are disturbed.

Key Points

- Neurulation in which neuroectodermal cells transform into a neural tube begins in gestation week 3, with migration of neocortical neurons occurring between weeks 12 and 24.
- Advanced MRI techniques are able to define cortical folding and the increase in cortical volume accompanying axonal and dendritic growth between approximately 28 and 40 weeks' gestation.
- Following neural migration, astrocyte proliferation supports multiple nutritive and structural functions, whereas oligocyte precursor maturation results in myelination.
- Brain malformations can be caused by environmental factors, genetic factors, or their interaction.
- Brain malformations may result from failed neural tube closure, defects in neural development, or proliferation and disorders of neural migration.

White Matter Damage and Encephalopathy of Prematurity

PETRA S. HÜPPI AND PIERRE GRESSENS

Brain injury in the premature infant is composed of multiple lesions, traditionally described as germinal matrix intraventricular hemorrhage (IVH) with or without parenchymal involvement, posthemorrhagic hydrocephalus (PHH), and periventricular leukomalacia (PVL). These mostly focal lesions mainly affecting white matter have, in recent years, been recognized to be associated with various other brain alterations, such as cortical and subcortical neuronal loss and distant alteration of white matter integrity.

Periventricular leukomalacia has classically been described as a disorder characterized by multifocal areas of necrosis, with formation of cysts in the deep periventricular cerebral white matter, which are often symmetrical and occur adjacent to the lateral ventricles. These focal necrotic lesions correlate well with the development of spastic cerebral palsy in very low birth weight (VLBW) infants. With the advances in neonatal care and the survival at increasingly low gestational ages, a large number of VLBW infants are now seen with mild motor impairment and often considerable cognitive and behavioral deficits,[91,147] which may relate to a more diffuse injury to the developing brain.

This chapter presents the current concepts of injury to the immature brain, which has been termed *encephalopathy of prematurity*, summarizing the old and new neuropathologic findings, mechanisms of pathogenesis through animal models,[84] and the characteristics of this type of lesions in modern neuroimaging.

Neuropathology of White Matter Injury

Historical View

Congenital encephalomyelitis was the term first used by Virchow in 1867 to describe a disease in newborns who demonstrated pale softened zones of degeneration within the periventricular white matter at autopsy. Microscopically, these lesions were characterized by glial hyperplasia, with the presence of foamy macrophages and signs of tissue destruction with necrosis. Interestingly, Virchow related the disease to acute infection, as many of the cases were seen in infants of infected mothers.[155] Clinically, he suggested that these lesions might be related to a disease described earlier by Little,[99] in which the patients suffered from spasmodic limb contractures, diplegia, and mental retardation, occasionally with an additional epileptic condition. Parrot, in 1873, first linked the pathologic entity to premature birth and proposed that the lesions were caused by a particular vulnerability of the immature white matter, as a result of nutritional and circulatory disturbances resulting in infarction.[124] Much later, Rydberg again proposed a hemodynamic etiology with a reduction of cerebral blood flow to the vulnerable regions of the immature white matter.[136] Banker and Larroche, in 1962, first introduced the term *periventricular leukomalacia* to define this characteristic lesion that they found in 20% of autopsies of infants deceased prior to 1 month of age and described the macroscopic and microscopic neuropathology in more detail.[12]

Periventricular Leukomalacia

Macroscopic Neuropathology

The topography of the lesions is uniform, primarily affecting the white matter in a zone within the subcallosal, superior fronto-occipital, and superior longitudinal fasciculi; the external and internal border zones of the temporal and occipital horns of the lateral ventricles; and some parts of the corona radiata.[55] These areas appear pale, usually bilateral, but without definite symmetry (Fig. 52.1). Although not unanimously accepted, it has been noted that the anatomic distribution of PVL correlates with the development of perforating medullary arteries and areas that represent the arterial borders or end zones, that arise between ventriculopetal and ventriculofugal arteries within the deep white matter (Fig. 52.2).[75] Immunohistochemical studies further confirm low vessel density in the deep white matter between 28-36 weeks' gestation, whereas in the subcortical white matter, the vessel density is low between 16 and 24 weeks and thereafter increases (Fig. 52.3).[114]

Abstract

This chapter presents the current concepts of injury to the immature brain, which has been termed *encephalopathy of prematurity*, and summarizes the old and new neuropathologic findings, mechanisms of pathogenesis through animal models, and the characteristics of this type of lesions in preterm infants with modern neuroimaging. Brain injury in the premature infant is composed of multiple lesions, traditionally described as germinal matrix intraventricular hemorrhage (IVH) with or without parenchymal involvement, posthemorrhagic hydrocephalus (PHH), and periventricular leukomalacia (PVL). These mostly focal lesions mainly affecting white matter have, in recent years, been recognized to be associated with various other brain alterations, such as cortical and subcortical neuronal loss and distant alteration of white matter integrity. It is, therefore, no longer a static brain lesion but very much a dynamically evolving injury with modification of the subsequent developmental steps all the way through to adulthood.

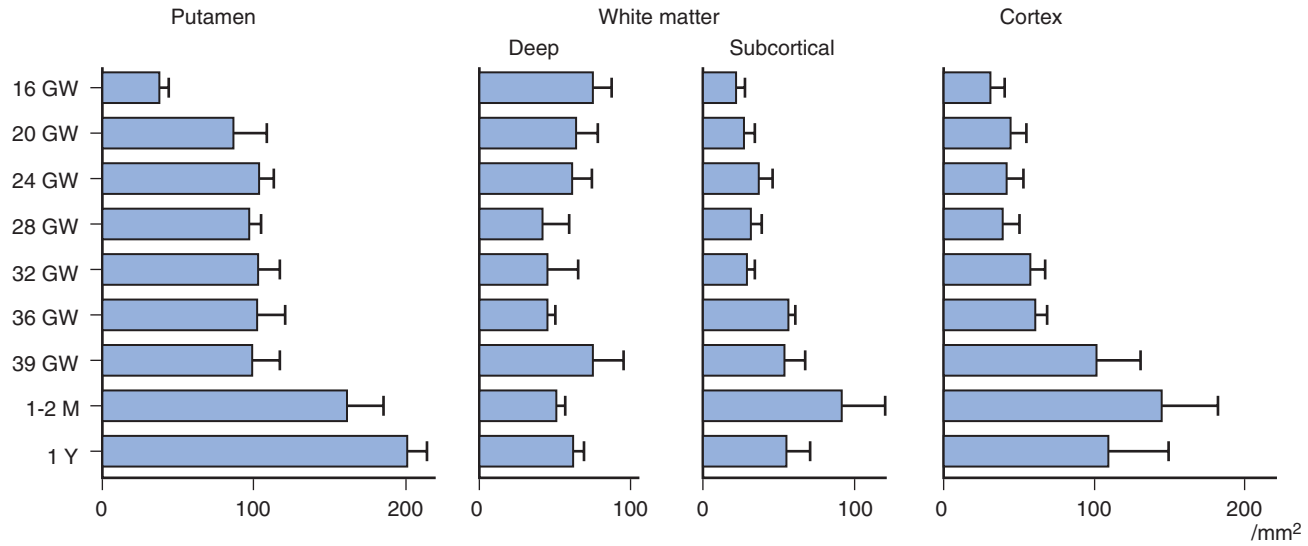
Microscopic Neuropathology



The earliest recorded changes are of coagulation necrosis of all cellular elements, with loss of cytoarchitecture and tissue vacuolation.[34] Axonal swelling and intense activated microglial reactivity and proliferation have been observed as early as 3 hours after an insult.[35,109] In addition, in the periphery of these focal lesions, a marked astrocytic and vascular endothelial hyperplasia characterize the brain tissue reaction at the end of the first week. After 1-2 weeks, macrophage activity, with characteristic lipid-laden macrophages, is predominant over the astrocytic reactivity, with progressive cavitation of the tissue and cyst formation thereafter. During subacute and chronic stages of PVL, swollen axons calcify, accumulate iron, and degenerate particularly at the periphery of the injured zone.[146] Additional minor changes are also found within gray matter, with some diffuse neuronal loss especially in the lower cortical layers, the hippocampus, and the cerebellar Purkinje cell layer. Many conventional neuropathology studies subsequently

• **Fig. 52.1** Neuropathology showing periventricular lesions primarily affecting the white matter and characterized by pale softened zones of degeneration (hematoxylin preparation) (*closed arrow*) and thinning of the corpus callosum with ventriculomegaly (*open arrow*). Lesions detected in infants with very low gestational age at birth tend to be diffuse, with more focal cystic lesions in infants with higher gestational age at birth.

• **Fig. 52.2** Schematic representation of vascular supply characterized by short subcortical end-arteries and long deep end-arteries and their relation to the diffuse and focal component of immature white matter injury. (From Rorke LB. Anatomical features of the developing brain implicated in pathogenesis of hypoxic-ischemic injury. *Brain Pathol.* 1992;2:211.)

• **Fig. 52.3** Developmental changes in vessel density in the human brain illustrate decrease in vessel density in long deep white matter arteries between 28 and 36 weeks. Low density of subcortical end arteries below 32 weeks. (From Miyawaki T, Matsui K, Takashima S. Developmental characteristics of vessel density in the human fetal and infant brains. *Early Hum Dev.* 1998;53(1):65-72.)

have noted widespread diffuse central cerebral white matter astrocytosis, often with abnormal glial cells,[95] which were termed *perinatal telencephalic leukoencephalopathy*. On the basis of these studies, Leviton and Gilles described, for the first time, a differentiation between focal and diffuse white matter damage.[94]

New Neuropathologic Insights

This diffuse white matter damage is macroscopically characterized by a paucity of white matter; thinning of the corpus callosum; ventriculomegaly and delayed myelination in the later stages; and, as shown in recent studies, reduction of thalamic, striatal, and hippocampal size and cortical gray matter.[84] With the use of immunocytochemical techniques, the assessment of autopsy tissue has allowed for further localization of cell-specific injury in white matter damage. The deep periventricular white matter is prone to showing focal necrosis regionally, consistent with the presumed vascular end zones/border zones, whereas in the peripheral white matter, diffuse injury could be characterized by preferential death or injury of late oligodendrocyte progenitors and immature oligodendrocytes (preoligodendrocytes [pre-OLs]; see Chapter 51).[9] This leads to a proliferative response of early pre-OLs, but their differentiation into mature cells remains partly arrested.[137,140] Postmortem data support the hypothesis that in very preterm infants, blockade of maturation of oligodendrocytes, rather than their death, is the key neuropathologic hallmark in diffuse white matter damage.[49,154] In addition, more recent neuropathologic studies on human preterm material have shown the extensive involvement of axonal damage,[63] especially thalamocortical fibers and damage to white matter neuronal populations (GABAergic interneurons),[85,86,135] and damage to the cerebellar white matter.[83]

These new neuropathologic features lead to the well-discussed hypothesis that the encephalopathy of the preterm infant is an amalgam of damage and disrupting development.[32,158]

Vulnerability of Oligodendroglia Cell Line

Several lines of evidence implicate damage to immature oligodendrocytes during a specific window of vulnerability as a significant underlying factor in the pathogenesis of PVL (see section on Models of Encephalopathy of Prematurity below). Oligodendrocyte progenitor cells proliferate and die by apoptosis (programmed cell death) (see Chapter 51), regulated by trophic factors, such as platelet-derived growth factor and insulin-like growth factor.[13] The activation of cytokine receptors on the surface of oligodendrocytes can lead to the death or maturation blockade of these cells. Studies in vitro have shown that the inflammatory cytokines tumor necrosis factor-alpha (TNF-alpha) and interferon-gamma (IFN- gamma) are toxic to cultured oligodendrocyte progenitor cells.[5] Selective injury to oligodendrocytes is mediated by induction of "death" receptors, such as Fas on the surface of oligodendrocytes. Direct axonal contact appears to be another important factor for the survival and maturation of oligodendrocytes.[24] Oligodendrocytes are further susceptible to oxidative damage mediated by free radicals, such as reactive oxygen and nitrogen species, and as a consequence of the depletion of the main antioxidant, glutathione are subject to epigenetic alterations.[8,115] Injury-induced swelling and disruption to axons within white matter leads to locally elevated glutamate, which also induces oligodendrocyte cell death and/or injury. Glutamate toxicity depends on the maturational stage of the oligodendrocyte and is mediated via the alpha-3-amin o-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor and potentially through N-methyl-D-aspartate (NMDA) receptors.[36,80]

Experimental data show, however, an important increase in NG2 (high-molecular-weight, integral membrane chondroitin sulfate proteoglycan)–positive oligodendrocyte progenitor cells within the area of the injury.[138,140] The role of this increase in NG2 cells is currently unknown, but this population is distinct from neurons, oligodendrocytes, astrocytes, and microglia. This cell population could comprise multipotent cells capable of differentiating into any other type of cells and playing a role in axonal growth and myelination and in regeneration after injury with functional integration in neural circuitry.[57]

Microglial Activity

Specific immunocytochemical markers (e.g., CD68) have identified a marked increase of activated microglia in diffuse white matter injury.[154] Microglia are already widely dispersed throughout the immature white matter by 22 weeks' gestation. These cells are fully capable of producing potentially toxic inflammatory mediators, free radicals, and reactive oxygen intermediates.[131] The phagocytic activity of microglia and their capacity for oxidative mediated injury are potently enhanced by inflammatory mediators (IFN-gamma, TNF-alpha, interleukin-beta [IL-beta], and bacterial lipopolysaccharide [LPS]).[1,60] Studies of pre-OLs of the same maturational stage as those populated in the immature white matter of the human premature infant show that cells are exquisitely vulnerable to attack by reactive oxygen species and reactive nitrogen species produced by activated microglia.[143] The presence of activated microglia inducing cell death in immature white matter, both in pre-OLs and in astrocytes, has been widely confirmed.[40,145] So far, it also seems that microglia and resident mononuclear phagocytes are the primary sources for the proinflammatory cytokines in PVL brains.[48]

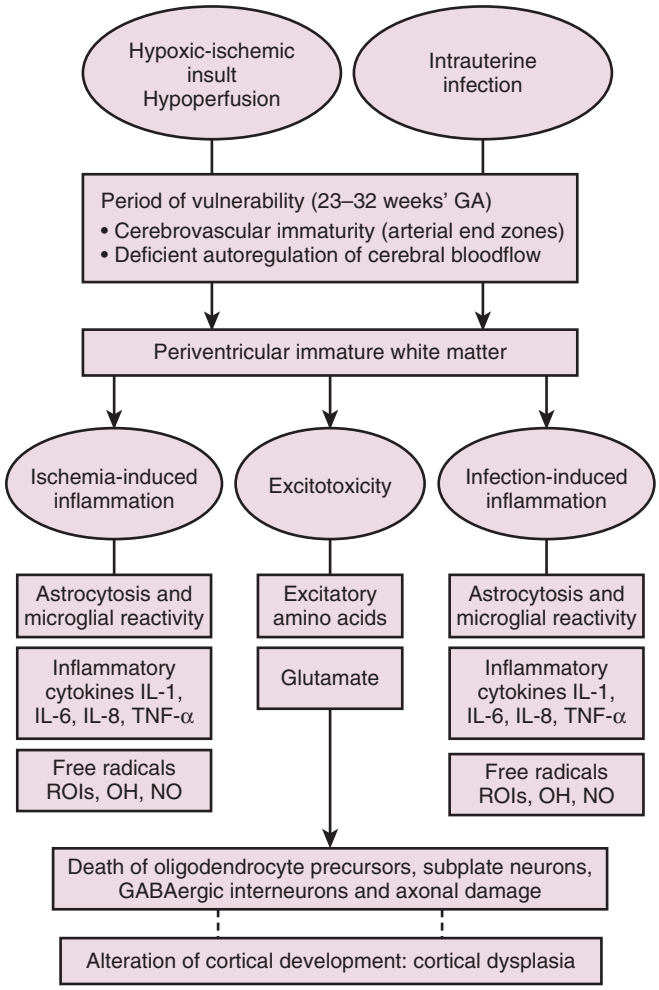
More recently, a translational experimental study has linked genetic polymorphisms controlling proinflammatory proteins in microglia to the microstructural changes in the brain of preterm infants.[89]

Neuronal/Axonal Damage

Previous studies have performed indirect assessment of axonal damage in classic PVL by immunostaining for beta-amyloid precursor protein, a neuronoaxonal protein. Immunostaining of damaged axons was found to be

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

predominant in the acute phase of PVL and was no longer detectable in the chronic stage.[109] Swollen axons calcify (probably owing to glutamatergic overactivation), accumulate iron, and degenerate; this has been shown to occur without overt coagulation necrosis of all tissue components.[65] Axons from the corticospinal tract (CST), thalamocortical fibers, optic radiation, superior occipitofrontal fasciculus, and superior longitudinal fasciculus may be affected and result in deficits in motor, sensory, visual, and higher cortical functions. Thalamocortical projections that course through the white matter develop prior to the functional development of cortical neurons. Therefore the ensuing disruption to these circuits and to the subcortical plate may affect not only the function but also the density, survival, and organization of the cortical neurons and the cortex itself[74,88] (see section on Subplate Damage).



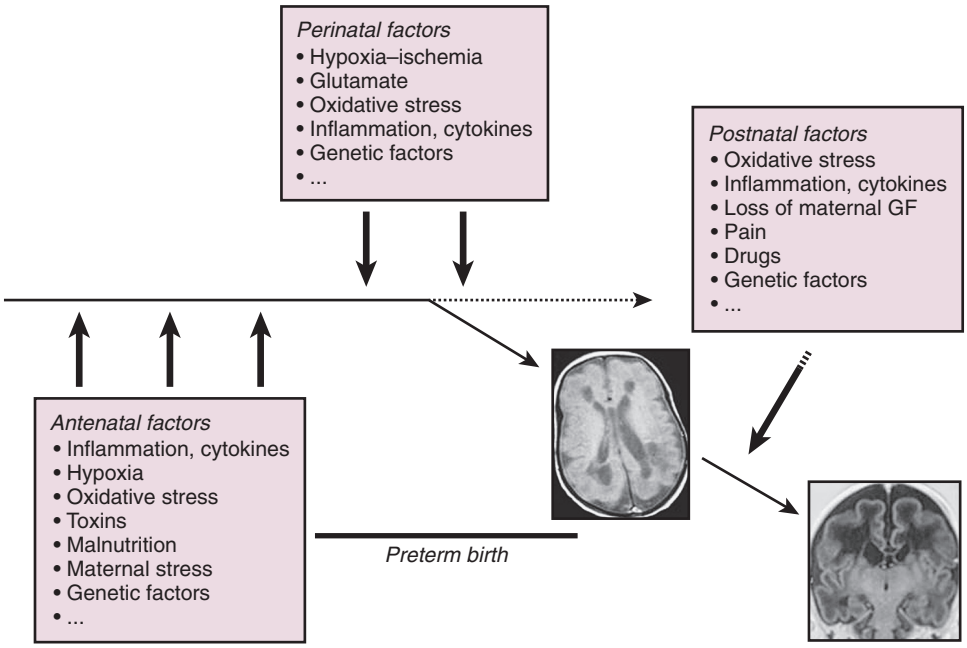
In addition, there is evidence for cell death of the progenitor cells, not of the neural stem cells in the subventricular zone after hypoxia–ischemia.[50] These destructive effects occur in parallel with potential trophic reactions, such as the proliferation of potentially pluripotent progenitor cells, also called *polydendrocytes* in the area of injury.[140] These cells are known to differentiate into oligodendrocytes and, to a lesser extent, into gray matter astrocytes and potentially even neurons.[120]

Studies have also suggested that preterm delivery decreases the number of interneurons in some cortical areas, indicating that the production, migration, and/or survival of interneurons is impaired.[25] Wnt signaling has been shown to be implicated in this neuronal migration arrest and responsible for subsequent alteration of circuit formation, relevant for both somatosensory as well as social behavior development.[20] Activated microglia in white matter could contribute to impairment of migration and/or survival of interneurons.

Subplate Damage

Damage to the early developing subplate neurons, with their critical role for the organization of the cortical plate (see Chapter 51), has long been postulated as a possible mechanism by which injury to the immature brain results in long-lasting motor and cognitive deficits.[156] McQuillen et al.[107] were able to show specific cell death in subplate neurons after hypoxia–ischemia in very immature animals. Lack of guidance for the thalamocortical connections ensued by the loss of subplate neurons may represent one of the major developmental disturbances after injury to the immature brain.[87] A recent model of induced mild apoptosis in cortical layer IV resulted in cortical anisotropy changes similar to those in preterm infants, hypomyelination in the subcortical white matter, and activated microglia, which indicates that subtle neuronal cell death can trigger white matter changes.[129]

The current concept of pathogenesis of encephalopathy of prematurity is based on the combination of destructive and developmental disturbances, which are presented schematically in Fig. 52.4.



• **Fig. 52.4** Schematic representation of the current main pathogenetic factors involved in immature white matter injury. (Adapted from Rezaie P, Dean A. Periventricular leukomalacia, inflammation and white matter lesions within the developing nervous system. *Neuropathology.* 2002;22:106-132; and Volpe JJ. Brain injury in premature infants: a complex amalgam of destructive and developmental disturbances. *Lancet Neurol.* 2009;8:110-124.)

Models of Encephalopathy of Prematurity: Implications for Pathogenesis

As mentioned, the etiology of white matter injury and encephalopathy of prematurity in human neonates has been widely described as multifactorial rather than being linked solely to cardiovascular instability and hypoxia–ischemia. The many preconception, prenatal, perinatal, and postnatal factors potentially implicated in the pathophysiology of these lesions include hypoxia–ischemia and hypercapnia, maternal infection with overproduction of cytokines and other proinflammatory agents, endocrine imbalances, genetic factors, growth factor deficiency, abnormal competition for growth factors, overproduction of free oxygen radicals, exposure to toxins, maternal stress, and malnutrition. Although some of these potentially noxious factors may suffice to permanently injure the developing brain, some researchers have developed a two-hit hypothesis, which

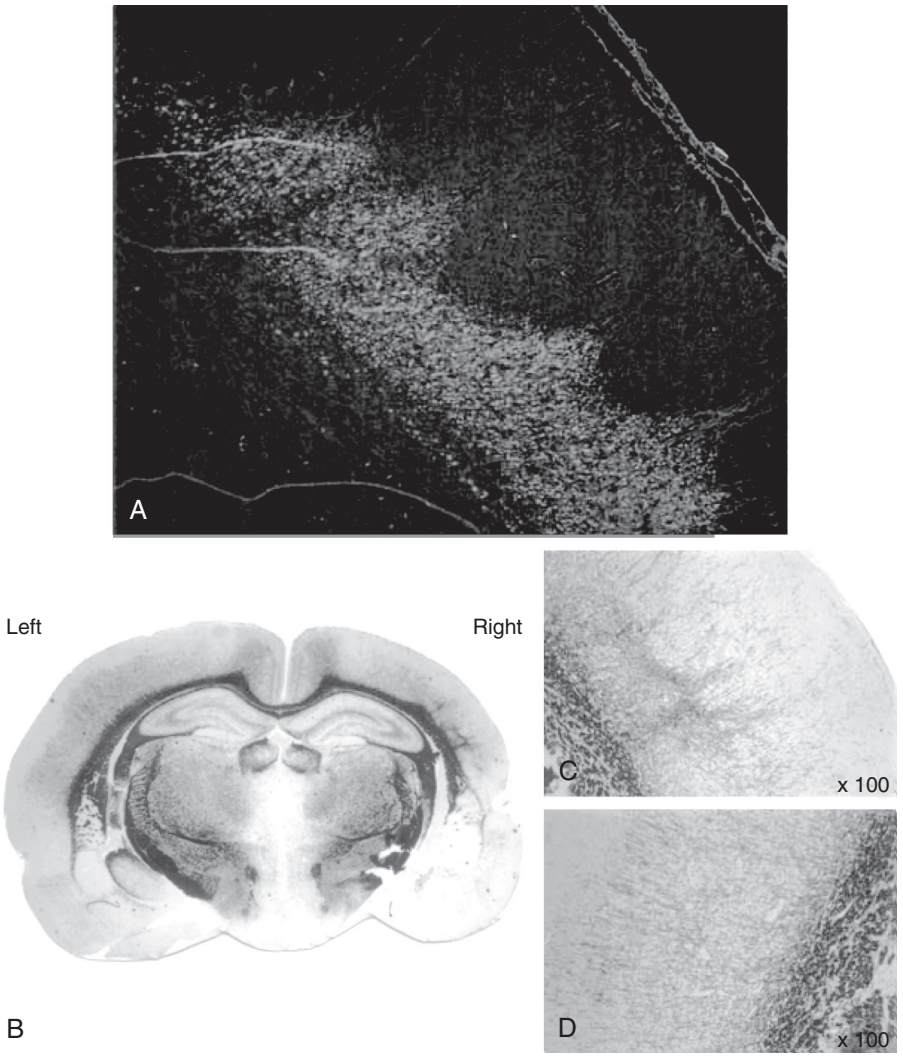
• **Fig. 52.5** Schematic representation of the multiple-hit hypothesis, in which a combination of two or more environmental or genetic factors occurring during the prenatal, perinatal, or postnatal period induces or modulates brain lesions. GF, growth factors.

suggests that early exposures increase the susceptibility of the brain to subsequent insults (Fig. 52.5).

The development and characterization of distinct, yet complementary, animal models should help to unravel the complex cellular and molecular pathophysiologic mechanisms underlying the occurrence of perinatal white matter lesions and encephalopathy of prematurity. In available animal models or in vitro paradigms, the insults most often used to induce white matter damage or oligodendrocyte cell death, respectively, are generally hypoxia, hypoxia–ischemia, infection, inflammatory factors, oxidative stress, or excitotoxic agents. The relevance of white matter damage produced in these animal models to human white matter injury is largely based on neuropathologic data, although some studies are also based on magnetic resonance imaging (MRI) parameters or on neurologic and behavioral deficits.[37]

The following section focuses on the most studied models of perinatal white matter damage, highlighting their major contributions to the understanding of the pathophysiology of these lesions. The interested reader can find more information and a more comprehensive bibliography in published reviews on this topic.[61,111,152]

Hypoperfusion and Hypoxia–Ischemia



Hypoxic–ischemic or hypoperfusion insults have been used in a large variety of neonatal species, including rats, mice, rabbits, pigs, and dogs. In most cases, these insults produce specific gray matter damage (mimicking lesions observed in human full-term infants), which has been the focus of most of these studies, whereas observed white matter damage is generally considered an extension of gray matter damage in the most severe cases. However, notable exceptions highlight some potentially important features of perinatal white matter damage.

In canine pups, hypoxic–ischemic insult by bilateral carotid ligation selectively induces white matter damage mimicking human PVL.[164] This selective vulnerability of white matter could underlie a genetic predisposition of the dog to white matter hypoxic–ischemic damage. Modern tools of genomics could unravel important genes involved in the pathophysiology of perinatal white matter damage.

In rats, the classic Rice-Vannucci model performed on postnatal day 7 or 9 predominantly leads to gray matter lesions. However, analyses have shown involvement of the periventricular white matter with involvement of immature oligodendroglial and progenitor cells.[53,132,141] More important, adaptation of this paradigm to more immature newborn rats (postnatal days 1 or 3) has allowed for production of important lesions in the periventricular white matter with relative sparing of the classic intracortical injuries (Fig. 52.6).[23,107,138] These studies have also highlighted the specific involvement of subplate neurons in brain damage. Altogether, these data obtained in newborn rats further support the notion of an ontogenic window of white matter sensitivity and subplate vulnerability to such insults as hypoxia–ischemia.

Asphyxia of sheep fetuses (around 65% of gestation) has been shown to induce periventricular (focal and diffuse) and subcortical (diffuse) white matter disease, accompanied by acute astrocyte and oligodendrocyte loss, as well as marked reactive microgliosis.[104] These studies support the concept of the association of focal (e.g., cystic lesions) and diffuse (e.g., diffuse microglial activation) white matter lesions,

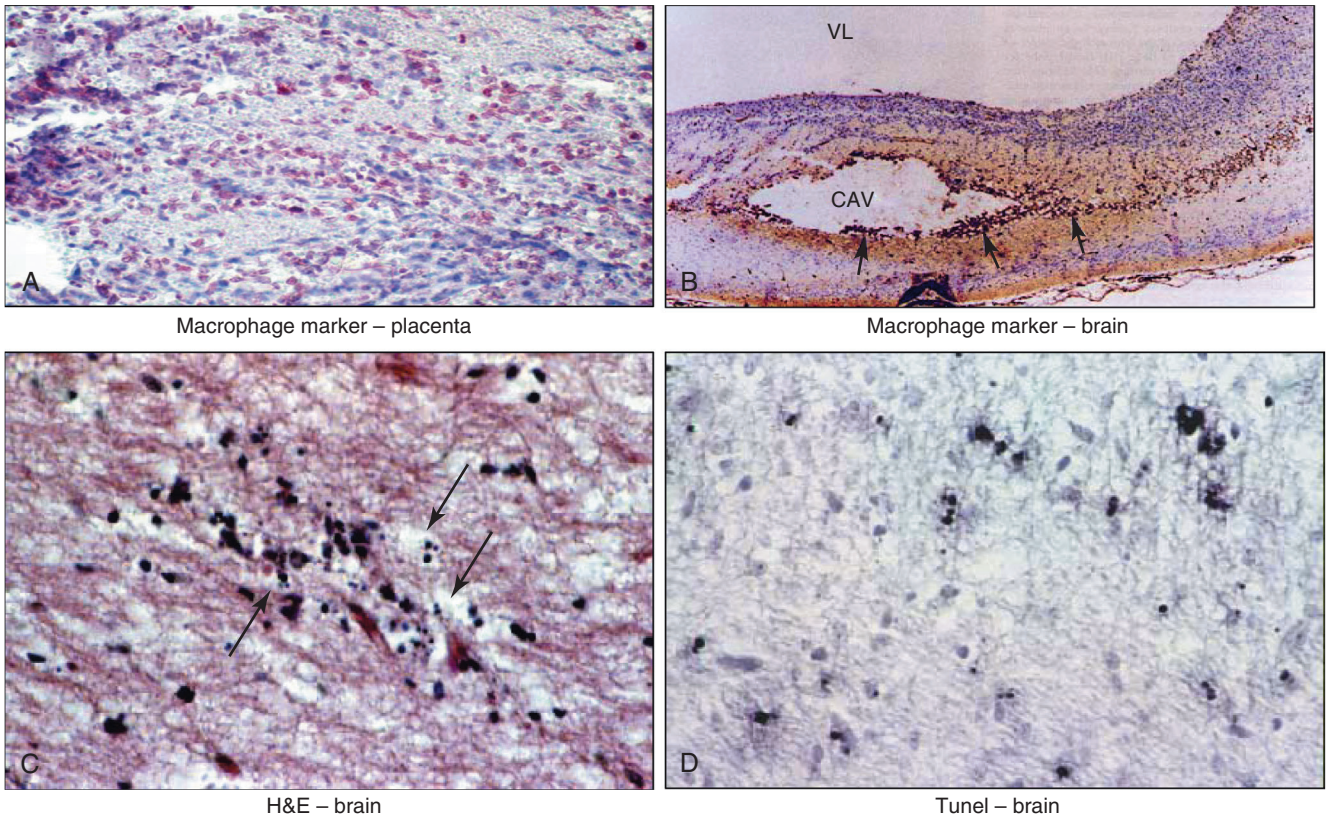
• **Fig. 52.6** Pattern of injury after hypoxic–ischemic injury in the postnatal day 3 (P3) rat brain. **A,** Degenerating neurons 24 hours after hypoxic–ischemic insult at P3 stained with Fluoro-Jade. Ipsilateral brain with severe damage: A columnar aspect of positive cells is present with confluence of positive cells in the deep cortical layers (magnification 100×). The outer cortical layers remained unaffected. **B,** Myelin basic protein immunostaining of the brain at P21 after hypoxic–ischemic injury at P3. Coronal section of brain at the level of the dorsal hippocampus (10×): a reduction of the cortical and myelinated areas in the ipsilateral right hemisphere extending from the cingulum to the rhinal sulcus can be seen. **C, D,** At 100× magnification, the alteration of the myelin pattern in the deep cortical layers is noticed in the ipsilateral right cortex (**C**) when compared with the left normal cortex (**D**).

the pathophysiology of which is potentially distinct. Furthermore, it has been shown by using microdialysis that white matter glutamate levels were significantly increased after asphyxia, supporting a role of excitotoxicity in the pathogenesis of such white matter lesions (see section on Excitotoxicity).[101]

Exposure of pregnant rats[16] or postnatal murine pups[149] to hypoxia induces pathologic changes in the periventricular white matter that are reminiscent of human periventricular leukomalacia, with inflammation, astrogliosis, and myelination delay in the prenatal model, and white matter atrophy, ventriculomegaly, and alteration of synaptic maturation in the postnatal paradigm. Although the initial insult is pure hypoxia, the observed effects are likely the result of the combination of different mechanisms, such as hypoperfusion, ischemia, inflammation, and/or oxidative stress induced by protracted hypoxia and the subsequent reoxygenation phase.

Infection and Inflammation



Systemic administration of LPS to immature cats, dogs, or rabbits induces white matter lesions.[4,54] Systemic administration of LPS can induce marked systemic inflammation and immune changes in the central nervous system, such as increased expression of CD14. Furthermore, high doses of LPS can induce hypotension, hypoglycemia, hyperthermia, and lactic acidosis, all potential factors predisposing to

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

brain damage. However, low doses of LPS, which do not induce significant hypotension, were also shown to induce white matter damage in fetal sheep.[61,103] In fetal sheep, the comparison of white matter damage induced by cord occlusion and by LPS injection revealed distinct patterns of microglia–macrophage activation, suggesting separate or partly separate underlying mechanisms.[103] However, systemic administration of LPS to newborn rats failed to induce detectable white matter lesions, although increased cytokine production and microglial activation were observed in white matter.[22,47] These data suggest that species differences that might be linked to species-related genetic susceptibility of the developing white matter to infectious–inflammatory factors. Interestingly, in vitro studies have shown that macrophages are necessary for LPS to induce pre-OL cell death.

Live infectious agents have also been used by a few research groups to produce models of white matter lesions. In pregnant rabbits, ascending intrauterine infection with *Escherichia coli* (*E. coli*) caused focal white matter damage in 6% of live fetuses,[163] whereas direct inoculation of *E. coli* in the uterine cavity combined with early antibiotics produced focal white matter cysts in about 20% of live fetuses and diffuse white matter cell death in almost all live fetuses (Fig. 52.7).[33] Cystic lesions are accompanied by macrophage–microglia activation and reactive astrogliosis, whereas diffuse white matter cell death does not induce such glial responses. These results suggest that these two types of brain damage have distinct pathophysiologic mechanisms.

In addition, a study has shown that infection of pregnant mice with *Ureaplasma parvum*, an organism rather frequently isolated in chorioamnionitis, induces central microgliosis and disrupted brain development, as detected by decreased numbers of calbindin-positive and calretinin-positive neurons in the neocortex, as well as myelination defect in the periventricular white matter.[121]

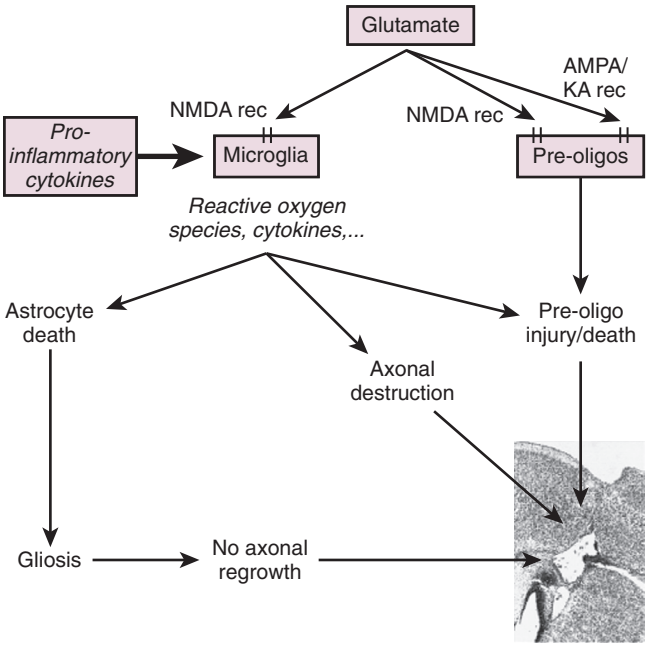
Intrauterine inoculation of Border disease virus to pregnant sheep induces decreased expression of white matter molecules, including myelin basic protein in the fetuses.[3] However, the virus also infects the thyroid and the pituitary gland, raising the question of the precise etiology of the white matter damage (low thyroid hormones versus infectious–inflammatory insult).



Exposure of newborn mice to low doses of systemic IL-1-beta induces a moderate and transient inflammatory response during the neonatal period that is sufficient to disrupt oligodendrocyte maturation, myelin formation, and axonal development.[49] These white matter abnormalities are moderate during the developmental period but do persist until adulthood. They lead to permanent deficiencies in cognition tests. The underlying molecular mechanisms include blockade of microglial activation, oligodendrocyte maturation blockade, and alterations of the transcription of genes implicated in oligodendrogenesis, myelin formation, and axonal maturation.

Excitotoxicity and Oxidative Stress

Glutamate can act on several types of receptors, including NMDA, alpha-3-amino-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), kainate, and metabotropic receptors. Excess release of glutamate has been suggested to represent a molecular mechanism common to some of the risk factors for brain lesions associated with cerebral palsy. In keeping with this possibility, injection of glutamate agonists into the striatum, neocortex, or periventricular white matter of newborn rodents (rats, mice, or hamsters), rabbits, or kittens produces, according to the stage of brain maturation, histologic lesions that mimic those seen in humans with cerebral palsy, such as neuronal migration disorders, polymicrogyria, cystic periventricular leukomalacia, and hypoxic–ischemic or ischemic-like cortical and striatal lesions.[1,53]

Studies exploring the pathophysiology of these excitotoxic white matter lesions in newborn rodents and rabbits have permitted the following contributions (Fig. 52.8)[39,53,130,145]:

1. Both NMDA and AMPA–kainate agonists can induce periventricular cystic white matter lesions.
2. NMDA receptor–mediated white matter lesions involve an early microglia–macrophage activation and astrocyte cell death, whereas AMPA–kainate receptor–mediated lesions involve pre-OL cell death; in addition, NMDA receptors expressed by pre-OLs could participate to the injury of these pre-OLs.
3. The periventricular white matter of newborn rodents and rabbits exhibits a window of susceptibility to excitotoxic insults.
4. Transient expression of NMDA receptors on white matter microglia–macrophages and transient expression of high levels of AMPA–kainate receptors on pre-OLs are likely important factors to explain the window of sensitivity of white matter to neonatal excitotoxic insults.
5. The study of NMDA receptor–mediated white matter lesions in newborn rabbits revealed that the excitotoxic white matter lesion extended into the subplate, but not in the overlying neocortical layers. With use of antioxidant molecules, excitotoxic white matter lesions involve excess production of reactive oxygen species, which play an important role in the pathophysiology of the lesions.

• **Fig. 52.8** Schematic representation of the potential cellular and molecular pathways by which excess release of glutamate and proinflammatory cytokines may lead to white matter lesions. KA, Kainate; oligo(s), oligodendrocyte(s); Rec, receptors.

Extensive in vitro studies have confirmed the exquisite susceptibility of pre-OLs to AMPA–kainate agonists and to oxidative stress.[80]

Combined Insults

To further support the hypothesis of a multifactorial hypothesis of perinatal brain damage (see Fig. 52.5), different studies have induced combined insults in newborn rodents.

Pretreatment of newborn mice with systemic proinflammatory cytokines (e.g. IL-1-beta, IL-6, or TNF-alpha) before an excitotoxic insult significantly exacerbates excitotoxic white matter lesions, demonstrating a causative link between circulating proinflammatory cytokines and white matter damage.[38] Results of various studies have suggested that this effect of proinflammatory cytokines is more pronounced with NMDA receptor agonists when compared with AMPA–kainate receptor agonists (see Fig. 52.8). The precise mechanism by which these cytokines systemically act on white matter excitotoxicity remains to be determined but could potentially involve activation of brain cyclooxygenase or activation of microglia with increased white matter production of reactive oxygen species and cytokines.

Similarly, systemic pretreatment with IL-9, a T-helper 2 (Th2) cytokine, was shown to exacerbate NMDA receptor–mediated white matter lesions.[38,126] The mechanism of IL-9 toxicity involves brain mast cell degranulation and excess release of histamine. Interestingly, increased circulating levels of IL-9 around birth was demonstrated in a subgroup of human infants who later developed cerebral palsy.[119] Chronic mild stress of pregnant mice has been shown to induce a significant exacerbation of excitotoxic white matter lesions in pups. LPS was also used to sensitize the newborn brain to hypoxia–ischemia. A low dose of this endotoxin, given 4 hours before a mild hypoxic–ischemic insult in postnatal day 7 rats induced extensive brain damage, whereas each insult given separately did not induce any detectable brain lesion.[47]

Several experimental paradigms have emerged for the study of white matter diseases of the preterm infant. These animal models have permitted identification of some of the potentially key cellular (e.g., pre-OLs, microglia–macrophages) and molecular (glutamate, cytokines, and other inflammatory mediators, reactive oxygen species, etc.) players involved in the pathophysiology of perinatal brain damage. These studies have also delineated potential targets for neuroprotection through the neurotrophic action of erythropoietin.[66,153] Future studies should incorporate imaging and behavioral studies to facilitate comparisons with human cases. Although it is clear that studies with rodents, because of their low cost and easy availability, are absolutely necessary to generate and test multiple hypotheses, the use of larger models, such as sheep, pigs, and monkeys, continues to be important for testing the relevance of the obtained data in a more reliable fashion for human cases.

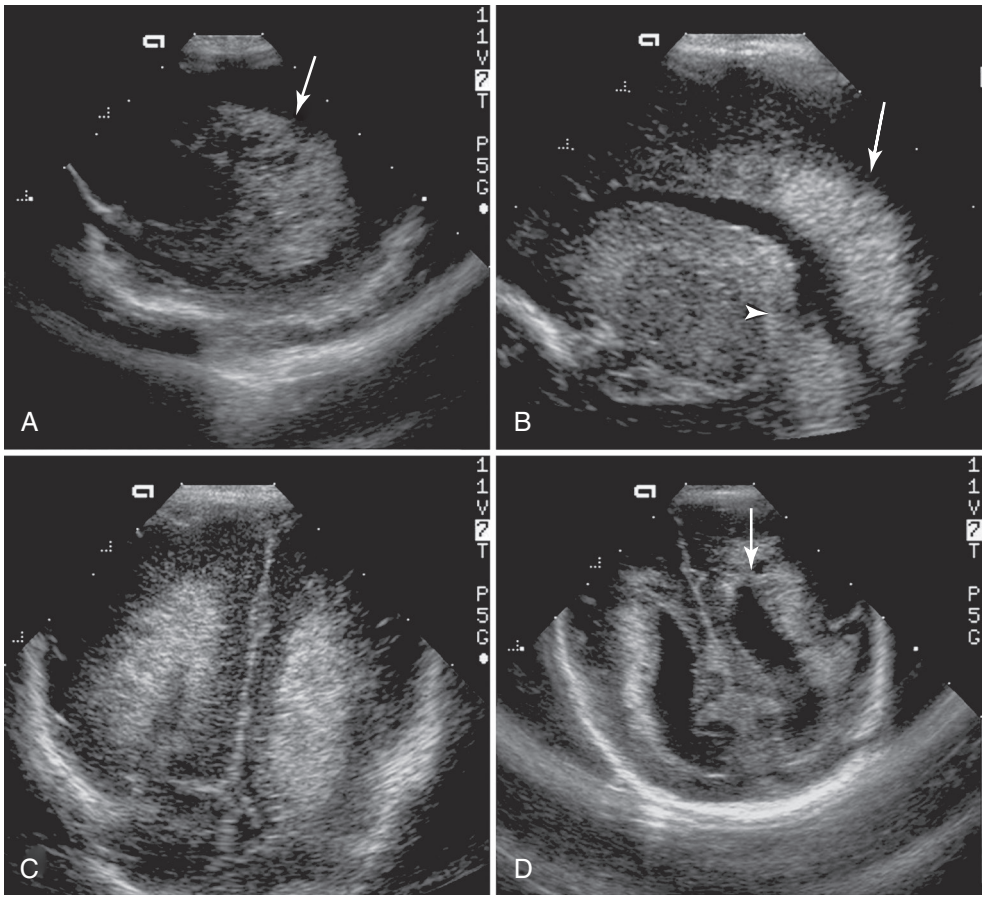
Neuroimaging of White Matter Injury

Neonatal Sonography

Neonatal sonography is the one major bedside technique to image the neonatal brain. Leviton et al. postulated, in 1990, that ultrasonographic white matter echodensities and echolucencies in low birth weight infants predicted later handicap more accurately compared with any other antecedent.[96] Unlike intraventricular hemorrhage, damage to the white matter can have different appearances, and depending on the timing of the injury, the imaging characteristics can be nonspecific, with generally an increase in echogenicity in the acute phase of the injury (Fig. 52.9). In clinical practice, at least in the older preterm infant, the condition of white matter is judged by its echogenic potential compared with that of the choroid plexus. Generally, the echogenicity found in early periventricular leukomalacia is similar in intensity to that of the choroid plexus. The echogenicity is bilateral but slightly asymmetric in appearance, can be sharply delineated, and may have nodular components. This has to be differentiated from normal peritrigonal flaring, which is perfectly symmetric and has a radial appearance. Evolution of such hyperechogenicity can be twofold, either complete disappearance or evolution into cysts and/or ventricular dilatation. Cyst formation analogous to neuropathology is a process typical for the second week (10-40 days) after the insult. De Vries et al.[31] proposed an ultrasound-based classification of four grades for PVL. Increasing grades are associated with increasing neurodevelopmental handicap. Grade I is defined as transient (>7 days) periventricular densities without cyst formation. If cysts develop and are few in number, localized primarily in frontal and frontoparietal white matter, this is classified as grade II. When they are widespread and extend into the parieto-occipital region they are referred to as grade III; these may grow and gradually disappear, leaving an irregularly dilated lateral ventricle. Grade IV cysts are present all the way into the subcortical area, resembling porencephaly (Table 52.1). In a pooled analysis based on data from 15 published studies, 11% of infants with small ultrasound-defined white matter echolucencies, 35% of those with medium echolucencies, and 60% of those with large echolucencies had an intelligence or developmental index less than 70,[67] which underscores the importance of potentially associated microstructural alterations in cortical development after white matter injury.

Ultrasonography may be perceived as the ideal mode of imaging to detect cystic PVL but has very limited value for detecting diffuse white matter injury and the processes leading to encephalopathy of prematurity as shown in studies comparing neonatal ultrasonography with MRI.[25,77,133] MRI has been found to be less sensitive for such pathologies as lenticulostriate vasculopathy or calcifications.[92]

Conventional Magnetic Resonance Imaging



Conventional T1- and T2-weighted imaging can show signal abnormalities in the periventricular white matter that are different from the cystic lesions detected by ultrasonography. The typical conventional MRI pattern in the subacute phase consists of punctate periventricular areas

TABLE 52.1 Ultrasound Classification of Periventricular Leukomalacia

Grade I	Transient periventricular echodensities (PVEs) (>7 days)
Grade II	PVE evolving into localized frontoparietal cystic lesions
Grade III	PVE evolving into extensive periventricular cystic lesions
Grade IV	Echodensities evolving into extensive periventricular and subcortical cysts

Classification needs longitudinal assessment with daily to weekly ultrasound evaluations.

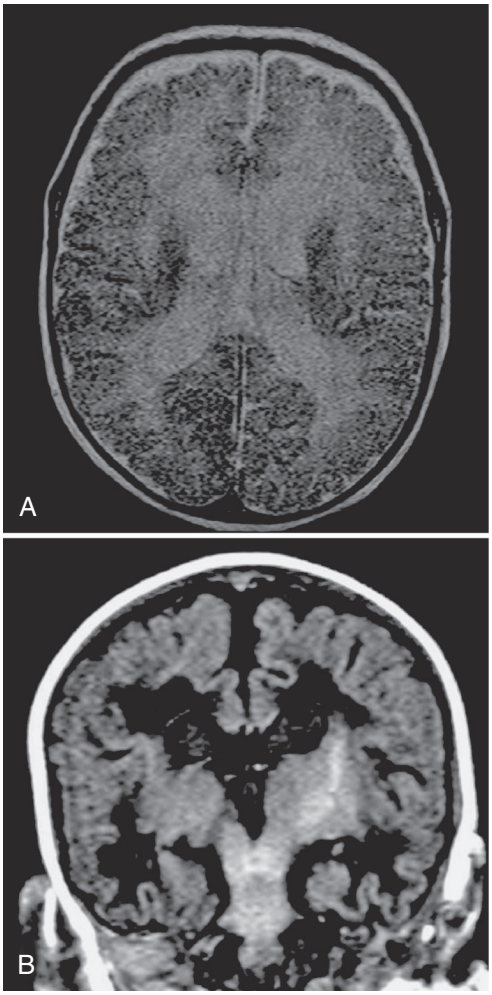
• **Fig. 52.9** Ultrasonography scans of periventricular echodensity in a preterm infant born at 27 weeks' gestational age with premature rupture of membranes and neonatal sepsis. **A** and **B,** Bilateral echodensities in sagittal view at 5 days of age (*arrows*). **B,** Echogenicity of similar intensity to echogenicity of choroid plexus (*arrowhead*). **C,** Bilateral echodensities in coronal view. **D,** Echolucency developing at 12 days in sagittal view (*arrow*) representing cystic transformation.

of T1 signal hyperintensities and T2 signal hypointensities (Fig. 52.10). The precise neuropathologic correlate of these signal abnormalities is not completely known but may be caused by some hemorrhagic components of the lesions and most likely represents the cellular reaction of glial cells and macrophages, which are known to contain lipid droplets (see section on Models of Encephalopathy of Prematurity) accounting for the high signal intensity on T1-weighted MRI scans. These abnormalities have been associated with the presence of markers of oxidative stress in cerebrospinal fluid (CSF).[76] Most of these lesions disappear by term age and then have little significance for later neurodevelopmental problems.[45] For the punctate T1 hyperintensities that persist to term age and are present in significant numbers (more than one or two isolated lesions), data indicate an association with subsequent neurodevelopmental delay in motor development as well as in cognitive development.[30,81]



A study of over 500 MRI scans obtained from preterm infants at term-equivalent age revealed that a large number of preterm infants had punctate white matter lesions (24%) that have not been seen on ultrasonography and had no other cerebral or cerebellar lesions on MRI. An increasing number of punctate lesions was associated with lower thalamic volumes and altered microstructure in CSTs and a significant association with impaired motor outcome, but this had a limited positive predictive value.[150]

Conventional MRI features of chronic white matter injury in the immature brain are characterized by cysts, comparable with those demonstrated not only by ultrasonography but also, more importantly, by a persistent high signal intensity of white matter on T2-weighted MRI representing higher water content or loss of white matter microstructural elements (Fig. 52.11).[28,72] This imaging characteristic can later be associated with thinning of the corpus callosum and loss of white matter volume, resulting in deep prominent sulci (see section on Impairment of Brain Growth). In several studies on the brain of the preterm infant, diffuse excessive high signal intensity (DEHSI) in the cerebral white matter on T2-weighted MRI was reported to be present in up to 40%-75% of low birth weight preterm infants imaged at term[102] and, combined with white matter loss, showed negative associations with neurodevelopmental outcome (Fig. 52.12).[45] Carefully designed studies aimed at assessing the risk of neurodevelopmental delay in specific neonatal white matter lesions have shown that DEHSI

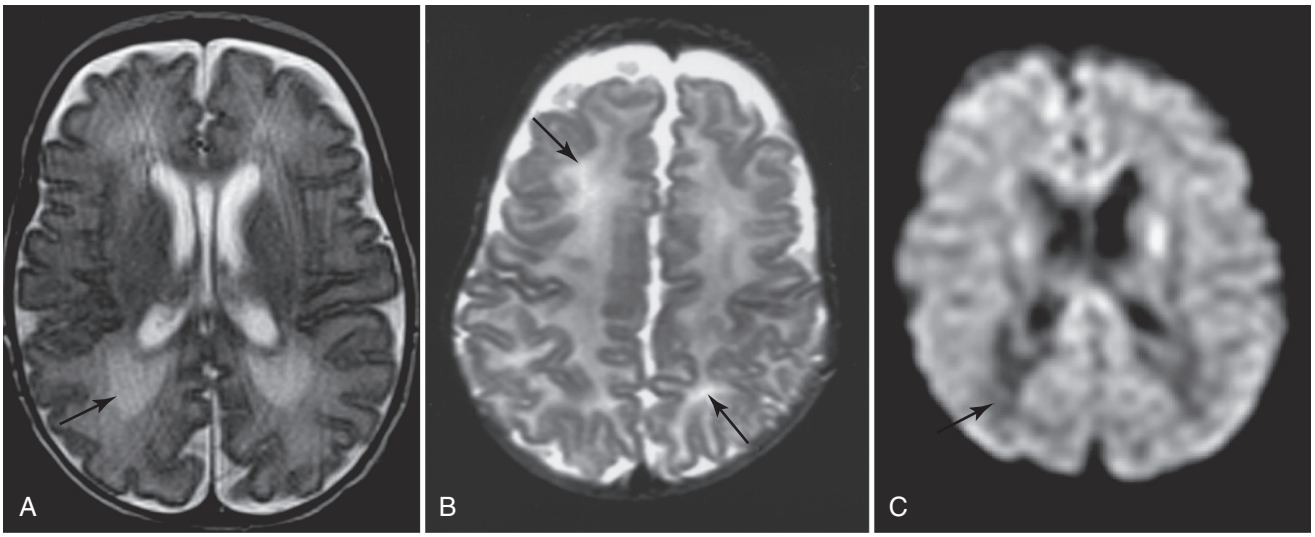
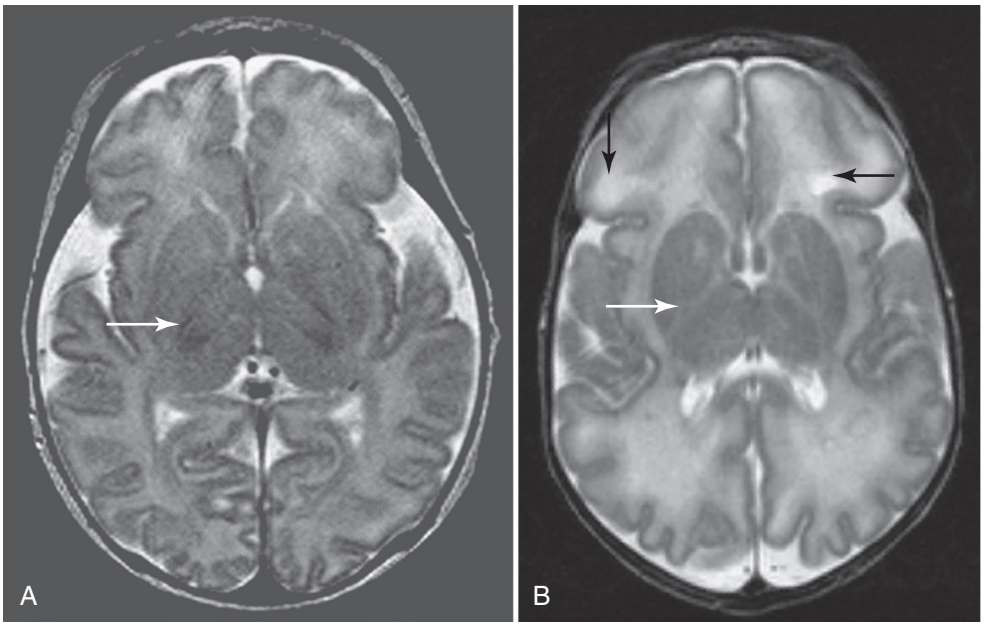
• **Fig. 52.10** A normal preterm infant at 31 weeks' gestational age. **A** and **B,** Conventional T1-weighted magnetic resonance imaging (MRI) scans in coronal and **(C)** axial plane; **B** and **C,** Bilateral periventricular lesions with high signal intensities (*white arrows*). If these lesions persist to term age and are numerous in the periventricular white matter, they are associated with increased risk for motor developmental delay.

• **Fig. 52.11** Magnetic resonance imaging (MRI) scan in a child who had been born at 25 weeks' gestational age imaged at age 40 weeks, with severe bronchopulmonary dysplasia and repetitive episodes of severe hypoxia. **A,** Conventional T2-weighted MRI shows widespread markedly increased T2 signal intensity in the central white matter and **(B)** low signal intensity on the inversion recovery (IR) MRI with T1-weighted signal characteristics in the central white matter, representative of diffuse white matter injury.



alone is not associated with significant neurodevelopmental delay.[30,62,82] Use of MRI is ideal to assess delayed myelination as well. The absence of myelination in the posterior limb of the internal capsule (missing T1 high signal intensity, T2 low signal intensity) at term age is a good indicator of later neuromotor impairment (Fig. 52.13). Woodward et al.[162] showed that 21% of preterm infants at term age had MRI-defined moderate to severe white matter abnormalities, but an even larger proportion of 49% had gray matter abnormalities characterized by poor cortical development. Furthermore, about half the preterm infants showed mild white matter abnormalities, and these infants had only marginal mental developmental indexes at age 2 years (Table 52.2). A recent neuroprotective trial with erythropoietin showed a reduction of MRI-based biomarkers of encephalopathy of prematurity in 1 of 7 preterm infants,[93] but neurodevelopmental outcome at 2 years was not significantly different in the two groups.[117] Generally, MRI-based biomarkers in the preterm infant at term-equivalent age have high negative predictive values for neurodevelopmental outcome, but much less positive predictive power.[90]

Diffusion Magnetic Resonance Imaging



Diffusion-weighted imaging (DWI) or diffusion tensor imaging (DTI) measures the self-diffusion of water. The two primary pieces of information available from DWI studies—water apparent diffusion coefficient (ADC) and diffusion anisotropy measures—change dramatically during development, reflecting underlying changes in tissue water content and cytoarchitecture (see Chapter 51).

Parameters of DWI also change in response to brain injury. The ADC decreases in acute injury, and possible mechanisms leading to this decrease are decrease in extracellular fluid due to cellular swelling (cytotoxic edema), swelling of mitochondria and reduction of cytoplasmic diffusion, axonal swelling, and other mechanisms, such as membrane changes resulting from fatty acid peroxidation.

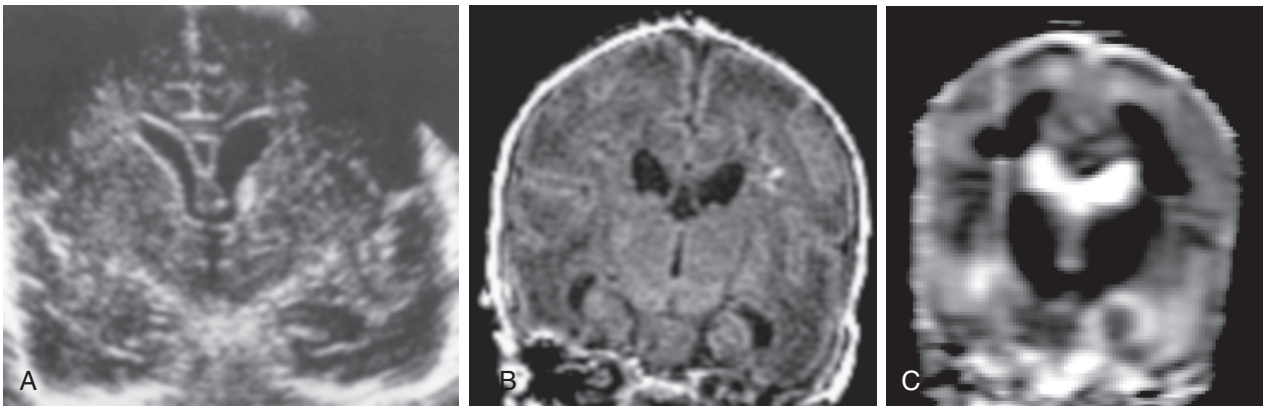
• **Fig. 52.12** Conventional T2-weighted magnetic resonance imaging (MRI) scan. **A** and **B,** Diffuse excessive high signal intensity (DEHSI) (*black arrows*). **C,** T2-weighted hypersignal is associated with low intensity on diffusion-weighted imaging (*black arrow*). This can indicate chronic white matter injury, but if mild, is not associated with neurodevelopmental impairment alone.

• **Fig. 52.13** Normal full term infant. **A,** Conventional T2-weighted magnetic resonance imaging (MRI) scan with thin area of low signal on the T2-weighted MRI scan, corresponding to myelin deposition in the posterior limb of the internal capsule (*white arrow*). **B,** Corresponding T2-weighted MRI with diffuse white matter lesions (*black arrows*) and missing signal change in the posterior limb (*white arrow*) of the internal capsule, indicating delay in myelination.

Early DWI assessment of periventricular white matter in preterm infants can reveal bilateral periventricular diffusion restriction similar to the typical distribution of PVL when ultrasonography and conventional MRI show no or nonspecific abnormalities (Fig. 52.14).[21] A reduced ADC in an otherwise normal preterm brain is considered an early indicator of white matter damage (just as a reduced ADC is seen shortly after the onset of an acute cerebral ischemic lesion in adults). The typical histologic changes in the acute phase of PVL outlined previously are characterized by some of the same mechanisms leading to restriction of water diffusivity. These changes are responsible for the diffusion changes described earlier in that they considerably change the microstructure of white matter and, therefore, change in water diffusivity.



The chronic phase of white matter injury again is characterized by cyst formation (Figs. 52.15 and 52.16) and by T2-weighted hyperintensities of the white matter for which studies demonstrate higher ADC values in the area of T2 hyperintensities, and this confirms the locally higher

tissue water content in those areas (see Fig. 52.12).[27,113] These high ADC values are similar to those seen in the very immature healthy white matter; therefore a potential explanation for the failure of ADC to decline from high levels in the extremely premature infant to lower levels in the term infant might be related to prior injury with destruction of normal cellular elements (i.e., pre-OLs) as discussed in the models of white matter injury.[157] Further quantitative measures of diffusion at term among premature infants with perinatal white matter lesions (both T2 hyperintensities as well as T1 hyperintensities [punctate lesions]), compared with preterm infants without white matter injury, showed lower anisotropy values not only in the area of the previous injury (i.e., central periventricular white matter) but also in the underlying posterior limb of the internal capsule (Fig. 52.17).[71,118] The lower anisotropy in the injured cerebral white matter suggests that the white matter fiber tracts were destroyed or their subsequent development was impaired. Whether this effect involves axon bundles per se, their packing density, or their encasement by premyelinating oligodendroglia is unknown. The lower anisotropy in the internal capsule further suggests a disturbance in the development of the descending CSTs.[6,14,70]

Fiber tracking is another technique applied to study quantitative assessment of specific pathway maturation in white matter in the developing brain.[2,44,159] Berman et al.[17] were able to show significant differences in the maturational changes in fractional anisotropy and transverse diffusion

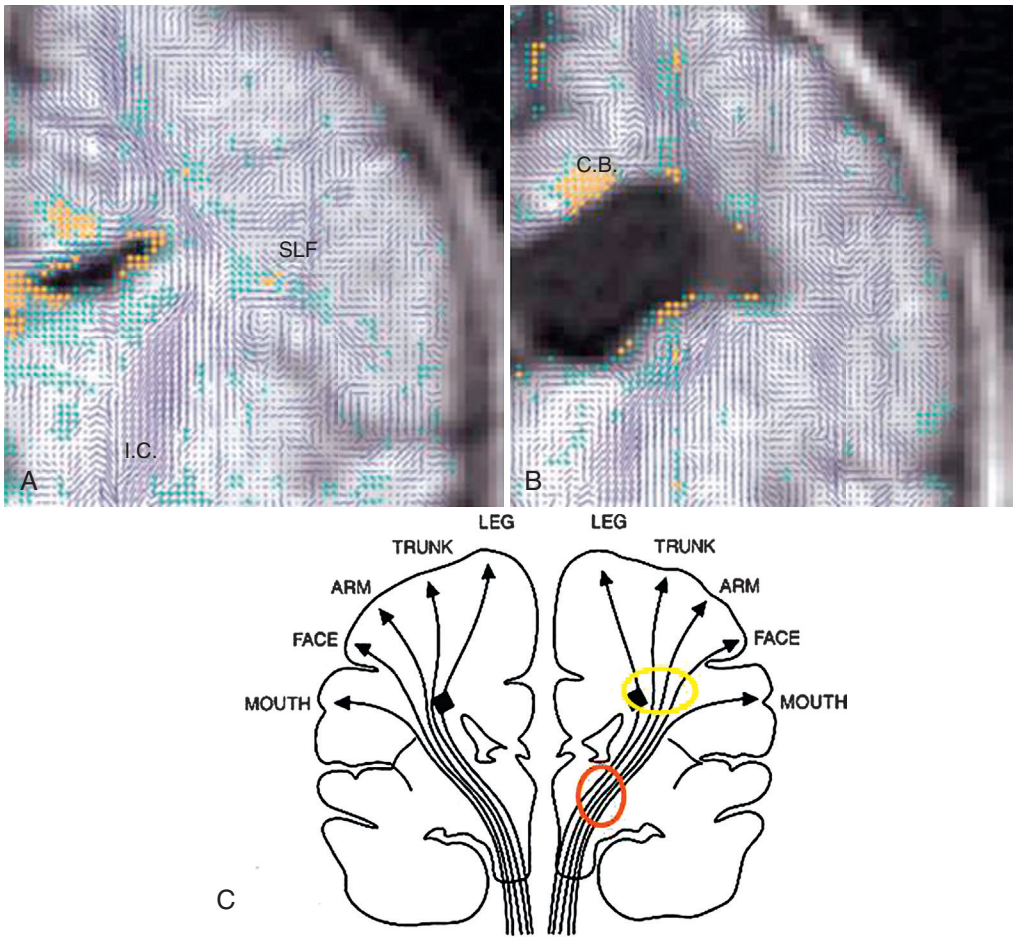
(**A,** from Inder T, et al. Early detection of periventricular leukomalacia by diffusion-weighted magnetic resonance imaging techniques. *J Pediatr.* 1999;134:631).



• **Fig. 52.16** Axial inversion recovery magnetic resonance imaging (MRI) scans with T1-weighted contrast illustrating chronic phase of periventricular leukomalacia (PVL), with multiple bilateral cystic lesions with high signal gliotic scars and calcifications in the periphery of the cystic lesions. Note also the loss of white matter volume with cerebral atrophy.

between the motor and somatosensory pathways in premature infants between 30 and 40 weeks' gestational age. This approach further allowed for the measurement of diffusion changes across multiple levels of the functional tract and, thus, the assessment of myelination progress over a given white matter fiber tract.[17,125]

The subsequent neurologic deficits after cerebral white matter injury are grouped together under the term *cerebral palsy*. Structural correlates of cerebral palsy have been assessed using DTI in the newborn period, adding to prognostication of cerebral palsy in the newborn period.[7,29,69] Tract-specific evaluation of children with cerebral palsy after PVL identified most frequent alterations in white matter fiber tract development in the retrolenticular part of the internal capsule, posterior thalamic radiation, superior corona radiata, and in commissural fibers of the corpus callosum.[116] In another study, regional measurements in the primary site of white matter lesions showed increased average diffusivity (D_{av}) values and decreased fractional anisotropy values suggesting primary degeneration, whereas the CST ipsilateral showed secondary degeneration with increased D_{av} and decreased fractional anisotropy; contralateral CST

Microstructural brain development after perinatal cerebral white matter injury assessed by diffusion tensor magnetic resonance imaging. *Pediatrics.* 2001;107:455; **C,** from Volpe JJ. *Neurology of the newborn*. St Louis: Elsevier; 2008).

showed increased D_{av} but an increase in fractional anisotropy, suggesting reorganization of sensorimotor tracts.[148]

The clinical relevance of injury and related modification of white matter architecture detected in this fashion is not yet known, and long-term follow-up studies of prematurely born children are under way, linking functional outcome to structural white matter development assessed by DTI.[6,15,26,41,56,90,142,151]

Given the diffuse character of neuropathologic features of encephalopathy of prematurity described earlier, the overall wiring of the brain, which is assumed to occur mostly during the second part of pregnancy, is most affected. Newer whole brain assessment methods, such as tract-based spatial statistics (TBSS), have enabled to show significant fractional anisotropy reductions in preterm infants with chronic lung disease at term-equivalent age in comparison with term newborns, despite any evidence of focal lesions on conventional MRI, in several white matter regions.[10] Neuroprotective interventions that aim at preventing and decreasing the long-term effects of the encephalopathy of prematurity, such as postnatal neuroprotection with the growth factor erythropoietin or the antenatal neuroprotective action of magnesium sulfate, have shown positive effects on brain connectivity in the preterm brain.[2,123] DWI with diffusion tensor analysis has provided new insights into the microstructural white matter development and seems to be

an ideal tool to assess alteration of white matter pathways in the developing brain of the preterm infant.[44]

Functional Magnetic Resonance Imaging—Functional Connectivity

The process of establishing permanent functional connectivity is influenced by several factors (e.g., neuron survival, competition for trophic factors, electrical activity of axons, and afferent inputs).[86] Functional connectivity can be studied even in the newborn period by resting state functional MRI and analysis of regional time course of blood-oxygenation-level-dependent (BOLD) fluctuations. Functional MRI uses deoxygenated hemoglobin as an endogenous contrast agent to produce a BOLD signal. By utilizing these BOLD signals in neonates, it is possible to identify networks with synchronous neuronal activity in sleeping neonates to study resting state functional connectivity. Studies indicate that aberrant functional connectivity relevant for cognitive outcome is observed in preterm infants[11] and depends on the severity of the brain injury.[64,144]

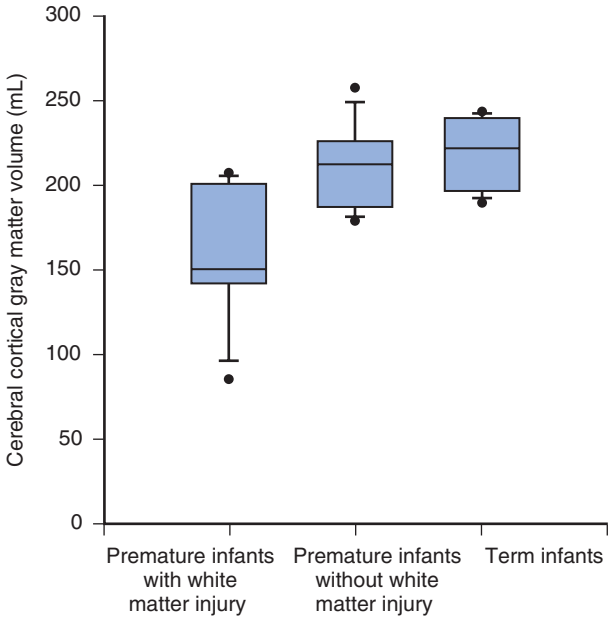
Magnetic Resonance Spectroscopy

One of the essential contributors to the progress in noninvasive detection of tissue metabolism and in vivo biochemistry has been magnetic resonance spectroscopy (MRS), which gives specific chemical information on the biochemistry of numerous intracellular metabolites. The biochemical characteristics of white matter damage in preterm infants have been studied in vivo by using MRS.[134] Similar to the high diagnostic value of MRS in term asphyxia, MRS in acute phase immature white matter injury can detect indicators of anaerobic glycolysis with increased intracerebral lactate. Data from studies suggest that white matter damage in the preterm infant studied around term gestational age resulted in high Lac/Cr and high Myo-Inositol/Cr ratios.[134] The increased presence of lactate at this chronic stage was not associated with changes in pH,[134] whereas N-acetylaspartate as a marker of neuroaxonal integrity was reduced in the damaged periventricular white matter. As outlined in Chapter 51, astrocytes further play a variety of complex nutritive and supportive roles in relation to neuronal metabolic homeostasis. For example, astrocytes take up glutamate and convert it to glutamine. This removal of glutamate from the extracellular space protects surrounding cells from excitotoxicity from glutamate. Glutamate uptake into astrocytes further stimulates glycolysis within the astrocyte with production of lactate that can be used by neurons as energy substrate. Given that chronic phase white matter injury is characterized by widespread cerebral white matter astrocytosis, this change in metabolite composition might be an expression of altered cellular composition and substrate utilization. A study found links between elevated glutamate and the occurrence of punctate white matter lesions, indicating their biomarker role for cellular injury.[161]

There are other metabolites that become visible with short echo-time spectroscopy, such as the macromolecules/lipids at 0.9 parts per million (ppm) and 1.3 ppm (see Fig. 52.8). These resonances show important changes in adult hypoxia–ischemia[58] and in experimental data on in vitro apoptosis.[19] Preliminary data have suggested that these metabolites are also present in acute periventricular white matter injury of the immature brain and may represent metabolites from membrane peroxidation. Consistent with the observation of these resonances, one study found elevated neonatal levels of lipid peroxidation and oxidative protein products in the CSF of infants with PVL, as documented by MRI.[76]

Impairment of Brain Growth and Long-Term Development

Periventricular white matter injury has been strongly associated with long-term neurodevelopmental deficits in preterm infants.[127,128] The significance of abnormalities in myelination in relation to functional (neurologic) development has been extensively studied. Correlation was found between neurodevelopmental delay and delay in myelination. The major long-term morbidity of the focal component of periventricular leukomalacia is spastic diplegia (Box 52.1). This motor disturbance has as its central feature a spastic paresis of the extremities with greater effect on lower than upper limbs. More severe lesions, with lateral and posterior extension into the centrum semiovale and corona radiata, are associated with effects on the upper extremities or visual and cognitive deficits (see Box 52.1).



The development of three-dimensional MRI methods, combined with image postprocessing techniques, has allowed volumetric assessment of brain development and an absolute quantitation of myelination.[160] Despite the challenging methods of mathematical morphology-based segmentation, these techniques have improved the reliable quantification of myelinated versus unmyelinated white matter tissue from in vivo MR images of the newborn.[59] These techniques allow for exact definition of brain volume and can, therefore, accurately monitor brain growth, measure CSF volume, and detect volume changes in cortical gray matter. Three-dimensional MRI volumetric techniques were used to evaluate the effect on subsequent brain development of

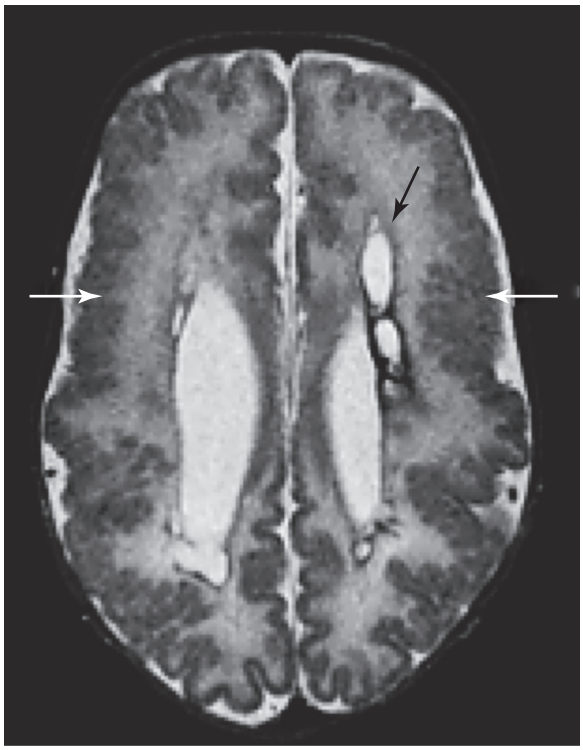
• **Fig. 52.18** Figure illustrating the effects of perinatal white matter injury on subsequent cortical gray matter development at term with a significantly lower cortical gray matter volume determined by three-dimensional magnetic resonance imaging (MRI) with postacquisition image analysis in a group of preterm infants with perinatal white matter injury compared with control preterm and full-term infants. (From Inder T, et al. The postmigrational development of polymicrogyria documented by magnetic resonance imaging from 31 weeks' postconceptional age. *Ann Neurol.* 1999;45:798).

early white matter injury in premature infants. Three groups of infants were studied at 40 weeks' postconceptional age: premature infants with preceding evidence for periventricular white matter injury by cranial ultrasonography and MRI; premature infants who had no prior evidence of white matter injury; and control term infants (Fig. 52.18). In premature infants with preceding white matter injury, the volume of myelinated white matter at term was significantly lower than in premature infants without prior white matter injury and infants born at term, measuring the degree of delay of myelination. Furthermore, this study showed a marked decrease in cortical gray matter volume in preterm infants with prior periventricular white matter injury, indicating impaired cerebral cortical development. This finding is in line with the neuropathologic findings of encephalopathy of prematurity and may explain the intellectual deficits associated with both cystic and noncystic periventricular leukomalacia in preterm infants.[79] Assessing moderately preterm infants without signs of white matter injury, cortical development was similar to full-term infants.[165] Regional assessment of white matter myelination in preterm infants further revealed particular delay in myelination in the central and posterior parts of the brain.[112] When assessing cerebellar volume at term, there was a significant reduction in cerebellar volume of preterm infants compared with that in term infants.[97] Unilateral cerebral white matter lesions resulted in contralateral reduction of cerebellar volume, indicating the trophic interplay resulting from loss of cerebrocerebellar connectivity.[98]



Long-term follow-up studies of preterm infants have confirmed the permanent character of these disruptive/adaptive changes in brain development. Evaluations with volumetric brain assessment of 8-year-old children who had been born prematurely showed persistence of cortical gray matter reduction accompanied by a reduction in the volume of hippocampus, which correlated with cognitive scores indicating long-term functional consequences.[100] Both cortical volume and cortical thickness were shown to be reduced in 15-year-old adolescents born prematurely.[106] Studying a larger cohort of preterm subjects at the same age, Nosarti[122] noted widespread alterations in both gray and white matter volumes throughout the brain. Of note, several gray matter regions, including the middle temporal gyrus, the superior temporal gyrus, and the sensorimotor region, as well as the precentral and postcentral gyri, were linearly related to gestational age for the preterm group. Furthermore, decreases in both gray and white matter volumes in the middle temporal gyrus were associated with cognitive impairment in the preterm group. With the development of whole brain connectivity analysis, specific long-term effects of prematurity and associated brain injury have been defined, affecting not only sensorimotor connectivity[68] but, more importantly, the prefrontal and the limbic cortico-basal-ganglia-thalamocortical loops as well, tightly linked to performance in executive function and social behavior.[51] New mathematical modeling techniques, such as graph model theory, have further evaluated the efficiency of brain networks in those born prematurely, indicating that their network efficiency can be altered both globally and regionally.[52] Neuroimaging has defined new biomarkers of later neurofunctional outcome and has become a useful adjunct to clinical practice.[110]

Human brain development is characterized by several interrelated steps. Neuronal and radial glial proliferation and migration are early events in brain development that are followed by a series of organizational events that result in the complex circuitry of axons and dendrites characteristic of the human brain. The immature cortex is characterized by radial organization seen both in rodents[139] and humans. The preterm cortex at term-equivalent age reveals a persisting fetal radial organization that can be characterized by DTI-based analysis (higher fractional anisotropy) and is associated with decreased cortical folding, which is more pronounced in preterm infants with signs of white matter injury.[46,108] Elaboration of dendritic and axonal ramifications and attainment of proper alignment and orientation is most likely one of the driving forces for the folding of the cerebral cortex during development. Several authors have investigated the influence of preterm birth on primary cortical folding. Biagioni[18] studied preterm infants of less than 30 weeks' gestational age and demonstrated that the degree of cortical folding significantly increased with postmenstrual age. Dubois et al.[42,43] observed a trend toward lower cortical surface areas and smaller cortical and white

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

matter volumes, but equivalent sulcation in female preterm infants compared with male preterm subjects. Furthermore, preterm neonates with intrauterine growth restriction had more pronounced reduction of volume in relation to surface area and increased sulcation with resultant changes in cortical thickness, which correlated with impaired behavioral functions. Infants with early white matter lesions at birth showed a trend to increased sulcation in overlaying cortex.[43] Early alteration of white matter connectivity and ensuing disruption to the white matter circuits and to the subcortical plate may, therefore, alter subsequent density, survival, and organization of the cortical neurons. In severe cases, secondary polymicrogyria after primarily early white matter injury have been described (Fig. 52.19).[78] Neuropathology of the cerebral cortex in preterm infants has revealed cortical dysplasia in cortical areas overlaying white matter destruction.[105] These abnormalities of cortical development are found secondary to disturbances of afferent input to and efferent output from areas of the cortex by disruption of the respective white matter axons.[105] Cortical volume changes in three-dimensional MRI, as described earlier, are probably representative of these cortical alterations and may explain the increased risk of cognitive impairment and epilepsy in infants with classic motor deficits (spastic diplegia) after injury to the immature white matter.

Many studies confirm the potential long-term effect of the earlier described brain abnormalities and make encephalopathy of prematurity one of the major concerns in neonatology.[73,90]

• **Fig. 52.19** Axial T2-weighted magnetic resonance imaging (MRI) scan in a preterm infant 25 weeks' gestational age at birth imaged at 31 weeks' gestational age showing cystic lesions in the periventricular white matter (*black arrow*) associated with bilateral polymicrogyria (*white arrows*). (From Inder T, et al. The postmigrational development of polymicrogyria documented by magnetic resonance imaging from 31 weeks' postconceptional age. *Ann Neurol.* 1999;45:798.)

Key Points

- Encephalopathy of the preterm infant is an amalgam of damage and disrupted development.
- Hypoxia–ischemia and intrauterine infection during a vulnerable period of 23-32 weeks' gestation may both contribute to white matter injury via axonal injury and aberrant oligodendrocyte maturation.
- Glutamate acting on its various receptors plays a key excitatory role in the molecular mechanisms contributing to brain injury.
- Neonatal ultrasonography clearly identifies cystic periventricular leukomalacia but is of very limited value for detecting diffuse white matter injury.
- DWI can identify early periventricular white matter injury, and newer imaging techniques will enable characterization of molecular and functional components of brain integrity.
- Periventricular white matter injury with accompanying motor deficits is frequently accompanied by reduced gray matter volume and intellectual delay.

Intracranial Hemorrhage and Vascular Lesions in the Neonate

LINDA S. DE VRIES

Germinal Matrix Hemorrhage–Intraventricular Hemorrhage

Incidence

Germinal matrix hemorrhage–intraventricular hemorrhage (GMH-IVH) mainly occurs in premature infants, and the risk is higher with decreasing maturity. A 2003 study, however, also showed that IVH, sometimes associated with a thalamic hemorrhage, can be seen in full-term infants, and this can be associated with a sinovenous thrombosis.[136] The first studies using computed tomography (CT) and ultrasonography were performed between 1978 and 1983 and showed an incidence of 40%-50% in infants with birth weights less than 1500 g. In the 1990s and more recently, several groups noted a decline in the incidence to approximately 20% of infants with very low birth weight,[47] but this decline has not been confirmed by others, and the decrease in severe GMH-IVH shown in a cohort of the Vermont Oxford Network was of borderline statistical significance.[49] In a recent study from the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network in 34,636 infants with a gestational age between 22 and 28 weeks, a decline in the incidence of severe IVH was seen from 19%-15% with the following trends between 1993 and 2012: A significant reduction was seen for those with a gestational age of 26-28 weeks (adjusted relative risk [RR] for the change per year, 26 weeks 0.987) (95% confidence interval [CI] 0.974-0.999), 27 weeks 0.964 (95% CI 0.971-0.997), and 28 weeks 0.973 (95% CI 0.958-0.989).[21,112]

Since the early 1980s, the incidence of intraparenchymal hemorrhage has also shown a decline, although this decline was not found in all studies. The average incidence for intraparenchymal hemorrhage is now 5%-11%.[21,25] An even lower incidence of 3% was reported in a French population-based cohort.[64,105] The decrease in the incidence of GMH-IVH is mainly attributed to the increased use of antenatal corticosteroids and postnatal use of surfactant.[47,98]

Timing of the Hemorrhage

Accurate timing of GMH-IVH is possible only when sequential ultrasonography is performed. A diagnosis of a hemorrhage of antenatal onset can be made only when the first ultrasonography is performed on admission, within a few hours after delivery. Many studies have shown that almost all hemorrhages develop within the first week after birth, and many of them within the first 48 hours after birth. Progression of a GMH-IVH over 1-2 days is not uncommon, and this applies especially to an IVH progressing to an intraparenchymal hemorrhage.[21] Impaired venous drainage of the medullary veins in white matter leading to venous infarction is the most likely underlying mechanism for this progression (see section on Neuropathology). Only approximately 10% of cases of GMH-IVH occur beyond the end of the first week, in contrast to periventricular leukomalacia, wherein late onset is not uncommon.[25]

Neuropathology

Pathologists have noted GMH-IVH developing after hemorrhage in the subependymal germinal matrix, a structure that is most prominent between 24 and 34 weeks of gestation and that has almost completely regressed by term. Germinal matrix tissue is abundant over the head and body of the caudate nucleus but can also be found in the periventricular zone. More recently, magnetic resonance imaging (MRI) has confirmed just how extensive this tissue is in preterm infants. The germinal matrix contains neuroblasts and glioblasts that undergo mitotic activity before migrating to other parts of the cerebrum. Bleeding into the caudothalamic part of the germinal matrix is predominant, but using a new MRI sequence, susceptibility weighted imaging (SWI), it has been noted that many cases also have bleeding into the temporal or occipital germinal matrix outer zones.[92] Using this MRI sequence, it has also been observed that preterm infants with GMH-IVH have a higher variability in anatomy of subependymal veins which may be a predisposing factor for GMH-IVH.[119] The germinal matrix

Abstract

Even though white matter damage is now considered the main determinant of cerebral palsy later in infancy, germinal matrix hemorrhage–intraventricular hemorrhage (GMH-IVH) is still a serious condition in premature infants, associated with a high mortality rate. Large IVHs, complicated by posthemorrhagic ventricular dilatation or associated with a unilateral parenchymal hemorrhage, are associated with an increased risk of adverse neurologic sequelae. The widespread use of cranial ultrasonography since the early 1980s has shown a gradual decrease in incidence of IVH and has helped with the identification of risk factors. The increased use of magnetic resonance imaging (MRI) has helped better define the site and extent of the lesion and to visualize associated white matter damage and cerebellar hemorrhages. The second part of this chapter is about extra-axial hemorrhages in the full-term infant and about perinatal stroke, including sinovenous thrombosis and perinatal arterial ischemic stroke (PAIS).

Keywords

germinal matrix/intraventricular hemorrhage
posthemorrhagic ventricular dilatation

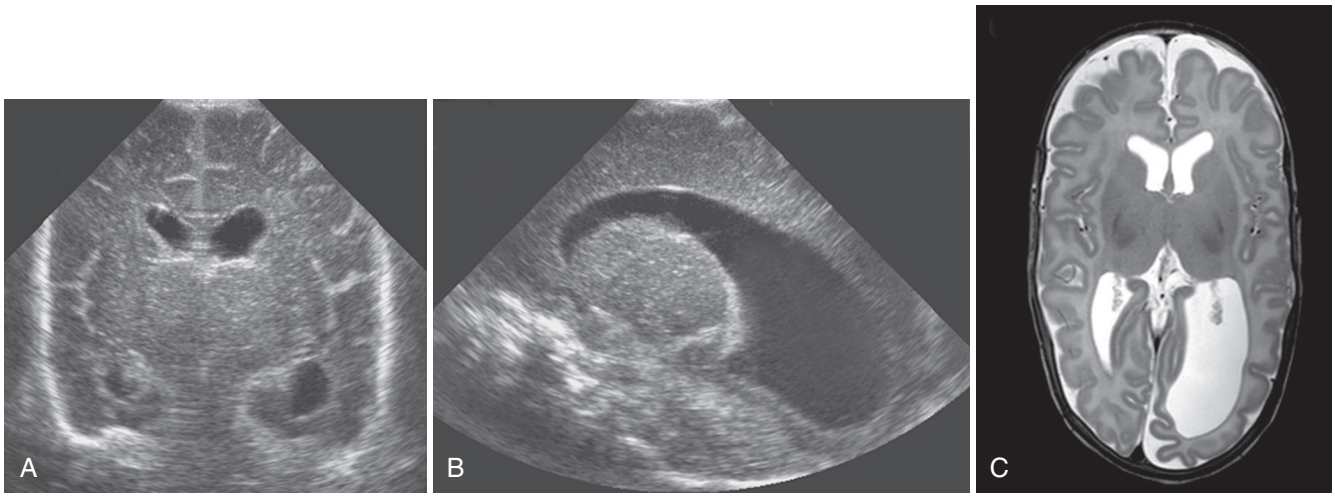
receives its blood supply from a branch of the anterior cerebral artery known as the *Heubner artery*. The rest of the blood supply is derived from the anterior choroidal artery and the terminal branches of the lateral striate arteries. Vessels in the germinal matrix are primitive and cannot be classified as arterioles, venules, or capillaries and are often referred to as the *immature vascular rete*. Venous drainage of the deep white matter occurs through a fan-shaped leash of short and long medullary veins through which blood flows into the germinal matrix and subsequently into the terminal vein, which is positioned below the germinal matrix. The anatomic distribution of parenchymal lesions associated with GMH-IVH suggests venous infarction resulting from obstruction of this vein.

Germinal Matrix Hemorrhage



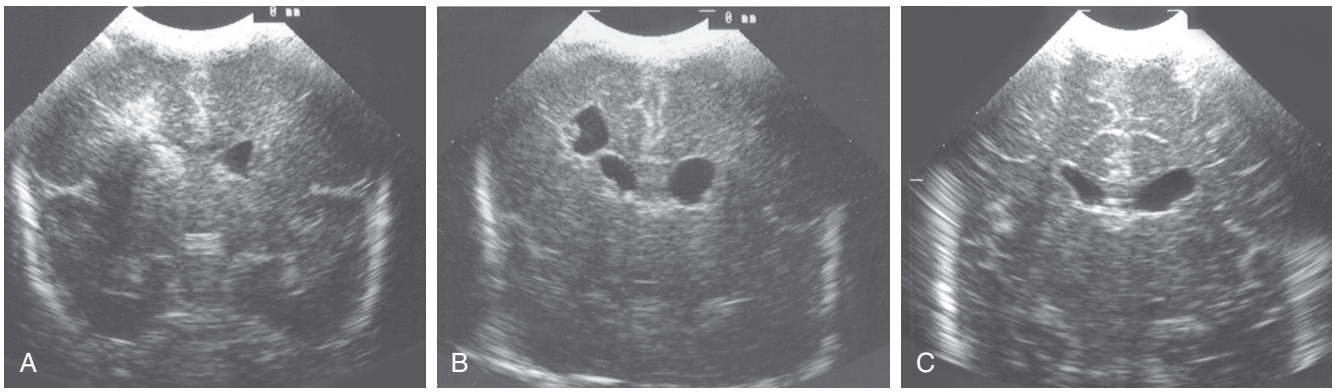
Most GMHs arise in the region of the caudate nucleus. Although GMHs at the level of the caudate nucleus are identified with ultrasonography, MRI using the SWI sequence has shown that GMH also occurs in the germinal matrix in the roof of the temporal horn.[92] The size of the GMH changes with the maturity of the infant: The less mature the infant, the larger the GMH. The site also varies with maturity, with occurrence over the body of the caudate nucleus in the less mature infant and over the head of the caudate nucleus in the more mature infant. A GMH can result in suppression of cell proliferation of the human ganglionic eminence.[26] When the GMH is followed longitudinally with ultrasonography, a subependymal cyst is seen as a sequel after several weeks, and this cyst is often still present at term-equivalent age and is better visualized with cranial ultrasonography than with MRI.

Intraventricular Hemorrhage

Hemorrhages occurring in the germinal matrix often rupture through the ependyma into the lateral ventricle and are then referred to as an *IVH*. These hemorrhages can vary considerably in size and, if large, can lead to acute distension of the lateral ventricle. Large clots can be present, seen as casts at postmortem examination or with cranial ultrasonography, and these can sometimes change position with repositioning of the infant. The blood can fill part of or the entire ventricular system, spreading through the foramen of Monro, the third ventricle, the aqueduct of Sylvius, the fourth ventricle, and the foramina of Luschka and Magendie to collect eventually around the brainstem in the posterior fossa. Clot formation can lead to outflow obstruction at any level, but most commonly at the level of the aqueduct of Sylvius or more diffusely at the level of the arachnoid villi. More gradual progressive ventricular dilation occurs especially in those with a large GMH-IVH; this is known as *posthemorrhagic ventricular dilation.* This can be transient or persistent. In a small group, it can be rapidly progressive and noncommunicating, usually because of obstruction at the level of the aqueduct of Sylvius or the outlet foramina of Luschka and Magendie. Unilateral outflow obstruction at the level of the foramen of Monro can lead to unilateral hydrocephalus (Fig. 53.1). In cases of communicating progressive posthemorrhagic ventricular dilation, the increase in ventricular size is more gradual and is considered to be caused by an obliterative arachnoiditis resulting from blood collecting in the subarachnoid spaces of the posterior fossa, leading to an imbalance between cerebrospinal fluid (CSF) production and reabsorption.[99]

Parenchymal Hemorrhage

The most severe type of hemorrhage involves the parenchyma. This type of lesion occurs in approximately 3%-15% of all hemorrhages.[64] A study by Dudink et al. described the different veins involved in this type of lesion.[28] Direct extension into the parenchyma from pressure of blood in the ventricle is now considered unlikely. Some still take the view



• **Fig. 53.1** **A,** Cranial ultrasonography, coronal view, shows posthemorrhagic ventricular dilation after a large left-sided hemorrhage. **B,** Note isolated enlargement of the left occipital horn on the parasagittal view. **C,** The magnetic resonance image, T2-weighted, spin-echo sequence still shows evidence of enlargement of the left occipital horn and enlargement of the frontal extracerebral space. Myelination of the posterior limb of the internal capsule (PLIC) is symmetric and seen as low signal intensity.

that all parenchymal hemorrhages are originally ischemic in origin, with any bleeding being a secondary complication. However, most agree that a unilateral parenchymal lesion accompanying GMH-IVH is most often caused by the presence of the GMH leading to impaired venous drainage and venous infarction. Gould et al.[41] showed that the ependyma remained intact, indicating that there had not been an extension of the preceding IVH. These lesions almost invariably show a moderate to large IVH on the ipsilateral side. The parenchymal hemorrhage is mostly unilateral but can occur in both hemispheres and is associated with a worse neurodevelopmental outcome.[73] A score was introduced, taking into account whether the lesion is unilateral or bilateral, the presence of a midline shift, and the number of regions that are involved.[5] The appearance of the intraparenchymal hemorrhage has changed since the early 1990s. Instead of a unilateral globular hemorrhagic lesion in continuity with the lateral ventricle and evolving into a single porencephalic cyst, a smaller, triangular parenchymal lesion can be seen with the tip of the triangle toward the lateral ventricle. There may be partial or even no communication of the parenchymal hemorrhage with the lateral ventricle, and an evolution into a few cystic lesions, separate from or partially in communication with the lateral ventricle, can be seen after several weeks (Figs. 53.2 and 53.3).[21] This type of lesion is sometimes classified as *unilateral periventricular leukomalacia* (PVL), but in view of the later MRI appearance, with very focal gliosis instead of diffuse gliosis, this appears to be incorrect. With the use of sequential ultrasonography, the underlying problem can be better understood because unilateral cystic lesions occurring after an ipsilateral IVH are more likely to be caused by a venous infarction rather than cystic PVL. It is possible that improvement in neonatal care is associated with the change in appearance of the unilateral parenchymal hemorrhage seen over time.

Intracerebellar Hemorrhage

Cerebellar hemorrhage was always considered uncommon, but the increased use of routine MRI in preterm infants has shown that this condition is more common than previously thought. This problem is especially common in very immature infants. The condition has been reported in 2.5% of high-risk preterm infants, but with the increased use of neonatal MRI, the diagnosis is more often made, and the reported incidence is now reported to be between 2% and 19%.[69,111,115] The high incidence includes all punctate lesions, which are not seen with ultrasonography, which is unable to recognize lesions less than 4 mm, but only with MRI.[21,111,115] Ultrasonography performed through the mastoid window is more successful in making the diagnosis,

• **Fig. 53.4** **A,** Cranial ultrasonography, axial scan through the temporal bone, shows a large right cerebellar hemorrhage. **B,** The magnetic resonance imaging (MRI) scan, T2-weighted, spin-echo sequence still shows evidence of blood (low signal intensity) at term equivalent age, as well as atrophy of the right cerebellar hemisphere.

but is still inferior to MRI (Fig. 53.4).[93] Cerebellar hypoplasia without an apparent cerebellar hemorrhage has also been reported as a common sequel of severe immaturity. Reduced cerebellar volumes were only shown on three-dimensional MRI in preterm infants at term-equivalent age in association with supratentorial pathology, such as hemorrhagic parenchymal infarction, intraventricular hemorrhage with dilation, and periventricular white matter damage.[109,136] More recent studies have confirmed significantly slower cerebellar growth at term-equivalent age in the presence of severe supratentorial IVH,[57] but no reduced cerebellar growth in the presence of associated white matter injury.[115]

Pathogenesis

The precise nature and origin of GMH-IVH remain uncertain. Although some groups have suggested that the capillaries in the germinal matrix do not rupture easily, others have suggested that they can because the vessels are immature in structure with little evidence of basement membrane protein and they are of relatively large diameter. Early neuropathologists considered subependymal bleeding to be entirely venous in origin. This theory was rebutted by Wigglesworth and Pape,[134a] who suggested, on the basis of their injection studies, that capillary bleeding was more prominent than terminal vein rupture. There has been a return to the concept that most parenchymal hemorrhages are caused by venous infarction[41] or by reperfusion injury after an ischemic insult. An anatomic analysis of the developing cerebral vasculature did not show precapillary arteriole-to-venous shunts.[4]

Prenatal Factors

Histologic signs of amniotic infection have been shown by some to increase the risk of GMH-IVH,[35,117] but not by others.[103] This fits in well with acute inflammatory placental lesions and increased serum levels of interleukin (IL)-1-beta, IL-6, and IL-8, noted to be associated with severe IVH in extremely premature infants.[45,117,138] In one of these studies, a correlation was shown between blood cytokine concentrations and altered hemodynamic function.[138] Cord blood IL-6 concentration correlated inversely with newborn systolic, mean, and diastolic blood pressures. The number of infants with an IVH was limited, but in the five infants with IVH, the placenta significantly more often showed evidence of fetal inflammation.[138] An increase in total leukocytes during the first 72 hours after birth, as well as an increased ratio of immature-to-total white blood cells (WBCs), was also recognized as an independent risk factor for GMH-IVH.[138]

Maternal preeclampsia has been associated with a reduced risk of GMH-IVH.[36] The protective effect appears to be a result of enhanced in utero maturation of the fetus. In a recent study, intrauterine growth restriction (IUGR) did not lead to increased neonatal brain injury on cranial ultrasonography but was associated with increased mortality.[74] Administration of antenatal corticosteroids is, according to several studies, the most important protective factor against development of GMH-IVH.[98] The effect may be caused by a direct maturational effect on the brain, but other factors, such as the reduction of the severity of lung disease and the decreased need for inotropes, may also be involved. Several studies have shown that male gender is associated with a high incidence of IVH and an increased rate of severe IVH.[54,83]

Intrapartum Factors

Whether the mode of delivery plays a role is still uncertain.[42] A reduced mortality, but not a reduced risk of a GMH-IVH, was reported in a Swedish population-based study for preterm infants with a gestation of 25-36 weeks, when avoiding vaginal breech delivery.[46] When specifically

studying the mode of delivery in 2885 small for gestational age (SGA) infants, no significant difference in IVH was noted between the cesarean delivery and vaginal delivery groups. Cesarean delivery compared with vaginal delivery was associated with increased odds of respiratory distress syndrome.[130] A vaginal breech delivery is, in some studies, associated with a higher risk of large GMH-IVH, but this effect was not found in a multivariable analysis.[97] In a population-based study from Israel, the rate of severe GMH-IVH was 7.7% for infants delivered by cesarean section compared with 13.6% in vaginal delivery ($P < 0.001$). In the multivariable model, cesarean delivery had no effect on the odds for severe IVH (odds ratio [OR] 0.98; 95% CI 0.77-1.24). Similar data were found in another study with a higher incidence of severe IVH in the vaginal delivery group (16.2%) versus 6.8% in the cesarean section group. The association was only seen in those born after less than 28 weeks' gestation (OR 2.05 [1.29-3.25].[37] Neonatal transport for infants born outside a tertiary center has also been shown to be a risk factor.[84] This was confirmed in another study, in which the overall incidence of IVH in the sample was 14.7%, and the transport group had more IVH compared with the inborn group (27.4% versus 13.4%): adjusted OR 1.75 (85% CI 1.64-1.86; $P < 0.001$). Severe IVH was higher in the transport group compared with the inborn group (44.1% versus 32.9%): adjusted OR 1.44 (95% CI 1.22-1.70; $P = .001$). It was recently suggested that the reason may not be the transport itself, but the association with underlying clinical variables.[128]

Delayed cord clamping was initially reported to be associated with a reduction in GMH-IVH as demonstrated by five infants (14%) in the delayed clamping group compared with 13 infants (36%) in the nondelayed group ($P = 0.03$).[78] The impact of delayed cord clamping on IVH was evaluated adjusting for gestational age and cesarean section. The final model indicated that the IVH rate was more than three times higher in the immediate cord clamping group (OR 3.5; 95% CI 1.1-11.1). In a meta-analysis of 18 randomized controlled trials (RCTs), there was significant reduction for infant deaths (RR 0.69; 95% CI 0.52-0.91), but no reduction in the incidence of IVH.[32] A recent RCT enrolling enrolled 1,566 infants with gestation of less than 30 weeks was unable to show a difference for the combined outcome of death or major morbidity at 36 weeks of gestation and no difference was found for development of GMH-IVH.[116] Being born outside office hours increased the risk of development of GM-IVH (OR 1.39; 95% CI 1.23-1.57).[51]

Neonatal Factors

Respiratory problems and respiratory distress syndrome (RDS), in particular, have been recognized as important risk factors in the development of GMH-IVH. This association is most likely not causal but results from complications, such as hypercarbia, pneumothorax, and acidosis, occurring during mechanical ventilation for RDS.[53,124] Because of improvement in ventilatory techniques, including an increased use of nasal continuous positive airway pressure, hypercarbia, and severe acidosis have become less common. Hypercarbia, a potent cerebral vasodilator, especially when combined with a severe acidosis, has been noted to be associated with GMH-IVH.[124]

Cardiovascular Factors

The immature brain is considered vulnerable to fluctuations in blood pressure because of limitations in autoregulation of cerebral blood flow. Impaired autoregulation renders the cerebral circulation "pressure passive" and, hence, unprotected from any wide swings or changes in blood pressure. This applies especially to sick preterm infants. Data initially obtained by using a radioactive xenon tracer showed a direct linear relationship between blood pressure and cerebral blood flow in a small number of infants. Similar findings were obtained by using near-infrared spectroscopy.[120] With use of these techniques, it was shown that routine caregiving procedures in critically ill preterm infants are associated with major circulatory fluctuations and that these cerebral hemodynamic changes were associated with early parenchymal ultrasound abnormalities.[70] Looking at a selected population of ventilated infants with evidence of asynchronous respiratory efforts, a significant reduction in IVH (any grade and severe IVH) was found, using muscle paralysis.[14] The fluctuating pattern may be exaggerated in hypovolemia. Hypotension is common in infants with severe RDS, and in the presence of a pressure-passive cerebral circulation may lead to hypoxia–ischemia of the germinal matrix. It has been shown that arterial hypotension precedes the development of GMH-IVH,[124] with the hemorrhage occurring during a period of reperfusion. In a study using continuous near-infrared spectroscopy and mean arterial blood pressure (MABP) measurements, MABP–regional cerebral oxygen saturation ($rScO_2$) correlation suggested more pressure-passive brain perfusion in infants with IVH.[3] In another study measuring flow in the superior vena cava, a low flow was detected during the first few hours of life before IVH occurs.[91] Delayed cord clamping was noted to be associated with a higher flow in the superior vena cava, and antenatal administration of steroids is associated with a reduction in the need for blood pressure support. Next to a reduction in the severity of RDS, this effect on blood pressure may be most protective for the development of a GMH-IVH. Early administration of fresh frozen plasma does not reduce the incidence of GMH-IVH.[63,90] A reduction in GMH-IVH has been seen during an era of closer attention to blood pressure, gentle handling, synchronous ventilation, and less severe RDS because of antenatal steroid and postnatal surfactant therapy, rather than because of any specific drug used as prophylaxis.

Genetic Factors

Thrombophilic disorders, including factor V Leiden mutation, which renders factor V resistant to cleavage by activated protein C, and prothrombin G20210A mutation, which was found to be associated with raised plasma

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

concentrations of prothrombin, were suggested to play a role in the development of GMH-IVH,[102] but a large prospective study was unable to confirm previously reported associations of hemostasis gene variants and development of severe IVH in infants with very low birth weight, except for an increased prevalence for the methylenetetrahydrofolate reductase 1298A>C variant.[2] In preterm infants with an atypical time of onset, either antenatal or beyond 96 hours after birth, an association was noted with polymorphism in the factor V Leiden gene.[44] Antenatal porencephaly was reported to be associated with a mutation in the collagen 4A1 gene (*COL4A1)* encoding procollagen type 4a1, a basement membrane protein in two preterm siblings and preterm twins.[8,20] The diagnosis can be made before birth and should be considered in the presence of a parenchymal hemorrhage, especially when associated with a cerebellar hemorrhage.[67]

TABLE 53.1 Grading System for Neonatal Intraventricular Hemorrhage*

Description	Generic Term
Grade I: Germinal matrix hemorrhage	GMH
Grade II: Intraventricular hemorrhage without ventricular dilation	GMH-IVH
Grade III: Intraventricular hemorrhage and with acute ventricular dilation (clot fills >50% of the ventricle)	GMH-IVH with acute dilatation
Intraparenchymal lesion—size, location	Intraparenchymal hemorrhage

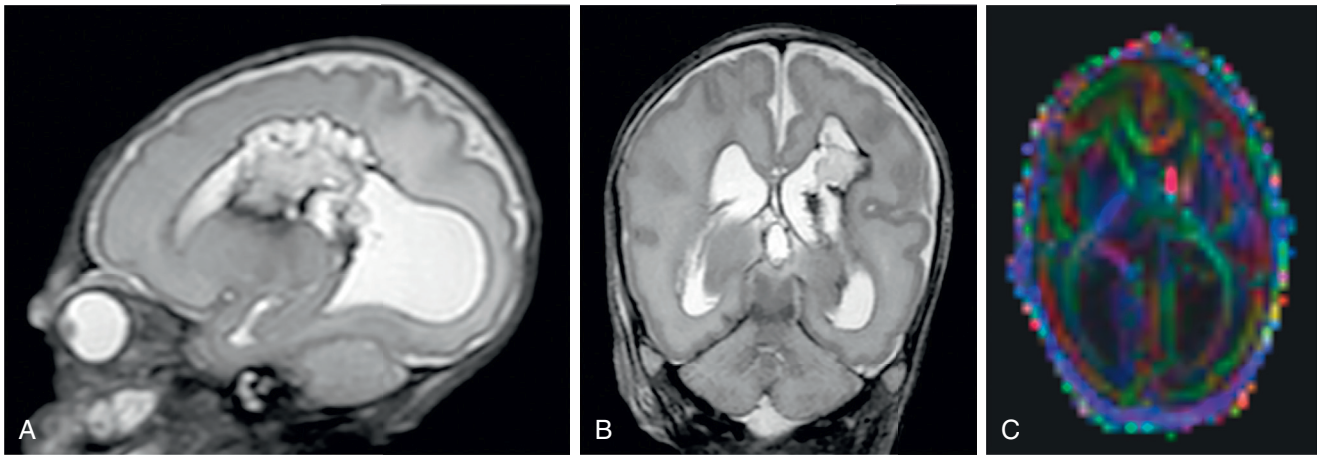
*This represents an evolution of the system described in Papile LA, Burstein J, Burstein R, Koffler H. Incidence and evolution of the subependymal intraventricular hemorrhage: a study of infants with birth weights less than 1,500 grams. *J Pediatr.* 1978;92:529.
GMH, Germinal matrix hemorrhage; IVH, intraventricular hemorrhage.

Diagnosis

With ultrasonography largely available in neonatal units, most high-risk preterm infants undergo routine ultrasonography soon after admission or within the first few days after birth. Three clinical syndromes, however, can be recognized in preterm infants not paralyzed or heavily sedated on the ventilator.[127] The first is known as *catastrophic deterioration*, noted by a sudden deterioration in the infant's clinical state, such as an increase in oxygen or ventilatory requirement, a fall in blood pressure, or acidosis. More often, however, a drop in hematocrit is seen without a clear change in the infant's condition. The *saltatory syndrome* is more common and gradual in onset, presenting with a change in spontaneous general movements. The third and most frequent presentation is *asymptomatic*; 25%-50% of infants with GMH-IVH have no obvious clinical signs.

A classification system suitable for describing early and late ultrasonography appearances, based on that suggested by Volpe,[127] is given in Table 53.1.[91a]

Ultrasonography is a noninvasive bedside technique that uses the anterior fontanel and increasingly also the posterior and mastoid fontanel as acoustic windows. The posterior fontanel improves detection of small IVHs.[15] The mastoid window allows for detection of cerebellar hemorrhages with a diameter of at least 4 mm.[111] Good correlations of GMH-IVH signs on ultrasonography with autopsy findings have been reported for the more severe hemorrhages. With the increased use of MRI, it has become apparent that GMHs at sites other than at the level of the caudate nucleus, such as the roof of the temporal horn, are not always identified with ultrasonography.[93] With ultrasonography, it also is not always possible to be certain about the presence or absence of a small associated IVH.[92] In contrast to MRI, immediate access to ultrasonography, as well as the fact that the examination can be repeated as often as indicated, still makes this technique the first-choice method.



Timing of the examination depends on the questions raised. An examination within hours after delivery helps in timing the lesion as antenatal or postnatal. When trying to determine risk factors, sequential scans until the GMH-IVH is diagnosed are also important. A single scan at the end of the first week shows 90% of all hemorrhages as well as their maximum extent. Further ultrasound examinations (up to two to three times weekly) are required in infants with any degree of hemorrhage to detect the occurrence of posthemorrhagic ventricular dilation (PHVD), which occurs in approximately 30%, and the occurrence of associated PVL.[88] The more severe the hemorrhage, the higher is the risk for development of PHVD, which tends to occur 10-20 days after the onset of GMH-IVH.[9]

Unilateral intraparenchymal hemorrhage associated with a bilateral or ipsilateral GMH-IVH is now considered to be caused by impaired drainage of the veins in the periventricular white matter, resulting in venous infarction.[21,41] This type of lesion is classically triangular or fan shaped, with the apex at the outer border of the lateral ventricle. In some cases, the lesion is globular, with the apex of the triangle at the midline and a smooth outer border. The globular type of lesion (usually unilateral) evolves over 2-3 weeks into a porencephalic cyst (Fig. 53.5), whereas those intraparenchymal hemorrhages that are clearly separate from the ventricle at the start often form multiple small cysts (see Fig. 53.3).[21]

Management

Clinical management of children who have GMH-IVH is not different from that of other at-risk preterm infants. Minimal handling, prevention of fluctuations in blood pressure or carbon dioxide (CO_2) levels, prevention of breathing against the ventilator, and optimization of any coagulopathy may be warranted in an attempt to prevent extension of the initial hemorrhage. A blood transfusion may be needed in the case of a large IVH associated with a drop

in the hemoglobin level. Continuous electroencephalography (EEG) monitoring may be helpful in the detection of subclinical seizures (see Chapter 55). The use of fibrinolytic therapy in an attempt to resolve the initial clot has been disappointing because it can even result in rebleeding.[99] Repeat scanning with ultrasonography is indicated to diagnose PHVD. Ventricular dilation seen on cranial ultrasonography usually precedes the development of clinical symptoms by several weeks. The clinical signs are a full fontanel, diastasis of the sutures, and a rapid increase in head size. "Sun setting" of eyes is a late sign. PHVD is transient in approximately half the infants and is persistent or rapidly progressive in the remaining cases.[88] Once it is recognized that the ventricles have begun to enlarge, the baseline size should be measured by using ultrasonography. The most widely adopted measurement system is that of Levene and Starte.[66] This "ventricular index" is the distance between the midline and the lateral border of the ventricle measured in the coronal view in the plane of the third ventricle. Another useful measurement is the depth of the frontal horn taken just in front of the thalamic notch, with height greater than 3 mm being used to define ventriculomegaly and one greater than 6 mm to suggest PHVD.[23] Measuring the occipital horn in a sagittal plane can also be useful because there can be a discrepancy between the anterior and posterior horn widths (see Fig. 53.1). Any measurement greater than 24 mm also suggests severe PHVD. The ventricular index graph of Levene indicates a gestational age range of 27-40 weeks. New reference values for the ventricular index, anterior horn width, and thalamo-occipital distance have been published, with an age range of 24-42 weeks.[10] Accurate measurement of CSF pressure is required to distinguish infants with progressive hydrocephalus (i.e., those with raised intracranial pressure) from those in whom the dilation is due to cerebral atrophy (low pressure). Raised CSF pressure can cause symptoms, including visual disturbance, seizures, feed intolerance, and apneas. In the long term, pressure-induced destruction of neuronal tissue can lead to motor handicap and cognitive impairment. Short-term adverse effects on the nervous system have been confirmed with use of somatosensory and visual evoked potentials, Doppler estimates of cerebral blood flow velocity, and near-infrared spectroscopy (NIRS).[62] Soul et al.[108] demonstrated a pronounced effect of CSF removal on cerebral perfusion regardless of the opening pressure and the amount of fluid removed. In another study of nine infants with PHVD, NIRS was used and a significant cerebral blood flow increase was measured (15.6%) following a ventricular tap (14.6 ± 4.2 to 16.9 ± 6.6 mL/100 g/min), but without a corresponding change in cerebral metabolic oxygen requirement ($CMRO_2$) (1.02 ± 0.41 mL O_2/100 g/min).[76] CSF hypoxanthine levels of IL-8, IFN-gamma, and sFas (soluble Fas) were noted to be raised in infants with PHVD and especially so in those with associated PVL.[104,106] Other CSF biomarkers were found to be increased in infants with PHVD (amyloid precursor protein [APP], soluble APP-alpha [sAPP-alpha]), L1 cell adhesion molecule (L1CAM), APP, and total protein were selectively increased in PHH (all $P < 0.001$) compared with preterm controls or infants with an IVH but without PHVD.

There is some evidence that early drainage of CSF alters the natural history or outcome of PHVD. In a large, retrospective, observational study, a significant reduction in the need for shunt placement was noted when intervention was started before the 97th percentile + 4 mm line of the graph of Levene and Starte[66] was crossed and when the threshold for inserting a subcutaneous reservoir was low.[9] A more recent retrospective study comparing two centers, treating early, on the basis of ultrasonography measurements, or treating late, on the basis of clinical symptoms, showed a worse outcome at 2 years in the latter group.[65] The initial data of the drainage, irrigation, and fibrinolytic therapy (DRIFT) study showed a reduced need for

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

shunt insertion: 22% compared with approximately 60% in previous multicenter studies.[134] A subsequent RCT showed a high risk (33%) of rebleeding in the group allocated to DRIFT without an apparent positive effect on the need for a ventriculoperitoneal shunt.[133] When these children were seen at 2 years' corrected age, 21 of the 39 (54%) infants assigned to DRIFT died or were severely disabled versus 27 of 38 (71%) in the standard group (adjusted OR 0.25 [95% CI 0.08-0.82]). Among the survivors, 11 of 35 (31%) in the DRIFT group had severe cognitive disabilities versus 19 of 32 (59%) in the standard group (adjusted OR 0.17 [95% CI 0.05-0.57]).[133] An interesting observation was that the use of quantitative cranial ultrasonography measurements was useful for predicting outcome.[50] Neither ventricular area nor ventricular width correlated with developmental quotient (DQ) in grade III IVH, but the intraventricular echodensity area correlated with motor DQ in infants with periventricular hemorrhagic infarction, and the parenchymal lesion area correlated significantly with later mental and motor DQ. A prospective international randomized study, randomizing for early or later placement of a subcutaneous reservoir, showed no difference in ventriculoperitoneal shunt requirement, but the percentage of shunts inserted was the lowest reported so far—19% when treatment was started when the P97 line was crossed and 23% when treatment was started once the p97 + 4 mm line was crossed.[21a] Even in infants started early, an effect on volume of the central gray nuclei ([95% CI]: −1.4 cc [−2.3; −0.5]), cerebellum (−2.7 cc [−3.8; −1.6]), ventricles (+12.7 cc [7.9; 17.4]), and extracerebral CSF (−11.2 cc [−19.2; −3.3]), and with apparent diffusion constant (ADC) values in occipital, parieto-occipital, and parietal white matter (beta: +0.066 to −-0.119 × 10(−3) mm^2/sec) was noted on term-equivalent age MRI (TEA-MRI) ($P < 0.05$).[11]

Neurodevelopmental Outcome

Data on long-term neurologic and developmental outcomes mainly are from children who had a large IVH with or without parenchymal involvement. These follow-up data are still mainly based on neonatal ultrasonography findings. Associated PVL may have been missed with use of this technique, especially in children with posthemorrhagic ventricular dilation, where the periventricular white matter is more difficult to visualize. Children with small hemorrhages were not considered to be at increased risk for development of a major handicap, even though MRI was performed in the majority of the infants to additionally assess subtle white matter injury and cerebellar hemorrhages.[96] In one study, these infants did not develop more handicaps but scored lower on tests assessing visual–motor integration.[126] Three-dimensional volumetric imaging studies, however, have shown reduced gray matter volumes at term-equivalent age[123] associated with a reduced mental development index (MDI) on the Bayley Scales of Infant Development (BSID)-II, but this was only significant in the most immature infants with less than 30 weeks' gestation. In a recent meta-analysis, outcome was poorer in preterm infants with mild GMH-IVH compared with those without a hemorrhage. Among survivors, the odds of moderate-to-severe neurodevelopmental impairment (NDI) were higher with mild GMH-IVH in both unadjusted (1.75; 1.40-2.20; 3 studies) and adjusted (1.39; 1.09-1.77; 3 studies) pooled analyses. Adjusted odds of cerebral palsy and cognitive delay were higher with severe but not mild GMH-IVH.[86] Another study using advanced imaging techniques, including tract-based spatial *statistics* (TBSS) showed lower fractional anisotropy (FA) and higher radial diffusivity (RD) of the corpus callosum, limbic pathways and cerebellar tracts, especially in those with gestational age less than 29 weeks. These *diffusion tensor imaging* (DTI) abnormalities were associated with poorer locomotor, eye–hand coordination, and performance outcomes at 24 months.[118] The risk of a poor outcome increases significantly with the presence of post-hemorrhagic ventricular dilation (50%) and even further in those who require shunt insertion (75%).[94,118]

Children with ventriculomegaly present at term are at higher risk of a poor outcome. Outcome data from children with a unilateral parenchymal hemorrhage show a major neurodevelopmental disability in approximately 50%-80%, depending on the size and especially the site of the lesion. The most common handicap is a hemiplegia contralateral to the side of the parenchymal hemorrhage. Ten infants with a porencephalic cyst following a parenchymal hemorrhage were followed up into adolescence.[105] At all ages assessed, rates of motor, cognitive, and overall impairment were significantly higher compared with those in preterm control subjects ($P \leq 0.002$ for all tests). Six of the 10 children who were ambulatory when seen at 16-19 years required learning assistance in school and had social challenges. In a retrospective hospital-based population study, outcome was considerably better than reported previously, with cerebral palsy occurring in only 7.4% of the infants with a large IVH (grade III) compared with 37 (48.7%) of the 76 infants with a parenchymal hemorrhage ($P < 0.001$).[9] Data from the study by Leijser et al. support that this better neurodevelopmental outcome was related to earlier treatment of PHVD. The data from this retrospective observational study[65] are very much in contrast to those of another study looking at a large group of infants with a grade III/IV hemorrhage with and without a shunt.[1] Of the 562 infants with a grade III hemorrhage, 103 (18%) needed a ventriculoperitoneal shunt compared with 125 of the 436 (29%) with a grade IV hemorrhage. Children with severe IVH and shunts had significantly lower scores on the BSID II compared with children with no IVH and children with IVH of the same grade and no shunt. An MDI less than 70 was found in 183 of 424 (43%) infants with a grade III hemorrhage without a shunt compared with 59 of 99 (60%) in those with a shunt. In those with a grade IV hemorrhage without a shunt, 143 of 295 (48%) had an MDI less than 70, compared with 87 of 115 (76%) of those requiring a shunt. Infants with shunts were at increased risk for cerebral palsy

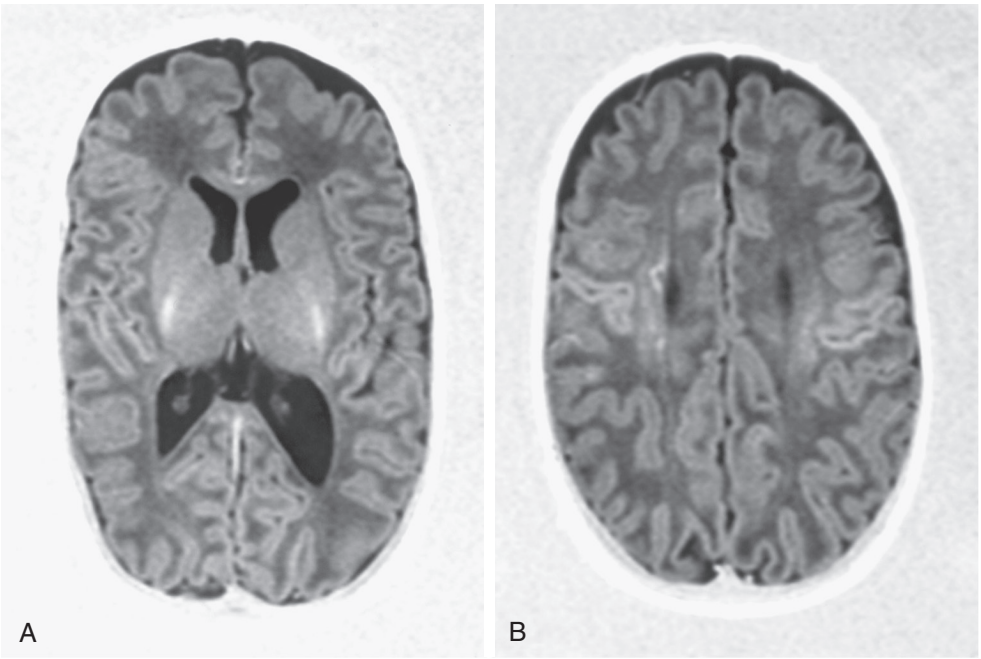
and head circumference at less than the 10th percentile at 18 months' adjusted age. Infants with a grade III hemorrhage without apparent associated white matter involvement are more likely to do well or may develop diplegia, whereas those with a periventricular hemorrhagic infarction are more at risk of developing hemiplegia, depending on the site and extent of the lesion.

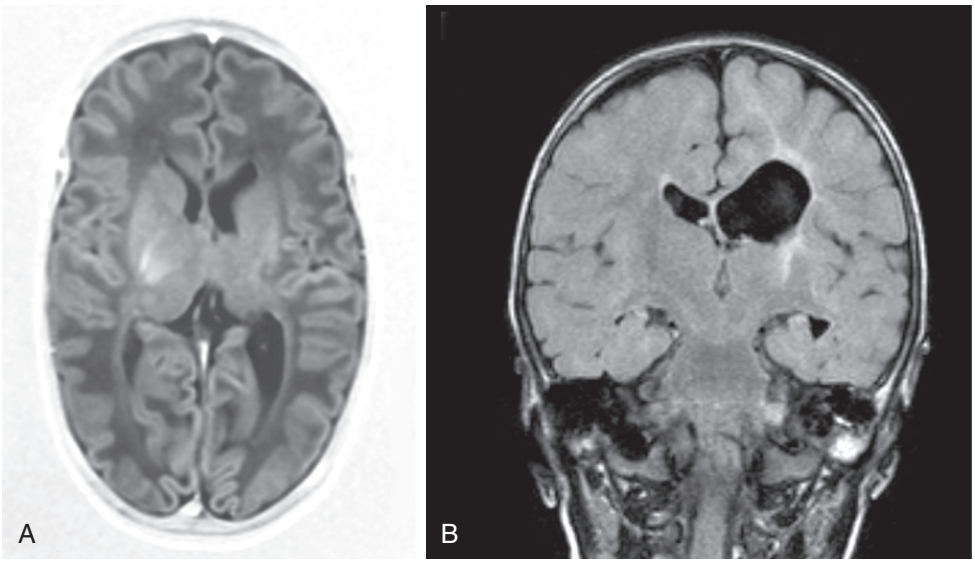
In a study by Goldstein et al.,[38] it was noted that neurodevelopmental impairment differed by gestational age in infants with a grade III hemorrhage, but not with grade IV hemorrhage. Contributors to neurodevelopmental impairment in infants with a severe hemorrhage included male gender, surgical necrotizing enterocolitis, and posthemorrhagic ventricular dilatation requiring a shunt.



Early prediction of development of a hemiplegia is now possible with use of neonatal MRI. At term, myelination of the posterior limb of the internal capsule should be present (Fig. 53.6). In infants in whom hemiplegia subsequently developed, asymmetry and even lack of myelination of the posterior limb of the internal capsule were noted (Fig. 53.7).[24] Using DTI, visualization of the tracts is also possible at an earlier stage.[101]

Outcome data from preterm infants with cerebellar hemorrhage have caused some concern.[68] Neurologic abnormalities were present in 66% of infants with isolated cerebellar hemorrhage compared with 5% of the control group. Compared with controls, infants with isolated cerebellar hemorrhagic injury had significantly lower mean scores on all tested measures performed at a median age of 32 months, including severe motor disabilities (48% versus 0%), expressive language (42% versus 0%), delayed receptive language (37% versus 0%), and cognitive deficits (40% versus 0%). The study concluded that cerebellar hemorrhagic injury in preterm infants is associated with a high prevalence of long-term pervasive neurodevelopmental disabilities. Outcome of infants who had small and punctate lesions in the cerebellum, which can only be recognized on MRI, appears not to be abnormal, at least during the preschool period.[49a,115]

Prevention



Both prenatal and postnatal pharmacologic prophylaxis have been used to reduce the incidence of GMH-IVH. With improvement in general neonatal care, a reduction has also been reported in many large neonatal units without the use of any drugs. Neonatal intensive care unit (NICU) characteristics were shown to affect the incidence of severe GMH-IVH, with NICUs with high patient volume and high neonatologist-to-staff ratio having a lower rate of severe GMH-IVH.[114]

The most promising specific prophylactic drugs are antenatal steroids. A systematic review published in 2017 involving more than 6000 babies showed a significant reduction in the risk for GMH-IVH, as diagnosed by ultrasonography (RR 0.55; 95% CI 0.40-0.76). There was no clear benefit toward improved long-term neurologic outcome (RR 0.64; 95% CI 0.14-2.98).[98] It is not certain whether the effect is mainly due to increased lung maturation and, therefore, less severe RDS, stabilization of postnatal blood pressure, or perhaps a direct protective effect on the brain. Betamethasone instead of dexamethasone is recommended because

• **Fig. 53.6 A,** Magnetic resonance imaging (MRI) scan, T1-weighted sequence, at term age, in same infant as in Fig. 53.2. A symmetric high signal at the level of the posterior limb of the internal capsule is seen. **B,** At a higher level, a small triangular area of high signal intensity is still seen as a sequel of the parenchymal hemorrhage.

• **Fig. 53.7** Magnetic resonance imaging (MRI) scan, T1-weighted sequence, at term age, in same infant as in Fig. 53.3. **A,** There is no symmetric high signal at the level of the posterior limb of the internal capsule. **B,** A fluid-attenuated inversion recovery (FLAIR) sequence at age 18 months shows high signal intensity suggestive of gliosis adjacent to the porencephalic cyst and across the internal capsule.

dexamethasone has been associated with an increased incidence of PVL. However, a more recent Cochrane review showed a reduced risk of IVH when dexamethasone rather than betamethasone was used (RR 0.44; 95% CI 0.21-0.92; 4 trials, 549 infants).[12]

Antenatal phenobarbital was shown to be protective in some but not all studies. The quality of some of these studies was not good because of lack of randomization or a placebo group. When these studies were excluded from a systematic review, no protective effect could be shown.[17]

Studies of antenatal administration of magnesium sulfate have yielded different results. A systematic review published in 2009 involving over 6000 babies substantially reduced the risk of cerebral palsy (RR 0.68; 95% CI 0.54-0). The number of women needed to be treated to benefit one baby by preventing cerebral palsy is 63 (95% CI 43-87).[27] In a multicenter RCT, no significant reduction was found for the incidence of a large GMH-IVH (2.1% versus 3.2 %; RR 0.64; 95% CI 0.38-1.06). Moderate or severe cerebral palsy occurred significantly less frequently in the magnesium sulfate group compared with the control group (1.9% versus 3.5%; RR 0.55; 95% CI 0.32-0.95).[100]

Maternal vitamin K administration was associated with a nonsignificant reduction in the overall rate of GMH-IVH (RR 0.76; 95% CI 0.54-1.06) and a significant reduction in severe GMH-IVH (grades 3 and 4) (RR 0.58; 95% CI 0.37-0.91).[18] Phenobarbital was the first drug used postnatally in the prevention of GMH-IVH. Although the first studies were promising, a meta-analysis of 12 trials was unable to show a reduction in either all GM-IVH (typical RR 0.91; 95% CI 0.77-1.08), or severe IVH (typical RR 0.77; 95% CI 0.58-1.04).[107]

Indomethacin has been the most promising prophylactic drug administered postnatally. The results of a meta-analysis involving 19 trials and a total of 2872 infants showed a significant reduction in the incidence of grades III and IV hemorrhage (pooled RR 0.66; 95% CI 0.53-0.82).[33] The children of the original cohort were assessed at 8 years of age, and no effect of indomethacin on long-term outcome was seen.[126] Analysis of the original cohort by gender, however, showed that indomethacin reduced the incidence of IVH by half, eliminated parenchymal hemorrhage, and was associated with higher verbal scores at ages 3-8 years in boys.[77] A meta-analysis of ibuprofen involving 33 studies did not show a reduction in the incidence of IVH in a subgroup of 571 infants (typical RR 1.21; 95% CI 0.74-1.98).[89]

Other Hemorrhages

Subdural and subarachnoid hemorrhages are probably underdiagnosed because they are difficult to recognize with use of cranial ultrasonography (see also Chapter 29). Clinical signs may be mild or absent. A significant subdural hemorrhage is most often related to birth trauma, but a small subdural hemorrhage was noted to be a common occurrence in an MRI study looking at 111 consecutive full-term infants.[132] A subdural hemorrhage occurred in nine infants—after a normal vaginal delivery in three (6.1%), after forceps-assisted delivery after an attempted ventouse delivery in five (27.8%), and after traumatic ventouse delivery in one (7.7%). Similar results were found on MRI in another study on 88 neonates with a mean age of 21 days). Sixteen infants had subdural hemorrhage, two subarachnoid hemorrhage, and six parenchymal hemorrhage. All neonates had been delivered vaginally, with a rate of intracranial hemorrhage of 26%. In this group, no association was seen with traumatic or assisted birth compared with uncomplicated vaginal births, and in all cases, the infants were

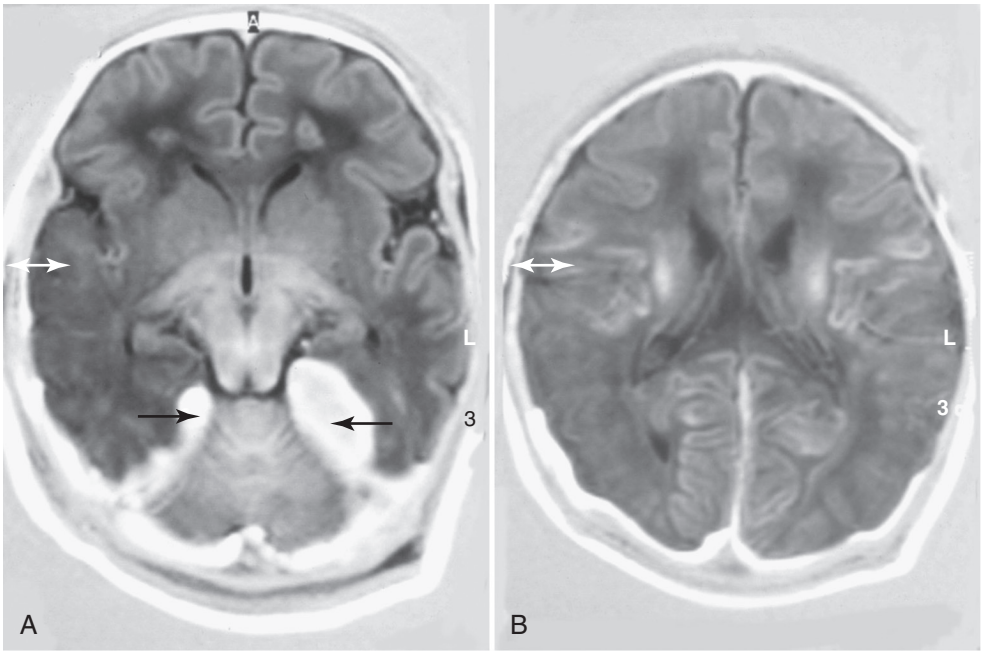
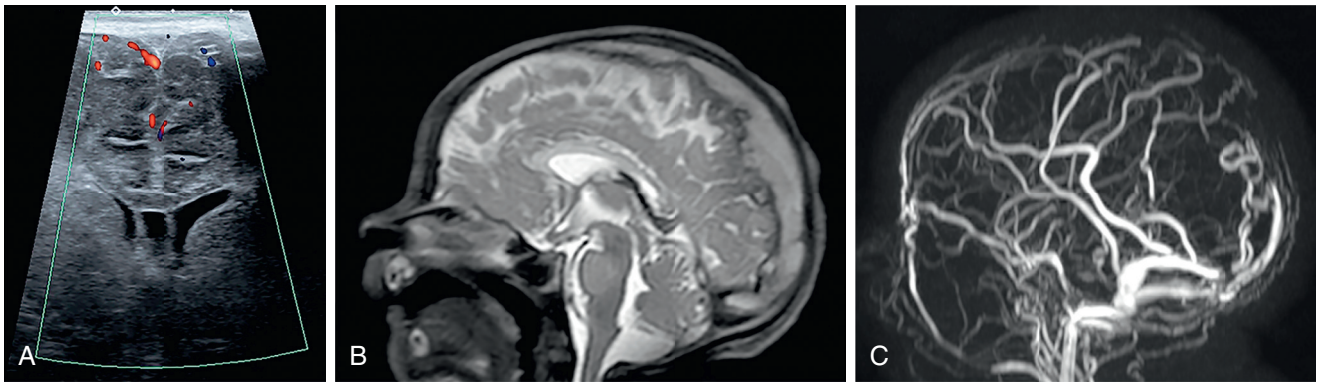
asymptomatic.[71] Underlying mechanisms can be tearing of the dura, occipital diastasis, or rupture of the bridging veins. Tearing of the dura can occur after a precipitous delivery or from use of instrumentation, both of which are not very common with preterm delivery. A dural tear results in extensive bleeding from the adjacent sinus. Occipital diastasis can occur during a vaginal breech delivery with excessive extension of the neck of the infant, although vaginal breech deliveries are not commonly performed on the basis of the results of several multicenter, randomized studies.[48] Rupture of the bridging veins is the most common etiology of subdural hemorrhage and may be seen in association with subarachnoid hemorrhage. Children are usually born at term and present with a full fontanel, lethargy, apnea, or seizures. In cases of severe hemorrhage, a midline shift may be seen, and surgery needs to be considered. Percutaneous needle aspiration of the subdural hematoma may be attempted, and a study showed that it was successful in five of seven infants and recommended it as the treatment of choice.[125] This was confirmed in another study, with successful intervention in eight infants.[14a] The diagnosis usually is made by using CT or MRI (Fig. 53.8). Hydrocephalus can develop from outflow obstruction and may require temporary external drainage, sometimes followed by permanent drainage.



Small subarachnoid hemorrhages, which are usually asymptomatic, are sometimes seen in preterm infants at postmortem examination. Blood can leak into the subarachnoid space after IVH by flowing through the aqueduct into the fourth ventricle and subsequently through the foramina of Luschka and Magendie into the subarachnoid space. Once again, the diagnosis is hard to make with ultrasonography unless the lesion is large and causes compression of brain tissue. Hydrocephalus is less commonly seen than in children with a subdural hemorrhage.

Cerebral Artery Infarction

Because of increased access to neonatal MRI, infarction of a major artery, or a branch arising from it, is better recognized. This condition is often referred to as *neonatal stroke* or *perinatal arterial ischemic stroke*.[59,95] Information about incidence is becoming available with the introduction of neonatal registries.[58] Newborn infants are susceptible to neonatal stroke because of a number of factors present around the time of delivery, such as the hypercoagulable state of the mother, mechanical stress during delivery, the transient right-to-left intracardiac shunt, and the risk of dehydration during the first few days after delivery often associated with a high hematocrit and blood viscosity[58,123] In another study, male gender (OR 2.8), family history of seizures (OR 6.5) or neurologic diseases (OR 4.9), and 1 or greater (OR 5.8) and 2 or greater (OR 21.8) intrapartum complications were independently associated with neonatal stroke.[75] Neonatal stroke can be classified into sinovenous thrombosis and arterial ischemic stroke.[22] Both conditions are still not always detected because presenting symptoms may not always be clear and appropriate imaging is not always performed. Arteriovenous malformations are discussed in Chapter 76.



Sinovenous Thrombosis

An incidence of 41 per 100,000 newborn infants with sinovenous thrombosis was found in the Canadian Pediatric

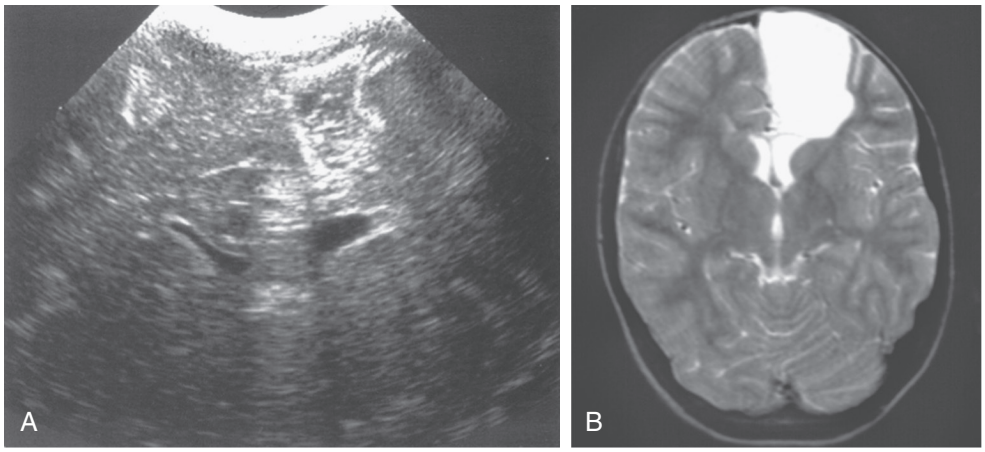
• **Fig. 53.9** Magnetic resonance imaging (MRI) scans obtained at age 12 days, after development of seizures on day 9. **A,** Doppler ultrasound does not show any flow in the superior sagittal sinus. **B,** On the midsagittal T2-weighted sequence, a large thrombus is seen at the level of the superior sagittal sinus. **C,** Magnetic resonance venography image shows loss of flow at the level of the superior sagittal sinus and straight sinus.

Ischemic Stroke Registry but was higher in a population-based study performed in the Netherlands.[7,22] Most cases (66%) come to medical attention within 48 hours of birth, although symptoms can also develop 10-14 days after delivery, sometimes associated with dehydration or infection.[7,85] Almost half the children (43%) with sinovenous thrombosis in this registry were newborns. Seizures are the most common presenting symptom and were reported in 70% of the infants from the Canadian Registry. Lethargy is also commonly present. The fontanel may be full, and the scalp veins may be prominent.

During the birth process, molding of the skull and overriding of the sutures of the different parts of the skull may occur and affect the underlying sinus, resulting in the occurrence of sinovenous thrombosis. Perinatal asphyxia is a commonly associated risk factor, as reported in 24% of the cases in the Canadian Registry. The superior sagittal sinus and the lateral sinuses are most commonly involved, but in the study by Berfelo et al.,[7] the straight sinus was most commonly affected, and an associated thalamic hemorrhage was common. Involvement of the straight sinus, the vein of Galen, and the internal cerebral vein has also been reported. The occurrence of associated IVH, especially a unilateral thalamic hemorrhage or periventricular congestion, may help clarify the diagnosis.[56,136] Wu et al.[136] noted that sinovenous thrombosis was significantly more common in full-term infants with IVH and unilateral thalamic hemorrhage (4 of 5) compared with newborns with IVH only (5 of 21). They strongly recommend the diagnosis of sinovenous thrombosis be considered in any full-term neonate presenting with IVH.

Risk factors for cerebral sinovenous thrombosis during the first 28 days of life include dehydration, infection, maternal fever/chorioamnionitis, hypoxic–ischemic injury, and thrombophilia.[7,119] In another study, risk factors were analyzed in 30 full-term infants with sinovenous thrombosis.[137] They reported that 29% of these newborn infants had been on extracorporeal membrane oxygenation and that 23% had congenital heart disease. Only seven infants were tested for a genetic thrombophilia, and four of these seven were found to be positive.



A diagnosis can be made by using Doppler flow ultrasonography, which may demonstrate absent or decreased flow in the affected sinus.[81] Contrast-enhanced CT can also be used and shows the so-called empty delta sign—the lack of contrast filling. The best modality is MRI, especially magnetic resonance venography, which helps make a definitive diagnosis by demonstrating a reduction or absence of venous flow in the affected venous sinus (Fig. 53.9).

There is no agreement about the use of antithrombotic therapy in this age group, even though recommendations in favor of its use have been made recently. Studies show that regional practices with regard to antithrombotic therapy show considerable variability.[52] Different treatment policies were noted, with physicians in the United States being less likely to treat neonates with cerebral sinovenous thrombosis with antithrombotic medications compared with physicians at centers in other countries—25% of these neonates being treated in the United States versus 69% in other countries.[52] About 25% of the infants show propagation of the thrombus.[85] Whether early anticoagulation therapy in those with involvement of the straight sinus may prevent development of a thalamic hemorrhage still needs to be assessed, but the use of antithrombotic therapy was shown to be safe in a study from the Netherlands.[7] Development of electrical status epilepticus during sleep is not uncommon after associated thalamic hemorrhage.[55] The number of infants with cerebral sinovenous thrombosis is limited; therefore enrollment in many centers will be required to be able to conduct a randomized study.

Greater than 90% of newborns with sinovenous thrombosis survive, with 48%-61% of survivors having moderate to severe disabilities and 9% experiencing a recurrence of cerebral or systemic thrombosis.[7,85]

In the retrospective study by Fitzgerald et al. who assessed 42 newborn infants, 57% presented with seizures and 60% had associated parenchymal infarcts, which were mainly hemorrhagic.[31] Of these 42 infants, 79% had any

form of impairment, with 59% having cognitive impairment, 67% cerebral palsy, and 41% epilepsy. Infarction was associated with the presence of later impairment.

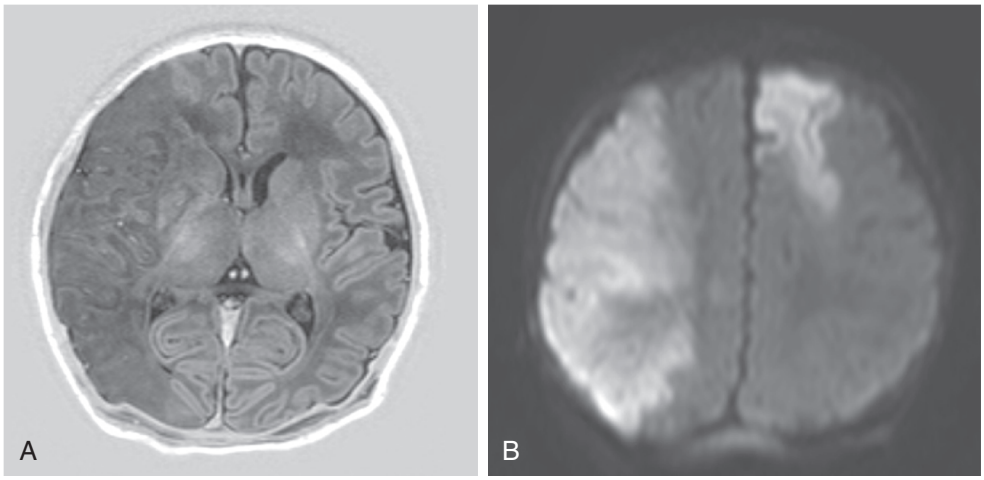
Perinatal Arterial Ischemic Stroke

Cerebral infarction in the neonate has been defined as a severe disorganization or even complete disruption of both gray matter and white matter caused by embolic, thrombotic, or ischemic events.[61,95] In infants dying in the acute stage of the condition, the hemisphere is swollen and deeply congested. There is involvement of both white matter and the cortex, with secondary hemorrhagic infarction in some cases. In infants who survive for longer, contraction of the affected area is seen with softening and multiple cystic degeneration, giving a honeycomb appearance on sectioning. It is recommended that a distinction be made between a unilateral parenchymal hemorrhage, which usually occurs in the preterm infant and evolves into a porencephalic cyst, and an infarct in the region of the middle cerebral artery, which usually occurs in a term newborn and evolves into an area of parenchymal cavitation. A porencephalic cyst occurring after parenchymal hemorrhage of antenatal onset has, however, been referred to as *fetal stroke*, and small porencephalic cysts occurring after antenatal venous infarction have also been included within the spectrum of presumed perinatal stroke.[60]

Lesions involving the left hemisphere are three to four times more common than those of the right hemisphere. This may be the result of hemodynamic differences early after birth in association with the patent ductus arteriosus or a preferential flow across the left common carotid artery. Middle cerebral artery infarction occurs twice as often as involvement of any other artery.[58]

A classification system based on the main artery involved can be used. Infarcts in the territory of the middle cerebral artery were further subdivided into main branch, cortical branch, and lenticulostriate branch infarction.

Incidence



In the Canadian Registry, the incidence of perinatal arterial ischemic stroke was as high as 93 per 100,000 newborn infants, which is much higher than reported previously. Neonatal stroke is the second most common cause of neonatal seizures. Data about focal infarction in preterm infants are scarce. In a hospital-based study, an incidence of 7 per 1,000 was found in preterm infants with gestational age less than 35 weeks.[6]

Seizures are the most common presenting symptom.[58] They are usually of the focal clonic variety, but multifocal tonic or subtle seizures also may be seen (see Chapter 55). Many of the infants show no major clinical neurologic abnormality between seizures. The largest population reported, to date, is that of 248 infants, of whom 72% presented with seizures, which were focal in almost all,[58] and 26% were admitted because of respiratory problems.[58] Symptoms can be very subtle, especially in the preterm infant,[6,29] and the diagnosis can be easily missed. Presentation with a hand preference later in infancy may lead to a diagnosis, with an area of cavitation on CT or MRI suggestive of a perinatal or in utero arterial ischemic stroke, which is now referred to as *presumed perinatal stroke*.[60]

Diagnosis

When a newborn without an obvious history of perinatal asphyxia presents with focal seizures, care should be taken to not miss the diagnosis of arterial ischemic stroke. The middle cerebral artery is most commonly involved, and the infarct occurs more often on the left than the right side.[58] Arterial infarcts of the anterior and posterior cerebral artery are less often diagnosed, possibly because of the lack of clinical symptoms in the neonatal period[121] (Fig. 53.10). Involvement of the smaller branches of the middle cerebral artery is more often seen in preterm infants, whereas obstruction of the main branch is less common in this age group.[6,29] Infarcts can be hemorrhagic

• **Fig. 53.11** Full-term infant, magnetic resonance imaging (MRI) scans obtained at age 4 days. **A,** T1-weighted sequence shows low signal intensity in the distribution of the right middle cerebral artery suggestive of main branch involvement. **B,** Diffusion-weighted imaging scan shows high signal intensity in the same area, as well as a smaller area of high signal intensity in the distribution of the left anterior cerebral artery.

in 20%, and bilateral infarcts can be seen in 10%-15% (Fig. 53.11).

In the absence of abnormalities on ultrasonography, MRI is recommended to confirm or exclude the diagnosis. Ultrasonography has not been considered reliable in making a diagnosis; this applies especially when the examination is made soon after the clinical presentation. By the end of the first week of life, a wedge-shaped area of echogenicity, often with a linear demarcation line, restricted to the territory of one of the main arteries, usually becomes apparent.[16] Cystic evolution can take place over the next 4-6 weeks, often associated with ex vacuo dilation of the ipsilateral lateral ventricle. Doppler ultrasonography can show asymmetry of arterial pulsations. Decreased pulsations on the affected side can be seen in the acute phase, whereas an increase in size and number of visible vessels in the periphery of the infarct and increased mean blood flow velocity in vessels supplying or draining the infarcted areas is often seen a few days later, and this is considered to result from luxury perfusion.

The threshold for performing MRI should be low in infants presenting with neonatal seizures.[129] The use of MRI plays an important role in making the diagnosis. If performed early after clinical presentation, diffusion-weighted imaging (DWI) is very helpful. This technique reveals abnormalities, indicating cytotoxic edema, at a very early stage, preceding abnormalities seen on conventional MRI. This technique also enables visualization of acute damage to the corticospinal tracts at the level of the midbrain.[61] Several studies have shown that these findings predict Wallerian degeneration and development of subsequent hemiplegia.[61] A repeat scan can show asymmetry at the level of the mesencephalon, which can be seen as early as 4-6 weeks after onset of the infarction and is referred to as *Wallerian degeneration*. Magnetic resonance angiography, which allows for investigation of the main vascular bed, can be used and can sometimes show dissection or occlusion of one of the main vessels. This may be rare, however, and this technique may also fail to show small vessel occlusion. Early assessment of structure–function relationship is possible with use of functional MRI. EEG showing focal electrographic and electroclinical seizures with ipsilateral suppression of the background activity and focal sharp waves are strongly suggestive of the presence of perinatal stroke.[72] Mercuri et al.[80] found an abnormal background pattern, even when recorded on two-channel EEG, to be the best early predictor of an adverse neurologic outcome.

Reorganization of the somatosensory cortex can be followed using a combination of transcranial magnetic stimulation and functional MRI.[30,37,110,122] Staudt et al.[110] showed that when a lesion abolishes the normal contralateral corticospinal control over the paretic hand, the contralesional hemisphere develops (or maintains) fast-conducting ipsilateral corticospinal pathways to the paretic hand. This reorganization with ipsilateral corticospinal tracts can mediate useful hand function. Normal hand function, however, seemed only possible with preserved crossed corticospinal projections from the contralateral hemisphere. Ipsilesional reorganization is less effective in the restoration of good motor function as opposed to contralesional reorganization.

Risk Factors

Perinatal complications have been reported in more than 50% of newborn infants who had suffered a perinatal stroke.[43,58,75] Perinatal stroke is multifactorial in origin, and when risk factors were compared with those in infants with neonatal encephalopathy, many were present in both groups; and cardiotocography results were abnormal in 67% of those with perinatal stroke and 77.5% of the infants with neonatal encephalopathy.[75] Stroke among infants admitted with neonatal encephalopathy is an uncommon

observation. Cardiac disease, extracorporeal membrane oxygenation, and portal vein thrombosis have all been reported as associated risk factors. Stroke was especially common (31%) among infants with transposition of the great arteries, and this was associated with balloon septostomy.[82] Maternal cocaine abuse has also been considered as a cause of perinatal stroke. An underlying genetic prothrombotic disorder is not considered likely, and extensive investigations should not be routinely performed.[19] Population-based studies using case-matched controls found diverse etiologic factors responsible for perinatal arterial stroke in term infants. Infertility, preeclampsia, prolonged rupture of membranes, chorioamnionitis, and hypoglycemia have been identified as independent maternal risk factors.[43] A recurrence risk of 1.2% was reported among 84 newborn infants with perinatal stroke.[34] Association with elevated maternal antiphospholipid antibodies (anticardiolipin antibodies, lupus anticoagulants) has also been reported. Data on risk factors in preterm infants are scarce.[6,29] Using case-matched controls (three controls per case, matched for gestational age), etiologic factors responsible for perinatal arterial stroke in preterm infants were studied, and it was noted that these were different from those in infants born at term. Twin–twin transfusion syndrome (19% versus 3%; OR 31.2; 95% CI 2.9-340.0; $P = 0.005$), fetal heart rate abnormality (58% versus 26%; OR 5.2; 95% CI 1.5-17.6; $P = 0.008$), and hypoglycemia (42% versus 18%; OR 3.9; 95% CI 1.2-12.6; $P = 0.02$) were identified as independent risk factors for preterm stroke.[6]

Prognosis

The outlook in most cases is relatively good. Published follow-up data from case reports suggest that the majority of the infants achieve independent walking before 13 months and that more than half of all infants surviving neonatal stroke are found to be doing well at age 12-18 months.[39,120] Spastic hemiplegia is the most important sequela, particularly after infarction of the main branch of the middle cerebral artery. There is an increased incidence among male infants. In a cohort studied by Mercuri et al., hemiplegia developed in only 5 of 24 infants (20%). Hemiplegia or asymmetric tone tended to develop only in those cases with involvement of the hemisphere, basal ganglia, and internal capsule on the first scan. At school age, 30% showed a hemiplegia, and another 30% showed some neuromotor abnormality. Involvement of the internal capsule was always associated with some motor disturbance.[79] The overall prevalence of cerebral palsy is approximately 1 in 2,000 children. On the basis of the estimated incidence of perinatal cerebral vascular infarction, it might be expected that this condition is the cause of the neurologic deficit in up to 20% of children with cerebral palsy. This is supported by data showing that 22% of 377 infants with cerebral palsy showed focal arterial infarction on head imaging.[135]

Two thirds of children with hemiplegia are of normal intelligence when seen at a young age. Deficits in higher-level cognitive skills may first become apparent during school, and this is more common in males, with development of epilepsy and involvement of the central gray nuclei.[87,131] Homonymous hemianopia may follow posterior cerebral artery infarction.[121]

Outcome data depend very much on the threshold for performing MRI, on the artery involved, and on whether the main branch is involved or only a cortical branch or one of the lenticulostriate branches.[127a]

Several groups have now shown that involvement of the lenticulostriate branches was more common in preterm infants.[6,29] Only three of 16 infants with involvement of a cortical branch or one or more lenticulostriate branches had cerebral palsy, in contrast to all five survivors with main branch involvement.[6]

Seizures are a common complication and occur beyond the neonatal period in 25%-67% of affected infants.[40] An infarct on prenatal ultrasonography and a family history of epilepsy were significantly associated with post-neonatal epilepsy in the univariate analysis. Because epilepsy may first develop later in childhood, the rate of epilepsy will be higher when follow-up is longer. In a recent study, the mean follow-up was 8 years and 5 months, and 16.4% of the patients developed post-neonatal epilepsy. The mean age at first post-neonatal seizure was 4 years and 2 months (range 1-10 years and 6 months).[113]

Even though the focus is often on motor outcome, other outcome parameters are also important and in a national cohort study, language was impaired in almost half (49%) of the children. Cerebral palsy, low academic skills, active epilepsy, and global intellectual deficiency were present in 32%, 28%, 11%, and 8%, respectively. Eventually, 59% of children were affected by at least one of the aforementioned conditions.[13]

Key Points

- Germinal matrix hemorrhage–intraventricular hemorrhage (GMH-IVH) is still a common problem in the extremely preterm infant.
- Posthemorrhagic ventricular dilation (PHVD) is an important complication of especially large IVH.
- Data are accumulating to suggest that PHVD should be treated prior to the onset of clinical symptoms.
- *Cerebral venous sinus thrombosis* should be suspected when an IVH with or without a thalamic hemorrhage is seen in a full-term infant.
- Perinatal arterial ischemic stroke occurs in about one in 2,300 full-term infants and usually presents with (hemi) convulsions.

Hypoxic–Ischemic Encephalopathy

FLORIS GROENENDAAL AND LINDA S. DE VRIES

Hypoxic–ischemic encephalopathy (HIE) following severe perinatal asphyxia (also referred to in the literature as *perinatal hypoxia–ischemia* or *asphyxia neonatorum*) has an incidence of 1-2 per 1,000 live births in the Western world and is far more common in developing countries (see Chapter 8). Although metabolic disorders may mimic perinatal asphyxia, and genetic and placental factors may contribute to the clinical picture, brain imaging techniques have demonstrated acute changes in the brain of the term neonate after perinatal asphyxia occurs.

The chance of irreversible damage or death after severe perinatal asphyxia is high—up to 65% of patients enrolled in trials of neuroprotective strategies. Therapeutic hypothermia is neuroprotective, as has been demonstrated in several trials, and is standard therapy for (near-) term neonates with severe perinatal asphyxia and encephalopathy.[33] Ongoing studies will aim at additive strategies to augment the neuroprotection of hypothermia.[26]

Experiments in animals have demonstrated that the immature brain is more resistant to hypoxia–ischemia than the brain of the term neonate. The several reasons to explain this difference are a lower cerebral metabolic rate; lower sensitivity to neurotransmitters with potential neurotoxicity; and the greater plasticity of the immature central nervous system. Nevertheless, in the fetus and in the preterm neonate, cerebral hypoxia–ischemia is a major cause of acute mortality and, in survivors, morbidity. However, the neuropathology will be different from that of the full-term neonate (see Chapters 52 and 54).

Definitions

Hypoxic–Ischemic Encephalopathy

The term *HIE* describes abnormal neurologic behavior in the neonatal period after perinatal hypoxia–ischemia occurs. Previously, the term *post-asphyxial encephalopathy* was used, and some suggest that the term *neonatal encephalopathy* is best used because the cause of encephalopathy is not always obvious. This has also been suggested by the American College of Obstetricians and Gynecologists' Task Force on Neonatal Encephalopathy.[18]

The severity of HIE can be defined as mild, moderate, or severe, depending on clinical findings, as described by Sarnat and Sarnat[61]; this classification is widely used and is summarized in Table 54.1. Other clinical scoring systems have been developed to assess the severity of HIE and are used to select infants for therapeutic hypothermia[77] (Table 54.2).

Hypoxia or Anoxia

This denotes a partial (hypoxia) or complete (anoxia) lack of oxygen supply to the brain or blood. Hypoxemia denotes lack of oxygen in blood.

Ischemia

Ischemia refers to reduction (partial) or cessation (total) of blood flow to an organ (e.g., the brain), compromising both oxygen and substrate delivery, such as glucose to the tissue. Global ischemia may occur as a result of reduced cardiac output, as in circulatory failure. Focal brain ischemia, or ischemic stroke, has been demonstrated more commonly during the last decade in both term and preterm neonates with the increased use of cranial magnetic resonance imaging (MRI), which is a sensitive technique to demonstrate stroke.

Perinatal Asphyxia

The term *asphyxia*, from the Greek word for suffocation, is used to describe the interrupted supply of oxygen through the placenta and umbilical cord to the fetus, leading to combined hypoxemia and hypercapnia. In case of total interruption of oxygen, within minutes, anaerobic glycolysis will occur and lactic acidosis, and thereby metabolic acidosis, will be produced. This can be measured by blood gas analysis. In addition, (fetal) bradycardia will develop and will add ischemia to the process and augment cerebral hypoxia and hypercapnia.

Pathophysiology

Systemic Adaptation to Hypoxic–Ischemic Insult

Severe fetal hypoxic–ischemic injury affects the entire organism, and these effects have been well studied in animal

models. In particular studies, instrumented fetal sheep and monkeys in the 1960s and 1970s have been used to describe the physiologic and pathologic changes in the brain after hypoxia has occurred.[14,47] Hypoxic–ischemic injury may occur at any time during pregnancy, the birth process, or the neonatal period. The pattern of brain damage is reflected by the gestational age of the fetus at the time that the injury occurs. Fetal hypoxic–ischemic injury may result from maternal, uteroplacental, or fetal problems (Box 54.1). The fetus may survive maternal hypoxia–ischemia, such as transient hypoxia or hypotension. Correctable placental factors include hyperstimulation with oxytocic agents or intermittent cord compression, but these may cause irreversible brain damage before recovery occurs.

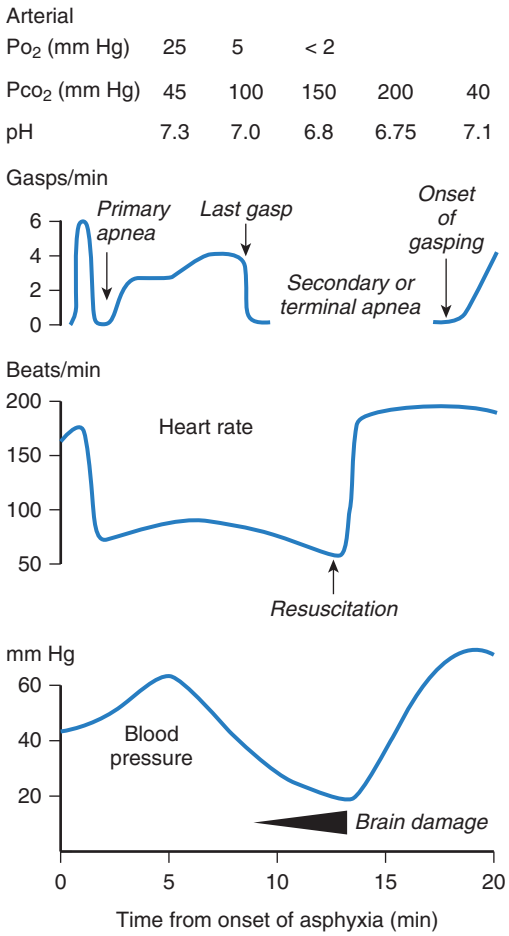
• BOX 54.1 Causes of Fetal Hypoxic–Ischemic Insult

Maternal



- Cardiac arrest
- Asphyxiation
- Severe anaphylactoid reaction
- Status epilepticus
- Hypovolemic shock

Uteroplacental

- Placental abruption
- Cord prolapse
- Uterine rupture
- Hyperstimulation with oxytocic agents

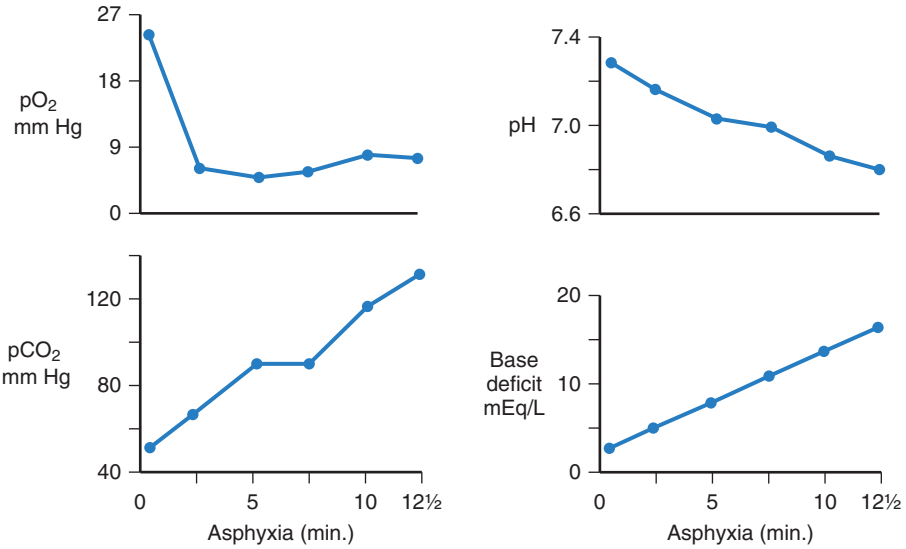
Fetal

- Fetomaternal hemorrhage
- Twin-to-twin transfusion syndrome
- Severe isoimmune hemolytic disease
- Cardiac arrhythmia

• Fig. 54.1 Physiologic responses of rhesus monkeys during asphyxia and on resuscitation. Brain damage was assessed histologically weeks or months after asphyxia. (From Dawes GS, ed. *Foetal and neonatal physiology: a comparative study of the changes at birth*. Chicago: Year Book Medical Publishers, Inc.; 1969.)

Fetuses with brain damage occurring as a result of early in utero hypoxic–ischemic insult do survive, but in the majority of cases, severe maternal hypoxia in the second trimester of pregnancy will result in fetal death. Occasionally, there is a history of a catastrophic maternal illness, such as suffocation, anaphylaxis, or major physical trauma. In other situations, the antecedent pathogenic event is confined to the fetus, sometimes resulting in symmetric thalamic lesions, with or without an associated abnormality of the uteroplacental unit. Whatever the cause of the cerebral hypoxia–ischemia, the neuropathologic consequence is often devastating.

In the more mature fetus, a period of mild to moderate hypoxemia produces a consistent pattern of responses (Fig. 54.1). Initially, there is fetal bradycardia with an immediate rise in blood pressure and, in particular, an increase in perfusion to the brain and other vital organs at the expense of the rest of the body. With ongoing hypoxemia, the fetal heart rate will decrease further, apnea will occur, and permanent brain injury occurs after 10-15 minutes. The fetus is very resistant to milder hypoxemia, and normal cardiovascular function will be maintained for up to an hour even with a partial pressure of oxygen (PaO_2) of 15 mm Hg (normal fetal PaO_2 is 25 mm Hg). With prolonged moderate hypoxia, cerebral perfusion will remain normal, but (asymmetric) fetal growth restriction will occur. In fetuses with such prolonged moderate hypoxia, lactate levels may be elevated, indicating that anaerobic glycolysis has occurred in some tissues. The rapid changes in blood gas values have been documented in numerous experiments (Fig. 54.2).



As the hypoxic insult becomes more severe, changes in regional cerebral blood flow occur. The brainstem is able to extract sufficient oxygen to maintain metabolism despite very low PaO_2 at the expense of the cerebrum. Failing myocardial function may cause a fall in cardiac output, and the watershed areas of the cerebral hemispheres are most exposed to damage (see section on Vascular Territories).

An acute hypoxic–ischemic insult, often referred to as a sentinel event, as may occur during cord prolapse or uterine rupture, is likely to damage the basal ganglia and brainstem, in contrast to the more chronic insult, which leads to damage in the cerebrum (see section on Neuropathology).[47]

Preconditioning

Preconditioning describes reduced sensitivity of the immature brain to injury, depending on whether it has been exposed to previous nondamaging hypoxic events some hours before the main hypoxic–ischemic insult. Preconditioning of immature rat pups by exposure to moderate hypoxia or inflammation before hypoxia–ischemia appears to be neuroprotective. Preconditioning may work through stabilizing hypoxia-inducible factor-1-alpha (HIF-1-alpha) during hypoxia. When dimerized with HIF-1-beta to HIF-1, it acts on hypoxia response elements in the promoter of hypoxia-responsive genes, which will lead to

• **Fig. 54.2** Changes in blood gas values in the term monkey fetus after acute, total asphyxia. (Adapted from Myers RE. Two patterns of perinatal brain damage and their conditions of occurrence. *Am J Obstet Gynecol*. 1972:112:246-276.)

induction of genes encoding erythropoiesis, angiopoiesis, and antiapoptosis.[35]

Perinatal Hypoxic–Ischemic Brain Damage

During the last decades, the processes leading to neuronal death in the neonate have been described in more detail. This knowledge is important when considering neuroprotective strategies (see section on Specific Neuroprotective Strategies).

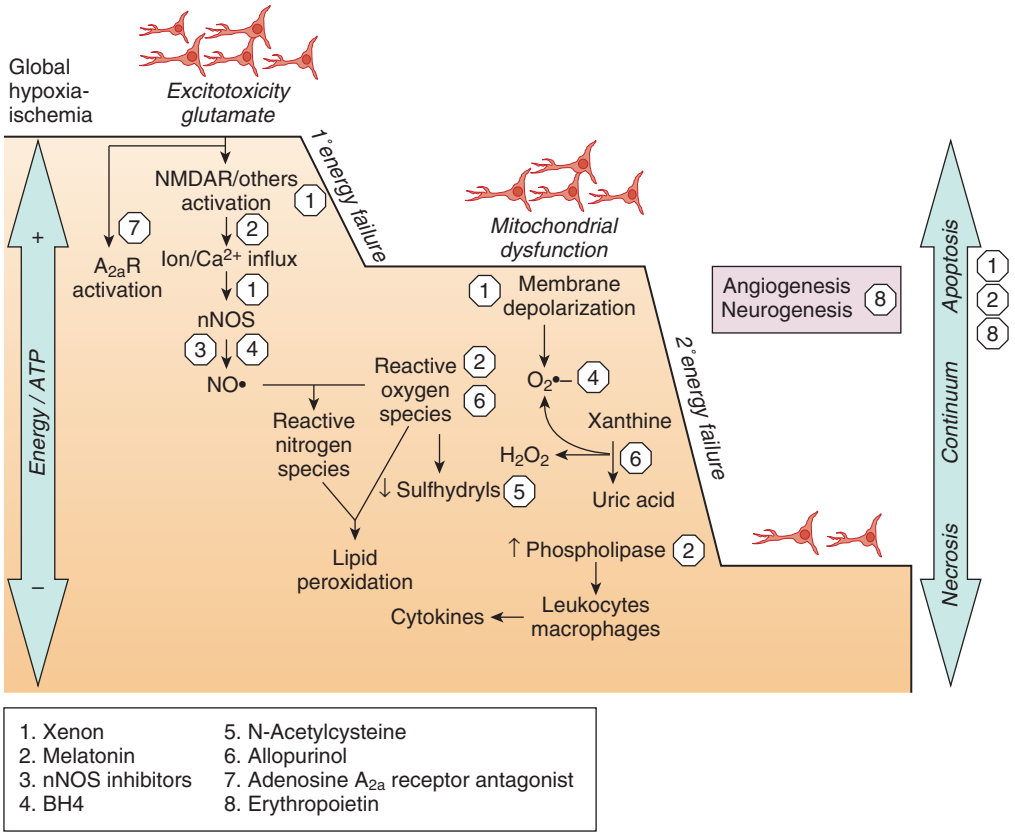
In contrast to adult ischemic stroke, neonatal hypoxia–ischemia is characterized in most cases by a combination of cerebral hypoxia (and ischemia during bradycardia), followed by reperfusion and potential excessive distribution of oxygen. The contribution of reperfusion to cerebral injury is recognized and has led to the restricted use of supplemental oxygen during neonatal resuscitation.[88]

An acute hypoxic–ischemic insult leads to events that can be broadly categorized as early (primary) and delayed (secondary) neuronal death. Previously, two different patterns of cell death were reported in neonates.[52] *Necrosis* is lytic destruction of cells, whereas *apoptosis* is programmed cell death, which is driven by adenosine triphosphate (ATP). More recently, these cell death patterns have been recognized to be in continuum. The final pathway is dependent on tissue circumstances such as oxygen content.

Early or primary neuronal damage occurs as a result of cytotoxic changes caused by failure of the microcirculation, inhibition of energy-producing molecular processes, increasing extracellular acidosis, and failure of Na^+/K^+–adenosine triphosphatase (ATPase) membrane pumps, which result in excessive leakage of Na^+ and Cl^- into the cell with consequent accumulation of intracellular water (cytotoxic edema). Free radical production is also initiated, which further compromises neuronal integrity. If not reversed, these processes lead to neuronal death of the necrotic type within a short time of the acute insult.

Recovery and reperfusion, as occur with resuscitation, fuel the pathways to late (secondary) neuronal damage through a relatively large number of pathophysiologic mechanisms.

It has been demonstrated in experimental settings that secondary energy failure starts within 6-8 hours after the primary insult. The term *energy failure* reflects the fact that high energy phosphates are reduced as can be demonstrated in vivo using phosphorus magnetic resonance spectroscopy (^{31}P-MRS). This technique uses the intrinsic magnetic properties of some atomic nuclei, such as ^{31}P. The peaks described for the ^{31}P spectrum are beta-ATP, alpha-ATP, gamma-ATP, PCr, phosphodiesters, inorganic phosphate (Pi), and phosphomonoesters. Depletion of ATP and an increase in Pi, associated with a change in the PCr/Pi ratio, have been reported using ^{31}P-MRS.[42] Secondary energy failure is a result of changes in mitochondria and may last up to 72 hours or even longer after the acute insult. Timing of moderate hypothermia for neuroprotection is based on this "therapeutic window" of 6 hours before the onset of secondary energy failure.



Secondary Neuronal Death

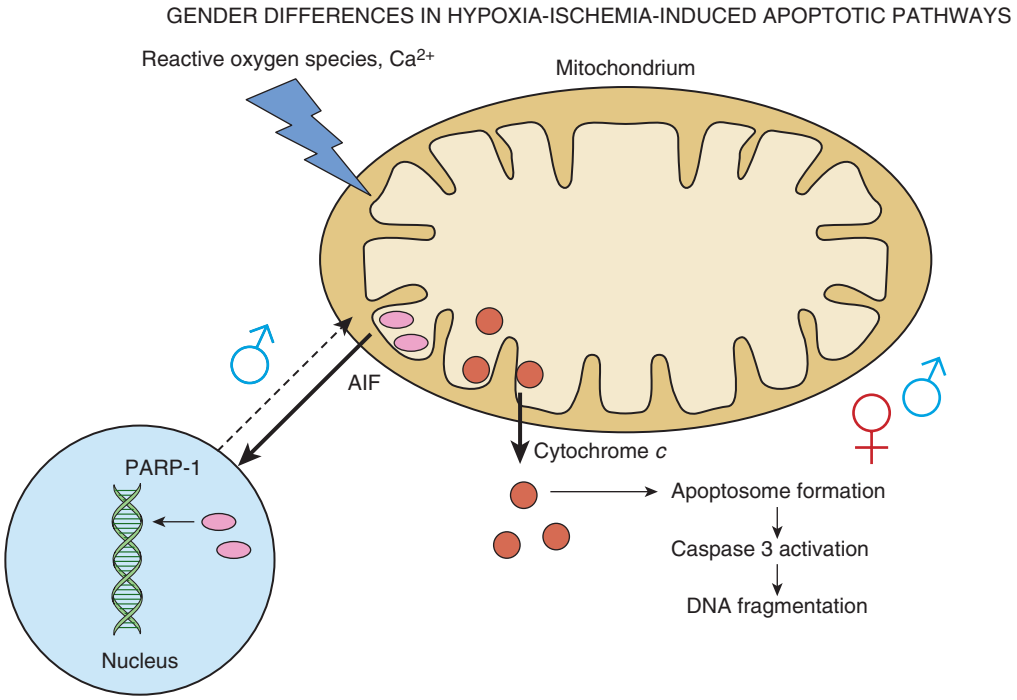
A complicated cascade of intracellular events is triggered by the initial hypoxic–ischemic insult, which results in either cell necrosis or apoptosis (Fig. 54.3).

Glutamate Injury (Excitotoxicity)

Excessive neuroexcitatory activity occurs as a result of the asphyxial event, and this is mediated through glutamate toxicity. Glutamate activates N-methyl-D-aspartate (NMDA)

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

• **Fig. 54.3** Intracellular neurotoxic cascade and potential targets for neuroprotection after hypoxia–ischemia. After global hypoxia–ischemia, glutamate-induced excitotoxicity proceeds via N-methyl-D-aspartate receptor (NMDAR) activation, producing calcium ion (Ca^{2+}) influx and therefore activation of Ca^{2+}-dependent nitric oxide synthase (NOS), particularly neuronal NOS. At high concentrations, $NO^{\bullet}$ reacts with superoxide ($O^{\bullet-}$) to produce peroxynitrite ($ONOO^{-}$), which, in turn, induces lipid peroxidation and mitochondrial nitrosylation. During the acute energy depletion, some cells undergo primary cell death. After reperfusion, the initial hypoxia-induced cytotoxic edema and accumulation of excitatory amino acids typically resolve in 30-60 minutes, with apparent recovery of cerebral oxidative metabolism. Mitochondrial failure is a key step leading to delayed cell death. Potential neuroprotective targets are indicated. (Adapted from Robertson et al. Which neuroprotective agents are ready for bench to bedside translation in the newborn infant? *J Pediatr*. 2012;160:544-552.[58])



receptors, which, in turn, cause calcium channels to open in an unregulated manner with excess entry of intracellular calcium ions (Ca^{2+}). The high concentrations of this ion activate lipases, proteases, endonucleases, and phospholipase C, which, in turn, break down organelle membranes. This sets up a variety of abnormal processes with release of free radicals, including nitric oxide (NO•) and superoxide ions. This has further adverse effects on cell membranes and leads to mitochondrial failure with the release of caspase-3 and eventual DNA fragmentation, poly(ADP-ribose) polymerase, which causes further energy failure of intracellular membrane function. This process also triggers an apoptotic response in the cell.[26] The process of cell death is very different from that seen in adults, requiring specific neonatal animal models in the research of perinatal asphyxia.

Furthermore, cell death pathways differ between male and female rat pups (Fig. 54.4).[57] Some compounds like erythropoietin appear to be more protective in female than in male pups. The relevance of this gender difference for human neonates is not yet established. Clinical trials of erythropoietin for neuroprotection after perinatal asphyxia or stroke are ongoing.[35]

Free Radical Formation

Oxygen free radicals cause peroxidation of unsaturated fatty acids, and because the brain is especially rich in polyunsaturated phospholipids, it is especially susceptible to free radical attack. Mechanisms for quenching and inhibiting free radical production exist within the brain, but in the immature organ these mechanisms may be underdeveloped. Consequently, the human neonatal brain is at particular risk for oxygen free radical–induced injury.[56] Brain arteriole endothelium is the main source of free radical production by the action of xanthine oxidase, but free radicals are also produced by activated neutrophils, microglia, and intraneuronal structures. During reperfusion, free radical production from the arteriolar endothelium results in blood–brain barrier leakage and release of platelet-activating factor, platelet adhesion, and neutrophil accumulation, which may

• **Fig. 54.4** Pathways of apoptosis in neonatal male and female animals. AIF, apoptosis-inducing factor; PARP, poly(ADP-ribose) polymerase. (Courtesy of CHA Nijboer, PhD, Laboratory of Neuroimmunology and Developmental Origins of Disease, University Medical Center, Utrecht, The Netherlands).

contribute to cellular damage. Resuscitation of human neonates with 100% oxygen has led to prolonged changes in oxidized glutathione as a result of excessive production of oxygen free radicals.[88]

A particularly important mechanism that exposes the newborn brain to oxygen free radical attack is the presence of free iron. Non–protein-bound ("free") iron is found in higher concentration in the immature animal because of low transferrin levels. Free iron catalyzes mildly reactive oxygen species to more toxic free radicals through the Fenton reaction. There is evidence that after a hypoxic–ischemic insult, there is an increased presence of intraneuronal free iron within the first 24 hours that persists for several weeks.

The second important mechanism that leads to (nitrogen) free radicals is the production of neuronal-derived NO•.[56] NO• is produced by three isoforms of the enzyme nitric oxide synthase (NOS): designated *neuronal* (nNOS), *endothelial* (eNOS), and *inducible* (iNOS). Production of NO• is accelerated by intracellular Ca^{2+} influx and NO• is neurotoxic in excessive concentrations. It is thought that up to 80% of NMDA toxicity is mediated through NO•. NO• also combines rapidly with superoxide to produce peroxynitrous acid, which gives rise to the free radical peroxynitrite. Excessive NO• can cause DNA strand breaks and induce neuronal apoptosis mediated through caspase-3 activation, and iNOS, produced during inflammatory processes, has also been reported to aggravate injury in the immature brain. However, NO• from endothelial cells (eNOS) is essential in maintaining cerebral perfusion. For neuroprotection, only nNOS- (and iNOS-) specific inhibitors can be used.

Apoptosis

Apoptosis (see Chapter 51), or programmed cell death, is perhaps the most important cause of neuronal death in the neonate following hypoxia–ischemia and resuscitation. It can be distinguished histologically from necrosis by shrinkage of affected cells with retention of the cell membrane. By contrast, necrosis is associated with cell rupture, which induces secondary inflammatory processes. DNA degradation develops in the apoptotic cell, giving a characteristic ladder appearance on gel electrophoresis.

Apoptosis is a gene-regulated process, and both proapoptotic and antiapoptotic genes, including *BCL2*, *Bax*, *APAF1*, and the caspase gene family, influence the process. A major role in the apoptotic mechanism is played by the caspase family of proteins, with caspase-3 identified as the execution protein. Inhibitors of caspase can block apoptosis and attenuate injury.

Apoptotic pathways have been shown to differ between males and females. Apoptosis via an apoptosis inducing factor–dependent pathway was demonstrated in cultured XY neurons, whereas a cytochrome c-dependent pathway was seen in XX neurons.[49,51,57]

Cytokines

There is evidence that some proinflammatory cytokines (tumor necrosis factor-alpha, interleukin [IL]-1-beta, and IL-18) are activated after a hypoxic–ischemic insult in immature experimental animal models, and they may have

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

neurotoxic properties. After hypoxic–ischemic insult, widespread expression of caspase-1 and IL-18 protein in microglia is found. These data suggest that hypoxic–ischemic insult may initiate an inflammatory response in the absence of infection, leading to neuronal injury.

Studies in animals and humans have shown that exposure to infection (gram-negative bacteria or lipopolysaccharide [LPS] in animal models)[82] and chorioamnionitis in pregnant women significantly exacerbate clinical and neuronal injury.[71]

Human Studies

Studies in human neonates have confirmed the presence of secondary energy failure after perinatal asphyxia. ^{31}P-MRS in affected term infants were usually normal within the first 6 hours after birth, suggesting that mitochondrial phosphorylation had initially recovered with resuscitation. After 8 hours, there was a significant decline in the high energy phosphates, such as phosphocreatine and ATP, with a further decline in the most severely affected infants at 48-72 hours. In some infants, recovery occurred to normal values within 7 days. The delayed fall in phosphocreatine/inorganic phosphate (PCr/Pi) ratio represents secondary energy failure.[32]

In addition, proton magnetic resonance spectroscopy (^{1}H-MRS) may show some lactate in the neonatal brain on very early scans, but higher levels of lactate could be demonstrated after 48 hours in most affected infants.[6,38] Studies using near-infrared spectroscopy (NIRS) have shown reduced oxygen uptake, and higher brain oxygen saturations in neonates with perinatal asphyxia, suggesting secondary energy failure.[39] Diffusion weighted imaging (DWI) studies have demonstrated reduced diffusion of water molecules represented as the apparent diffusion coefficient (ADC), suggestive of cytotoxic edema returning to normal ADC values after approximately 1 week. In cystic areas, these ADC values will increase to above-normal values.[1]

Doppler studies of major intracranial arteries demonstrated loss of normal carbon dioxide (CO_2) reactivity with high diastolic blood flow, first seen 12-24 hours after birth.[4] Recently, MRI studies using arterial spin labeling (ASL) have demonstrated higher perfusion values in neonates with HIE and an adverse neurodevelopmental outcome.[15]

Selective Vulnerability

In the human neonate, as well as in animal experiments, different patterns of brain injury following HIE have been demonstrated, depending on the developmental stage of the fetus, and severity and duration of the hypoxic–ischemic insult. The factors influencing brain injury after perinatal hypoxia–ischemia can be summarized as follows:

- Cellular susceptibility
- Maturity
- Vascular territories
- Regional susceptibility
- Type of hypoxic–ischemic insult
- Others, such as genetic predisposition and placental factors

Cellular Susceptibility

In the term neonate, the neuron is the most sensitive cellular element to hypoxic–ischemic insult. In the preterm neonate, neurons as well as precursors of oligodendrocytes are sensitive cell types.

Maturity

Gestational age plays an important role in the changing susceptibility of cerebral structures to hypoxic–ischemic insult for a number of reasons, including rapid changes in neuronal development, changing vascular watersheds, and biochemical variables within cells, such as relative proportions of excitotoxic and inhibitory expression. In addition, a low susceptibility of the immature myocardium compared with that of the term neonate may result in a more preserved cerebral perfusion during hypoxia.

Hypoxic–ischemic insults before 20 weeks' gestational age, as may occur as the result of severe maternal illness, may lead to neuronal heterotopia or polymicrogyria because the insult to the fetal brain occurs during the stage of neuronal migration, which is not complete until 21 weeks of gestation. Insults affecting the brain during midgestation (26-36 weeks) predominantly damage white matter, leading to cystic periventricular leukomalacia, and may have secondary negative effects on growth of the deep gray matter or may increase the risk of intracranial hemorrhage. Primary hypoxic–ischemic injury to the basal ganglia and thalamus in preterm infants has been reported and resulted in a poor outcome. Insults near or at term (35 weeks and beyond) result predominantly in damage to the deep gray matter or the watershed areas of the brain.[73]

Vascular Territories

Watershed injury refers to tissue damage that occurs in regions that are most vulnerable to reduction in cerebral perfusion as the result of having the most tenuous blood supply. These tissues are at the farthest points of arterial anastomoses and are exposed to damage when perfusion pressure falls, usually as the result of impaired cardiac output and low blood pressure. Watershed areas change with advancing development.

In the term brain, a cortical watershed area (the parasagittal region) is present among the three main arteries supplying each hemisphere. Volpe et al. used positron emission tomography (PET) to measure regional cerebral blood flow in 17 full-term newborns who had suffered asphyxia and found a consistent decrease in blood flow to the parasagittal region of both cerebral hemispheres in most of the infants.[89] Modern techniques, such as DWI, have demonstrated these watershed-type lesions in the full-term neonate (see section on Neuroimaging).[13]

The depths of the sulci are also sensitive to hypoxic–ischemic insult as the result of being watershed areas at term. Reduction in perfusion in small vessels at the base of sulci during hypoxia–ischemia leads to columnar necrosis and may lead to ulegyria in the older child's brain.[73]

Ischemic infarction (stroke) has been recognized more commonly with the increased use of MRI in neonates with or even without encephalopathy. Although infarction of a major cerebral artery has been found in neonates with a hypoxic–ischemic insult, thrombosis and embolus, vasospasm, maternal smoking, or hypoglycemia are more common etiologic factors.[28,59] The location of the lesions and neurodevelopmental outcome is dependent on the cerebral artery involved.[89a]

Regional Susceptibility

Some regions of the brain are particularly sensitive to hypoxic–ischemic insult as a result of certain vascular factors, as discussed previously, but high metabolic rates of individual nuclei may predispose them to damage during cerebral hypoxia and hypoperfusion. This may account for the susceptibility of the posterior and lateral thalamic nuclei and lentiform nuclei to damage after acute total asphyxia in the term neonate. Another factor accounting for regional variability to hypoxia–ischemia is the distribution of glutamate excitotoxic receptors. Regional cerebral glucose use has been investigated with PET after perinatal cerebral hypoxia–ischemia. Occipital regions of the brain appear to be particularly vulnerable to hypoglycemia in full-term infants.

Types of Hypoxic–Ischemic Insult

Animal studies on primates have modeled two different patterns of hypoxic–ischemic insult and have shown different patterns of neuronal injury, depending on the type of insult.[47] Acute total asphyxia was produced in fetal monkeys by clamping the umbilical cord and preventing the animal from breathing. This produced injury to the thalamus, brainstem, and spinal cord structures. The longer the duration of the acute insult, the more extensive the damage occurred in these regions. Little damage was reported in higher structures.

The second model attempted to mimic a prolonged, partial asphyxial insult lasting 1-5 hours. This produced damage predominantly in the cerebral hemispheres and particularly in the watershed distribution (see section on Vascular Territories), often with sparing of the brainstem, hippocampus, and temporal and occipital lobes. Damage was also seen, not uncommonly, in the basal ganglia and the cerebellum.

Others

Other types of hypoxic–ischemic insults include maternal fever during labor, which may accelerate fetal brain injury, fetal starvation with reduction in intracerebral glucose availability, sepsis, and twinning. The effects of these factors may act through one or a number of the variables discussed previously.

There has been much debate as to the role of pre-existing antenatal factors in exacerbating intrapartum HIE. Recently, placental changes were seen in full-term neonates with encephalopathy who suffered asphyxia. Chronic villitis was associated with the basal ganglia/thalamus pattern of injury, whereas decreased placental maturation was linked to white matter and watershed injuries.[20,30] Polymorphisms of the *MTHFR* gene were demonstrated more often in neonates with HIE and cerebral lesions of the watershed type.[27]

An MRI study of term infants with hypoxic–ischemic encephalopathy has suggested that the majority of the brain damage present in these infants occurred in the immediate perinatal period and was not the result of long-standing damage. DWI is a technique that visualizes the motion of water molecules. Increased use of DWI in human infants has demonstrated restricted diffusion in cytotoxic edema during the first week after perinatal asphyxia, indicating absence of long-standing injury.[1,7,12]

Neuropathology

The neuropathologic features of hypoxic–ischemic injury vary, depending on the type and duration of the insult and the gestational age of the child at the time of the insult. The pathologic features evident on examination also depend on the interval between the insult and death. The neuropathologic features become more apparent as they develop in a temporal sequence. Some of the more consistent features of hypoxic–ischemic injury are discussed below. Of course, findings on neuropathology are biased by the fact that these neonates have died. Thus, these findings will show different patterns when compared with those on imaging studies, for example, MRI findings, in a cohort of neonates who survived after hypoxic–ischemic encephalopathy. In addition, MRI is less sensitive in detecting cerebral hypoxic–ischemic changes compared with histology.[2]

Cerebral Edema

Brain edema is thought to occur frequently in infants who have sustained a severe cerebral hypoxic–ischemic insult and is widely reported in autopsy studies. Cellular edema develops rapidly and resolves by 7 days after its onset, although imaging cannot reliably detect edema until 24 hours after the event because of the higher water content of the neonatal brain. In primate studies of intrapartum asphyxia, partial intermittent hypoxia–ischemia with marked and prolonged hypoxemia was associated with severe edema in all cases, whereas brain swelling was not a feature of severe, acute, total hypoxic–ischemic insults. If the brain damage has been widespread and severe, on gross examination, the brain appears swollen, with slitlike lateral ventricles, widening and flattening of the cerebral gyri with

associated obliteration of the sulci, and herniation of hippocampal structures. In the most severe cases, herniation of the cerebellar tonsils and vermis through the foramen magnum has been described, but this is seen rarely in clinical practice. Brain edema is seen mainly in the most severe ("near total") pattern of neonatal brain injury after perinatal asphyxia.[13]

Cellular Responses

Different cell lines in the brain react in varying ways to an acute hypoxic–ischemic insult. Neurons may undergo either necrosis or apoptosis (see section on Pathophysiology). The nature of these two mutually exclusive processes can be distinguished to some extent by histologic staining. In necrosis, sections stained with hematoxylin and eosin (H&E) show changes 5-6 hours after the injury. Nuclear membranes degenerate, with release of nuclear chromatin and a secondary inflammatory reaction.

Activated microglia express a number of cytotoxic cytokines. Although microglial cells respond rapidly after a hypoxic–ischemic insult and undertake the function of ingesting and lysing dead tissue, CD68-positive cells, indicating activated microglia and macrophages, were seen not earlier than at least 24 hours after the hypoxic–ischemic insult in a cohort of 22 full-term neonates who died as a result of severe perinatal asphyxia.[25] In this paper, caspase activity could be seen in the brain examined within 24 hours of the hypoxic–ischemic insult. In addition, nitrotyrosine staining, considered the product of NO• toxicity, was present in brain and spinal cord tissues.

Hemoglobin released from damaged red blood cells (RBCs) is mobilized in this way, leaving residual hemosiderin present in the macrophage. Microglial cells present in the dentate gyrus are a reliable indication of previous hypoxic–ischemic insult in infants younger than 9 months of age.

Glial cells respond to hypoxic–ischemic insult by enlarging, proliferating, and later developing fibrillary processes with the expression of glial fibrillary acidic protein, which can be recognized by specific staining. A glial response occurs from 17 weeks of gestation.[73]

Calcification

Deposition of calcium in damaged neurons is commonly seen after hypoxic–ischemic insult and, if extensive enough, may be apparent on brain imaging. Insults other than those caused by hypoxia–ischemia may also cause extensive calcification, including viral infection and certain metabolic disorders.

Chronic Lesions

Cerebral atrophy is the end stage of cellular loss in the brain. Atrophy affects particularly vulnerable areas of the brain (described earlier under section on Selective Vulnerability). Various specific forms of end-stage pathologic lesions have been recognized in the brain for many years.

Status marmoratus describes a patchy, marble-like appearance of the basal ganglia and thalamus that may develop approximately 6 months after a severe perinatal hypoxic–ischemic insult. Histologic study shows abnormal myelination of glial bundles rather than neurons.

Ulegyria refers to a particular form of pathology seen in the depths of the cortical sulci and is probably caused by particular watershed vulnerability (see section on Vascular Territories). The chronic phase of this process produces the appearance of mushroom-like gyri because of loss of the deep gray matter in the sulci.[73]

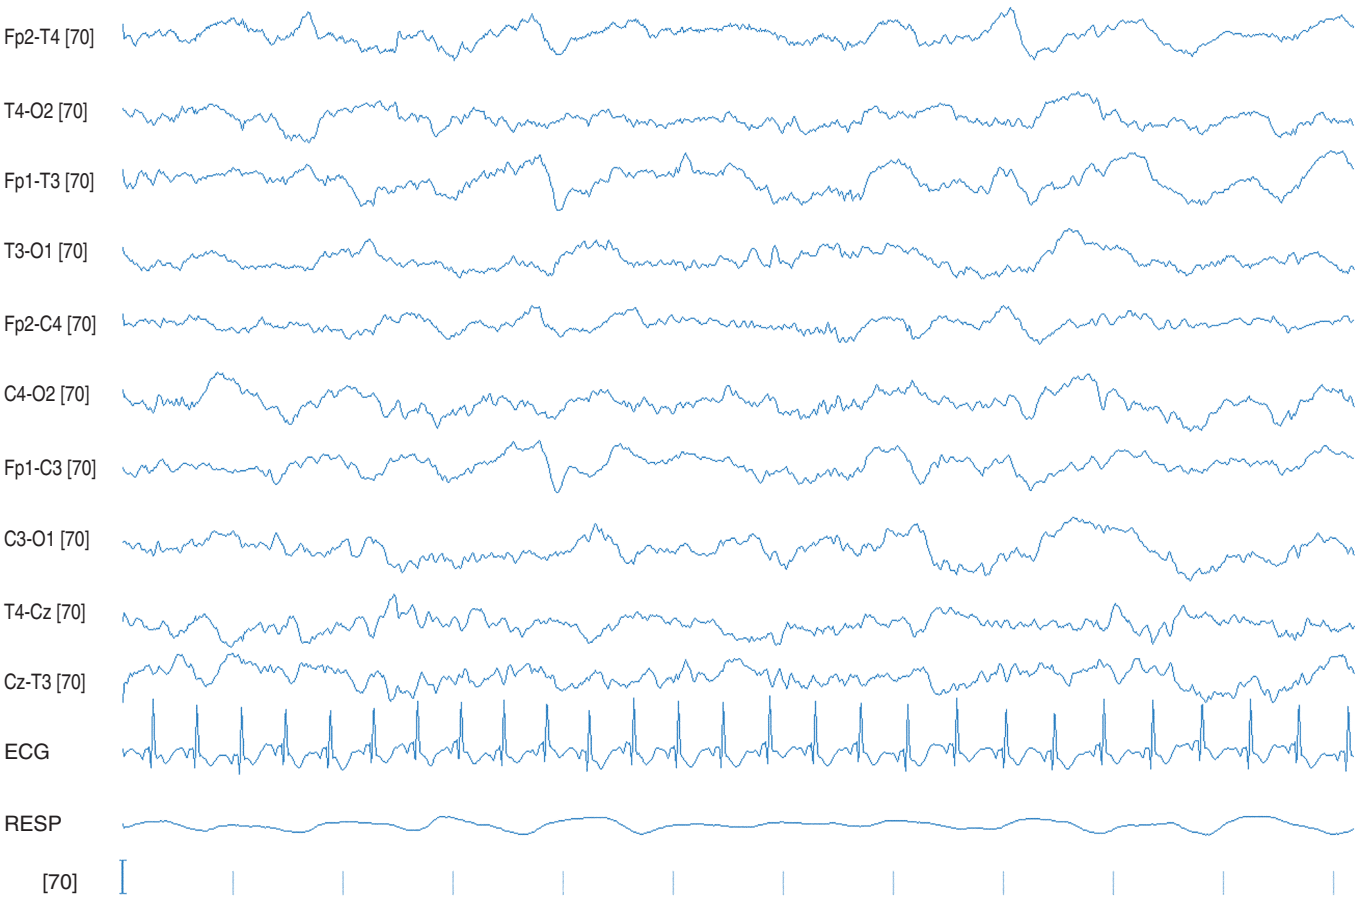
Assessment Tools

Many different tools have become available to aid in the more precise prediction of neurodevelopmental outcome in the full-term infant with HIE.

Clinical Examination

Previous studies have described in detail the clinical changes in the term neonate with encephalopathy. The Sarnat classification is based on clinical and electroencephalography (EEG) findings 24 hours after the insult. It has been modified to be used shortly after the insult for neonates to determine eligibility for therapeutic hypothermia.[61]

The Thompson score is based on several clinical items and results in a quantitative score (see Table 54.2).[77] Classification systems have been used not only for clinical purposes but also for inclusion of patients in clinical trials, as well as for stratification of patients within those trials. Although the predictive value for long-term neurodevelopment of mild and severe encephalopathy is good (no handicaps following mild encephalopathy, almost invariably poor outcome after severe encephalopathy), the predictive value for moderate encephalopathy is poor.



Neurophysiology

Electroencephalography

Neonatal EEG is a well-recognized method to assess brain integrity after hypoxia–ischemia that results in hypoxic–ischemic encephalopathy. In newborn infants, EEG commonly uses 16 channels; it requires skilled technicians and highly trained and experienced neurophysiologists to interpret the recordings. The 16-channel EEG provides detailed information and, when performed with simultaneous video recording, helps make a distinction between clinical and subclinical seizures. In 2011, the American Clinical Neurophysiology Society published guidelines on continuous EEG monitoring in neonates.[70] Although it is clear that using continuous full EEG with video recording is optimal, this can, at present, be achieved only in a limited number of centers. With use of these guidelines, data of 426 consecutive neonates with clinically suspected

seizures and/or electrographic seizures were studied in seven tertiary centers.[21] In agreement with findings from previous studies, the most common seizure etiologies were HIE (38%), ischemic stroke (18%), and intracranial hemorrhage (11%). There was a high seizure burden, with 59% having ≥7 electrographic seizures and 16% having status epilepticus; 52% received ≥2 antiepileptic drugs. During admission, 17% of the neonates died; 49% of survivors had abnormal neurologic examination at hospital discharge. In an adjusted analysis, high seizure burden was a significant risk factor for mortality, length of hospital stay, and abnormal neurologic examination findings at discharge. One study made it very clear that continuous EEG or amplitude-integrated EEG (aEEG) is required to accurately diagnose seizures. Those authors showed that less than 10% of neonatal seizures were correctly identified by the neonatal staff, compared with simultaneous video-EEG recordings (see Chapter 55).[46] With the use of continuous aEEG or continuous EEG (cEEG) monitoring, a reduction in the use of antiepileptic medication was noted, when compared with a period when intermittent EEG was used.[34] Normal and severely abnormal results on EEG are of important predictive value. Normal traces almost invariably predict a normal outcome, whereas persistent, severely abnormal traces predict an adverse outcome (Fig. 54.5). Prediction in children with mild to moderate EEG abnormalities is less reliable and requires sequential recordings. EEG activity is fully differentiated in full-term infants. During quiet sleep, a discontinuous pattern (*tracé alternant*) alternates with a high-voltage continuous delta pattern. In wakefulness, the EEG is characterized by low-voltage mixed theta–delta activity. In active sleep, a mixed medium-voltage delta–theta activity is seen. Abnormalities on the EEG can be classified as background abnormalities, ictal abnormalities, and abnormalities in the organization of states and maturation. Background pattern abnormalities are highly predictive of outcome (Fig. 54.6). One should take into account the fact that antiepileptic drugs can (transiently) affect sleep states and the background pattern, especially in children with severe encephalopathy. The following background patterns can be recognized: isoelectric and extremely low voltage (less than 5 μV); burst suppression pattern with long periods of inactivity (usually longer than 10 seconds) mixed with bursts of abnormal activity. Outcome is especially poor with long periods of inactivity and brief periods of bursts (<6 seconds) with small-amplitude bursts and interhemispheric asymmetry and asynchrony.[8] Among a group of 90 infants undergoing therapeutic hypothermia 43 (48%)

had electrographic seizures, including 9 (10%) with electrographic status epilepticus. Abnormal initial EEG background classification (excessively discontinuous, depressed and undifferentiated, burst suppression, or extremely low voltage) was strongly associated with seizures.[22]

To overcome the problem of difficult access and lack of continuity, a continuous monitoring device, the aEEG, is now increasingly being used.[80] This simple device was initially used as a single-channel EEG from a pair of parietal electrodes. The EEG signal is first amplified and passed through an asymmetric band-pass filter that strongly attenuates activity below 2 hertz (Hz) and above 15 Hz to minimize artifacts from electrical interference. The EEG processing involves semilogarithmic amplitude compression, rectification, smoothing, and time compression. The digital devices also provide raw EEG data and can use more than a single channel. Easy around-the-clock access and easy interpretation based on pattern recognition have led to an increase in continuous monitoring of brain activity in the neonatal intensive care unit (NICU). Several groups have compared simultaneous aEEG with a 16-channel EEG recording. A good correlation was noted for the background pattern (Fig. 54.7). Seizures that will not be detected with aEEG are short seizures, low-amplitude seizures, and focal discharges (Fig. 54.8). Sensitivity of seizure recognition can be considerably improved when using a two-channel bilateral centroparietal aEEG recording with access to the corresponding raw EEG data. The sensitivity for detecting seizures in one- or two-channel aEEG recordings without access to the raw EEG data was 27%-56%, whereas 76% of the seizures were detected by using two aEEG channels, with corresponding raw EEG data.[64] Performing at least one 16-channel EEG during the aEEG recording is, therefore, strongly recommended. Use of continuous aEEG recording provided information about the improvement that can occur in infants with very poor background patterns immediately after delivery. Recovery of a burst suppression pattern within the first 24 hours was sometimes noted to be associated with a normal outcome. However, children with a continuous voltage pattern could deteriorate after 24 hours during a period of secondary energy failure, showing deterioration of their background pattern and late onset of seizures. In most infants, however, a good prediction of later neurodevelopmental outcome could be made on the basis of the aEEG background pattern obtained at 6 or even 3 hours after birth. The early predictive value of the background pattern assessed with this technique has led to its use for selection of newborn infants in intervention

studies, such as therapeutic hypothermia.[78] A longer recording will also allow for assessment of the presence, quality, and time of onset of sleep–wake cycling (SWC). The presence, time of onset, and quality of SWC reflects the severity of the hypoxic–ischemic insult to which newborns have been exposed. The time of onset of SWC helps predict neurodevelopmental outcome on the basis of whether SWC returns before 36 hours (good outcome) or after 36 hours (bad outcome).[53] It has been shown that recovery of background activity tends to be slower during hypothermia, and care should be taken when predicting outcome. The positive predictive value (PPV) for predicting a poor outcome during the first 3-6 hours was only 59% in the infants receiving hypothermia compared with 84% in those with normothermia. Infants with a good outcome normalized their background pattern by 24 hours, but by 48 hours if treated with hypothermia.[78] This observation has been confirmed by others.

The presence of subclinical seizures can be better evaluated using aEEG, and it was noted that newborns very often show electroclinical dissociation, especially after administration of the first drug given for clinical seizures. Scher et al. found that 58% of infants with seizures persisting after treatment with phenobarbital or phenytoin showed uncoupling of electrical and clinical seizures.[62] Status epilepticus (ongoing seizure activity for at least 30 minutes) is not uncommon and was noted in 18% in a cohort monitored with continuous aEEG. In this study, there was a significant difference in background pattern, as well as in duration of the status epilepticus between infants with a poor outcome and those with a good outcome.

Efficacy of treatment of seizures was noted to be poor, as already reported by others using intermittent 16-channel EEGs. The most commonly used drugs (phenobarbital and phenytoin) were shown to treat seizures effectively in less than 50% of the patients when given as a single drug. Other drugs, such as lidocaine, were noted to be more effective but are not yet widely used.[91] Antiepileptic drugs, such as levetiracetam and topiramate, are increasingly used in newborn infants. Similar to the cEEG study mentioned above, a high seizure burden on two-channel aEEG was independently associated with greater injury on MRI (odds ratio [OR] 5.00; 95% confidence interval [CI] 1.47-17.05).[65] The same group also used the aEEG and raw EEG data to calculate discontinuity and showed that a mean discontinuity greater than 30 sec/min–long epoch had a specificity and PPV of 100%, sensitivity of 71% and a negative predictive value (NPV) of 88% for unfavorable neurodevelopmental outcome at a 10-μV threshold.[16]

Evidence that neonatal seizures themselves can lead to damage of the immature neonatal brain is accumulating in the literature.[87] Electroclinical and electrographic neonatal seizures produce an increase in cerebral blood flow velocity. It is suggested that electrographic seizures are associated with disturbed cerebral metabolism and that treatment of neonatal seizures until electrographic seizure activity is abolished may improve outcome.

Animal studies have shown that neonatal seizures can permanently disrupt neuronal development.[31] Seizures superimposed on hypoxic ischemia in rat pups were noted to significantly exacerbate brain injury. However, antiepileptic drugs are not without side effects, and data have shown apoptotic neurodegeneration in the developing rat brain at plasma concentrations relevant for seizure control in humans.

Long-term outcomes in children who had neonatal seizures vary considerably in reports. This is probably because of differences in inclusion criteria and methods of diagnosing neonatal seizures. Postneonatal epilepsy is not uncommon (20%-50%), also after subtle seizures. In studies using aEEG and treating clinical as well as subclinical seizures, postnatal epilepsy developed in less than 10% of the survivors.[80] In a study of 151 neonates undergoing therapeutic hypothermia, 8 (6%) were diagnosed to have epilepsy (International League against Epilepsy definition, www.ilea.org), of whom 3 (2%) received antiepileptic drugs. Of the 103 children seen at age 4-8 years, 14 (13%) had developed epilepsy, with 7 (7%) receiving treatment with antiepileptic drugs.[40] There is little data about the best time to discontinue antiepileptic drugs given for acute symptomatic seizures during therapeutic hypothermia. Seizures after hospital discharge were rare and only seen in 4 of 35 infants who had acute symptomatic seizures. There was no increased risk in the development of postneonatal epilepsy when antiepileptic drugs were discontinued prior to discharge.[19]

Evoked Potentials

Evoked potentials can further aid in the prediction of neurodevelopmental outcome of full-term infants with HIE.[81] Brainstem auditory evoked potentials (BAEPs) or brainstem evoked response and visual evoked potentials (VEPs) are technically easier to perform than somatosensory evoked potentials (SEPs).

The BAEPs are responses generated in the auditory brainstem pathway after an acoustic stimulus (see Chapter 59). They are used to assess both the peripheral sensitivity and the neurologic integrity of the auditory pathway. Seven positive waves can be recognized; these are indicated with Roman numerals. BAEPs are regarded as the most objective and reliable method of evaluating peripheral auditory function in neonates. Because perinatal asphyxia is a well-known risk factor for sensorineural hearing loss, hearing should always be assessed in the neonatal period. This may be performed using automated auditory brainstem response (AABR) or BAEPs. The incidence for a permanent hearing impairment ranges from 5%-10%.[72] Using logistic regression, the high incidence of 10% was noted to be associated with a high trough level of gentamicin, which was present in 90% of those with hearing impairment, a low cord pH, and hypoglycemia within an hour after birth (<46.8 mg/dL).

Initial studies using BAEPs to predict neurodevelopmental outcome were not as consistent as those using SEPs and VEPs. BAEPs are not often used in the prediction of outcome in infants with HIE.

The VEP is a gross electrical signal generated by the occipital area of the cortex in response to a visual stimulus. The stimulus can be either a diffuse flashing light or a patterned visual stimulus. In the neonatal unit, light-emitting diode goggles or small light-emitting diode screens are most widely used. The P200 and the N300 are the major components that can be recognized in the neonatal period. Flash VEPs (FVEPs) are good predictors of cerebral visual impairment after perinatal asphyxia in non-cooled infants. A high correlation between FVEPs and neurodevelopmental outcome was found by the same group. Absent FVEPs carried a poor prognosis, whereas persistently abnormal FVEPs also predicted an abnormal outcome. Normal FVEPs, however, were not always associated with a good outcome, and FVEPs appeared to be more resistant than SEPs. When FVEP recording was performed within 6 hours after birth, a PPV of 77% was found, slightly lower than

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

for SEPs (82%) or aEEG (84%).[17] With use of FVEPs in the prediction of outcome in infants receiving therapeutic hypothermia, no response was found in infants with a severely abnormal EEG.[50]

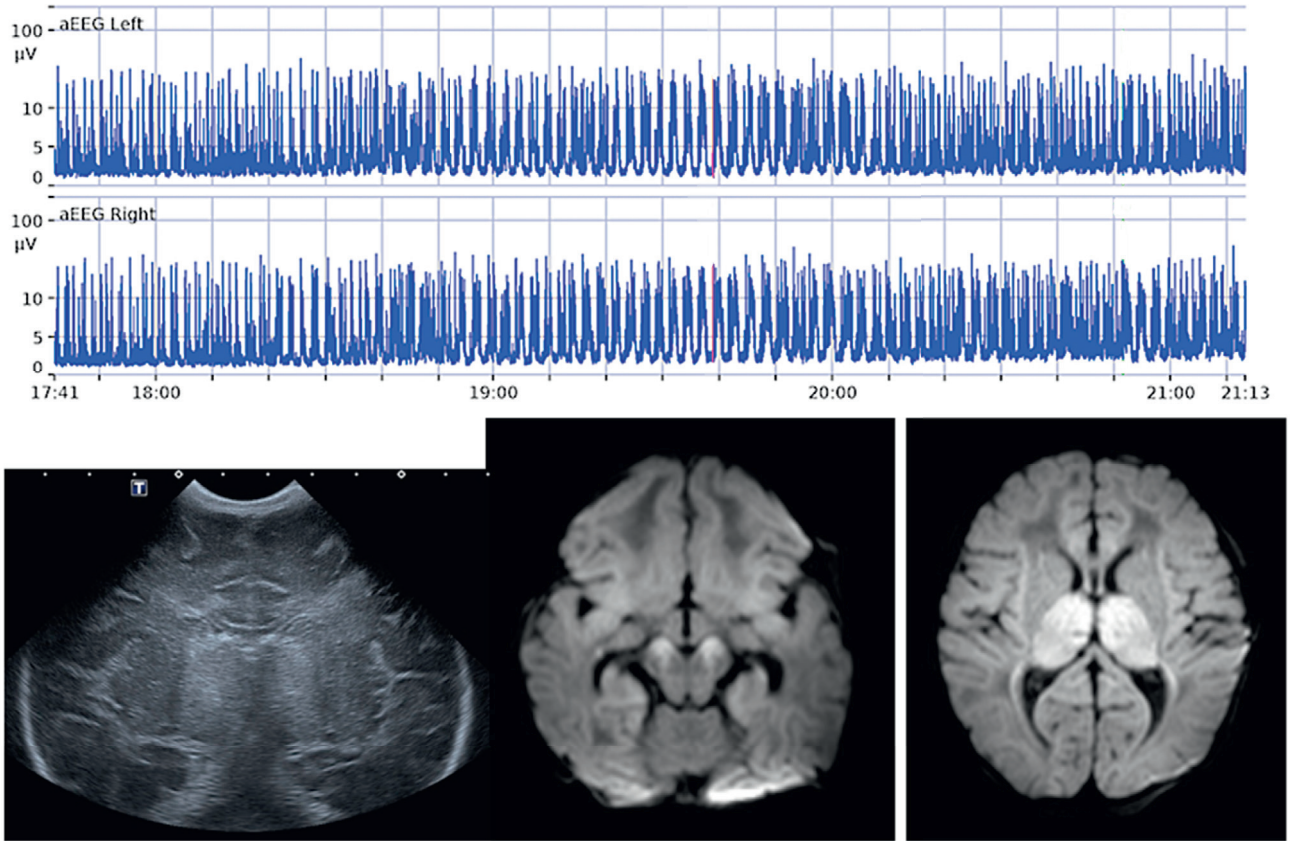
Technically, SEPs are the most difficult to perform and, by far, the most time consuming. The median nerve is usually stimulated because this is better tolerated than stimulation of the tibial nerve. At the scalp, contralateral to the site of stimulation and overlying the primary somatosensory cortex, wave N19 is recorded, which is considered cortically generated. In the newborn, this component is usually referred to as N1. The predictive value of SEPs in full-term infants with HIE has been confirmed since by several groups.[81] A group of 56 infants with HIE who had neonatal aEEG and SEPs underwent a full neuromotor and neurocognitive assessment and an MRI at 9-10 years.[36] A normal SEP latency performed during the first 5 days after birth was associated with a normal neuromotor outcome, and a prolonged day 3 latency with lower childhood intelligence quotient (IQ). The presence of multiple seizures in the aEEG, as well as a moderate or severe injury on the neonatal MRI, was associated with a poor neuromotor score.

When comparing FVEPs and SEPs, some studies showed SEPs to be superior in the prediction of neurodevelopmental outcome. Because the predictive value within the first 6 hours after birth was noted to be similar for aEEG and evoked potentials, aEEG is preferred because of easy access, application, and interpretation. Recently, several studies have shown that SEPs and FVEPs persist during hypothermia and are still of predictive value in infants who are exposed to therapeutic hypothermia.[50] In the study by Nevalainen et al.,[50] 28 of the 50 infants included were treated with hypothermia. The FVEPs and SEPs were performed between 15 hours and 10 days, simultaneously with the routine EEG. The prediction accuracy was highest with SEPs (98%), followed by EEG (90%), and lowest with VEPs (84%). Those authors only looked at absent responses, rather than delayed or absent responses, which were outcome measures in prehypothermia studies. In the subgroup of newborns that received therapeutic hypothermia, the prediction accuracy of SEPs was 100% and that of EEG 96%. In a larger group of 58 infants, all treated with hypothermia, similar values were found by using neonatal MRI rather than neurodevelopmental outcome.[74] Bilaterally absent responses were obtained in 10 (17%) of the 58 neonates, and all showed moderate or severe MRI abnormalities; 36 (75%) of 48 neonates with present SEPs had normal MRI results. The PPV of SEPs for MRI outcome was of 1.00, whereas the NPV was 0.72. The data obtained in another study that included 26 cooled infants were less promising, with an abnormal outcome in only 4 of 11 infants with bilateral absent SEPs (PPV 0.36). The NPV was, however, high, with correct prediction of a normal outcome in 14 of 15 infants (0.93).

Overall, the predictive power of evoked potentials and aEEG for neurodevelopmental outcome is good and may especially be of additional value in those with moderate HIE and moderately abnormal EEG background activity.[81]

Neuroimaging

As discussed earlier, certain regions of the brain are preferentially affected under different circumstances. Different imaging modalities can be used, but recent data have shown MRI to be superior to ultrasonography and computed tomography (CT).[24]



Cranial ultrasonography has a poor reputation when it comes to assessment of abnormalities of the brain of the full-term infant with HIE. Ultrasonography can be helpful, especially when performed sequentially during the first week after birth (Fig. 54.9). Changes in the thalami and basal ganglia may be subtle but usually become clearer by the end of the first week.[24] Alterations of the signal in white matter can sometimes be seen on admission, suggesting that the insult is of antenatal onset. More often, echogenicity develops gradually over a period of days. In severe cases, the ventricles are difficult to visualize because of edema and are described as "slitlike." A Doppler signal can be obtained during ultrasonography, at the level of the anterior or preferably the middle cerebral artery. Several studies have shown that an increase in diastolic flow, resulting in a reduced resistance index (<0.55) and an increase in cerebral blood flow velocity (>3 standard deviations [SDs]), is associated with a poor neurodevelopmental outcome. Changes usually developed after the first 24 hours after birth.[4] Color Doppler flow across the sagittal sinus can be used to diagnose or exclude a sinovenous thrombosis.

CT is less sensitive than MRI for detecting changes in the central gray nuclei, which is the most common problem in full-term infants with HIE. A decrease in attenuation of white matter may be difficult to differentiate from normal unmyelinated white matter. CT is only useful in an infant admitted after a very traumatic delivery and suspected of having extra-axial hemorrhage. In such cases, ultrasonography may miss these blood collections unless they are large, with an associated midline shift. Furthermore, CT may be more accessible than MRI, and in the likelihood of possible emergency surgical intervention, CT can be performed soon after admission.

The most appropriate technique to use is MRI because it can show different patterns of injury. After an acute sentinel event, the basal ganglia and thalami are most commonly involved.[13] An altered, sometimes reversed signal at the level of the posterior limb of the internal capsule can be seen during the second half of the first week in term infants, and this has been noted to be of very high PPV for neurodevelopmental outcome.[44] Signal changes in the basal ganglia and thalami have also been reported in preterm infants after a sentinel event.[41]

With the use of DWI, abnormalities in the thalami and basal ganglia can often be seen within days after birth, but the alterations in signal intensity may be more pronounced

later in the first week (Fig. 54.10). Calculation of ADC is important to assess the severity of the insult. DWI changes and the ADC show so-called pseudonormalization after the first week of life, which decreases the predictive value of this technique after the first week of life, although this process may be a few days delayed by therapeutic hypothermia.[1,7] Changes in the basal ganglia are often seen together with changes at the level of the central gyrus, and this combination carries a poor prognosis. Dyskinetic cerebral palsy is a result of injury to these brain areas. Additional lesions in the pons will result in feeding problems, whereas signal changes involving the cortex may be followed by epilepsy. Additional MRI abnormalities in the occipital white matter are likely to result in cerebral visual impairment.[45]

The second most common pattern of injury is to the watershed regions, which is especially well recognized with DWI.[13] The severity of white matter abnormalities can be different from that of focal lesions, often with punctate white matter lesions, and these were recently noted to be especially common in infants with milder encephalopathy. White matter lesions can also be very diffuse with loss of gray matter–white matter differentiation, preceding cystic evolution. These more severe white matter abnormalities can be seen in isolation or in association with abnormalities of the basal ganglia. Early changes on MRI correlate well with neonatal EEG findings, later MRI findings, and the neurodevelopmental outcome. Early cognitive and motor outcome in infants with extensive watershed lesions without involvement of the basal ganglia is often more favorable than expected, but these children need to be seen until school age because they may grow into their deficits.[29] Although cerebral injury in infants with hypoxic–ischemic encephalopathy was reduced by therapeutic hypothermia, the PPV of MRI for subsequent neurologic impairment was maintained.[1] Punctate white matter lesions are commonly seen in infants with cardiac and noncardiac congenital malformations. The pattern of cerebral involvement appears to be influenced by the presence and type of placental pathology (see section on Selective Vulnerability).

Focal ischemic lesions are also well detected with use of this technique. The middle cerebral artery, most often the left branch, is most commonly affected. DWI allows for detection of the area involved at a time when conventional MRI may not yet be very reliable. Involvement of the descending corticospinal tracts can be well visualized with DWI and is referred to as *pre-Wallerian degeneration*, which is highly predictive of subsequent Wallerian degeneration and development of a hemiplegia. Diffusion tensor imaging

• **Fig. 54.10** *Left*, Magnetic resonance imaging (MRI), T2-weighted image, and apparent diffusion coefficient (ADC) map, performed on day 3 in a full-term infant with hypoxic–ischemic encephalopathy grade III. A decreased signal is seen in the thalami, posterior part of the corpus callosum, and optic radiation. *Right*, Proton magnetic resonance spectroscopy (^{1}H-MRS) shows elevated lactate and a moderately decreased N-acetylaspartate–to-choline (NAA/Cho) ratio. This MR spectrum does not show the original MRS data, but a fitted spectrum.

(DTI) and tractography may aid in the prediction of asymmetric neuromotor development.[85]

Magnetic resonance angiography (MRA) can further aid in the visualization of abnormal flow across the artery involved in case of an embolism or dissection. The area of cavitation noted on a repeat scan performed a few months later usually is smaller than expected on the basis of the area of abnormal signal intensity seen on the initial scan, but the tissue surrounding the cavity is altered and shows gliotic scarring later in infancy. Sinovenous thrombosis was considered a rare condition, but with the introduction of MRI and magnetic resonance venography (MRV), it is more often diagnosed.[24] Conventional MRI shows an increased signal in the sinus on a T1-weighted image, and MRV shows lack of flow across the sinus. The sagittal sinus, straight sinus, or the deep veins of the basal ganglia can be affected. An associated unilateral thalamic hemorrhage can be present. Novel techniques, such as arterial spin labeling, have been used to demonstrate hyperperfusion in infants with severe perinatal asphyxia. Higher arterial spin labeling perfusion values in full-term infants with HIE were associated with a worse neurodevelopmental outcome.[15]

Metabolic assessment with use of ^{1}H-MRS or ^{31}P-MRS can be performed during MRI examination. The most commonly used nucleus for clinical applications is ^{1}H because it is the most abundant and the strongest nucleus. N-acetylaspartate, creatine/phosphocreatine, choline-containing compounds, myoinositol, glutamine and glutamate, and lactate can all be recognized within the proton spectrum. A decrease in N-acetylaspartate and a high lactate peak have been reported for ^{1}H-MRS. A recent meta-analysis comparing conventional MRI diffusion-weighted imaging and ^{1}H-MRS as potential early biomarkers found the deep gray matter Lac/NAA ratio to be the most accurate quantitative MR biomarker within the neonatal period for prediction of neurodevelopmental outcome after hypoxic–ischemic encephalopathy. This predictive value of ^{1}H-MRS was retained after therapeutic hypothermia.[1,36a]

A comparison of ^{1}H-MRS and DWI performed on the first day after birth showed that ^{1}H-MRS was better in accurately depicting the severity of injury at this very early stage.[38]

PET has been infrequently used. A study of regional cerebral metabolic rates of glucose (CMRgl) showed localized increases, which were in good agreement with changes seen with other neuroimaging techniques, whereas in another study, the deep subcortical areas, thalamus, basal ganglia, and sensorimotor cortex were identified as the most metabolically active brain areas. Total CMRgl were inversely related to the severity of HIE.[24]

Chemical Biomarkers

Numerous compounds were tested to be used as biomarkers of adverse neurodevelopmental outcome. These tests included analysis of blood gases; early lactate levels; liver enzymes, such as lactate dehydrogenase; erythroblastosis; cytokines in cerebrospinal fluid (CSF); hypoxanthine in CSF; isoprostanes; and more specific brain proteins, such as creatine kinase (BB), S-100B, and neuron-specific enolase.[75] Although these compounds may reflect the severity of hypoxia–ischemia, or even the severity of brain involvement, they have limited value for the prediction of long-term neurodevelopment because of lack of a specific origin within the brain.

Management

Primary Prevention

Prevention of fetal asphyxia is, by far, preferable to the prospect of managing the newborn who has suffered a hypoxic–ischemic insult during birth. The aim of modern obstetrics is to recognize the compromised fetus before irreversible organ damage occurs and rescue it from the hostile environment.

Electronic fetal monitoring (EFM) is widely used to identify infants with hypoxia (see Chapter 12). A Cochrane Review of 13 randomized controlled trials (RCTs) showed a statistically significant decrease in the number of neonatal seizures in the infants born in the EFM group (relative risk [RR] 0.50; 95% CI 0.31-0.80). This effect was noted in only two of the larger studies, where the option of pH estimation was available for unfavorable traces. There was no significant difference in overall perinatal death rate (RR 0.86; 95% CI 0.59-1.23). These studies also showed a significantly increased risk of delivery by cesarean section in the EFM group (RR 1.63; 95% CI 1.29-2.07). Follow-up data from the surviving infants was available in two studies, but both failed to show any reduction in long-term neurologic adverse effects.[3]

Fetal electrocardiography (ECG) waveforms have been evaluated as a more sensitive method for the detection of fetal hypoxia rather than EFM. Two different methods have been studied: the PR to R-R ratio and the ST waveform. In the PR to R-R ratio, there is normally a positive correlation between the PR interval and the R-R interval so that when the heart rate increases, both PR and R-R intervals shorten. The hypoxemic heart behaves differently, with shortening of the PR interval and lengthening of the R-R interval so that change in the PR to R-R ratio is a predictor of fetal heart hypoxic compromise. An alternative method assesses changes in the ST waveform in much the same way as exercise ECG assessment in adults with myocardial disease.

A Cochrane analysis of seven RCTs of fetal ECG use in labor has been reported by Neilson. All trials assessed fetal ECG as an adjunct to EFM alone during birth. The studies of ST waveform resulted in no fewer infants born with severe metabolic acidosis (pH <7.05; base deficit [BD] >12 mmol/L), or babies with neonatal encephalopathy. There were fewer operative vaginal deliveries, but no difference in admissions to the NICU. The author concluded that there was "little strong evidence that ST waveform analysis had an effect on the primary outcome measures."[48] Other fetal monitoring strategies, such as fetal pulse oximetry, fetal scalp lactate values, fetal movement counting, and use of NIRS, have been investigated, but without beneficial effects (see www.cochrane.org; accessed December 21, 2017).

In summary, intrapartum assessment of severe hypoxia may result in improved condition at birth and reduce the risk of hypoxic–ischemic encephalopathy, but there is little evidence to support the notion that hypoxic–ischemic brain damage can be prevented.

Resuscitation

The key to resuscitation (see Chapter 31) is to restore adequate oxygenation and perfusion of vital organs, particularly the brain. Systemic acidosis developing as a result of intrapartum asphyxia impairs cardiac contractility, but its effect on cerebral function is less clearly understood. Infants may be born in unexpectedly poor condition and require immediate resuscitation. Most infants born in suboptimal condition can be anticipated (Box 54.2), and staff trained in neonatal resuscitation should be available at the birth. It is estimated, however, that approximately 20% of infants who require resuscitation do not fall into this group. The importance of expert resuscitation has been recognized, and every infant, wherever born, must have personnel available with expert resuscitation skills and all the appropriate equipment in good working order. The introduction of obstetric emergencies training courses can result in a significant reduction in low 5-minute Apgar scores and HIE. With continued training, it is possible to sustain this improvement.

During the last decade, novel insights have been developed into the technique of neonatal resuscitation. This has led to a change in guidelines. Most recent guidelines suggest the use of as little oxygen as needed.[55] Further research is aimed at the benefit of delayed cord clamping, especially in preterm infants.[76]

Systemic Management

The diving reflex occurs during experimental asphyxia to maintain blood flow to vital organs, such as the brain, at the expense of less-vital organs. This is the basis of systemic complications after a clinically significant hypoxic–ischemic insult, and the heart, kidneys, and liver are the most vulnerable organs. Almost all infants with HIE show compromise in at least one organ system other than the brain.[67] The clinical course after a hypoxic–ischemic event in labor is unpredictable, so problems should be anticipated and the infant appropriately observed by trained staff in a clinical environment. Hypoxic–ischemic insult affects the whole

• BOX 54.2 Conditions in Which the Need for Resuscitation at Birth May Be Anticipated

Prelabor Factors

Maternal

- Toxemia (eclampsia)
- Diabetes mellitus
- Drug addiction
- Cardiovascular disease
- Infectious disease
- Collagen vascular disease

Uteroplacental

- Placental abruption
- Umbilical cord prolapse
- Placenta previa
- Polyhydramnios
- Premature rupture of the membranes

Intrapartum Factors

- Isoimmunization
- Multiple birth
- Preterm birth
- Cardiopulmonary abnormalities
- Abnormal presentation
- Precipitous delivery
- Fetal distress
- Thick meconium staining
- Prolonged labor
- Difficult forceps delivery
- Intrauterine growth restriction
- Prolonged pregnancy

organism, and any organ system may be compromised. Brain-oriented management is discussed later; the following section discusses management of systemic complications.

Renal System

Renal impairment is reported to occur in 23%-70% of asphyxiated infants.[67] Acute renal failure (plasma creatinine >130 μmol/L [1.2 mg/dL] for at least 2 consecutive days) is reported in 19% of asphyxiated infants of gestation age greater than 33 weeks. In a study using a more sensitive measure of renal tubular function (N-acetylglucosaminidase), there was a relationship between elevated N-acetylglucosaminidase levels and degree of HIE in the infant.[67] Because of the fear of renal failure and fluid overload, many clinicians have adopted a policy of fluid restriction in newborns with asphyxia, but there is no evidence that normal fluid volumes contribute to cerebral edema in the newborn. Fluid restriction is necessary in infants who have inappropriate antidiuretic hormone secretion or those with known renal tubular impairment. Fluid intake in these infants should be titrated against measurements of the infant's serum and urinary electrolytes.

Oliguria is managed by careful maintenance of fluid balance with daily measurement of plasma and urinary creatinine levels, and serum and urinary electrolytes, as well as daily assessment of the infant's weight. Acute renal failure and anuria lasting more than a day should be initially managed conservatively (see Chapter 92). Chronic renal failure and the need for dialysis are extremely rare in severely full-term infants with asphyxia.

Cardiovascular System

Myocardial contractility is impaired after hypoxic–ischemic insult, causing a significant reduction in cardiac output, hypotension, and further impairment of cerebral blood flow and perfusion of other organs. Myocardial dysfunction detected by Doppler ultrasonography has been shown to occur in many newborn infants with asphyxia. Other cardiac pathologic processes recognized to occur after a severe hypoxic–ischemic insult include acute cardiac dilation with functional tricuspid valve regurgitation, myocardial ischemia present on ECG assessment, and ischemic necrosis of papillary muscle. Cardiac biomarkers, such as troponin T, as markers for perinatal myocardial damage are currently under investigation. Although the risk of persistent pulmonary hypertension (PPHN) is not significantly increased by therapeutic hypothermia, PPHN is common when perinatal asphyxia is seen in combination with early-onset sepsis or meconium aspiration syndrome. PPHN may have a profound impact on brain oxygenation in term newborns with asphyxia treated with hypothermia during the first days after birth, and this can be assessed by using NIRS. In addition to inhaled NO, milrinone is used to improve circulation.

Hypotension is common after severe hypoxic–ischemic insult, and volume support is often ineffective in restoring normotension. Inotropes have been shown to be effective in restoring blood pressure in infants with asphyxia.

Hepatic and Gastrointestinal Systems

Elevated liver enzymes occur in 80%-85% of asphyxiated full-term newborn infants during the first week of life. Irreversible liver damage appears to occur very rarely after asphyxia at birth. Necrotizing enterocolitis is a well-recognized complication in infants with asphyxia but this etiology is relatively rare.

Hematologic System

Coagulation impairment is relatively common after a severe asphyxial insult. The bone marrow may be transiently damaged, leading to thrombocytopenia. Disseminated intravascular coagulation (DIC) occurring after birth asphyxia is also well recognized, with low levels of factor XIII and elevated thrombin–antithrombin complexes; D-dimer, fibrin, and fibrinogen degradation products; and soluble fibrin monomer complexes.

Coagulation impairment should be anticipated and screening for hematologic abnormalities undertaken in all severely asphyxiated newborn infants. Supportive treatment

with platelets, vitamin K, or clotting factors may be indicated by specific abnormalities on the coagulation screen. The management of DIC is controversial, but there is no indication for systemic heparinization (see Chapter 79). Hypothermia has no effect on coagulation, but thrombocyte counts are lower during hypothermia.[33]

Brain-Oriented Management

Careful attention must be paid to maintain cerebral homeostasis by anticipation of complications that may have a direct or indirect effect on brain function and recovery after a severe hypoxic–ischemic insult. More standard brain-specific complications affecting the infant after a severe hypoxic–ischemic insult are discussed in the following section.

Glucose

Hypoglycemia has been shown to be an additional adverse factor for the immature brain in conjunction with a hypoxic–ischemic insult. Immature hypoglycemic animal models subjected to anoxia have a considerably increased mortality rate compared with anoxic, normoglycemic animals. The presence of ketone bodies as an alternative brain fuel ameliorates this effect despite low levels of circulating glucose. The facilitative glucose transporter proteins (GLUT1) transport glucose across the blood–brain barrier, and related proteins (GLUT3 and 45-kd GLUT3) mediate transport into the neuron and glial cells, but these proteins are in low concentration in the immature brain. Hypoxic–ischemic insult initially enhances both GLUT1 and GLUT3 expression in the brain, but GLUT3 decreases after 72 hours, in association with extensive cellular necrosis. Asphyxia initially increases the cerebral metabolic rates of glucose (CMRgl), and consumption of glucose during hypoxic–ischemic insult causes depletion of intracerebral glucose. Very limited numbers of infants have been studied after asphyxial insults by using PET, with conflicting results. In five term infants, CMRgl was increased 2-3 days after the insult, whereas another study of CMRgl in 20 human infants with asphyxia showed a high correlation between the more severe degree of HIE and lowest values of CMRgl. These low levels were obtained at a median age of 11 days, which was later than that in the first study and may account for the differences in values.

Studies have shown that there are major differences in the behaviors of the mature brain and the immature brain to glucose infusion. The infusion of glucose in the immature organism, unlike in adults, before a hypoxic–ischemic event, appears to have protective effects compared with subjects not given sugar supplementation. The pretreated hyperglycemic group had better preservation of PCr and ATP compared with the normoglycemic group. Preconditioning the animal before a major hypoxic–ischemic insult may afford protection, which appears to be caused by enhanced intracerebral glycogen levels, increased expression of GLUT1, and increased availability of alternative brain fuels. The clinical question of whether glucose infusion after hypoxic–ischemic insult is of value remains controversial.

Although routine use of high-concentration glucose is not advised after a hypoxic–ischemic event in the neonate, it is clear that hypoglycemia must be avoided. In addition, 3 decades ago, it has been shown that insulin levels are elevated in the hours after perinatal asphyxia, when stress hormones tend to decrease and the chance of hypoglycemia is considerable.[11] Regular blood glucose testing in neonates after resuscitation is of utmost importance. At present the importance of high glucose levels is not completely established.

Seizures

Seizures (see Chapter 55) occur in many infants who have sustained a significant hypoxic–ischemic insult; indeed, seizure is a feature of moderate and severe HIE. In general, the more severe or prolonged the hypoxia–ischemia, the more seizure activity the infant will have. In the past, there has been considerable debate as to whether seizure activity after a hypoxic–ischemic event confers an additional risk factor on the infant in terms of adverse neurodevelopmental outcome. Several studies have demonstrated adverse effects of repetitive seizures on the developing brain, and these should be treated, even if subclinical and demonstrated by using only EEG techniques.

A hypoxic–ischemic insult sets in train a cascade of intraneuronal events that may result in cell death. In animal studies, the induction of multiple short seizures over the first days of life does not result in neuronal loss but does result in morphologic changes involving cortical activation and cell density that are evident when the brain was examined in adult life. Furthermore, these animals exhibited impaired learning and lower seizure threshold in later life. In human neonates, there is often dissociation between clinically evident seizures and seizures recognized on EEG monitoring, so the frequency of seizure activity after a hypoxic–ischemic insult may well be underestimated by clinical observation. Therefore, asphyxiated infants are very likely to have a significant seizure burden that may be underestimated by clinicians. There is evidence that although the majority of irreversible neuronal injury after recovery from hypoxic–ischemic insult is due to the underlying cause of the condition, additional functional injury may ensue secondary to the seizure burden. This strengthens the case for effective management of seizure activity after a hypoxic–ischemic event.

Fully effective anticonvulsant therapy in the neonatal period is difficult, but some drugs, such as lidocaine as add-on therapy, are effective for controlling both clinical and electrographic seizures. Phenobarbital is still the drug of first choice. A study comparing the efficacy of phenobarbital against phenytoin in the management of EEG-diagnosed seizures found that in a single-blind RCT, there was complete seizure control in less than 50% of infants

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

with either drug. When both drugs were given, complete seizure abolition occurred in only 50% of infants.[54]

In a study of term infants with asphyxia, high-dose phenobarbital (40 mg/kg) was associated with a significant reduction in severe neurodevelopmental disability. In many cases, the phenobarbital was given before the first evidence of seizure activity. A meta-analysis of five studies comparing barbiturates with conventional therapy after occurrence of hypoxic–ischemic encephalopathy found no difference in risk of death or severe neurodevelopmental disability in survivors. Phenobarbital has also been shown to have toxic effects on brain growth, neuronal toxicity, and adverse cognitive and behavioral effects when given to immature animals. Other anticonvulsants used to treat seizures occurring after a hypoxic–ischemic insult include phenytoin (no greater efficacy than phenobarbital), benzodiazepines (clonazepam, midazolam, lorazepam), lidocaine, thiopentone, sodium valproate, lamotrigine, and levetiracetam. These drugs have been evaluated in an uncontrolled manner, and the information on effect is largely anecdotal.

In Europe, lidocaine is more commonly used as a second- or third-line anticonvulsant; however, it should not be used if phenytoin has been administered because cardiotoxicity may occur. Lidocaine was more effective in abolishing (electroconvulsive) seizures when used as add-on therapy after phenobarbital than midazolam, especially during therapeutic hypothermia.[91] It is essential that new RCTs be started to evaluate the efficacy of the newer anticonvulsant drugs, such as levetiracetam or topiramate, in the management of seizures occurring after perinatal asphyxia. There has been accumulating evidence from animal studies that antiepileptic drugs have adverse effects, including apoptosis, inhibition of brain growth, and adverse behavioral and cognitive effects in adult life, when the drugs are administered at an early age. It is of interest that several studies have shown a decreased seizure burden in neonates with HIE who received cooling. This finding may explain some of the therapeutic benefits of cooling seen in term neonates with (moderate) HIE. As pharmacokinetics of anticonvulsants may be changed by therapeutic hypothermia, dose adjustments are needed, in particular for lidocaine and midazolam.[83,84]

The duration of anticonvulsant administration should be minimized to avoid the potential adverse effects of prolonged exposure. The optimal duration of anticonvulsants is unknown. Some clinicians withdraw treatment as soon as the neurologic examination normalizes. In case of serious cerebral injury documented with MRI, some clinicians continue phenobarbital administration for 2-3 months, but there is no evidence to support this.

Cerebral Edema

Cerebral edema may occur after a severe hypoxic–ischemic insult. Studies of intracranial pressure (ICP) monitoring in human infants who have suffered a severe hypoxic–ischemic insult have shown that severely raised ICP (>15 centimeters of water [cm H_2O]) was found in a minority of infants monitored by a median time of 26 hours. In this group of infants with asphyxia and raised ICP, successful treatment of the ICP, as judged by a significant benefit on outcome, was estimated to have occurred in less than 10% of cases. There is no evidence that routine monitoring of ICP is of benefit to the infant. Raised ICP is most probably an end result of the abnormal pathophysiologic processes that occur after hypoxic–ischemic insult and, in itself, is a marker of damage, rather than a cause of it. Consequently, the management of raised ICP becomes relatively less important.

Corticosteroids

There are few data to suggest that corticosteroids are effective in the management of hypoxia–ischemia. Animal studies on immature rat pups have shown that pretreatment with dexamethasone before a hypoxic–ischemic insult resulted in less severe injury than in untreated control animals, but treatment with dexamethasone after the insult was ineffective in alleviating cerebral edema. Steroids are routinely used in older children and adults with focal edema, as occurs in tumor or traumatic brain injury, but appear to be much less effective after a global hypoxic–ischemic insult.

There is concern about the long-term effects of large doses of dexamethasone given shortly after birth, particularly in preterm infants, in whom it is estimated that there is a significant increase in the risk of cerebral palsy. There is no scientific justification for the use of steroids after an intrapartum hypoxic–ischemic insult to treat cerebral edema.

Specific Neuroprotective Strategies

A number of studies have attempted to make preliminary investigations into the role of different strategies in neonatal brain protection after a hypoxic–ischemic insult, but few useful clinical data are currently available. Moderate hypothermia is the only specific neuroprotective therapy that is part of routine care.

Hypothermia

In recent years, interest in neuroprotection by brain cooling has shown benefit in both animals and humans. Studies in animal models have shown that in a variety of immature species, varying degrees of mild hypothermia (2°C-5°C below normal) for 3-72 hours were effective in maintaining brain function. Hypothermia has been suggested to have an effect by reducing cerebral metabolism and ATP consumption and downregulating many intracerebral metabolic processes associated with rapid expression of early gene activation.

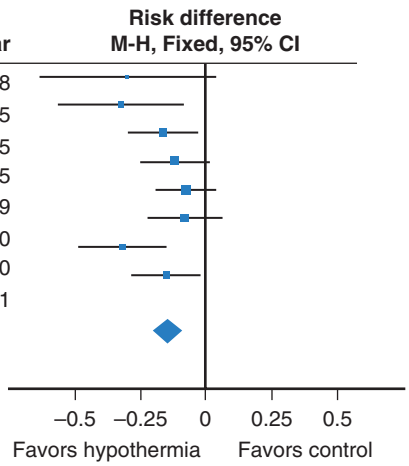
Since the reports in 2005 of RCTs in full-term neonates with perinatal asphyxia, hypothermia has become standard of care for infants when perinatal asphyxia is followed by encephalopathy.[68] In the Cochrane analysis that

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

has been updated frequently since then, no differences have been demonstrated between head cooling or whole body hypothermia.[33]

With whole body hypothermia, the rectal temperature is decreased to 33°C-34°C for 72 hours, whereas with the cooling cap perfused with a coolant solution at 10°C and body temperature is maintained between 34°C and 35°C. The primary outcome in the RCTs was death or disability at 18 months. All infants had been cooled within 6 hours of birth.

Despite the differences in the findings from the RCTs, the outcome at 18 months is remarkably consistent in showing improved survival without neurologic abnormality and significantly reduced cumulative outcome of death and severe disability (Fig. 54.11). Neuroprotection is better in neonates with moderate encephalopathy than in those with severe encephalopathy. Overall, with death or severe handicaps taken together as poor outcome, number to treat is approximately 7. Of interest, control infants in the trials who became hyperthermic had worse outcomes. The therapeutic effects of moderate hypothermia are sustained when examining these children at school age.



Reported complications of hypothermia are sinus bradycardia and thrombocytopenia (Fig. 54.12).[68] Anecdotal reports mention increased pulmonary hypertension and subcutaneous fat necrosis, but this has not been demonstrated in the RCTs and subsequent meta-analyses.

It is important to note that the temperature of the hypothermic babies needs to be maintained within preset limits, because more severe hypothermia (<33°C) may have detrimental effects, such as cardiac arrhythmia. Therapeutic hypothermia has been confined to studies in mature infants younger than 35 weeks' gestational age. Historical studies have shown a vast excess of deaths in very immature babies who became to chilled, and this form of treatment is at present not recommended in premature infants.

Both the therapeutic window, set at 6 hours, and the duration of therapy (72 hours) are based on the development

and duration of secondary energy failure in animal models. Starting hypothermia later than 6 hours after the insult is less effective.[37] Studies of longer or deeper therapeutic hypothermia did not show any benefit.[69] Therapeutic effects of moderate hypothermia in infants with milder encephalopathy have not yet been confirmed.

Other Strategies

A number of studies have attempted to make preliminary investigations into the role of different strategies in neonatal brain protection after a hypoxic–ischemic insult, but few useful clinical data are currently available.

The calcium channel blocker nicardipine was given to four infants who had sustained severe intrapartum hypoxic–ischemic insult. In 3 of 4, the mean arterial blood pressure dropped precipitously with a fall in cerebral blood flow. The systemic effects of the relatively nonspecific calcium channel blockers significantly limit their value for brain protection.

Magnesium sulfate ($MgSO_4$) is an NMDA receptor antagonist and has been proposed to be an effective agent for brain protection and is used extensively in preterm labor for fetal neuroprotection. Although studies have evaluated the role of $MgSO_4$ in term infants with asphyxia, no sustained benefits have been reported.

Potential neuroprotective agents for postnatal treatment are melatonin, erythropoietin (EPO), N-acetylcysteine, allopurinol, selective NOS inhibitors, and noble gases, such as xenon and argon and have been among the agents ranked highest. Melatonin is produced mainly by the pineal gland, allowing the entrainment of circadian rhythms of several biologic functions. Melatonin can also function as an antioxidant and has antiapoptotic effects. Although melatonin may have beneficial effects, more pharmacokinetic studies need to be performed. EPO messenger RNA expression is markedly increased in cerebral tissue neurons in response to hypoxia. EPO triggers several different signaling pathways. Neuroprotective effects have been associated with stimulation of production of growth factors, including vascular endothelial growth factor secretion and brain-derived neurotrophic factor. In one study, EPO appeared to improve neurologic outcomes in newborns with hypoxic–ischemic encephalopathy, but these patients did not receive hypothermia treatment. Studies combining hypothermia and EPO are ongoing.

Selective inhibitors of nitric oxide synthase (NOS), inhibiting neuronal and inducible, but not endothelial NOS, have been developed in preclinical studies, and pharmacokinetic studies with or without concurrent hypothermia are also ongoing.

N-acetylcysteine is a precursor of glutathione and can, therefore, act as an antioxidant and is also a scavenger of oxygen free radicals. In animal experiments, it has been used in combination with hypothermia, but clinical studies in humans have not yet been performed.

Allopurinol is an inhibitor of xanthine oxidase and has free radical scavenging action. The long-term effects of allopurinol after perinatal asphyxia in 23 neonates were published in 2011. At follow-up at a mean age of 5 years, no differences in long-term outcome between the allopurinol-treated infants and controls were demonstrated. However, subgroup analysis of the group with moderate asphyxia showed significantly less severe adverse outcome in the allopurinol-treated infants compared with controls (25% versus 65%; RR 0.40; 95% CI 0.17-0.94). In a trial, fetal levels of allopurinol could be achieved through maternal administration, and small effects were seen in a subgroup analysis. A neonatal trial is ongoing (NCT03162653).

Xenon, a noble gas, has been shown to be a very safe anesthetic and a potent neuroprotectant. Xenon is a noncompetitive antagonist of the NMDA subtype of the glutamate receptor, although other mechanisms of action have been reported. Xenon appears to be neuroprotective in animal models of perinatal asphyxia. At present, clinical trials are examining the neuroprotection by xenon in addition to hypothermia. Large-scale use of xenon may be limited by the excessive costs. A recent study did not show beneficial effects of xenon in combination with therapeutic hypothermia.[5] Argon, a cheaper alternative to xenon, has been used only in preclinical studies.

Stem cells or progenitor cells may have multiple beneficial effects on outcome after hypoxic–ischemic injury, as has been shown in preclinical studies. Trials of infusion of autologous cord blood are ongoing in several centers.

Prognostic Factors

Perinatal asphyxia is an important cause of neonatal mortality and morbidity, including dyskinetic cerebral palsy, cognitive deficits, behavioral problems, visual disturbance, deafness, and epilepsy. The outcome of infants with hypoxia–ischemia and encephalopathy is influenced by several factors, including the duration and severity of the insult to the brain; gestational age; presence of seizures; associated infectious, metabolic, and traumatic derangements; and effects of therapeutic hypothermia. Although the prognosis for any single newborn often is difficult to formulate, certain clinical and laboratory abnormalities, along with perinatal cerebral hypoxia–ischemia, are associated with a high risk of neurologic morbidity (Box 54.3). However, the value of some early prognostic factors that have been established previously has changed by the use of hypothermia.[60]

The degree of maturity at birth is an important predictor of mortality in infants suffering asphyxia at birth. In the early days of neonatal intensive care, Nelson and Ellenberg also reported an appreciably higher death rate in premature infants, but an increased risk for cerebral palsy in the full-term survivors. The lower morbidity among the premature infants was related, in part, to the small number of survivors in this group. Epidemiologic data in the present era of neonatal intensive care are only available for full-term neonates.[33]

• BOX 54.3 Predictors of Mortality and Neurologic Morbidity After Perinatal Hypoxic–Ischemic Insult

- Apgar score ≤4 at 10 minutes
- Prolonged abnormal neonatal neurologic examination
- Abnormal brain imaging using ultrasonography and magnetic resonance imaging, and proton magnetic resonance spectroscopy (^{1}H-MRS)
- Abnormal electrophysiology: suppressed background pattern on electroencephalography (EEG) or amplitude-integrated EEG (aEEG), status epilepticus; abnormal evoked potentials (visual, brainstem auditory, and somatosensory)

Apgar Scores and Condition at Birth

Several studies have demonstrated the low sensitivity of the 1- and 5-minute Apgar scores in predicting long-term neurologic outcomes. However, the extended Apgar score is a reliable predictor of ultimate neurologic morbidity, especially when very low scores are obtained at 20 minutes.[10]

The time from birth until onset of spontaneous, sustained respirations also has been correlated with long-term neurologic function. Full-term infants who were apneic for 30 or more minutes were universally and severely damaged. Data have suggested that a prolonged delay in the initiation of spontaneous respirations is a reasonable indicator of irreversible brain damage. However, the predictive value has changed by the use of therapeutic hypothermia. In a recent study in Australia, 4 of 13 infants with a 10 minute Apgar score of zero were normal at 1 year.[66]

Acidosis

Obstetricians have long used blood acid–base status to ascertain the presence or absence of asphyxia in the fetus during the intrapartum period. Obstetricians concentrate on more severe degrees of acidosis and on the extent to which the altered pH reflects an underlying metabolic (lactic) acidosis. In the study of Goldaber et al., 2.5% of 3,506 full-term newborns exhibited an umbilical artery pH of less than 7.00, 66.7% of whom had a metabolic component to their acidosis. Significantly more of the severely acidotic newborns exhibited low (less than 3) 1- and 5-minute Apgar scores compared with infants with higher umbilical artery pH values.[23] In addition, neonatal death was significantly more frequent in the severely acidotic group. Low et al. compared 59 full-term fetuses exhibiting metabolic acidosis with 59 fetuses with normal umbilical blood acid–base status and 51 fetuses exhibiting only a respiratory acidosis at birth.[43] Various complications, including encephalopathy, were apparent in the majority of newborns experiencing metabolic acidosis, compared with very low complication rates in those infants with either respiratory acidosis or no acidosis at all. In addition, Low et al. had previously demonstrated a positive correlation between the severity and duration of intrapartum metabolic acidosis and neurodevelopmental outcome at 1 year. The predictive value of cord blood gases has been tested recently in infants treated with therapeutic hypothermia, and metabolic acidosis at birth was still associated with severe brain injury.[60]

Other Biochemical Predictors of Outcome

Prostanoids and non–protein bound iron represent specific plasma oxidative biomarkers reflecting oxidative stress injury to neuronal cells.[75] Activin A, glial fibrillary acid protein, neuron specific enolase, S100B, and adrenomedullin have all been suggested as biomarkers of brain damage and of the degree and extension of the lesion.[63]

Severity of Encephalopathy

Neurologic examination of the infant in the immediate newborn period provides a useful index for predicting later developmental outcome, especially in the full-term infant. Follow-up studies have shown that those infants assessed as having only mild HIE had virtually no risk of subsequent major neurodevelopmental disability, and in infants with moderate HIE, approximately 75% survived without major neurologic deficits. Infants with severe HIE had a very poor outcome, with 50%-100% mortality rate and severe disability incidence of 65%-75% in survivors.

A numeric scoring system based on features of hypoxic–ischemic encephalopathy has been shown to be able to predict, with a high degree of accuracy, outcome at 12 months of age.[77]

Electrophysiology and Imaging

In other sections of this chapter, the usefulness of electrophysiology and brain imaging in the assessment of the infant with perinatal asphyxia has been addressed. Abnormal findings of electrophysiology, such as abnormal evoked potentials, a high seizure burden, prolonged suppressed background patterns of the EEG, and delayed development of SWC are all associated with an adverse neurodevelopmental outcome.[78,81] Abnormal imaging findings with cranial ultrasonography, in particular to the deep grey matter, as well as abnormalities on DWI and ^{1}H-MRS of gray matter, are strongly associated with an adverse outcome and can be used to select patients for additional (experimental) treatment or in extreme cases to redirect care.[1,9,90]

Association Between Hypoxic–Ischemic Encephalopathy and Less Severe Neurodisability

It has become apparent that the outcome of HIE may be more heterogeneous than was previously thought. It has been suggested that if HIE caused damage in an infant, then the outcome involved severe cerebral palsy with or without

intellectual impairment. There are published data on less severe forms of disability in older children who have survived a perinatal hypoxic–ischemic insult at term. Children with mild-to-moderate HIE, but without major neurologic deficit, had lower full-scale IQ values, minor neurologic dysfunction and/or perceptual motor difficulties, and attention deficit hyperactivity disorder requiring additional educational support.[86] Children who had suffered moderate hypoxic–ischemic encephalopathy in the neonatal period had a greater need for special education in school.

The prognosis for children with HIE depends on the severity and duration of the neurologic abnormality. To understand the development of HIE, an assessment of all potential contributing factors, including maternal medical history, obstetric antecedents, intrapartum factors (including fetal heart rate monitoring results, and issues relating to the delivery itself), and placental pathology is recommended.[18] Major neurodevelopmental problems occur only after moderate and severe HIE, and death is a significant risk and still common after severe HIE. Emerging data strongly support the observation that a significant number of children with perinatal hypoxic–ischemic insult previously considered to be without major problems do have significant perceptual–motor difficulties or a reduction in cognitive abilities. The predictive values of neuroimaging procedures and other investigative techniques have been described earlier. The use of MRI and EEG assessments provides the basis for the most accurate prediction of disability not only in later childhood but also after the introduction of treatment with hypothermia.

Acknowledgment

The authors and editors acknowledge the important contributions of Malcolm I. Levene to the previous editions of this chapter, some parts of which remain unchanged.

Key Points

- Perinatal asphyxia, with the resulting encephalopathy, is still one of the major problems in full-term neonates.
- Brain monitoring at many centers using continuous or amplitude-integrated EEG provides important prognostic information for standard care of infants with encephalopathy.
- Therapeutic hypothermia has reduced adverse outcome in infants with HIE from approximately 65% to 45%.
- MRI and ^{1}H-MRS are good predictors of an adverse motor outcome.

Seizures in Neonates

TERRIE E. INDER

Seizures are a common and important clinical manifestation of neurologic dysfunction in the newborn. Building on a traditional foundation of knowledge regarding seizures in the newborn, the last decade has brought new insights into the clinical-electroencephalographic correlates, pathophysiology, and treatment that will be reflected in this chapter.

The incidence of seizures varies with gestational age and birth weight and is most common in the very low birth weight (VLBW) infant. Estimated incidences are 58/1000 live births in the very low birth weight (VLBW) infant and 1-3.5/1000 live births in the term infant.[26,62] Seizures in the newborn differ in their clinical appearances, electrographic characteristics, etiologies, management, and outcomes compared to any other later developmental period. Thus recognition of seizures in the newborn period can be very difficult because of subtle or absent clinical manifestations. To assist in both the accurate identification of seizures in the newborn and successful treatment with antiepileptic drug therapy, electrophysiologic monitoring—either conventional or limited channel monitoring—now plays a critical role within the neonatal intensive care unit. Treatment of neonatal seizures is generally considered necessary since experimental and human evidence suggest seizures may lead to secondary brain injury and are associated with less favorable outcomes.

Pathophysiology of Newborn Seizures—Unique Maturational Features Increasing the Likelihood of Seizures in the Newborn

A seizure results from an excessive synchronous electrical discharge (i.e., depolarization) of neurons within the central nervous system.[48] Neuronal depolarization is produced by the influx of sodium (Na^+), and repolarization is produced by the efflux of potassium (K^+). Maintenance of the potential across the membrane requires an energy (adenosine triphosphate, ATP) dependent pump, which extrudes sodium and takes in potassium. In the newborn brain, it appears that excessive depolarization may occur because of the imbalance of neural excitation over inhibition. The factors contributing to this include developmental factors unique to the immature brain with an excess of excitatory neurotransmitters, particularly in relation to the principal excitatory neurotransmitter, glutamate, and a relative deficiency of inhibitory neurotransmitters. Developmentally, this enhanced excitation is important for activity-dependent synaptogenesis but predisposes to excitation and seizures. Secondly, the common pathologic processes in the newborn brain of hypoxemia-ischemia and hypoglycemia can result in failure of the ATP-dependent sodium-potassium pump disabling the cell from maintaining a stable membrane potential. Finally, other molecules can influence the membrane's sensitivity to depolarizations, such as calcium and magnesium that interact with the neuronal membrane to inhibit Na^+ movement. Thus, hypocalcemia or hypomagnesemia increase Na^+ influx resulting in depolarization.

In understanding why and how the seizure phenomena in newborns differ from those observed in older humans, it is important to understand that in the vast majority of neonatal seizures, electrical onset is focal or multifocal with the spread of the seizure occurring within one hemisphere and secondary generalization to the contralateral hemisphere occurring only rarely.[10] Thus, newborns rarely have well-organized, generalized tonic-clonic seizures, and premature infants have even less well-organized seizures than do term infants. The precise reasons for these differences relate to the status of neuroanatomical and neurophysiologic development in the perinatal period. Neuroanatomically, a propagation of seizures appears related to the completed cortical lamination and organization with myelination of cortical efferent systems and interhemispheric commissures.[101] The relatively advanced cortical development apparent in limbic structures in the human newborn infant and the connections of these structures to the diencephalon and brainstem may underlie the frequency and dominance of oral-buccal-lingual movements (e.g., sucking, chewing, or drooling), oculomotor movements, and apnea as clinical manifestations of neonatal seizures.

From a neurophysiologic viewpoint, the relation of excitatory to inhibitory synapses is important in determining the capacity of a focal discharge to both form and then to spread to contiguous and distant brain regions. Strong evidence indicates that the rates of development of the excitatory and inhibitory synaptic activities differ in

Abstract

Seizures in the newborn infant represent the most distinctive frequent manifestations of neurologic disease in the neonatal period. The incidence of seizures varies with gestational age and birth weight and is most common in the very low birth weight (VLBW) infant. Estimated incidences are 58/1000 live births in the very low birth weight (VLBW) infant and 1-3.5/1000 live births in the term infant. Compared to seizures at later developmental stages, seizures in the newborn differ in their clinical appearances, electrographic characteristics, etiologies, management, and outcomes. Since the majority of seizures during the newborn period are acute symptomatic seizures due to cerebral injury or dysfunction, seizures are an important manifestation to alert the clinician to underlying neurologic disorders. However, recognition of seizures in the newborn period can be very difficult due to subtle or absent clinical manifestations. To assist in both the accurate identification of seizures in the newborn and successful treatment with antiepileptic drug therapy, electrophysiologic monitoring—either conventional or limited channel monitoring—now plays a critical role within the neonatal intensive care unit. Treatment of neonatal seizures is generally considered necessary since experimental and human evidence suggest seizures may lead to secondary brain injury and are associated with less favorable outcomes. However, anti-seizure medications may have associated risks, and there are few data to guide evidence-based management. This chapter reviews the pathophysiology and clinical aspects of neonatal seizures with particular emphasis on the influence of the developmental characteristics of the immature brain.

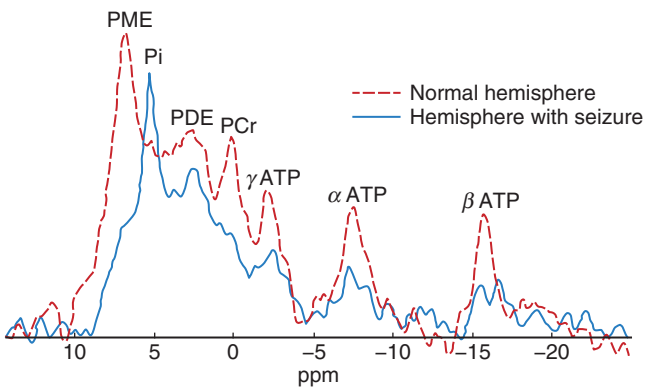
• **Fig. 55.1** Schematic depiction of maturational changes in glutamate and GABA receptor function in the developing brain. Equivalent developmental periods are displayed for rats and humans on the top and bottom axes, respectively. Activation of GABA receptors is depolarizing in rats early in the first postnatal week and in humans up to and including the neonatal period. Functional inhibition, however, is gradually reached over development in rats and humans. Before full maturation of GABA-mediated inhibition, the NMDA and AMPA subtypes of glutamate receptors peak between the first and second postnatal weeks in rats and in the neonatal period in humans. Kainate receptor binding is initially low and gradually rises to adult levels by the fourth postnatal week. (From Rakhade SN, Jensen FE. Epileptogenesis in the immature brain: emerging mechanisms. *Nat Rev Med*. 2009;5:380-391.) AMPA, α-Amino-3-hydroxy-5-methyl-4-isoxazole propionate; GABA, γ-aminobutyric acid; NMDA, *N*-methyl-D-aspartate; P, postnatal day.

the newborn cerebral cortex (Fig. 55.1). Excitatory activity is mediated by glutamate through two key receptor types, N-methyl-D-aspartate (NMDA) and alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA). These two excitatory receptors are the predominant neurotransmitter receptors found in the immature brain, with a relative paucity of the principal inhibitory receptors for gamma-aminobutyric acid (GABA). Indeed, the neonatal period is characterized by levels of excitatory neurotransmitter expression and function that exceed those observed in adult cortical neurons, while inhibition is not yet at adult levels (see Fig. 55.1).[58]

Moreover, properties of these two glutamate receptors enhance their excitatory function. NMDA receptors in the neonatal period exhibit prolonged duration of the NMDA-mediated excitatory postsynaptic potential, reduced ability of magnesium to block NMDA receptor activity, diminished inhibitory polyamine binding sites, and a greater sensitivity to glycine enhancement.[45] Similarly, AMPA receptors in the neonatal period are deficient in the GluR2 subunit responsible for rendering the AMPA channel impermeable to calcium. Thus these immature AMPA receptors are permeable to calcium and, as a consequence, enhanced excitation.[81] In addition, early in development, the principal inhibitory neurotransmitter, GABA, acts at the major postsynaptic $GABA_A$ receptor ($GABA_A$) to produce excitation rather than inhibition, as occurs later in development. Consistent with these developmental phenomena, it is easier to produce epileptic activity in the immature animal than in the adult.[58]

Insights into the critical developmental relationship between neuronal chloride (Cl^-) levels and Cl^- transport in the perinatal period have major implications for understanding the basis of GABA excitation and thus key clinical and therapeutic aspects of neonatal seizures. GABA activation of the major postsynaptic $GABA_A$ receptor causes Cl^- flux. In the mature neuron, there is Cl^- influx down an electrochemical gradient. However, in developing brains, at maturational stages comparable to the human perinatal period, GABA activation causes Cl^- efflux, and GABA activation is, therefore, excitatory.[17] The basis for this paradoxical effect relates to a developmental mismatch between the two Cl^- transporters that determine neuronal Cl^- levels. Thus in the perinatal period, in human cerebral cortex, the expression of the Na^+-K^+-Cl^- cotransporter (NKCC1) responsible for Cl^- influx reaches a peak, whereas the expression of the K^+-Cl^- cotransporter (KCC2) responsible for Cl^- efflux is relatively low.[61] The result is a high internal neuronal level of Cl^-, so when the $GABA_A$ receptor is activated there is efflux (rather than influx) of Cl^- resulting in depolarization and excitation. These findings may explain the therapeutic inconsistency of GABA agonists, such as phenobarbital and benzodiazepines, to be effective anticonvulsants in the newborn infant with seizures. The NKCC1 inhibitor, bumetanide, has potent antiseizure properties by enhancing GABA-mediated inhibition through blockage of Cl^- uptake and lowering of neuronal Cl^- levels (see later).[17] Moreover, because the maturation of the two cotransporters and neuronal Cl^- levels occurs in a caudal-rostral direction, spinal cord and brainstem motor neurons would be expected to exhibit GABA-mediated inhibition before the cerebral cortical regions. This maturational process could explain the frequent occurrence of electroclinical uncoupling/dissociation in which antiseizure medications with GABA agonist mechanisms (i.e., phenobarbital and benzodiazepines) suppress motor manifestations of seizures (by spinal cord and brainstem inhibition) but not cortical EEG manifestations (due to lack of cortex inhibition). The presence of a relative overexpression of NKCC1 versus KCC2 has been documented in postmortem human neonatal brain,[17] and combined with the efficacy in rodent neonatal seizure models, studies have been initiated to examine the safety and pharmacokinetics of the use of bumetanide as a combination anticonvulsant in human infants suffering from acute neonatal seizures. Results to date are conflicting on safety and efficacy (see later).



Biochemical and Physiologic Consequences of Seizures in the Immature Brain—Implications for the Clinician

The most prominent acute biochemical effects of seizures involve energy metabolism.[20] Seizures are associated with a greatly increased rate of energy-dependent ion pumping, which is accompanied by a fall in the concentration of ATP and phosphocreatine, the storage form of high-energy

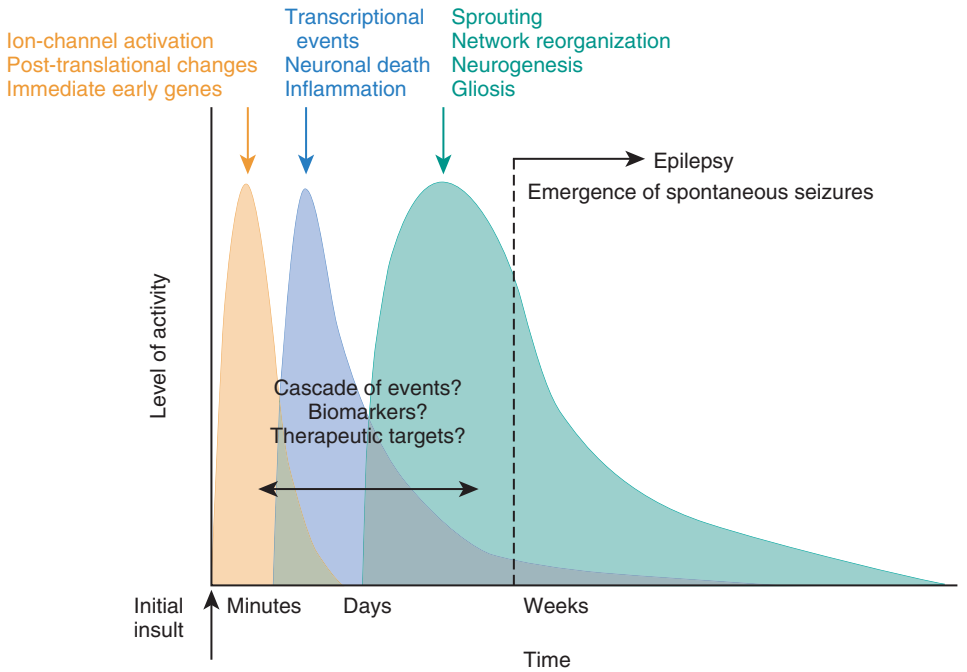
phosphate in brain. The resulting rise in adenosine diphosphate (ADP) leads to stimulation of glycolysis and to a shift of the redox state in the cytoplasm toward reduction (i.e., NADH). The excess of lactate has the beneficial effect of causing local vasodilation and a consequent increase in local blood supply and substrate influx.[14] In addition, seizures are associated with elevated blood pressure, which contributes to increased cerebral blood flow (CBF) and substrate influx.[55] This pressor effect is presumed to be a central autonomic component of the seizure, because it can be interrupted by section of the spinal cord or by administration of sympathetic ganglion-blocking agents.

Despite these important compensatory factors, in experimental animals, neonatal seizures are accompanied by reductions in brain glucose concentrations.[87] In the neonatal rat, rabbit, dog, and monkey, despite normal or slightly elevated blood glucose concentrations, brain glucose concentrations fall dramatically within 5 minutes of onset of seizure to nearly undetectable levels after 30 minutes. Concomitant with the fall in brain glucose is a rise in brain lactate, which is used readily as a metabolic fuel in the neonatal brain.[20,103] This fall in brain glucose concentration and rise in brain lactate are directly reminiscent of a hypoxic-ischemic brain insult and presumably relate to the accelerated rate of glucose utilization in an attempt to preserve supplies of phosphocreatine and ATP. Glucose conversion to lactate, which is accelerated with neonatal seizures, results in only two molecules of ATP for each molecule of glucose, as opposed to the 38 molecules of ATP generated when pyruvate enters the mitochondrion and is oxidized to carbon dioxide. MRS studies by Younkin and colleagues in the human newborns demonstrate the relevance of these experimental data to the clinical situation (Fig. 55.2).[104] Four newborns had seizures during MRS imaging. The seizures resulted in substantial (~50%) decrease in the phosphocreatine to inorganic phosphate (PCr/Pi) ratio. One newborn's seizures were successfully treated with intravenously administered phenobarbital, which caused an immediate increase in the PCr/Pi ratio. Further, newborns had PCr/Pi ratios of less than 0.8 during seizures and developed long-term neurologic sequelae, indicating that neonatal seizures may increase cerebral metabolic demands above energy supply, thereby causing or exacerbating injury. These observations indicate that seizures may lead to secondary brain injury in an already injured neonatal brain and, therefore, have important implications for prognosis and therapy.

• **Fig. 55.2** Magnetic resonance (phosphorus-31) spectra from a full-term infant during subtle seizure activity (oral-buccal-lingual movements, i.e., lip smacking and chewing). The electroencephalogram demonstrated seizure activity emanating from the left temporal region. The magnetic resonance spectrum from the nonictal hemisphere (*dotted line*) is normal. The spectrum from the ictal hemisphere (*solid line*) exhibits a marked decrease in phosphocreatine (PCr) and adenosine triphosphate (ATP) and a corresponding increase in inorganic phosphate (Pi). PDE, Phosphodiesters; PME, phosphomonoesters.

The deleterious effects of seizures may be divided into those related to prolonged seizures (in which the most prominent feature is cell loss) and those related to briefer recurrent seizures (in which the most prominent feature is altered development). While minimal data are available in human newborns, experimental studies are abundant, primarily in developing rodent models. Importantly, although the threshold for seizure generation is lower in the developing brain than in the mature brain, developing neurons are less vulnerable to injury from single prolonged seizures than are mature neurons. This may be due to a lower density of active synapses, lower energy consumption, and immaturity of relevant biochemical cascades to cell death.

For prolonged seizures, the best-documented mechanisms leading to brain injury include hypoventilation and apnea, which may result in hypoxemia and hypercapnia; cardiac dysfunction and diminished cardiac output as late complications of seizures, resulting in hypotension, diminished cerebral blood flow (CBF) and impaired energy metabolism. Importantly, increases in CBF have also been documented. In a study of 12 newborns with seizures, ictal measurements of regional CBF by single photon emission computed tomography showed a 50%-150% increase, and this increase occurred in newborns with subtle seizures and EEG-only seizures.[8] Although the increase in CBF with seizures may be initially an adaptive response to increase substrate supply to the brain at a time of excessive metabolic demand, this response could become maladaptive in some newborns. For example, depending on such factors as the gestational age of the newborn or the neuropathologic substrate for the seizures, some newborns may have highly vulnerable capillary beds, such as the germinal matrix in the premature infants or the margins of ischemic lesions in premature infants or asphyxiated term newborns.



Repeated prolonged seizures may be deleterious for the brain, even in the absence of prominent disturbances of ventilation or perfusion. Such prolonged and repeated seizures eventually lead to decreases in brain ATP and phosphocreatine concentrations such that progressive and irreparable brain injury may result.[64] Nevertheless, most studies indicate that the neonatal brain is more resistant to seizure-induced neuronal necrosis than is the adult brain.

An additional mechanism for the genesis of brain injury with severe seizures relates to excitatory amino acids.[44] Injury to neuronal dendrites and cell bodies, the most prominent acute manifestations of injury from seizures, occurs particularly in limbic structures (e.g., hippocampus)

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

and in distant sites intimately connected with limbic structures (e.g., selected areas of thalamus and cerebellum). When diminution of energy supplies is added, the energy-dependent reuptake systems for excitatory amino acids in presynaptic nerve endings and astrocytes are impaired, and the local accumulation of the neurotransmitters is accentuated. A particular vulnerability of the developing brain of the newborn may relate to the rich expression in the developing brain of glutamate receptors, which appear to play an important role in neuronal differentiation and plasticity.

Although most evidence does not suggest serious structural or functional defects from a single neonatal seizure, recurrent seizures, even if not prolonged, appear to be associated with long-term functional, morphologic, and physiologic deficits, particularly functional deficits in cognition.[35] Visual–spatial memory and learning have been particularly involved, and these deficits are consistent with the locus of the principal structural deficits in the hippocampus. The morphologic correlates of the functional disturbances involve neuronal developmental abnormalities rather than neuronal cell loss. The most severe disturbances occur in the hippocampus and include dendritic spine loss in CA3 pyramidal cells and a distinctive pattern of synaptic reorganization of axons and terminals of the dentate granule cells (i.e., mossy fibers).[35] The degree of this "sprouting" of mossy fibers correlates with the severity of the cognitive deficits. Additionally, dentate granule cell neurogenesis, which, unlike in other cortical areas, persists in the neonatal period, is impaired after recurrent seizures. Recurrent seizures also lead to physiologic and molecular alterations that favor subsequent neuronal excitability and, therefore, epileptogenesis (Fig. 55.3), as well as the occurrence of neuronal injury with subsequent insults.[35] Alterations include increases in excitatory amino acid receptors (NMDA and AMPA/kainate), decreases in GABA receptors, post-translational alterations in AMPA receptors (resulting in a decrease in the GluR2 subunit) that render them permeable to calcium, imbalanced excitatory and inhibitory systems, and altered intrinsic neuronal membrane properties, all of which favor excitation. A critical question, of course, is the extent to which these changes occur in the human newborn who experiences recurrent seizures and what seizure burden may produce such adverse neurobiologic consequences. Although this question remains unanswered, there is mounting evidence that seizures are associated with less favorable neurobehavioral outcomes.

• **Fig. 55.3** Time course of epileptogenesis. An initial insult, such as traumatic brain injury and/or status epilepticus, is followed by a latent period lasting weeks to months or even years before the onset of spontaneous seizures. During this latent period, a cascade of molecular and cellular events occurs that alters the excitability of the neuronal network, ultimately resulting in spontaneous epileptiform activity. The alterations that occur during the latent period might provide a good opportunity for biomarker development and therapeutic intervention. The cascade of events that are presently suggested by experimental evidence can be classified temporally following the initial insult. Early changes, including induction of immediate early genes and post-translational modification of receptor and ion-channel related proteins, occur within seconds to minutes. Within hours to days, there can be neuronal death, inflammation, and altered transcriptional regulation of genes, such as those encoding growth factors. A later phase, lasting weeks to months, includes morphologic alterations such as mossy fiber sprouting, gliosis, and neurogenesis. (From Rakhade SN, Jensen FE. Epileptogenesis in the immature brain: emerging mechanisms. *Nat Rev Med*. 2009;5:380–391.)

Classification of Seizures in the Newborn

Seizure Types

A seizure is defined clinically as a paroxysmal alteration in neurologic function (i.e., behavioral, motor, or autonomic function). Such a definition includes clinical phenomena that are associated temporally with seizure activity identifiable on an EEG and, therefore, are clearly epileptic (i.e., related to hypersynchronous electrical discharges that may spread and activate other brain structures). The clinical seizure definition also includes paroxysmal clinical phenomena that are not consistently associated temporally with EEG seizure activity; how many of these clinical phenomena without identifiable EEG correlates are epileptic and just not identifiable on surface-recorded EEG and how many are nonepileptic is not resolved (see later discussion). The classification of neonatal seizures presented here categorizes clinical seizures and designates those clinical seizures likely to be associated with EEG seizure activity.

The classification schemes for neonatal seizures have varied over time and have been recognized to have common and uncommon electroencephalographic correlates (Table 55.1).[89] A consensus statement on neonatal EEG terminology by the American Clinical Neurophysiology Society defined three types of neonatal seizures: (1) clinical-only seizures in which there is a sudden paroxysm of abnormal clinical change that does not correlate with a simultaneous EEG seizure, (2) electroclinical seizures in which there is a clinical seizure coupled with an associated EEG seizure, and (3) EEG-only seizures in which there is an EEG seizure that is not associated with any outwardly visible clinical signs. EEG-only seizures are also referred to as subclinical, nonconvulsive, or occult seizures. Neonatal EEG seizures are described as having (1) a sudden EEG change; (2) repetitive waveforms that evolve in morphology, frequency, and/or location; (3) amplitude of at least 2 microvolts; and (4) duration of at least 10 seconds.[84]

Generalized	+	

Electrographic seizure definitions are summarized in Box 55.1. It is important to distinguish between electrographic seizures and other related EEG patterns. While a seizure on EEG is comprised of an evolving pattern of epileptiform discharges, not all epileptiform discharges are seizures. Epileptiform discharges are brief abnormalities that stand out from the EEG background, usually because of a peaked or sharp appearance. They are sometimes referred to as "sharp waves" or "spikes" because of this EEG appearance. It is normal for newborns to have some sharp waves, and many newborns with epileptiform discharges do not experience seizures. However, epileptiform discharges that occur in runs or are clustered in one brain region are associated with an increased risk of seizure occurrence.[84]

For those seizures with a clinical correlate, the organization of this chapter will retain emphasis of the classification of clinical seizures noted in Table 55.1. Despite great efforts to carefully describe the appearance of neonatal seizures, inter-rater agreement in neonatal seizure identification by clinical observation is suboptimal. Malone and colleagues presented clinical data and video clips of abnormal neonatal movements from 20 newborns to 137 observers, including 91 physicians from seven neonatal intensive care units. Observers classified the movements as seizure or nonseizure. The average number of correctly classified events was only 50%, as compared to the gold standard of EEG classification. Further, interobserver agreement was poor for both physicians and other health care professionals.[42] Similarly, in a study of staff observing high-risk newborns, only 9% of 526 electrographic seizures were identified by clinical observation, indicating underdiagnosis of seizures occurred. Additionally, 78% of 177 nonictal events were incorrectly identified as seizures, indicating overdiagnosis of seizures occurred.[49] Problematically, the more difficult-to-diagnose seizure types tend to occur more often than the more readily diagnosed seizure types in newborns. A study of 61 seizures in 24 newborns classified seizures by their most prominent clinical features. Clonic and tonic seizures, which might be more readily identified, only occurred in 20% and 8%

• BOX 55.1 Electrographic Criteria for Neonatal Seizures

- Sudden change in EEG
- Repetitive waveforms that evolve in morphology, frequency, and/or location
- Amplitude: at least 2uV
- Duration: at least 10 seconds
- Seizures must be separated by at least 10 seconds to be considered separate.
- Clinical signs may or may not be present.

respectively, while orolingual, ocular, and autonomic features which might be more difficult to identify, were the main features in 55%.[50] Despite the limitations in clinical recognition of seizures discussed above, attempts at clinical recognition and classification of neonatal seizures are critical to diagnose seizures and differentiate them from nonictal events. Four essential clinically evident seizure types can be recognized: subtle, clonic, tonic, and myoclonic (see Table 55.1). Subtle seizures do not have a clear position in the most recent International League Against Epilepsy Seizure Classification Report,[4] but they are very common in newborns, and the term is used frequently throughout the literature. Thus the term is retained as part of the categorization system in this chapter. As discussed further below, a critical fifth seizure type to consider in newborns is a seizure with no observable clinical correlate, which have been referred to as EEG-only seizures, subclinical seizures, nonconvulsive seizures, and occult seizures.

An important initial distinction in classifying a seizure is whether it has a generalized or focal mechanism of onset. Focal seizures have a defined region of onset and electrical activity initially spreads through neural networks in that region, although the seizure may spread within the hemisphere or to the contralateral hemisphere with time. Generalized seizures may begin from a specific point but almost immediately involve bilateral neural networks, such that electrical activity appears on both sides of the brain simultaneously on EEG.[4] In the vast majority of neonatal seizures, onset is focal or multifocal. Spread of the seizure is less common in newborns than in older children because of the immaturity of the network connections in the newborn brain as discussed previously.

Subtle Seizures

The clinical manifestations of certain neonatal seizures may be overlooked even by skilled observers, and these paroxysmal alterations in neonatal behavior and motor or autonomic function are defined as subtle seizures. Available information from studies using EEG recording simultaneously with video recording or direct observation suggests that (1) subtle seizures are more common in premature than in full-term infants, and (2) some subtle clinical phenomena in full-term infants are not consistently associated with EEG seizure activity (i.e., clinical-only seizures). Common ictal clinical manifestations, confirmed by simultaneous abnormal EEG discharges, in a group of premature infants of 26-32 weeks of gestation included sustained opening of eyes, ocular movements, chewing, pedaling motions, and a variety of autonomic phenomena.[57] Similar subtle clinical phenomena occur in association with EEG seizure activity in full-term newborns, although slightly less commonly than in preterm newborns.[47] Thus, eye opening, ocular movements (often sustained eye opening with ocular fixation in premature infants and horizontal deviation in term newborns), peculiar extremity movements (e.g., resembling "boxing" or "hooking" movements), mouth movements, and apnea have been documented in association with EEG seizure activity.

The frequency with which subtle clinical seizure phenomena are associated with concomitant EEG seizure activity is uncertain. In one study, 22 newborns, approximately 85% of whom were of greater than 36 weeks of gestation, exhibited paroxysms of such ocular abnormalities as eye opening or blinking, oral-buccal-lingual movements, pedaling or stepping movements, or rotary arm movements with an "inconsistent association" with EEG seizure activity. Only tonic horizontal deviation of the eyes was consistently associated with EEG seizure activity.[47] In another report of 44 newborns (28 premature), subtle clinical phenomena accounted for 70%-75% of all clinical seizures with simultaneous EEG correlates.[66] It is more common for subtle clinical events to have an electrographic correlate (i.e., electroclinical seizures) if the newborn has other types of seizures; these events are somewhat less likely to be seizures when they are the only behavior of clinical concern.

The issue of apnea as a seizure manifestation deserves special consideration. Although apnea has been demonstrated as a seizure manifestation in the premature infant, most apneic episodes in premature infants are not epileptic in origin. However, apnea has been documented with electrical seizure activity, more commonly in the full-term newborn.[34] Of additional value in the clinical identification of apnea as a seizure is the observation that apnea accompanied by EEG seizure activity (i.e., convulsive apnea) is less likely to be associated with bradycardia than is nonconvulsive apnea.

Clonic Seizures

A clonic seizure is defined as a seizure characterized by "rhythmic movements of muscle groups in a focal distribution, which consist of a rapid phase followed by a slow return movement." Clonic seizures appear as repetitive and rhythmic jerking movements that can affect any part of the body, including the face, extremities, and even diaphragmatic or pharyngeal muscles. Clonic seizures represent the clinical seizure type associated most consistently with EEG seizure activity.[47]

Clonic seizures in the newborn are often classified as focal or multifocal (see Table 55.1). Focal clonic seizures involve the face, upper or lower extremities on one side of the body, or axial structures (neck or trunk) on one side of the body. Newborns commonly are not clearly unconscious during or after a focal seizure. The neuropathologic condition often is focal (e.g., cerebral infarction), although focal clonic seizures may occur with metabolic encephalopathies. Multifocal clonic seizures involve several body parts, often in a migrating fashion, although the migration most often "marches" in a non-Jacksonian manner (e.g., left arm jerking may be followed by right leg jerking). Generalized clonic seizures (i.e., diffusely bilateral, generally symmetrical, and synchronous movements) are rarely, if ever, observed in newborns. Clonic seizures are often reliably recognized by clinical observation, but they must be distinguished from other repetitive movements such as jitteriness, tremulousness, and myoclonus. Unlike those nonepileptic

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

movements, the muscle twitches of a clonic seizure cannot be suppressed with gentle pressure and occur spontaneously.

Tonic Seizures

Tonic seizures are defined as a "sustained flexion or extension of axial or appendicular muscle groups." Two categories of tonic seizures should be distinguished: focal and generalized tonic seizures (see Table 55.1). Focal tonic seizures consist of sustained posturing of a limb or asymmetrical posturing of the trunk or neck. Mizrahi and Kellaway also classified horizontal eye deviation as a focal tonic seizure, although some classify those events as subtle seizures.[47] Focal tonic seizures are associated consistently with EEG seizure discharges. Generalized tonic seizures are characterized by tonic extension of both upper and lower extremities (mimicking "decerebrate" posturing) but also by tonic flexion of upper extremities with extension of lower extremities (mimicking "decorticate" posturing). The possibility that such clinical seizures represent posturing and are not ictal has been raised because of the frequent association with severe intraventricular hemorrhage and the often poor response to antiseizure medication therapy.[68] Approximately 85% of such clinical seizures were not accompanied by electrographic activity or by autonomic phenomena. The 15% of generalized tonic seizures that were accompanied by electrographic seizure activity were also accompanied by autonomic phenomena.[37] Thus, these generalized tonic events may represent "brainstem release" phenomena and uninhibited extensor posturing that appears similar to tonic stiffening in patients with severe brain injury. As an additional mimic to generalized tonic seizures, episodes of generalized hypertonia provoked by minor tactile or other stimuli are characteristic of hyperekplexia.[37]

Myoclonic Seizures

Myoclonus is defined as a rapid, isolated jerk that can affect one or multiple muscle groups, can be ictal or nonictal in etiology, and can arise from injury to any level of the nervous system. Myoclonic seizures are clinical episodes that are usually not associated with EEG discharges (see Table 55.1).[47] Myoclonic movements are distinguished from clonic movements by the faster speed of the myoclonic jerk and the predilection for flexor muscle groups. There are three categories of myoclonic seizures: focal, multifocal, and generalized myoclonic seizures. Focal myoclonic seizures typically involve flexor muscles of an upper extremity. Of 41 focal myoclonic seizures studied by Mizrahi and Kellaway,[47] only 3 were associated with EEG seizures. Multifocal myoclonic seizures are characterized by asynchronous twitching of several parts of the body. In five episodes studied by Mizrahi and Kellaway,[47] none had associated EEG seizure discharges. Generalized myoclonic seizures are characterized by bilateral jerks of flexion of upper and occasionally of lower limbs. These seizures may appear identical to the infantile spasms observed in older infants. Generalized myoclonic seizures are more likely to be associated with EEG seizure discharges than are focal or multifocal myoclonic seizures. Of 58 generalized myoclonic seizures studied by Mizrahi and Kellaway, 35 had associated EEG seizure discharges.[47] All three varieties of myoclonic seizures may occur as a feature of severe neonatal epileptic syndromes.

Myoclonic seizures must be distinguished from nonepileptic myoclonus, which can occur with injury to any level of the nervous system and from normal physiologic myoclonus, which occurs in normal newborns. Unlike such other forms of myoclonus, myoclonic seizures are not induced by stimuli and cannot be suppressed by pressure to the affected body part. Furthermore, newborns with myoclonic seizures almost always have abnormal neurologic exams, whereas newborns with benign myoclonus are otherwise normal.

EEG-Only (Subclinical, Nonconvulsive, Occult) Seizures

A major issue with clinical diagnosis of seizures in newborns is the high incidence of EEG-only seizures in newborns.[98] Numerous studies have indicated that about 80%-90% of electrographic seizures do not have any associated clinical correlate and, therefore, would not be identified without continuous EEG monitoring, even by the most expert and observant bedside caregivers.[97] Clancy and colleagues evaluated 41 newborns with seizures occurring frequently enough to occur during a routine EEG. Only 21% of 393 seizures identified on EEG were accompanied by clinically evident seizure activity (i.e., electroclinical seizures), while 79% of the seizures identified on EEG were EEG-only seizures. Electroclinical seizures and EEG-only seizures had similar durations, and there were no differences in the degree of encephalopathy. The authors concluded that "unaided visual inspection of infants seriously underestimates true seizure frequency" and that "long-term EEG monitoring may be necessary in many infants to determine their real seizure frequency and to judge the adequacy of antiepileptic drug treatment."[12] In a related study, Murray and colleagues evaluated 51 term newborns with continuous video EEG. Nine newborns experienced a total of 526 electrographic seizures, and only 19% of the electrographic seizure time was accompanied by clinical manifestations. Further, only 9% of electrographic seizures were accompanied by clinical seizure activity that was identified by neonatal staff.[49] These data indicate that the majority of neonatal seizures are EEG-only, that is, identifiable only with EEG monitoring.

In newborns with clinically evident seizures, administration of antiseizure medications may lead to termination of the clinically evident seizures while electrographic seizures persist, an occurrence referred to as electromechanical uncoupling or electromechanical dissociation.[65] In the study by Clancy and colleagues, 79% of 393 electrical seizures recorded were not accompanied by clinical seizure activity monitored by direct observation; 88% of the total population of patients had been treated with one or more antiseizure medications.[12] Thus when clinically evident electroclinical seizures terminate following antiseizure medication administration, EEG monitoring may be needed to assess for ongoing EEG-only seizures.

The reasons for electroclinical dissociation/uncoupling are probably multiple, but data concerning the development of Cl^- transporters in the perinatal human brain provide a rational explanation. As discussed earlier, a developmental mismatch occurs between the transporter responsible for Cl^- influx (NKCC1) and the transporter responsible for Cl^- efflux (KCC2), such that in human perinatal brain, neuronal Cl^- levels are likely high. Thus GABA activation results in Cl^- efflux with resulting depolarization and consequently excitation. Therefore, after treatment with common anticonvulsant medications such as phenobarbital and benzodiazepines, which are principally GABA agonists, electrographic seizures are not consistently terminated. However, because the maturation of the transporters occurs in a caudal-to-rostral direction, neuronal Cl^- levels in the brainstem and spinal cord motor systems would be expected to decrease to normal levels before cortical neuronal levels. Thus, GABA activation induced by antiseizure medications would eliminate the motor phenomena of the seizure but not the cortical electrographic component, resulting in electroclinical dissociation/uncoupling.

The findings described earlier have led to an increased reliance on EEG monitoring with either conventional EEG or amplitude-integrated EEG (aEEG) for three main reasons. First, many newborns experience solely EEG-only seizures, and EEG-only seizures constitute the majority of neonatal seizures. Second, even in newborns with clinically evident electroclinical seizures, administration of antiseizure medications may induce electromechanical dissociation/uncoupling with termination of clinically evident seizures but persistence of EEG-only seizures. Third, clinical events may be difficult to distinguish as seizure-based on clinical observation, potentially leading to unnecessary exposure of newborns to antiseizure medications for nonepileptic events. As a result, many neonatal intensive care units place increased importance on EEG monitoring, either using conventional EEG or aEEG, to identify neonatal seizures,[24] and, as noted earlier, an expanded role for EEG monitoring has been advocated by recent guidelines, consensus statements, and committee reports (see later discussion).[84]

Nonepileptic Movements

Nonepileptic neonatal movements can be difficult to distinguish from seizures by appearance alone, and EEG assessment may be required. Some nonictal movements are benign events while others, although not seizures, are nonetheless abnormal and indicative of underlying brain injury or dysfunction.

Jitteriness

Jitteriness is characterized by movements with qualities primarily of tremulousness but occasionally of clonus. The most consistently defined causes of jitteriness are hypoxic-ischemic encephalopathy, hypocalcemia, hypoglycemia, and drug withdrawal. Five characteristics aid in distinguishing between jitteriness and seizure (Table 55.2). First, jitteriness is not accompanied by ocular phenomena (i.e., eye fixation or deviation); seizures often are associated with ocular phenomena. Second, jitteriness is exquisitely stimulus sensitive; seizures generally are not stimulus sensitive. Third, the dominant movement in jitteriness is tremor (i.e., the alternating movements are rhythmic and of equal rate and amplitude); the dominant movement in seizure is clonic jerking (i.e., movements with a fast and slow component). Fourth, the rhythmic movements of limbs in jitteriness usually can be stopped by gentle passive flexion of the affected limb; seizures do not cease with this maneuver. Finally, jitteriness is not accompanied by autonomic changes (e.g., tachycardia, increase in blood pressure, apnea, cutaneous vasomotor phenomena, pupillary change, salivation, or drooling); seizures may be accompanied by one or more of these autonomic changes. These same distinguishing clinical features are useful in the clinical distinction of episodic movements other than jitteriness that may mimic a seizure.

TABLE 55.2 Distinguishing Between Jitteriness and Seizure

Clinical Feature	Jitteriness	Seizure
Abnormality of gaze or eye movement	0	+
Movements stimulus sensitive	+	0
Predominant movement	Tremor	Clonic jerking
Movements cease with passive flexion	+	0
Associated autonomic changes	0	+

0, Absent; +, present.

Nonepileptic Myoclonus

Nonepileptic myoclonus may be benign or pathologic. Healthy premature infants often demonstrate occasional spontaneous myoclonus. Benign neonatal myoclonus, alternately termed benign neonatal sleep myoclonus, can be pronounced, typically is most prominent in sleep, and can last up to several minutes. Benign neonatal myoclonus may be differentiated from pathologic myoclonus in that benign myoclonus can be stopped by rousing the infant and typically does not involve the face.[60] The episodes usually last for several minutes or more and occur only during sleep, particularly quiet (non–rapid eye movement) sleep. They can be provoked by gentle rocking of the crib mattress in a head-to-toe direction and cease abruptly with arousal. The EEG pattern during the episodes does not show an ictal correlate, and interictal EEG findings are either normal or show minor, nonspecific abnormalities. The episodes can be exacerbated or provoked by treatment with benzodiazepines and resolve within approximately 2 months. Neurologic outcome is normal.

Pathologic Myoclonus

This is attributed to a brainstem release phenomenon from loss of cortical inhibition of lower circuits. It is frequently seen in infants with severe global brain injury from hypoxia-ischemia, severe intraventricular hemorrhage, and toxic-metabolic disturbances including drug withdrawal and glycine encephalopathy. These newborns have abnormal neurologic exams and abnormal background patterns on EEG.[36]

Hyperekplexia

Hyperekplexia is also known as startle disease or congenital stiff-man syndrome.[28] It is characterized principally by two abnormal forms of response to unexpected auditory, visual, and somesthetic stimuli—an exaggerated startle response and sustained tonic spasms. Additional features are generalized hypertonia and prominent nocturnal myoclonus. The "minor" form of hyperekplexia only involves excessive startle, while the "major" form is associated with additional problems, including generalized stiffness while awake, nocturnal myoclonus, and an increased risk of sudden infant death syndrome from apnea. Hyperekplexia may be caused by glycine receptor gene mutations, and clonazepam can be an effective treatment for excessive startle. The episodes usually cease spontaneously by approximately the age of 2 years. In some patients, the disorder is inherited in an autosomal dominant fashion, and the responsible gene is on chromosome 5 and known to encode the alpha-1 subunit of the glycine receptor.[1]

Does Absence of EEG Seizure Activity Indicate That a Clinical Event Is Nonepileptic?

Data from older children and adults, as well as in newborns, indicate that epileptic phenomena can occur in the absence of surface-recorded EEG discharges, and such phenomena can be generated at subcortical (i.e., deep limbic, diencephalic, brainstem) levels.[18] Thus one should continue to use some aspect of clinical judgment in the decision-making process of trials of anticonvulsant therapy or consider electroencephalographic silence as a key indicator of abnormality in a high-risk newborn.

Seizure Etiology

The majority of neonatal seizures occur in the context of acute neurologic disorders. Thus most neonatal seizures may be considered acute symptomatic seizures, which have been defined as seizures occurring at the time of a systemic insult or in close temporal association (often 1 week) with a documented brain insult.[3] The current International League Against Epilepsy classifies seizure causes as genetic, structural/metabolic, and unknown.[5] Within that classification scheme, the majority of neonatal seizures are structural/metabolic in etiology.

Determination of the seizure etiology is critical, because it affords the opportunity to provide specific treatment and important prognostic information. While there are many causes for neonatal seizures, a relatively limited group of etiologies accounts for the majority of affected newborns. The most common causes and their usual time of onset in premature or full-term infants are shown in Table 55.3. The most common underlying etiologies are hypoxic-ischemic encephalopathy, stroke, intracranial hemorrhage, intracranial infections, and cerebral dysgenesis.[82] Less common but important etiologies include inborn errors of metabolism and neonatal epileptic syndromes, such as benign familial neonatal epilepsy, benign nonfamilial neonatal seizures, early myoclonic epilepsy, early infantile epileptic encephalopathy, and malignant migrating partial seizures of infancy.

TABLE 55.3 Neonatal Seizure Etiologies in Relation to Time of Seizure Onset and Relative Frequency

	Time of Onset		Relative Frequency†	
Cause	0-3 Days	>3 Days	Premature	Full Term
Hypoxic-ischemic encephalopathy	+		+++	+++
Cerebrovascular stroke	+		+	+++
Intracranial hemorrhage	+	+	++	+
Intracranial infection	+	+	++	++
Developmental defects	+	+	++	++
Hypoglycemia	+		+	+
Hypocalcemia	+	+	+	+
Other metabolic	+			+
Epilepsy syndromes	+	+		+

†Relative frequency of seizures: +++, most common; ++, less common; +, least common.

The Neonatal Seizure Registry consortium of seven tertiary care pediatric centers in the United States prospectively collected data related to etiology in a cohort of 426 newborns with seizures who underwent cEEG. The most common seizure etiologies were hypoxic-ischemic encephalopathy in 38%, ischemic stroke in 18%, neonatal onset epilepsy in 13%, intracranial hemorrhage in 11%, neonatal genetic epilepsy syndrome in 6%, congenital cerebral malformation in 4%, and benign familial neonatal epilepsy in 3%. Additionally, for all these etiologies, the seizure burden was high, with 59% of subjects having >7 electrographic seizures and 16% having status epilepticus. There was no significant difference in seizure burden between preterm and term newborns or among the three most common causes of seizure (hypoxic-ischemic encephalopathy, ischemic stroke, and intracerebral hemorrhage).[25] These etiologies were similar to those reported in a study by Weeke and colleagues of 378 newborns obtained over a 14-year period with seizures confirmed by EEG or aEEG from a level 3 neonatal intensive care unit. The most common etiologies identified were hypoxic-ischemic encephalopathy (46%), intracranial hemorrhage (12.2%), and perinatal arterial ischemic stroke (10.6%).[92] These etiologies are quite similar to those found in a study by Tekgul and colleagues in which 89 newborns underwent careful etiologic evaluation. The most common etiologies were global hypoxic-ischemic encephalopathy in 40%, focal ischemic injury in 38%, intracranial hemorrhage in 17%, cerebral dysgenesis in 5%, transient metabolic disturbance in 3%, infection in 3%, and an inborn error of metabolism in 1%. The etiology remained unknown in 12%.[82] Thus, in summary, three key conditions account for nearly 75% of neonatal seizures—hypoxic-ischemic brain injury (40%-50%), arterial stroke (10%-15%), and intracranial hemorrhage (10%-20%). The next two most common etiologies are intracranial infection (5%) and cerebral dysgenesis (5%). The remaining less common conditions, accounting for 5%-10% of all seizures, remain important due to potential therapeutic interventions in transient metabolic disorders and inborn errors of metabolism.

Hypoxic-Ischemic Encephalopathy

Hypoxic-ischemic encephalopathy is the most common cause of neonatal seizures in both full-term and premature infants, accounting for close to one-half of the causes. The seizure burden is often high in the term newborn with hypoxic-ischemic encephalopathy and may result in electrographic status epilepticus in between 10%-15% of cases. A multicenter observational study of 90 newborns treated with therapeutic hypothermia for hypoxic-ischemic encephalopathy and who underwent conventional EEG monitoring–identified electrographic seizures in 48%, including 10% with electrographic status epilepticus. Abnormal EEG background features (excessively discontinuity, depressed and undifferentiated patterns, burst suppression, or extremely low voltage) were associated with seizures, but no perinatal variables, including pH <6.8, base excess ≤−20, or 10-minute Apgar score ≤3, predicted seizure occurrence.[27] Similarly, an earlier single center of 26 consecutive newborns with hypoxic-ischemic encephalopathy undergoing therapeutic hypothermia and continuous conventional EEG monitoring identified electrographic seizures in 65%, which were entirely nonconvulsive in 47% with seizures and constituted electrographic status epilepticus in 23% with seizures.[99] Regarding the timing of seizures in hypoxic ischemic encephalopathy (HIE), conventional teaching has been that seizures generally occur in the initial 24 hours of life and become more frequent from 12-24 hours after birth. Recent studies using EEG monitoring in consecutive newborns with hypoxic-ischemic encephalopathy confirmed that seizures are most common in the initial 24 hours but that they can initiate during hypothermia, rewarming, and rarely after return to normothermia.[69] There is some evidence that therapeutic hypothermia may reduce electrographic seizure exposure in newborns. However, comparing seizure incidence on studies conducted prior to and after therapeutic hypothermia utilization may not reflect a reduction in seizures since most studies performed initially relied on clinical observation for seizure identification, while most studies performed later used EEG monitoring for seizure identification. Data obtained prior to the implementation of therapeutic hypothermia as a neuroprotective strategy reported electroencephalographic seizures in 22%-64% of newborns.[71] In newborns with moderate to severe hypoxic-ischemic encephalopathy managed with therapeutic hypothermia, seizures were identified in 30%-65%.[100]

Ischemic Stroke

Ischemic stroke is the second-most common cause of neonatal seizures in full-term newborns, accounting for between 10%-20% of cases.[25,82,92] The incidence of perinatal arterial stroke is approximately 1 in 1600-5000. At least half of neonatal stroke cases are not recognized in the neonatal period, but for those that are diagnosed in the neonatal period, up to 97% present with seizures and 50% have seizures as the only recognized sign.[30] Compared to newborns with more diffuse brain injury, such as hypoxic-ischemic encephalopathy, those with neonatal stroke as a cause of seizures are more likely to appear active and alert between seizures. Additionally, seizures caused by arterial ischemic stroke tend to occur after the first 12 hours of life, that is, somewhat later than those caused by hypoxic-ischemic encephalopathy. The risk of developing subsequent epilepsy ranges from approximately 10%-50%, depending on time to follow-up and inclusion criteria.[30]

Cerebral sinus venous thrombosis occurs less frequently than arterial stroke in newborns, affecting approximately 1 in 8000-38,000 children per year; 42%-78% of these newborns have experienced a venous infarct. Seizures are the presenting symptom or a complication of cerebral sinus venous thrombosis in 55%-80% of the cases, but affected

newborns usually also manifest diffuse and focal neurologic deficits.

Intracranial Hemorrhage

Intracranial hemorrhage may be difficult to establish conclusively as a cause of seizures distinct from hypoxic-ischemic or traumatic injury because of the frequent association of one or both of these factors with the hemorrhage. Nevertheless, approximately 15% of term infants have intracranial hemorrhage as the primary cause of their seizure. In the contemporary, multicenter, neonatal seizure registry study described earlier, intracranial hemorrhage was the etiology in 12% of newborns with seizures,[25] and in the large previously described single-center cohort, 12% had intracranial hemorrhage as the etiology.[92]

Primary subarachnoid hemorrhage, although very common, is usually not of major clinical significance. Nevertheless, seizures can occur secondary to subarachnoid hemorrhage in the full-term infant, and in that context the spells most often have their onset on the second postnatal day. Newborns with subarachnoid hemorrhage in association with hypoxic-ischemic encephalopathy usually exhibit seizures on the first postnatal day, probably as a result of the encephalopathy rather than the hemorrhage. In the interictal period, newborns with seizures secondary to uncomplicated subarachnoid hemorrhage often appear remarkably well.

Germinal matrix-intraventricular hemorrhage, emanating from small blood vessels in the subependymal germinal matrix, is principally a lesion of the premature infant, occurring in the first 3 days of life. Seizures in association with this type of hemorrhage usually occur with severe lesions or with accompanying parenchymal involvement or both. Recent studies have documented a high incidence of seizures in the preterm infant in the first 72 hours of life and these were strongly associated with the presence of high-grade intraventricular hemorrhage (IVH).[88]

Subdural hemorrhage is often associated with a traumatic event, and it is probably the associated cerebral contusion that results in the convulsive phenomena. The most common variety of subdural hemorrhage is the convexity type, and the seizures in this setting are often focal. Historically, in one large series, convulsive phenomena occurred in 50% of newborns with subdural hemorrhage and appeared in the first 48 hours of life.[16] However, in more recent series with less severe hemorrhages, the vast majority of subdural hemorrhages are asymptomatic.[94] In most newborns with extra-axial hemorrhage, no neurosurgical intervention is required, and following resolution of the acute, symptomatic seizures, prognosis is excellent.

Intracranial Infection

Intracranial bacterial and nonbacterial infections are not uncommon causes of neonatal seizures. In the contemporary multicenter neonatal seizure registry study described earlier, infection was the etiology in 4% of newborns with seizures.[25] There is an equal incidence in preterm and term infants. Infections can include congenital infections (such as TORCH infection) or acute central nervous system infections. Of the bacterial infections, meningitides secondary to Group B *streptococci* and *Escherichia coli* are the most common pathogens. The onset of seizures in these instances is usually in the latter part of the first week and subsequent to that period. The relevant nonbacterial infections include the various neonatal encephalitides: toxoplasmosis, herpes simplex, coxsackievirus B infection, rubella, and cytomegalovirus infection. In intrauterine toxoplasmosis or cytomegalovirus infection that is severe enough to result in neonatal seizures, the episodes occur in the first 3 days of life. Seizures associated with herpes simplex encephalitis tend to occur after 7 days of life. Early-onset disseminated herpes simplex virus (HSV) disease does not usually present with seizures. Seizures are more common in term infants with localized CNS rather than disseminated disease. The infant with this variety of neonatal HSV infection usually has been discharged from the hospital before the illness begins. The usual signs are stupor and irritability, which evolve to seizures (often focal) and, perhaps, coma.

Developmental Defects

Many aberrations of brain development can result in seizures, which begin at any time during the neonatal period. In the contemporary, multicenter, neonatal seizure registry study described previously, brain malformations were the etiology in 4% of newborns with seizures.[25] Similarly, in prior studies, malformations of cortical development accounted for 5%-9% of neonatal seizures.[82] Common malformations include tuberous sclerosis, focal cortical dysplasia, hemimegalencephaly, lissencephaly, subcortical band heterotopia, periventricular nodular heterotopia, schizencephaly, and polymicrogyria. Although these disorders may be the cause of a substantial percent of neonatal seizures, most patients with these malformations do not have seizures in the neonatal period. In tuberous sclerosis, only 5% of children develop seizures in the neonatal period. Outcomes depend primarily on the type and severity of malformation.

Metabolic Disturbances

In the contemporary, multicenter, neonatal seizure registry study described previously, the etiology was a transient metabolic disturbance in 4% and an inborn error of metabolism in 3% of newborns with seizures.[25]

Hypoglycemia

Hypoglycemia is most frequent in small newborns, most of whom are small for gestational age, and in infants of mothers who are diabetic or prediabetic. Hypoglycemia is thought to be responsible for approximately 3% of neonatal seizures, although the incidence has been falling with improved neonatal care. The most critical determinants for the occurrence

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

of neurologic symptoms in neonatal hypoglycemia are the duration of the hypoglycemia and, as a corollary, the amount of time elapsed before treatment is begun. Neurologic symptoms consist most commonly of jitteriness, stupor, hypotonia, apnea, and seizures. The onset is usually the second postnatal day. Hypoglycemia significant enough to trigger seizures is often associated with adverse neurodevelopmental outcomes.[63]

Hypocalcemia

Hypocalcemia has two major peaks of incidence in the newborn. The first peak, which takes place in the first 2-3 days of life, occurs most often in low-birth-weight newborns, both of average and below-average weight for gestational age, and in infants of diabetic mothers. In a recent series, hypocalcemia was the cause of 3% of neonatal seizures.[25,92]

When hypocalcemia appears later in the neonatal period, without the complicated associated factors of early onset hypocalcemia, delineation of hypocalcemia as the major etiologic factor in the convulsive phenomena is easier. Classically, these hypocalcemic newborns are large, full-term infants who avidly consume a milk preparation with a suboptimal ratio of phosphorus to calcium and phosphorus to magnesium (e.g., cow milk or a high-phosphorus synthetic formula). Hypomagnesemia is a frequent accompaniment or more rarely may be present without hypocalcemia. The neurologic syndrome is consistent and distinctive, involving primarily the following: hyperactive tendon reflexes; knee, ankle, and jaw clonus; jitteriness; and seizures. The convulsive phenomena are often focal, both clinically and electroencephalographically. Later-onset hypocalcemia of the nutritional type is unusual in the United States. Later-onset hypocalcemic seizures are associated more commonly with endocrinopathy (maternal hyperparathyroidism, neonatal hypoparathyroidism) or with congenital heart disease (with or without DiGeorge syndrome).

Inborn Errors of Metabolism

Inborn errors of metabolism may also present with neonatal seizures. Disturbances of amino acid or organic acid metabolism may result in neonatal seizures, virtually always in the context of other neurologic features. The most common of these associated with neonatal seizures are nonketotic hyperglycinemia, sulfite oxidase deficiency, multiple carboxylase deficiency, multiple acyl-coenzyme A dehydrogenase deficiency (glutaric aciduria, type II), and urea cycle defect. Hyperammonemia or acidosis, or both, most commonly accompanies these disturbances. Transient disturbance of the glycine cleavage enzyme may cause neonatal seizures; the diagnosis can be missed if CSF glycine levels are not determined because plasma glycine levels may be normal. The process resolves spontaneously after approximately 6 weeks of age.[67]

Additional unusual causes of neonatal seizures in this context include mitochondrial or peroxisomal disturbance. Of the former, pyruvate dehydrogenase deficiency and cytochrome c oxidase deficiency, with elevated lactate in blood and CSF, are the most common. Although not strictly a "metabolic" disturbance, peroxisomal disease, especially Zellweger syndrome or neonatal adrenoleukodystrophy, associated with elevations of blood levels of very-long-chain fatty acids and other biochemical changes, is associated with severe neonatal seizures caused by associated cerebral neuronal migrational defects.

Pyridoxine dependency, a disturbance in pyridoxine metabolism, may produce severe seizures that are recalcitrant to usual therapy. Onset is usually in the first hours of life, but intrauterine seizures as well as onset after the neonatal period have been observed. Seizures are usually multifocal clonic and recalcitrant to all therapeutic modalities. There is an associated newborn encephalopathy, which may manifest as hyperalertness, tremulousness, or hypothermia. A prodrome of restlessness, irritability, and emesis preceding seizures has been described. A progressive encephalopathy and ultimately death ensue if treatment is not initiated. Clinical studies also indicate that the disorder may begin after days or weeks, that the seizures may respond initially to anticonvulsant medications, and that doses of pyridoxine greater than 100 mg may be necessary to stop the seizures.

Any suspicion of the disorder should lead to a therapeutic trial of pyridoxine. The diagnosis may be suspected from the EEG that usually shows an unusual paroxysmal pattern consisting of generalized bursts of bilaterally synchronous, high-voltage, 1- to 4-Hz activity with intermixed spikes or sharp waves. Diagnosis is supported by documentation of cessation of seizures and normalization of the EEG findings within minutes after intravenous injection of 50-100 mg of pyridoxine. The EEG findings may not normalize for several hours, even when a prompt seizure response is observed. Subsequently, complete control of seizures on pyridoxine monotherapy and recurrence on withdrawal established the diagnosis. Most infants have exhibited subsequent intellectual disability despite therapy from the first days of life. Nevertheless, early therapy may decrease the likelihood or severity, or both, of intellectual deficit; indeed, 8 of the 10 reported infants with normal intellect were identified and treated in the first month of life. The molecular defect involves the active form of pyridoxine, pyridoxal-5-phosphate necessary for the action of glutamic acid decarboxylase (GAD), which leads to the synthesis of the inhibitory neurotransmitter GABA.[91]

Pyridoxamine phosphate oxidase deficiency (PNPO) is a related neonatal epileptic disorder involving synthesis of pyridoxal-5-phosphate. The molecular defect involves PNPO, required for synthesis of pyridoxal-5-PO_4. The clinical presentation often includes fetal seizures, and infants are often premature and exhibit an encephalopathy as well as seizures. The disorder requires treatment with pyridoxal-5 phosphate; pyridoxine, not unexpectedly, is not effective therapy. Folinic acid–responsive seizures refer to a clinical syndrome of neonatal seizures with onset as early as the first hours of life, responsiveness to oral administration of folinic

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

acid, and the presence on CSF analysis for monamine neurotransmitters of two unknown metabolic peaks. The disorder is accompanied by a discontinuous EEG pattern with multifocal sharp waves and progressive cerebral cortical and white matter atrophy. The seizures respond to oral folinic acid at doses ranging from 2-20 mg twice daily; the lowest doses have been used in the neonatal period. At least 50% of the infants have had subsequent cognitive deficits. Recent data indicate that folinic acid responsive seizures and pyridoxine-dependent seizures are syndromes caused by the same genetic defects.

A disorder of glucose transport from blood to brain is important to recognize, because prompt treatment can lead to cessation of seizures and improved neurologic development. This disorder is caused by an autosomal dominant, heterozygous mutation in the GLUT1 transporter (*SLC2A1* gene). Approximately 25% of cases have had onset of seizures in the first 2 months of life. The mean age of onset of seizures is 5 months. The striking metabolic findings are low glucose concentrations in CSF with normal blood glucose concentration. The mean ratio of CSF to blood glucose has been 37%. That the hypoglycorrhachia was not the result of increased glycolysis, but rather of impaired glucose transport, is shown by the consistent finding of a low (rather than high) lactate level in CSF. The impaired glucose transport is related to a defect of the glucose transporter (Glut1) responsible for the facilitative diffusion of glucose across the blood–brain endothelial barrier and across the neuronal plasma membrane. Treatment with a ketogenic diet, which supplies usable metabolic fuel for brain energy metabolism not transported by the glucose transporter, is generally effective in leading to seizure control and may blunt the impaired neurologic development that is a consistent feature of the disease. However, in general, the beneficial effect of the ketogenic diet is most apparent for seizure control.

DEND refers to a syndrome characterized by developmental delay, epilepsy, and neonatal diabetes. Characteristic features are a severe neonatal-onset epileptic encephalopathy and diabetes mellitus, associated with a channelopathy involving the endocrine pancreas and the brain. The molecular defect involves an ATP-dependent potassium channel (KATP), responsive to the ratio of intracellular ATP/ADP concentrations. This channel normally closes when the ATP/ADP ratio rises (i.e., in association with increased blood glucose). Thus potassium remains intracellular, and the cell depolarizes. The depolarization leads to Ca^{2+} influx and thereby to physiologic insulin release. This mechanism serves to regulate insulin release moment-by-moment in response to blood glucose. In DEND, the channels are unable to close properly. Treatment with insulin is inadequate and does not ameliorate the neurologic manifestations. However, sulfonylurea, an oral hypoglycemic agent, binds to the channel, promoting closure and physiologic insulin release. Prompt recognition and treatment of this syndrome with oral hypoglycemic agents, and not systemic insulin administration, is essential for a good neurologic outcome.

Drug Withdrawal

A rare cause of seizures is passive addiction of the newborn and drug withdrawal despite the increasing problem of neonatal abstinence syndrome. The drugs particularly involved are narcotic-analgesics (e.g., methadone), sedative-hypnotics (e.g., shorter-acting barbiturates), propoxyphene, tricyclic antidepressants, cocaine, and alcohol. The usual time of onset of seizures in this setting is the first several days of life.

Neonatal Epilepsy Syndromes

As described earlier, most neonatal seizures represent acute symptomatic (provoked) seizures, but there are rare newborns with epilepsy. Several neonatal syndromes are distinguished principally according to their clinical features. The current International League Against Epilepsy classification system defines several electroclinical syndromes with onset in the neonatal and infantile periods. An epilepsy syndrome was defined as "a complex of clinical features, signs, and symptoms that together define a distinctive, recognizable clinical disorder." These distinctive disorders are identifiable on the basis of a typical age of onset, specific EEG characteristics, seizure types, and other factors that, when taken together, permit a specific diagnosis. The classification and terminology used to describe these syndromes have evolved over time. The five major neonatal epilepsy syndromes are discussed next.

Benign Familial Neonatal Epilepsy (BFNE)

This syndrome is an autosomal dominant condition manifesting with seizures in the first week of life.[76] Seizure onset is usually on the second or third postnatal day, and in the interictal period the newborn appears well. The seizures most often are focal clonic, focal tonic, or apneic, and may occur with a frequency of 10-20 per day or higher. The electroclinical characteristics are typical and consist of an initial brief period of EEG flattening, accompanied by apnea and motor activity, followed by a bilateral discharge of spikes and slow waves, accompanied by clonic activity. The disorder is usually self-limited, with cessation of seizures in 1-12 months. Neurologic development is usually normal. However, about 10%-15% of children develop epilepsy later in life. Family histories indicate autosomal dominant inheritance with incomplete penetrance. However, because of the benign course of the disorder, the history of previously affected family members may be overlooked unless specifically sought by direct questioning of parents and sometimes grandparents. Two separate chromosomal loci have been identified (i.e., chromosome 20q13.3 and chromosome 8q24). Both genes encode voltage-gated potassium channels (KCNQ2 on chromosome 20 and KCNQ3 on chromosome 8), which may function in the same heteromeric complex to regulate the threshold for neuronal excitability. BFNE has also been reported in patients with mutations in PRRT2 and genes coding for a sodium channel subunit

TABLE 55.4 Early Onset Epileptic Encephalopathies Characterized by Burst-Suppression

Clinical Features	Early Myoclonic Encephalopathy (EME)	Early Infantile Epileptic Encephalopathy (EIEE) (Ohtahara Syndrome)
Major clinical seizure types at onset	Myoclonic (also focal motor clonic and tonic)	Tonic spasms (also focal motor clonic)
Electroencephalographic interictal pattern	Suppression burst	Suppression burst
Relation to sleep	Enhanced by sleep	Same asleep and awake
Evolution	Persistent suppression burst	Transition to hypsarrhythmia
Etiology	Metabolic (rarely structural or genetic)	Bilateral structural cerebral lesions (rarely metabolic or genetic)
Outcome	Unfavorable	Unfavorable
Genes	ERBB4, PIGA, SETBP1, SIK1, SLC25A22	STX BP1 in ~30%; KCNQ2 in ~20%; SCN2A in ~10%; AARS, ARX, BRAT1, CACNA2D2, GNAO1, KCNT1, NECAP1, PIGA, PIGQ, SCN8A, SIK1, SLC25A22

(SCN2A).[76] Mutations in these genes are associated with a spectrum of diseases, including neonatal epileptic encephalopathies. A study of 36 families that included 33 families with BFNE found that 27 of these families had KCNQ2 mutations, one had a KCNQ3 mutation, and two had SCN2A mutations.[29]

Benign Nonfamilial Neonatal Convulsions

This syndrome is also referred to as "fifth-day fits" or benign idiopathic neonatal seizures. It is characterized by the onset of seizures in the latter part of the first week of life in apparently healthy full-term infants. The peak time of onset is the fifth day, and approximately 80%-90% have had their onset between the fourth and sixth days of life. The seizures are usually multifocal clonic, often with apnea. Status epilepticus has occurred in approximately 80% of cases. Despite the abrupt onset and frequent status epilepticus, in most patients seizures cease after 24 hours and in all patients within 15 days. The patient is normal between seizures; diagnostic testing, including standard laboratory tests and neuroimaging, are normal; and the prognosis is consistently favorable. The interictal EEG is generally normal, although a nonspecific theta pattern referred to as "theta pointu alternant" has been described in some patients. Anticonvulsant medications are often administered acutely in view of status epilepticus, but long-term therapy is generally not needed in view of the self-resolution of seizures in these patients. The possibility that some cases of benign nonfamilial neonatal convulsions are related to de novo mutations of KCNQ2, the K^+ channel most commonly affected in benign familial neonatal seizures (described previously), is suggested by preliminary data.

Early Myoclonic Encephalopathy (EME) and Early Infantile Epileptic Encephalopathy (EIEE, Ohtahara Syndrome)

Early myoclonic encephalopathy (EME) and early infantile epileptic encephalopathy (EIEE) or Ohtahara syndrome, characteristically present clinically in the first weeks of life (Table 55.4).[2] However, in some patients, these may not present until several weeks, or rarely, even several months of life. Intrauterine onset has been documented. These disorders are characterized by severe recurrent seizures, principally myoclonic and clonic at the onset in EME and tonic spasms at the onset in EIEE, and a striking suppression-burst EEG pattern. Patients with EME tend to have myoclonic seizures involving any part of the body but may also experience focal motor seizures and tonic spasms. Patients with EIEE tend to have frequent clusters of tonic spasms but may also have focal motor seizures. However, the characteristics of the suppression-burst EEG pattern differ (see Table 55.4); in EME, the burst-suppression feature is enhanced by sleep and tends to involve high amplitude bursts followed by brief periods of suppression, whereas in EIEE, the pattern is not altered by sleep or waking and is a more typical burst-suppression pattern. Further, the evolution of the EEG pattern differs; in EME, the burst-suppression pattern persists, whereas in EIEE, the pattern evolves to hypsarrhythmia and West syndrome. The primary etiologies also differ; in EME, the causes are primarily metabolic (especially nonketotic hyperglycinemia but also other amino acid and organic acid disorders), whereas in EIEE, the causes are primarily structural (primarily dysgenetic [i.e., migrational defects, microencephaly, or hemimegalencephaly], but also encephaloclastic [i.e., hypoxic-ischemic disorders]). Definition of an etiologic mechanism is possible in most cases of EIEE, whereas as many as 50% of cases of EME are cryptogenic. Additionally, while structural malformations are the most common causes of EIEE, many genetic mutations have been reported to cause EIEE (Table 55.5). The predominant genetic defect in EIEE is STXBP1, found in 20%-30% of patients. STXBP1 promotes the formation of functional vesicle fusion complexes via interaction with two N-terminal domains of syntaxin 1a, and a loss of function mutation impairs this interaction. Patients with STXBP1 encephalopathy present in the neonatal period with severe

TABLE 55.5 Genes Involved in Early-Onset Epileptic Encephalopathy

Gene	Type / Inheritance	Clinical Manifestation	Protein Function
ARX	EEIE1 / XLR	Ohtahara syndrome	Transcriptional repressor and activator
SLC25A22	EIEE3 / X homozygous	Ohtahara syndrome	Glutamate transport into mitochondrion
STXBP1	EEIE4 / AD	Ohtahara syndrome	Modulator of synaptic vesicle release
SCN1A	EEIE6 / X de novo	Dravet syndrome	Subunit of voltage-gated sodium channel
PNKP	EEIE10 / AR	Microcephaly, seizures, and developmental delay	Enzyme involved in DNA repair
PLCB1	EIEE12 / AR homozygous	Malignant migrating partial seizures in infancy	Phospholipase-C role in intracellular transduction of extracellular signals
KCNT1	EEIE14 / sporadic	Malignant migrating partial seizures in infancy	Sodium-activated potassium channel subunit

Data adapted from Hwang SK, Kwon S. Early-onset encephalopathies and the diagnostic approach to underlying causes. *Korean J Ped*. 2015;58:407-414.

epilepsy and a suppression burst pattern on EEG. While refractory seizures are typical, the core of the phenotypic spectrum is the encephalopathy, which is present in the neonatal period.

Diagnosis

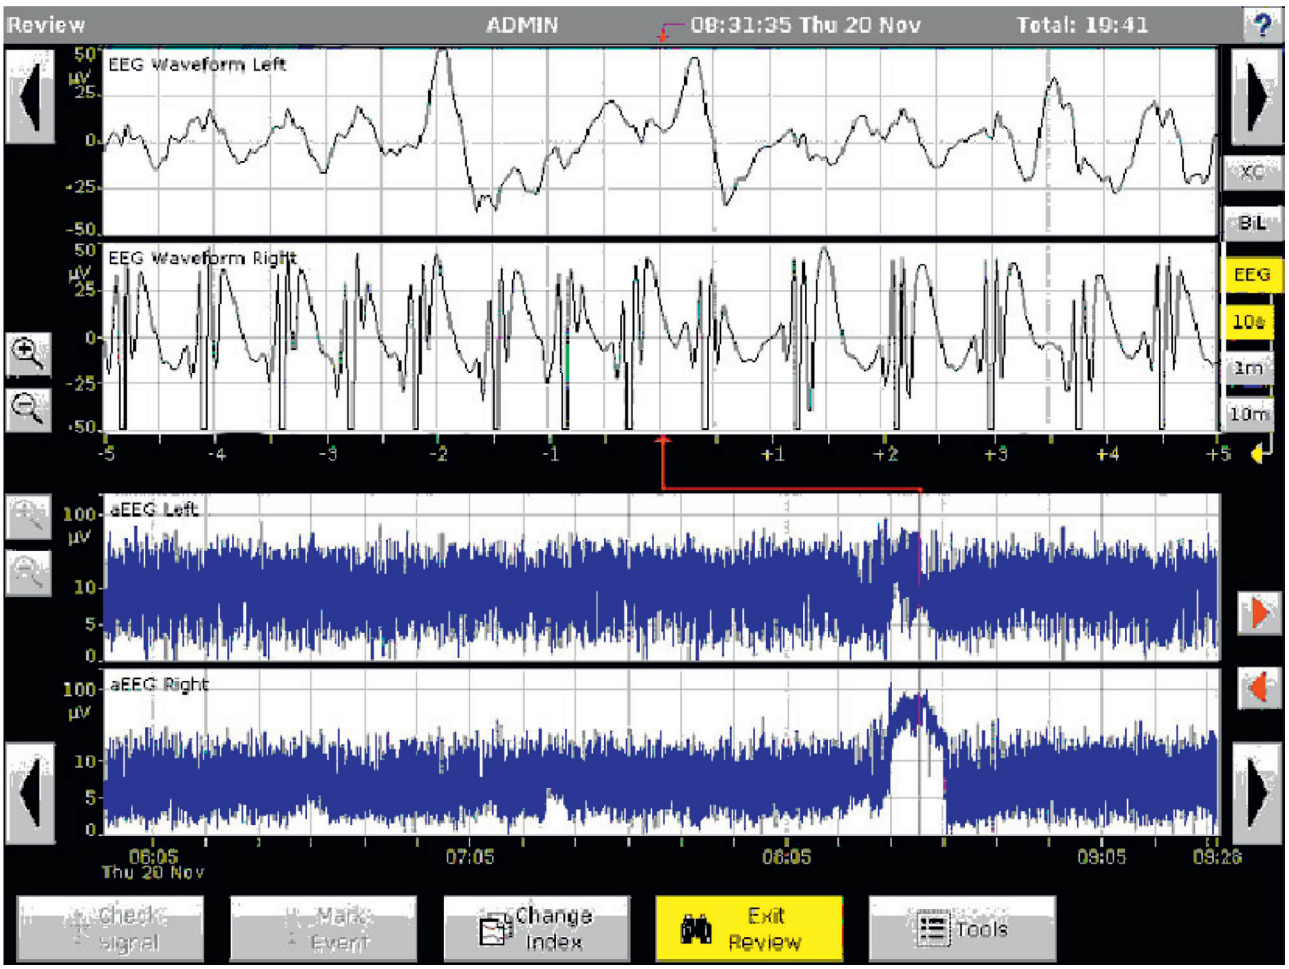
Appropriate diagnostic procedures in the newborn infant with seizures can be surmised from the discussion of causes. However, the diagnostic evaluation often is made unnecessarily complicated, and many diagnoses can be strongly suspected by such uncomplicated maneuvers as obtaining a complete prenatal and natal history and performing a careful physical examination. The first laboratory tests to be performed are directed against the two disorders that are dangerous but readily treated when recognized promptly: hypoglycemia and bacterial meningitis. Thus, blood glucose determination and lumbar puncture should be performed as soon as clinically feasible. In addition, blood should be drawn for determinations of Na^+, K^+, calcium, phosphorus, and magnesium levels. Other imaging and laboratory studies should be directed by specific clinical features. Focal seizures should lead to neuroimaging because of the frequency of focal ischemic cerebral lesions, and MRI is preferred since many focal lesions may not be detected by cranial ultrasound evaluation. As noted earlier, the most common etiologies of neonatal seizures are hypoxic-ischemic encephalopathy, intracranial hemorrhage, and perinatal arterial ischemic stroke. In one study of 354 patients with MRI and ultrasound performed, the diagnosis of important brain lesions would be frequently missed by ultrasound alone. Additionally, MRI contributed information beyond ultrasound to the diagnosis in about 40%.[92] Similarly, in a large cohort registry study by the Vermont Oxford Network, the deficiencies of cranial ultrasound and CT scanning as compared to MR imaging for clinically relevant lesions of deep nuclear gray matter injury and focal cortical and white matter injury were highlighted.

Warning signs for inborn errors of metabolism as a cause of neonatal seizures include: (1) seizures beginning in the antepartum period, (2) seizures refractory to anticonvulsant medications, (3) progressive worsening of clinical and electroencephalographic abnormalities, (4) EEG showing burst suppression, (5) MRI showing prominent brain atrophy, or (6) findings of hypoxic-ischemic encephalopathy without any obvious hypoxic-ischemic event identified. When laboratory testing is performed, the presence of low CSF glucose but normal blood glucose should suggest glucose transporter defect; the presence of elevated CSF glycine despite normal blood amino acids should suggest transient or true nonketotic hyperglycinemia; and the presence of elevated CSF lactate should suggest a mitochondrial disorder.

Electroencephalogram and Electroencephalographic Monitoring

EEG provides important diagnostic and prognostic information. Moreover, increasingly, continuous EEG monitoring is performed in neonatal intensive care facilities for several important reasons. EEG data can assist in the determination of whether clinical events are correlated with electrical seizures requiring anticonvulsant medication or with nonepileptic events in which anticonvulsant medication administration can be avoided. As discussed earlier, some seizures have readily identifiable clinical manifestations (i.e., clonic or tonic components), while many seizures have more subtle manifestations (i.e., orolingual, ocular, or autonomic). Thus clinical diagnosis of seizures may be difficult and unreliable. As described earlier, when compared to the gold standard of electroencephalographic data, observers only classify clinical events correctly as seizures about half of the time, and there is poor interobserver agreement.

As a result of these data, there is increasing emphasis on continuous EEG monitoring to aid in management of seizures in newborns. Many neonatal intensive care units report using EEG monitoring, with conventional EEG or



Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

aEEG, to identify and manage neonatal seizures.[9,70] Additionally, guidelines and consensus statements have advocated for EEG monitoring.[73] This recommendation has included the need for confirmation of seizures by EEG in specialized settings prior to therapy.

The most comprehensive guideline on continuous EEG monitoring in the newborn was produced in 2011 by the American Clinical Neurophysiology Society.[73] The guideline was created to standardize care and define best neuromonitoring practices in the neonatal population while recognizing that not all recommendations would be feasible or applicable across institutions. The guideline recommendations included that (1) electrodes be placed using the International 10-20 system with additional electrocardiogram, respiratory, eye, and electromyography leads; (2) at least 1 hour of recording be assessed to adequately assess cycling through wakefulness and sleep; (3) high-risk newborns be monitored for at least 24 hours to screen for the presence of electrographic seizures; and (4) in newborns with seizures, monitoring occur during seizure management and for an additional 24 hours after the last electrographic seizure. Video EEG recording was recommended for 24 hours rather than a briefer EEG recording, since many newborns will not have seizures in the first hour of recording but will experience electrographic seizures within the first day. Accurate delineation of seizure phenomena by EEG in the newborn requires experienced electroencephalographers with training in the normal developmental features of EEG in the newborn and skilled EEG technologists for the application of the EEG.

Amplitude-Integrated EEG (aEEG)

Amplitude-integrated EEG (aEEG) is in widespread use, especially by neonatologists, as a method to identify electrographic seizures at the bedside. The technique uses a reduced number of electrodes compared to a conventional EEG recording to generate a single channel (2 electrodes) or dual-channel (4 electrodes) EEG tracing. The EEG signal is modified and compressed using algorithms, which vary slightly between manufacturers to generate the final display showing several hours of aEEG data on a single screen. Electrographic seizures are characterized by upward arches (Fig. 55.4). The primary advantages of

• **Fig. 55.4** aEEG demonstrating typical seizure morphology with elevation of baseline and spike wave pattern seen on raw EEG above.

aEEG relate to its relative ease of use. The limited electrode array can be applied by those without specialized training (i.e., not EEG technologists), and the display can be interpreted by bedside caregivers, generally without involvement of electroencephalographers or neurologists. As a result of these advantages and the resource intensity of conventional EEG monitoring, aEEG is widely used in neonatal intensive care units for seizure identification and management.

Some challenges with aEEG have been identified. For example, neonatologists may not have confidence in their ability to interpret the aEEG. In addition, aEEG may underestimate the true incidence of electrographic seizures. In a systematic review of 10 studies of aEEG in newborns for seizure diagnosis,[59] when aEEG was used with the raw EEG tracing available, the median sensitivity was 76% (range 71%-85%) and the median specificity was 85% (range 39%-96%). When aEEG was used without the raw EEG tracing, the results were worse; the median sensitivity was 39% (range 25%-80%), and the median specificity was 95% (range 50%-100%). Additionally, seizures that had low amplitude, were brief duration, or occurred distant from the aEEG recording sites were less likely to be identified. The American Clinical Neurophysiology Society's guidelines on EEG monitoring in newborns states that aEEG can be a "useful, initial complementary tool" to EEG monitoring, which remains the gold standard.

Despite the limitations of aEEG, some studies indicate that in comparison to use of clinical signs alone, aEEG may assist in recognition and management of seizures. In a study of 202 newborns, those who underwent aEEG monitoring had greater precision in the diagnosis of neonatal seizures than in contemporary controls with diagnosis by clinical signs alone.[72] Further, more accurate diagnosis of seizures and subsequent management may reduce seizure exposure in newborns. In a randomized study of 33 infants, neonatologists were allowed to view aEEG in their routine clinical care for 19 patients but were blind to the aEEG data for 14 patients. Among those newborns in whom aEEG was available to neonatologists, there was a trend toward reduced seizure exposure. Further, patients with lower duration of seizures exhibited less severe brain injury on MRI.[86] Similarly, a prospective single center study assessed 26 newborns who were randomized to have management guided by clinical data only (n = 16) or by clinical and electroencephalographic data including cEEG and aEEG (n = 10). The group with electroencephalographic data used for clinical management had a lower seizure burden and more rapid time to treatment completion. Additionally, newborns with increasing seizure burden had worse MRI injury scores and lower performance on cognitive, motor, and language composite Bayley scores.[79] More data with larger series will be of great interest, and two large randomized controlled trials of the impact of aEEG monitoring of newborns suspected of having seizures versus standard clinical evaluation are underway in Australia and the Netherlands.

Prognosis

General Outcomes

The major determinant of prognosis in newborn seizures is the neuropathologic process that underlies the seizures. However, two other considerations are of importance. The first is that although the outcomes of all high-risk newborns, including those with seizures, have improved, there continues a significant risk of disability. A recent review of 4538 children with a history of neonatal seizures demonstrated that 18% developed epilepsy, with nearly 70% having onset within the first year. Associated neurologic impairments were present in 81% of the children with epilepsy, including 18% with intellectual impairment, 6% with cerebral palsy, and 45% with both cerebral palsy and intellectual impairment.[54] The second key factor influencing outcome following seizures in the newborn is the gestational age of the infant. Clinical seizures in the preterm infant are commonly associated with severe brain injury and, thus, a poor prognosis.

Predicting Outcome in Individual Patients

The overall factors regarding prognosis discussed earlier do not answer the question that is most critical to the physician caring for a newborn with seizures: "How can I predict the outcome in my patient?" The two most important factors in predicting outcome for an individual infant are the infant's underlying neuropathology and the EEG pattern.

Relation of Neurologic Disease to Outcome

The most important determinant of neurologic prognosis is the nature of the neuropathologic process that underlies the seizures. The relationship of prognosis with the underlying disease producing the seizures is summarized in Table 55.6. Importantly, nearly all the data are based on follow-up periods that do not extend to school age; thus, the incidence of subtle but potentially important intellectual deficits is largely unknown. Additionally, in many studies, premature and term infants are considered together. The neurologic outcomes related to specific neurologic disorders are discussed in other chapters.

Relation of EEG to Outcome

Two aspects of the EEG are useful in assessment of outcome (i.e., the EEG background and the quantitation of seizure burden). A considerable amount of work has focused on the EEG background, proving that it is valuable for prognostic estimate with the qualification that evaluations of neonatal EEG findings are sometimes difficult and may vary among interpreters. Recent standardized terminology has been proposed by the American Clinical Neurophysiology Society.[84] In several careful studies, the background EEG pattern was found to correlate well with outcome in both full-term and premature infants with seizures. Most newborns with seizures occurring on a normal EEG background generally

TABLE 55.6 Prognosis of Neonatal Seizures: Relation to Neurologic Disease

Neurologic Disease*	Normal Development†
Hypoxic-ischemic encephalopathy	50%
Intraventricular hemorrhage‡	10%
Primary subarachnoid hemorrhage	90%
Hypocalcemia	
Early-onset	50%§
Later-onset	100%#
Hypoglycemia	50%
Bacterial meningitis	50%
Developmental defect	0%

*Prognosis is for those cases with the stated neurologic disease when seizures are a manifestation.
†Values are rounded off to nearest 5%.
‡Usually, severe intraventricular hemorrhage.
§Typically in the first 72 hours of life.
#After 7 days of life.

have a normal outcome, while 90% of newborns with seizures on an abnormal EEG background (e.g., attenuation in voltage, burst-suppression, or excessive discontinuity) have an abnormal outcome. The burst-suppression pattern is particularly typical of the newborn with severe bilateral cerebral disease and is characterized by relatively long periods of voltage suppression (<5μV) or by no electrical activity at all in the intervals between the bursts of activity. Moderate background abnormalities, which generally account for approximately 15%-30% of the tracings, are associated with an intermediate likelihood of sequelae.

The preponderance of data concerning the predictive role of EEG concern newborns with hypoxic-ischemic encephalopathy. Normal EEG background, particularly in the first day of life, is associated with normal outcomes in 80%-100% of newborns, burst-suppression background is associated with unfavorable outcomes in 80%-100% of newborns, and an attenuated EEG background is associated with unfavorable outcomes in 90%-100% of newborns. Consideration of the impact of sedating medications on the EEG background is important; some newborns with backgrounds that predicted unfavorable outcome yet had favorable outcomes may have had their backgrounds worsened by phenobarbital. Additionally, since EEGs may evolve over time, repeat EEG tracings may be useful. EEGs that remain abnormal are more predictive of unfavorable outcomes.

The second major value of EEG in assessment of prognosis is quantitation of seizure burden. An important question is whether seizures in the newborn lead independently to brain injury and thereby worsen outcome. The answer to this question underlies decisions regarding the importance and aggressiveness of seizure identification and management. Data related to seizures and outcome in experimental animals were discussed in earlier sections. The extent to which seizures produce secondary brain injury versus serving as biomarkers of more severe acute brain injury in human newborns remains uncertain, and the relationship in an individual newborn is likely dependent on the etiology and severity of the acute brain injury, seizure burden, and seizure management strategies. Studies using univariate analyses show associations between seizures and less favorable outcomes, but such studies cannot determine whether the seizures contributed to the worse outcomes (i.e., led to secondary brain injury) or merely served as biomarkers of more severe brain injury and thus predicted worse outcomes. Studies using multivariate analyses may be more informative as to the impact of seizures on outcome. Several such reports have identified associations between seizures, particularly high seizure exposures, and unfavorable outcomes in models adjusting for variables reflecting acute brain injury etiology, acute brain injury severity, and critical illness severity. For example, in a study of 63 term-born infants with hypoxic-ischemic encephalopathy who were randomized to treatment of all seizures (clinical + aEEG) compared to treatment of only clinical seizures, a positive correlation was found between seizure duration and MRI injury severity across the entire cohort ($p < 0.001$).[86] Of note, this relationship was only significant for the newborns treated for only clinical seizures ($p = 0.001$), but not for those treated for both aEEG and clinical seizures ($p = 0.292$). In a similar study design of 69 term-born infants with moderate-severe hypoxic-ischemic encephalopathy and clinical seizures randomized to treatment with or without access to EEG data, an association between increasing seizure burden and worsened MRI injury scores ($p < 0.03$) was seen.[79] Of greater importance, an association was found between seizure burden and more adverse neurodevelopmental outcomes on Bayley Scales of Infant Development (cognitive composite $R = 0.502$, $p = 0.03$; motor composite $R = 0.497$, $p = 0.01$; language composite $R = 0.444$, $p = 0.03$). The infants in the aEEG-monitored group experienced a lower seizure burden, although neurodevelopmental outcomes were not shown to be statistically different. Larger data sets from current randomized controlled trials with aEEG monitoring that may lower seizure burden in monitored infants across diverse neuropathologies are required to definitely answer the question of the adverse impact of seizures in the newborn infant. However, the current data support that at least in some newborns, seizures may cause or accentuate secondary brain injury and subsequent worsening of neurobehavioral outcomes.

Management

Selection of Who to Treat

The selection of who to treat requires the accurate identification of the infant with epileptic seizures. As noted earlier, to accurately recognize a newborn infant with seizures requires continuous electrophysiologic monitoring with either gold standard, conventional video EEG, or, if

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

unavailable, limited channel aEEG because of the very high incidence of clinically silent seizures. Why should the infant with seizures be treated with anticonvulsant medication at all? The answer relates to the potential adverse effects of seizures on ventilatory function, circulation, cerebral metabolism, and subsequent brain development, as discussed previously in the chapter. However, more recent reports, characterized by quantitation of electrographic seizures and multivariate analyses adjusting for severity of brain injury, suggest that seizures may accentuate brain injury, especially in newborns with hypoxic-ischemic brain injury. Although not unequivocally established in the human newborn, the balance of information indicates that repeated seizures should be stopped, because they may induce secondary brain injury and less favorable neurobehavioral outcomes. While there remains uncertainty as to the extent to which seizures worsen outcomes and in which patients, whether treatment actually improves outcomes, how aggressively to treat seizures, and what medications are optimal for seizure treatment, the large majority of clinicians treat neonatal seizures.[85] The World Health Organization guideline on neonatal seizures recommended treatment of all clinical and electrographic seizures.[95]

The value of implementation of a standardized treatment protocol has been documented in recent studies. One investigation evaluated neonatal status epilepticus management for 6 months before and 12 months after implementation of a standardized algorithm for therapy in newborn seizures.[32] This included a reduction in the maximum phenobarbital concentrations (57 versus 41 micrograms/mL), fewer patients progressing to status epilepticus (46% versus 36%), and decreased hospital length of stay by 10 days in survivors. Although increased attention to neonatal seizure management may lead to concern for overtreatment and elevated exposure to phenobarbital, there is some evidence that early treatment using a coordinated and consistent approach prevents overadministration of anticonvulsant medication. This conclusion is supported by a recent study of 108 newborns with hypoxic-ischemic encephalopathy cared for before and after implementation of a neonatal neurocritical care service. Nearly all newborns with seizures received phenobarbital at similar dosing (30-33 mg/kg). Although the era after implementation of the service had improved EEG monitoring and improved vigilance for seizures, after adjustment for seizure burden, newborns managed after implementation of the Neonatal Neurocritical Care Service received an average of 30 mg/kg less cumulative phenobarbital and were on maintenance therapy 5 fewer days.[96] These data indicate that even in the absence of an entirely evidence-based approach to neonatal seizure management, implementation of a logical and consistent plan may provide benefit.

Adequacy of Treatment

The decision to initiate seizure therapy and the assessment of the adequacy of treatment rely on accurate identification of seizures. The goal of therapy is the elimination of electrical seizure activity, based on the fact that many seizures in the newborn infant are clinically silent. In addition, the administration of anticonvulsant medications often leads to electromechanical uncoupling/dissociation in which there is cessation of clinical seizures despite persistence of EEG-only seizures. Given these difficulties in seizure identification, clinicians must rely on EEG monitoring as the only means for accurate determination of the adequacy of anticonvulsant therapy. A survey of 193 international neurologists, neonatologists, and specialists in neonatal neurology conducted in 2010 reported that the majority of centers used either EEG, aEEG, or a combination for newborns with seizures or at risk for seizures.[24] Thus the importance of electrophysiologic monitoring to determine accurately the presence of seizure activity appears essential in determination of the success of anticonvulsant therapy.

As management progresses, the goal of total elimination of electrical seizure activity may have to be adjusted based on individual circumstances. Although the goal of therapy is generally total or near-total elimination of electrographic seizures, in some newborns the doses of anticonvulsant medications required lead to potentially dangerous disturbances of cardiac function, blood pressure, and ventilation. For example, because a newborn with cardiovascular instability may not tolerate multiple anticonvulsant medications, the goal may evolve toward reducing seizure burden as much as possible without worsening cardiovascular function. Similarly, if a diagnosis of brain malformation or other neonatal-onset epileptic encephalopathy is made, the goal might be to reduce seizures as much as possible with an anticonvulsant medication regimen that retains acceptable alertness for long-term use.

Usual Sequence of Therapy

The infant exhibiting repeated seizure activity should be treated promptly. Although there are many knowledge gaps related to neonatal seizure management, a systematic approach to management is valuable. The lack of extensive, evidence-based information is notable however. For example, a 2004 Cochrane Database systematic review identified only two randomized controlled trials related to neonatal seizures, and the authors concluded that there were insufficient data to recommend one anticonvulsant medication over any other medication.[7] Similarly, a 2013 systematic review identified 571 publications related to neonatal seizure management but only two randomized controlled trials and only three additional studies with comparison groups. However, partially evidence-based treatment algorithms have been published (see Fig. 55.4).[77] Similar neonatal management algorithms have been developed by others.[33]

Phenobarbital is recommended as the first agent, and internationally phenobarbital is the most frequent initial medication administered for neonatal seizures. However, because of the lack of available data, there is substantial variability with regard to subsequent medication choices

TABLE 55.7 Expected Response of Neonatal Clinical Seizures to Sequence of Therapy

Anticonvulsant Drug* (Cumulative Dose)	Cessation of Seizures (Cumulative Percentage)
Phenobarbital, 20 mg/kg	40%
Phenobarbital, 40 mg/kg	70%
Phenytoin, 20 mg/kg	85%
Lorazepam, 0.05-0.10 mg/kg	95%-100%

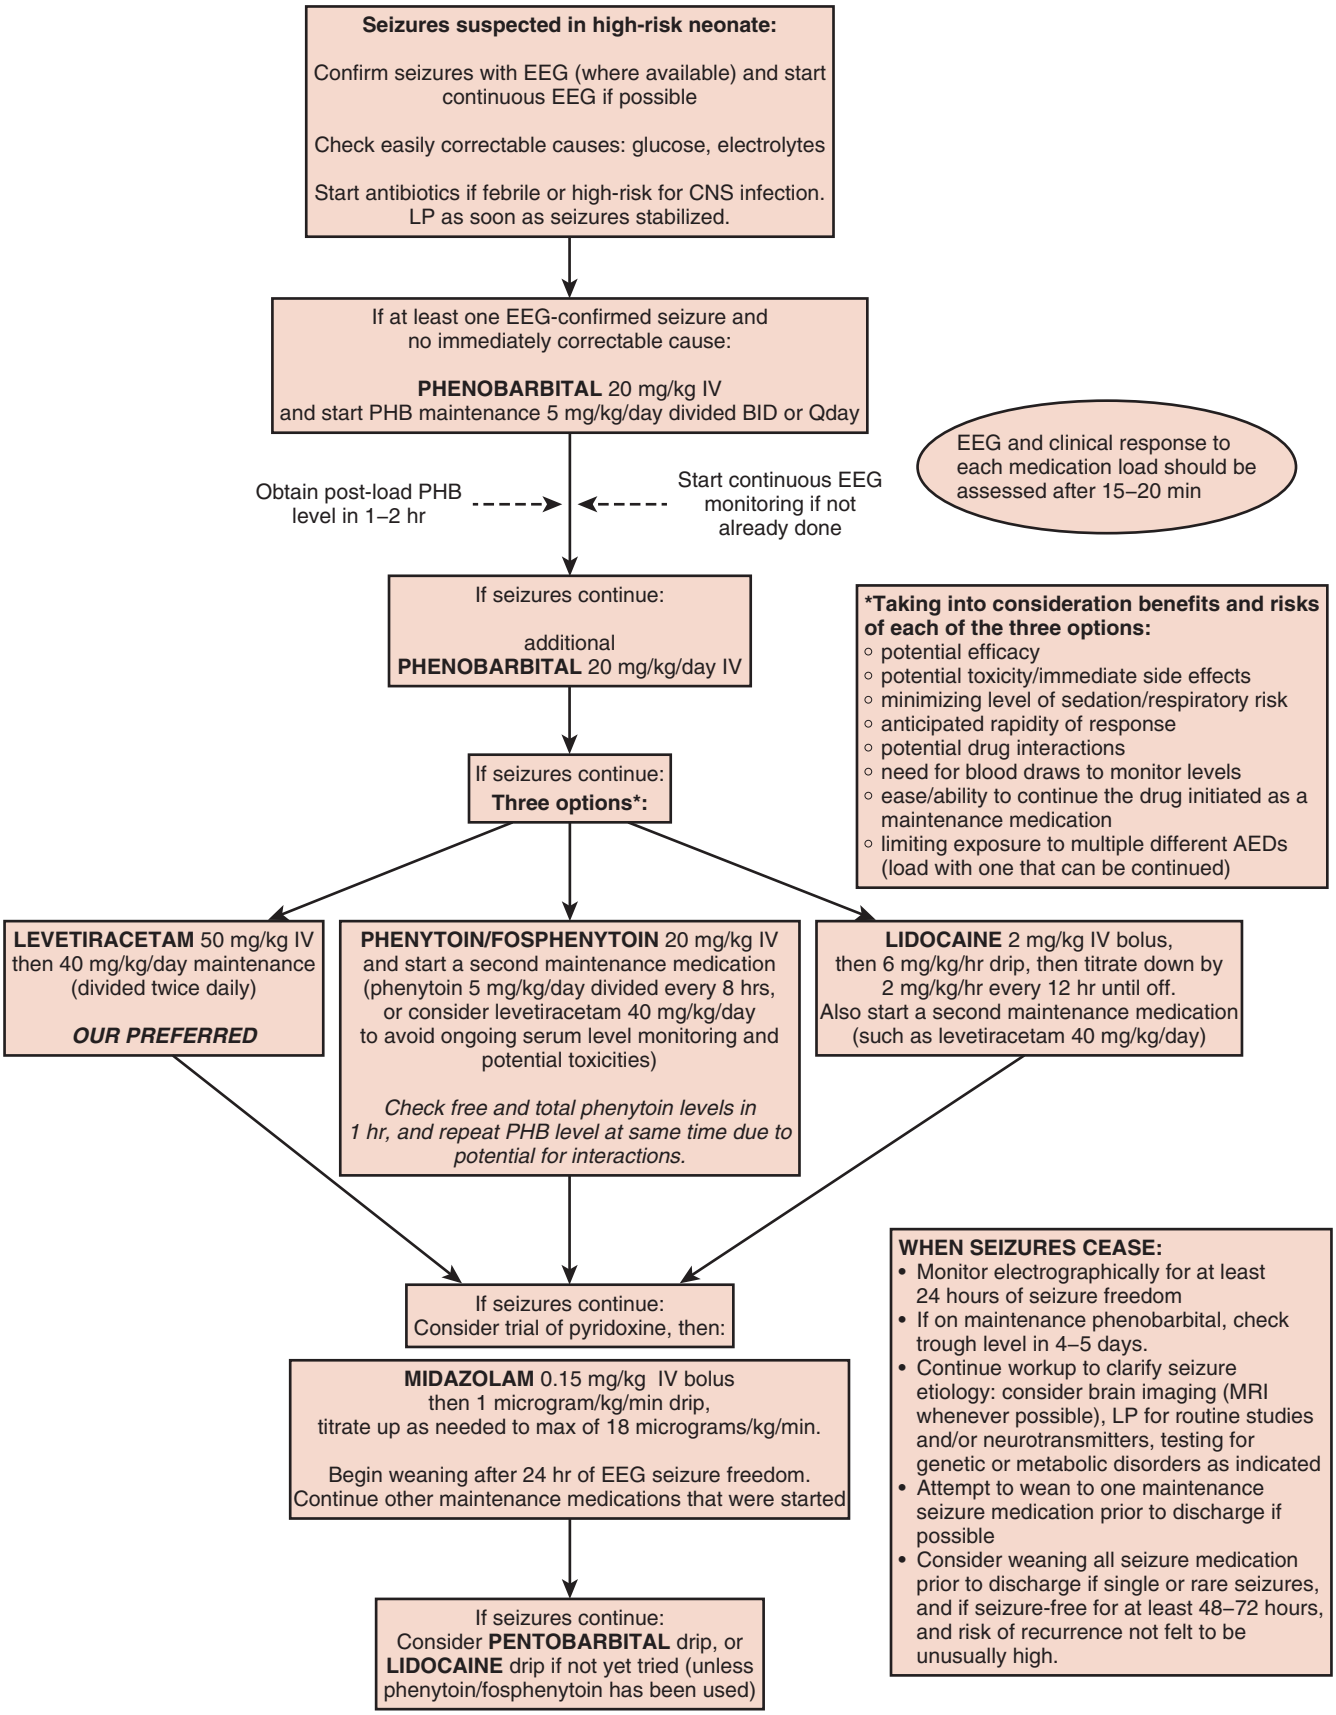
*All drugs administered intravenously.
Based largely on data of Gilman JT, Gal P, Duchowny MS, Weaver RL, et al. Rapid sequential phenobarbital treatment of neonatal seizures. *Pediatrics*. 1989;83:674-678; and on personal experience.

and the duration of therapy. A survey of 193 international neurologists, neonatologists, and specialists in neonatal neurology conducted in 2010 found that the most common first, second, and third line antiseizure medications were phenobarbital, phenytoin, and levetiracetam, respectively.[24] A typical sequence of therapy is provided in Table 55.7. There is varying familiarity and availability of these medications between institutions and countries, so practice is partially hospital specific.

Before reviewing the individual aspects of the sequence of therapy, it is important to emphasize that before instituting any anticonvulsant therapy, the physician should assess and manage ventilation and perfusion. Moreover, because the administration of certain anticonvulsant medications may impair ventilation, the necessary equipment for support of ventilation should be immediately available, with the expectation that the need for intubation is highly likely. If hypoglycemia is present and if the infant is having seizures, then 10% dextrose is given intravenously in a dose of 2 mL/kg (0.2 g/kg), and the newborn should be maintained on intravenous dextrose at a rate as high as 0.5 g/kg/hour (8 mg/kg/minute) if necessary.

Anticonvulsant Medications

Phenobarbital



The initial anticonvulsant medication (Fig. 55.5) is most often phenobarbital administered intravenously in a loading dose of 20 mg/kg, which is generally delivered over 10-15 minutes. Careful surveillance of respiratory effort is important under these circumstances. This dosing is necessary to achieve a blood level of approximately 20 μg/mL, which achieves a clearly measurable anticonvulsant effect in the newborn. Weight or gestational age does not appear to influence the dose–blood level relationship appreciably, although infants less than 30 weeks' gestational age may require slightly lower doses to achieve the same blood level. If the initial 20 mg/kg dose of phenobarbital is not effective in controlling seizures, many clinicians administer additional doses of 5-10 mg/kg each until seizures have ceased, a total dose of 40 mg/kg has been administered, or the patient develops dose-limiting adverse effects. The goal is to achieve a phenobarbital blood concentration of approximately 40 μg/mL.

Using phenobarbital in approximately this manner, Gilman and colleagues[23] and Gal and colleagues[22] attained control of clinical seizures in approximately 70% of 71 newborns. Painter and colleagues used approximately similar doses in a later controlled study of 59 newborns, and the drug completely controlled electrographic seizures in only 43% of newborns.[51] An open-label randomized controlled trial in India also compared phenobarbital (20 mg/kg) to phenytoin (20 mg/kg) in patients with varied seizure etiologies. Seizures were controlled (defined as a seizure-free period of 24 hours) in significantly more newborns with phenobarbital (72%) than phenytoin (15%). If seizures persisted, newborns crossed over to the other drug. Overall seizure cessation occurred in significantly more newborns who received phenobarbital first than phenytoin first (91% versus 80%).[52] A retrospective study of newborns with electrographically confirmed seizures (but excluding newborns with status epilepticus) found that of 91 newborns who received phenobarbital, 63% responded completely (cessation of clinical and electrographic seizures), 17% responded partially (reduction but not cessation of electrographic seizures with the first bolus, response to the second bolus), and 21% did not respond.[78] The presence of EEG-only seizures and more abnormal EEG backgrounds predicted a lack of response to phenobarbital.[78]

Even with a favorable initial response to anticonvulsant medication, close observation is necessary since additional management may be needed. A study using EEG monitoring reviewed by experts calculated electrographic seizure exposure in 19 newborns for 1-hour epochs.[40] The seizure burden was compared in the hour before and subsequent hours after phenobarbitone administration. The seizure burden was reduced by 14 minutes (74% reduction) in the 1 hour after the administration of phenobarbitone, but the reduction was temporary and not significant within 4 hours following phenobarbitone administration. Additionally, only phenobarbitone doses of 20 mg/kg resulted in a significant reduction at 1 hour.[40] Total loading doses of phenobarbital in excess of 40-50 mg/kg generally do not provide additional benefit. Additionally, high levels appreciably sedate the newborn for several days, thereby impairing neurologic analysis, and may lead to toxic effects on the cardiovascular system.

Certain pharmacologic properties of phenobarbital are beneficial in the treatment of neonatal seizures. Thus the drug enters CSF (and presumably the brain) rapidly and with high efficiency (i.e., 30 minutes after an intravenous loading dose was administered, the CSF to blood ratio was 0.58 ± 0.07); the blood level is largely predictable from the dose administered; the agent can be administered intramuscularly as well as intravenously (preferably the latter) for acute therapy; and maintenance therapy is accomplished easily with oral therapy (see later discussion). Moreover,

experimental data suggest that entrance of phenobarbital into brain is accelerated by the local acidosis associated with seizure.

Despite the concerning adverse profile of phenobarbital on neurons in experimental models, there are some data that phenobarbital-related reduction in seizures might yield more favorable neurobehavioral outcomes. A prospective cohort of 42 newborns with hypoxic-ischemic encephalopathy treated with therapeutic hypothermia were either administered phenobarbital (20 mg/kg) prophylactically (20 newborns) or only if clinical seizures occurred (22 newborns). On univariate analysis, the use of prophylactic phenobarbital was associated with a decreased occurrence of seizure in the neonatal period (15% with prophylaxis versus 82% without prophylaxis, $p < 0.0001$) and decreased occurrence of seizures in the first 24 hours of life (5% with prophylaxis versus 64% without prophylaxis, $p < 0.0001$). On multivariate analysis, with birth weight and Apgar scores, the use of prophylactic phenobarbital was associated with more favorable neurodevelopmental outcomes.[46]

As discussed earlier, anticonvulsant medications with GABA agonist properties, such as phenobarbital (or benzodiazepines), may not be ideal agents because $GABA_A$ receptors are likely to be excitatory rather than inhibitory in most immature cortical neurons. More rational approaches might convert $GABA_A$ receptors from excitatory to inhibitory and thereby could enhance effectiveness of phenobarbital. Bumetanide inhibits NKCC1, the Cl^- cotransporter responsible for the elevated neuronal Cl^- levels and the depolarizing (excitation) rather than hyperpolarizing (inhibitory) response on $GABA_A$ receptor activation (see earlier). Blockade of NKCC1 decreases neuronal Cl^- levels and restores the inhibitory response of $GABA_A$ receptor activation. Bumetanide suppresses epileptiform activity in neonatal rat hippocampal slices in vitro and in neonatal rat brain in vivo. This drug has been used safely as a diuretic in the newborn, and an intravenous preparation is available.[39,80] These features have led to the hypothesis that bumetanide used concurrently with phenobarbital (or benzodiazepines) could be particularly effective, because bumetanide would allow the $GABA_A$ receptor activation produced by phenobarbital to lead to inhibition. A phase 2 feasibility study of combination bumetanide and phenobarbital therapy in newborns with hypoxic-ischemic encephalopathy and electrographic seizures enrolled 14 subjects.[56] Five had seizure reductions, but only two did not need additional rescue therapy. There were no acute adverse effects, but all 11 surviving newborns had hearing impairment. The trial was stopped early because of the concerns over the potential negative auditory adverse effects and limited evidence for efficacy by seizure reduction.[56] A second study of bumetanide for neonatal seizures is currently enrolling subjects.[13]

Phenytoin and Fosphenytoin

In the newborn who continues to experience electrographic or clinical seizures after as much as 40 mg/kg of phenobarbital, or in the severely asphyxiated infant in whom less than the full phenobarbital loading dose is deemed appropriate due to cardiopulmonary concerns, phenytoin or fosphenytoin is generally administered as second-line medication (see Fig. 55.5). Phenytoin's mechanism involves blocking of sodium channels and, therefore, represents an alternative mechanism to the action of barbiturates (i.e., phenobarbital) and benzodiazepines, which both act on chloride channels. The usual loading dose is 20 mg/kg for phenytoin or 20 mg phenytoin-equivalents/kg for fosphenytoin. When this approach is used in newborns who continue to exhibit electrographic seizures after 40 mg/kg of phenobarbital, approximately 15% more experience seizure cessation (i.e., to a total of nearly 60%). The cumulative response to the combined phenobarbital and phenytoin therapy is similar regardless of which medication is administered first. In the study by Painter and colleagues, when phenytoin was used as a first-line medication, 45% had seizure cessation.[51] If clinical seizure is the response endpoint, nearly 85% of newborns respond. However, as noted earlier, clinical seizure is not a suitable parameter for measuring seizure response. If 80% or more reduction of electrographic seizure is considered a favorable response, then the combination of phenobarbital and phenytoin achieves this level of benefit in fully 80% of newborns.

The 20 mg/kg loading dose of phenytoin results in a therapeutic blood level of approximately 15-20 μg/kg. The dose of phenytoin should be administered at a rate of no more than 1 mg/kg/minute to avoid disturbance of cardiac function, particularly cardiac rhythm. Cardiac rate and rhythm should be monitored during the infusion. Phenytoin should be administered directly into the intravenous line, because it is relatively insoluble in aqueous solutions and precipitates in standard dextrose intravenous solutions.

Fosphenytoin, a phosphate ester prodrug of phenytoin, has proved to be a major advance in therapy of status epilepticus and acute seizures. The drug's advantages include high water solubility and a pH value closer to neutral, ease of preparation in standard intravenous solutions, safe intramuscular administration, absence of tissue injury with intravenous infiltration, and a faster allowable rate of intravenous administration. Fosphenytoin is dosed in "phenytoin equivalents" (1.5 mg of fosphenytoin yields approximately 1 mg of phenytoin), and the effective dose is essentially identical to that described for phenytoin. The drug is converted to phenytoin, primarily by plasma phosphatases, in approximately 8 minutes. While fosphenytoin may be associated with fewer potential risks, it is more expensive and not readily available in some hospitals or countries.

Phenytoin has complicated pharmacokinetics, which make neonatal use complex. It is highly protein bound, so free levels can be difficult to achieve in newborns with renal or hepatic issues. It also induces hepatic metabolism of many other medications, including phenobarbital which is often concurrently administered. Thus levels of hepatically metabolized medications may need to be monitored. Further, maintaining an adequate and stable drug level is difficult, particularly for maintenance administration.

Maintenance doses of 5 mg/kg/day divided twice per day (for intravenous formulations) or three times per day (for enteral formulations) are recommended. Drug levels should be followed closely as they can fluctuate substantially.

Benzodiazepines (Lorazepam, Diazepam, Midazolam)

Approximately 20% or more of newborns with electrographic seizures do not respond to the sequential administration of phenobarbital and phenytoin. Like barbiturates, benzodiazepines act on the GABA receptor and its chloride channel, thus hyperpolarizing the neuron. Thus benzodiazepines share the mechanistic problems related to GABA activation and chloride levels (see prior discussion) and the adverse effects associated with phenobarbital, including respiratory and, more rarely, cardiovascular depression.

Lorazepam is a benzodiazepine anticonvulsant medication of proven efficacy in older infants and children. Lorazepam enters the brain rapidly and produces a pronounced anticonvulsant effect in less than 5 minutes. Of importance, however, lorazepam is less lipophilic than diazepam, and thus lorazepam does not redistribute from brain as rapidly as diazepam. The duration of action for lorazepam is generally 6-24 hours (i.e., longer than diazepam). Moreover, lorazepam appears less likely to produce respiratory depression or hypotension than does diazepam. Lorazepam has been investigated in the newborn in several studies.[43] It has been effective in treatment of neonatal clinical seizures, whether as a second drug (after phenobarbital) or as a third drug (after phenobarbital and phenytoin). The onset of effect has been in 2-3 minutes, and the duration has extended to 24 hours. The effective dose is 0.05-0.10 mg/kg, administered intravenously in 0.05 mg/kg increments over several minutes. The half-life of lorazepam in asphyxiated newborns is approximately 40 hours (i.e., two- to threefold higher values than in the adult). This prolonged half-life could relate to decreased hepatic glucuronidation activity, a normal neonatal finding perhaps accentuated by asphyxial hepatic injury.

Diazepam is an effective anticonvulsant in the newborn but is less used than lorazepam for several reasons. First, diazepam is a poor drug for maintenance because of extremely rapid clearance from the brain (minutes after intravenous administration). Second, when used with barbiturate, diazepam carries an increased risk of severe circulatory collapse with respiratory failure. Third, the therapeutic dose is variable and is not necessarily less than the toxic dose (doses of 0.30 and 0.36 mg/kg have led to respiratory arrest). Fourth, the vehicle for intravenous diazepam, in many preparations, contains sodium benzoate, which is a very effective uncoupler of the bilirubin-albumin complex and theoretically could increase the risk of kernicterus.

Midazolam is a short-acting benzodiazepine in common use in the treatment of refractory status epilepticus in older infants and children. This drug has the advantage of less respiratory depression and sedation than lorazepam or diazepam. Reports suggest that midazolam is useful in refractory neonatal seizures. In a recent study of 13 newborns with electrographic seizures nonresponsive to phenobarbital with or without phenytoin, 8 responded to midazolam administered as a 0.15 mg/kg bolus followed by infusion of 0.4 mg/kg/hour.[11] The remaining 5 nonresponders responded after an additional bolus and somewhat higher infusion rates (maximum of 1.1 mg/kg/hour). Control of seizures generally was rapid (<2 hours), especially when treatment was begun promptly after failure of phenobarbital. Midazolam is usually started with a loading dose of 0.05-0.2 mg/kg and an infusion of 0.05-0.1 mg/kg/hour. If seizures persist, additional loading doses may be administered, and the infusion may be increased by 0.05-0.1 mg/kg/hour to maximum doses of about 0.5 mg/kg/hour.

Lidocaine

Lidocaine can be used as a second or third-line agent for refractory neonatal seizures. The medication has good central nervous system penetration and acts as a depressant, although its mechanism of action as an anticonvulsant medication is uncertain. Lidocaine is used much more frequently in Europe than in North America; one study has shown it to be the third-line agent of choice at multiple major European medical centers. A retrospective study of 319 term and 94 preterm newborns described the response rate to lidocaine for neonatal seizures confirmed by aEEG.[93] Lidocaine had a good (>4 hours with no seizures, no need for rescue medication) or intermediate (0-2 hours with no seizures, but rescue medication needed after 2-4 hours) effect in 71.4%. Full-term newborns had a better response rate than did preterm newborns (76% versus 55%). Additionally, among full-term infants the response to lidocaine was significantly better than to midazolam as second-line antiseizure medication (21% vs. 13%), and there was a trend toward lidocaine superiority as a third-line medication as well (68% vs. 57%).[93]

Because of the cumulative risk of toxicity, lidocaine must be stopped within 36 hours. Furthermore, the dose must be reduced in premature infants, or if the newborn is undergoing therapeutic hypothermia, as clearance decreases during hypothermia. Lidocaine can cause arrhythmias and bradycardia. The risk of such side effects can be significantly reduced by carefully following blood levels; the presumed threshold for cardiac and nervous system toxicity is >9 mg/L. It should be avoided in newborns who have congenital heart issues or have received other pro-arrhythmic drugs like phenytoin. In a retrospective study of lidocaine in 368 term and 153 preterm newborns with seizures described earlier,[93] a second analysis assessed cardiac events. Cardiac events were reported in 11 patients (2%) of the 521 patients, and in 7 patients a causal relationship was considered plausible. Risk factors for cardiac events were unstable serum potassium levels, cardiac dysfunction, and concurrent phenytoin use.

Levetiracetam (Keppra)

As a newer anticonvulsant medication, levetiracetam has become a medication used for the treatment of refractory

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

neonatal seizures. In some centers, it is used as a second-line agent before using phenytoin, benzodiazepines, or lidocaine. Levetiracetam likely has a different mechanism of action from other anticonvulsant medications, since it prevents neurotransmitter release by binding to a presynaptic vesicle protein, SV2a. Experimental studies have yielded mixed results in terms of the impact of levetiracetam as a neuroprotective strategy, with some data indicating that it may be neuroprotective and other data indicating that in some situations (such as high-dose with hypothermia) the drug is associated with apoptosis.

While levetiracetam use is increasing, few data are available regarding efficacy. Clinical data consisting of mostly case reports and small series have reported that seizures terminate or decrease in frequency in about 52%-80% of newborns after receiving levetiracetam. Based on available data, levetiracetam does seem to have a reasonable safety profile with few side effects and without drug–drug interactions, and it is available in an intravenous formulation.[38,102] Many child neurologists report using levetiracetam off-label for neonatal seizures and often describe a beneficial response.[74] Optimal dosing is unknown, but common dosing involves intravenous loading doses of 30-50 mg/kg, with escalation to total intravenous loading doses of about 80-100 mg/kg if needed. Maintenance doses of 40-100 mg/kg/day divided twice or three times per day can be used. Blood levels typically are not followed, as they often take several days to return and are not clearly correlated with efficacy. There are ongoing studies of levetiracetam for treatment of neonatal seizures.

Topiramate

Topiramate is a blocker of the AMPA type of glutamate receptor and was shown in the neonatal rat to have potent anticonvulsant effects versus hypoxia-induced seizures, to have protective properties for neuronal or premyelinating oligodendrocyte injury, and not to exhibit neurotoxicity to developing neurons. Unfortunately, although case series describe benefit in some newborns, an intravenous preparation of topiramate is not yet available. Many child neurologists report using topiramate off-label for neonatal seizures and often describe a beneficial response.[74]

Other Drugs and Treatments

Valproic acid, administered orally as adjunctive therapy, led to control of neonatal seizures recalcitrant to phenobarbital (mean blood level >40 μg/mL) in five of six cases.[21] However, elevation of blood ammonia required cessation of therapy in three infants. Because of the uncertain risk of valproate hepatotoxicity in this age group, the value of this drug in the treatment of neonatal seizures is uncertain.

Carbamazepine was reported to be effective as an initial agent in the treatment of neonatal seizures in a study of 10 full-term infants with hypoxic-ischemic encephalopathy.[75] All patients showed an "excellent" clinical response. Therapeutic levels were achieved within 2-4 hours after a loading dose of 10 mg/kg administered by nasogastric tube. However, variability in blood levels suggests that more data are needed to determine the value of this agent.

There have been case reports of successful use of the ketogenic diet for refractory neonatal seizures of unclear etiology.[15] The ketogenic diet is the treatment of choice for patients with glucose transporter defects.

Other medications approved for the treatment of seizures in children or adults are often used in newborns with refractory seizures. These include oxcarbazepine, lamotrigine, felbamate, and vigabatrin. These medications are not available in intravenous formulations and can therefore be more difficult to administer in critically ill newborns. Furthermore, all of these medications are increased slowly over days to weeks, so they are not adequate for the rapid treatment of seizures.

Other Modes of Therapy

Metabolic Strategies

Seizures related to other metabolic disturbances or infection require therapeutic approaches that are better discussed in relation to these specific problems. Pearl has developed a useful clinical approach to neonatal or infantile onset epileptic encephalopathy,[53] and Ficicioglu and Bearden have described a useful treatment algorithm for neonatal seizures caused by some of the most common inborn errors of metabolism.[19]

Recurrent seizures that are not accompanied by any obvious associated findings to aid in diagnosis should raise the possibility of pyridoxine dependency. As noted earlier, the molecular defect involves an aldehyde dehydrogenase (antiquitin or ATQ) in the lysine degradation pathway; the gene involved is *ALDH7A1*. To interrupt seizures, a dose of 100 mg of pyridoxine-HCl is given intravenously accompanied by simultaneous monitoring of the EEG pattern, or orally/enterally with 30 mg/kg/day. Infants with pyridoxine dependency may exhibit hypotonia or even apnea after pyridoxine infusion perhaps because of an abrupt increase of synthesis of GABA in brain and activation of inhibitory GABA receptors in brain stem. Therefore, newborns should be monitored closely during and after the infusion. Any uncertainty regarding the response should provoke repeated 100-mg infusions of pyridoxine (to a maximum of 500 mg), a longer trial of oral pyridoxine (15-30 mg/kg/day), or both. To ensure that a late and masked response is not missed, treatment with oral/enteral pyridoxine should be continued until the aldehyde dehydrogenase deficiency is excluded by negative biochemical or genetic testing. Long-term treatment dosages vary between 15 and 30 mg/kg/day in infants or up to 200 mg/day in newborns and 500 mg/day in adults. As described earlier, some infants not responsive to pyridoxine may require pyridoxal-5-phosphate (PLP), the active form of vitamin B_6. In general, a dose of 50-100 mg/kg divided six times per day is administered for at least a 3-5 day trial. PLP is only available in enteral forms and has side effects similar to pyridoxine. In most of the PLP-responsive cases, PNPO (pyridox[am]

ine phosphate oxidase) deficiency has been identified as the underlying genetic condition (see previous), but idiopathic PLP response occurs as well. has the potential to treat ATQ deficiency as well as PNPO deficiency. Some centers advocate the use of PLP (30 mg/kg/day divided into 3 dosages), as the first-line vitamin B_6, while other centers advocate the consecutive use when pyridoxine, given over 3 consecutive days, has failed to control seizures. Finally, pyridoxine-dependent epilepsy is an organic aciduria caused by a deficiency in the catabolic breakdown of lysine; a lysine restricted diet may assist in addressing the potential toxicity of accumulating metabolites.

Folinic acid responsive seizures (FARS) are genetically identical to ATQ deficiency and require specific therapy. FARS were first described in 1995 in patients with intractable seizures and encephalopathy who had two characteristic, but yet unidentified, peaks (peak X) in the HPLC chromatogram for CSF monoamine neurotransmitter analysis. Patients showed an improvement of seizures upon administration of folinic acid (3-5 mg/kg/day). Thus in refractile epilepsy unresponsive to pyridoxine a trial of folinic acid (leucovorin) should also be considered, with 3-5 mg/kg/day administered for at least 3-5 days.

Seizures associated with biotinidase deficiency tend to present slightly later, often in the second month of life, and there are often other symptoms such as an eczematous rash to suggest the diagnosis; in addition, the newborn screen captures at least some of these cases. Because treatment with biotin 10 mg/day can lead to favorable neurologic outcomes, this disorder should be considered in those newborns with intractable epilepsy of unclear etiology.

The ketogenic diet is the optimal treatment for newborns with a glucose transporter defect with onset of seizures in the neonatal period.

Maintenance Therapy

Typically, maintenance doses are begun 12 hours following administration of the loading dose. These are usually administered in divided doses every 12 hours.

For phenobarbital, intravenous, intramuscular, or oral administration are adequate, although the parenteral routes should be used in the seriously ill infant. Drug accumulation results within 5-10 days when maintenance doses of phenobarbital of 5 mg/kg/day are used. These rates are particularly slow in some asphyxiated infants, presumably secondary to hepatic involvement, renal involvement, or both, and lead more readily to drug accumulation than in nonasphyxiated infants. However, elimination rates do increase with increasing duration of therapy, and dose requirements may increase.

For fosphenytoin, intravenous administration is preferred, although fosphenytoin can be administered intramuscularly. For phenytoin, oral administration of phenytoin is less desirable than intravenous, although pharmacokinetic data have modified the prior notion that phenytoin absorption is poor in the newborn. Maintenance administration of phenytoin in the newborn is particularly difficult because of its nonlinear kinetics and rapid decrease in elimination rates in the first weeks of life. Thus the apparent half-life of the drug decreases from 57 hours in the first week of life to 20 hours in the fourth week. Careful attention to blood levels is particularly necessary when this drug is used for maintenance.

Carbamazepine may be a useful alternative to phenobarbital or phenytoin in maintenance therapy. Oral doses of 10-15 mg/kg/day were associated with good seizure control.

If medications used to control seizures initially are discontinued quickly and seizures recur, some clinicians initiate therapy with standard anticonvulsant medications such as levetiracetam or oxcarbazepine, which appear to have better tolerability, including less sedation, for long-term use than might occur with re-initiation of phenobarbital. However, more data are needed regarding the role of these newer anticonvulsant medications in young children.

Duration of Therapy

The optimal duration of anticonvulsant therapy for newborns with seizures relates principally to the likelihood of seizure recurrence if the drugs are discontinued. What is the risk of subsequent epilepsy in newborns with seizures? The overall incidence of subsequent epilepsy in neonatal seizure survivors has been reported as between approximately 10% and 30%.[83] This range can be refined by considering three important, readily identified determinants. The first of these is the neonatal neurologic examination. The risk of seizure recurrence is increased to approximately 50% when the neurologic examination at discharge is abnormal. The second determinant is the cause of the neonatal seizures. The risk of subsequent epilepsy after neonatal seizures secondary to perinatal asphyxia is approximately 30%-50%, and after seizures secondary to cortical dysgenesis, the risk is about 100%. However, simple, late-onset hypocalcemia has essentially no associated risk. Finally, the third determinant is the background EEG pattern. Of the 54 asphyxiated infants studied by Watanabe and colleagues, none developed subsequent epilepsy when the results of the neonatal interictal EEG tracing were normal or showed only "minimal" or "mild" depression. In contrast, 41% of infants with "marked" depression developed subsequent epilepsy.[90] The value of EEG patterns in determining the risk of subsequent epilepsy has been shown in other studies. Each of these factors should be assessed carefully to determine duration of therapy.

Phenobarbital is often maintained for several months because of concern that seizures may recur if the medication is discontinued early. However, there is growing concern about the sedating and potentially neurotoxic effects of anticonvulsant medications, particularly phenobarbital, which have led some clinicians, including ourselves, to attempt discontinuation of anticonvulsant medication as early as possible. Initial data suggest that early discontinuation of phenobarbital may not impact long-term outcomes. A

study of 146 newborns compared 33 taking phenobarbital and 99 not taking phenobarbital at discharge from the neonatal intensive care unit and found no difference in seizure recurrence or neurologic development at 1-11 years.[31]

Experimental studies have raised the possibility that phenobarbital may have deleterious long-term effects on the developing brain. Initial studies involved rats and cultured cells of neural origin. The relation of these data to the human infant is unclear. The time period of the experiments in the rat corresponded to a period in the human from approximately the sixth month of gestation to years postnatally. Particularly concerning are studies in neonatal rats that showed pronounced apoptotic neurodegeneration within 24 hours after administration of phenobarbital, phenytoin, diazepam, clonazepam, and valproate.[6] Combinations of drugs produced greater effects. Doses and blood levels attained were generally comparable to those used in human infants. The neuronal death was associated with reduced expression of neurotrophins and survival-promoting proteins in the brain.

Some human data suggest possible risk associated with phenobarbital exposure. Studies of human children exposed in utero to several antiseizure medications, including phenobarbital and phenytoin, have demonstrated an increased risk of cognitive impairments in later childhood. A deleterious effect of phenobarbital on cognitive development of infants treated for febrile seizures raised further questions concerning potential toxicity of phenobarbital.

Some of these issues may be slightly less problematic with levetiracetam and topiramate.[58] In fact, experimental data suggest that levetiracetam can be anti-epileptogenic, and both may be neuroprotective in the setting of hypoxic-ischemic encephalopathy. A study of 280 newborns with comparable seizure etiology and neuroimaging characteristics, which adjusted for the number of electrographic seizures and gestational age, found that exposure to increasing doses of phenobarbital and levetiracetam were both associated with worse Bayley Scales of Infant Development scores at 24 months. However, the reductions were more pronounced with phenobarbital. Increased exposure to phenobarbital was associated with worse cognitive and motor scores (8.1- and 9-point decrease per 100 mg/kg; $P = 0.01$). Increased exposure to levetiracetam also was associated with worse cognitive and motor scores (but to a lesser extent than phenobarbital 2.2- and 2.6-point decrease per 300 mg/kg, $p = 0.01$). Increasing doses of phenobarbital were also associated with cerebral palsy while levetiracetam was not.[41]

Together, the facts that prolonged exposure to anticonvulsant medications may not provide benefits in terms of long-term neurodevelopment or epilepsy and may have associated risks suggest that attempts to wean such medications early are appropriate. A review by the World Health Organization recommends consideration of weaning of anticonvulsant medication after 72 hours of treatment if the neurologic examination and/or EEG are normal. The nature of the underlying neuropathology, including the nature and extent of neuroimaging abnormalities, may also assist in determining the risk-benefit of the duration of anticonvulsant therapy, although no formal studies using these guidelines have been undertaken. For those infants who required multiple medications for control, each drug should be weaned individually, with phenobarbital being the last to be discontinued.

Key Points

- Neonatal seizures are common in both the preterm and term born infant.
- Electroencephalography is essential to diagnose and treat neonatal seizures because of the frequency with which clinical signs are misinterpreted as seizures OR seizures or status epilepticus can be clinically silent.
- Seizures are a sign of neurologic dysfunction from a variety of etiologies, including hypoxic ischemia, such as stroke, and metabolic and infectious etiologies. Investigation to determine the etiology of neonatal seizures is necessary and often requires blood and cerebrospinal fluid sampling, electroencephalography, and magnetic resonance imaging.
- Therapy for neonatal seizures is important to limit both the short-term physiologic impact of the seizures and the potential contribution to long-term outcomes. Phenobarbitol remains first-line anticonvulsant therapy.
- Length of time with anticonvulsant therapy for neonatal seizures remains unknown, although more recent trends are to minimize exposure to anticonvulsants unless a protracted risk for seizures persists.

Hypotonia and Neuromuscular Disease in the Neonate

NANCY BASS

Clinicians who care for newborns are often required to consider the possibility that a neuromuscular disorder might be present in a hypotonic infant. The ability to determine the normal expected tone of that infant is vital to assess what additional evaluation might be warranted. Hypotonia can be the result of an insult or disorder in any part of the nervous system, including the brain, spinal cord, and peripheral nervous system. The assessment begins with determination of the normal tone of the neonate. When placed in the supine position, the normal full-term infant shows active movement of flexed limbs. The hips are flexed 70-90 degrees and abducted approximately 10-20 degrees. If passive extension of the legs at the knees is attempted, resistance is met when the popliteal angle is approximately 90 degrees. When the child is pulled to the sitting from the supine position, only slight head lag is present, and on reaching the sitting position, the head should wobble in the midline for a few seconds. Similarly, a predominance of flexor tone is found in the upper limbs. When the infant is held under the axilla, normal tone prevents the infant from slipping through the examiner's hands, and the infant seems to sit in the air. In horizontal suspension, the limbs are flexed, the back is straight, and the head is maintained in the midline for a few seconds. These findings need to be modified for the premature infant who shows decreasing degrees of flexor tone depending on gestational age.[6,29]

The weak, hypotonic infant has a decrease in the expected resistance of muscle to stretch, and there is a decrease in spontaneous movement. If supine, the infant lies in a frog-like position with abduction of the hips and an abnormal extension of the limbs. When pulled to a sitting position, there is head lag with a lack of compensation when the sitting position is reached. In vertical suspension, decreased tone of the shoulder girdle causes the infant to slip through the examiner's hands, and the legs are more extended than flexed. On horizontal suspension, the back hangs over the examiner's hand, and the head and limbs hang loosely. (For further details, see Chapter 28.)

Diagnosis

Almost any condition that affects the central nervous system (CNS; brain or spinal cord) or peripheral nervous system of a newborn can be expressed by a reduction of tone. Furthermore, most acute or multisystem illness in neonates is accompanied by some degree of hypotonia. Therefore, the examiner initially must consider whether the infant is acutely ill from sepsis, organ failure, metabolic dysfunction, or other systemic illness. In addition, medications given to the mother in the time right before birth can have an effect on the infant's muscle tone. Most commonly implicated is magnesium sulphate to prevent preterm labor. If these illnesses are not present, the next step is to consider whether a primary disorder of the CNS or the peripheral nervous system is the cause. In general, a central cause leads to a reduction in tone out of proportion to the degree of muscle weakness, and the limbs demonstrate antigravity power.[30]

Although this finding is useful, there are exceptions. In some hypotonic neonates, there are abnormalities in both the central and peripheral nervous systems. Examples include congenital muscular dystrophy (CMD); congenital myotonic dystrophy; acid maltase deficiency; cervical spinal cord injury; and some mitochondrial, lysosomal, and peroxisomal disorders. In addition, some disorders that are primarily central may initially present with profound hypotonia and weakness. Examples are Prader-Willi syndrome and acute disease such as hemorrhage or infarction involving the deep central gray matter of the brain or spinal cord. Babies with near total asphyxia typically have involvement of the brainstem and at times the upper spinal cord, and thus typically present with profound hypotonia and absence of reflexes, similar to spinal shock seen in acute spinal cord injuries. Conversely, the infant with a mild congenital myopathy demonstrates some antigravity power in the limbs. Finally, hypotonia might be present in the infant without acute systemic or metabolic illness or abnormalities of the nervous system. In these children, there is an unusual

Abstract

Diagnosis of a neuromuscular disorder in a newborn can be challenging. Hypotonia can result from an abnormality in the central or peripheral nervous system. In addition, conditions such as sepsis, chromosomal disorders, and acute multisystem diseases can also lead to hypotonia. Infants can be hypotonic with preserved strength or can manifest weakness. Those with weakness and hypotonia tend to be more likely to have a neonatal neuromuscular disorder. Many of these disorders present later in infancy or childhood whereas some do have their presentation in the neonatal period. As these diseases have varied presentations, accurate diagnosis is vital. These disorders include abnormalities of the anterior horn cell such as the spinal muscular atrophies, abnormalities of the peripheral nerves such as the hereditary motor sensory neuropathies, and abnormalities of the neuromuscular junction such as the congenital myasthenic syndromes. In addition, disorders of the muscles include congenital muscular dystrophies, congenital myopathies, and metabolic myopathies. Recently, there have been tremendous advances in the genetics of these disorders, which have led to many being diagnosed without the need for invasive procedures such as tissue biopsies. In addition, great progress has been made recently in the treatment of some of these disorders, which were previously considered progressive fatal diseases. This has potential implications for addition of these disorders to the newborn screening panel. These emerging therapies demonstrate the importance of accurate diagnosis of neonatal neuromuscular disorders.

Keywords

neonatal hypotonia
infantile spinal muscular atrophy
neonatal myasthenia
congenital muscular dystrophy
congenital myotonic dystrophy
congenital myopathies
infantile Pompe disease

degree of ligamentous laxity such as that seen in Ehlers-Danlos syndrome and osteogenesis imperfecta.

The diagnosis of a neonatal muscle disorder requires a methodical approach similar to that used in the older infant or child. A detailed family, obstetric, and delivery history should be taken. Clues to the presence of a neuromuscular disorder include polyhydramnios, a decrease in fetal movement, and malpresentation, although these conditions can be present in any pregnancy with fetal akinesia (paucity of movement). Information should be obtained about whether there was any birth trauma or asphyxia and on the condition of the infant immediately after delivery.

The general examination begins with observation. Does the infant look sick or distressed? The skin should be examined for pallor, trauma, bruising, or petechiae. Any dysmorphic features or congenital defects of the head, neck, or spine should be noted, as should weight, length, and head size and shape. Each system is then examined with a particular emphasis on respiratory rate, pattern, and diaphragmatic movement; cardiovascular status; the presence of organomegaly; the genitalia; the hips; and the presence of contractures. On neurologic examination, initial observations include the degree of alertness and whether the infant fixes or follows. Posture and spontaneous movements are noted. In particular, movement against gravity should be sought, and the examiner should observe whether movement is greater proximally or distally. When formal examination of the cranial nerves is performed, particular attention should be paid to eye movements. These can be observed as spontaneous movements, elicited by a face or a red ball or induced by gentle rotation of the head (oculovestibular reflex). Caution should be taken when checking this reflex in an infant with possible high cervical cord injury. A lack of fixation or following, but movement with the oculovestibular reflex, suggests a lesion above the brainstem. If the infant is not in severe distress and there is no possibility of cervical spine injury, the degree of hypotonia is assessed by pulling the infant to a sitting position and holding him or her in vertical and horizontal suspension. Passive movement of the joints can assess power and tone in the limbs more gently. Resistance to gentle shaking of an arm or leg also provides a subjective assessment of tone.

On initial observation of a newborn, cerebral dysfunction should be suspected if there are abnormalities in primitive reflexes, poor arousal, paucity of movements in general, or fisting of the hands. Fisting can appear as a "cortical thumb" posture. This is where the thumb is flexed and lies under the first and second fingers. Persistence of this posture is felt to be associated with cerebral dysfunction.[34] The character of the deep tendon reflexes helps distinguish between an upper or lower motor neuron lesion. An upper motor neuron lesion involves descending motor tracts in the brain and spinal cord, whereas a lower motor neuron lesion involves the anterior horn cell, peripheral motor nerve, or muscle. If they are abnormally brisk with clonus, then an upper motor neuron lesion is suggested. Five to ten beats of ankle clonus is considered normal in the infant. Sustained clonus or that which is persistently asymmetric is typically abnormal and suggests an upper motor lesion.[84] If absent, a neuropathic lesion or a severe myopathy is more likely. As mentioned above, infants with near total asphyxia may have absent reflexes despite their lesion being of central origin. Assessment of sensation should be attempted, because this may indicate a spinal cord lesion. Although quite atypical to present in the newborn, abnormalities in sensation could point to a hereditary sensory neuropathy.[9]

Facial diplegia is a particular finding in some neuromuscular disorders and less likely in others. It is most commonly seen in such disorders as congenital myotonic dystrophy and the congenital myasthenic syndromes. It can also be an early feature of severe acute basal ganglia damage. Note should be made of the infant's ability to suck and swallow, the pooling of secretions, the character of the cry, and the presence of tongue fasciculations. The latter is most often seen in acute infantile spinal muscular atrophy (SMA) but can be seen in any condition in which there is hypoglossal motor neuron damage, examples of which include storage disorders such as acid maltase deficiency, hypoxic-ischemic damage, and infantile neuronal degeneration.

Neonatal Neuromuscular Disorders

Neonatal neuromuscular disorders are caused by lesions that affect specific parts of the nervous system, including the anterior horn cell, peripheral nerve, neuromuscular junction, or muscle (Box 56.1). Rapid and continuing advances are being made in our understanding of the molecular genetic basis of these disorders.

There are a number of CNS conditions in which hypotonia is of sufficient severity that a neuromuscular disorder should be suspected. These are not discussed in detail here, but they include chromosomal disorders such as Prader-Willi syndrome and Smith-Magenis syndrome (Smith-Magenis syndrome can be particularly hard to distinguish from a neuromuscular disorder as it can often be associated with hyporeflexia or areflexia),[41] multiple minor congenital anomaly syndromes, and metabolic multisystem disorders.

Spinal Muscular Atrophies

The SMAs are predominantly autosomal recessive disorders characterized by degeneration of the anterior horn cells in the spinal cord and motor nuclei in the lower brainstem. The most frequent and best known is infantile SMA, also called Werdnig-Hoffmann disease (SMA type I).[51] Approximately 95% of individuals with SMA are homozygous for a deletion of exon 7 of the survival motor neuron (SMN) gene (*SMN1*) on chromosome 5q13.[73] Although the phenotype varies in severity and age of onset, the acute infantile subtype is well defined and often presents during the neonatal period. This phenotype tends to "run true" in families. Clinically, infants exhibit a severe symmetric flaccid paralysis, which is characteristically greater in the lower limbs than in the upper limbs and greater proximally than distally.

• BOX 56.1 Neonatal Neuromuscular Disorders

Anterior Horn Cell

- Traumatic myelopathy
- Hypoxic-ischemic myelopathy
- Acute infantile spinal muscular atrophy
- Infantile neuronal degeneration
- Neurogenic arthrogryposis

Congenital Motor and Sensory Neuropathy

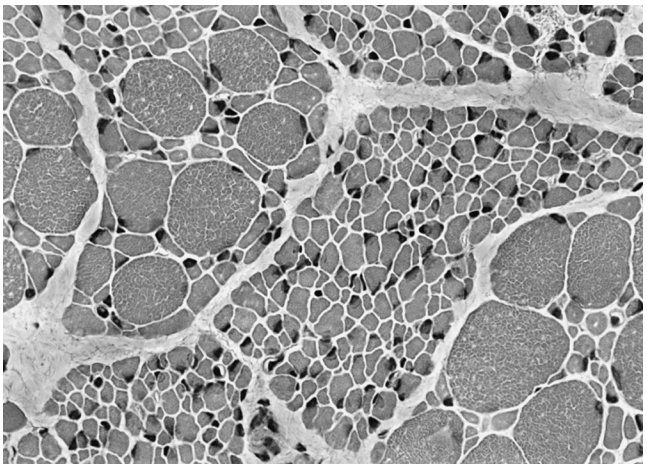
- Congenital hypomyelinating neuropathy
- Charcot-Marie-Tooth disease
- Dejerine-Sottas disease
- Hereditary sensory and autonomic neuropathy

Neuromuscular Junction

- Acquired transient neonatal myasthenia
- Congenital myasthenia
- Infantile botulism
- Magnesium toxicity
- Aminoglycoside toxicity

Congenital Myopathy

- Nemaline myopathy
- Central core disease
- Myotubular myopathy
- Multi-minicore myopathy



Muscular Dystrophy

- Congenital muscular dystrophy with merosin deficiency
- Congenital muscular dystrophy without merosin deficiency
- Walker-Warburg syndrome
- Muscle-eye-brain disease
- Fukuyama-type congenital muscular dystrophy
- Congenital myotonic dystrophy
- Duchenne dystrophy (Xp21-linked dystrophinopathy)
- Early infantile facioscapulohumeral dystrophy

Metabolic and Multisystem Disease

- Mitochondrial disorder
- Peroxisomal disorder
- Neonatal adrenoleukodystrophy
- Cerebrohepatorenal syndrome (Zellweger syndrome)
- Pompe disease (acid maltase deficiency)
- Severe neonatal phosphofructokinase deficiency
- Severe neonatal phosphorylase deficiency
- Debrancher deficiency
- Carnitine deficiency

The onset of this weakness may be identified by the mother, who experiences a decrease or loss of fetal movement during late pregnancy. Although decreased fetal movements may be reported in SMA I (Werdnig-Hoffman disease), this is more commonly reported in patients diagnosed with the prenatal-onset forms of SMA. Respiratory muscle function is poor in the infant. However, it is the intercostal muscles that are weak, because there is relative sparing of the diaphragm. This gives rise to abdominal breathing and a later characteristic bell-shaped deformity of the chest. Deep tendon reflexes are absent or difficult to elicit. The upper cranial nerves are spared, giving rise to an infant with an alert expression, a furrowed brow,

• **Fig. 56.1** Histologic section of muscle showing spinal muscular atrophy. Groups of circular atrophic fibers are interspersed among fascicles of hypertrophied type 1 fibers. Low magnification. (Courtesy of Hannes Vogel, MD, Baylor College of Medicine, Houston.)

and normal eye movements. The bulbar muscles are weak, which is reflected by a weak cry, poor suck and swallow reflexes, pooling of secretions, aspiration, and tongue fasciculations. Cardiac muscle is not affected, and classic arthrogryposis is usually not a feature although rarely it can be. Nerve conduction testing demonstrates normal or slightly decreased motor nerve conduction velocities and normal sensory nerve action potentials. Electromyography shows abnormal spontaneous activity with fibrillations and positive sharp waves as well as an increased mean duration and amplitude of motor unit action potentials, some of which are polyphasic. Serum creatine kinase activity is normal or only slightly elevated. Muscle biopsy reveals large groups of circular atrophic type 1 and 2 muscle fibers (Fig. 56.1). These fibers are interspersed among fascicles of hypertrophied type 1 fibers, which are three or four times normal size and represent fibers reinnervated by sprouting of surviving nerves.[51] This pattern might not be seen during the neonatal period, when there is often only widespread atrophy of type 1 and 2 muscle fibers, making histologic diagnosis difficult. With the advances made in the genetic diagnosis of this disorder, biopsies are rarely needed; however, a later biopsy should show evidence of reinnervation with large hypertrophied fibers and group atrophy.

The infant who presents during the neonatal period with severe acute infantile SMA characterized by profound hypotonia and weakness rarely survives beyond 1 year of age. It is the severity of weakness at the onset that determines outcome in SMA rather than the age of onset, although in most cases the earlier the onset, the greater the weakness. Artificial ventilation of an infant with severe early-onset SMA leads to an alert but completely paralyzed infant who is totally ventilator dependent.[51]

With the identification of the *SMN* gene in 1995, the diagnosis of SMA has been greatly facilitated, limiting the need for more invasive investigations. Additional understanding of the molecular genetics and protein function

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

may provide insight into potential therapies for this otherwise fatal condition. The SMN coding region on chromosome 5q11.2-13.3 contains a telomeric and centromeric copy of the *SMN* gene, designated *SMN1* and *SMN2*, respectively. These genes are nearly identical in their coding sequence. A single nucleotide polymorphism (840C>T) in SMN2 causes disruption of normal translation.[62] The resultant protein produced by the centromeric copy is often truncated and nonfunctional. SMN2 can produce a small amount of full-length protein, providing partial compensation for mutations in SMN1, but the majority must be produced by SMN1. A direct relationship exists between the number of copies of the *SMN2* gene and the age of disease onset, with the SMA type I phenotype correlating with the lowest number of *SMN2* gene copies. Although continued progress has been made recently in defining the exact function of SMN protein, it still remains to be further defined. It is known to play a role in critical housekeeping function: so-called spliceosomal small nuclear ribonucleoprotein assembly, which is important for all cells.[33] How this translates into loss of the specific motor neuron cell RNA has yet to be elucidated.[8]

In December 2017, nusinersen became the first FDA-approved drug for the treatment of 5q SMA. It is an antisense oligonucleotide and acts to modify pre-mRNA splicing of SMN2 to promote increased production of full-length SMN protein.[47] Results of a randomized, double-blind, sham-controlled, phase 3 efficacy and safety trial showed that a significantly higher percentage of infants in the nusinersen group than in the control group had a motor-milestone response (37 of 73 infants [51%] vs. 0 of 37 [0%]). These patients also had a statistically significant likelihood of event-free survival.[36] Additional therapy with single-dose gene replacement is currently in clinical trials.[58] Preliminary results are promising. With these emerging therapies, SMA is now a treatable disorder. This opens the door for consideration of this disorder to be included in newborn screening.

There are a number of genetically heterogeneous SMA variants, but most of these do not present during the newborn period. The variants most important in neonatal or prenatal presentations of SMA include SMA with pontocerebellar hypoplasia, X-linked SMA with arthrogryposis owing to mutations in the *UBE1* gene, and SMARD1 (spinal muscular atrophy with respiratory distress or distal infantile SMA with diaphragm paralysis) that is caused by mutations in the *IGHMBP2* gene, the gene encoding the immunoglobulin μ-binding protein.[39,40]

Arthrogryposis multiplex congenita is a heterogeneous group of disorders characterized by congenital contractures of multiple joints. It is typically the result of decreased fetal movement and can have multiple etiologies from neurogenic, muscular, and genetic syndromes, as well as connective tissue disorders. Many times, the specific etiology cannot be found.[52] The neurogenic arthrogryposes are genetically heterogeneous, and both autosomal recessive and X-linked inheritance have been reported.[17,55] A subgroup of neurogenic arthrogryposis is allelic with SMA type I, and deletions of *SMN* gene have been reported.[17] These disorders are of variable severity. Some show no progression, and muscle strength can even improve. In other cases, bulbar and respiratory function is severely affected, and the prognosis is poor. In the X-linked form, there is disease progression and early death.[55]

As noted above, infants with SMARD1 can present as neonates with congenital contractures along with their severe SMA presentation. Traumatic high cervical spinal cord injury (see Chapter 29) is a rare cause of myelopathy that can be misdiagnosed as SMA. In the absence of an asphyxial brain injury, the infant is alert with no cranial nerve signs. The myelopathy is manifested as a flaccid areflexic paralysis, which might be asymmetric. Clues to the diagnosis include evidence of trauma such as bruising or fractures and normal results on cranial nerve examination. After a few days, evidence of the myelopathy becomes more apparent with the appearance of bladder distention, priapism, and an absence of sweating below the level of the spinal lesion. Sensory testing is difficult but can be assessed by demonstrating facial grimacing to a prick on the face but no response below the neck (see Chapter 29).

In severe hypoxic–ischemic injury, there can be an areflexic flaccid paralysis resulting from death of spinal motor neurons.[21] However, there are also signs of an encephalopathy and multiorgan system damage.

Hereditary Motor and Sensory Neuropathies

The hereditary motor and sensory neuropathies are a genetically heterogeneous group of disorders with a spectrum of phenotypes that includes Charcot-Marie-Tooth disease types 1 and 2, hereditary neuropathy with liability to pressure palsies, Dejerine-Sottas syndrome, and congenital hypomyelinating neuropathy. These diseases may demonstrate an autosomal dominant, autosomal recessive, or X-linked mode of inheritance. Charcot-Marie-Tooth disease type 1 and hereditary neuropathy with liability to pressure palsies are demyelinating neuropathies, whereas Charcot-Marie-Tooth disease type 2 is an axonal disorder. Congenital onset is unusual, and these three forms of hereditary motor and sensory neuropathy most often present in the older child or young adult.[75] The two types that may present in the neonate include congenital hypomyelinating neuropathy and, less commonly, Dejerine-Sottas syndrome.[51,74]

Clinical manifestations vary. Affected infants are weak, hypotonic, and areflexic. The weakness is generalized, but a greater distal weakness might be detected. Arthrogryposis may be present in more severe forms. There are usually swallowing and respiratory difficulties. Sometimes facial weakness is present, but extraocular movements are usually normal. Any associated sensory loss is difficult to detect clinically. Prognosis depends on the initial degree of weakness. In some cases, there is an improvement in strength.[37]

The disorders are characterized by markedly decreased motor nerve conduction velocities (typically less than 10 m/s) and elevated cerebrospinal fluid protein. Sural nerve biopsy in relatively mild cases shows varying degrees of hypomyelination with atypical onion-bulb formation. (Nerve biopsy in the neonatal period would be less likely to show the onion bulb formation.) More severe cases may show complete lack of myelin.[51] These disorders result from mutations in different genes. Moreover, different mutations in the same gene cause different phenotypes (Charcot-Marie-Tooth disease type 1, Dejerine-Sottas syndrome, congenital hypomyelinating neuropathy) and, at present, the clinical phenotype cannot always be predicted on the basis of the gene mutation. Identified alleles include Schwann cell genes involved in the formation, structure, and maintenance of peripheral myelin (*EGR2*, *PMP22*, *MPZ*, *CX32*, *6JB1*, *PRX*), neuronal genes involved in axonal transport (*NEFL*), and genes affecting both Schwann cell and neuronal structure (*MTMR2*).[72,73] Testing for these mutations is available on a clinical basis.

Hereditary Sensory and Autonomic Neuropathies

The hereditary sensory and autonomic neuropathies are characterized by selective involvement of peripheral sensory and autonomic neurons (Box 56.2). These disorders are autosomal recessive with the exception of hereditary sensory and autonomic neuropathy type I, which is autosomal dominant. All present with varying degrees of autonomic dysfunction or insensitivity to pain and temperature.[51] In some, there is absence of the normal axonal flare response to intradermal injection of histamine. In the older child, there is striking self-mutilation.

The best known of the hereditary sensory neuropathies is familial dysautonomia (Riley-Day syndrome; hereditary sensory and autonomic neuropathy type III). This disorder has a high carrier rate in individuals of Ashkenazi Jewish descent and has been mapped to chromosome 9q31-q33. Mutations in the gene for IkB kinase-associated protein (*IKBKAP*) account for 99% of affected individuals.[9] The clinical diagnosis of familial dysautonomia is based on five cardinal criteria: (1) absence of overflow tears, (2) absence of lingual fungiform papillae, (3) depressed patellar reflexes, (4) lack of axonal flare reaction after intradermal injection of histamine, and (5) Ashkenazi Jewish extraction. Additional clinical features typically include hypotonia, labile temperature and blood pressure, breath holding, pallor, poor feeding, failure to thrive, vomiting, loose stools, and irritability.

Treatment of these disorders is mainly supportive, and survival has improved with modern medical therapies. Patients who reach adulthood continue to demonstrate slow progression of their disease. Cognition may be impaired in some forms of the disease.[10]

Clinical testing is available for familial dysautonomia. Until more molecular genetic information is available, differentiation between the other various hereditary sensory neuropathies will continue to be made by distinct characteristics of the history and examination, sensory nerve conduction and action potential size, and changes on sural nerve biopsy.[10]

Congenital central hypoventilation syndrome should be considered in the differential diagnosis of a neonate presenting with an autonomic neuropathy. The classic neonatal form of this disease presents with an infant with hypotonia, decreased or absent deep tendon reflexes, hypoventilation with absence of response to hypercarbia, and autonomic dysfunction.[11,13] These infants typically have a mutation in the *PHOX2B* gene and are at risk for Hirschsprung disease and tumors of neural crest origin.[5,79,86]

• BOX 56.2 Hereditary Sensory and Autonomic Neuropathies

HSAN type I (hereditary sensory radicular neuropathy, autosomal dominant)
HSAN type II (congenital sensory neuropathy)
HSAN type III (Riley-Day syndrome, or familial dysautonomia)
HSAN type IV (congenital insensitivity to pain with anhidrosis)
HSAN type V (congenital insensitivity to pain with partial anhidrosis)
Progressive pan-neuropathy and hypotonia
Congenital autonomic dysfunction with universal pain loss
Familial amyloid neuropathy (autosomal dominant)

Neuromuscular Junction Disorders

Neuromuscular junction disorders are infrequent causes of weakness during the neonatal period. The principal conditions include transient acquired neonatal myasthenia, congenital myasthenia, infantile botulism, and toxic amounts of magnesium or aminoglycosides. These disorders are characterized by abnormal neuromuscular transmission, which is manifested by abnormal muscle fatigability and weakness that is sometimes permanent, particularly in the congenital forms.

Autoimmune myasthenia gravis in children and adults is caused by autoantibodies directed against neuromuscular junction proteins. In 80% of patients, acetylcholine receptor antibodies are detected in the serum. In the remaining patients, other pathologic antibodies, including those directed against muscle-specific kinase, interfere with the normal function of the acetylcholine receptor, resulting in disease.[82]

In acquired neonatal myasthenia gravis, the disease is more often active in the mother. However, she may have less obvious disease, be in remission, or not show clinical manifestations until after the pregnancy.[82] Transfer of immunoglobulin G antibodies occurs readily across the placenta. However, typical features develop in only 20% of infants born to mothers with myasthenia.[46,84] The proportion of

maternal immunoglobulin G antibodies directed against the fetal type versus the adult type of acetylcholine receptor appears to have a strong influence on neonatal manifestations. Although there is no correlation between maternal antibody titers or disease severity and the development of neonatal myasthenia, there is an inverse relationship between maternal disease duration and the incidence of neonatal myasthenia. Maternal thymectomy may be protective against neonatal disease.[28]

The disorder usually presents within a few hours of birth, and onset after the third day has not been reported.[66,67] The most common presentation is generalized weakness and hypotonia.[63] Bulbar weakness is usually present, with feeding difficulties from poor sucking and swallowing, and a weak cry. Facial diplegia can be prominent, but ptosis and ophthalmoplegia are seen less frequently. Pooling of secretions and respiratory difficulties occasionally necessitate artificial ventilation. Deep tendon reflexes are normal. Assuming a correct diagnosis and management, most infants recover within a few weeks.[67] Some infants are severely affected with a history of polyhydramnios and the presence of arthrogryposis multiplex at birth.[27] Treatment is more difficult, and recovery is slower in these infants.

The diagnosis of transient neonatal myasthenia should always be suspected in the infant of a mother with active generalized acetylcholine receptor antibody-positive myasthenia gravis. When signs appear, a cholinesterase inhibitor is administered and the response gauged. To be sure of the diagnosis, an unequivocal and objective response should be chosen, such as an improvement in ventilation and oxygenation or sucking ability. Neostigmine methylsulfate, IM or SC, in a dose of 0.15 mg/kg is the preferred diagnostic anticholinesterase agent. The drug takes effect within 15 minutes of injection and lasts 1-3 hours. Muscarinic side effects (diarrhea, increased tracheal secretions) might require the use of atropine in appropriate doses. Although edrophonium chloride has a more rapid onset and less intense muscarinic side effects, there is a risk of respiratory arrest.[67] When necessary, the diagnosis can be confirmed with repetitive nerve stimulation,[44] which should be performed before and after the administration of a cholinesterase inhibitor. A diagnostically positive response occurs when the amplitude of the fifth evoked compound muscle action potential is reduced by 10% or more of the amplitude of the first response, and this decrement is corrected by a cholinesterase inhibitor.[67]

The management of transient neonatal myasthenia gravis must be early and vigorous, because these infants can deteriorate rapidly. Small, frequent tube feedings should be given and early ventilatory support considered. Neostigmine methylsulfate is given in a dose of 0.05-0.1 mg/kg, IM or SC, 30 minutes before feeding. The oral dose of neostigmine is approximately 10 times the intramuscular dose and is given approximately 45 minutes before feeding. Excessive doses can cause diarrhea, increased secretions, muscle fasciculations, and cholinergic weakness. Disappearance of disease activity is monitored clinically by assessing responses to gradual decreases in the anticholinesterase dose. In addition, repetitive nerve stimulation tests can be performed as well as measurement of acetylcholine receptor antibodies. Tube feeding and artificial ventilation are usually not required for longer than 1-2 weeks, and the average duration of treatment is 4 weeks, with recovery in 90% of infants in less than 2 months.[67]

The congenital myasthenic syndromes are infrequent causes of neuromuscular junction failure during the neonatal period but have become increasingly recognized. They are a group of genetic disorders that are acetylcholine receptor antibody negative and are caused by either presynaptic or postsynaptic inherited defects of the neuromuscular junction. Their precise characterization requires sophisticated laboratory techniques, which are not widely available.[32] Those manifested during the neonatal period are shown in Box 56.3. Postsynaptic disorders of the acetylcholine receptor are the most common. The subunit defect form is associated with significant ptosis and variable ophthalmoplegia. The rapsyn mutation involves a mutation of the receptor-associated protein at the synapse.[48] Typically, this is a more severe presentation than the subunit deficiency. In general, unlike acquired transient neonatal myasthenia gravis, ptosis is usually present in addition to varying degrees of ophthalmoplegia, bulbar palsy, and respiratory weakness. Fluctuating, generalized hypotonia and weakness are seen, and episodes of life-threatening apnea can occur. Exacerbations can be induced by activity, febrile illness, or other stress. These disorders often improve with age, but spontaneous exacerbations occur with a risk of sudden infant death. Arthrogryposis has been reported in one form of the disease.[32] A diagnostic response to cholinesterase inhibitors is variable but useful when positive. Some forms of the disorder, such as congenital endplate cholinesterase deficiency, are refractory to or worsened by cholinesterase inhibitors. The diagnosis is supported by a decremental response to repetitive nerve stimulation at low frequency (2 Hz). However, the low-frequency decremental response

• BOX 56.3 Congenital Myasthenic Syndromes Presenting During the Neonatal Period

Presynaptic Defects (8%)

- Choline acetyltransferase deficiency
- Paucity of synaptic vesicles and reduced quantal release
- Similar to Eaton-Lambert syndrome

Synaptic Basal Lamina-Associated Defects (16%)

- Endplate acetylcholine esterase deficiency

Postsynaptic Defects (76%)

- Kinetic abnormality of acetylcholine receptor (slow- and fast-channel syndromes)
- Acetylcholine receptor deficiency (subunit defect)
- Acetylcholine receptor deficiency (rapsyn mutation)

can be absent in infants with a defect in acetylcholine resynthesis or packaging but can be induced by prolonged 10-Hz stimulation.

A number of toxic agents disturb neuromuscular transmission in the newborn. Hypermagnesemia, usually secondary to IV administration of magnesium sulfate to the mother, causes a presynaptic failure of acetylcholine release by blocking calcium release.[70] The infant shows profound generalized weakness, areflexia, and respiratory dysfunction. In addition, the CNS and smooth muscle are affected, giving rise to stupor and an ileus. Exposure to excessive amounts of aminoglycosides, particularly in conjunction with neuromuscular blockers, can be followed by prolonged weakness from a presynaptic block. Bladder, bowel, and pupillary function are affected.[84,88] Both hypermagnesemia and the neurotoxic effects of aminoglycosides are worsened by hypocalcemia.

Infantile botulism affects infants between 2 weeks and 6 months of age (see Chapter 48).[23,38,84] Unlike botulism in children and adults, which is caused by ingesting the exotoxin of *Clostridium botulinum*, infantile botulism occurs when the intestine is colonized by the clostridia bacteria, where they produce their toxin. This toxin causes a presynaptic cholinergic blockage that affects autonomic as well as skeletal and smooth muscle function. The disorder has a clinical spectrum. Presentation varies from mild constipation and hypotonia to unexpected death. The classic form of the disorder presents with constipation and poor feeding followed by progressive hypotonic weakness and loss of deep tendon reflexes. There is usually marked cranial nerve dysfunction, which includes pupillary paralysis and ptosis. The weakness often progresses in a descending fashion. The illness usually lasts 1-2 months but relapses in a small number of patients.[38] Diagnosis is made by demonstrating an incremental response to repetitive nerve stimulation at high rates (20-50 Hz) and by the appearance of short-duration, low-amplitude motor unit potentials on electromyography.[50] Confirmation of the diagnosis is made on isolation of the organism from the stool. Prompt treatment with human-derived botulism immunoglobulin may significantly reduce the length of time needed for clinical recovery.[69] Management is otherwise supportive.

Congenital Muscular Dystrophy

The CMDs are a variable group of autosomal recessive disorders that share the common presentation of weakness and hypotonia at birth in conjunction with a dystrophic muscle biopsy. The muscle biopsy typically shows endomysial and perimysial connective tissue proliferation, replacement of muscle by fat, and variations in muscle fiber size (Fig. 56.2). There is little evidence of necrosis or regeneration. Immunocytochemical studies help distinguish between different types.[20,64] Clinically, muscular weakness is generalized and usually involves the face. Bulbar and respiratory muscle involvement is variable but can be severe. The creatine kinase level is elevated in some types but is normal or only moderately elevated in others.[51] Arthrogryposis is a common feature.

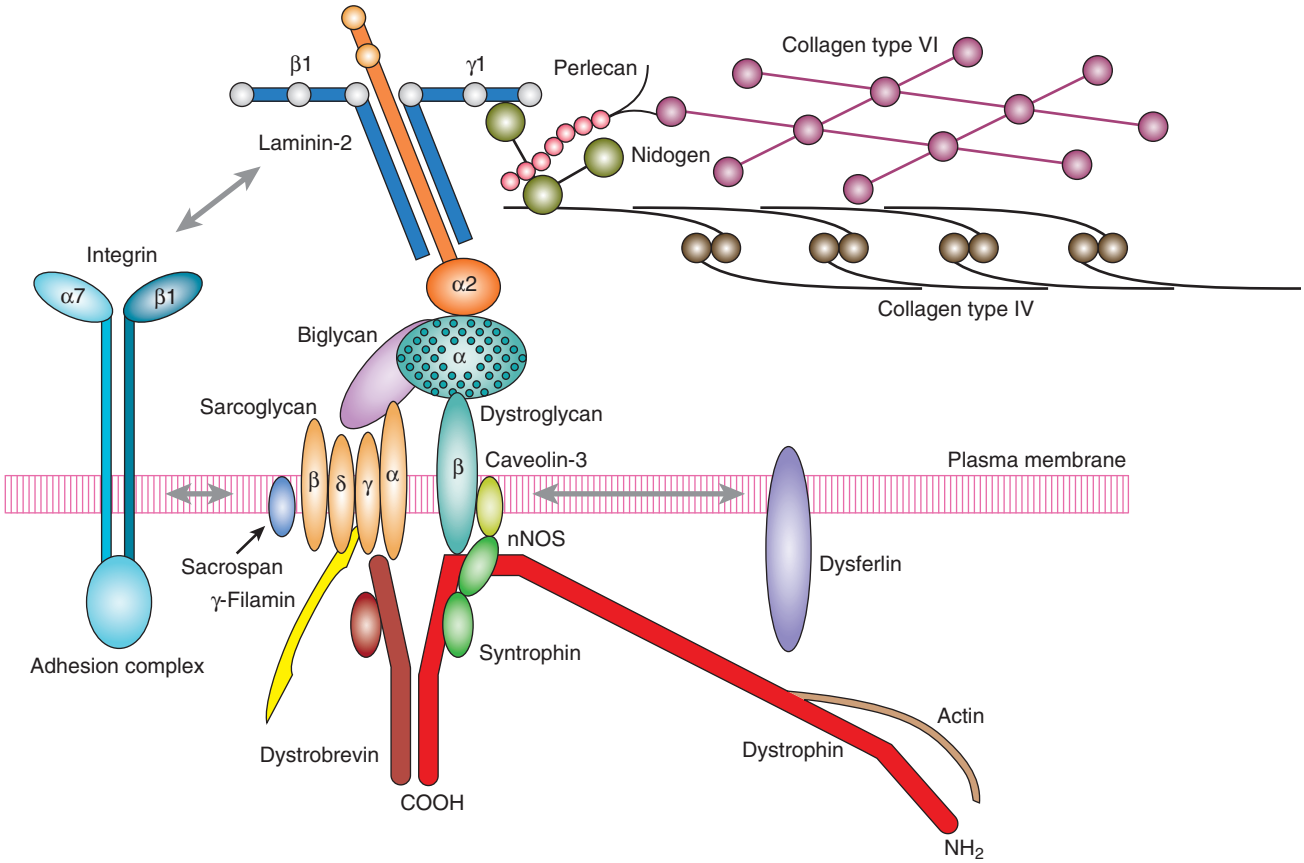
• BOX 56.4 Congenital Muscular Dystrophies

Classic CMD

- Merosin-deficient CMD
- Primary merosin deficiency
- Secondary merosin deficiency
- Merosin-positive CMD
- Classic CMD without distinguishing features
- Rigid spine syndrome
- CMD with distal hyperextensibility (Ullrich type)



Syndromic Forms of CMD

- Fukuyama CMD
- Muscle-eye-brain disease
- Walker-Warburg syndrome

The CMDs have historically been divided into the nonsyndromic ("classic") forms, typified by normal cognition, and the syndromic forms, associated with brain malformations and mental retardation (Box 56.4). This distinction between the classic and syndromic forms has been blurred by advances in molecular genetics showing similarities between the groups and reports of classic CMD presenting with posterior pachygyria in association with cognitive defects.[54]

The classic forms are subdivided into merosin-positive and merosin-deficient subtypes. The merosin-negative form accounts for nearly 50% of all CMDs. Merosin is the heavy α2 chain of the heterotrimeric protein laminin 2 (Fig. 56.3). By linking the extracellular matrix with transmuscle-membrane, dystrophin-associated glycoproteins, the protein plays a critical role in myogenesis and myotubule membrane stability. It is also expressed in Schwann cells, trophoblasts, skin, and cerebral blood vessels. Mutations in the α2-laminin gene (*LAMA2*) on chromosome 6q are responsible for the disease. Sequence analysis of the

LAMA2 gene is available. Diagnosis can also be achieved with muscle biopsy showing complete absence of merosin with immunocytochemical staining.[20] The CMDs can be classified according to the protein defect and, in many cases, this can be identified by immunocytochemistry or DNA analysis.[64] Abnormalities of extracellular matrix protein defects include laminin α2-deficient CMD (MDC1A) and collagen 6A deficiencies as in Ullrich CMD (UCMD 1, 2, and 3); integrin α7 deficiency (ITGA7); abnormalities of glycosyltransferases, which lead to abnormal O-glycosylation of α-dystroglycan and include O-mannosyltransferase 1 (POMT1), O-mannosyltransferase 2 (POMT2), o-linked mannose β1,2-N-acetyl glucosaminyl transferase (POMGnT1), fukutin, fukutin-related protein (FKRP), and acetylglucosaminyltransferase-like protein (LARGE); and endoplasmic reticulum proteins such as selenoprotein N, which causes rigid spine syndrome.

The clinical presentation of merosin deficiency typifies the classic form of the CMDs. There is marked neonatal hypotonia with generalized weakness and atrophy. Although facial weakness may be present, the eye muscles are spared. Contractures occur early and affect multiple joints. Involvement of chest wall muscles results in respiratory difficulties. Cognition is usually not affected. A peripheral neuropathy reflecting absence of merosin expression in Schwann cells can be seen as well. In addition, neuroimaging shows white matter changes, most appreciable after 6 months of age. The abnormality is best characterized by diffuse increased signal intensity on T2-weighted MRI sequences. These findings are thought to correlate with lack of merosin in the cerebral vessel walls.[81] A small minority of patients show structural dysgenesis with occipital pachygyria or agyria. Epilepsy is encountered in one-third of patients.[53]

Although similar in presentation, the other forms of classic CMD can be differentiated based on distinct clinical features and underlying molecular genetics. Ullrich CMD is associated with mutations in the protein subunits of type VI collagen and presents with rigidity of the spine and distal joint hyperextensibility.[25,45] Distinct from Ullrich CMD, CMD with rigid spine is associated with early rigidity of the spine and restrictive lung disease. A considerable number of these patients have been found to have mutations of the selenoprotein N gene on chromosome 1p36-p35.[61] Selenoprotein N mutations have also been described in patients with multi-minicore disease, a type of congenital myopathy. The function of the protein is unknown. Mutations

of the gene for fukutin-related protein on chromosome 19q13 may result in either a severe CMD (CMD type 1C, or MDC1C) or childhood-onset limb-girdle muscular dystrophy.[53] Fukutin-related protein is a putative glycosyltransferase and, similar to the syndromic CMDs (discussed later), this form is associated with defective glycosylation of α-dystroglycan protein in the muscle membrane (see Fig. 56.3). A secondary merosin deficiency is also present on histochemical staining.[20] CMD with a partial merosin deficiency has been defined in a number of patients by biochemical studies. The partial deficiency is thought to be secondary to an underlying α-dystroglycan abnormality with abnormal binding of associated proteins. Linkage to chromosome 1q42 has been made in some of these cases.[15]

The syndromic forms of CMD are associated with brain malformations and ocular findings. The three main types are Walker-Warburg syndrome, muscle-eye-brain disease, and Fukuyama CMD. All three forms result from mutations in genes encoding distinct glycosyltransferases and related proteins involved in post-translational modification of α-dystroglycan, a pathogenetic mechanism shared by the more classic phenotype MDC1C, as previously discussed.[53] Muscle membrane integrity is compromised by the defective α-dystroglycan, which is unable to bind effectively with either extracellular laminin or transmembranous β-dystroglycan (see Fig. 56.3). Muscle biopsy immunocytochemical techniques demonstrate the abnormal α-dystroglycan expression.[20,64] In the brain, abnormal alpha dystroglycan on glial scaffolds, neurons, and their processes are associated with neuronal migrational defects that include disarray of cerebral cortical layering, fusion of the cerebral hemispheres and cerebellar folia, and aberrant migration of granule cells. Disruption of the glial limitans results in cobblestone lissencephaly.[64,65]

Walker-Warburg syndrome is the most severe of the syndromic CMDs. Few infants survive for more than a few months, although prolonged survival is possible with modern medical techniques. Along with muscular dystrophy, typical features of the syndrome include cobblestone lissencephaly with agenesis of the corpus callosum, cerebellar hypoplasia, hydrocephalus, and encephalocele.[65] In contrast with other forms of lissencephaly, there is dysmyelination, with the white matter appearing dark on computed tomography scan and abnormally bright on T2-weighted magnetic resonance images. Ocular findings can include cataracts, microphthalmia, buphthalmos, persistent hyperplastic primary vitreous, and Peter anomaly.[22] Some patients with Walker-Warburg syndrome have been found to have mutations in the protein O-mannosyltransferase (*POMT1*) gene. The gene encodes an enzyme potentially involved in the biosynthesis of specific glycans associated with dystroglycan. The lack of *POMT1* mutations in many patients with Walker-Warburg syndrome suggests genetic heterogeneity.[65]

Muscle-eye-brain disease has many features in common with Walker-Warburg syndrome but is less severe.[22] Brain malformations can include cobblestone lissencephaly, absent septum pellucidum, dysgenesis of the corpus callosum, hydrocephalus, and white matter changes similar to Walker-Warburg syndrome. Eye findings include myopia, choroidal hypoplasia, optic nerve pallor, glaucoma, iris hypoplasia, cataracts, and colobomas. Newborns present with hypotonia, weakness, feeding difficulties, poor vision, and apathy. Distal contractures can be present. All infants ultimately exhibit mental retardation and seizures. In contrast to Walker-Warburg syndrome, most infants have a prolonged survival. However, independent ambulation is unusual. The development of high-amplitude visual evoked potentials by 2 years is a particular feature, and the electroencephalogram is always abnormal by 1 year of age.[31] A significant number of patients with muscle-eye-brain disease have mutations in the gene coding for the glycosyltransferase POMGnT1.[89]

Fukuyama CMD is almost entirely confined to Japan. Overall, the brain and ocular manifestations are less severe than in Walker-Warburg syndrome and muscle-eye-brain disease. A large proportion of patients have mutations of the fukutin gene on chromosome 9q31. The protein function is unknown. Muscle biopsy staining reveals absence of fukutin as well as abnormal glycosylation of α-dystroglycan.[20] In the brain, the cerebral cortex has a cobblestone appearance with pachygyria and polymicrogyria, but there are also areas with normal gyral patterns.[78] Other abnormalities, which differentiate the condition from Walker-Warburg syndrome, include white matter changes, which improve with age, and only mild ventriculomegaly and cerebellar polymicrogyria. Cerebellar and pyramidal tract hypoplasia are probably not features. Eye anomalies are minor and typical of Fukuyama-type CMD. Affected infants present with generalized weakness, hypotonia, and varying degrees of muscle contractures. Facial and bulbar involvement is usually present. Seizures are frequent, and mental retardation is moderate or severe. Survival into adolescence is typical.

Congenital Myotonic Dystrophy

Myotonic dystrophy is an autosomal dominant multisystem disorder of variable expression that is characterized by muscular dystrophy and myotonia in adults. In addition to involvement of muscle, many other systems are affected, including the gastrointestinal, endocrine, and skeletal systems, as well as the heart, brain, and eyes.[43,57] Two loci for the disease have been found and are characterized as DM1 and DM2. The genetic basis for DM1 is an expansion of CTG repeats in the myotonic dystrophy protein kinase (*DMPK*) gene on chromosome 19q13.3.[18] An amplification of greater than 45 repeats is usually associated with disease expression. DM2 is associated with a CCTG tetranucleotide expansion in the zinc finger 9 (*ZNF9*) gene on chromosome 3q21.[56] DM1 has a more severe clinical phenotype, with a progressively earlier onset in successive generations (genetic anticipation). Congenital myotonic dystrophy is the earliest presenting form of DM1, and it is an important cause of neonatal neuromuscular dysfunction, with an incidence of at least 1 in 3500 live births. These

infants usually have greater than 1000 CTG repeats at the DMPK locus. Nuclear accumulation of the abnormal messenger RNA generated by this large repeat size is thought to cause a delay in the differentiation and maturation of skeletal muscle.[2] With rare exceptions, the disease is inherited from the mother.[90] This is related to oligospermia in male patients as well as a greater propensity for larger repeat expansions (more than 1000) during oogenesis than during spermatogenesis.[49,57] The earlier the onset of the disease in the mother and the more severe the clinical expression, the greater the risk for congenital myotonic dystrophy.[43,71] However, the disease can still be seen in offspring of only mildly affected mothers. The phenotypic variation in tissue expression is probably the result of somatic instability of the CTG repeat.[87]

At birth, affected infants frequently require resuscitation and are subject to the mortality and morbidity associated with neonatal encephalopathy (see Chapter 54). A history of polyhydramnios (from failure of fetal swallowing) and decreased fetal movements is frequent, and premature birth can complicate the diagnosis. Furthermore, delivery can be complicated by prolonged labor and postpartum hemorrhage because of poor uterine contractions.[43,71] Generalized weakness and hypotonia in the infant are profound, with facial diplegia and a characteristically tent-shaped triangular upper lip. Deep tendon reflexes are absent or difficult to elicit, and congenital talipes (clubfoot) is often present. Occasionally, joint contractures are more widespread.[43] There is often respiratory distress, and poor suck and swallow reflexes present the danger of aspiration. Eye movements are full, although the infant might not readily fix and follow. Poor respiratory function is due not only to muscle weakness but also to pulmonary immaturity and poor central respiratory control.[43] An elevated diaphragm on the right can be seen on radiographic examination and is probably caused by the presence of the liver on that side and weak diaphragmatic muscles. Hydrops fetalis can occur in infants with cardiac failure. Cardiac conduction defects are commonly seen later and typically are not a presenting finding in the newborn. Poor feeding is commonly seen in infants with this disorder. This is most likely multifactorial, including weakness of the facial muscles and most likely delayed gastric motility in these babies.[14,42] Laboratory investigations in general are not helpful, and the creatine kinase level is normal.

The pathologic appearance of muscle differs from that in adults. The fibers are small and round with central nucleation and display poor fiber type differentiation or relatively small type 1 fibers, giving an immature appearance.[2] The typical adult features appear later. Electromyography is often noncontributory because of poor movement, although myopathic potentials can be demonstrated. Clinical and electrical myotonia are not present but appear later, during early childhood. Neuroimaging reveals ventriculomegaly, intraventricular hemorrhage, subarachnoid hemorrhage, or early periventricular leukomalacia in premature infants. The ventriculomegaly is probably of prenatal origin.[26]

Diagnosis of myotonic dystrophy is supported by clinical and electromyographic examination of the mother and confirmed by molecular genetic analysis. If the infant survives, the hypotonia and severe weakness gradually improve and are no longer evident by later childhood, although motor development is delayed. The facial diplegia with ptosis, open jaw, and triangular mouth persist, giving rise to a characteristic appearance.[43,59] Many affected infants die early, even with intensive care. There is increased mortality among infants requiring greater than 30 days of ventilation, although eventual maturation of diaphragmatic musculature allows for independent ventilation in most.[19] In most patients, mental retardation or significant learning difficulties develop.[43] Unless there is a superimposed cerebral palsy syndrome from a complication of prematurity or perinatal asphyxia, most children walk by age 3 years.[59] All patients with congenital myotonic dystrophy eventually manifest the complete spectrum of features typical of adult-onset disease.

Other Muscular Dystrophies

Severe Xp21-linked dystrophin-deficient muscular dystrophy (Duchenne type) is a degenerative muscle disorder that rarely presents during the neonatal period.[68] Information is scarce on a typical phenotype during the neonatal period. Distinguishing features are an absence of arthrogryposis, high serum creatine kinase, and regeneration or degeneration on muscle biopsy. Diagnosis is made by DNA analysis and immunoelectrophoresis or immunocytochemistry.[51]

Facioscapulohumeral muscular dystrophy is an autosomal dominant disorder that usually presents during early adolescence. Although usually a fairly benign disorder, there is intrafamilial variability, and the disease can present in early infancy.[16] The responsible abnormal gene has been assigned to the subtelomeric region of chromosome 4.[51] Affected patients have a reduction in the normal number of repeats in the DNA sequence termed *D4Z4*. In normal individuals, the EcoR1-digested DNA fragment is usually larger than 28 kilobases (kb), whereas a shorter fragment of 14-28 kb is detected in cases of facioscapulohumeral muscular dystrophy, correlating with the smaller number of repeats.[51] In the early infantile form of the disease, facial weakness is characteristic, and the only manifestation might be partially open eyes during sleep. Progression is variable. In some cases, weakness is relatively mild, with later development of facial and shoulder girdle weakness. In other cases, there is early progressive weakness of the face, shoulder girdle, and ankle dorsiflexion, with loss of independent ambulation by late childhood. Bilateral sensorineural hearing loss is present in many cases. Retinal vascular abnormalities can also be found, which sometimes progress with exudation and retinal detachment. Creatine kinase levels are only moderately elevated. Biopsy of a proximal shoulder girdle muscle shows mild myopathic changes. Other pathologic findings include small, angular fibers; "moth-eaten" fibers; and cellular infiltrates that can be extensive and appear

inflammatory. Although steroids in general are not beneficial in this disorder, albuterol has shown some modest benefit.[54] Electromyography of an affected muscle reveals a myopathic pattern with short-duration, low-amplitude polyphasic potentials.

Congenital Myopathies

The congenital myopathies are primary muscle disorders that are present at birth. Although their expression might not be apparent during the neonatal period, infancy, or childhood, these myopathies are probably all genetically determined. Muscular dystrophies, inflammatory myopathies, muscle diseases caused by metabolic disorders, and inborn errors of metabolism are not included in this group. Congenital myopathies are usually characterized on the basis of their histologic and histochemical features. Although more than 30 different types of congenital myopathies have been described, most of these are rare and unlikely to represent clinically distinct entities. The four myopathies discussed here are relatively common and represent distinct clinical entities with unique histochemical findings.

Nemaline Myopathy

Nemaline myopathy is so called because of the characteristic rod bodies in muscle, which in longitudinal section appear threadlike (Fig. 56.4). They are best seen after modified Gomori trichrome staining of frozen sections, in which they appear red against a blue-green myofibrillar background.[20] The rod bodies are usually subsarcolemmal, and their numbers in muscle are variable and not correlated with the severity of the disease. However, intranuclear rods can be seen in the severe neonatal form of the disease. On electron microscopy, the rods appear to originate from the Z-discs in conjunction with Z-disc thickening and streaming and are composed of thin filament proteins, α-actinin, and actin. In addition to nemaline rods, muscle biopsy shows variations in fiber size with a predominance of type 1 fibers, which are smaller than the type 2 fibers.

• **Fig. 56.4** Histologic section of muscle showing nemaline myopathy. Shown are variations in fiber size. Characteristic rod bodies are seen in the muscle fibers. Low magnification. (Courtesy of Hannes Vogel, MD, Baylor College of Medicine, Houston.)

The disorder has a wide clinical spectrum. A severe congenital form presents with generalized weakness and hypotonia involving the face, bulbar, and respiratory muscles but clinically sparing the eye muscles.[71] Milder forms present during the neonatal period or early childhood. It is relatively nonprogressive and has a facioscapuloperoneal pattern of weakness. The face is long and thin, the palate is arched, and muscle bulk is poor. A relatively mild adult-onset form also exists. All variants can show preferential diaphragmatic weakness with a significant percentage requiring prolonged assisted ventilation. The severity of respiratory involvement at delivery predicts survival. Motor outcome parallels respiratory involvement in the neonatal form.[72] Cardiac involvement is rare and secondary to respiratory disease and pulmonary hypertension. Likewise, a neonatal encephalopathy is related to respiratory failure with hypoxic-ischemic injury.[72] The creatine kinase is usually normal or only slightly elevated. Electromyography in the older child usually shows myopathy, but in the newborn infant it is typically not helpful. Most cases are sporadic, although both autosomal dominant and autosomal recessive inheritance can occur.

Mutations in seven genes encoding for muscle thin filaments have been identified. These include: alpha-tropomyosin (*TPM3*), beta-tropomyosin (*TPM2*), alpha-actin (*ACTA1*), nebulin (*NEB*), troponin T1 (*TNNT1*),[72,85] *CFL2* (muscle specific cofilin), and *KBTBD13 13*. Sequence analysis of these genes is available on a clinical basis.[1]

Mutations in the *TNNT1* gene on chromosome 19q13.4 cause a severe autosomal recessive form of the disease in the Amish population that usually has a fatal outcome in the second year of life.[64] There is otherwise no correlation between mutations in the same gene, mode of inheritance, and clinical severity. In addition, there is considerable intrafamilial variation in course and outcome.[1]

Central Core Disease

Central core disease is an autosomal dominant disorder. Muscle biopsy reveals characteristic central cores of degenerated myofibrils in type 1 fibers, which predominate.[20] The disorder is usually mild when it presents during the neonatal period. Muscle weakness and hypotonia are usually more prominent proximally, and congenital hip dislocation is a frequent associated finding.[51] Mild delay in motor maturation occurs, and scoliosis and contractures can develop later. The gene locus responsible for almost 80% of cases has been mapped to chromosome 19q12-13.2, which is closely linked to the gene for malignant hyperthermia and the ryanodine receptor (*RYR1*).[64] All affected patients are at risk for malignant hyperthermia.

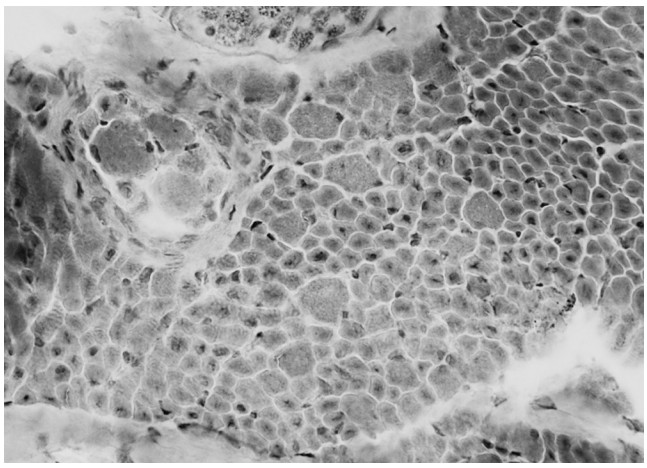
Multi-Minicore Myopathy



Multi-minicore disease is characterized by multiple small areas of sarcomeric disorganization that lack oxidative activity.[35] There is a predominance of small type 1 fibers. Four homogeneous phenotypes have been defined. The classic form presents with mild proximal weakness, joint laxity, scoliosis, and respiratory insufficiency with a rigid spine. An ophthalmoplegic form is associated with facial and generalized weakness. An early onset form may result in arthrogryposis. A slowly progressive form presents with hand amyotrophy. Cardiomyopathy may occur. Both autosomal recessive and sporadic inheritance may occur.[35] Diagnosis is by muscle biopsy, and mutations in the *SEPN1* or *RYR1* gene account for many of the cases.

Myotubular Myopathy

Myotubular myopathy presenting in the neonatal period is an X-linked recessive condition and one of the most severe congenital myopathies. It is caused by mutations in the myotubularin gene (*MTM1*) on chromosome Xq28. The protein tyrosine phosphorylase encoded by this gene is thought to have a vital role in normal myogenesis. The myopathy is characterized pathologically by muscle fibers that contain large central nuclei and resemble fetal myotubes (Fig. 56.5).[20] This central area also lacks myofibrils and appears as a clear area with adenosine triphosphatase staining. There is a predominance of small type 1 fibers. The appearance of the muscle is not caused by a general arrest in muscle development but rather is related to a persistence of fetal cytoskeletal proteins, vimentin, and desmin, which preserve the immature central portions of the nuclei.[20]

With onset during the fetal period, there is often history of polyhydramnios. Death may occur soon after birth or within the first year of life from respiratory failure, although long-term survival is possible. Typical clinical features include generalized hypotonia with facial weakness and ophthalmoplegia. Congenital contractures may be present. Although the disease is nonprogressive in survivors, these patients remain extremely weak, wasted, and unable to sit unsupported. Female heterozygotes may exhibit early onset of limb-girdle weakness but are usually asymptomatic.[76]

Diagnosis of the neonatal variants is initially made by muscle biopsy. Genetic analysis of the myotubularin gene is available and allows for prenatal diagnosis. The creatine kinase level is usually normal, and electromyography is not helpful.

• **Fig. 56.5** Histologic section of muscle showing myotubular myopathy. Shown are large muscle fibers with central nuclei seen primarily in small, predominantly type 1 fibers. Low magnification. (Courtesy of Hannes Vogel, MD, Baylor College of Medicine, Houston.)

Metabolic and Multisystem Disorders

A large number of metabolic disorders directly involve the neuromuscular system and are broadly divided into primary abnormalities of glycogen, lipid, mitochondrial, and peroxisomal metabolism.[84] Some are responsible for well-defined clinical syndromes, such as acid maltase deficiency, which causes Pompe disease, whereas others are protean in their manifestations (see Chapter 90).

Mitochondrial Myopathies

Mitochondrial myopathies are categorized according to the involved area of abnormal metabolism, as follows: (1) defects of substrate transport, (2) defects of substrate utilization and the citric acid cycle, and (3) defects of the electron transport chain and oxidative phosphorylation coupling.[71] In the newborn, defects in electron transport (respiratory chain) are those most likely to lead to prominent muscle disease. Other abnormalities of mitochondrial metabolism, such as pyruvate carboxylase and pyruvate dehydrogenase complex deficiency, are more likely to present with features of a progressive encephalopathy. The most common of the respiratory chain disorders presenting as a myopathy during the neonatal period is cytochrome-*c* oxidase deficiency.[51] Typically, the infant presents with profound generalized weakness, hypotonia, hyporeflexia, poor feeding reflex, respiratory difficulty, and lactic acidosis. Other features may include hepatomegaly, cardiomyopathy, renal tubular defects (de Toni-Fanconi syndrome), and macroglossia. Death occurs within a few months. A reversible form of cytochrome-*c* oxidase deficiency also occurs.[51] The disorder presents in a fashion similar to the severe form, but improves biochemically and clinically over the next 1-2 years. Early diagnosis is vital to provide continuing support while improvement takes place. Cytochrome-*c* oxidase deficiency should be suspected in any weak infant with lactic acidosis, particularly in conjunction with multisystem involvement. The creatine kinase level can be slightly elevated, but electromyography is usually not helpful. Muscle biopsy shows nonspecific myopathic changes, ragged red fibers on Gomori trichrome staining, and an absence of histochemical staining for cytochrome-*c* oxidase. Electron microscopy of muscle fibers demonstrates lipid and glycogen

accumulations and an increased number of large, abnormal-looking mitochondria. The benign and severe forms are differentiated by immunohistochemical techniques, using antibodies directed against different subunits of cytochrome-*c* oxidase. In the fatal form, there is an absence of DNA-encoded subunit VIIa, b. In the benign form, however, both this subunit and the mitochondrial DNA-encoded subunit II are absent.[51] Cytochrome-*c* oxidase deficiency in Leigh syndrome (encephalopathy and magnetic resonance imaging changes) has been recently associated with mutations of *SURF1*, a gene located on chromosome 9q34. However, mutations have not been found in patients with cytochrome-*c* oxidase without Leigh syndrome.

Disorders of Glycogen Metabolism

Apart from acid maltase (alpha-glucosidase) deficiency (Pompe disease), the autosomal recessive disorders of glycogen metabolism (see Chapter 90) present only rarely during the neonatal period.[84] These rare presentations occur with debrancher enzyme deficiency, phosphorylase deficiency, and phosphofructokinase deficiency.

Pompe Disease (Type II Glycogen Storage Disease)

The infantile form of Pompe disease is caused by a deficiency of acid maltase (alpha-glucosidase). The disorder can present during the neonatal period, although clinical onset during the second month of life is more usual.[51,80] The enzyme deficiency causes glycogen accumulation in anterior horn cells of the spinal cord and in the muscles, heart, liver, and brain. Infants present with profound generalized weakness, hypotonia, hyporeflexia, impaired awareness, heart failure, and hepatomegaly. Tongue fasciculations, a large tongue, and severe bulbar weakness are often present. The chest radiograph and electrocardiogram demonstrate cardiomegaly, short PR intervals, and giant QRS complexes. The serum creatine kinase and liver enzymes are elevated, and electromyography shows combinations of denervation and myopathy, including fibrillations and small polyphasic potentials. Muscle biopsy reveals vacuoles containing glycogen, which stain with periodic acid-Schiff. The gene for the alpha-glucosidase enzyme protein is located on chromosome 17q23-25. Diagnosis typically is made by demonstrating the enzyme deficiency in leukocytes, lymphocytes, fibroblasts, or muscle or by demonstrating mutations in both alleles. Glucosidase alpha, acid (GAA), is the only gene known to be associated with Pompe disease. However, there is extensive genetic heterogeneity, and common mutations are found only in ethnic groups such as Ashkenazi Jews or the Amish in Pennsylvania. Prenatal diagnosis has been successful by demonstrating enzyme deficiency in cultured amniotic cells, linkage analysis, and mutation analysis. Prognosis is usually poor, with most infants dying within the first 6 months of life. Enzyme replacement therapy can in some cases delay the need for ventilator support and cardiac morbidity, but response is highly variable.[3,4,80]

Debrancher Enzyme Deficiency (Type III Glycogen Storage Disease)

Rarely, debrancher enzyme deficiency can present during the neonatal period with hypotonia, weakness, hypoglycemia, hepatomegaly, and liver dysfunction. Muscle biopsy shows abnormal glycogen storage, and diagnosis is established by demonstration of the debrancher enzyme deficiency.[51]

McArdle Disease (Type V Glycogen Storage Disease)

There are three different isozymes of phosphorylase (liver, brain, muscle), genes of which have been cloned and localized to different chromosomes.[77] Deficiency of the muscle enzyme on chromosome 11p13 causes McArdle disease.[51] Clinical presentation occurs typically during adolescence, with exercise intolerance, cramps, and myoglobinuria. However, the disorder shows clinical variability and rarely presents during the neonatal period.[24] Infantile McArdle disease presents as a weak, hypotonic infant typically with feeding difficulties. In some infants, the weakness is extreme, contractures are present, and the outcome fatal.[60] Even in the less severe neonatal form, the weakness is slowly progressive but without significant cranial nerve dysfunction. Muscle biopsy shows variations in fiber size, absence of phosphorylase staining, and subsarcolemmal glycogen-containing vacuoles. Unlike Pompe disease, the accumulated glycogen is not membrane bound.[20] Definitive diagnosis is made by demonstrating deficiency of the muscle isozyme or by demonstrating mutations in the phosphorylase gene. Treatment for this condition remains limited. There has been some success with high-protein diets or ingestion of sucrose before exercise.[83]

Phosphofructokinase Deficiency (Type VII Glycogen Storage Disease)

Phosphofructokinase deficiency usually presents with cramps on exercise and myoglobinuria. A severe infantile form presents during the neonatal period.[7] Affected infants exhibit hypotonia, progressive weakness, and contracture formation. Some infants have seizures, cortical blindness, and mental retardation.[84] The muscle biopsy findings are similar to those of McArdle disease, with non-membrane-bound subsarcolemmal glycogen deposits. Diagnosis is established by demonstrating a reduction of phosphofructokinase activity biochemically and histochemically.[20]

Primary Carnitine Deficiency

Primary carnitine deficiency is caused by a deficiency in the transport of carnitine from plasma into the cells of affected tissues.[51] The disorder usually presents in early childhood with a cardiomyopathy, proximal muscle weakness, or recurrent encephalopathy. Rarely, it presents during the neonatal period with weakness, hypotonia, and cardiomyopathy. Hypoketotic hypoglycemia is a clue to diagnosis.[84] Muscle biopsy shows lipid-containing vacuoles, and serum

and muscle carnitine levels are low. The carnitine transporter defect can be demonstrated in cultured fibroblasts.[51]

Peroxisomal Disorders

Peroxisomal disorders can present during the neonatal period with profound hypotonia, weakness, and, at times, hyporeflexia or areflexia. Signs include CNS dysfunction; facial dysmorphism, as in Zellweger syndrome; hepatomegaly; cataracts; retinopathy; calcific stippling of epiphyses; and rhizomelia.[12] These disorders are discussed in Chapter 90.

Acknowledgments

The author would like to acknowledge the contributions of Drs. Timothy E. Lotze and Geoffrey Miller, who were authors of this chapter in previous editions.

Key Points

- Infants with a neonatal neuromuscular disorder typically have severe muscle weakness in addition to hypotonia that is more commonly seen without weakness if secondary to a central cause.
- Infantile spinal muscular atrophy, a previously untreatable and frequently fatal disorder, now has an FDA-approved medication for treatment with additional emerging therapies on the horizon.
- Neuromuscular junction disorders are infrequent causes of weakness in the neonate but illustrate the importance of a good maternal history to be aware of the acquired types such as acquired neonatal myasthenia gravis.
- Congenital muscular dystrophies are a group of disorders typically presenting with severe weakness and hypotonia with central (leukoencephalopathy and brain migrational abnormalities) as well as peripheral causes (dystrophic muscle).
- Congenital myotonic dystrophy is a trinucleotide repeat disorder that presents with severe hypotonia, generalized weakness, and a tent-shaped triangular upper lip, typically from maternal inheritance.
- Nemaline myopathy is one of the congenital myopathies that can present in the neonatal period with severe weakness involving the face, bulbar, and respiratory muscles.

Intracranial and Calvarial Disorders

KRYSTAL TOMEI AND MICKEY SMITH

Summary

This chapter explores those conditions that cause abnormal head shape or head size in the newborn infant. The underlying causes, clinical presentation, diagnosis, and available interventions will be presented.

Examination of the Head

Abnormalities are first identified by observation of the general shape and texture of the head and scalp. Palpation of neurocutaneous lesions are noted. The anterior fontanelle, demarking the junction of the frontal and parietal bones at the intersection of the metopic, coronal, and sagittal sutures, should always be palpated. It is usually soft, flat, and pulsatile with the heartbeat. The anterior fontanelle may be tense or full when a child is crying, but sustained bulging of the fontanelle may be indicative of a pathologic process associated with elevated intracranial pressure. It usually closes by 18 months of age, although some recent studies have shown that it can take up to 24 months to fully close (mean 16.3 months for boys and 18.8 months for girls).[2,17] The posterior fontanelle is smaller and denotes the junction of the parietal and occipital bones at the intersection of the sagittal and lambdoid sutures. It usually closes by 3 months. Palpation for abnormal splaying or overlap of the cranial sutures, measured in millimeters, should also be recorded.

Head circumference measurement should be recorded with each examination, as it is a gauge of intracranial volume. The occipitofrontal circumference (OFC) is obtained with a tape measure firmly pressed against the scalp to include the occiput at or just above the external occipital protuberance (inion) and the forehead just above the glabella. Gestation age-adjusted measurements should be made on growth charts for preterm infants.[4,22] Normal head growth occurs at approximately 2 cm per month in the first 3 months, 1 cm per month the next 3 months, and then 0.5 cm per month for the next 6 months.

The Neonate

Neurulation and Cleavage

An in-depth review of craniofacial development is beyond the scope of this chapter; however, there are well-studied defects in embryogenesis that lead to abnormally shaped heads in the neonate. Microcephaly, or a small head, is a primary manifestation of embryologic and congenital abnormalities resulting in a small brain[18] (Fig. 57.1). Briefly, the embryologic process begins with primary neurulation between days 17 and 27 of gestation. Errors in neurulation and neural tube closure lead to dysraphic malformations. The most devastating of all neural tube defects is anencephaly (Fig. 57.2). This fatal condition results from failure of the anterior neuropore to close, and leads to an absent cranial vault.

Abnormal cleavage, which is the normal separation of the embryonic forebrain to form paired telencephalic hemispheres by day 33 of gestation, can lead to conditions such as holoprosencephaly.[6,7,28] Varying degrees of holoprosencephaly exist, with the most complete form being alobar holoprosencephaly and lesser forms termed semilobar and lobar (Fig. 57.3). Associated median facial defects can range from a single midline eye to orbital hypotelorism, nose flattening, cleft lip and palate, or trigonocephaly.

Migration

Neuronal migration is the radial and tangential process by which the cerebrum is formed.[1] Progenitor cells migrate from the ventricular zone and basal forebrain to create the cortex. There is cortical disruption when this migration does not occur normally, and conditions like schizencephaly (cleft in the hemisphere) (Fig. 57.4), lissencephaly ("smooth brain") (Fig. 57.5), or polymicrogyria occur (Fig. 57.6). The hallmark features include gyral anomalies.[13] Midline structures are also often involved, such as failure of the corpus callosum to form completely or agenesis of the corpus callosum (Fig. 57.7). The septum pellucidum can also be absent.

Abstract

Examination of the infant head shape and size is critical to evaluate for underlying pathologies that may impair neurologic development. Embryologic errors such as abnormal neurulation, cleavage, or migration can lead to congenital defects that inhibit normal formation of the central nervous system and then, in turn, external craniofacial development. Other factors, like in utero infections, can alter brain development and ultimately head size. Hydrocephalus is a common comorbidity in the infant with macrocephaly. Post-hemorrhagic hydrocephalus is frequently diagnosed in premature neonates. Congenital brain malformations like Dandy-Walker and Chiari II are other frequent comorbid conditions with hydrocephalus. Finally, craniosynostosis is a primary cause of misshapen heads in infants, but practitioners should be able to delineate true craniosynostosis from positional plagiocephaly, which is more common.

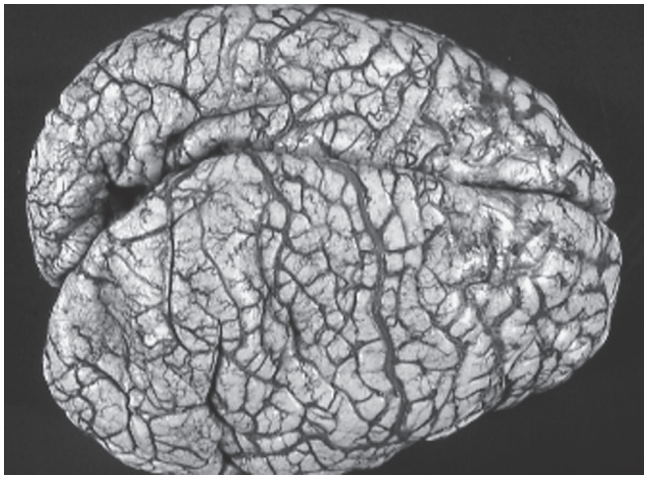
• **Fig. 57.4** Open-lipped schizencephaly. T1-weighted coronal MRI shows a large open cleft communicating with the right lateral ventricle and absence of the septum pellucidum.



External features can lead to abnormally shaped heads (Fig. 57.8). Abnormal migration can also lead to syndromes of neuronal heterotopias, such as Aicardi syndrome characterized by microcephaly.[1]

Neural crest cells, first formed in a zone between the neural plate and the ectoderm, also play a major role in the formation of the fetal skull and face. Errors in that process, including in the migration of neural crest cells, lead to improperly formed face and heads.[1] Examples include Waardenburg syndrome and craniofrontal dysplasia.

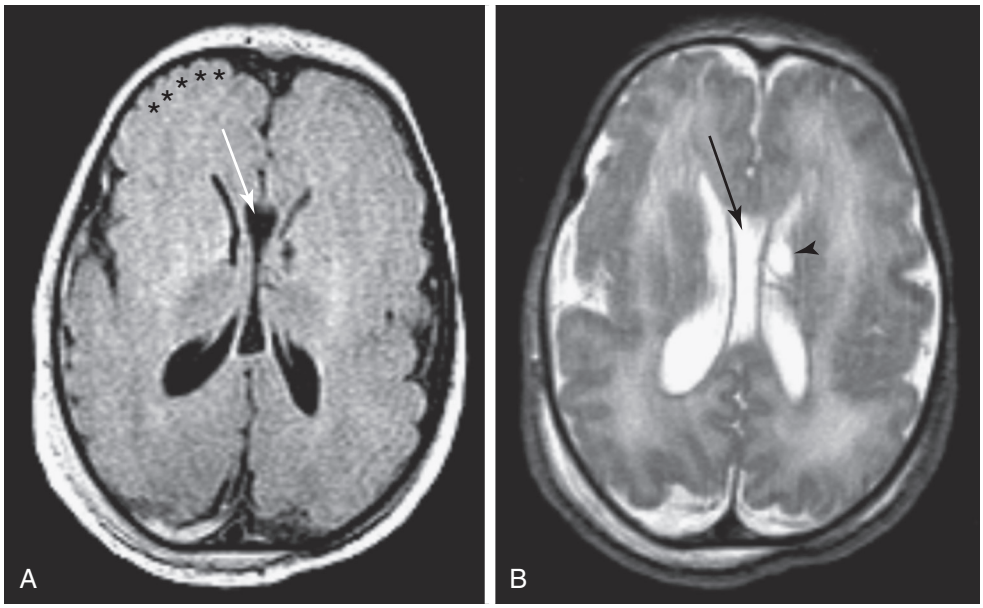
Congenital Infections

In utero infections, collectively known as TORCH infections, also produce insults in the development of the craniofacial system. Implicated infections of the TORCH syndrome include toxoplasmosis, other agents (syphilis, varicella-zoster, parvovirus), rubella, cytomegalovirus, and herpes simplex virus. Microcephaly, seen even with hydrocephalus in the case of a toxoplasmosis infection, can be observed[14] (Fig. 57.9).

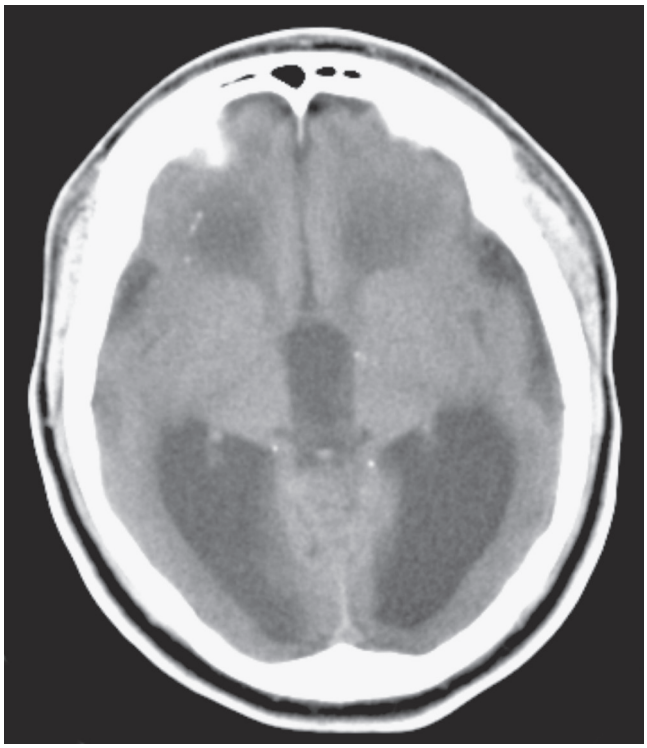
Hydrocephalus

Macrocephaly, conventionally defined as an orbitofrontal circumference more than two standard deviations above the mean, can be attributed to three possible processes. Macrencephaly, enlargement of the brain itself, can lead to large



• **Fig. 57.7** Agenesis of the corpus callosum. T1-weighted MRI also demonstrates absence of septum pellucidum and a large midline cerebrospinal fluid collection.

heads and is seen in certain genetic, neurocutaneous, or metabolic syndromes.[20] Another cause of a large cranium includes neoplastic or enlargement of other structures, including vascular lesions like vein of Galen malformations. Here, we will focus on hydrocephalus and its macrocephalic and neurologic manifestations.



The normal rate of cerebrospinal fluid (CSF) production is about 0.3 mL/min, or 20 mL/hr.[5,19] In premature infants, the rate of CSF formation is lower. The newborn has a total volume of about 50 mL, and the majority is produced in the choroid plexus. Normal reabsorption into the venous system occurs via arachnoid villi granulations in the venous sinuses. An impaired balance between production and absorption leads to enlargement of the CSF fluid spaces. Failure from any reason, including structural or metabolic, to absorb CSF at a rate concomitant to its production leads to this imbalance. The clinical manifestation of hydrocephalus, including symptoms related to increased intracranial pressure, depends on the status of the cranial sutures. In a newborn with open sutures, macrocephaly may be a presenting sign, but a child over 2 years can present without macrocephaly but with elevated intracranial pressure signs such as headache, irritability, vomiting, lethargy, or sunsetting eyes. In the infant, external features include tense and bulging fontanelles and split sutures.

Hydrocephalus may be categorized as either acquired or congenital. Acquired causes include post-hemorrhagic hydrocephalus and post-meningitic hydrocephalus. Congenital causes include Dandy-Walker, Chiari malformations, or even aqueductal stenosis.[3]

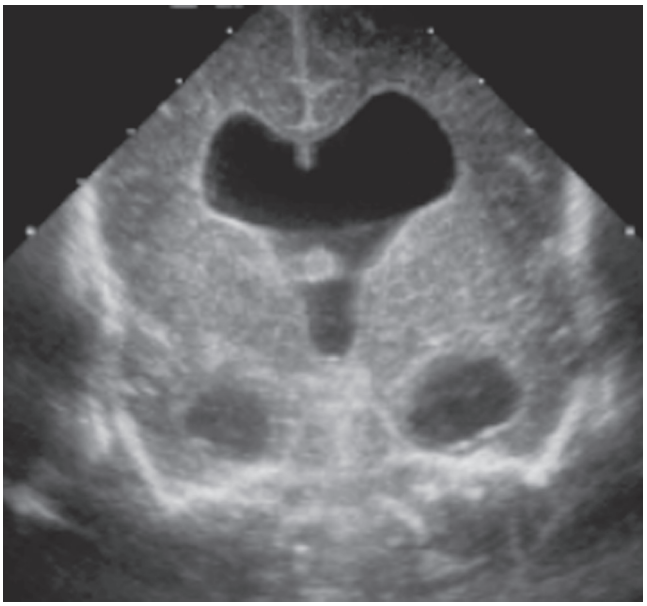
• **Fig. 57.9** Congenital toxoplasmosis. Noncontrast CT scan shows ex vacuo hydrocephalus and periventricular calcifications.

Intraventricular Hemorrhage



Post-hemorrhagic hydrocephalus can occur as a consequence of trauma resulting in intraventricular hemorrhage (IVH), but it is most often seen in premature infants with germinal matrix hemorrhage. The germinal matrix is a rich vascular network found in the periventricular subependyma, which normally involutes by 36 weeks' gestation.[21,25] However, in premature neonates this involution does not occur completely. In this context of lack of vascular support tissue, intraventricular hemorrhage, therefore, is most common in prematurity, with some studies showing up to 27% of preterm infants under 1500 grams being affected.[24] Nonetheless, term infants with coagulopathies can also develop IVH and as many as half developing delayed symptomatic IVH.[24]

Intraventricular hemorrhage by itself may result in ventriculomegaly without clinical hydrocephalus. A grading system of IVH based on the site of hemorrhage and with or without ventriculomegaly or intracerebral hemorrhage is often used when describing IVH and applying prognostication. Grade 1 is isolated to blood within the germinal matrix; in grade 2 IVH, there is bleeding within the ventricles without enlargement; in grade 3 IVH there is bleeding within ventricles with enlargement; and in grade 4 IVH the hemorrhage includes the surrounding brain parenchyma (Fig. 57.10). Close observation in those neonates with IVH and ventriculomegaly is recommended with weekly head ultrasounds and daily OFC measurements to monitor for the development of hydrocephalus.[21] The progression to clinical post-hemorrhagic hydrocephalus is defined as ventriculomegaly, signs of elevated intracranial pressure, and increasing OFC. The post-hemorrhagic hydrocephalus is typically an obstructive form, secondary to malfunctioning arachnoid villi due to the arachnoiditis from the blood (Figs. 57.11 and 57.12). Efforts to halt progression can include serial lumbar taps, ventricular taps through the fontanelle, medications to reduce CSF production, and

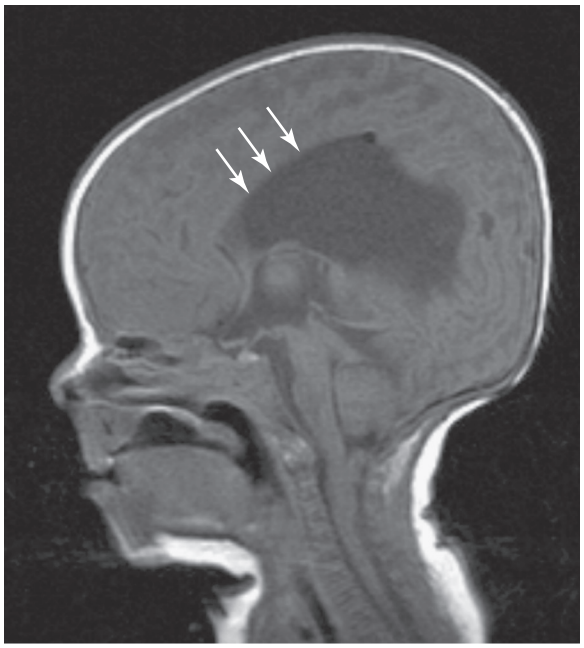
• **Fig. 57.12** Posthemorrhagic hydrocephalus. Coronal ultrasound scan shows enlarged lateral ventricles and intraventricular blood.

• **Fig. 57.11** Posthemorrhagic hydrocephalus after grade IV intraventricular hemorrhage of prematurity. CT scan demonstrates lateral ventricle enlargement and left frontal encephalomalacia (*asterisks*) at the site of parenchymal hemorrhage.



• **Fig. 57.13** Dandy-Walker malformation. T1-weighted sagittal MRI demonstrates cystic transformation of the fourth ventricle with posterior fossa enlargement, elevation of the torcular herophili, and dysgenesis of the inferior cerebellar vermis.

temporary methods of temperization including ventricular reservoir placement with serial reservoir taps or a subgaleal shunt.[11,15,16] Permanent diversion with CSF shunting may ultimately be required.

Congenital Brain Malformations

Congenital malformations, which typically produce macrocephaly and hydrocephalus, include those of the Dandy-Walker and Chiari variety. The Dandy-Walker malformation is characterized by fourth ventricular cystic transformation, partial or complete agenesis of the cerebellar vermis, and posterior cranial fossa enlargement with upward displacement of the torcula heterophili, transverse sinuses, and tentorium (Fig. 57.13). The resultant obstructive hydrocephalus leads to supratentorial ventriculomegaly present at birth or progressive over time. The previously described errors in neuronal migration such as agenesis of the corpus callosum and septum pellucidum or polymicrogyria may be appreciated on imaging. Externally, patients may have a high riding

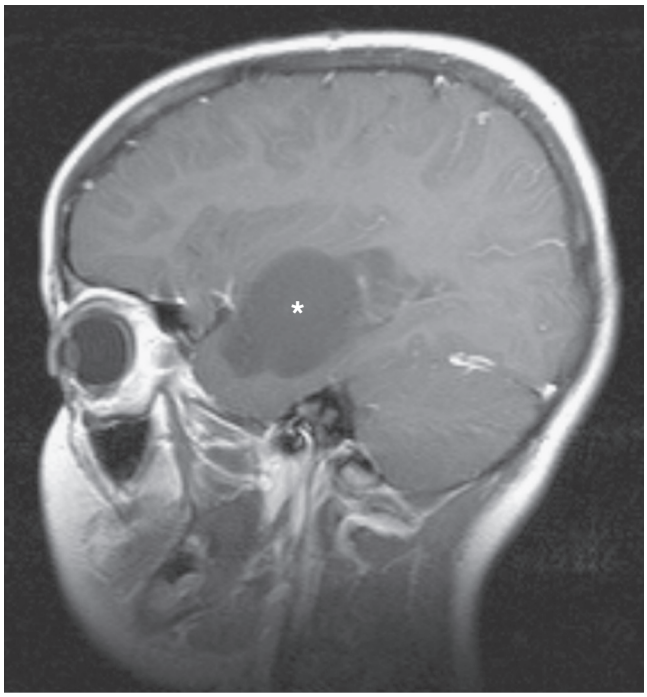
• **Fig. 57.14** Chiari II malformation. T1-weighted sagittal MRI shows partial agenesis of the corpus callosum (*arrows*) and multiple anomalies, including enlargement of the massa intermedia, beaking of the tectum, herniation of the cerebellum below the foramen magnum, and kinking of the medulla.

• **Fig. 57.15** Aqueductal stenosis. T1-weighted sagittal MRI shows noncommunicating hydrocephalus secondary to stenosis of the aqueduct of Sylvius (*arrow*). The lateral and third ventricles are enlarged, with a normal-sized fourth ventricle. An arachnoid cyst is present inferior to the cerebellum.

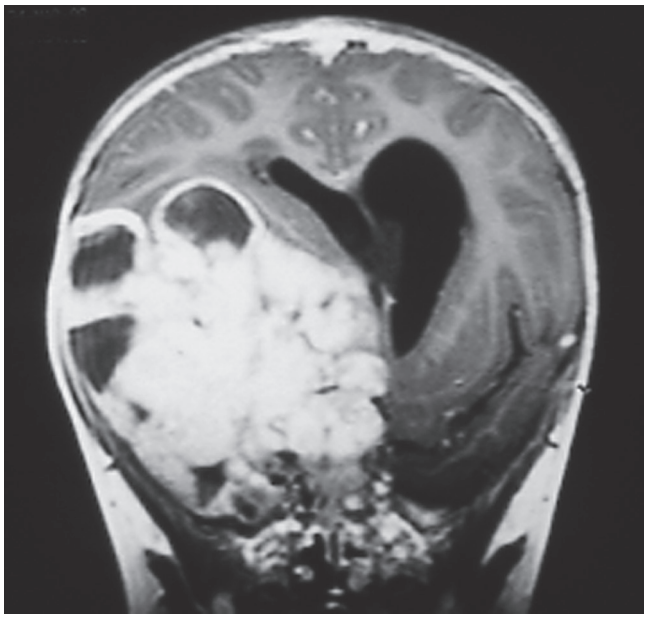
external occipital protuberance. Occipital encephaloceles or meningoceles, cleft lip and palate, or other craniofacial malformations are frequently observed.[23] The malformation is more frequent in girls than boys, and it occurs in approximately 1 in 25,000 live births.[23]

The Chiari II malformation is another congenital anomaly resulting in hydrocephalus and possibly macrocephaly. The malformation is characterized by an abnormal hindbrain, owing to a small posterior fossa, low-lying transverse sinuses, low-lying tentorium, and herniation of the cerebellar vermis below the foramen magnum. The tectum is beaked, and there may be supratentorial ventriculomegaly (Fig. 57.14). This malformation is uniformly associated with a lumbosacral myelomeningocele.[12] Externally, the head may not be enlarged at birth, with even a possibility of the OFC being small due to decompression of the CSF into the myelomeningocele sac. However, after closure of the myelomeningocele, it is important to continue to trend the OFC, as it may begin to rapidly expand. The clinical hydrocephalus is of the obstructive type, with other manifestations including cranial neuropathies or brainstem dysfunction due to exacerbation of the Chiari II malformation from downward pressure of untreated hydrocephalus.



Other Causes

Other causes of hydrocephalus and concomitant macrocephaly include aqueductal stenosis, neoplasms, and vascular malformations. Each of these entities cause noncommunicating, or obstructive, hydrocephalus and are not always evident at birth.



Stenosis of the cerebral aqueduct can be congenital or acquired, and it accounts for up to 10% of pediatric hydrocephalus. Radiographically, there is enlargement of the lateral and third ventricles and a normal fourth ventricle size (Fig. 57.15). A narrowed aqueduct, which normally measures about 0.5 mm in diameter and 3 mm in length at birth, alters dynamic flow and reabsorption of CSF.[8] Macrocephaly again may not be evident at birth but may progress prior to suture closure if the stenosis is severe. Acquired aqueductal stenosis can occur as the consequence of a neoplasm. However, changes in head shape or size may not be evident unless the neoplasm was present at birth or at an early age prior to suture closure. Examples include slow-growing tumors such as choroid plexus papilloma, low-grade astrocytoma, and ganglioglioma (Fig. 57.16), or rapidly growing ones such as primitive neuroectodermal tumor and teratoma (Fig. 57.17).

Vascular lesions are a rare cause of macrocephaly with possible hydrocephalus in the newborn. The vein of Galen malformation often presents with macrocephaly and clinical hydrocephalus. This malformation arises in the third trimester of pregnancy because of a persistent embryonic promesencephalic vein of Markowski. Patients present with refractory, high-output congestive heart failure. Treatment of the malformation is the mainstay of intervention; however, hydrocephalus may require intervention in symptomatic children in whom endovascular intervention is not possible or must be staged. Options for treatment include endoscopic third ventriculostomy or ventricular shunting.

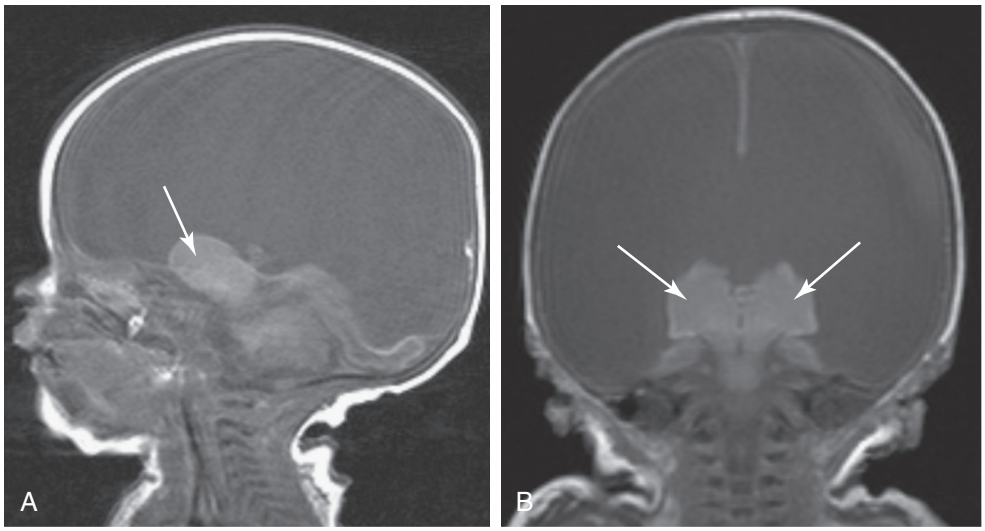
• **Fig. 57.17** T1-weighted, contrast-enhanced MRI demonstrating a large primitive neuroectodermal tumor of the right temporal lobe deforming the brain.

Hydranencephaly

Hydranencephaly is a rare congenital anomaly marked by almost complete absence of the cerebral hemispheres. It is thought to occur as the result of a major in utero vascular insult during the second trimester, particularly bilateral occlusion of the carotid arteries. The brain undergoes intrauterine liquefaction and is essentially reduced to a bag of water, a meningeal sac containing CSF with high protein content. The diencephalon, brainstem, and posterior fossa structures are spared, and a thin occipital cortical rim may permit some visual function.

The newborn with hydranencephaly may appear neurologically normal at birth because of the normally functioning thalami and brainstem. Difficulty with visual fixing and following may be appreciated. The head size may be normal or even small at birth but can enlarge rapidly owing to malabsorption of the proteinaceous CSF. On occasion, the diagnosis of hydranencephaly is made after several months because of failure to achieve developmental milestones.

Significant macrocephaly may be treated with a ventriculoperitoneal shunt. The decision to shunt can be difficult because shunting is primarily done to make it easier to care for the infants and does not lead to an improved level of neurologic function. The long-term outcome for infants with hydranencephaly is poor, and most do not live for more than 1 or 2 years.



Hydranencephaly can be diagnosed by ultrasound, although magnetic resonance imaging (MRI) is much more accurate (Fig. 57.18). Hydranencephaly is distinguished from anencephaly by the presence of intact meninges and skull. It is important to distinguish between hydranencephaly and advanced hydrocephalus, which may have a similar clinical and radiographic presentation. The compressed cerebral mantle in hydrocephalus can expand, sometimes dramatically, after ventricular shunt placement.

Craniosynostosis

Abnormally shaped heads of infancy go beyond micro- or macrocephaly. In this instance of misshapen heads, craniosynostosis and deformational plagiocephaly are the two most common causes. The hallmark of craniosynostosis is the premature fusion of cranial sutures. The pathologic fusion of sutures places infants at risk for head shape abnormalities as well as elevated intracranial pressure secondary to craniocephalic disproportion if left untreated. Although the incidence of elevated intracranial pressure varies highly in the literature, it is estimated to be between 4.5%-44% of untreated children with craniosynostosis.[26] Most often, only a single suture is involved, causing characteristic head shapes that will be described further. Other times, multiple suture fusions combine as part of a greater craniofacial syndrome. Thus, craniosynostosis can be subdivided to either nonsyndromic or syndromic (Box 57.1). It should also be noted that while the majority of craniosynostosis is caused by primary closure of sutures, secondary causes can include metabolic or hematologic disorders, such as rickets, hyperthyroidism, polycythemia vera, and thalassemia.

The characteristic head shapes seen in craniosynostosis occur as a result of failure of perpendicular growth of the bones of the skull vault relative to the suture.[9] Compensatory growth at perimeter nonfused sutures can also contribute to the odd-shaped head. Molecularly, defects in fibroblast growth factor receptors (FGFRs) have been implicated in

- Pfeiffer syndrome
- Saethre-Chotzen syndrome

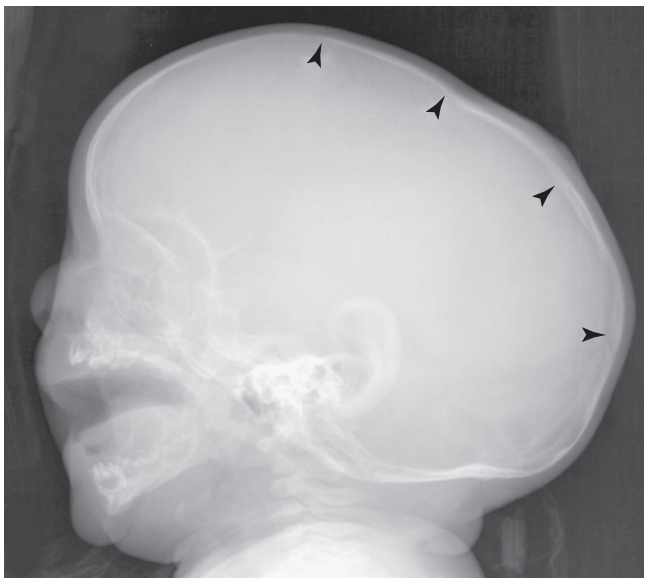
Deformational Plagiocephaly

the etiology of craniosynostosis.[9,10] Normally, signals from the dura promote patent sutures until completion of brain growth. However, those signals are altered in the case of craniosynostosis.

The physical exam is the first step in diagnosing premature suture closure, as craniosynostosis is diagnosed clinically. Knowledge of the general types of misshapen heads can lead one to identify the typical fused suture (Table 57.1). In neonates, sutures are relatively mobile, and fusion of the suture can be diagnosed on physical exam by the absence of mobility along the suture of concern in combination with the shape of the infant's head. Plain skull x-rays can confirm the diagnosis, which demonstrate sclerosis along all or part of the fused suture. A CT scan increases sensitivity for diagnosis and may be useful in children who are older, where suture mobility is not as easily palpable and can be useful for operative planning should a reconstruction be warranted.

TABLE 57.1 Abnormal Head Shapes

Term	Definition	Fused Suture
Scaphocephaly	Boat head	Sagittal
Dolichocephaly	Long head	Sagittal
Clinocephaly	Saddle head	Sagittal
Brachycephaly	Short head	Bilateral coronal or lambdoid
Plagiocephaly	Oblique head	Unilateral coronal, lambdoid, deformational
Trigonocephaly	Triangular head	Metopic
Turricephaly	Towering head	Multiple
Acrocephaly	Peaked head	Multiple
Oxycephaly	Pointed head	Multiple
Hypsicephaly	High head	Multiple
Kleeblattschädel	Cloverleaf head	Multiple



Nonsyndromic Craniosynostosis

Sagittal craniosynostosis is the most common type of nonsyndromic craniosynostosis. Premature sagittal suture fusion occurs in approximately 1:1000 live births with a 4:1 male to female preponderance.[9] A typical presentation will be an infant with scaphocephaly, or "boat-shaped head" (Figs. 57.19 and 57.20). In addition, there is often a narrow biparietal diameter, compensatory frontal bossing, temporal hollowing, and a prominent occipital protuberance. Neurologically, scaphocephalic infants are most often normal. Numerous surgical procedures exist to remodel the head, with most successful outcomes achieved when surgery

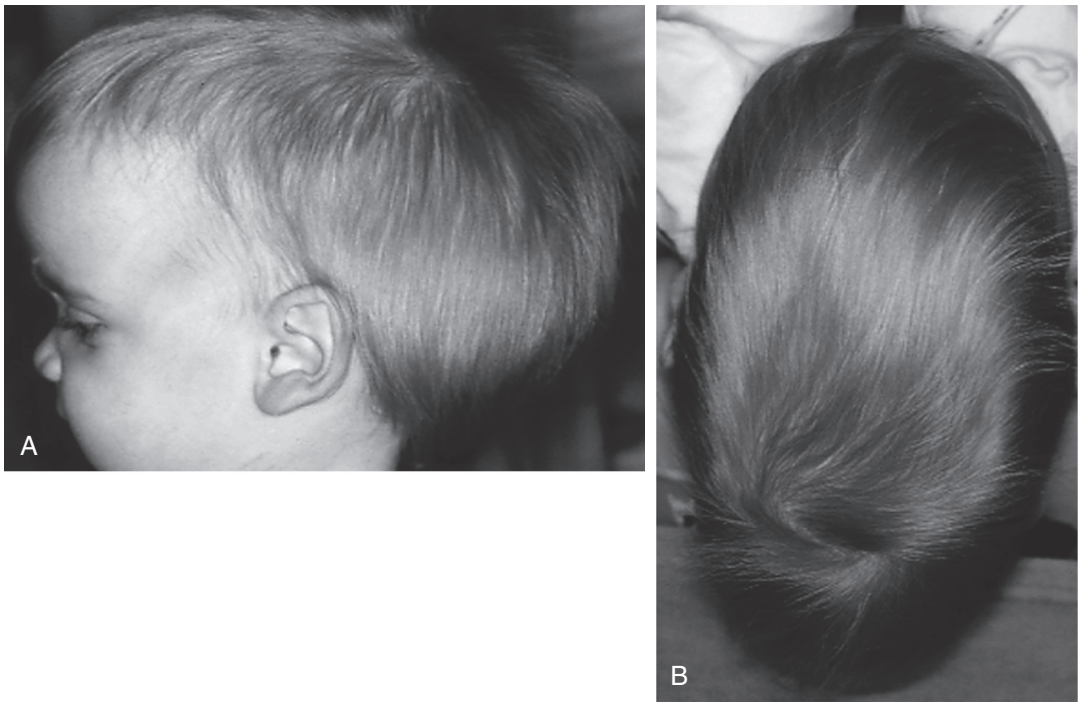
is performed before 6 months of age.[9] This allows the brain growth, which triples in weight within a year, to help guide the remodeled head to a more normal shape.

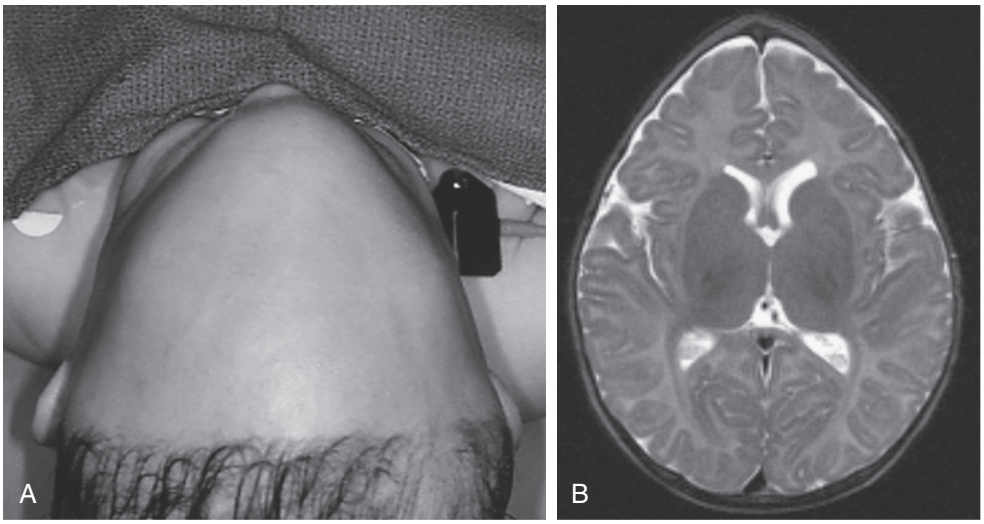
Metopic craniosynostosis presents with trigonocephaly. A triangular-shaped forehead with a vertical keel over the forehead is noted clinically when the metopic suture prematurely fuses (Fig. 57.21). The anterior cranial vault is small, and there is usually associated hypotelorism, lateral canthi elevation, and temporal hollowing. Infants with severe craniofacial deformities can be treated surgically with endoscopic procedures or bifrontal craniotomy with orbital bar advancements.



• **Fig. 57.19** Sagittal synostosis. Skull radiograph shows fusion of the sagittal suture (*arrowheads*) with scaphocephaly and frontal bossing.

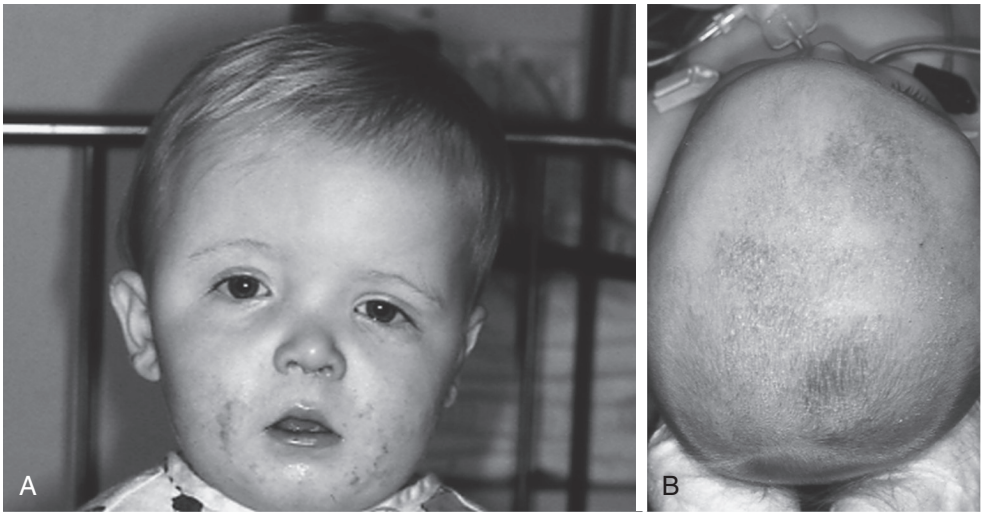
Premature fusion of the coronal suture produces either plagiocephaly or brachycephaly, depending on whether one or bilateral coronal sutures are fused. Unilateral coronal synostosis is characterized by the "oblique" shaped head of anterior plagiocephaly. There is flattening of the ipsilateral forehead and compensatory bossing of the contralateral forehead (Fig. 57.22). The ipsilateral orbit is shallow with the superolateral margin drawn upward and backward, giving rise to the "harlequin eye" deformity seen radiographically (Fig. 57.23). Cranial vault reconstruction also includes craniotomy with orbital bar advancement.

Bicoronal craniosynostosis presents with brachycephaly, or "short" head. There are palpable ridges over both coronal sutures with the head foreshortened in the anterior–posterior plane. Sometimes, there is widening of the head and compensatory increased height, termed turricephaly (Fig. 57.24). Surgical correction is similar to that for unicoronal synostosis. Although most commonly nonsyndromic, all children with bicoronal synostosis should be evaluated to rule out underlying malformations, because premature bicoronal suture fusion is a hallmark pattern of syndromic craniosynostosis.[27]



Positional Plagiocephaly

Also known as deformational posterior plagiocephaly, cranial asymmetry caused by flattening of the occiput is a common neurosurgical referral to rule out true craniosynostosis.



• **Fig. 57.20** Sagittal synostosis, with scaphocephaly, frontal bossing, and protuberance at the occiput. **A**, Side view. **B**, Top view.

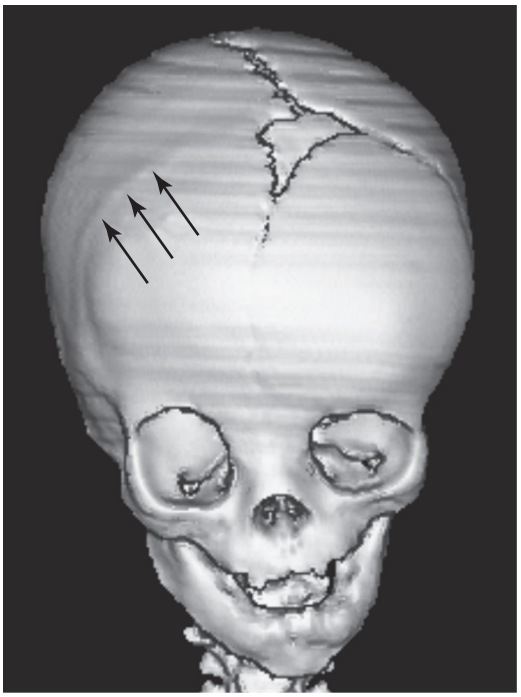
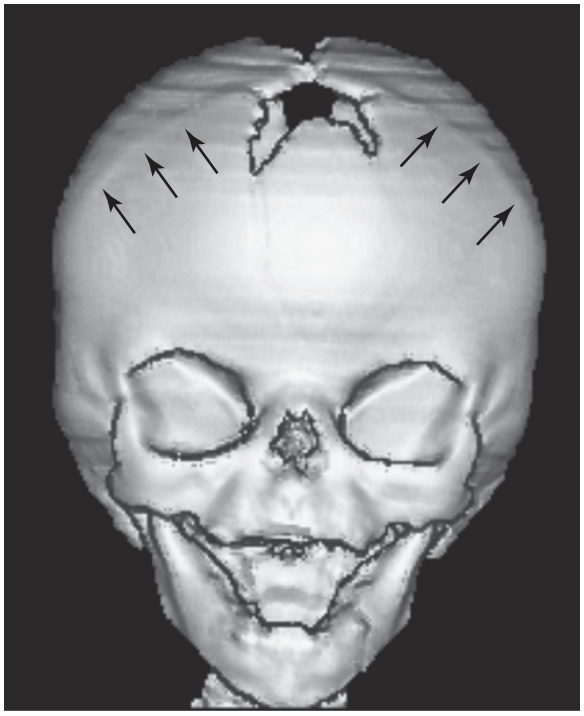
• **Fig. 57.21** Trigonocephaly secondary to premature fusion of the metopic suture. **A**, Top view. **B**, T1-weighted MRI.

• **Fig. 57.22** Unilateral right coronal synostosis. There is facial asymmetry, ipsilateral frontal flattening, and vertical orbital dystopia with inferior displacement of the contralateral orbit. **A**, Front view. **B**, Top view.



Often, a child will be referred with posterior plagiocephaly with concern for lambdoid craniosynostosis. Premature closure of the lambdoid suture is quite rare, estimated to account for approximately 3% of all craniosynostosis cases.[9] However, a thorough physical exam can quickly help decipher deformational from true plagiocephaly. In positional plagiocephaly, the head is typically described in shape of a parallelogram when viewed from above. There is unilateral occiput flattening, with ipsilateral frontal prominence. A major hallmark distinguishing positional plagiocephaly from plagiocephaly associated with lambdoid craniosynostosis is the position of the ipsilateral ear. It is displaced forward with both ears in the same horizontal plane in positional plagiocephaly from positional shifting of the ipsilateral skull, whereas it is displaced posteriorly in lambdoid synostosis from restriction of growth perpendicular to the ipsilateral lambdoid suture (Fig. 57.25).

Syndromic Craniosynostosis



Craniofacial syndromes with craniosynostosis are often inherited in an autosomal dominant fashion. The most frequent syndromes have been localized to mutations encoding fibroblast growth receptor genes.[27] Clinically, there are a few associations common to craniofacial syndromes. Hearing loss, usually conductive, is shared by many of the syndromes. Respiratory difficulties, including obstructive sleep apnea, are common and are thought to be related to midface hypoplasia.[27] Various cognitive deficits are also often apparent, with or without the development of hydrocephalus.

Muenke syndrome is the most common of the syndromic craniosynostoses, afflicting as many as 1 in 30,000 live births.[27] It is inherited in an autosomal dominant fashion, with the *FGFR3* gene implicated. Most often, the coronal suture is involved in these patients, with bilateral

synostosis more common than unilateral. However, there is variability in presentation, because the spectrum of premature suture closure ranges from a single suture to pansynostosis. Sensorineural, rather than conductive, hearing loss is also more common in this syndrome compared to others. Genetic testing confirms the diagnosis. In addition to the calvarial shape predicated by which suture closes, there is also often mild midface hypoplasia with hypertelorism.

Apert syndrome can affect up to 1 in 65,000 births. Most mutations causing this syndrome are sporadic, although there are reports of autosomal dominant transmission.[27] The *FGFR2* gene is most often implicated. Clinically, the external head shape depends again on which suture(s) closes, but most often patients present at birth with brachyturricephaly with a flattened occiput (Fig. 57.26). Most often, the coronal sutures are fused with a widely open anterior fontanelle and metopic suture. Other hallmark features

• **Fig. 57.27** Crouzon syndrome (craniofacial dysostosis) with brachyturricephaly, exophthalmos, and maxillary hypoplasia. **A**, Frontal view. **B**, Side view.

• **Fig. 57.28** Pfeiffer syndrome. **A**, Side view. There is brachyturricephaly, maxillary hypoplasia, and choanal atresia (note indwelling tracheostomy). **B,** Undersurface of the skull at craniofacial reconstruction demonstrates convolutional markings from increased intracranial pressure.

include maxillary hypoplasia, symmetric hand syndactyly, and cognitive delay.

Crouzon syndrome patients present similar in appearance to Apert syndrome; however, the craniofacial anomalies are not present at birth. Frequently, the coronal sutures are involved, and brachycephaly is most often observed. Other typical features include exophthalmos and maxillary hypoplasia (Fig. 57.27). Unlike Apert syndrome, cognitive delay is infrequent.

Other syndromes include Pfeiffer syndrome and Saethre-Chotzen syndromes. In Pfeiffer syndrome, there is usually involvement of the coronal sutures, although sagittal and lambdoid sutures are commonly involved as well. There is brachyturricephaly, maxillary hypoplasia, and choanal atresia (Fig. 57.28). Noncranial hallmark features of Pfeiffer syndrome include broad thumbs and great toes. Patients with Saethre-Chotzen syndrome present with brachycephaly, low-lying hairlines, ptosis, and hypertelorism.

Conclusion

Examination of the infant head shape and size is critical to evaluate for underlying pathologies that may impair neurologic development. Macrocephaly or accelerated head growth in the neonate should prompt evaluation for hydrocephalus or mass lesions. Premature infants remain at risk for germinal matrix hemorrhage which may predispose infants to post-hemorrhagic hydrocephalus. Finally, abnormalities in head shape should prompt evaluation for craniosynostosis, although positional plagiocephaly remains a much more common etiology for an abnormal head shape in an infant.

Key Points

- An abnormally large head is a common sequela of hydrocephalus in infants; however, there are a range of causes of hydrocephalus in these patients.
- Early identification, surveillance, and intervention are critical to successful outcomes in hydrocephalus.
- A thorough physical exam will most often provide the diagnosis in the setting of an abnormal head shape.

Spinal Dysraphisms

BYRON HILLS AND KRYSTAL TOMEI

Summary

This chapter reviews open and closed neural tube defects. We discuss imaging evaluation as well as physical exam findings. Finally, we discuss current trends in treatment and perinatal care.

Introduction

Neural tube defects (NTD) are the second-most common birth defect after congenital heart defects, affecting 1-2 in 1000 pregnancies worldwide. Spinal dysraphisms are a subset of neural tube defects and are classified as open or closed. The most common open spinal dysraphisms are meningocele and myelomeningocele. Closed spinal dysraphisms include a wider range of conditions, including spina bifida occulta, tethered cord, lipomyelomeningocele, split cord malformations, neuroenteric cyst, and several other conditions.[19] Although open spinal dysraphisms are usually compatible with postnatal survival, they can result in severe neurologic impairment correlating with the level of the lesion: inability to ambulate, urinary incontinence, hydrocephalus, scoliosis, and gastrointestinal (GI) disorders. Closed spinal dysraphisms are often less severe and sometimes asymptomatic but can cause severe neurologic impairment secondary to spinal cord tethering.[25] Given both the neurologic complexity and severity of these conditions, it is paramount to understanding the embryology, screening, management, and treatment to offer the best neurologic outcome for these patients.

Embryology

Understanding the embryology of spinal dysraphisms has helped in making advancements to improve the technology used when treating patients with spinal dysraphisms. Spinal dysraphisms result from a failure of one of the following processes: gastrulation, primary neurulation, disjunction, or secondary neurulation. Gastrulation is the process by which the bilaminar embryonic disc becomes trilaminar: consisting of mesoderm, endoderm, and ectoderm. When gastrulation occurs, a neuroenteric canal forms, creating a temporary connection between the dorsal and ventral surface of the trilaminar disc. Conditions such as split cord malformations and neuroenteric cysts are thought to arise from a persistent neuroenteric canal. Neurulation begins with the notochord-inducing formation of the central nervous system by signaling the ectodermal tissue to differentiate into the neuroectoderm and form the neural plate. The neural plate then folds inward until the edges of the plate contact one another, a process referred to as primary neurulation. Primary neurulation is thought to be initiated at multiple closure sites and proceeds in a zipperlike fashion, bidirectionally. At the end of primary neurulation, the neural tube separates from the surface ectoderm in a process called disjunction. During disjunction, the mesoderm migrates between the surface ectoderm and neural tube, forming the meninges, vertebrae, skull, and paraspinal muscles. Premature or incomplete disjunction can lead to lipomyelomeningocele and dermal sinus, respectively. Secondary neurulation represents the formation of spinal cord caudal to the midsacral region. During this process, multipotent cells come together to form a tail bud, which undergoes canalization to form the secondary neural tube.[9] Open spinal dysraphisms result from a severe delay or cessation of the progression of primary neurulation along the body axis. When the neural fold does not close properly the sclerotome is unable to cover the neuroepithelium, and a bifid vertebral canal results, leading to an open spinal dysraphism. Although unclear, it is believed that some closed spinal dysraphisms are a result of abnormalities of secondary neurulation, causing malformation of the lower sacral and coccygeal regions. This is thought to be the case, because these dysraphisms do not open to the external environment, resulting in tethering of the spinal cord because of faulty tissue separation, and the cell types contained within these dysraphisms usually have multiple germ layers, owing to the multipotential nature of the tail bud formed in secondary neurulation.[19]

Several signaling pathways and cellular functions are involved in the development of neural tube defects; these include planar cell polarity signaling (PCP), sonic hedgehog signaling (SHH), bone morphogenic signaling (BMP), grainyhead-like genes (GHRL), retinoid signaling (RA), and many cellular functions such as apoptosis and cellular proliferation. Several factors are responsible that can increase

Abstract

Neural tube defects are one of the most common congenital anomalies encountered by neonatologists, occurring in 1-2 of 1000 pregnancies worldwide. Spinal dysraphisms are a small subset of neural tube defects ranging from severe conditions such as myelomeningocele to less severe conditions such as spina bifida occulta and are classified as open or closed. This book chapter highlights the embryology, pathology, and physical examination findings of various spinal dysraphisms. Finally, it offers insight into both the management and treatment of these conditions in hopes to provide the best care for these patients in the neonatal ICU.

the risk of developing neural tube defects and include both environmental and genetic factors. Environmental factors that affect the embryology of the central nervous system (CNS) and lead to an increased risk of development of NTDs include valproic acid, fumonisin (a fungal product), carbamazepine, trimethoprim, folate or vitamin B12 deficiency, inositol, and maternal diabetes mellitus. Genetic factors include the C67TT and a1298C polymorphisms of the gene methylenetetrahydrofolate reductase, which result in a 1.8-fold increased risk of NTDs and several modifier genes.[19]

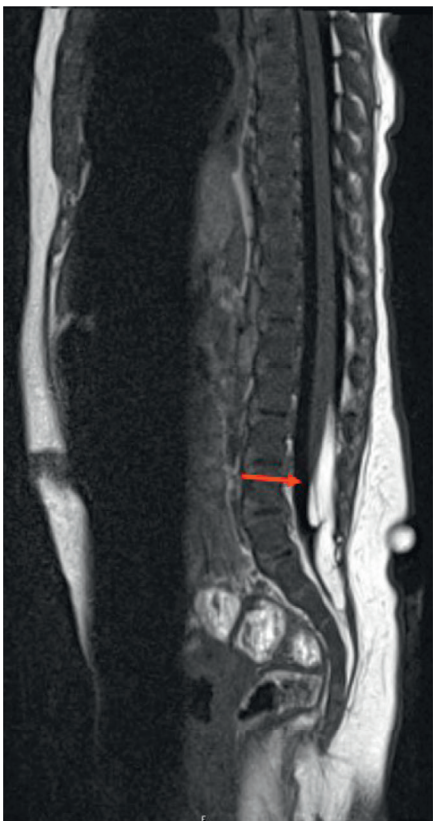
Pathology

Understanding the pathology of spinal dysraphisms is important in diagnosis and management, including both surgical and nonsurgical treatments. Spinal dysraphisms are typically divided into open and closed dysraphisms. Open dysraphisms include meningocele and myelomeningocele (Table 58.1).

Open Spinal Dysraphisms

Meningoceles are usually classified by location as either posterior lumbar, sacral, or thoracic; posterior cervical and limited dorsal myeloschisis; and anterior sacral. These lesions vary in size, are pedunculated, transilluminate well, and may be covered by cutaneous elements (Fig. 58.1). In meningoceles, the meninges herniate through a defect in the posterior vertebral arches, but the spinal cord remains in the spinal canal. Thus, the spinal cord and nerve roots are normal in their structure and position in the spinal canal.[27] Myelomeningocele represents 50% of all neural tube defects. It is often subdivided into spinal bifida cystica and spina bifida aperta. In spina bifida cystica, there is an open spinal cord covered by a meningeal sac. In spina bifida aperta, the spinal cord is exposed (Fig. 58.2). Myelomeningocele-affected infants typically show neurologic deficits below the level of the lesion and may be associated with other conditions such as hydrocephalus, skeletal, renal, and GI disorders.[19,25]

• **Fig. 58.1** Meningocele—note the large fluid-filled sac protruding from the lumbar region. The skin edges terminate at the junction to the meninges.



• **Fig. 58.2** Myelomeningocele—note the large central placode and open defect without an overlying meningeal sac.

Closed Spinal Dysraphisms

Closed spinal dysraphisms are subdivided into categories based on whether a subcutaneous mass is present. Closed spinal dysraphisms consist of spina bifida occulta, lipomyelomeningocele, dorsal dermal sinus, split cord malformation,

• **Fig. 58.3** Lipomyelomeningocele—the red arrow denotes the area of tethering of the subcutaneous lipoma to the neural placode.

• **Fig. 58.4** Dermal sinus tract—similar to a lipomyelomeningocele but with an additional fibrous tract (red arrow) extending from a superficial skin dimple to the placode.

neuroenteric cyst, and several other conditions. They are often grouped into a generic term "tethered cord syndrome" that more appropriately describes the constellation of symptoms that can be associated with these disorders.

Spina bifida occulta is the mildest form of spina bifida and occurs when one or more vertebrae are split at the level of the spinous processes, but the spinal cord and corresponding nerve roots remain intact and in place. In this entity, the vertebral defect is covered by skin and can be associated with several cutaneous stigmata, including midline dimple, tuft of hair, change in skin coloration, sinus tract, and hemangiomatic lesion. Spina bifida occulta may be asymptomatic for years but can present later in life with varying degrees of neurologic compromise if associated with other closed dysraphisms.[19]

Lipomyelomeningocele is a complex closed spinal dysraphism that usually occurs in the lumbar or sacral region. It is characterized by a subcutaneous lipoma that extends through the lumbosacral fascia, vertebral arches, and dura to attach to the spinal cord as a tethering mass (Fig. 58.3). Given its association with spinal cord tethering, severe neurologic deterioration can result if left untreated. Nevertheless, because the subcutaneous fatty mass is usually evident at birth, patients are often diagnosed prior to neurologic symptoms developing, with as many as 48% of patients being neurologically intact at the time of initial diagnosis. Spinal lipomas differ in that the lipoma does not extend through the lumbar fascia and typically remains encased within the spinal canal. The various forms of lipomas are categorized into three types that are defined by their anatomic attachment to the spinal cord: dorsal, transitional, and caudal (or chaotic). In the dorsal type, there is an attachment of the lipoma with the dorsal spinal cord at the level of myeloschisis, or neural placode. The transitional type has a lipomatous attachment that extends beyond the level of myeloschisis down to the conus medullaris and may involve the nerve roots. The caudal type has a lipomatous attachment, which arises from the caudal end of the conus medullaris, often encasing the nerve roots. Patients with lipomyelomeningocele have both a congenital malformation of their spinal cord as well as a risk of retethering their spinal cord after release due to scarring. These patients may develop neurogenic bladder or bowel, orthopedic deformities, scoliosis, and spasticity as a result of their tethered cord.[24]

Dorsal dermal sinus is a rare spinal dysraphism that involves a tract lined by epithelium that traverses a variable depth usually terminating in or on the thecal sac (Fig. 58.4). This type of closed dysraphism is usually seen at the extremes of the neuraxis and may be associated with life-threatening

infections, such as meningitis from bacteria tracking into the cerebrospinal fluid space. It can be associated with symptoms of a tethered cord, diastematomyelia, and inclusion cysts. Thus, despite the benign external appearance of this dysraphism, it can result in neurologic deficit and harbor great risks for patients if not addressed in a timely manner.[9,27]

Diastematomyelia is commonly referred to as split cord malformation and describes a phenomenon in which the spinal cord is split into two hemicords with each hemicord having its own set of ventral and dorsal nerve roots. They may be encased in a single dural sac, or the dural sac may be split at the level of the dysraphism. In addition, a fibrous or bony septum may be present between the hemicords. Frequently, the conus medullaris is low lying and tethered by a thickened filum terminale. This dysraphism can be associated with other dysraphisms such as myelomeningoceles and neuroenteric cyst. There is also a high instance of bony vertebral column abnormalities with split cord malformations, including butterfly vertebra, a widened spinal canal, fusion of pedicles, or failure of vertebral body segmentation. Neuroenteric cysts are closely associated with split cord malformation, and they often occur together because they both occur due to errors in gastrulation. Neuroenteric cysts occur most frequently at the lower cervical or upper thoracic regions and at the conus medullaris. These cysts can be extra- or intradural and, if intradural, can be anterior, posterior, or within the spinal cord.[12,28]

An abnormal filum terminale is the mildest form of a closed dysraphism, which can result in a tethered spinal cord. A filum is considered thickened when it is greater than 2 mm in diameter and contains an increased amount of connective tissue or fat with a low-lying conus medullaris. Similar to the other forms of closed spinal dysraphisms, these patients may be at risk of developing tethered cord syndrome and, if untreated, developing neurogenic bladder or lower extremity issues.[27]

Prenatal Screening and Prevention

In the early 1970s, maternal serum screening for fetal congenital malformations began with the advent of alpha fetoprotein (AFP) screening for neural tube defects. Today, screening has evolved with highly complex protocols utilizing cell-free DNA markers. However, AFP levels still represent the mainstay of screening for open neural tube defects. Maternal serum AFP screening is conducted between 15 and 21 weeks of gestation. Median maternal serum AFP levels increase steadily from 15-21 weeks' gestation. To account for the upward trend in maternal AFP that occurs in pregnancy, values are converted into multiples of the gestational age-specific median (MoMs). The typical cutoff for maternal serum AFP screening is 2.0-2.5 MoM, but using a cutoff of 2.0 MoM increases detection of open spina bifida by 10%. This cutoff brings the specificity for open spina bifida cases to 90%, and the sensitivity for anencephaly to 100% for the maternal serum AFP assay. Patients with elevated maternal serum AFP can opt to have amniocentesis to increase the likelihood of detection.[17] The amniotic fluid AFP level is then tested, and elevations along with a positive acetylcholinesterase confirmation test can detect 96% of open spina bifida cases. Ultrasound can also be used as a screening tool to detect open neural tube defects, with a sensitivity of 97% and specificity of 100% in the hands of an experienced sonographer.[18]

Risk of neural tube defects in humans is increased with folic acid deficiency and exposure of the embryo to excessive retinoic acid or vitamin A. Several studies have shown that 70% of neural tube defects can be prevented by preconception folic acid supplementation of 0.4 mg/day.[17,18] Mothers with one affected infant are at a higher rate than the general population for a second affected infant and should take 4 mg/day of folic acid before and during subsequent pregnancies.

Cutaneous Stigmata

Cutaneous stigmata are commonly found in closed spinal dysraphisms, because the skin and nervous system share an intimate embryologic origin. Recognition of cutaneous stigmata commonly associated with closed spinal dysraphisms is important, because early identification and intervention may prevent irreversible neurologic damage associated with tethered cord syndrome. Cutaneous stigmata are found in 4.2%-7.2% of all neonates with closed spina bifida, and the presence of two or more cutaneous stigmata has a high predictive value of a closed spinal dysraphism. Additionally, there should also be a high suspicion for closed spinal dysraphism when cutaneous stigmata occur in combination with anogenital or urogenital malformations. When assessing patients with cutaneous lumbosacral stigmata, it is important to recognize concerning features, thus these stigmata are typically separated into high-, intermediate-, and low-risk categories. High-risk cutaneous findings include two or more cutaneous lumbosacral stigmata, infantile hemangioma greater than 2.5 cm, dermoid cyst or sinus, lipoma, acrochordon, pseudotail, true tail, aplasia cutis, and congenital scars. Intermediate-risk cutaneous findings include atypical dimple (>5 mm diameter or >2.5 cm from anal verge), infantile hemangioma <2.5 cm, and hypertrichosis. Low-risk cutaneous findings include simple dimple, hyper- or hypopigmentation, melanocytic nevi, teratomas, port-wine stain, or telangiectases (Table 58.2). Based on the risk category, certain imaging modalities are recommended. MRI is recommended for all high-risk cutaneous findings. For intermediate-risk cutaneous finding, ultrasound is recommended for those <6 months and MRI for those >6 months. Lastly, most cases of low-risk cutaneous stigmata do not require imaging; if overly concerned, ultrasound can be performed.[26]

Imaging

The two major imaging modalities used to confirm and characterize spinal dysraphisms are spinal ultrasonography

TABLE 58.2 Common Neurocutaneous Stigmata Separated Into Risk Category

High Risk	Intermediate Risk	Low Risk
• Lipoma • Acrochordon • Pseudotail • Aplasia cutis • Dermoid cyst or dermal sinus • Infantile hemangioma • >2.5 cm • >2 Cutaneous stigmata	• Atypical dimple • Infantile hemangioma <2.5 cm • Hypertrichosis	• Simple dimple • Hyper-or hypopigmentation • Melanocytic nevi • Teratomas • Port-wine stain or telangiectases

and MRI. Ultrasound is possible in newborns and in early infancy prior to 6 months of age because of the lack of ossification of the predominantly cartilaginous posterior elements of the spine. Spinal ultrasound can sometimes be performed after 6 months if a persistent posterior spinal defect is present. However, as the posterior elements ossify, the quality of ultrasound images decrease. MRI is extremely useful in the evaluation of pediatric spinal anomalies. Given the resolution provided by MRI of the soft tissues, it allows for improved diagnosis of spinal dysraphisms and has enhanced the possibility of earlier and case-tailored treatment, especially in the case of complex dysraphisms where there may be rotation of the neural elements. Thus, MRI is the gold standard for imaging spinal dysraphisms.[13]

Ultrasonography is widely used today for prenatal screening for spinal dysraphism. It represents a cost-effective imaging modality for diagnosing and treating spinal anomalies in utero. High-resolution ultrasonography offered today can accurately localize the site of osseous and soft tissue defects. This has made it possible to accurately diagnose conditions such as myelomeningocele, lipomyelomeningocele, and diastematomyelia in utero. During the second trimester fetal anatomic survey, it is important to visualize the longitudinal, sagittal, coronal, and axial images of the spine. This allows for a complete view of the spine to analyze for spinal anomalies. If the transabdominal scan is not optimal, transvaginal scans are done to evaluate the spine. In addition to localization of the conus medullaris and spinal defects, it is important to measure any visualized sacs, especially if in utero repair is planned, as larger defects may require tissue matrix for closure.[21] The components of any visualized sac are analyzed to determine the presence of neural elements, which appear as linear echogenic areas surrounded by anechoic cerebrospinal fluid. The neural placode of the myelomeningocele can also be visualized and appears as a hypoechoic, ovoid region within the sac.[4] The wall of the myelomeningocele is also assessed on the ultrasound and characterized as thin or thick. The accuracy of ultrasonography varies greatly and depends on operator experience, maternal obesity, fetal movement, and fetal positioning. Nevertheless, correct identification of spinal anomalies and associated CNS and non-CNS abnormalities has been reported to have a sensitivity rate of 97% and specificity rate of 100%.[6,9]

MRI is a useful adjunct imaging modality in the fetus, infants, and children for detecting and further characterizing spinal anomalies. The high resolution of the soft tissues offered by this imaging modality can provide better visualization and more understanding of patient-specific pathology prior to surgical intervention. It is useful in detecting the degree of hindbrain herniation prior to repair and evaluating both brain and spinal cord anatomy when ultrasound is limited. Fetal MRI is important to obtain when in utero repair of spinal dysraphism is being considered. If good-quality images are able to be obtained prenatally, it may eliminate the need for postnatal images, which often require sedation to obtain a quality image.[2,14,22]

Overall Management

Spinal neural tube defects can cause a wide variety of presentations and neurologic deficits. Thus it is of the utmost importance to properly manage these patients to improve their neurologic outcome and prevent infection in open spinal defects. The urgency and timing of intervention differs greatly between open and closed spinal dysraphism. Open spinal dysraphism requires more urgent management and intervention, because the neural tissue and cerebrospinal fluid are directly exposed to the outside environment, predisposing these children to infections such as meningitis. Myelomeningocele is one of the most morbid and debilitating of the open spinal neural tube defects. It can cause severe neurologic deficit, hydrocephalus, and meningitis in the postnatal period. Although some centers repair myelomeningoceles in utero during the prenatal period, postnatal repair of myelomeningoceles remains the standard of care. Nevertheless, no specific guidelines exist regarding the management of these conditions. Although each institution may differ in how they manage myelomeningoceles, the overall premise of management remains the same.[7] (See also Chapter 13.)

When myelomeningocele is diagnosed in utero, the first issue that arises is mode of delivery. Many institutions advocate for cesarean section prior to labor when compared to

TABLE 58.3 Corresponding Motor and Sensory Levels for Assessment of the Functional Level of a Patient With Myelomeningocele

Level	Motor Function	Sensory Level
T10	Rectus	Umbilicus
L1	Hip flexion	Anterolateral thigh
L2	Hip adduction	Anteromedial thigh
L3	Knee extension	Knee and shin
L4	Dorsiflexion	Dorsum of foot
L5	Extensor Hallucis Longus	1st-2nd toe interspace
S1	Plantar Flexion	Plantar foot

Note: In general, hip flexion indicates higher lumbar, knee extension indicates mid-lumbar, and isolated club feet indicate a low-lumbar lesion.

TABLE 58.4 Signs and Symptoms of Hydrocephalus and Symptomatic Chiari II Malformation

Hydrocephalus	Chiari II Malformation
• Bulging anterior fontanelle • Increasing head circumference • Sunsetting eyes • Dilated scalp veins • Weakness • Irritability, vomiting • Hemodynamic instability (Cushing's triad)	• Nystagmus • Apnea • Gagging • Swallowing difficulties • Syncope • Weakness • Hemodynamic instability (lower brainstem)

vaginal delivery or cesarean section after labor. Some studies have shown improved motor function at 2 years of age in patients delivered via cesarean section prior to labor when compared to any mode of delivery after labor. Other studies have shown that once labor commences, there is no change in outcome based on mode of delivery. Given the impact upon the mother, if a cesarean section is recommended, this is often a discussion between the obstetrician and the neurosurgeon in the prenatal period that takes into consideration the presence or absence of hydrocephalus, which may preclude a vaginal delivery if the head size is too large. After the fetus is delivered, focus turns to prevention of infection, including prophylactic antibiotics, maintaining the sterility of the open dysraphism with sterile coverings, and timing of intervention.[3,15]

After delivery of the fetus, the size and location of the lesion should be noted. The lesion should also be assessed for leaking of cerebrospinal fluid. When assessing the lesion, sterile, nonlatex gloves are recommended to minimize the risk of latex sensitization.[11,23] The defect should be covered with a sterile, saline-soaked dressing. Larger defects should be covered by a plastic wrap to prevent heat loss. The infant should also be placed in a prone or lateral position to avoid prolonged pressure on the lesion.[20] A thorough neurologic examination should also be performed with the objective of defining the baseline neuropathology of the patient, paying attention to the observation of spontaneous activity, extent of muscle weakness, leg posture and paralysis, response to sensation, deep tendon reflexes, and anocutaneous reflex for assessment of spinal cord function. The functional level of the lesion is as important as the anatomic level, as there may not be an exact correlation depending on the functionality of the exposed neural tissue (Table 58.3). The newborn should also be evaluated for club feet, flexion, or extension of the hips, knees, or ankles, as this helps to define the level of the lesion. In addition, one should evaluate for signs of hydrocephalus, including a measurement of head circumference, assessment of the fontanelle and sutures for signs of splaying or fullness, and signs of brain stem compression from a Chiari II malformation. Concerning signs of apnea or bradycardia, lower brainstem dysfunction may be an indication to treat the hydrocephalus, and persistence of symptoms after treatment is a poor prognostic sign (Table 58.4). The spinal column may demonstrate kyphosis, and assessment should include evaluation for other congenital anomalies involving the heart, airway, kidneys, or GI tract.

Although there is no consensus for the specific type of prophylactic antibiotic used in these patients, the agents often used are ampicillin in addition to either gentamycin or cefotaxime. This provides coverage for group B streptococcus and gram-negative bacteria. Antibiotics should be started within 1 hour of birth and continued until at least 48 hours after repair. Prophylactic antibiotics and wound sterility greatly reduce the risk of early CNS infection, but timely repair of the defect also significantly reduces the risk of CNS infection.[8] Postnatal repair should be performed within 48-72 hours after birth.[5,7,10] However, most would advocate closure within 24-48 hours. Postoperatively, patients should remain in the prone or lateral position to avoid pressure on the incision and allow for wound healing. Close attention should also be placed to preventing urine or feces from entering the wound, and bumpers with drapes are often used between the wound and diaper to prevent diaper contents from affecting the wound and causing an infection. Given the high risk of hydrocephalus in this patient population, the infant should be monitored for signs and symptoms of hydrocephalus, and at the very least get daily head circumference measurements and weekly head ultrasounds.[7]

Closed spinal dysraphism management is less urgent than open spinal dysraphisms. This is because the defect is covered by skin and not directly exposed to the outside environment. Thus, prophylactic antibiotics are not needed for these conditions, with the potential exception being dermal sinus tracts that have direct extension into the thecal sac and an opening at the skin. Nevertheless, thorough neurologic examination should be performed in these patients to

assess for any neurologic deficit given the close association with tethered spinal cord. Thorough cutaneous examination should also be performed to look for cutaneous stigmata for a subcutaneous fatty mass as in the case of lipomyelomeningocele. MRI of the entire spine is recommended for patients who have two or more cutaneous lumbosacral spine lesions, a subcutaneous back mass, or neurologic symptoms concerning for tethered cord syndrome. MRI or ultrasound is also recommended for patients with isolated midline cutaneous lumbosacral spine lesion. Patients with radiographically confirmed closed spinal dysraphism should be referred to neurosurgery for an evaluation. Surgery in these cases is nonurgent and is usually performed more urgently in patients with neurologic deficits in the setting of tethered cord. Conservative management with observation is reasonable for patients who are asymptomatic from a closed spinal dysraphism, although surgery may be considered as a prophylactic means of treatment because of the high risk of neurologic deterioration and potential for irreversible neurologic injury.[10,24]

Surgical Treatment

Open spinal dysraphisms require timely surgical intervention to reduce the risk of early CNS infection and further neurologic decline. Myelomeningocele, the most common open spinal dysraphism, can be treated either pre- or postnatally, although postnatal treatment still represents the standard of care. The Management of Myelomeningocele Study (MOMS) was a randomized study of 183 patients at several pediatric centers across the United States comparing prenatal to postnatal repair of myelomeningocele and published in 2011. Patients were randomly assigned to undergo either prenatal repair of the myelomeningocele before 26 weeks' gestation or standard postnatal repair. The primary endpoints of the study included fetal or neonatal death, need for shunt at 12 months, as well as mental development and motor function at 30 months. Of the 183 patients enrolled, 158 patients were evaluated at 12 months and results showed that only 40% of patients required shunt after prenatal repair compared to 82% in the postnatal group. The study also showed that the prenatal group had improved mental and motor development at 30 months when compared to the postnatal group. Secondary outcomes such as hindbrain herniation and ambulation at 30 months were also improved in the prenatal group. Although the study offered promising results, enrollment was stopped due to efficacy secondary to increased risk of preterm delivery and uterine dehiscence at delivery. In addition, the population of mothers who were able to enroll in the study due to the location restrictions associated with fetal repair narrowed the applicable population of both appropriate maternal candidates and size and location of lesion. The MOMS II trial is ongoing to look at delayed results and will hopefully provide more insight on the risks and benefits for prenatal repair.[1,16] Since the MOMS trial, other centers have started performing fetoscopic repair; however, these results are not widespread yet. Given the risks of prenatal repair as well as that these interventions are occurring at limited centers, postnatal repair still represents the standard of care for treatment. Repair is usually performed in a timely manner, between 24-48 hours, and involves approximation of the lateral edges of the open neural plate in the midline to form a neural tube, closure of a meningeal sac, and closure of the skin over the open defect. Although there is no specific data to support neural tube closure, it is believed that reforming the neural tube decreases the incidence of tethered spinal cord by decreasing the raw edge at risk of scarring. The most common condition to develop after repair is hydrocephalus, and infants must be monitored closely with head circumferences and head ultrasounds. Upwards of 60%-80% of infants with myelomeningocele develop hydrocephalus and require placement of shunt.[29] Other conditions that require monitoring and possible treatment in this patient population include Chiari II malformation, tethered cord, shunt malfunction, neurogenic bladder and bowel, and several orthopedic deformities.[10]

Closed spinal dysraphism is amenable to a delay in surgical intervention when compared to the open dysraphism, as the defect is not exposed to the external environment. Surgical treatment is often required for infants with tethered cord syndrome with a neurologic deficit, as some patients can be asymptomatic from their closed spinal dysraphism. Surgical treatment involves removal of the subcutaneous mass (if any), identification of the defect and release of the tethered, possible release of the filum terminale, preservation of neural elements, and prevention of retethering of the spinal cord. Given the complexity of the surgery for neural tube defects, surgery is not without significant risks. Common risks of surgical intervention include neurologic decline from tethered cord or secondary to nerve injury during the surgery, incomplete wound healing or wound dehiscence, infection, and meningitis. Patients with lipomyelomeningocele have a complication rate between 10% and 30%, a 5.8% risk of worse neurologic function after surgery, and between a 10% and 20% risk of retethering postoperatively.[24]

Conclusion

Spinal neural tube defects are a diverse group of congenital spinal anomalies and can result in severe neurologic outcomes. These conditions range from open spinal dysraphisms, which require prompt delivery, ICU management, and surgical intervention, to closed spinal dysraphism which may initially be asymptomatic, and can be treated in a delayed fashion. These infants may have other severe conditions that can require complex management in the neonatal ICU. Thus, it is paramount for clinicians to understand the embryology, pathogenesis, physical examination findings, management, and treatment to provide the optimal care for these patients in the ICU.

Key Points

- Spinal dysraphisms include both open and closed defects with varying degrees of neurologic impairment.
- Open defects include meningocele and myelomeningocele, which may be repaired prenatally but more commonly are repaired postnatally and warrant urgent surgical repair and perinatal antibiotic prophylaxis to prevent meningitis.
- Monitoring for signs of infection, hydrocephalus, and symptoms of a Chiari II malformation are critical in the perinatal period.
- Closed spinal dysraphisms may be amenable to delayed treatment to prevent neurologic decline from a tethered spinal cord.

Hearing Loss in the Newborn Infant

BETTY VOHR

Background

Tremendous progress has been made during the past 25 years in the identification of hearing loss (HL) in newborns. The National Institutes of Health issued a "Consensus Statement on Early Identification of Hearing Impairment in Infants and Young Children" in 1993 that concluded that all infants admitted to the neonatal intensive care unit (NICU) should be screened for HL before hospital discharge and that universal hearing screening should be implemented for all infants within the first 3 months of life.[47] The percentage of infants screened for HL in the United States has increased from 46% in 1999 to 98.4% in 2014 (https://www.cdc.gov/ncbddd/hearingloss/2014-data/2014_ehdi_hsfs_summary_h.pdf). The percentage of infants who fail the screening process is about 1.6%, and rates of permanent HL subsequently diagnosed by comprehensive audiology testing range from 1-3 per 1000, making congenital HL the most common birth defect diagnosed as a result of the newborn screening process. However, a report to assess the impact of universal hearing screening in a large cohort of infants identified a prevalence of deafness by school age of 3.65/1000 compared to a neonatal rate of 1.79/1000.[69] It is important to recognize that the neonatal screen does not identify all HL and is least sensitive to mild impairments. Undetected, HL in young infants and children negatively affects communication development, academic achievement, literacy, and social and emotional development,[73,77] whereas early identification and intervention, particularly within the first 6 months of life, clearly provide benefit for communication development in infants.[41,46,63-66,73] There is accumulating evidence that the brain may be optimally responsive to language input early in life.[13,14,29,59]

Based on these findings, the Joint Committee on Infant Hearing 2007 Position Statement published the 1-3-6 recommendation to maximize the outcomes of infants with all degrees of HL[3]: 1) All infants in the NICU and well-baby nursery should be screened for HL no later than 1 month of age. 2) Infants who do not pass the screen should have a comprehensive evaluation by an audiologist skilled in assessing infants and children, no later than 3 months of age for confirmation of hearing status. 3) Infants with confirmed HL should receive appropriate intervention no later than 6 months of age from professionals with expertise in HL and deafness in infants and young children.[75]

Normal Hearing and Hearing Loss

The ear consists of outer, middle, and inner components. The external ear includes the pinna and the outer ear canal. Sound waves travel through the air and are conducted through the outer ear canal to the tympanic membrane, where vibrations enter the middle ear and are amplified and transmitted through the ossicles to the fluid within the cochlea (inner ear). Sound waves in the inner ear are transmitted through the fluid and stimulate both the outer and inner hair cells of the cochlea. The outer hair cells respond to sound energy by producing an echo of sounds called otoacoustic emissions, and the inner hair cells act by converting mechanical energy into electrical energy transmitted to the cochlear branch of the eighth cranial nerve, the brainstem, and finally the auditory cortex for perception of the meaning of sounds. In normal hearing individuals, all components of the pathway are intact and functioning. Blockage of sound conduction in the outer or middle ear may result in either a transient (fluid or debris) or permanent (anatomic abnormality such as atresia or microtia) conductive HL. Failure of sound transmission within the cochlea, outer and inner hair cells, and eighth cranial nerve are a manifestation of sensorineural HL, whereas pathology of the inner hair cells and eighth cranial nerve with intact outer hair cells is characteristic of neural HL, also referred to as *auditory neuropathy* or *auditory dyssynchrony*.[11,57,60]

Hearing loss can be classified as bilateral or unilateral and as slight, mild, moderate, severe, or profound. Hearing loss severity is defined by measuring the hearing threshold in decibels (dB) across frequencies (Box 59.1). Normal hearing has a threshold of 10-15 dB. It is important to recognize that the presence of even slight and mild HL can impact on language development in young children and may be progressive. For children with bilateral HL, the severity of loss is based on the better-functioning ear.[6]

The types of transient and permanent HL that can be identified at birth with newborn screening include sensorineural, neural, and conductive (Table 59.1). Transient conductive HL may also be present, especially in infants who

Abstract

Rates of permanent hearing loss subsequently diagnosed by comprehensive audiology testing range from 1 to 3 per 1000, making congenital hearing loss the most common birth defect diagnosed as a result of the newborn screening process. Permanent hearing loss is found in association with genetic mutations, over 400 congenital syndromes, and medical risk factors such as extreme prematurity and CMV infection. Undetected hearing loss in infants and children negatively affects communication development, academic achievement, literacy, and social-emotional development. There is substantial evidence that early diagnosis and intervention for infants and young children with permanent hearing loss is associated with improved outcomes. The current EHDI 1-3-6 recommendation for success is to screen by 1 month, diagnose by 3 months, and provide appropriate intervention services consistent with family choice by 6 months. Successful care coordination of the child with hearing loss requires the partnering of the primary care provider, audiologist, otolaryngologist, early intervention provider, developmental pediatrician, geneticist, and family.

• BOX 59.1 Definitions of Degrees of Hearing Loss

• No hearing loss	10-15 dB
• Slight	16-25 dB
• Mild	26-40 dB
• Moderate	41-55 dB
• Moderately severe	56-70 dB
• Severe	71-90 dB
• Profound	≥ 91 dB

TABLE 59.1 Types of Hearing Loss

Type	Characteristics
Sensorineural	Pathology involving cranial nerve VIII and outer hair cells and inner hair cells of the cochlea that impairs neuroconduction of sound energy to the brainstem
Permanent conductive	Anatomic obstruction of the outer ear (atresia) or middle ear (fusion of ossicles) that blocks transmission of sound
Neural or auditory neuropathy or auditory dyssynchrony	Pathology of the myelinated fibers of cranial nerve VIII or the inner hair cells that impairs neuroconduction of sound energy to the brainstem. The function of the outer hair cells remains intact.
Transient conductive	Debris in the ear canal or fluid in the middle ear that blocks the passage of sound waves to the inner ear
Mixed hearing loss	A combination of sensorineural or neural HL with transient or permanent conductive HL

have been hospitalized in a NICU. Mixed HL is a combination of permanent HL and transient conductive HL.

Neonatal hearing screening programs in the United States are conducted under the guidance of an audiologist. An audiologist, experienced in assessing infants and young children, is responsible for completing the comprehensive diagnostic assessment needed to confirm the diagnosis of HL. Increasing numbers of NICUs are completing the diagnostic assessment prior to discharge to avoid a delay in the diagnosis for the most medically high-risk infants.

Tests for Hearing Loss

Screening and diagnostic hearing tests are shown in Table 59.2. Physiologic tests include those that measure electrical activity or reflexes and include otoacoustic emissions (OAEs) and auditory brainstem response (ABR) testing. These tests do not require an active response from the infant and can be performed when the infant is asleep or quiet awake. Otoacoustic emission screen measurements are obtained using a sensitive microphone within a probe inserted into the ear canal that records the sound produced by the outer hair cells of a normal cochlea in response to a sound stimulus. Abnormal outer and middle ear function caused by blockage or background noise may interfere with recording OAEs. Automated auditory brainstem response (AABR) for screening and ABR for diagnostic testing are obtained from surface electrodes that record neural activity in the cochlea, outer and inner hair cells, auditory nerve, and brainstem in response to a click stimulus. In AABR, a predetermined algorithm provides an automated pass-or-fail response to the presence or absence of wave 5 on the ABR. Both OAE and ABR detect sensorineural and conductive HL. A false-positive fail screen for permanent HL may result from outer or middle ear dysfunction, including the presence of a transient conductive HL (fluid or debris) or noise interference. Otoacoustic emissions cannot be used to screen for neural HL, because pathology in this disorder involves the inner hair cells, eighth cranial nerve, and brainstem with intact outer hair cells. Infants with neural HL will, therefore, fail ABR but pass OAE. The Joint Committee on Infant Hearing 2007 states that infants cared for in the NICU for greater than 5 days are at highest risk for neural HL and, therefore, should be screened only with AABR.[3,48] Some hospitals use a two-step screen with both AABR and OAE. Screen time with OAE is quicker and more cost effective, and OAE is, therefore, considered an acceptable screen in the well-baby nursery. OAE will not identify auditory neuropathy and, therefore, is not recommended for screening in the NICU.

Tympanometry (immittance) testing is used to assess the peripheral auditory system, including the function, intactness, and mobility of the tympanic membrane, the pressure in the middle ear, and the mobility of the middle ear ossicles. A probe is placed in the inner ear, and air pressure is changed to assess the movement of the tympanic membrane. The tympanogram shows the response of the tympanic membrane in response to the pressure stimulus: A type A curve is considered a normal response. A completely flat response may be reflective of fluid in the middle ear or perforation of the tympanic membrane. Tympanometry is not used for screening.

Behavioral tests include vision reinforcement audiometry (VRA), which is appropriate for rested alert infants with a developmental age of at least 6 months. The infant must have the functional capability of turning to sounds. For administration of VRA, the infant sits on the mother's lap in a sound booth, earphones are inserted, and the infant is conditioned to turn to sounds that are paired to animated toys that appear either to the right or left side. Traditional behavioral testing is used for toddlers at least 2.5 years of age. Children respond by placing a block in a box each time they hear a sound.

For confirmation of an infant's hearing status, a test battery is required to cross-check results of both the

TABLE 59.2 Tests for Hearing Screening and Diagnosis

Test	Mechanism	Type of Hearing Loss
Otoacoustic emissions (OAE) screen	OAE tests represent a response of the outer hair cells in the cochlea to a sound stimulus; the hair cells produce echolike responses that can be detected and recorded with a high-sensitivity microphone. Automated equipment is available.	Sensorineural Conductive
Automated auditory brainstem response screen (AABR)	Automated auditory brainstem response screen tests based on threshold algorithms have become standard for screening.	Sensorineural Conductive Neural
The Following Physiologic and Behavioral Tests Are Used As Part of a Diagnostic Battery		
Auditory brainstem response (ABR) diagnostic	Auditory brainstem response potentials are a reflection of electrical activity in cranial nerve VIII and auditory brainstem pathway that can be detected with scalp electrodes to produce an auditory brainstem response.	Sensorineural Conductive Neural
Tympanometry battery	This measure of middle ear function is part of the battery for all children. For infants younger than 6 months, a high-frequency probe tone of 1000 Hz is indicated.	Conductive
Vision reinforcement audiometry (>6 months of age) Conditioned audiometry response (>2.5 years of age)	Observations of the infant's behavioral responses to sounds	Sensorineural Conductive Neural
Standard audiometry (>4.5 years of age)	Observation of the child's behavioral responses to a task in response to sounds	Sensorineural Conductive Neural

physiologic measures and the behavioral measures.[70] The purposes of the audiologic test battery are to assess the integrity of the auditory system, estimate hearing sensitivity across the frequency range, and determine the type of loss. Infants who fail a newborn screen should have a diagnostic assessment as soon as possible after the newborn screen and not later than 3 months of age.

Primary care physicians and health centers are beginning to implement routine surveillance and hearing screening of children with OAE and tympanometry during well-child visits.[4,5,31,56] This would appear to be an important adjunct to newborn screening because of the known rate of late onset by school age, which is equivalent to the rate identified in newborn screening. However, NICU infants who fail the newborn screen should never be screened in the medical home but should be referred to an audiologist. In addition, children who do not pass the OAE screen in the medical home need to be referred to audiology for further diagnostic testing.

Early Intervention Services

There is a body of evidence supporting the importance of early enrollment in early intervention services to improve the outcomes of children with HL. Before universal hearing screening, children with severe to profound HL were identified at 24-30 months of age and subsequently demonstrated significant delays in communication, language, and literacy. The Colorado study first reported that children with HL who received intervention services before 6 months of age had speaking, sign, or total communication language scores comparable with hearing children at 3 years of age.[73,74] A second report demonstrated that at 12-16 months, children with HL who were enrolled in early intervention at 3 months or younger had significantly higher scores for number of words understood, words produced, early gestures, later gestures, and total gestures compared with children enrolled after 3 months of age.[64] The Joint Committee on Infant Hearing 2007 recommends that infants with all degrees of unilateral or bilateral HL need to be referred to early intervention services at the time of diagnosis and receive services no later than 6 months of age. These services should be provided by professionals who have expertise in HL, including educators of the deaf, speech-language pathologists, and audiologists. The 2013 Supplement to JCIH 2007 Position statement provides comprehensive guidelines for early intervention after confirmation that the child is deaf or hard of hearing.[33] The 12 best practice goals and guidelines recommended provide an evidence-based framework for family-centered culturally competent, individualized early intervention services to meet the diverse needs of children and families regardless of type and degree of HL and modality of communication (Table 59.3).

TABLE 59.3 Best Practice Guidelines for Early Intervention Services for Children who are Deaf or Hard of Hearing

Goal 1	Access to timely and coordinated entry into EI programs supported by a data management system capable of tracking
Goal 2	Timely access to coordinators with specialized knowledge and skills related to working with children and adults who are deaf or hard of hearing
Goal 3	• EI providers who have the professional qualifications and core knowledge and skills to optimize the child's development and child/family well-being • EI services to teach American Sign Language provided by professionals who have native or fluent skills and are trained to teach parents/families and young children • EI services to develop listening and spoken language provided by professionals who have specialized skills and knowledge
Goal 4	Children with additional disabilities have access to specialists with the qualifications and specialized skills to support optimal outcomes.
Goal 5	Children from culturally diverse backgrounds and/or non-English-speaking homes have access to culturally competent services of the same quality and quantity as provided to majority culture families.
Goal 6	All children have progress monitored every 6 months to 36 months, with standardized, norm-referenced developmental assessments for language (spoken and/or signed), the modality of communication (auditory, visual, and/or augmentative), and social–emotional, cognitive, and motor skills.
Goal 7	Children with all degrees of hearing loss, including unilateral or slight hearing loss, auditory neuropathy, and progressive or fluctuating hearing loss, receive appropriate monitoring and immediate referral to EI services as needed.
Goal 8	Families are participants in the development and implementation of EHDI systems at the state/territory and local level.
Goal 9	Families have access to other families who have children who are D/HH and are trained to provide culturally and linguistically sensitive support and guidance.
Goal 10	Individuals who are D/HH are active participants in the development and implementation of EHDI systems at the national, state/territory, and local levels.
Goal 11	Children who are D/HH and their families have access to support, mentorship, and guidance from individuals who are D/HH.
Goal 12	All children who are D/HH and their families are ensured of fidelity in the implementation of EI.

D/HH, Deaf or hard of hearing; EHDI, early hearing detection and intervention; EI, early intervention.

Etiology of Hearing Loss

It is estimated that at least 50% of congenital HL is hereditary. Nearly 400 syndromes and hundreds of genes associated with HL have been identified.[15,45,72] Genetic HL is about 30% syndromic and 70% nonsyndromic. Among children with nonsyndromic HL, 75%-85% of cases are autosomal recessive (*DFNB, deafness*, *neurosensory*, *autosomal recessive*), 15%-24% are autosomal dominant (*DFNA*, *deafness*, *neurosensory*, *autosomal dominant*), and 1%-2% are X-linked (*DFN*). Therefore, most infants with HL have nonsyndromic autosomal recessive HL and are born to hearing parents. A single gene, *GJB2*, which encodes Connexin 26, a gap-junction protein expressed in the connective tissues of the cochlea, accounts for up to 50% of all cases of profound nonsyndromic HL. More than 100 mutations of *GJB2* have been identified. A single *GJB2* mutation, 35delG, accounts for up to 70% of the mutations. The etiology of HL will be reviewed relative to the risk factors for HL published by the Joint Committee on Infant Hearing 2007 (Box 59.2).

Several mitochondrial DNA mutations of the 12S rRNA gene are associated with aminoglycoside-induced nonsyndromic HL. This is potentially important for NICU infants, because aminoglycosides are one of the most common medications administered in the NICU.[16] Two studies have examined the frequency of these genes in NICU populations and identified a rate of ≈1%-1.8%.[24,32] Neither study, however, identified an association in neonates between the presence of the genetic marker in conjunction with aminoglycoside administration and HL. Neonatal genetic screening with rapid turnaround is not available. A concern with the current reports, however, is that mitochondrial HL has variable age of onset and may not be identified in the newborn period. In addition, it has been suggested that there may be a modifier gene effect that is protective.[32]

Risk Factors

The first two risk factors in Box 59.2 are obtained by parent report. Parents may not be aware of a family history of HL (risk factor 2) or of syndromes associated with HL until

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• BOX 59.2 Risk Factors Associated with Permanent Congenital, Delayed Onset, or Progressive Hearing Loss

1. Caregiver concerns* regarding hearing, speech, language, or developmental delay
2. Family history of permanent HL*
3. Neonatal intensive care for greater than 5 days, and hyperbilirubinemia requiring exchange transfusion regardless of length of stay
4. In utero infections, such as cytomegalovirus,* Zika virus, herpes virus, rubella, syphilis, and toxoplasmosis
5. Craniofacial anomalies, including atresia, microtia, and temporal bone anomalies
6. Physical findings, such as white forelock, that are associated with syndromes known to include a sensorineural or permanent conductive HL
7. Syndromes associated with HL or progressive or late-onset HL,* such as neurofibromatosis, osteopetrosis, and Usher syndrome. Other frequently identified syndromes include Waardenburg, Alport, Pendred, and Jervell and Lange-Nielsen.
8. Neurodegenerative disorders* such as Hunter syndrome or sensory motor neuropathies such as Friedreich ataxia or Charcot-Marie-Tooth disease
9. Culture-positive postnatal infections* associated with sensorineural HL, including confirmed bacterial and viral (especially herpesviruses and varicella) meningitis
10. Head trauma, especially basal skull or temporal bone fracture that requires hospitalization
11. Chemotherapy*

*Risk factors that are of greater risk for delayed onset or progressive hearing loss. HL, Hearing loss.

discussing the possibility with relatives. If a family history of HL is reported for an infant who passes the screen, ongoing surveillance is indicated with at least one follow-up audiologic assessment by 24-30 months of age. All families with an infant with HL, regardless of family history of HL, will benefit from a genetics consultation. Risk factor 1, caregiver concern regarding hearing, speech, language, or developmental delay in the first 2-3 years of life,[21] has also been shown to be associated with an increased risk for late-onset or progressive HL not detected in a newborn screen. It is important to remember that the rate of HL doubles between birth and school age from 1-3 per 1000 in newborns to about 3-4 per 1000 at school age[70]; therefore, caregiver concern should prompt a referral for further evaluation.

Medical complications are associated with 40% of childhood permanent HL. Risk factor 3 includes infants requiring NICU care for greater than 5 days *and any of the following exposures regardless of length of stay*: extracorporeal membrane oxygenation, assisted ventilation, exposure to ototoxic medications (gentamicin and tobramycin) or loop diuretics (furosemide or lasix), and hyperbilirubinemia requiring exchange transfusion.[27,53,71] Risk factor 4 includes in utero infections such as cytomegalovirus, herpes, rubella, syphilis, toxoplasmosis, and Zika virus.[23] Cytomegalovirus remains the most common medical cause of both early- and delayed-onset HL in infants and children.[9,28] Most infants with congenital cytomegalovirus infection have no clinical findings at birth, and the diagnosis goes unrecognized. Treatment of children with positive CMV, but without clinical findings or HL, with valgancyclovir remains controversial because of an increased risk of side effects.[12,34] Zika virus is also a neurotropic virus that has emerged and is associated with early and possibly delayed onset HL. It may occur in association with abnormalities of the central nervous system, and the type of HL is either sensorineural or auditory neuropathy.[20,35] Because of the association with CNS abnormalities, these infants should be screened with AABR.

Risk factors 5-8 are all associated with congenital abnormalities or syndromes. Risk factor 5 includes craniofacial anomalies, such as those involving the pinna or ear canal, ear pits, and temporal bone anomalies.[62] These defects are common in both the well-baby nursery and the NICU. Many of these findings reflect abnormalities in the embryologic development of the ear. The external ear, middle ear, and Eustachian tube develop from the branchial apparatus beginning at the fourth week of gestation. The pinna arises from the coalescence of the first and second arch tissues of the first branchial cleft, which will become the external auditory canal. The Eustachian tube and middle ear space develop from the first pharyngeal pouch, and the ossicles from the mesoderm of the first and second arches. The inner ear develops from surface ectoderm and neuroectoderm beginning in the third week of gestation, with the cochlea, semicircular canals, utricle, and saccule formed by 15 weeks. The inner ear reaches adult size by 23 weeks. Risk factor 6 includes visible physical findings such as white forelock, which is associated with Waardenburg syndrome.

Risk factor 7 includes syndromes associated with neonatal, progressive, or late-onset HL such as neurofibromatosis, osteopetrosis, and Usher syndrome. Usher syndrome is the most common cause of autosomal recessive syndromic HL (4%-6% of children with HL). Affected individuals develop vestibular problems secondary to progressive retinitis pigmentosa and become blind with increasing age. Subtypes are associated with either mild to severe or severe to profound HL. Early diagnosis is critical, because a visual means of communication is not an option for a child who will become blind with increasing age. Other frequently identified syndromes include Waardenburg, Pendred, Jervell and Lange-Nielsen, and Alport syndromes.[2,15,44] The most common autosomal dominant syndrome is Waardenburg syndrome. It occurs in 1%-4% of children with HL. Children have sensorineural or permanent conductive HL and associated heterochromia iridis. Pendred syndrome is the second most common autosomal recessive cause of syndromic HL. It is characterized by severe to profound HL and euthyroid goiter, which presents during adolescence or later. An abnormality called Mondini dysplasia or dilated vestibular aqueduct, which is diagnosed by computed tomography examination of the temporal

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

bones, is associated with Pendred syndrome. Jervell and Lange-Nielsen syndrome is characterized by prolongation of the QT segment on electrocardiogram and is associated with sudden infant death and syncope. Children with QT prolongation should be seen in consultation by cardiology for management. Branchio-otorenal syndrome is autosomal dominant and occurs in 2% of HL. It is characterized by preauricular pits, malformed pinnae, branchial fistulas, and renal anomalies. Alport syndrome is X-linked or autosomal recessive, occurs in 1% of children with HL, and is associated with progressive HL.

Risk factor 8 consists of neurodegenerative disorders such as Hunter syndrome or sensory motor neuropathies such as Friedreich ataxia and Charcot-Marie-Tooth syndrome.[44]

Risk factor 9 is culture-positive postnatal infections and includes confirmed bacterial and viral (especially herpesviruses and varicella virus) meningitis. Meningitis is associated with an increased incidence of sensorineural HL.[1,17] Children with cochlear implants may be at increased risk of meningitis.[8,51]

Risk factors 10 and 11 are risk factors encountered after discharge. Serious head trauma, especially basal skull or temporal bone fractures requiring hospitalization, is a risk factor for HL in childhood.[7,37] Although rare in children, chemotherapy for leukemia or cancer remains a risk factor, which in some cases is reversible.[30] Box 59.2 specifically identifies the risk factors associated with delayed-onset HL. Although all children with a risk factor should have ongoing surveillance in the medical home and at least one follow-up visit with an audiologist, children with increased risk for delayed-onset HL may benefit from more frequent assessments.

Medical Workup for Hearing Loss and Care Coordination

An initial physician visit is beneficial after a newborn hearing screen is failed. At that time, parents are informed of the risk of HL and the importance of follow-up with an audiologist. A second physician visit should be scheduled with the family as soon as a diagnosis of HL is made to discuss the audiologist's report, provide information on community resources, and support for the family during a stressful time. During the postdiagnosis appointment, the physician reviews the pregnancy, neonatal, and family history for HL, re-examines the child for evidence of any craniofacial abnormalities or a syndrome associated with HL, and discusses the benefits of early intervention services and amplification. The primary care physician, therefore, needs to be aware of community resources and to support the family choice of early intervention program and mode of communication. Ongoing communication of the primary provider with the family is necessary to answer questions and provide support. Sharing evidence of significantly improved outcomes as a result of early diagnosis and early intervention provides some reassurance and comfort to the family. During this time of transition, some families derive benefit from meeting other families with young children with HL who are farther along in the process. Successful care coordination of the child with HL requires the partnering of the primary care provider, audiologist, otolaryngologist, early intervention provider, developmental pediatrician, geneticist and, most important, the family.

Every infant with confirmed HL should be evaluated by an otolaryngologist with knowledge of pediatric HL. The otolaryngologist conducts a comprehensive assessment to determine the etiology of HL and provides recommendations and information to the family, audiologist, and primary care provider on candidacy for amplification, assistive devices, and surgical intervention, including reconstruction, bone-anchored hearing aids, and cochlear implantation.

Because of the prevalence of hereditary HL, all families of children with confirmed HL should be offered a genetics evaluation and counseling. This evaluation can provide families with information on etiology, prognosis, associated disorders, and the likelihood of HL in future offspring. The geneticist will review the family history for specific genetic disorders or syndromes, examine the child, and complete genetic testing for syndromes or gene mutations for nonsyndromic HL such as *GJB2* (Connexin 26).[15,58]

Additional referrals may be made at that time for a developmental assessment or other indicated specialty evaluation. Because 30%-40% of children with confirmed HL have comorbidities or other disabilities, the primary care physician should closely monitor developmental milestones and initiate referrals related to suspected disabilities as needed.[31,42] Because of the association of HL with vision impairments and the importance of vision for children with HL, it is recommended that each child with a permanent HL have at least one examination to assess visual acuity by an ophthalmologist experienced in evaluating infants.

Middle Ear Disease

Otitis media with effusion (OME) is highly prevalent among young children, and about 90% of children have an episode of OME before starting school.[38] Middle ear status should be monitored closely in children with permanent HL, because the presence of middle ear effusion can further compromise hearing. Recommendations related to diagnosis of OME include examination with a pneumatic otoscope and documentation of laterality, duration of effusion, and severity of symptoms. Although about 40%-50% of children with OME do not have symptoms,[54,55] some children may have associated balance problems.[25] Medical management of OME in children with permanent HL may include hearing testing, amplification adjustment, and tympanostomy tubes.[38,55] Most OME is self-limited, and 75%-90% of cases spontaneously resolve in 3 months.[54] Therefore, a 3-month period of observation is recommended. Evidence suggests that no benefit is derived from the use of antihistamines or decongestants in children. Children with

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

persistent OME (≥4 months' duration) with associated persistent HL or structural injury to the tympanic membrane or middle ear become candidates for surgical intervention with tympanostomy, which has been shown to be associated with decreases in middle ear effusion and improved hearing.

Communication Options

One of the important decisions that the family needs to make for the child is the communication mode that will work optimally for the child and family. There are five options. Auditory oral communication encourages the use of residual hearing and amplification with visual support (speech reading), and the goal is spoken language. Auditory verbal communication is based on listening skills alone, and the goal is spoken language. Cued speech uses a visual communication system that combines listening with eight hand shapes in four placements near the face and supports spoken language. Total communication combines all means of communication and encourages simultaneous use of speech and sign. Deaf children learn American Sign Language, and English is learned as a second language once American Sign Language is mastered. The choice of communication option for the family may change over time depending on the progress of the child and the degree of HL. For example, for an infant born with a profound HL, the family may initially choose total communication, but after a cochlear implant at 12 months of age, may use predominantly auditory verbal or auditory oral communication.

Audiologic Devices

Hearing Aids

Hearing aids are compact and worn either in-the-ear (ITE) or behind-the-ear (BTE), and can be fitted on an infant in the first month of life. The main components are the microphone that picks up sounds and the amplifier. The audiologist uses computer programming to adjust the sound for an individual child's needs. If the child has different degrees of HL at different frequencies, the audiologist adjusts the gain (loudness) by frequency. Normal speech range is from 500-2000 Hz. Ear molds are made from an impression of the child's ear. As a young infant grows, the ear molds may need to be replaced every 6-8 weeks.

Frequency-Modulated Systems

Frequency-modulated (FM) systems were developed for individuals with HL to hear better in noisy environments. An FM system consists of a microphone and a receiver. A small radio transmitter is attached to a microphone and a small radio receiver. A parent or teacher wears the FM transmitter and microphone while the child wears the FM receiver. The FM transmitter sends a low-power radio signal to the FM receiver that needs to be within 50 feet of the transmitter. The FM receiver gets the signal from the microphone and sends it to a personal hearing aid or cochlear implant. Listening to the FM signal is similar to listening to speech only inches away. Frequency-modulated systems can be used in a variety of situations, including in the home, while shopping, or at school.

Cochlear Implants

Children and adults who are deaf or severely hard of hearing can be fitted for cochlear implants. According to the US Food and Drug Administration (FDA), as of December 2012, approximately 324,000 people worldwide have received implants. In the United States, roughly 58,000 adults and 38,00 children have received them.[22] Candidacy criteria for pediatric cochlear implantation currently is 18 months or older for children with severe to profound bilateral sensorineural HL and 12-18 months for children with profound HL. There are increasing reports demonstrating the beneficial effects on speech and language for infants with bilateral profound HL implanted before 12 months of age.[36,40,76] In cases of deafness caused by meningitis, implants may be placed early in the first year of life. A lack of benefit in the development of auditory skills with amplification needs to be demonstrated for eligibility for an implant. Children up to 7 years of age appear to derive the greatest benefit from a cochlear implant for the development of speech.[29,59] Because of an increased risk for bacterial meningitis, it is recommended that physicians monitor all patients with cochlear implants, particularly children whose implants have a positioner,[8,51] for middle ear and other infections. *Streptococcus pneumoniae* is the most common pathogen causing meningitis in cochlear implant recipients.[51] All children with cochlear implants should be vaccinated according to the American Academy of Pediatrics high-risk schedule.

Continued Surveillance

The Joint Committee on Infant Hearing 2007 has recommendations for ongoing surveillance in the medical home for all infants with and without risk factors for HL.[3] Regular surveillance of developmental milestones, auditory skills, parental concerns, and middle ear status should be performed in the medical home, consistent with the American Academy of Pediatrics periodicity schedule.[3] All infants should have an objective standardized screen of global development with a validated screening tool at 9, 18, and 24-30 months of age or at any time if the health care professional or family has concern.[3] Language screens that can be used in the primary care setting include the Early Language Milestone Scale,[18] the MacArthur Communicative Development Inventory,[26] the Language Development Survey,[52] and Ages and Stages.[10]

Infants who do not pass the speech-language portion of a global screening or for whom there is a concern regarding hearing or language should be referred for speech-language evaluation and audiology assessment. This recommendation

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

was implemented because of the known increase in the number of children identified with HL between the newborn screen and school age. This is related to three factors: (1) mild HL is missed with newborn screening tools, (2) some children experience delayed-onset or progressive HL such as that associated with cytomegalovirus, and (3) some children experience late-onset HL secondary to trauma or chemotherapy. Infants with OME may have transient HL and associated language delays.

Further management and evaluation of hearing skills and HL have been outlined by Cunningham et al. in an AAP Clinical Report. In addition to risk factors for hearing loss, it specifically addresses the need for continued surveillance of speech and language milestones in the first 36 months of life.[19]

Stress and Impact on the Family

Parents perceive varying degrees of stress when they are informed that their infant has failed a newborn hearing screen. Although the screen result may be either a false-positive or a true fail, most parents will have some increase in worry until their infant is rescreened. Neonatal intensive care infants have higher false-positive rates and higher fail rates than well-baby nursery infants. In one study of well-baby nursery infants, parents reported increased "worry" at 2-8 weeks of age when they returned for the rescreen.[68] Mothers who were more informed about hearing screening experienced decreased worry. Physicians who understand the screening process can support the family whose infant fails the screen, encourage the family to return for the rescreen, and follow up with the family about the rescreen results. A second study reported that mothers of infants with a false-positive screen did not report increased levels of stress or impact at 12-16 months or at 18-24 months.[67] In addition, greater family resources were protective against persistent stress, whereas NICU stay contributed to prolonged stress.[67]

There is a continuum of increasing stress for families whose infants are identified with HL that increases as they progress through the hearing screen fail, rescreen fail, diagnostic fail, and intervention process.[61] Perception of stress at the time of diagnosis varies significantly among parents. Parents who are culturally deaf may have anticipated the diagnosis and be totally comfortable with it. Hearing parents of children diagnosed with an HL perceive greater stress, which is, in part, related to the fear of disability.[49,50,67] About 95% of children with congenital HL are born to hearing parents. Prompt sharing of diagnostic test results with the family and physician and referral to early intervention services by the audiologist on the day of diagnosis may provide needed information and support to parents to mediate stress.

If the physicians become aware of financial difficulties experienced by the family, the case manager from Part C Early Intervention should be alerted to assist the family to identify resources such as a hearing aid loaner program, Social Security benefit, Katie Beckett Program, or eligibility for Medicaid. The physician may also facilitate referrals to parent support groups such as Hands and Voices and Family Voices. Because half of the children identified with congenital HL had been in a NICU and because about 40% of children with permanent HL have other disabilities, these children may require the resources of a number of different medical and educational disciplines, adding to both the financial and emotional burden.[39,43]

In summary, infants born in 2017 with congenital HL who have early identification, amplification, and intervention have enhanced opportunities for successful communication and academic achievement.

Key Points

- Neonates requiring care in the NICU are at increased risk of auditory neuropathy and should always be screened with AABR.
- Hearing loss is found in association with genetic mutations, over 400 congenital syndromes, and medical risk factors such as extreme prematurity and CMV infection.
- Undetected hearing loss in infants and children negatively affects communication development, academic achievement, literacy, and social–emotional development.
- Early amplification and increased daily use of hearing aids are associated with improved speech and developmental outcomes.
- Provision of early intervention services no later than 6 months of age is associated with improved speech and American Sign Language communication skills.
- Newborn hearing screening does not identify all hearing loss, and ongoing surveillance of hearing skills and language skills in the medical home to identify progressive and late onset hearing loss is indicated.

Early Childhood Neurodevelopmental Outcomes of High-Risk Neonates

DEANNE E. WILSON-COSTELLO AND ALLISON H. PAYNE

Advances in obstetric and neonatal care, which have been responsible for the improved survival of high-risk neonates, have not resulted in decreased morbidity. Since perinatal interventions can alter later growth and development, long-term follow-up is essential to ensure therapies such as oxygen administration and postnatal steroids, which demonstrate dramatic and immediate positive effects, are not associated with adverse long-term outcomes. The earliest follow-up studies of preterm infants after the introduction of modern methods of neonatal intensive care in the 1960s described a decrease in adverse neurodevelopmental sequelae compared with that of the preceding era. During the 1980s and 1990s, there was a continued decrease in mortality, and thus the absolute number of both healthy and neurologically impaired survivors increased.[29] Furthermore, the survival of increasing numbers of extremely immature infants with low birth weight resulted in a relatively high disability rate in the subpopulation of infants born weighing less than 750 g or born at less than 26 weeks' gestation.[121] Since 2000, mortality rates for infants with very low birth weight have leveled off. Several studies suggest declining rates of major neurodevelopmental impairment, including cerebral palsy.[113] As the initial survivors of neonatal intensive care have reached young adulthood, a myriad of more subtle neurodevelopmental issues such as visuomotor problems, learning disabilities, autism, or developmental coordination disability have flooded the literature. Additionally, the survival of increasingly immature infants along with improvements in managed care systems have resulted in early discharge of infants with unresolved medical or surgical issues such as oxygen dependence, need for assisted ventilation, maintenance of external medical devices, or dependence on gastrostomy feeds.

Infants at highest risk for later neurodevelopmental problems resulting from perinatal sequelae include those who had severe asphyxia, severe intracranial hemorrhage, infarction or periventricular leukomalacia, meningitis, seizures, respiratory failure resulting from pneumonia, persistent fetal circulation, or bronchopulmonary dysplasia, and multisystem congenital malformations, as well as children born with extremely low birth weight or at extremely early gestational age (Boxes 60.1 and 60.2). The rates of health problems and neurodevelopmental sequelae are inversely proportional to both birth weight and gestational age (Fig. 60.1 and Table 60.1).

Although most survivors of prematurity are not significantly impaired, there are a variety of medical and neurodevelopmental sequelae that necessitate scrutiny. Therefore, follow-up programs should be an integral extension of every neonatal intensive care unit. The goals of effective follow-up programs include early identification of neurosensory or developmental disability, parental counseling, identification and treatment of medical complications, identification of risk factors for impairment, evaluation of the impact of therapeutic interventions, and provision of feedback for perinatal and pediatric caregivers. In particular, specialized follow-up care must consider problems of growth, development, behavior, and chronic disease. If possible, follow-up care should initially involve the coordinated and complementary effort of the neonatologist and the primary care pediatrician. If there are concerns for developmental or neurologic problems, the child should also be referred to a subspecialist or a child development center.

The initial continuity of care by the neonatologist is important to reassure the family that the same personnel responsible for the life-saving decisions are continuing to assume responsibility for the child's adaptation into home life. Neonatal care providers also benefit from involvement in follow-up care by maintaining contact with infants leaving the nursery and observing the long-term consequences of prematurity and neonatal morbidities. Growth (weight, height, and head circumference), neurologic development, psychomotor and cognitive development, vision, and hearing all should be longitudinally assessed within follow-up. Transitioning care of these infants to the general pediatrician gradually may greatly benefit the patient, the family, and the pediatrician as trust and familiarity are developed.

In planning neonatal follow-up programs, various models of care are possible but may be constrained by

Abstract

Improved survival of extremely preterm infants has not resulted in decreased morbidity. As the total number of survivors at risk for neurodevelopmental problems increases, the need for better understanding of the long-term medical and neurodevelopmental issues that confront these children also grows. Medical complications, including chronic lung disease, poor growth, neurologic sequelae, feeding issues, and sensory deficits, require ongoing interventions, such as home oxygen administration, apnea monitoring, high-caloric-density formulas, and physical and occupational therapy. These survivors are at risk for a variety of cognitive, motor, psychiatric and behavioral problems. High-risk neonates have increased likelihood of school-age learning disability, special education, lower IQ, and decreased productivity in adulthood. This chapter will evaluate risk factors, medical complications, neurodevelopmental assessments, neurodevelopmental problems, and long-term outcomes of high-risk neonates.

available resources.[59] A minimal requirement for the clinical monitoring of outcomes is a periodic assessment of growth and neurosensory development during the first 2 years of life. The ideal is a comprehensive program involving all aspects of care, including well-baby care, evaluation of outcome, social and educational intervention, and therapy when needed. A home nurse visiting program, especially during the early postdischarge period, and parent support groups for selected high-risk conditions (e.g., children with chronic lung disease) also should be considered. There is evidence that educational enrichment during infancy and early childhood might improve the early childhood outcome of high-risk and preterm infants, especially those from socioeconomically deprived groups. The lack of hypothesis-driven

• BOX 60.1 Factors Affecting Outcome of the Infant With Very Low Birth Weight

- Birth weight less than 750 g or less than 25 weeks' gestation
- Periventricular hemorrhage (grades III and IV) or infarction
- Periventricular leukomalacia
- Persistent ventricular dilation
- Neonatal seizures
- Chronic lung disease
- Neonatal meningitis
- Subnormal head circumference at discharge
- Parental drug abuse
- Poverty and parental deprivation
- Coexisting congenital malformation

• BOX 60.2 Factors Affecting Outcome of the Term Infant

- Birth depression or asphyxia
- Persistent pulmonary hypertension
- Meningitis
- Intrauterine growth failure
- Intrauterine infection
- Symmetric growth restriction (microcephaly)
- Major congenital malformations
- Neonatal seizures
- Extracorporeal membrane oxygenation (ECMO) and nitric oxide therapy
- Persistent hypoglycemia
- Severe hyperbilirubinemia

• **Fig. 60.1** Percentage of 8-year-old children born very preterm between 24 and 32 weeks' gestation from 1997-1998 with major impairments. (Data from Marret S, et al. Brain injury in very preterm children and neurosensory and cognitive disabilities during childhood: the EPIPAGE cohort study. *PLoS ONE* 8 (5): e62683. doi:10.1371/journal.pone.0062683.)

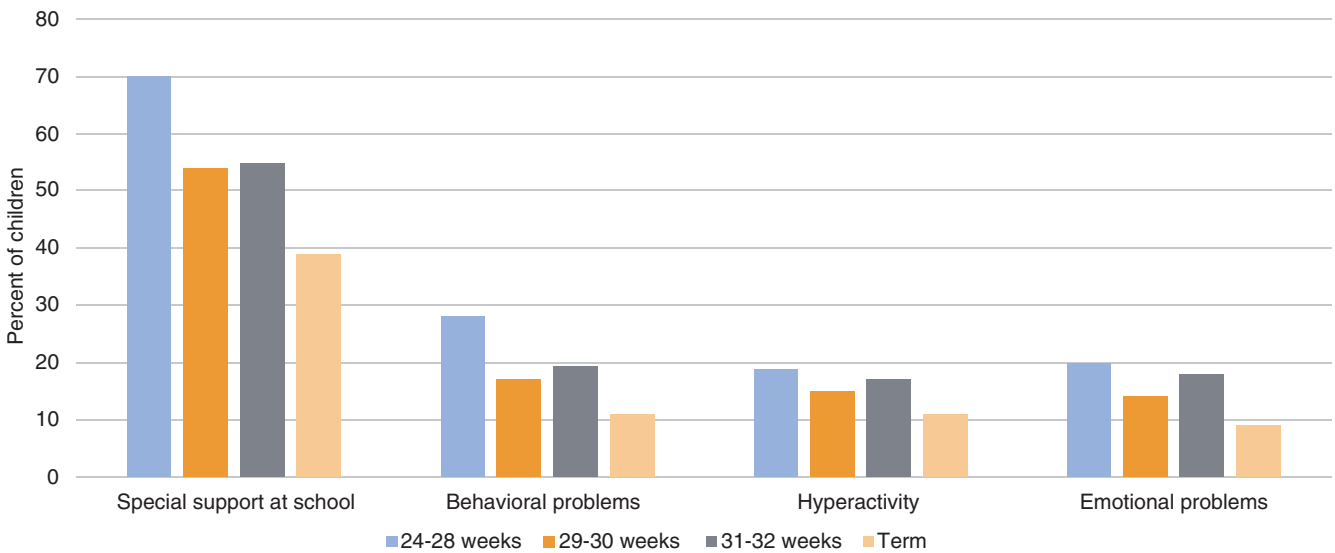
trials of early developmental intervention has resulted in little evidence of sustained improvement in school-age neurodevelopmental outcomes.[81]

Outcomes from different centers are heavily influenced by the demographic and socioeconomic profile of the parents, the regional incidence of extreme prematurity, the percentage of inborn patients at a given center, a selective treatment or admission policy, site-specific practice patterns, and the rate of follow-up. Intercenter differences in neonatal sequelae and outcome are well described.[116] Regional results, rather than national or international cohort data, may therefore reflect a more accurate picture of outcome, because they include all infants born in an area. This is the ideal situation, but such studies are rarely available in the United States. Individual centers should be aware of their own patients' social risk factors and rates of neonatal morbidity and, if possible, maintain their own follow-up outcome data.

TABLE 60.1 Health Outcomes by Birth Weight at 8 Years

	Birth Weight (kg)			
	<1	1-1.49	1.5-2.49	≥2.5
Asthma (%)	17	18	12	11
Rehospitalization, previous year (%)	7	7	5	2
Limitation of >1 activity of daily living because of health (%)	46	34	27	17



Data from Hack M, et al. Long-term developmental outcomes of low birth weight infants. *Future Child.* 1995;5:176.

Any evaluation of the outcome studies of high-risk infants must include the population status (inborn, outborn, or regional) and the choice of a comparison group that includes either a normal birth weight group or infants within a similar birth weight or gestational age range who do not have the condition or therapy under study. It also is essential to control for sociodemographic factors, such as maternal marital status, ethnicity, and education, and to consider possible genetic factors when evaluating cognitive outcome or school performance.[67]

Consideration of neonatal mortality is important for judging the aggressiveness and level of neonatal care, which might influence the quality of outcome of the survivors. Other factors to be considered are the rate of loss of infants to follow-up, the neonatal and postdischarge death rate, the age at follow-up, and the method of follow-up. Two years is the earliest age to get a fairly reliable assessment of neurodevelopmental outcome. At age 4-5 years, cognitive function and language can be better measured, and follow-up at age 7-9 years allows an assessment of subtle neurologic and behavioral dysfunction and school academic performance (Fig. 60.2).[44,89,109]

Because it is impossible to provide ongoing high-risk follow-up care for all infants treated in the neonatal intensive care unit, specific criteria have been proposed to identify children at greatest risk for sequelae.[72] Traditionally, follow-up programs primarily targeted children with birth weight of less than 1500 g or gestational age of less than 32 weeks. However, therapies such as inhaled nitric oxide and extracorporeal membrane oxygenation have increased the demand for highly specialized follow-up clinics for term infants with persistent pulmonary hypertension, meconium aspiration, and sepsis.

In addition, a growing number of infants with major congenital malformations such as congenital diaphragmatic

• **Fig. 60.2** Rates of school problems among 8-year-old very preterm versus term-born children. (Data from Larroque B, et al. Special care and school difficulties in 8-year-old very preterm children: the EPIPAGE cohort study. *PLoS One.* 2011;6(7):e21361.)

• BOX 60.3 Suggested Criteria for Severe Disability at Age 2 Years

Malformation
- Impairs the performance of daily activities

Neuromotor Function
- Unable to sit
- Unable to use hands to feed
- Unable to control head movement (or no head control)

Seizures
- More than 1 per month despite treatment

Auditory Function
- Hearing impaired despite aids

Communication
- Unable to comprehend
- Unable to produce more than five recognizable sounds

Visual Function
- Blind or sees light only

Cognitive Function
- About 12 months behind at 2 years

Other Physical Disability

Respiratory
- Requires continual oxygen therapy
- Requires mechanical ventilation

Gastrointestinal Function
- Requires tube feeding
- Requires parenteral nutrition

Renal Function
- Requires dialysis

Growth
- Height or weight more than 3 standard deviations below mean for age

From Johnson A. Follow up studies: a case for a standard minimum data set. *Arch Dis Child.* 1997;76:F61.

hernia now survive the neonatal period to require intensive ongoing follow-up support. Centers with active research components could select additional candidates for follow-up in the high-risk clinic on the basis of participation in specific research studies. Because of the significant costs associated with evaluating all eligible follow-up patients in the clinic setting, parent and teacher questionnaires have been suggested. These questionnaires typically provide a checklist of various individual measures of health status and disability (Box 60.3).[53]

Medical Problems

A variety of common problems of prematurity often continue after NICU discharge. Following birth, hemoglobin concentrations decrease more severely among premature infants, necessitating the subsequent monitoring of hemoglobin levels and reticulocyte counts, which typically rise by 3-6 months age. One hospital-based study suggests that the liberal use of blood transfusions may improve neurologic outcomes and decrease apnea.[11,125] Apnea of prematurity, resulting from immature regulation of breathing, obstruction due to immature airway reflexes, or delayed coordination of sucking, swallowing, and breathing, may recur in preterm infants who develop upper respiratory infection or receive general anesthesia for surgical procedures such as inguinal hernia repair. In these cases, the use of caffeine in conjunction with cardiorespiratory monitoring may be considered.[46,125] For infants discharged on caffeine and home monitoring, the medication may be either weaned or discontinued abruptly; however, monitoring should continue for at least 1-2 weeks following the withdrawal of medication. The AAP suggests that home monitoring for apnea of prematurity may be stopped by 43 weeks' postmenstrual age; however, others have recommended discontinuation at 45 weeks for the most immature infants.[1,108]

Neonatal medical complications include chronic lung disease, intraventricular hemorrhage, retinopathy of prematurity, hearing loss, increased susceptibility to infections, and sequelae of necrotizing enterocolitis. These in turn can contribute to multiple rehospitalizations after discharge, poor physical growth, and an increase in postneonatal deaths. Children with neurologic sequelae such as cerebral palsy and hydrocephalus have a higher rate of rehospitalization for conditions such as shunt complications, orthopedic correction of spasticity, and eye surgery. Furthermore, a high percentage of children with chronic lung disease, extreme prematurity, or both, require rehospitalization during their first year. Comprehensive reviews on the prevention and treatment of bronchopulmonary dysplasia emphasize changing epidemiology and risk factors for bronchopulmonary dysplasia.[8,123] The survival of extremely immature infants has resulted in a large number of infants requiring oxygen past 28 days of life with the preferred definition of bronchopulmonary dysplasia being oxygen requirement at 36 weeks' postconceptual age. These children may require home oxygen and other medications such as diuretics or bronchodilators after discharge. Infants on home oxygen require intermittent pulse oximetry monitoring, as they are at risk for cardiopulmonary complications such as cor pulmonale. Those receiving diuretics require periodic evaluation of their electrolyte status. Drugs such as furosemide, which increase urinary calcium excretion, may need to be discontinued or replaced with diuretics such as aldactone or chlorothiazide if nephrocalcinosis develops. With increased work of breathing, infants with chronic lung disease may require fortification to more than 120-150 kcal/kg/day for weight gain, as well as fluid restriction. Immunoglobulin therapy to prevent respiratory syncytial virus infection is recommended for infants less than 32 weeks with bronchopulmonary dysplasia. Since they are prone to recurrent respiratory infections, poor nutrition, and growth failure

related to chronic lung disease, they require multispecialty follow-up, including neonatal, developmental, nutrition, and pulmonary specialists. The medical complications of bronchopulmonary dysplasia tend to become less prominent after the second year of life, although airway reactivity and asthma may persist.

Central nervous system complications such as posthemorrhagic hydrocephalus, periventricular leukomalacia (PVL), and porencephaly, which typically appear prior to discharge, place affected infants at greatest risk for ongoing neurodevelopmental problems.[18] Although infants with grades III and IV periventricular hemorrhage are at greatest risk for these complications, ELBW infants with grade I subependymal or grade II intraventricular hemorrhage may also have neurodevelopmental problems.[85,117] Infants with ventriculoperitoneal shunts are at risk for shunt malfunction due to occlusion of the cannula, with subsequent increase in intracranial pressure or shunt infection, which may present as lethargy, irritability, apnea, vomiting, seizures, or increasing head circumference. Infants with intracranial shunts require ongoing surveillance of head circumference for rapid or slow growth. Improved detection of cerebellar hemorrhage in extremely premature infants has demonstrated its significant association with cognitive and motor impairment.[126] MRI evaluations of very preterm infants at term have detected more subtle periventricular leukomalacia caused by ischemic white matter damage or abnormalities of the corpus callosum, increasing the risk of cerebral palsy.[4] Because of the improved predictability of neurodevelopmental outcomes with MRI, many centers use MRI scans at term to assist in parental counseling and follow-up of very preterm infants.[96]

Physical Growth

Intrauterine or neonatal growth restriction, or both, occurs commonly in preterm infants. The poor neonatal growth is related to inadequate nutrition during the acute phase of neonatal disease, feeding intolerance, and chronic medical sequelae that result in increased calorie requirements. These include chronic lung disease, recurrent infections, and malabsorption secondary to necrotizing enterocolitis. The use of postnatal steroids may also contribute to growth failure. A multicenter prospective study of ELBW infants suggests that neonatal growth influences subsequent neurodevelopment and growth outcomes.[30] Prolonged intubation and repetitive insertion of nasogastric tubes can lead to aversions in oral feeding. Additionally, incoordination in suck, swallow, and breathing patterns accompanied by a hyperactive gag reflex may cause apnea and aspiration in preterm infants and parental anxiety. Since most preterm infants require 110-130 kcal/kg/day, fortification or supplementation of feeds is essential. Catch-up growth may occur later in infancy and childhood until ages 2-3 years. While some SGA infants show a rapid increase in weight gain after discharge, many continue to have poor catch-up growth. Poor feeding in chronically ill or neurologically impaired children may also affect neonatal growth. The parents' size contributes to the eventual growth outcome.

Assessment of head growth is an essential element of preterm follow-up. The largest frontal-to-occipital diameter is used to determine head circumference, which typically increases by 0.7 cm/week. Increases of more than 1.2 cm/week may suggest ventricular dilatation. By 12-18 months, the rate of head growth decreases significantly. Intrauterine and neonatal brain growth failure and lack of later brain catch-up growth can affect cognitive functioning and correlates with MRI imaging findings.[9,21] Any infants with very low birth weight who are small for gestational age also have subnormal head growth, and brain growth failure can occur during the neonatal period. Catch-up brain growth can occur during infancy in infants with very low birth weight who are either appropriate or small for gestational age; however, as many as 10% of infants with very low birth weight who are appropriate for gestational age and 25% who are small for gestational age still have a subnormal head size at 2-3 years of age that persists at school age. Poor growth attainment is especially apparent in the child with an extremely low birth weight or gestational age and typically begins in the NICU.

Growth after discharge is a good measure of physical, neurologic, and environmental well-being. Premature infants typically require 110-130 kcal/kg/day to maintain growth. However, infants at high risk for postnatal growth failure, including those with severe bronchopulmonary dysplasia and increased work of breathing, infants with short bowel syndrome predisposed to dumping or receiving home parenteral nutrition, those with congenital heart disease on diuretics, and others with major malformations or inborn errors of metabolism may require more calories to sustain growth. To promote optimal catch-up growth of high-risk infants, neonatal nutrition must be maximized. This is especially important because catch-up of head circumference occurs only during the first 6-12 months after the expected date of delivery. Increased-calorie postdischarge formulas have been introduced to support higher caloric and mineral delivery. These formulas have been associated with improved growth to 9 months. Reports of osteopenia or rickets of prematurity associated with breast milk have increased with the improved survival of extremely premature infants whose birth precedes the period of greatest in utero mineral accretion. Despite the increased risk of osteopenia, early childhood neurodevelopmental outcomes are improved by breastmilk.[114] Although rickets of prematurity appears to be a self-resolving disease, postdischarge formulas with higher calcium and phosphorus content have enhanced growth and bone mineral accretion among preterm infants. However, it is important to balance appropriate catch-up growth and mineral supplementation with an avoidance of excessive rates of growth, which are concerning for promotion of later metabolic syndrome and obesity. Emerging data raises questions about the relationship between early catch-up growth and increased risk of obesity, cardiac disease, and hypertension in adulthood.[27,66]

Neurodevelopmental Outcome

Transient Neurologic Problems

A high incidence of transient neurologic abnormalities, ranging from 20%-40%, occurs in high-risk infants, with a peak incidence of transient dystonia occurring at 7 months' corrected age.[16] Transient abnormalities of muscle tone such as hypertonia or hypotonia (occurring as poor head control at 40 weeks' postconceptional age), poor back support at 4-8 months, or a slight increase in muscle tone of the upper extremities are associated with increased risk of later cognitive and motor problems. Because some degree of physiologic hypertonia normally exists during the first 3 months, it may be difficult to diagnose the early developing spasticity related to cerebral palsy.

Children who will later develop cerebral palsy often initially have hypotonia (poor head control and back support) and only later develop spasticity of the extremities. Spasticity during the first 3-4 months is, however, a poor prognostic sign. Persistence of primitive reflexes also might be a sign of early cerebral palsy. Although mild hypotonia or hypertonia persisting at 8 months usually resolves by the second year, it might indicate later subtle neurologic dysfunction.[45]

Major Neurologic Sequelae

Major neurologic sequelae can usually be diagnosed during the latter part of the first year of life or even earlier if they are very severe. Major neurologic disability is usually classified as cerebral palsy (spastic diplegia, spastic quadriplegia, or spastic hemiplegia or paresis), hydrocephalus (with or without accompanying cerebral palsy or sensory deficits), blindness (usually caused by retinopathy of prematurity), seizures, or deafness (Box 60.4). The intellectual outcome can differ greatly according to neurologic diagnosis. For example, children with spastic quadriplegia usually have severe developmental delay, whereas children with spastic diplegia or hemiplegia may have better mental functioning. Cognitive function is not easily measurable until after 2-3 years of age, especially among neurologically impaired children.

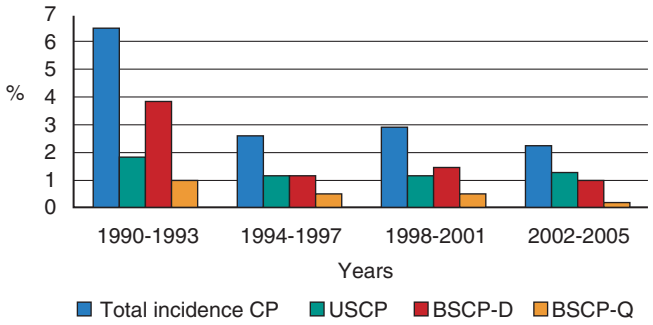
• BOX 60.4 Types of Neurologic Dysfunction in Children Who Were High-Risk Neonates

- Motor deficits
- Spastic diplegia
- Spastic quadriplegia
- Spastic hemiplegia
- Mental retardation
- Seizures
- Hearing deficits
- Visual abnormalities
- Eye motility dysfunction
- Posthemorrhagic hydrocephalus
- Visuomotor deficits
- Learning deficits
- Subtle neurologic dysfunction
- Hyperactivity
- Poor attention

Most neurologic problems either resolve or become permanent during the second year of life. During the second year, the environmental effects of maternal education and social class begin to play a major role in the various cognitive outcome measures. Further problems could emerge during the school-age years. These include subtle motor, visual, and behavioral difficulties even among children with normal intelligence. These are best diagnosed and treated in a psychological and educational, rather than a medical, follow-up setting.

Cerebral palsy, an umbrella term that refers to "a group of non-progressive, but often changing, motor impairment syndromes secondary to lesions of the developing brain," occurs about 70 times more frequently among infants with extremely low birth weight than among controls with normal birth weight. Risk factors include periventricular echolucencies noted on cranial ultrasound, intrauterine and neonatal infection, hypotension, severe respiratory distress, hypothyroxinemia, postnatal corticosteroid exposure, and multiple gestation.[39,98,102] Despite these identified factors, most cerebral palsy cases, especially among term infants, do not have a readily identifiable cause. Protective factors could include maternal antenatal corticosteroid therapy, preeclampsia, and antenatal magnesium sulfate.[24,69] Although birth asphyxia has been identified as a frequent cause of cerebral palsy among term infants, low Apgar scores have correlated poorly with cerebral palsy for preterm infants.

Epidemiologic studies of cerebral palsy rates have been hampered by disagreement over both the specific diagnostic criteria used and the age at which a diagnosis should be made. Furthermore, studies differ on their estimates of the prevalence of cerebral palsy depending on the denominator used for calculation. For example, assessments may be reported relative to the number of live births, the number of NICU admissions, or the number of survivors evaluated. The risk of developing CP is higher in infants of lower gestational age. Typically, term infants have a risk of 1 per 1000 births, versus rates of 10 per 1000 for infants between 32 and 36 weeks' gestation and 100 per 1000 for those born at extremely low gestational ages.[82]



Most of the cases of cerebral palsy among preterm children pertain to children with spasticity rather than to the athetotic or dyskinetic types of cerebral palsy. These include the subtypes with bilateral (diplegia, quadriplegia) or unilateral (hemiplegia) spasticity. Diplegia and hemiplegia are the most common types of cerebral palsy seen in preterm children. Spastic cerebral palsy accounts for approximately 85% of all cases and greater than 90% of preterm CP cases. The neurologic symptoms of spastic CP include increased tone with velocity-dependent increased resistance to passive movement; pathologic reflexes such as hyperreflexia or pyramidal signs like the Babinski response; and abnormal

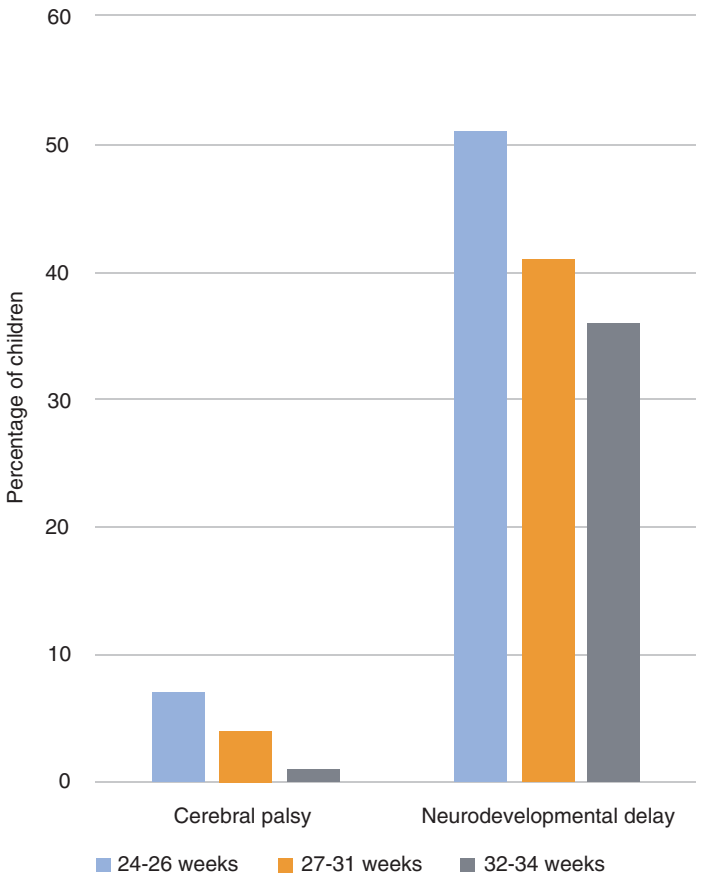
patterns of movement and posture characterized in the lower limbs by equines foot, crouch gait, internal rotation, and hip adduction. In the upper limbs, the typical posture is arm flexion with fisted hands, adducted thumbs, and poorly coordinated finger movements. Symptoms of bilateral spastic cerebral palsy include motor deficit with contractures impairing normal gait, cognitive problems (which are seen less often in preterm than term children), visual problems such as blindness or strabismus, and epilepsy in the most severe cases.

Children with global hypotonia are usually not included in the diagnosis of cerebral palsy. Cerebral palsy was previously defined as mild, with no loss of function and independent walking; moderate, with functional disabilities requiring assistance for walking with aids or walkers; and severe, nonambulatory, requiring a wheelchair. Cerebral palsy was alternatively labeled *disabling* or *nondisabling* to incorporate a crude measure of functional impairment. With the exception of these descriptive terms, there was no reliable measure of the severity of motor disability or consideration of other cognitive or neurosensory problems associated with cerebral palsy. In 2004, an international workshop on the definition and classification of cerebral palsy proposed inclusion not only of motor disorders but also of other associated deficits that may coexist, including seizures and cognitive, perceptual, sensory (visual and hearing), and behavioral impairments.[10] The 2004 classification also includes anatomic and radiologic findings and causation and timing of the lesion. This new system has enhanced the evaluation of functional outcomes for children with cerebral palsy.[60] In the future, its use should also improve studies of trends in the rates of cerebral palsy and its correlates.

The diagnosis of cerebral palsy is usually delayed until motor development has been established. The minimal age before a definitive diagnosis can be made should be at least 3 years and preferably 5 years of age. This is because in some cases the neurologic findings may decrease or disappear by 5 years of age, and in other mild cases, the findings may only become apparent later.[7,84,102] The longest study of trends in the rates of cerebral palsy has been that of Hagberg and colleagues. They monitored the rates in western Sweden in a series of nine reports from 1954 until 1998.[47] During the 1950s, very few of the children with cerebral palsy in the western Swedish register were born before 28 weeks' gestation, whereas by 1995-1998, 20%-25% of these children were born at this extremely low gestation, evidence of the increase in survival of these infants. Survival increased progressively during the periods of study. Overall, the prevalence of cerebral palsy among preterm infants decreased between the periods 1954-1958 and 1967-1970, partly owing to discontinuation of various iatrogenic therapies such as prolonged starvation and discontinuation of limitation of oxygen thought to cause retinopathy of prematurity. After the introduction of methods of neonatal intensive care and the increase in survival of infants of extremely low birth weight and gestation, the rates of cerebral palsy increased

• **Fig. 60.3** Cerebral palsy (CP) incidence and type from 1990-2005. BSCP-D, Bilateral spastic CP-D (diplegia); BSCP-Q, bilateral spastic CP-Q (quadriplegia); USCP, unilateral spastic CP. (Data from van Haastert IC, Groenendaal F, Uiterwaal CS, et al. Decreasing incidence and severity of cerebral palsy in prematurely born children. *J Pediatr.* 2011;159(1):86-91.e1.)



from 1987-1990, with an increase in cases with severe multiple handicaps. Similar trends were noted by others. The prevalence then decreased significantly from 1995-1998. Data continue to show encouraging trends with decreasing incidence and severity of cerebral palsy in prematurely born children (Fig. 60.3).[113]

In contrast to these optimistic reports, population-based studies from France (EPIPAGE and EPIPAGE-2) showed that survival without moderate to severe disability increased for infants born at 25-26 weeks' gestation (46% vs 62%) and for those born at 27-31 weeks' gestation (82% vs 90%); however, there was no difference in survival without major disability for infants born earlier than 24 weeks' gestation (29% vs 26%).[3] The EPIPAGE follow-up studies continue to demonstrate declining rates of cerebral palsy and neurodevelopmental delays with advancing gestational age (Fig. 60.4).[86] In a population-based study from the United Kingdom (EPICure study) of infants born less than 26 weeks, survival improved from 39% in the 1990s to 52% in 2006. At 3 years, there was a higher proportion of survivors without disability (6%-16%); however, there was no change in the proportion of survivors with severe disability (18% vs 19%).[74]

The advent of modern neuroimaging techniques such as magnetic resonance imaging (MRI) offers improved potential to comprehensively visualize brain lesions associated with cerebral palsy. Cranial ultrasound was judged as normal in 35% of children with cerebral palsy in the entire EPIPAGE study of all preterm children born below 33 weeks' gestation. In systematic review of MRI studies in children with cerebral palsy, roughly 90% of preterm-born children had cerebral abnormalities, most commonly periventricular white matter lesions (see Chapter 52).[112]

Isolated motor disorders, such as developmental coordination disorder (DCD), which affect approximately one-third of preterm children, are more common than cerebral palsy. By definition, these children have no neurosensory impairment and demonstrate intact cognitive function. They display a variety of fine and gross motor delays

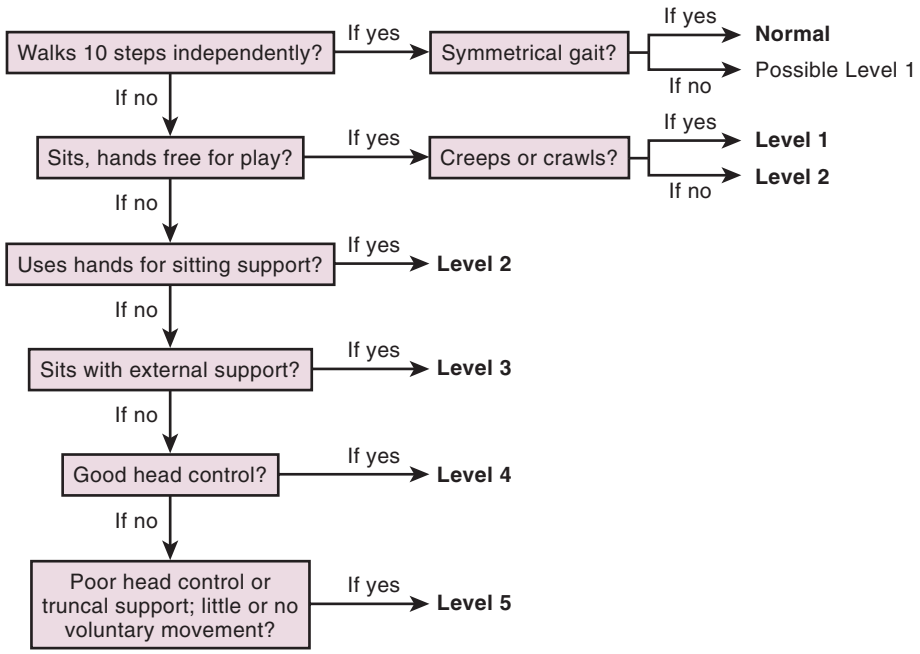
• **Fig. 60.4** Rates of cerebral palsy and neurodevelopmental delay at 2 years by gestation. (Data from Pierrat V, et al. Neurodevelopmental outcome at 2 years for preterm children born at 22-34 weeks gestation in France in 2011: EPIPAGE-2 cohort study. *BMJ.* 2017;358:j3448.)

resulting in difficulties with common motor tasks, such as manipulating pencils or silverware, pedaling a bicycle, or performing routine motor tasks of daily living.[118] Associations have been made between these "minor" motor disorders and cognition, behavior, and overall decreased function at school age.[33]



Assessment of Functional Outcomes

One of the most widely used tools to classify gross motor function for children with cerebral palsy is the Gross Motor Function Classification System (GMFCS) introduced by Palisano.[83] This tool defines motor function according to self-initiated movement with emphasis on sitting, walking, and mobility using a five-level classification system in which criteria meaningful to daily living distinguish the levels. Distinctions are based on functional limitations; the need for hand-held mobility devices such as walkers, crutches, or wheeled mobility; and, to a much lesser extent, quality of movement. Because classification of motor function is dependent on age, separate descriptions are applied over a variety of age ranges. The focus of GMFCS is on determining which level best represents the child's present abilities and limitations. Emphasis is placed on usual performance in home, school, and community settings rather than on what the children can do as their best capability. An example of the classification system used for toddlers is presented in Fig. 60.5.

Other measures used in examining functional outcomes include limitations in activities of daily living, such as difficulty feeding, dressing, and toileting, as well as the inability to play or communicate with other children. Instruments for measuring functional status include the Functional Independence Measure for Children,[77] the Vineland Adaptive Behavior Scale,[99] and the Battelle.[78] Most of these functional assessments are applicable only after 2 years of age.

The functional measures of outcome that focus on the consequences of the various diverse medical, behavioral, and cognitive disorders resulting from prematurity are more suited for planning services for children with special health care needs. Additional measures that can be used include the assessment of the overall health status of the child, the Child Health and Illness Profile, and the QUICCC (Questionnaire for Identifying Children with Chronic Conditions), and measures of the quality of life of the child.[61,91,103,104] Children with a birth weight of less than 750 g or gestational age younger than 26 weeks have higher rates of functional limitations, greater compensatory dependence, and an increased need for services compared with those with a birth weight of greater than 750 g.[43] Data

• **Fig. 60.5** Gross motor function classification system for toddlers. (Data from Palisano RJ, et al. Development and reliability of a system to classify gross motor function in children with cerebral palsy. *Dev Med Child Neurol.* 1997;39:214.)

from Europe indicate that increased survival of infants with a birth weight of less than or equal to 750 g coincided with slightly greater impaired neurodevelopmental outcome at 2 years of age. Small-for-gestational-age infants are especially at risk. With the exception of a few children (3%-5%) with severe disability, the major needs for services are those related to special education for the various academic learning and behavioral problems in school. Although reports by Saigal and associates and others note an acceptable quality of life for most adolescents and young adults who were born preterm, even for those with disability, educational and behavioral problems persist into adolescence and young adulthood.[14,91]

Timing of Follow-Up Visits

The initial follow-up visit should occur shortly after discharge from the neonatal nursery. This visit is important for evaluating how the child is adapting to the home environment. During the visit, accuracy of home medication and oxygen administration, formula preparation, and parental concerns are particularly important to address. The frequency of subsequent follow-up visits is determined by the severity of specific active medical and neurodevelopmental issues of the individual child, the intensity of follow-up, and the optimal age for developmental assessment. Multidisciplinary follow-up clinics have merged primary pediatric care with neurodevelopmental follow-up, creating a "medical home" for children with sequelae of prematurity. Such comprehensive clinics have been suggested to improve outcomes at reduced cost. A clinic visit at about 4-6 months of corrected age is important for documenting problems of inadequate catch-up growth and severe neurologic abnormality that might require intervention or occupational and physical therapy. Since many of the active medical issues have resolved, this visit offers the opportunity to direct families toward emerging developmental and behavioral issues. Eight to twelve months of corrected age is a good time to identify the suspicion or presence of cerebral palsy or other neurologic abnormality. It also is an excellent time for the first developmental assessment to be performed, usually the Bayley Scales of Infant Development, because the children show little stranger anxiety at this age and most are cooperative. Although behavioral patterns are becoming established, early cognitive skills are still very dependent on motor function.

By 18-24 months of age, most transient neurologic findings will have resolved, and the neurologically abnormal child will be showing some adaptation, with improving functional ability. Environmental factors exert increasing influences on functional assessment. Most potential catch-up growth will have occurred. At the same time, the cognitive and language scales of the Bayley Scales of Infant Development provide some assessment of the child's cognitive functioning independent of motor development. Evaluating performance at 2 years on the basis of corrected age rather than chronologic age is controversial but conventionally accepted. Since formal testing of development rather than intelligence is conducted, an underestimate of subtle problems may occur. Results of individual developmental testing may be readily compared with multicenter network data.

At 3 years, other measures of cognitive function can be performed that better validate the child's mental abilities.

Expressive and receptive language is well measurable at this age. Verbal and nonverbal skills can be readily differentiated. Measures of pre-academic readiness, visual-motor integration, executive function, and attention may be compared by standardized methods. The predictability of later intelligent quotient (IQ) scores on the basis of scores at this age is acceptable. From 4 years of age, more subtle neurologic, visuomotor, and behavioral difficulties are measurable. Neuropsychologic evaluation may identify problems with attention, learning, behavior, and socialization, which may affect school performance, even in children who have normal intelligence.[50]

Developmental and Neurologic Testing

The neurologic examination during infancy is largely based on changes in muscle tone that occur during the first year of life. The examination developed by Amiel-Tison measures the progressive increase in active muscle tone (head control, back support, sitting, standing, and walking) together with the concomitant decrease in passive muscle tone. This also documents visual and auditory responses and some primitive reflexes. This method gives a qualitative assessment of neurologic integrity, which is defined as normal, suspect, or abnormal. A conventional neurologic examination should be performed thereafter, together with the Amiel-Tison method for early childhood.[2] Under normal conditions, general movements triggered by the neonatal nervous system and generated by the central pattern generators located in the neonatal brainstem lend variability to motor output. Reduced modulation of the central pattern generators results in less variable movements and may indicate fetal or neonatal compromise. The Prechtl General Movement Assessment has demonstrated merit for identification of infants at risk for neuromotor deficits.[101] A systematic review suggests that General Movement Assessment of Infancy is the most sensitive and specific test available for early prediction of spastic cerebral palsy in high-risk infants.[15]

The Bayley Scales of Infant Development is the most commonly used tool for monitoring early cognitive and motor development for high-risk infants. During the past 25 years, longitudinal follow-up programs have used this assessment tool to evaluate early outcomes. It is also used clinically to identify infants who might benefit from interventional services. The scales were developed for children 1 month to 3 1/2 years of age. The first and second editions of the Bayley Scales were divided into three subtests or scales (mental, motor, and behavior) and provided a Mental Developmental Index (MDI) and Psychomotor Developmental Index (PDI) with a mean of 100 and a standard deviation of 15. The Mental Development Index and Psychomotor Development Index scores have long served as useful tools for neonatal outcomes research. The 1992 revision yielded lower scores than those described for children born during the 1980s and early 1990s and tested with the original Bayley Scales.

In 2006, the third edition of the Bayley Scales was introduced. A primary goal was to add additional scales that meet federal and state mandates requiring assessment of five development domains from birth through 3 years of age. As a result, the newest version contains five scales: cognitive, language, motor, social-emotional, and adaptive behavior, the latter two in the form of parent questionnaires. Thus, the third edition of the Bayley Scales does not generate a "mental developmental index" but rather separate cognitive and language scores. The adoption of Bayley III has resulted in controversy as scores are higher compared to prior editions.[6] Preliminary evaluations have suggested improved early cognitive outcomes for preterm infants using the third edition of the Bayley Scales. However, there is concern that this apparent "improvement" in early cognitive outcomes from the Bayley II and Bayley III era may reflect an underestimation of impairment on the Bayley III rather than a true improvement in outcome.[115] Bayley III includes at-risk toddlers in 10% of its normative sample. Furthermore, score differences between Bayley III and the previous editions are greatest at the lower end of the neurodevelopmental function scales, increasing concern for under-identification of neurodevelopmental impairment. As the subscales differ between the two versions and direct comparisons of Bayley II MDI and Bayley III cognitive or language scores are not feasible, conversion methods suggest the new cognitive score is 6-10 points higher than the MDI and the motor score is 8-14 points higher.[75] Similar trends have been reported with Bayley III use in full-term children, suggesting the need for term control groups in the evaluation of outcomes of NICU therapies.

It is not clear that infant tests measure the same constructs as intelligence tests that are administered to older children and adults. Infant tests are seen as a description of current functioning and thus are not predictive. Generally, infant tests have not been shown to have long-term validity, especially for some clinical subgroups. The poor prediction is considered to result from difficulties in infant testing, measurement error, changes in function of the child, and environmental influences that become more evident after 2 years of age. Several studies of children with extremely low birth weight have reported significantly lower rates of intellectual impairment at school age than during early childhood.[88]

The Ages and Stages Questionnaire may be used as a screening tool for children aged 3 months to 5 years to identify developmental delays.[17] The tool uses parents as the source of information about child development and has been successful in identifying cognitive and motor delays in the follow-up of premature infants and those with hypoxic ischemic encephalopathy.[63] However, it does not give a quantitative assessment and thus cannot be used to quantify outcome in specific high-risk populations. The Wechsler Scales may be used with prekindergarten and school-age children. The Wechsler Intelligence Scale for Children, third edition, is probably the most commonly used instrument for school-age assessment. The Kaufman Test was standardized

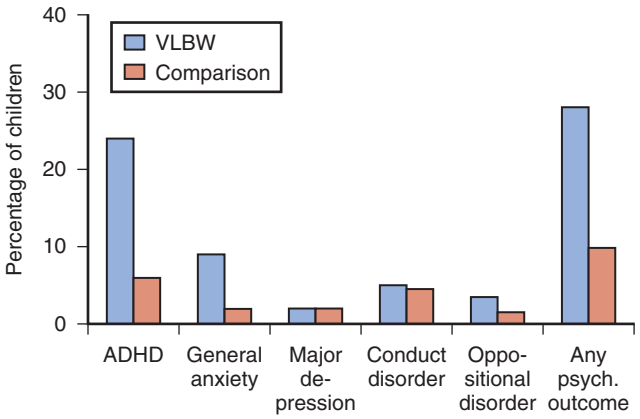
on a 2 1/2- to 10-year-old population and is less heavily weighted by verbal items than other tests. Other useful early school-age evaluations include the Behavior Rating Inventory of Executive Function (BRIEF), the Developmental Neuropsychological Assessment (NEPSY-II), the Attention Deficit Hyperactivity Rating Scales, and the Woodcock-Johnson III. Neurodevelopmental follow-up assessments used for surveillance, research, or both require serial evaluations because of rapid developmental changes and test-taking behavioral issues among young children.

Ophthalmologic testing should be performed in all high-risk children. AAP has published guidelines for screening of retinopathy of prematurity.[35] If the results are abnormal, repeat examinations should be done at the discretion of the ophthalmologist. Complete vascularization typically occurs by 44-48 weeks' corrected age. Serial examinations should continue until the neonatal retina is fully vascularized. Preterm children with a history of retinopathy should be screened for refractive abnormalities and amblyopia at 6 months' corrected age, 12 months' corrected age, 2-3 years, prior to beginning school, during grade school, and during adolescence when rapid ocular growth occurs (see Chapter 96 for specific examination timetables).

Hearing loss is more prevalent among NICU graduates than in the general population. Hearing should be screened before discharge from the neonatal intensive care nursery. Most hearing screening programs use the otoacoustic emissions test, in which a small earphone and microphone are inserted into the infant's ears. When sounds are played, a normally functioning ear will create an echo that can be picked up by the microphone. In a baby with hearing loss, no echo can be detected. Otoacoustic emissions can reliably detect hearing losses greater than 1500 Hz but only in the presence of outer hair cell dysfunction. Auditory brainstem response testing may be used for infants who fail the initial hearing screen. The auditory brainstem response test uses electrodes to detect brain waves. As sounds are played, the test measures the brain's response. The test can detect improper functioning in the inner ear, acoustic nerve, and auditory brainstem pathways associated with hearing. It can detect hearing sensitivity from 1000-8000 Hz (see Chapter 59). Hearing should be re-examined at 12-24 months, because hearing loss can appear later as a sequela of ototoxic drugs such as diuretics. In addition, late-onset hearing loss can occur secondary to cytomegalovirus infection in the newborn period. Hearing loss related to middle ear infections can also occur after the neonatal period and during the first 2 years of life.

Methodologic Considerations in Neurodevelopmental Outcome Studies

Many biologic and environmental factors affect the outcomes of preterm infants. In addition to gestational age, birth weight, gender, and the severity of medical complications, socioeconomic factors such as social support and exposure to positive or negative life experiences all affect outcome. In general, the evidence suggests that biologic risk factors play a greater role in determining early outcome than social factors. Neurodevelopmental outcome has been increasingly used as the benchmark to determine the efficacy of medical interventions. Unfortunately, long-term follow-up studies are expensive, relatively slow to yield results, subject to human factors that are difficult to control such as subject dropout, and often deemed not as precise as bench research. Nevertheless, long-term follow-up is critical to identify possible negative effects of interventions that are not obvious in the nursery. For example, the use of postnatal steroids for the treatment of chronic lung disease enhanced extubation success but only later revealed severe neurodevelopmental sequelae. Because the results of long-term follow-up are being used to guide future interventions, it is imperative that outcome studies be rigorous and hypothesis driven. The following methodologic flaws that may compromise outcome studies have been described: inadequate description of the study population, lack of consideration to perinatal course, single-hospital samples, lack of appropriate comparison groups, excessively high dropout rates, no assessment of environment, too short follow-up duration, vague outcome measures, variability in diagnostic criteria, inclusion of severely handicapped children in the computation of mean scores, lack of consensus on correction for prematurity, change in testing instruments, changes in medical therapies during the study period, and intrinsic problems unique to birth weight or gestational age cohorts. Cause-and-effect inferences must be tempered by alternative explanations of observed events that could be produced by confounders. Both mediating and moderating variables can alter the attributable influence of any particular variable on outcome. Regional or geographically based data derived from nationwide, collaborative networks are most generalizable. Established multicenter networks enable assessment of low-incidence issues and allow for adequate sample sizes. Several large multicenter networks include the NICHD Neonatal Research Network (15 centers), the Vermont Oxford Network (>400 centers), and the Canadian Neonatal Network (17 centers).



Subject loss can bias the rates of impairment as risk for dropout increases in larger, less sick babies from lower socioeconomic backgrounds. Recommended retention rates of 90% for early childhood, 80% for school age, and 70% for young adulthood have been suggested. Comparison of children who drop out and those who continue in follow-up is essential to prevent data bias. Illness severity scores such as the SNAP (Score for Neonatal Acute Physiology) or Neurobiologic Risk Score may be used to weigh the impact of individual but competing biologic factors on outcome. Early evaluations, below 1 year of age, may be more affected by recovery from medical issues and place more weight on motor outcomes. These early assessments are limited in their ability to evaluate behavior or language. By 18-24 months, environmental factors become more influential, language becomes more elaborate, and cognitive processes

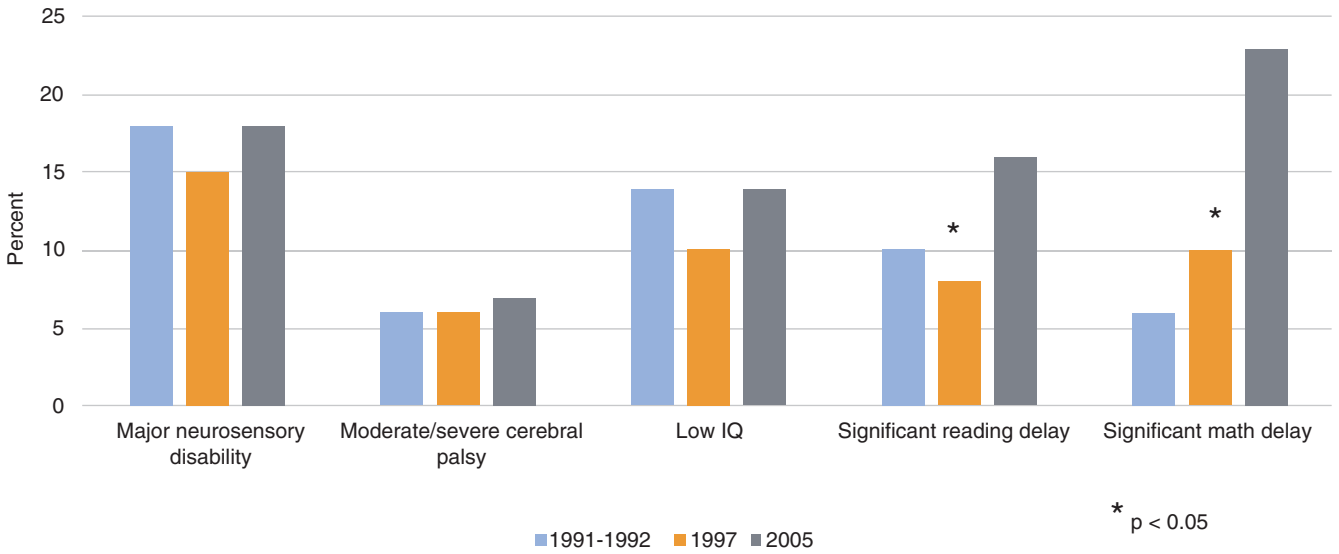
show improved prediction of later function. A trend toward worsening outcomes of preterm children at school age is a significant concern.[68] Demand for higher-level skills may cause frustration and loss of motivation, resulting in refusal to test or behavioral disorders such as attention deficit hyperactivity disorder. Although the incidence of major disability, such as moderate to severe cognitive disability, sensorineural deficits, cerebral palsy, or neurodevelopmental impairment, has decreased to 6%-8% of low birth weight infants (<2500 grams), 14%-17% of very low birth weight infants (<1500 grams), and 20%-34% of extremely low birth weight infants (<1000 grams), more subtle problems with motor coordination, executive function, and behavior occur frequently with decreasing gestational age.[19,87]

School-Age Outcome

Measuring school-age outcomes is an important landmark in longitudinal follow-up. Most of the school-age outcome studies of very premature children have been descriptive rather than hypothesis driven and have included measurements of growth, health, school performance, behavior, quality of life, self-esteem, cognition, motor function, and various neuropsychologic assessments. They have compared these premature survivors with children of normal birth weight, documenting significantly more major and subtle neurologic dysfunction, lower intelligence, poorer performance on tests of language and academic achievement, and more behavioral difficulties than control groups of children with normal birth weight who have similar race, gender, and sociodemographic backgrounds.[57] When only those children free of major neurologic impairment are considered, some of these differences disappear. However, significant differences in tests of visuomotor function and mathematics continue.[110] There are also behavioral differences that interfere with the child's attention and ability to complete a task (Fig. 60.6).[44] In a multicenter ELGAN (Extremely Low Gestational Age Newborns) study of survivors born less than 28 weeks' gestation, one-quarter of children had moderate to severe cognitive impairment at 10 years of age, with boys having greater risk than girls.[57]



• **Fig. 60.6** Psychiatric (psych.) outcomes in adolescent children who had very low birth weight (VLBW). ADHD, Attention deficit hyperactivity disorder. (Data from Botting N, et al. Attention deficit hyperactivity disorders and other psychiatric outcomes in very low birth weight children at 12 years. *J Child Psychol Psychiatry.* 1997;38:931.)

Few studies have compared school-age outcomes among premature infants over time. Cheong et al. compared 8-year outcomes of infants less than 28 weeks' gestation within Australia's Victorian Infant Collaborative Study between birth cohorts of 1991-1992, 1997, and 2005. Survival rates to age 8 improved from 53%-70% between eras and moderate-severe disability rates were stable. However, the improvement in survival was not an improvement in survival without disability, attributed largely to an increase in mild intellectual disabilities. Although mean intelligence scores did not differ, academic achievement scores for reading and mathematics were lower in 2005 than in 1997, accompanied by increased rates of academic problems in the later period. These outcomes were not explained by differences in perinatal care or sociodemographic variables between eras[22] (Fig. 60.7).

Longitudinal follow-up of preterm-born cohorts from birth to school age suggests that although rates of impairment decline with advancing age, significant neurodevelopmental disabilities persist for many preterm survivors. In the EPICure study of infants born less than 26 weeks' gestation from Great Britain and Ireland, disability was evaluated at 30 months, 6 years, and 11 years of age. Although rates of severe disability decreased from 30% at 30 months of age to 22% at 6 years, at 11 years of age 45% had serious functional disability compared with 1 percent of term-born classmates. In addition, more than half of the extremely preterm survivors had special education needs.[54,55] In terms of their overall health status, extremely preterm children have many more functional limitations and compensatory dependency needs and require many more services above routine than term-born children.[43] These differences persist even when children with neurosensory impairments are excluded. Although most children with very low birth weight remain in the regular school system, many have difficulty coping with the demands of school learning and require more special education and remedial resources.[70] The problems that appear to be most related to academic success, in addition to cognition, fall within the neuropsychologic and psychiatric domains and include deficits in attention, memory, and behavior.[37] Most preterm children who are free from major disability are functioning within the low-normal range on intelligence quotient tests. Sociodemographic and environmental factors may contribute more to the differences in cognitive outcomes than biologic risk factors, with social risks becoming more pronounced as the children age. Structural brain abnormalities detected by magnetic resonance imaging and involving the lateral ventricles, corpus callosum, and white matter are more common among preterm survivors than among controls. These findings provide an anatomic basis for neurodevelopmental problems.

• **Fig. 60.7** Comparison of rates of school age neurodevelopmental problems among infants born extremely preterm at <28 weeks' gestation over the past two decades. (Data from Cheong J, et al. Changing neurodevelopment at 8 years in children born extremely preterm since the 1990s. *Pediatrics.* 2017;139.)

School-Age Behavioral Problems

The most commonly reported childhood behavioral problems of prematurity are disorders of attention and hyperactivity, emotional difficulties, and socialization issues. Rates of attention deficit hyperactivity disorder (ADHD) range from 20%-30% for preterm children versus 5%-10% for term-born children. In a meta-analysis of six behavioral studies of preterm infants, Bhutta et al. reported a relative risk for ADHD of 2.64 (95% confidence intervals [CI] 1.85-3.78).[13] Poor cognition may contribute to attention deficits in preterm children or vice versa. In the EPICure study evaluating the outcomes of children born before 26 completed weeks of gestation in the United Kingdom and Ireland, Wolke reported no difference in the prevalence of ADHD between preterm and term controls after adjusting for IQ.[119] Reports based on screening assessments have suggested that autism may be more prevalent among preterm children.[34,62] The EPICure 2 study reported a positive screening result on the Modified Checklist for Autism in Infants and Toddlers (M-CHAT) in 41% of children born at 26 weeks of which 62% had coexisting disabilities, suggesting that the screen must be viewed in light of other neurodevelopmental problems.[58] In a young adult study of more than 900,000 subjects from a Norwegian national registry, autism spectrum disorder occurred nearly three times more frequently among preterm survivors and nearly 9 times more frequently among those born at extremely low birth weight.[76] Although no single perinatal or neonatal factor has been identified in the etiology of autism spectrum disorder, the increasing trend emphasizes the importance of early screening. Internalizing problems such as depression, anxiety, and poor adaptive skills have all been associated with prematurity, resulting in socialization and peer relationship difficulties. Furthermore, motor delays due to extreme prematurity may compromise playground skills, causing peer victimization and rejection. Immature behavioral patterns leading to parental overprotection may yield additionally poor socioemotional adjustment.

Young Adult Outcomes

Information on the young adult outcomes of the initial survivors of neonatal intensive care has been reported from around the developed world.[43,92,128] The studies have differed with regard to whether they were regional or hospital-based and the birth weight group, rate of survival, sociodemographic status, and types of outcome studied. Despite these differences, the overall results suggest that neurodevelopmental and growth sequelae of prematurity persist into young adulthood. Traditionally, educational attainment, employment, independent living, marriage, and parenthood have been considered as markers of successful transition to adulthood. When compared with controls with normal birth weight, young adults with very low birth weight have poorer educational achievement, more chronic illnesses such as asthma or cerebral palsy, and less physical activity. Higher rates of obesity among females have also been reported. In terms of brain structure, diffuse abnormalities including reduction in gray and white matter volume, increased ventricular volume, thinning of the corpus callosum, and periventricular gliosis have all been reported among young adults born prematurely.[32,97] The impact of these structural differences on brain function is uncertain; however, cognitive and behavioral differences have been reported. In general, young adults with very low birth weight report less risk taking. Fewer females born at very low birth weight have ever dated or been involved

in an intimate relationship. In addition, pregnancy and childbirth rates are lower for young women with very low birth weight. Alcohol and marijuana use also tend to be less prevalent among the former preterm adults.[41] Although the information varies, there is currently no clear evidence of an increase in attention deficit hyperactivity disorder or psychosis among adult preterm survivors. However, there is some evidence for an increase in anxious, withdrawn, and depressed symptoms, predominantly among women. This may affect both the development of adult social interactions and the formation of permanent relationships and predispose to further psychopathology later in life.[40]

The adult outcomes described to date pertain mainly to preterm infants born in the 1970s and early 1980s, a time when neonatal mortality was high and few extremely immature infants survived. In one such Canadian study of adults in the third decade of life, those born at extremely low birth weight had lower levels of employment, income, and self-esteem. In addition, fewer were married or had children.[90] Despite statistically significant differences in most outcomes measured, including educational achievement, health status, and socialization, most preterm survivors born during the early years of neonatal intensive care do well and live fairly normal lives. In fact, studies have demonstrated similar self-esteem, overall health satisfaction, and quality of life compared with adults with normal birth weight.[92,128]

Researchers in Sweden and Norway have used national longitudinal databases to examine the adult outcomes over the complete spectrum of gestational age, ranging from 23 weeks to term gestation, thus allowing for the examination of the relative outcomes of extremely preterm, late preterm, and term-born children.[64,76,107] These national studies, which link birth data to later outcomes, also have the advantage of including all the subjects of interest with very little loss to follow-up. Data reported from these national databases pertain to health, functional, educational, and developmental outcomes of importance to society but provide very little in-depth analysis of the correlates and predictors of specific outcomes. The two major predictors of adult outcomes are lower gestational age, which reflects perinatal injury, and family sociodemographic status, which reflects both genetic and environmental effects. Preliminary long-term follow-up data suggest that preterm and low birth weight children have a higher incidence of hypertension, visceral obesity, asthma, neurodevelopmental problems, and perturbations in glucose-insulin homeostasis. Speculation exists regarding the relationship between these noncommunicable disorders and possible alterations in genetic programming caused by events such as intrauterine growth restriction, premature interruption of pregnancy with change in redox state, nutritional and pharmacologic protocols used in the nursery, and postdischarge maximization of catch-up growth. The association among insulin sensitivity, altered glucose metabolism, and premature birth has been reported in a number of studies from many parts of the world. Additionally, a prevalence of type 2 diabetes in subjects born prematurely has also been reported. Unfortunately, there is a limited understanding of the mechanisms underlying these possible programming effects.

Children Born at the Threshold of Viability

Infants born at less than 24 weeks' gestation are often considered to be born at the threshold of viability. With advanced perinatal care, survival of this subpopulation has improved from 32%-46% in the early 1990s[105] to 45%-70% in the 2000s.[28,49-51,74,94,95,106,111] Evaluating the outcomes of these infants born at the threshold of viability is one of the most difficult dilemmas facing obstetricians and pediatricians. Outcome data are variably reported by birth weight or gestational age classifications and are exquisitely dependent on many covariates. Data may also suffer bias related to varying medical and societal approaches to intervention for this subpopulation.[25,31,93] Published outcome reports derive from a range of cohorts, including those from single tertiary centers with selected patients and others based on geographically defined areas. Furthermore, survival and morbidity show wide variation between cohorts, which may be partly attributed to differences in definitions or denominators. Additionally, even within this narrow subpopulation, variation in survival and outcomes can be seen from the lower to the higher end of the gestational age range.[28,36,51,74,94,95]

As the mortality rate of extremely premature infants declines, the natural next questions concern the outcomes of the survivors. The increase in survival reported by several cohorts between eras has been associated largely with a stable but broad range of rates (7%-67%) of moderate-severe impairment.[23,28,48,74,94] However, there is some evidence that the incidence of mild disability and/or developmental delay may be increasing.[28]

In the largest cohort of infants less than 27 weeks' gestation (EPICure 2 birth cohort 2006) compared to EPICure 1 (birth cohort 1995), there was an observed improvement in survival without disability of NICU-admitted infants from 23%-34%. Improvements in developmental testing scores and reduction in neurologic morbidity, but no change in the rates of severe impairment, were also reported. Of note, these outcome gains were significant only in infants born at 24-25 weeks, whereas the differences between cohorts for 22- to 23-week infants did not change.[74] In a similar comparison of less than 25-week outcomes between two epochs (1999-2001 versus 2002-2004) from the Neonatal Research Network, Hintz et al. found no statistically significant differences in survival or 18- to 22-month outcomes between the epochs with moderate-severe cerebral palsy in 11%-15%, cognitive impairment in 45%-51%, and composite neurodevelopmental impairment in 50%-59%.[48]

Factors influencing outcomes at the threshold of viability are similar to those in the larger very preterm population. In multivariate analyses, exposure to antenatal corticosteroids, female sex, singleton birth, higher birth weight, and greater gestational age have been associated with reductions in the risk for death or profound impairment. Maternal chorioamnionitis, neonatal sepsis, transient hypothyroxinemia,

jaundice, postnatal steroid exposure, and the major neonatal morbidities of chronic lung disease, severe brain injury, and severe retinopathy of prematurity have all been associated with increased risk of poor neurodevelopmental outcomes.[5,38,110,122,124]

School-age follow-up of the EPICure 1 cohort at 6 years revealed cognitive impairment in 21% of the children, severe disability in 22%, and disabling cerebral palsy in 12%.[68] In terms of overall function, the EPICure children demonstrated school difficulties, language problems, poor respiratory health, and a variety of pervasive behavioral problems, including attention deficit, hyperactivity, and social-emotional problems.[120] At 11 years of age, the EPICure 1 survivors continued to demonstrate cognitive impairment with specific problems in reading and mathematics. Fifty-seven percent required special educational services.[54] Similar results have been reported at school age for regional cohort of children born weighing less than 1000 g or before 28 weeks' gestation in Australia.[26]

A review of the international literature on survivors of a birth weight of less than 750 g or before 26 weeks' gestation reveals that during early childhood, the rates of severe neurosensory disability range from 9%-37%, with cerebral palsy occurring in 5%-37%, blindness in 2%-25%, and deafness in 0%-7%. Subnormal cognitive function is noted in 15%-47% of survivors.[50] A meta-analysis of the early school age outcomes of extremely preterm survivors born between 22 and 25 weeks' gestation demonstrates a substantial likelihood of moderate to severe neurodevelopmental impairment among this entire group[73] (Fig. 60.8).

This population of children thus represents a subgroup of preterm children who are at the highest risk for poor school performance.

• **Fig. 60.8** Rates of moderate to severe neurodevelopmental impairment at 4-8 years for children born 22-25 weeks' gestation. (Data from Moore G, et al. Neurodevelopmental outcomes at 4-8 years of children born at 22-25 weeks' gestational age. A meta-analysis. *JAMA Pediatr.* 2013;167(10):967-74.)

Early Intervention

Strategies to positively impact the neurodevelopmental outcomes of premature infants after the acute neonatal period have been actively sought as survival rates for the population have improved. Interventions in the neonatal or infant/toddler period have typically focused on parent education, parent–infant relationships, infant stimulation, infant development, and specific therapies such as physical therapy, occupational therapy, speech therapy, or infant special education.

The Infant Health and Development Program is the largest randomized trial using a comprehensive early intervention program and family support services. The study involved a 3-year birth cohort (1985-1988) of low birth weight infants (<2500 g) from eight US centers with program implementation from neonatal discharge to 36 months' corrected gestational age and extended longitudinal follow-up to 18 years of age. The program improved the intelligence quotient scores of the children at 3 years of age; however, children of the lowest birth weight (<1000 g) and thus at greater biologic risk were less responsive to the intervention. Subsequent follow-up of the cohort at age 8 years demonstrated improvement in growth status for the intervention cohort but only minimal effects of the intervention on cognitive status, school achievement, or behavior.[20] A study suggests that longer, more intensive community-based early intervention services may be associated with higher kindergarten skill levels.[65] Late adolescent outcomes of children enrolled in the Infant Health and Development Program have been reported, suggesting slight improvements in full-scale IQ, mathematics, vocabulary, and behavior among those who received early intervention; however, these improvements were noted only among the larger preterm children.[71]

A large meta-analysis of randomized trials of early developmental interventions with initiation at less than 1 year of age suggested that such interventions lead to significant positive differences in cognitive and behavioral outcomes at infant and preschool ages but that the effects do not persist to school age or into adulthood.[42,100] Small improvements in motor outcome at infant ages were found in the meta-analysis as well but were not sustained past infancy. Additional studies of the impact of early intervention on childhood outcomes have yielded mixed results.[52,56,79,80,127]

Despite these findings, there continues to be optimism for the potential of early intervention programs. Most intervention outcome assessments include cognitive, behavioral, and motor components that are best suited to identify major disabilities. There is speculation that such measures may lack sufficient sensitivity to identify or monitor improvement in minor problems or disabilities that are believed to be related to long-term neurodevelopmental outcomes.[81] In addition, it has been suggested that early interventions may have meaningful impact on parent outcomes such as maternal anxiety, depression, and self-efficacy, which may, in turn, influence infant outcomes.[12] Childhood interaction with family members and other children is an important part of normal development. This process may be compromised among preterm children whose parents are recovering from the emotional stress of multiple medical problems in a vulnerable child. Intervention programs can help maximize the potential for developmentally normal interactions for these parents and children.

Key Points

- Preterm-born children are at increased risk for impaired neurodevelopmental outcome, which includes cognitive abnormalities, motor deficits, cerebral palsy, and vision and hearing losses, with the risk of impairment increasing with decreasing gestational age.
- Neonatal complications associated with increased risk of poor outcome include bronchopulmonary dysplasia, severe intraventricular hemorrhage, poor growth, severe retinopathy of prematurity, and congenital anomalies. Socioeconomic factors such as poor education, maternal drug abuse, and low income also increased risk.
- Former preterm infants are more likely to develop psychologic and behavioral problems, including attention deficit hyperactivity disorder, anxiety, depression, and autism spectrum disorder.
- School-age children born preterm are at increased risk for functional disabilities that impact daily activities.
- Many adults who were born preterm report a similar quality of life to those born at term.

The Role of Neonatal Neuroimaging in Predicting Neurodevelopmental Outcomes of Preterm Neonates

SUSAN R. HINTZ AND NEHAL A. PARIKH

Cranial Ultrasound

Cranial ultrasound (CUS) is the most widely used neuroimaging method for preterm infants. Cranial ultrasound uses high-frequency sound waves, transmitted through open fontanelles, to detect differences in echogenicity between tissues and allow identification of anatomic structures, hemorrhage, and fluid collections. Early reports of CUS to image brain injury in preterm infants utilized anterior fontanelle views.[75,90] Since that time, the importance of mastoid (posterolateral) and posterior fontanelle views have been highlighted as critical to appropriately visualize other areas of the brain, including cerebellum, vermis, fourth ventricle, posterior fossa subarachnoid space, and trigone and occipital horns of the lateral ventricle.[30,61] CUS is an operator-dependent modality, imaging procedures and views may differ among institutions and studies, and there is no uniform approach to serial imaging protocols. Nevertheless, in skilled hands, with optimized technology and views, CUS can provide detailed information with improved accuracy compared with earlier studies.[26] Furthermore, CUS is a bedside, noninvasive neuroimaging modality and, therefore, is ideal for repeated imaging.

Brain Injury among Preterm Infants Diagnosed by CUS

A grading approach to categorize severity of intracranial hemorrhage (ICH) in preterm infants was published in the late 1970s.[76] In this system, hemorrhage confined to the germinal matrix is defined as grade I, into the ventricle without dilation as grade II, into the ventricle with dilation as grade III, and with parenchymal hemorrhage as grade IV, which in the original description was defined as accompanying intraventricular hemorrhage (IVH). This system remains broadly applied, both for research and for family counseling. Using these traditional definitions, severe ICH may be decreasing over time among extremely preterm infants. The *Eunice Kennedy Shriver* NICHD Neonatal Research Network (NRN) reviewed from 1993-2012 maternal and neonatal care, as well as morbidities and mortality among infants born at 22+0/7 weeks' to 28+6/7 weeks' gestational age in one of the participating academic US centers.[96] Among extremely preterm infants overall, the proportion with severe ICH (defined as grade III or IV IVH) decreased from 1993-2012 (19%-13%), with significant reductions for infants born at 26 weeks', 27 weeks', and 28 weeks' gestational age (GA) but not for those 22-25 weeks' GA. Cystic periventricular leukomalacia (cPVL) also decreased for infants 26, 27, and 28 weeks' GA, with 2012 rates 4%, 3%, and 2% respectively.

However, the complexity of the interpretation of CUS findings, evolving recognition of neuropathologic etiologies of intraparenchymal echogenicity or periventricular hemorrhagic infarction (PVHI), and limitations of outcomes prediction with any single neuroimaging or other finding, should give clinicians cause for prudence and careful consideration in using these classifications alone for prognostic guidance. The grading system does not include consideration for nonhemorrhagic periventricular echogenicity or echolucency such as cPVL, nor does it include ventricular dilation not associated with hemorrhage, or cerebellar hemorrhage, all of which have been associated with neurodevelopmental impairment.[13,55,57,77] In some studies, persistence of periventricular echodensity or "flaring" on CUS is assessed,[24] a finding that has been suggested to be predictive of neuromotor outcome. Since the initial description of these grades, periventricular hemorrhagic infarction (PVHI) has been proposed to be caused by impairment of venous drainage leading to venous infarction, with subsequent hemorrhagic evolution in periventricular white matter,[34,36] thus may exist as an isolated finding. Furthermore, the extent and severity of the injury associated with PVHI is not further quantified. Nevertheless, strong associations between major ICH

Abstract

Neonatologists, neurologists, and other providers who care for high risk, very premature infants in the neonatal intensive care unit (NICU) have at times been frustrated by the inability to give families more accurate, informed answers to their questions about the neurodevelopmental outcomes of their children. Our ability to prognosticate about individual cognitive and developmental outcomes in early childhood is limited. Prediction of school age and later childhood endpoints at the time of NICU discharge, including complex academic, behavioral, and executive function outcomes, presents still greater challenges. With advances in development and utilization of cranial ultrasound (CUS) and magnetic resonance imaging (MRI), enhanced and detailed delineation of brain injury in the preterm infant has led to research to improve our understanding of links to developmental outcomes. But despite extensive and evolving experience with neonatal neuroimaging, substantial controversies exist as to when, how, and which neuroimaging studies should be performed for preterm infants and how these results should be interpreted and presented to families.

and adverse neurodevelopmental outcomes among preterm infants have been described in numerous single-center, multisite, and population-based analyses. Detailed evaluation of these associations, however, may point more to a mechanism via white matter (WM) injury rather than hemorrhage into a ventricle in and of itself.

CUS Findings and Neurodevelopmental Outcomes

The focus of many investigations has been on exploring the prognostic capabilities of major CUS findings with cerebral palsy (CP). The majority of studies have found significant associations of severe CUS abnormalities with neuromotor outcomes at 18-36 months. The EPIPAGE study followed a French regional cohort of 22-32 weeks' GA infants to 2 and 5 years of age.[3,12] Cerebral palsy (CP) was determined by questionnaires sent to pediatricians. At 2 years, among children with a history of white matter abnormalities (defined as PVL, ventricular dilation, or intraparenchymal hemorrhage or cyst), 24% were diagnosed with CP; 57% of those with cystic PVL were diagnosed with CP. The presence of cerebral lesions on neonatal CUS was independently associated with CP at 5 years. At 5 years, among those with cystic PVL, 61% had CP; among those with intraparenchymal hemorrhage, 50% had CP. At both 2 and 5 years, among those with no CUS abnormalities, CP was diagnosed in just over 4%. In EPICure 1, a population-based study of infants 20-25 6/7 weeks' GA born in the United Kingdom and Ireland from March 1995 to January 1996,[107] severe CUS abnormalities (defined as parenchymal hemorrhage, cystic changes, or ventricular dilatation on the last CUS) were associated with CP (OR 4.95, 95% CI 2.25–10.85) and with severe motor disability (OR 7.15, 95% CI 2.73–18.74). Of importance, when children with motor disability were excluded, severe CUS abnormality was not significantly correlated with Bayley Scales of Infant Development 2nd edition (BSID-II) mental developmental index (MDI) score. The NICHD Neonatal Research Network (NRN) reported the 18-22 months' corrected age outcomes of a cohort of extremely low birth weight (ELBW) infants born in the 1990s[56] and also found that after adjusting for numerous confounding variables, grade III or IV IVH (OR 2.4, 95% CI 1.8–3.1) and cPVL (OR 10.5, 95% CI 7.2–15.2) were associated with moderate to severe CP. Among extremely preterm infants <25 weeks' GA in the NRN, IVH grade III or IV, and cystic PVL were also independently associated with moderate to severe CP.[42] The Extremely Low Gestational Age Newborn (ELGAN) study was a multicenter study designed to identify characteristics and exposures that increase the risk of neurodevelopmental impairments at early childhood follow-up among children born before 28 weeks' gestation.[54,73,74] Three CUSs were required at specified age ranges during NICU hospitalization. At 2 years, intraparenchymal hemorrhage was strongly independently associated with moderate to severe CP (RR 4.2, 95% CI 2.1–8.1), but white matter injury on CUS as defined by echolucency (RR 16, 95% CI 7.6–32) and ventriculomegaly (RR 11, 95% CI 5.5–21) demonstrated even stronger associations.[54] In multivariable analyses adjusting for numerous confounders, isolated IVH without white matter injury did not appear to be associated with neurologic or developmental impairment at 2 years as defined by BSID II psychomotor developmental index (PDI) and MDI scores.[73,74] Only when accompanied by white matter lesions was IVH independently associated with significantly increased risk for CP and no more than a minimal increased risk for adverse developmental outcome.

These studies and others show that severe neonatal CUS abnormalities are associated with subsequent neuromotor impairment. Nevertheless, the risk for CP is not completely eliminated with the finding of a normal CUS, although it is reassuring. In the EPIPAGE study,[3,12] only 4.4% of those with normal CUS went on to be diagnosed with CP at 2 years. However, evaluating the data in a different way, of the 164 children diagnosed with CP, more than one-third had no abnormality on neonatal CUS. In the ELGAN study, almost half of the children with CP at 2 years had all normal CUSs, and the positive predictive value (PPV) of ventriculomegaly or echolucency for moderate or severe CP was poor.[54,73,74] Nevertheless, with meticulous technical attention and serial CUS imaging, impressive predictive capability for CP has been reported. In a single center, de Vries et al. reported 76% sensitivity and 95% specificity of CUS abnormalities for CP at 2 years for patients <32 weeks' GA.[25] Of importance, among those with major CUS abnormalities who developed CP, approximately 30% were noted only after 28 days of age on serial imaging, including some cystic changes that were found only on late scans or were observed to collapse or coalesce over time. In longer-term follow-up at 5 years of age in the EPIPAGE cohort, major CUS abnormalities remained strongly associated with motor challenges, with CP seen in 61% of those with cPVL and 50% in those with intraparenchymal hemorrhage, compared with 4% in infants with normal neonatal CUS.[12]

Although severe CUS findings are associated with subsequent adverse motor findings, CUS findings alone are poorly predictive of early developmental outcomes or later childhood cognitive and learning outcomes unless more detailed CUS and other factors are taken into account. Hack et al. found that severely abnormal CUS findings among ELBW infants was independently associated with abnormal neurologic outcome but not with BSID II MDI <70, at 20 months.[37] However, about 40% of ELBW infants with neurologic abnormality at 20 months did not have abnormal CUS, and about half of those with abnormal CUS did not go on to have neurologic abnormality. Similarly, among ELBW infants in the NICHD NRN with at least two neonatal CUSs during hospitalization and all CUSs reported as normal, either BSID II MDI <70 or CP was still present in 29% at 18-22 months.[56] Further analyses demonstrate that the presence of severe IVH on CUS accounts for a very small fraction of the variation in

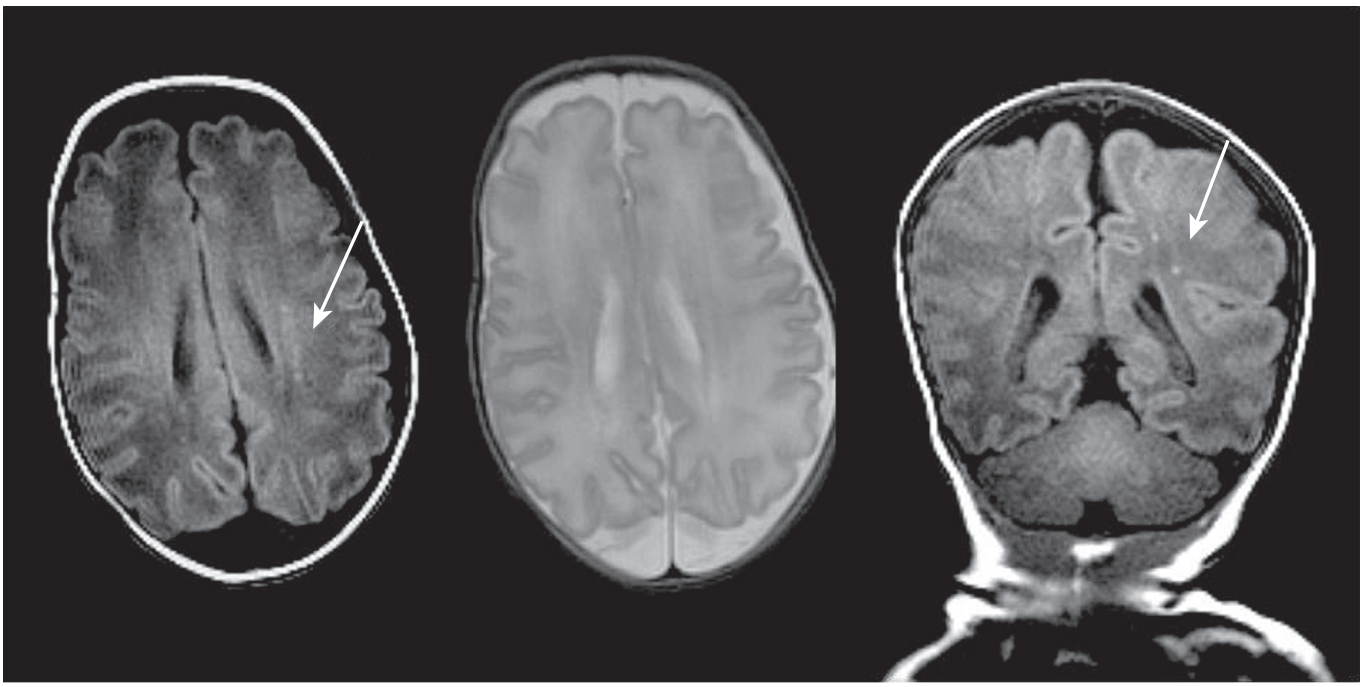
major handicap or low MDI score,[2] and models that include clinical variables predict neurodevelopmental outcomes significantly better than those with CUS variable alone.[16] Even with serial CUS and evaluation of detailed findings, major CUS abnormalities have not been found to be strongly associated with cognitive delay at 2 years.[25] In the 8-year follow-up of the EPIPAGE cohort, ~40% of those with major neonatal CUS abnormalities had no significant cognitive or learning challenges identified, whereas 30-40% of those with no neonatal CUS abnormalities had moderate to severe challenges.[65] This underscores the need for long-term surveillance through childhood for all born extremely preterm regardless of neuroimaging findings.



Potential Limitations to Interpretation

Details pertaining to severity of IVH and PVHI may be important to understanding implications for outcome, as can the presence or absence of other clinical findings and morbidities. Any grade III and IV ICH have often been combined into a single "severe" category both for the purposes of research and clinical counseling. However, Bassan and colleagues scored the severity of PVHI on CUS on the basis of extent, bilaterality, and midline shift.[11] Two-thirds of those with PVHI had significant neurodevelopmental impairments, but severity of outcome was correlated with CUS PVHI severity score. Merhar et al. found that the rate of neurodevelopmental impairment increased with unilateral to bilateral ICH, as well as with sepsis and postnatal steroid exposure.[67] Of note, the group also found that although infants with bilateral grade IV had substantially worse BSID-II MDI and PDI scores than those with unilateral, those with bilateral and unilateral grades I–III IVH had similar outcomes, and those with grade III had similar outcomes to those with grades I-II. Among preterm infants surviving after intraparenchymal hemorrhage in a single center spanning a more recent era when Bayley Scales 3rd edition (Bayley-III) was in use, Tsai and colleagues found significant predictors of CP, including ventriculomegaly, intraventricular echodensity, and ventricular shunt, but no clinical, imaging, or sociodemographic factors were significantly associated with low cognitive scores.[100] In a retrospective analysis of extremely preterm infants diagnosed with grade III or IV ICH in the NICHD NRN with 18-22 month follow-up including Bayley-III, bilaterality of the findings as well as the presence of PHVI were associated with death or impairment, although birth weight, presence of shunt, and exposure to postnatal steroids influenced prediction.[27] Conversely, "low-grade" (grades I and II) hemorrhage is often considered to confer no additional risk for adverse neuromotor or developmental outcomes. In a single-center study, ELBW infants with uncomplicated grade I or II IVH were reported to have poorer neurodevelopmental outcomes at 20 months than those with normal CUS, even after adjusting for confounding risk factors.[79] However, a multicenter study of infants <27 weeks' GA born 2006–2008 found that 18-22 month outcomes did not differ for those with grades I and II than for those without hemorrhage.[80] A large, single-center, case-control study of infants 24-32 weeks' GA found no difference in neurodevelopmental outcomes between those with grade I-II and those with normal CUS,[83] whereas grade I-II was found to be associated with adverse neurodevelopmental outcomes among 23-27 weeks' GA infants in a regional cohort in Australia.[15] In evaluating associations of neonatal CUS findings with later outcomes, the National Brain Hemorrhage Study cohort isolated germinal matrix, and IVH without ventricular enlargement was not associated with adverse outcomes at 6 and 9 years.[81] In even longer-term follow-up, utilizing data from the low birth weight sample of the Infant Health and Development Program study, grades I and II were also not independently associated with cognitive, behavioral, or academic outcomes at 3, 8, or 18 years of age.[7] These disparate findings with regard to low-grade hemorrhage may be reflective of differences in patient population, era, brain imaging and outcomes, ascertainment tools, and details of brain injury.

Interpretation of the applicability of studies relating severe or low-grade CUS findings with neurodevelopmental outcomes may also be challenged by the validity of findings. The NICHD NRN assessed interobserver reliability of CUS findings between two central readers and accuracy of local compared with central readers.[43] Agreement between central readers was high for major CUS findings such as grade III or IV IVH and degree of ventriculomegaly (kappa = 0.84 and 0.75, respectively) but much worse for lower-grade IVH (kappa = 0.4). The sensitivity of local reader interpretation was also excellent for severe IVH (88%-92%) but poor for grade I or II IVH (48%-68%). Also, in many studies, no specific CUS protocols were required, and the frequency of CUS was not specified. A primary guideline for CUS screening in the United States is the Practice Parameter for Neuroimaging of the Neonate in 2002,[66] which recommends screening with CUS for all infants with GA <30 weeks at 7-14 days, and "optimally" again at 36-40 weeks' postmenstrual age. However, more frequent and detailed surveillance protocols using high-resolution techniques may increase the sensitivity of CUS for identifying infants at high risk for adverse outcomes.[24,25,57]

It is clear that CUS alone can be a valuable tool to assist in prediction of neuromotor outcomes. But studies of neonatal CUS and later outcomes have implicated white matter injury as the important underlying etiology linking abnormal brain imaging findings with adverse neurodevelopmental outcomes among preterm infants. This has led to the suggestion that white matter injury can be better recognized and more comprehensively characterized; we may be better able to predict adverse motor and developmental outcomes and potentially anticipate specific needs for early evaluation and intervention. More importantly, a better understanding of the connection between perinatal events and brain injury may allow for prevention or amelioration of brain injury in the preterm. These broad hypotheses have formed the basis for investigation of magnetic resonance imaging (MRI) as

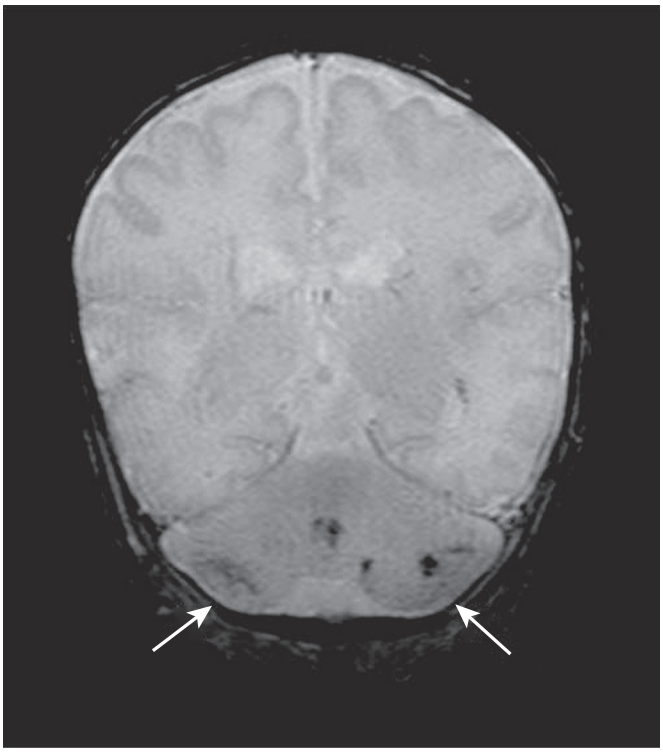
• **Fig. 61.1** Noncystic punctate white matter injury on MRI. Selected brain MRI images (axial T1, axial T2, coronal T1) of an infant born at 24 5/7 weeks' GA at 35 2/7 weeks' PMA. Images show noncystic punctate white matter injury, as demonstrated by areas of hyperintensity on T1 (*arrows*) in the absence of marked hypointensity on T2. Qualitative cerebral volume loss is also appreciated.

a routine or adjuvant neuroimaging modality for preterm infants.

Conventional (Qualitative) Magnetic Resonance Imaging

Brain MRI has been increasingly utilized for research and clinical purposes since the 1980s. With optimization of MR methods for detecting neonatal brain injury, greater availability of MR scanners closer to and within the neonatal intensive care unit (NICU), and broader availability of MR-compatible monitoring, transport, and imaging equipment, MRI has become a more routine advanced neonatal neuroimaging approach.[40,68] An enhanced understanding that nonsedated scans can be obtained for premature infants with simple feeding and swaddling, or by using polystyrene bead-filled "huggers," has also led to greater utilization of MRI.[70,108]



White Matter Abnormalities

A major focus of interest and study for preterm neuroimaging and outcomes has been on white matter injury. As described previously, CUS markers of white matter injury have been shown to be risk factors for adverse neuromotor outcomes. White matter injury, such as cystic PVL and ventriculomegaly due to periventricular white matter loss, should be easily detectable by CUS. However, CUS does not detect diffuse white matter injury or subtle white matter lesions as well as MRI[47,69] (Fig. 61.1). A relatively low sensitivity of CUS for detection of noncystic white matter abnormalities has been reported,[29,47,69] although many of these studies have not performed frequent sequential scans during the neonatal period. Existing and increasing evidence points to the fact that white matter injury in preterm infants is associated with broader brain maturational disturbances. White matter abnormality (WMA) on MRI in preterm infants is associated with reduced cortical and deep gray matter volume,[13,48] which in turn is associated with lower developmental scores and working memory in early childhood.[60,104] Pre-oligodendroglial cells of the developing white matter are known to be vulnerable to a number of perinatal and neonatal clinical factors, including hypoperfusion, systemic inflammation, and infection.[105,106] But perhaps more important than direct injury to developing white matter, subplate neurons, and axonal growth and elongation processes is the resulting reduced connectivity affecting the cerebral white matter, deep gray matter, cortex, and cerebellum.[103] Reduction of crucial connections during a period in rapid brain development may be associated with brain maturational disturbances, suggesting an overall link to impaired neural connectivity.[28,105] Classification systems have been used to "score" or "grade" white matter injury by MR imaging at term equivalent age,[48,69] and an updated classification system includes cerebellar injury and volumetric measures.[52]

Areas of the Brain and Findings of Interest

Compared with CUS, MRI offers a more complete visualization of anatomic features and details of injury. However, to what extent this added detail can improve neurodevelopmental outcome prediction is an area of active research. For example, among preterm infants, CUS and MRI evidence of cerebellar injury has been associated with adverse developmental outcomes, including motor, cognitive, communication, and behavioral impairments.[41,59,60,104] Adverse neurodevelopmental outcomes appear, at least in part, to be linked to developmental disruption to the cerebral cortex associated with the cerebellar injury.[58,60] The cerebellum can be visualized by CUS, using mastoid fontanelle views, but MRI allows delineation of cerebellar lesion topography and identification of supratentorial injury, which may help predict severity of neuromotor delays[59] (Fig. 61.2). Limperopoulos and colleagues followed preterm infants with isolated cerebellar hemorrhagic injury, age-matched controls, and with cerebellar hemorrhagic injury in addition to parenchymal injury.[59] At a mean of 32 months, infants with isolated cerebellar hemorrhagic injury had high rates of severe motor disabilities (48%), expressive language (42%), delayed receptive language (37%), and cognitive deficits (40%), whereas the control group was reported to have none of these delays. Those with cerebellar hemorrhagic injury plus parenchymal injury were not at higher risk for these disabilities, although neuromotor impairment was more severe. In a different cohort with lower cerebellar injury rates, cerebellar injury was not found to be strongly related to 2-year developmental or motor outcomes.[52] However, cerebellar injury seen only on MRI, not on CUS, has been shown to be common among very preterm infants and associated with significantly increased odds of abnormal neuromotor exam at approximately 5 years,[97] although others have reported very small cerebellar hemorrhage to be less frequent and not associated with adverse neurodevelopmental outcomes at 2 years corrected age.[95]

• **Fig. 61.2** Cerebellar injury on MRI. Brain MRI image of an infant born at 24 3/7 weeks' GA at 36 1/7 weeks' PMA. Images show injury of the cerebellum (*arrows*), as demonstrated by bilateral areas of hypointensity on gradient echo (GRE) sequences (*dark areas in the cerebellum*), consistent with mineralization or hemorrhage.

Several classic studies demonstrated that MRI provides prognostic information that is complementary to that provided by CUS. Using an approach of sequential CUS and subsequent term-equivalent age MRI with assessment of myelination of the posterior limb of the internal capsule (PLIC), de Vries and colleagues demonstrated a positive predictive value of 96% for death or CP at 2 years, with a negative predictive value of 69%. Of note, the authors caution that performing MRI at an earlier time point (35-38 weeks' PMA) may not be reliable to assess myelination of the PLIC.[24] Among infants with CUS evidence of periventricular echodensities, Sie et al. reported that neonatal MRI identified additional punctate to extensive white matter lesions, accurately predicted the location and extent of brain injury on MRI at 18 months, and that neonatal MRI scores (based on severity and extent of lesions) predicted motor and visual outcomes at 18 months extremely well.[87] These researchers suggested that, particularly among infants with inhomogeneous periventricular echodensities on CUS, neonatal MRI provided additional valuable information for predicting later outcomes. Other investigators have demonstrated that neonatal MRI may be complementary to specific exam findings in predicting neuromotor outcomes among very and extremely preterm infants.[88,93]

Neonatal MRI to Predict Early Neurodevelopmental Outcomes

Early studies that compared predictive capability of MRI with CUS focused on neuromotor impairments as primary outcome, were primarily small single-center efforts, and were limited by size and different approaches to timing of imaging.[23,70,87] Subsequently, white matter abnormality scoring systems have been implemented, and larger cohort investigations have been published, among the first of which was a multicenter prospective study in Australia and New Zealand comparing serial CUS with near-term MRI findings and their association with 2-year outcomes in 167 infants <30 weeks' GA.[108] The authors demonstrated 1) that the presence of moderate-severe white matter abnormalities on MRI was significantly associated with severe motor delay and CP, independent of CUS abnormalities and other risk factors; 2) a significant correlation between white and gray matter abnormalities; 3) increasing severity of white matter injury was linearly related to worse BSID II

MDI scores, but an independent association of "moderate-severe white matter injury" with "severe cognitive delay" was not found; 4) gray matter abnormality on neonatal MRI was not significantly associated with later neuromotor or cognitive impairments after adjusting for CUS findings. Although sensitivity of moderate-severe WMA to predict CP (65%), neurosensory impairment (82%), and severe cognitive delay (41%) was greater than that of CUS abnormalities (18%, 16%, and 15%, respectively), the total number of the cohort with moderate (n = 29) or severe (n = 6) white matter injury was small, approximately half of those with moderate-severe white matter injury by neonatal MRI did not have neurodevelopmental impairment at 2 years, and the sensitivity of CUS to predict outcome was much lower than in other studies. In a cohort of extremely preterm infants in Sweden, Skiold et al. found an overall lower rate of moderate to severe impairment at 30 months' corrected age than had previously been reported but utilized the Bayley-III.[89] The authors found that infants with moderate-severe WMA on MRI had lower cognitive and language BSID III scores compared with infants with none or mild white matter abnormalities, but there was no difference in motor scores. Furthermore, 35% of those with CP at 30 months had none or only mild white matter abnormalities on MRI. Of note, the authors had previously demonstrated that infants in this group with a normal CUS at term had normal or only mild white matter abnormalities on MRI.[45] The NICHD Neuroimaging and Neurodevelopmental Outcomes (NEURO) study was a prospective study of early and late CUS and near-term MRI, including 480 infants <28 weeks' gestation, with outcomes including BSID-III assessed at 18-22 months.[41] Late CUS and near-term MRI were performed within 2 weeks of each other, thus allowing for comparison of relatively contemporaneous neuroimaging findings. In multivariable models, both late CUS findings reflective of WM injury and MRI findings of significant cerebellar injury remained independently associated with adverse neurodevelopmental outcomes. In models that did not include late CUS, MRI findings of both moderate to severe WMA and significant cerebellar lesions were independently associated with adverse outcomes. Early CUS findings were not associated with adverse outcomes when any late neuroimaging was taken into account. These results demonstrate the need to understand the evolution of brain injury over time rather than to rely on early findings. In a recently published extremely preterm Dutch cohort follow-up study of term equivalent MRI among infants 24-28 weeks, the prognostic value of the expanded MRI scoring system[52] for 2-year outcomes utilizing Bayley-III was limited, with scores accounting for just a small amount of variance in neurodevelopmental outcome.[18]

In addition, many groups have now reported on outcomes relative to diffuse excessive high-signal intensities (DEHSI) on term equivalent MRI. This is a common finding, reported on term equivalent MRI in 50%-90% of preterm infants; due to links between this qualitative finding and quantitative measures, DEHSI was hypothesized to represent WMA.[21,55] However, follow-up studies have demonstrated that DEHSI is not associated with neurodevelopmental outcome among preterm infants in early childhood,[22,50,89] nor has it been shown to be associated with mild neurologic dysfunction, scores on MABC assessment, cognition, visual-motor integration, or behavior at 6-7 years.[17]

Later Childhood Outcomes and Need for Further Study

The incremental advantage of term equivalent age MRI over sequential, carefully performed CUS to predict very early childhood neurodevelopmental outcomes is not clear. But 18-30-month outcomes do not provide a complete picture of the subtle neurologic, functional, or cognitive future for these high-risk infants. Later childhood follow-up of neuroimaging cohorts is providing additional clues to what can be understood from injury detected on MRI. Woodward and colleagues reported that among children born very preterm, white matter injury on neonatal MRI was independently associated with neurocognitive delays at 4 and 6 years of age.[109] Furthermore, those with no white matter abnormalities on neonatal MRI showed no neurocognitive impairments compared with their full-term peers. The presence of any white matter abnormalities on neonatal MRI also appears to be independently correlated with expressive language scores among children born very preterm at 5 years of age.[46] Spittle and colleagues demonstrated that the presence of moderate to severe white matter abnormalities on neonatal MRI was associated with a nine-fold increase in the odds of motor impairment at 5 years as measured by the Movement ABC.[94] Nevertheless, the authors noted that nearly one-third of those with no white matter abnormality on neonatal MRI still had motor impairment at 5 years. Behavioral and psychiatric outcomes may be associated with injury detectable by neonatal MRI.[20,99] Recent studies have also shown term equivalent brain MRI scores to be associated with lower IQ, math and motor scores,[5] and poorer memory and learning performance[72] at 7 years among very preterm children.

Neurologic and particularly cognitive outcomes are influenced by a multitude of variables. Even in an era of advanced neuroimaging, it is naïve to consider that there is a single, perfect test to allow for individual prediction of later neurodevelopmental outcome; furthermore, presenting neuroimaging results to families without a clear context of the limitations of these findings is neither reasonable nor appropriate.[49] A recent publication has suggested avoidance of "routine" term equivalent conventional brain MRI for screening purposes due to "insufficient evidence that the practice improves long term outcomes."[44] Yet numerous studies in preterm infants have delineated the links between near-term conventional MRI findings and neurodevelopmental outcomes through early childhood, particularly highlighting the strengths of associations with neuromotor outcomes.[4] Although capability of conventional MRI or indeed any neonatal neuroimaging modality

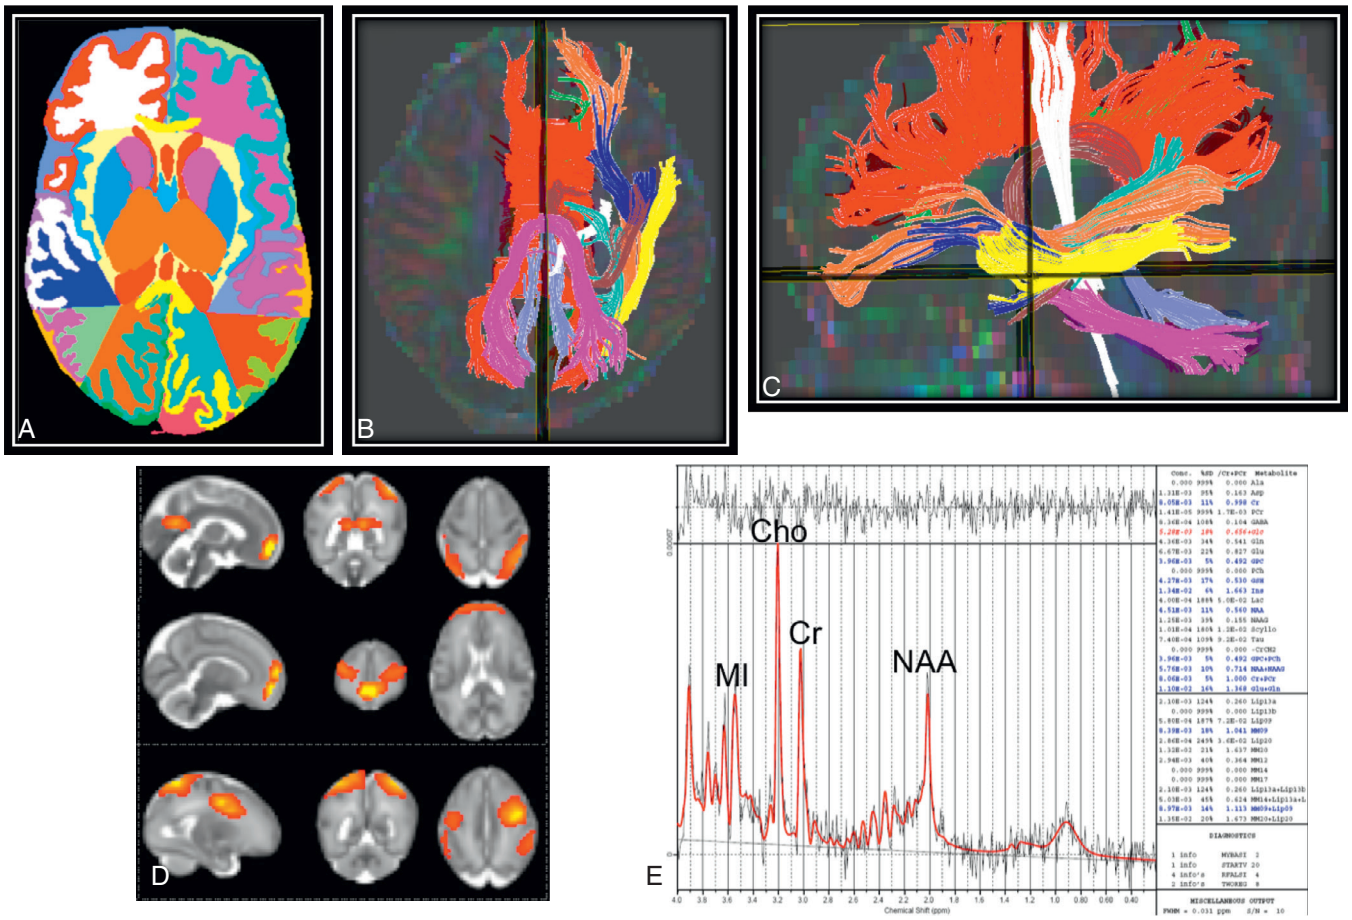
to predict complex early cognitive or behavioral outcomes is limited,[102] the number of potentially informative neonatal neuroimaging studies with school age and later childhood follow-up is restricted. Systematic reviews have highlighted numerous factors which influence cognitive development. There is still certainly much to be gained by optimization of current institutional CUS imaging protocols and continued rigorous research evaluation and comparison of neuroimaging methods. At the present time, brain MRI is likely to be used in most institutions as a complementary tool to CUS in the preterm infant, with this bedside imaging modality serving as the primary neuroimaging method[23,71] and with high-risk preterm patients identified that may benefit from further evaluation and identification of subtle injury based on CUS findings and clinical course.[24,32,33,86] There is great potential in continuing research to elucidate how clinical events and processes affect the preterm brain and how that injury is linked with outcome, with the ultimate goal of undertaking well-conceived studies of neuroprotective strategies and interventional programs to improve the outcomes of preterm infants. To that end, future studies can further focus on identifying specific high-risk groups of preterm infants for which MRI would improve our understanding of injury to the developing brain and the connections with neurodevelopmental outcomes, and, importantly, to allow for risk stratification for neuroprotective and interventional trials. Patient-oriented research to better delineate potential benefit of MRI findings to patients and to families will also be critical. Investigations using advanced MR techniques including diffusion MRI (dMRI), resting state functional connectivity MRI (fcMRI), volumetric methods, and surface morphometry hold enormous promise to help to explore these questions.[4]

Advanced MRI: Opening a New Window into the Preterm Developing Brain

Over the past two decades, scientists have built upon the solid foundation of conventional brain MRI and pushed the technologic envelope to develop more sensitive modes of MRI. Advanced MRI such as dMRI, volumetric MRI, magnetic resonance spectroscopy (MRS), and fcMRI is an umbrella term for any quantitative, more sensitive mode of MRI that can peer deeper into the brain to provide more objective measures of regional gray and white matter microstructure, macrostructure, metabolites, and function (Fig. 61.3). These advanced imaging modalities appear to offer the greatest potential to develop sensitive and accurate diagnosis of the encephalopathy of prematurity and prognostic biomarkers of neurodevelopmental impairment (NDI).[8,10,78,104] Early evidence suggests that such modalities are more sensitive than conventional MRI in detecting and can further improve our ability to understand perinatal brain injury, impaired brain development, and functional impact on NDI.[8,62,78]



Numerous epidemiologic,[38] neuropathologic,[104] and advanced MRI studies[14,101,110] have now confirmed that overt perinatal brain injuries such as intraventricular/periventricular hemorrhage and periventricular leukomalacia are decreasing in prevalence due to improved care. These have been supplanted by highly prevalent and more subtle, diffuse brain abnormalities and brain maturational delays that are more readily detected using advanced MRI modalities.[104] The high prevalence of brain maturational delays/abnormalities and their association with NDI were largely unrecognized prior to the use of advanced brain MRI.[1,19,31,82] Some signal abnormalities that are visible on structural MRI can only be reliably quantified using dMRI and specialized image processing software.[39,53] Structural and functional connectivity studies using dMRI and fcMRI have demonstrated altered cortical–subcortical and short-range corticocortical connections, respectively, in very preterm infants as compared to healthy term controls by term-equivalent age.[6,9,35,85,91,98] These observations suggest that very premature birth and subsequent NICU care result in widespread decreased/altered neural connectivity. These connectivity abnormalities may be the neurobiologic antecedents of the cognitive and behavioral abnormalities that are commonly observed in this population of high-risk infants.

Predicting Motor, Cognitive, and Behavioral Abnormalities with Advanced MRI

Currently, it takes between 2 and 5 years to detect and accurately diagnose motor, cognitive, and behavioral/psychiatric abnormalities despite that many of these functional disabilities are the result of early injuries, abnormalities, or delays in brain development. Earlier identification could readily facilitate targeted early intervention therapies during the first 3 years after birth, when brain development is explosive and exhibits the greatest neuroplasticity.[51] Currently, advanced MRI applications offer the best opportunity for early, accurate identification of later functional disabilities in high-risk preterm infants. A recently completed systematic review examined the accuracy of advanced MRI measures in very preterm infants at term-equivalent age as prognostic biomarkers for NDI at 18 months' corrected age or later.[78] Of a total of 47 eligible studies that were identified, the two most common modalities studied were dMRI and morphometric studies such as volumetric MRI or two-dimensional brain measurements (Table 61.1). No fcMRI prognostic studies were found. More recent studies used 3.0 T scanners to take advantage of improved signal to noise and/or faster scanning times.

Several studies demonstrated an independent or incremental benefit of advanced MRI over cranial US or conventional MRI. This is despite the fact that most studies did not combine biomarkers; such an approach is sure to enhance outcome prediction. Almost all studies attempted to predict NDI only at 18-24 months' corrected age. While this is the current standard for most clinical trials in neonatology, it is now well recognized that testing at this young age using standardized tests such as the Bayley-III has suboptimal reliability and exhibits poor sensitivity in predicting

TABLE 61.1 Summary of Important Findings from Advanced MRI Prognostic Biomarkers Systematic Review

dMRI (N = 25); morphometric studies (N = 25); Magnetic Resonance Spectroscopy (MRS) (N = 5)	
Most common cerebral quantitative measurements	1) Regional brain diameter or volume on structural MRI; 2) fractional anisotropy and/or mean diffusivity on dMRI; 3) brain metabolites, most commonly N-acetylaspartate (NAA)/choline ratio on MRS
Brain regions most predictive of NDI (identified in three or more studies)	Corpus callosum; centrum semiovale; sensorimotor cortex; subcortical gray matter; posterior limb of the internal capsule; cerebellum
Predicted outcomes examined	Cerebral palsy; minor motor abnormalities; permanent hearing loss; cognitive deficits; working memory; executive function; psychological/behavioral abnormalities

NDI, Neurodevelopmental impairment.
With permission from Parikh NA. Advanced neuroimaging and its role in predicting neurodevelopmental outcomes in very preterm infants. *Semin Perinatol.* 2016;40(8):530-541.

infants with intellectual impairments at school age.[63,64,92] Nevertheless, this limitation has also plagued most conventional MRI studies and likely contributes to decreased prediction accuracy. Ongoing studies are attempting to follow study cohorts to older ages to address this limitation.

In addition to the reliance on predicting shorter-term outcomes, additional limitations include the enrollment of small, single-center cohorts, no reporting of inter- or intrarater measurement reliability, lack of blinding to imaging and other prognostic variables, no reporting of systematic differences in infants lost to follow-up, and lack of reporting of prognostic test properties.[78] These limitations may, in part, explain the slow translation of advanced MRI research into clinical practice. Other explanations likely include the need for expensive advanced MRI hardware and software and robust post-processing software for acquired images. Such post-processing software is still being modified or developed specifically for neonates/infants, and there remains a lack of consensus on which software or methods to use. Despite the practical and technologic limitations, brain macrostructure, microstructure, and metabolite prognostic biomarkers appear very promising for early, accurate prediction of NDI in very preterm infants. Such an advance will improve parental counseling and provide early post-NICU discharge risk stratification. Further development is also needed to identify biomarkers that are predictive of treatment response and to develop advanced MRI as a surrogate endpoint.

Future Developments

Advanced MRI modalities possess several novel features that have contributed to their greater sensitivity in diagnosing abnormalities and predicting NDI. These features include:

- ability to query morphometric, microscopic, metabolic, and physiologic/functional derangements;
- quantitative nature, which lends greater study power than qualitative assessments for diagnostic and prognostic studies; and
- objective measurements that are increasingly being made using automated methods, which increases study power and validity by reducing measurement error.

Resting state fcMRI studies in very preterm infants have shown reduced or aberrant connectivity in the thalamocortical network and other rich club or important nodes as compared to healthy term controls.[9,85,91] While such widespread connectivity changes have yet to be correlated with NDI, other than in one recent study,[84] the likelihood that functional connectivity will be independently predictive of functional impairments is high. More studies are ongoing and will likely confirm the value of this new tool for accurate prognostication.

Advances in imaging hardware, software, computing power, and artificial intelligence have accelerated the development of these modalities and permitted increasingly objective, observer-independent automated tools designed to process big data, specifically for infant brains.[8] To be sure, many challenges remain due to infants' smaller brain size, paucity of myelination, and high risk of motion artifacts that reduce image resolution and necessitate development of infant-specific atlases and image processing methods. Nevertheless, the future is very bright for advanced MRI. If additional research can validate the sensitivity of advanced MRI measures, such as structural and functional connectivity, to identify most high-risk infants soon after birth, neonatologists will be able to facilitate targeted postdischarge early intervention or enrollment into neuroprotective trials. Such improvements could also provide prompt safety and/or efficacy assessment of NICU clinical practices and neonatal neuroprotective clinical trials and serve as a surrogate measure for later developmental and motor challenges.

Key Points

- Cranial US is the most widely used neonatal neuroimaging, and severe intracranial hemorrhage is associated with adverse neuromotor outcomes. However, limitations of outcome prediction with any single neuroimaging should give clinicians cause for prudence in prognostic guidance.
- Conventional brain MRI, which offers a more complete visualization of the brain and greater sensitivity to detect white matter injury than cranial US, has been increasingly utilized for research and clinical purposes. Existing and increasing evidence points to the fact that white matter injury in preterm infants is associated with broader brain maturational disturbances.
- Many studies in preterm infants have delineated the links between near-term conventional MRI findings and neurodevelopmental outcomes through early childhood, particularly highlighting the strengths of associations with neuromotor outcomes.
- Advanced MRI tools have opened a new window into preterm brain development and uncovered the high prevalence of diffuse white matter injuries and brain immaturity in very preterm infants.
- Despite extensive and evolving experience with neonatal neuroimaging, substantial controversies exist as to when, how, and which neuroimaging studies should be performed for preterm infants, and how these results should be interpreted and presented to families.

Lung Development and Maturation

SUHAS G. KALLAPUR AND ALAN H. JOBE

A Brief History

An understanding of lung development and maturation is central to the care of preterm infants, because lung function is so critical to survival of the preterm. Pattle and Clements first noted surface-active substances in pulmonary edema foam and lung extracts. In 1959, Avery and Mead correlated respiratory failure with decreased surfactant levels in saline extracts from the lungs of infants with respiratory distress syndrome (RDS).[3] Once the association between atelectasis with hyaline membranes and surfactant levels was appreciated, a large international research effort was focused on the surfactant system. The first direct clinical benefit was the development in 1971 of the lecithin-sphingomyelin (L-S) ratio, using amniotic fluid to predict lung immaturity and the risk for RDS in preterm infants by Gluck and colleagues. Phosphatidylglycerol was identified for lung maturity testing in 1976 by Hallman and colleagues.[24] The induction by Gregory and colleagues of continuous positive airway pressure to maintain functional residual capacity (FRC) for infants with RDS was the first application of the respiratory physiology of RDS to improve outcomes.[22] Liggins and Howie first reported a decreased incidence in RDS with maternal corticosteroid treatments in 1972.[42] The feasibility of surfactant treatment for lung immaturity was demonstrated in animal models in the 1970s, primarily by Robertson and Enhörning,[57] and surfactant was successfully used in humans by Fujiwara and colleagues in 1980.[20] This research resulted in the development of perhaps the two most effective treatments for RDS in neonatology—antenatal corticosteroids and postnatal surfactant. This progress in the application of research to the pulmonary care of the infant is continuing as molecular and cell biologic observations improve the general understanding of lung development. The major challenge for the future is the prevention of bronchopulmonary dysplasia (BPD) in infants who are very preterm.

Lung Structural Development

Embryonic Period

The lung first appears as a ventral bud off the esophagus just caudal to the laryngotracheal sulcus.[10,61] The grooves between the lung bud and the esophagus deepen, and the bud elongates within the surrounding mesenchyme and divides to form the main stem bronchi (Fig. 62.1). Subsequent dichotomous branching forms to the conducting airways. The branching of the endodermal endothelium is controlled by the underlying mesenchyme, because removal of the mesenchyme stops branching. Transplantation of the mesenchyme from a branching airway to more proximal airway induces airway development in the new location.

The commitment of endodermal cells to epithelial cell lineages requires the expression of families of transcription factors that include thyroid transcription factor-1, forkhead gene family members, and others.[69] At least 15 homeobox domain-containing genes (*HOX* genes) also contribute to lung morphogenesis. Multiple other growth and differentiation factors, such as retinoic acid and the fibroblast growth factor family members (FGF)-7 and FGF-10 and their receptors, are temporally and spatially expressed and are critical to early lung morphogenesis and subsequent development. Genetic ablation of these transcription and growth factors causes lung developmental abnormalities that range from trachea-esophageal fistula and altered branching morphogenesis to severe lung hypoplasia and complete aplasia of the lungs. Lobar airways are formed by about 37 days, with progression to segmental airways by 42 days and subsegmental bronchi by 48 days in the human fetus. The pulmonary vasculature branches off the sixth aortic arch to form a vascular plexus in the mesenchyme of the lung bud. Major regulators of vascular development are vascular endothelial growth factor (VEGF) and its receptors in the mesenchyme. Vascular development additionally requires extracellular matrix (fibronectin, laminin, type IV collagen) and other growth factors such as platelet-derived growth factor. The pulmonary artery can be identified by about 37 days, and venous structures appear somewhat later. Abnormalities in early lung embryogenesis cause trachea-esophageal syndromes, branching morphogenesis abnormalities, and aplasia.

Pseudoglandular Stage

The 15-20 generations of airway branching occur in the pseudoglandular period of lung development from about the fifth to the eighteenth week, when airway branching

Abstract

Lung development and maturation are the critical organ developmental processes that are essential for early neonatal transition following birth. Abnormalities in early gestational lung development result in congenital anomalies such as tracheal-esophageal fistula, pulmonary hypoplasia, and lung atresia. The basic airway branching pattern is complete prior to very preterm viability. The saccular preterm lung alveolarizes after about 32 weeks with alveolarization continuing through adolescence. Early or induced lung maturation is frequent and contributes to the survival of extremely preterm infants. The clinical interventions with antenatal corticosteroid therapy and postnatal surfactant are major contributors to improved lung function and survival of preterm infants. Surfactant treatments improve multiple aspects of lung function. Chorioamnionitis will expose the fetal lung to inflammation, which will induce early lung maturation and enhance the effects of prenatal corticoid treatments. The remarkable survival of early gestation infants depends on early lung maturation.

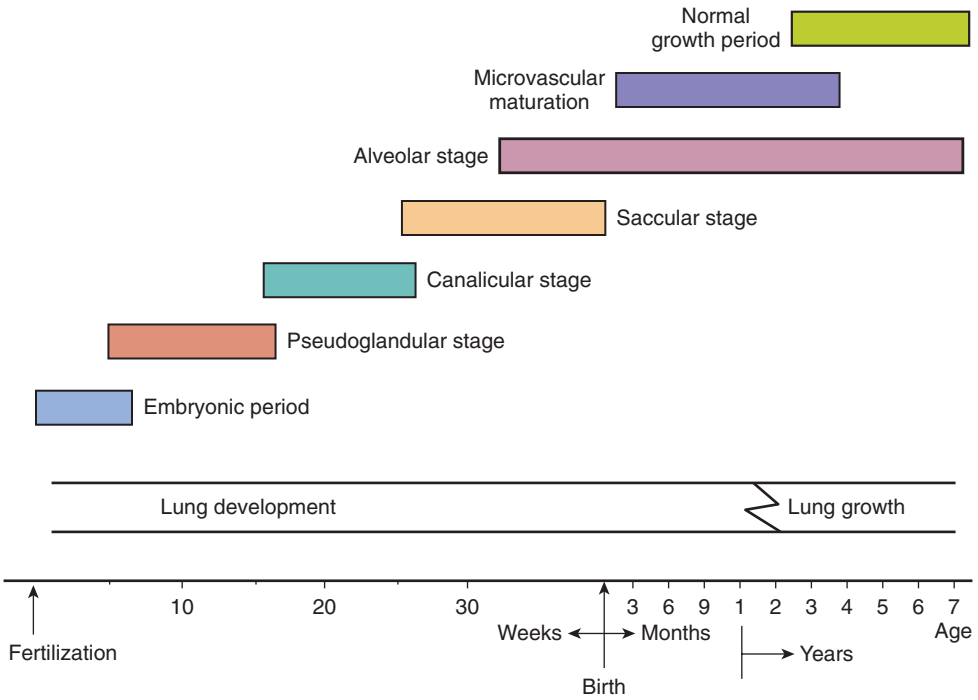
• **Fig. 62.1** Embryonic lung development. At 26 days, the lung first appears as a protrusion of the foregut. By 33 days, the lung bud has branched, and by 37 days the prospective main bronchi are penetrating the mesenchyme. Airways to the lobar and initial segmental bronchi have formed by 42 days. (Modified from Burri PW. Development and growth of the human lung. In: Fishman AP, Fisher AB, eds. *Handbook of physiology: the respiratory system.* Bethesda, MD: American Physiological Society; 1985:1, with permission.)

is complete (Fig. 62.2). The developing airways are lined with simple cuboidal cells that contain large amounts of glycogen. Neuroepithelial bodies and cartilage appear by 9-10 weeks. Ciliated cells, goblet cells, and basal cells are in the epithelium of proximal airways by 13 weeks. In general, epithelial differentiation is centrifugal in that the most distal tubules are lined with undifferentiated cells with progressive differentiation of the more proximal airways. There are multiple regulators of branching morphogenesis such as FGF-10, FGF-7, endothelial growth factor, transforming growth factor-α, and their receptors.[65] Upper lobar development occurs earlier than lower lobe development in animals, and a similar pattern of development probably occurs in humans. Early in the pseudoglandular stage, the airways are surrounded by a loose mesenchyme with the developing vasculature and capillaries. Pulmonary arteries grow in conjunction with the airways, with the principal arterial pathways being present by 14 weeks. Pulmonary venous development is in parallel but with a different pattern that demarcates lung segments and subsegments. By the end of the pseudoglandular stage, airways, arteries, and veins have developed in the pattern corresponding to that found in the adult.



Canalicular Stage

The canalicular stage between 16 and 25 weeks' gestation represents the transformation of the previable lung to the

• **Fig. 62.2** Airway branching, fetal age, and number of branches during lung development. Airway branching results in about 16 generations of airways by about 18 weeks' gestation. Branching of distal saccular structures yields respiratory bronchioles and alveolar ducts in the saccular lung by about 32 weeks' gestation. Alveolarization continues from 32 weeks until maturity. (Modified from Burri PW. Development and growth of the human lung. In: Fishman AP, Fisher AB, eds. *Handbook of physiology: the respiratory system*. Bethesda, MD: American Physiological Society; 1985:1.)

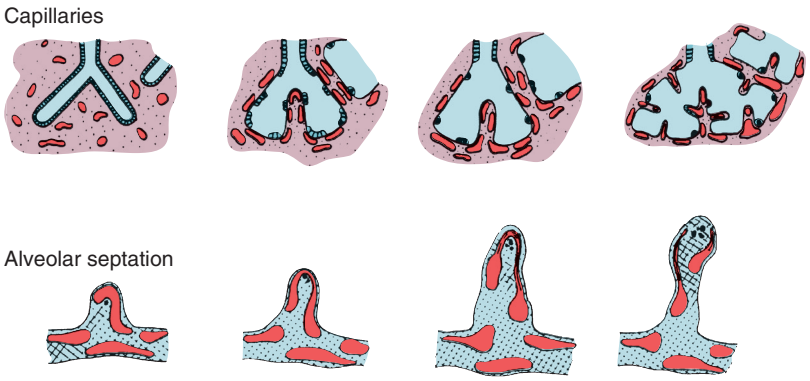
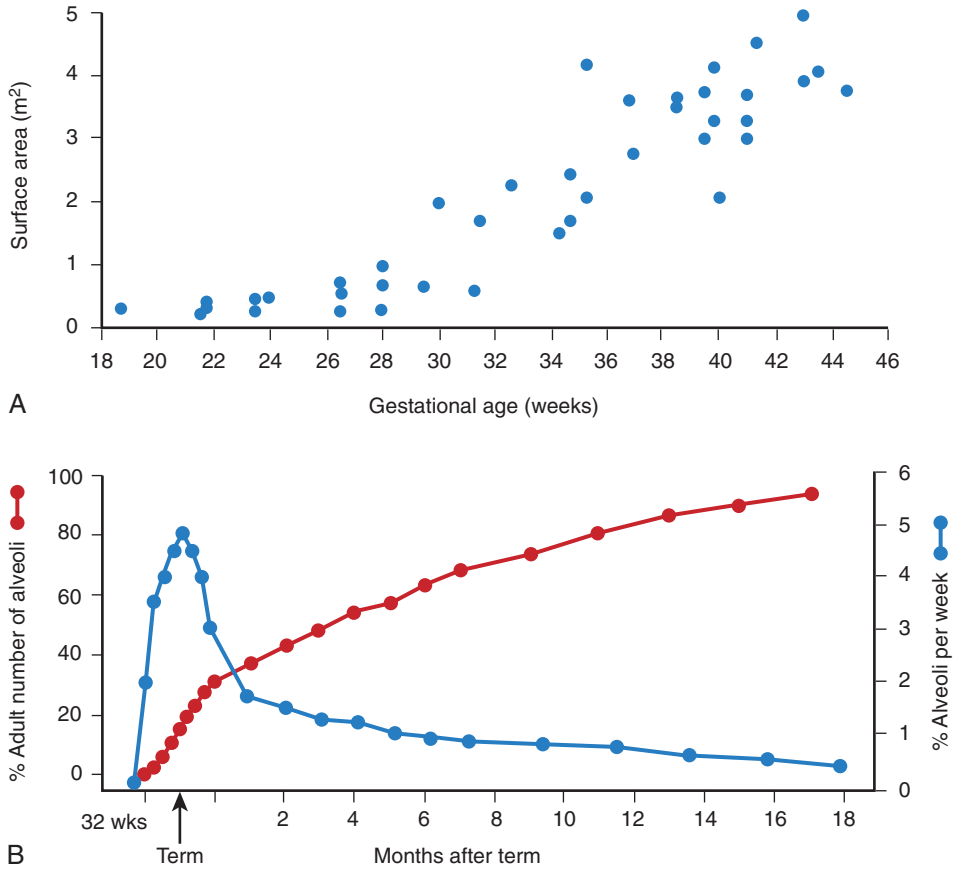
• **Fig. 62.3** Timetable for lung development. The timing of the saccular and alveolar stages and the period of microvascular maturation overlap with indeterminate initiation and endpoints. (Modified from Zolner TB, Burri PH. The postnatal development and growth of the human lung: II. Morphology. *Respir Physiol.* 1987;67:269, with permission from Elsevier Science.)



potentially viable lung that can exchange gas (Fig. 62.3).[73] The bronchial tree has completely branched, and respiratory bronchioles are forming. The three major events during this stage are the appearance of the acinus, epithelial differentiation with the development of the potential air-blood barrier, and the start of surfactant synthesis within recognizable type II cells.[10] The acinus in the mature lung is the tuft of about 6 branching generations of respiratory bronchioles, alveolar ducts, and alveoli originating from a terminal bronchiole (see Fig. 62.2). This saccular branching is the critical first step for the development of the future gas exchange surface of the lung. The mesenchyme surrounding the airways becomes more vascular and more closely approximated to the airway epithelial cells (Fig. 62.4). Capillaries initially form as a double capillary network between future airspaces and subsequently fuse to form a single capillary. With fusion of the vascular and epithelial basement membranes, a structure comparable to the adult air-blood barrier forms. If the double capillary network fails to fuse, the infant will have severe hypoxemia resulting from alveolar-capillary dysplasia. The total surface area occupied by the air-blood barrier begins to increase exponentially toward the end of the canalicular stage, with a resultant fall in the mean wall thickness and an increased potential for gas exchange.

Epithelial differentiation is characterized by proximal to distal thinning of the epithelium by transformation of cuboidal cells into thin cells that line tubes. The tubes grow both in length and in width with attenuation of the mesenchyme, which is simultaneously becoming vascularized. During the canalicular stage, many of the cells would best be characterized as intermediary cells, because they are neither mature type I nor type II epithelial cells.[71] These epithelial cells develop characteristics of mature type II cells such as lamellar bodies, supporting the concept that type I cells are derived from type II cells or intermediary cells that then further differentiate into type I cells. After about 20 weeks in the human fetus, cuboidal cells rich in glycogen begin to have lamellar bodies in their cytoplasm. The transcription factors TTF-1, FOXa1, FOXa2, and GATA 6 mediate type II cell differentiation.[71] The glycogen in type II cells provides substrate for surfactant synthesis as the lamellar body content increases. In the adult human lung, the thin type I cells occupy about 93% of the alveolar surface versus 7% for type II cells. About 8% of lung cells are type I cells, and about 16% of lung cells are type II cells.



Saccular and Alveolar Stages

The saccular stage encompasses the period of lung development during the potentially viable stages of prematurity from about 24 weeks to term. The terminal sac or saccule is the developing respiratory bronchiole or alveolar duct that is elongating, branching, and widening prior to the initiation of alveolarization at about 32 weeks in the fetal human lung.[61] Alveolarization is initiated from these terminal saccules by the appearance of septa in association with capillaries, elastin fibers, and collagen fibers (see Fig. 62.4). Shallow alveolar structures with crests (or septa) with elastin at the free margin of the crests can be identified by 28 weeks' gestation in the human. Alveolar numbers increase

• **Fig. 62.4** Development of alveolar septa and capillaries. An alveolar septum is identified by the epithelium folding over elastic fibers with subsequent elongation of the septum. Capillaries arrange themselves around epithelial tubes. The double-capillary network becomes progressively more closely associated with the epithelium of the developing airspace with subsequent loss of the double-capillary network. (Modified from Burri PW. Development and growth of the human lung. In: Fishman AP, Fisher AB, eds. *Handbook of physiology: the respiratory system*. Bethesda, MD: American Physiological Society; 1985:1, with permission.)

• **Fig. 62.5** Increases in surface area and alveoli with development. **A,** The large increase in lung surface area does not occur until after the saccular lung begins to alveolarize. **B,** Alveolar number and weekly rate of accumulation of alveoli are expressed as a percentage of the adult number of alveoli. The curves assume that the term infant has 30% of the adult number of alveoli. (**A,** Redrawn from Langston C, et al. Human lung growth in late gestation and in the neonate. *Am Rev Respir Dis.* 1984;129:607. **B,** Idealized curves based on Langston C, et al. Human lung growth in late gestation and in the neonate. *Am Rev Respir Dis.* 1984;129:607; and Hislop AA, Wigglesworth JS, Desai R. Alveolar development in the human fetus and infant. *Early Hum Dev.* 1986;13:1.)

rapidly from about 32 weeks' gestation to term when the human lung contains between about 50 and 150 million alveoli.[41] For comparison, the adult human lung has about 500 million alveoli.[52] The most rapid rate of accumulation of alveoli occurs between 32 weeks' gestational age and the first months after term delivery (Fig. 62.5). The potential lung gas volume and surface area increases from about 25 weeks' gestation to term. This increase in lung volume, and the surface area of sacculi, establishes the anatomic potential for gas exchange and thus for fetal viability. There is a wide range of lung volumes and surface areas at a given gestational age. Therefore, the gas exchange potential of different fetuses at the same gestational age will be determined in part by the structural development of the lung. Human newborns born at 22 or 23 weeks' gestation can have a sufficiently mature lung structure to support gas exchange,

indicating that structural lung maturation can be induced at very early gestational ages. Since antenatal corticosteroids increase survival at these early gestational ages, their use must support maturation of this early gestational potential for gas exchange.[11]

Alveolarization progresses rapidly from late fetal to early neonatal life. The traditional view was that alveolar development was completed by early childhood and that new alveoli do not develop in adults. Newer evidence in rats using 3-D visualization with high-resolution synchrotron radiation x-ray tomographic microscopy demonstrated that new alveoli continued to be formed well into adulthood.[62] Using hyperpolarized helium MRI, Narayanan et al. demonstrated that alveolar formation continues until at least 20 years of age.[48] This potential for continued alveolar growth explains why many preterm infants with interrupted lung development at birth can have relatively good lung function later in life.

A number of factors that can stimulate or interfere with alveolarization have been identified (Box 62.1).[39] Chronic mechanical ventilation of preterm animals using modest tidal volumes and low oxygen exposures interrupts both alveolarization and vascular development (Fig. 62.6).[13] Mechanical ventilation of the saccular lung disrupts elastin at the developing crests and induces an "arrest in development" characterized by lack of secondary crest formation and resulting in fewer and larger alveoli without much fibrosis or inflammation (Fig. 62.7).[6] Preterm infants who have died after long-term ventilation or after the development of bronchopulmonary dysplasia (BPD) also have decreased alveolar numbers and an attenuated microvasculature with less prominent airway injury and fibrosis than in the past.[5] Factors that likely contribute to this arrest of lung development include many of the components of care of preterm infants. Antenatal glucocorticoid treatments in monkeys and sheep cause thinning of the interstitium and an increased surface area for gas exchange with delayed alveolar septation. Postnatal glucocorticoid treatments of the saccular lung also interrupt alveolarization and capillary development. Hyperoxia or hypoxia and poor nutrition can interfere with alveolarization. In transgenic mice, overexpression of proinflammatory mediators in the pulmonary epithelium interferes with alveolar development. Antenatal lung inflammation associated with chorioamnionitis in sheep causes delayed alveolar and microvascular development.[72] Thus, multiple factors may contribute to delayed alveolarization in preterm infants. Because lung growth following the completion of alveolarization is by increase in airway and alveolar size, any event that decreases alveolar number could impact lung function as the individual ages. However, the growth potential of the human lung is remarkable, and infants with mild BPD had normal alveolar numbers at 10 to 14 years of age as estimated by hyperpolarized helium MRI.[47] The residual lung structural abnormalities in the lungs of infants who have survived severe BPD remain to be characterized.

Fetal Lung Fluid

The fetal airways are filled with fluid until delivery and the initiation of ventilation. Most of the information concerning quantitative aspects of fetal lung fluid is from the fetal lamb with sonographic and pathologic correlates available for the human. The fetal lung close to term contains enough fluid to maintain the airway fluid volume at about 40 mL/kg of body weight, which is somewhat larger than the FRC once air breathing is established.[43] The composition of fetal lung fluid is unique relative to other fluids in the fetal sheep and most other mammalian species.[30] The chloride content is high (157 mEq/L), whereas the bicarbonate and protein contents are very low. In contrast, the bicarbonate and chloride concentrations in fetal lung fluid from the rhesus monkey are not different from plasma values, demonstrating species differences in ion composition of fetal lung fluid. The electrolyte composition is maintained by transepithelial chloride secretion with bicarbonate reabsorption. Fetal lung fluid contains little protein, because the fetal epithelium is quite impermeable to protein. Active transport of Cl^- from the interstitium to the lumen yields a production rate for fetal lung fluid of 4-5 mL/kg per hour. Assuming the fetus is 3-4 kg, the daily production of fetal lung fluid is about 400 mL per day. Fetal lung fluid flows intermittently into the pharynx with fetal breathing movements, and some of this fluid is swallowed while the rest mixes with the amniotic fluid. The pressure in the fetal trachea exceeds that in the amniotic fluid by about 2 mm Hg, maintaining an outflow resistance and the fetal lung fluid volume. The secretion of fetal lung fluid seems to be an intrinsic metabolic function of the developing lung epithelium, because changes in vascular hydrostatic pressures, tracheal pressures, and fetal breathing movements do not greatly alter fetal lung fluid production rates.

Although normal amounts of fetal lung fluid are essential for normal lung development, its clearance is equally essential for normal neonatal respiratory adaptation.[51] Fetal lung fluid production can be completely stopped at term by vascular infusions of epinephrine at concentrations that approximate the levels of epinephrine present during labor. The epinephrine-mediated reversal of fetal lung fluid flux from secretion to reabsorption does not occur in the preterm lung. However, epinephrine-mediated clearance can be induced by pretreatment of fetal sheep with the combination of corticosteroid and triiodothyronine. Inhibition of prostaglandin synthesis with indomethacin in the fetus reduces the production of fetal lung fluid and urine. Fetal lung fluid production and volumes are maintained in the fetal sheep until the onset of labor. During active labor and delivery, fetal lung fluid volumes decrease, leaving about 35% of the fetal lung fluid to be absorbed and cleared from the lungs with breathing. Most of the fluid moves rapidly into the interstitial spaces and subsequently into the pulmonary vasculature, with less than 20% of the fluid being cleared by pulmonary lymphatics. The clearance of the fluid from the interstitial spaces occurs over many hours. Fluid clearance after birth results from active sodium transport via the epithelial sodium channel (ENaC). Genetic ablation of subunits of ENaC causes death in newborn mice because fetal lung fluid is not cleared from the lungs. Glucocorticoids upregulate the messenger RNA (mRNA) for the ENaC subunits in the fetal human lung. Transient respiratory difficulties in many infants are caused by delayed clearance of fetal lung fluid.

Pulmonary Hypoplasia

Pulmonary hypoplasia is a relatively common abnormality of lung development, with a number of clinical associations and anatomic correlates.[15] Primary pulmonary hypoplasia is unusual and is likely caused by abnormalities of the transcription factors and growth factors that regulate early lung morphogenesis, such as thyroid transcription factor-1 and FGF family members.[71] Severe forms of acinar aplasia result from abnormal regulation of lung growth and development. Secondary pulmonary hypoplasia is associated with either a restriction of lung growth or the absence of fetal breathing (Box 62.2). Any reduction of the chest cavity by a mass, effusion, or external compression can impact lung growth. Lung hypoplasia can be minimal or severe. Severe pulmonary hypoplasia associated with renal agenesis and prolonged oligohydramnios is characterized by a decrease in lung size and cell number together with narrow airways, a delay of epithelial differentiation, and surfactant deficiency. Relatively short-term oligohydramnios caused by ruptured membranes in the sixteenth to twenty-eighth week of gestation also can result in pulmonary hypoplasia; the magnitude in general correlates with the severity and length of the oligohydramnios. Infants with congenital diaphragmatic

• BOX 62.2 Clinical Associations of Pulmonary Hypoplasia

Thoracic Compression

- Renal agenesis (Potter syndrome)
- Urinary tract outflow obstruction
- Oligohydramnios before 28 weeks' gestational age
- Extra-amniotic fetal development

Decreased Intrathoracic Space

- Diaphragmatic hernia
- Pleural effusions
- Abdominal distension sufficient to limit chest volume
- Thoracic dystrophies
- Intrathoracic masses

Decreased Fetal Breathing

- Intrauterine central nervous system damage
- Fetal Werdnig-Hoffmann syndrome
- Other neuropathies and myopathies

Other Associations

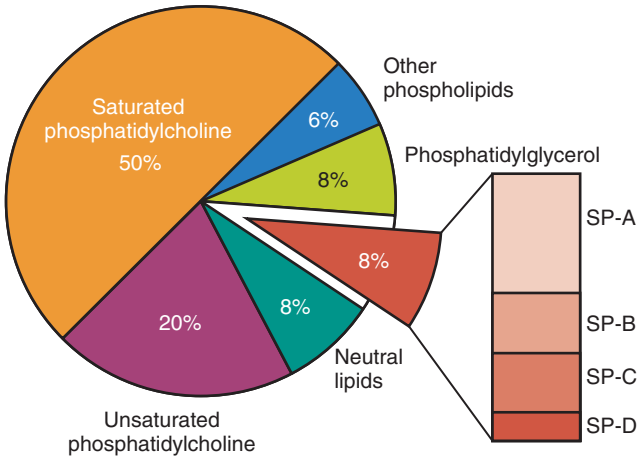
- Primary pulmonary hypoplasia
- Trisomy 21
- Multiple congenital anomalies
- Erythroblastosis fetalis

hernia have more severe hypoplasia on the ipsilateral side than on the contralateral side, although the contralateral lung also may be hypoplastic. The lungs have fewer and smaller acinar units, delayed epithelial maturation, and an associated surfactant deficiency. In experimental models, tracheal occlusion in late gestation can reverse much of the pulmonary hypoplasia resulting from diaphragmatic hernia, but the occlusion induces a decrease in type II cells and surfactant deficiency. Fetal tracheal occlusion is being introduced as a therapy for very high-risk fetuses with some success.[1]

Other Disorders of Lung Development

Congenital malformations of the lung, including the distal parenchyma, trachea–bronchial tree, and vascular structures, are relatively rare but may present with severe respiratory compromise during the neonatal period. Congenital cystic adenomatoid malformations (CCAM) are characterized by multicystic areas of over-proliferation and dilatation of terminal respiratory bronchioles with lack of normal alveoli. CCAM are intrapulmonary lesions that contain various types of epithelial linings and maintain communication with the normal trachea–bronchial tree and retain a normal blood supply. They are usually unilobar and unilateral. Stocker's classification subdivides the cysts into five categories dependent upon the size and epithelial lining of the cyst.[17]

Bronchogenic cysts are usually single, unilocular cysts filled with fluid or mucous; however, when located in the lung parenchyma they may be multiple. They are lined by pseudostratified ciliated columnar respiratory epithelium and contain hyaline cartilage plates. Bronchogenic cysts most commonly occur in the mediastinum, although they may occur anywhere throughout the thoracic cavity or elsewhere. When located in lung parenchyma or alongside airways, there is no communication between the cysts and the trachea–bronchial tree.[17] Congenital lobar emphysema is identified as hyperinflation of one or more pulmonary lobes and leads compression of surrounding structures. This compression may lead to mediastinal shift. Most commonly, the left upper or right middle lobes are affected.[17] Pulmonary sequestrations are portions of the lung that are in isolation from neighboring lung tissues and with no communication to the bronchial tree. Pulmonary sequestrations receive blood supply from a systemic artery, and venous drainage may occur through either a pulmonary or systemic vein. Pulmonary sequestrations can be divided into two categories: intralobar (15%) and extralobar sequestrations (85%).



Alveolar capillary dysplasia with misaligned pulmonary veins is a rare and lethal congenital malformation of the lung that involves both acinar structure and intrinsic pulmonary vasculature. A majority of infants with this disorder have mutations in the *FOXF1* gene, with abnormal development of the capillary vascular system around the alveoli of the lungs. The characteristic pathologic finding is misaligned pulmonary veins located with the pulmonary artery with medial hypertrophy in the same adventitial sheath.[63] Although 60%-80% of the infants have extrapulmonary abnormalities, the characteristic presentation is severe persistent pulmonary hypertension unresponsive to therapy. Congenital acinar dysplasia (CAD) is a very rare form of primary interstitial lung disease characterized by diffuse bilateral impairment of pulmonary acini (the respiratory bronchioles, alveolar ducts, and alveoli). Most cases are fatal.[59]

Alveolar Macrophages

The sentinel immune cells of the lung are alveolar macrophages. In adult humans and animals these cells are located in the airspaces directly in contact with the alveolar hypophase. Alveolar macrophages derived from monocytes from the circulation take residence in the lung. Local cues and growth factors including GM-CSF and the transcription factor PU.1 differentiate these monocytes to alveolar macrophages.[46] Once differentiated, alveolar macrophages do not recycle and have a relatively long life span under normal conditions. Important functions of alveolar macrophages include immune surveillance, phagocytosis of invading microorganisms, antigen presentation, interactions with adaptive immune cells, and surfactant homeostasis.

Fetuses do not normally have alveolar macrophages. In nonhuman primates and sheep, very few macrophages are found in the fetal lung.[38] Alveolar macrophages begin to populate the lung in large numbers postnatally with the onset of air breathing. Exposure to chorioamnionitis—an

PC, Phosphatidylcholine; Sat, saturated.

infection in the amniotic fluid and fetal membranes—can mature the lung macrophages and stimulate their migration into the fetal alveolar spaces.

Surfactant Metabolism

Composition

Surfactant recovered from lungs of all mammalian species by alveolar wash procedures contains 70%-80% phospholipids, about 8% protein, and about 10% neutral lipids, primarily cholesterol (Fig. 62.8). The composition of the phospholipids in surfactant is unique relative to the lipid composition of lung tissue or other organs. About 60% of the phosphatidylcholine species are saturated, meaning that both fatty acids esterified to the glycerol phosphorylcholine backbone are predominantly the 16-carbon saturated fatty acid, palmitic acid. Most other phosphatidylcholine species in surfactant have a fatty acid with one double bond in the two position of the molecule. Saturated phosphatidylcholine is the principal surface-active component of surfactant and can be used as a relatively specific probe of surfactant metabolism. The acidic phospholipid phosphatidylglycerol is present in surfactant in small amounts that vary between 4% and 15% of the phospholipids in different species (Table 62.1). Surfactant phospholipids from the immature fetus or newborn contain relatively large amounts of phosphatidylinositol, which then decrease as phosphatidylglycerol appears with lung maturity.[24] Phosphatidylglycerol in amniotic fluid can be measured as a test for lung maturity. The surfactant from the preterm lung is qualitatively inferior relative to surfactant from the mature lung when tested for in vivo function than is surfactant from term newborns.[32]

There are four relatively surfactant-specific proteins.[70] SP-A is a water-soluble 24-kDa collectin that is heavily glycosylated in the carboxy-terminal region with blood group antigen as well as other carbohydrate moieties to yield a protein of about 36 kDa. SP-A monomers contain a collagen domain and form a collagen-like triple helix that then aggregates to form a multimeric protein with a molecular size of 650 kDa. SP-A contributes to the biophysical properties of surfactant primarily by decreasing protein-mediated inhibition of surfactant function. Mice that lack SP-A have no tubular myelin but have normal lung function and surfactant metabolism, indicating that SP-A is not critical to regulation of surfactant metabolism. The major function of SP-A is as an innate host defense protein and as a regulator of inflammation in the lung.[37] SP-A binds to multiple pathogens such as group B streptococcus, *Staphylococcus aureus*, and herpes simplex type 1. The protein facilitates phagocytosis of pathogens by macrophages and their clearance from the airspace. SP-A can prevent influenza virus infection and decrease the inflammation caused by adenovirus. Patients with a deficiency of SP-A have not been identified, although polymorphisms in SP-A are associated with increased risk for RDS, BPD, and viral bronchiolitis.[23] SP-A levels are low in surfactant from preterm lungs and increase with corticosteroid exposure. SP-A is not a component of surfactants used for treatment of RDS.

SP-B and SP-C are two small hydrophobic proteins that are extracted with the lipids from surfactant by organic solvents. These proteins contribute about 2%-4% to the surfactant mass.[70] The primary translation product of SP-B is 40 kDa, from which SP-B is clipped to become an 8-kDa protein before it enters lamellar bodies for co-secretion with the phospholipids from the type II cell. SP-B facilitates surface absorption of lipids and low surface tensions on surface area compression. Animals with antibodies to SP-B develop respiratory failure, and infants with a genetic absence of SP-B have lethal respiratory failure after term birth. The genetic absence of SP-B is most frequently caused by a two base-pair insertion (121 ins 2) resulting in a frameshift and premature termination signal resulting in a

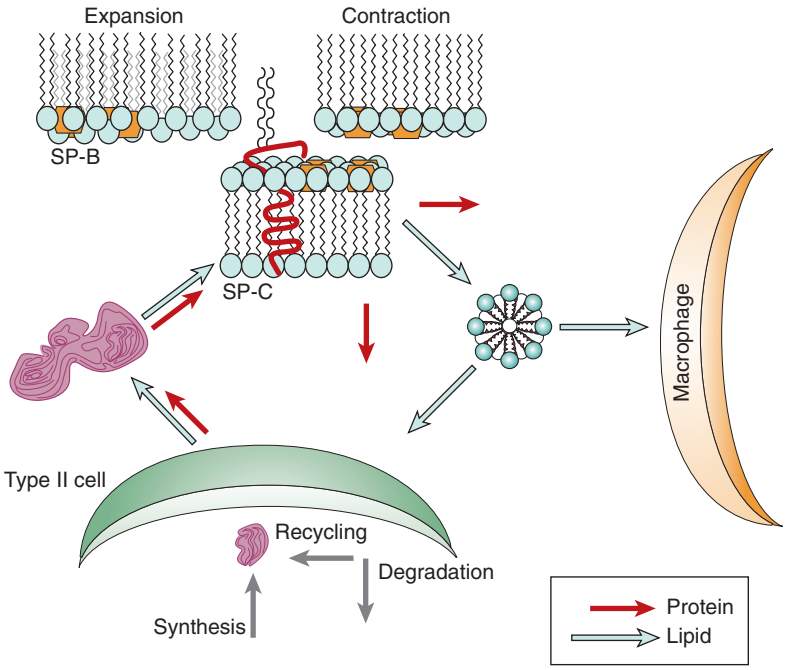
complete absence of SP-B. Multiple other mutations resulting in complete or partial SP-B deficiencies have been described.[50] The lack of SP-B causes a loss of normal lamellar bodies in type II cells, a lack of SP-C, and the appearance of incompletely processed SP-C in the airspaces. These pro-SP-C forms are diagnostic of SP-B deficiency. Respiratory failure develops in mice that have less than about 20% of the normal amount of SP-B.[28]

The primary translation product of SP-C is a 22-kDa protein that is processed to an extremely hydrophobic 4-kDa protein that is associated with lipids in lamellar bodies.[70] The mRNA for SP-C appears in cells lining the developing airways from early gestation. With advancing lung maturation, the mRNA for SP-C becomes localized only to type II cells. Although the sequence and cellular localization of the protein have been remarkably conserved across species, mice that lack SP-C have normal lung and surfactant function at birth. However, the mice develop progressive interstitial lung disease and emphysema as they age. Infants with a progressive interstitial lung disease can lack SP-C, as can large kindreds of patients with the onset of interstitial lung disease at variable ages.[50] These patients generally do not have genetic alterations in the coding region of the protein but have dominant negative mutations that disrupt the processing of SP-C. SP-B and SP-C probably work cooperatively to optimize rapid adsorption and spreading of phospholipids on a surface and to facilitate the development of low surface tensions on surface area compression. Surfactants prepared by organic solvent extraction of natural surfactants or from lung tissue contain variable amounts of SP-B and SP-C. Such surfactants are similar to natural surfactants when evaluated for in vitro surface properties or for function in vivo.[54] Surfactant recovered from preterm animals has low amounts of SP-B and SP-C, which may, in part, explain its poor function.[67]

SP-D is a hydrophilic protein of 43 kDa that is a collectin with structural similarities to SP-A.[70] It has a collagen-like domain as well as a glycosylated region that gives it lectin-like functions. This protein is synthesized by type II cells and Clara cells as well as in other epithelial sites in the body. Like the other SPs, its expression is developmentally regulated by glucocorticoids and inflammation. SP-D is a large multimer that functions as an innate host defense molecule by binding pathogens and facilitating their clearance. The absence of SP-D results in increased surfactant lipid pools in the airspaces and emphysema but no major deficits in surfactant function in mice. The addition of SP-D to a surfactant used to treat preterm lambs decreased the ventilator-mediated inflammation.[60] No humans with SP-D deficiency have been described.

The incidences of genetic abnormalities of the surfactant system are not well known. A report of more than 300 term infants with severe RDS found about 14% had SP-B deficiency. A deficiency of the ATP-binding cassette transporter gene *ABCA3* was more common.[7] This *ABCA3* gene product is localized to lamellar bodies and functions as a lipid transporter. The clinical presentation of ABCA3 deficiency is very much like SP-B deficiency. Some of the lethal RDS in term infants is explained by mutations in genes essential for surfactant metabolism. However, other infants with respiratory failure probably have yet-to-be-identified mutations in genes that disrupt other aspects of lung development.



Synthesis and Secretion

The type II cell is responsible for the major pathways involved in surfactant metabolism (Fig. 62.9). The synthesis and secretion of surfactant is a complex sequence of biochemical synthetic events that results in the release by exocytosis of the lamellar bodies to the alveolus. The basic pathways for the synthesis of phospholipids are common to all mammalian cells. Specific enzymes within the endoplasmic reticulum use glucose, phosphate, and fatty acids as substrates for phospholipid synthesis. The uniqueness of a phospholipid is determined by the character of the fatty acid side chains esterified to the glycerol carbon backbone and by the head group (e.g., choline, glycerol, and inositol) linked to the phosphate. Although the overall synthetic pathways are known, the details of how the components of surfactant condense with SP-B and SP-C to form the surfactant lipoprotein complex within lamellar bodies remain obscure. Ultrastructural abnormalities of type II cells with SP-B deficiency and ABCA3 deficiency in term infants indicate that these gene products are critical to lamellar body formation.[70] If SP-B is absent, lamellar bodies are abnormal, and SP-C is not processed correctly. Normal surfactant secretion can be stimulated by a number of mechanisms. Beta-agonists and purines such as adenosine triphosphate are potent stimulators of surfactant secretion. Surfactant secretion also is stimulated by mechanical stretch such as with lung distention and hyperventilation. The surfactant secretion that occurs with the initiation of ventilation following birth probably results from the combined effects of elevated catecholamines and lung stretch.

Surfactant Pool Sizes

Following the observation of Avery and Mead that saline extracts of the lungs of infants with RDS had high minimum surface tensions,[3] decreased alveolar and tissue surfactant pools were demonstrated in preterm animals. Increasing surfactant pool sizes correlate with improving compliances during development, although other factors such as structural maturation also influence compliance. Infants with RDS have surfactant pool sizes on the order of about 5 mg/kg of body weight. Preterm lambs with RDS can be managed with continuous positive airway pressure if their surfactant pool sizes exceed about 4 mg/kg.[45] The quantity of surfactant recovered from the airspaces of infants with RDS is not much less than the amount of surfactant found in the alveoli of healthy adult animals or humans. However, much less surfactant is recovered from preterm than healthy term animals, who have surfactant pool sizes of about 100 mg/kg of body weight.[32] The large amount of

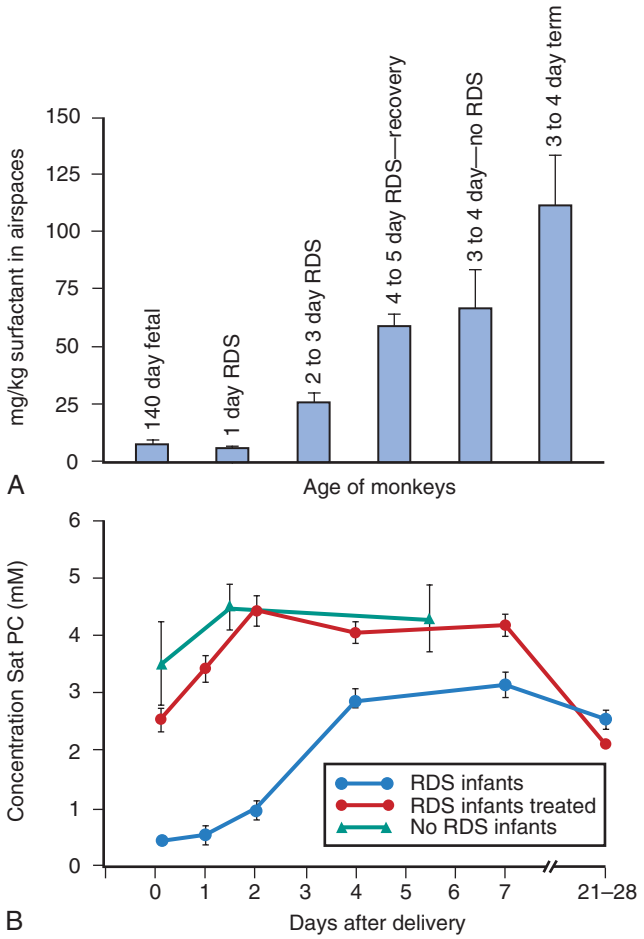
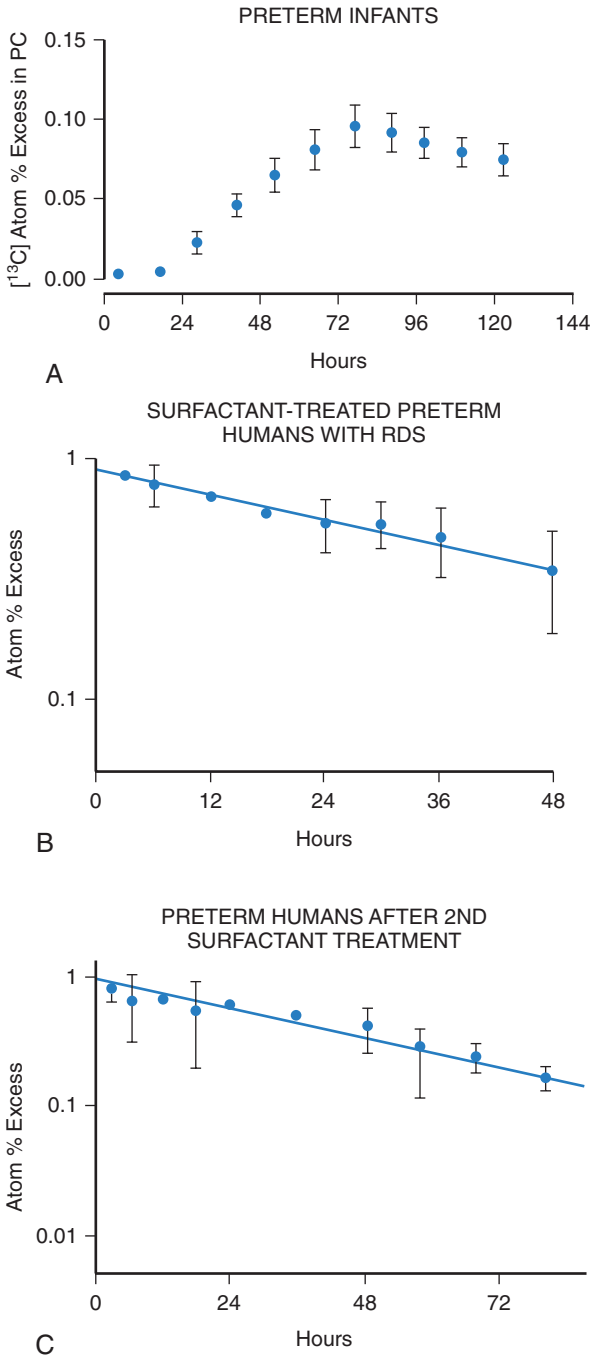
• **Fig. 62.9** Surfactant metabolism in the type II cell in the alveolus. The lipid-associated surfactant proteins B (SP-B) and SP-C track with the lipid from synthesis to secretion and surface film formation. The small vesicular forms of surfactant do not contain SP-B or SP-C.



surfactant in amniotic fluid in the human at term indicates that the term human fetal lung also has large pool sizes. Both the quantity and the quality of the surfactant from the preterm together with inhibition of surfactant function contribute to the deficiency state. The clinical observation that many preterm infants and animals respond remarkably to surfactant treatment supports the conclusion that in many infants surfactant deficiency is the primary problem. The endogenous pool sizes of surfactant that are sufficient for good lung function are lower than for treatment doses of surfactant, probably because the endogenous surfactant is optimally distributed and treatment doses of surfactant are not distributed uniformly at the alveolar level.

The rate of increase in the pool size of alveolar surfactant after preterm birth was measured in ventilated preterm monkeys recovering from RDS (Fig. 62.10).[29] The surfactant pool size increased toward the 100 mg/kg value measured in term monkeys within 3-4 days. Hallman and colleagues measured the concentration of saturated phosphatidylcholine in airway samples from infants recovering from RDS and compared the results with values for infants without RDS and for surfactant-treated infants.[25] The concentration of saturated phosphatidylcholine increased over a 4- to 5-day period to become comparable with values for normal or surfactant-treated infants. This slow increase in pool size is consistent with a clinical course of RDS of 3-5 days without surfactant treatment. The explanation for why surfactant pool sizes increase slowly after preterm birth is apparent from measurements of the kinetics of surfactant secretion and clearance in the newborn (Fig. 62.11). Following the intravascular injection of radiolabeled precursors of surfactant phosphatidylcholine, incorporation into lung phosphatidylcholine is rapid. However, there are long time delays between synthesis and the movement of surfactant components from the endoplasmic reticulum through the Golgi apparatus to lamellar bodies for eventual secretion. Phosphatidylcholine secretion was measured in human infants with RDS using intravascular infusions of the glucose and palmitic acid precursors labeled with stable isotopes.[8,9] Glucose-labeled phosphatidylcholine was detected in the airway samples after about 20 hours, and peak enrichment of the stable isotope occurred at about 70 hours. Therefore, delays between synthesis and secretion and the interval to peak airway accumulation of endogenously synthesized surfactant lipid are long in the preterm human.[14]



The slow secretion and alveolar accumulation of surfactant are balanced in the term and preterm lung by slow catabolism and clearance. Trace amounts of stable isotope labeled surfactant phospholipid given into the airspaces with treatment doses of surfactant to infants with RDS had half-life values of several days.[66] Trace or treatment doses of surfactant given into the airspaces do not remain static in the airspaces. The surfactant phospholipids move from the airspaces back to type II cells, where they are taken up by an endocytotic process into multivesicular bodies. In the term and preterm lung, about 90% of the phospholipids are recycled back to lamellar bodies and re-secreted to the airspace. The phospholipids are recycled as intact molecules without degradation and resynthesis. In the adult lung, this process is perhaps only 50% efficient.

The metabolic characteristics of surfactant phospholipids in the preterm are favorable for surfactant treatment strategies.[32] Alveolar and tissue pool sizes are small, and the rate of accumulation is slow. Treatment acutely increases both the alveolar and tissue pools, because the exogenously administered saturated phosphatidylcholine is taken up into type II cells and processed for re-secretion. The surfactants

used clinically are not equivalent in function to native surfactant in the mature lung. However, within hours following surfactant treatment of preterm animals, the surfactant recovered by alveolar wash has improved function, indicating that the preterm lung, if uninjured, can transform the surfactant used for treatment with poor function into a good surfactant.[67] Also of benefit is the slow catabolic rate of the lipid components of surfactant. This characteristic of the system means that the surfactant used for treatment remains in the lungs and is not rapidly degraded. Infants treated with surfactant can be extubated earlier if they maintain higher surfactant pool sizes.[68] Treatment doses of surfactant do not feedback-inhibit the endogenous synthesis of

saturated phosphatidylcholine or the surfactant proteins. No adverse metabolic consequences of surfactant treatment on the endogenous metabolism of surfactant or other lung functions have been identified.

There is less information about the metabolism of the surfactant proteins in the preterm lung. SP-A, SP-B, and SP-C all seem to be recycled to some degree from the airspace back into lamellar bodies for re-secretion with surfactant.[32] All three proteins have alveolar clearance kinetics that are similar to saturated phosphatidylcholine in the preterm lung. Therefore, the critical surfactant components are conserved by recycling. The presumed function of the recycling pathways is to reassemble the components to regenerate biophysically active surfactant. SP-B and SP-C enter the lamellar bodies during their biogenesis in parallel with the phospholipids. In contrast, de novo synthesized SP-A is secreted independently of the lamellar bodies. This protein then associates with the phospholipids to form tubular myelin in the airspace. Lung injury of the preterm results in abnormalities in surfactant metabolism and function.

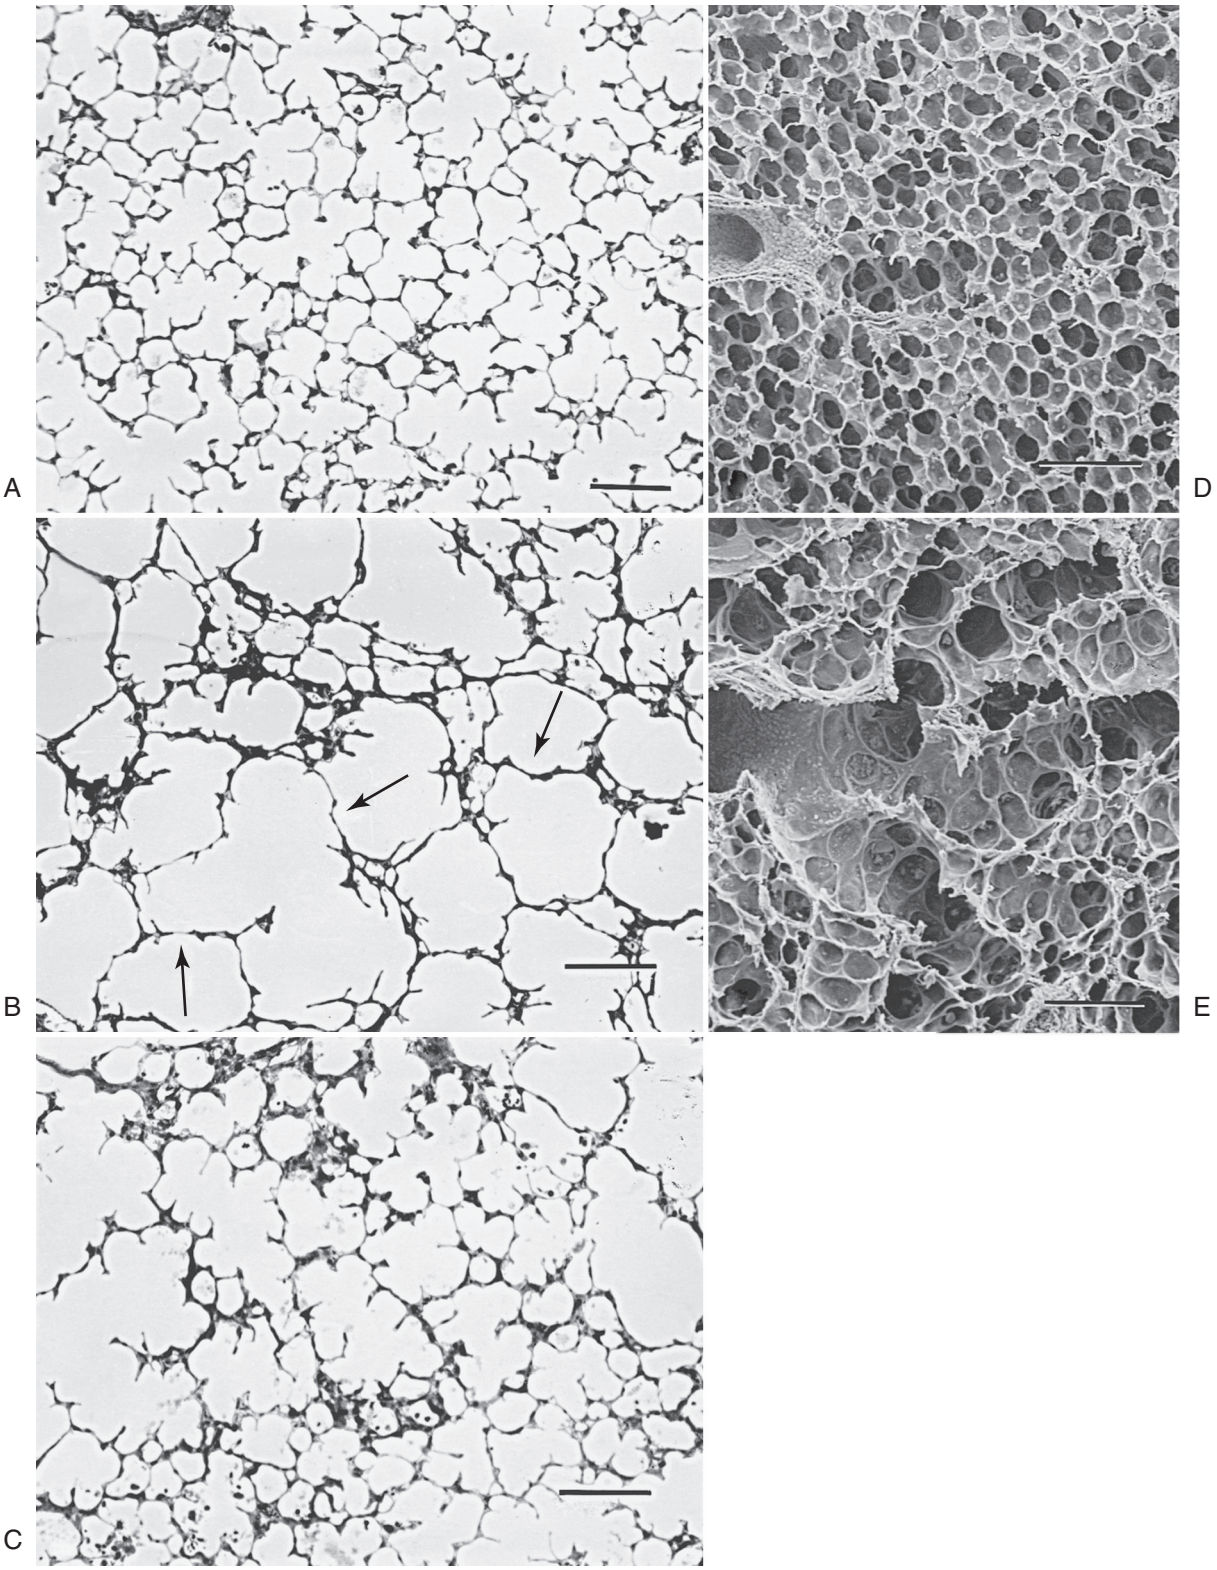
Alveolar Life Cycle of Surfactant

After secretion as lamellar bodies, surfactant goes through a series of form transitions in the airspace.[32] The lamellar bodies "unravel" into an elegant structure called *tubular myelin.* This lipoprotein array has SP-A at the corners of the lattice and requires at least SP-A, SP-B, and the phospholipids for its unique structure. Tubular myelin and other surfactant lipoprotein arrays are the reserve pool in the fluid hypophase for the formation of the surface film within the alveolus and small airways. Area compression of this film then squeezes out unsaturated lipid and some protein components of surfactant with concentration of saturated phosphatidylcholine in the surface film. New surfactant enters the surface film and "used" surfactant leaves in the form of small vesicles, which then are cleared from the airspaces. The major difference in composition between the surface-active tubular myelin and loose lipid arrays and the small vesicular forms is that the small forms contain little SP-A, SP-B, or SP-C. Although a complete surfactant contains multiple lipid and protein components, all of the components are not essential for biophysical function. Surfactants for treatment work well despite lacking some components of native surfactant.

Just preceding and following birth, lamellar bodies are secreted to yield an alveolar pool that is primarily lamellar bodies and tubular myelin. This surfactant then begins to function with aeration of the lung. As the newborn goes through neonatal transition, the percentage of surface active forms falls as the small vesicular forms increase. At equilibrium, approximately 50% of the surfactant in the airspaces is in a surface-active form and 50% is in the inactive vesicular form.[67] The vesicular forms of surfactant are believed to be the pools used for recycling of the phospholipid components of surfactant. The total surfactant pool size is not equivalent to the amount of active surfactant. In the preterm, conversion from surface active to inactive surfactant forms occurs more rapidly. Pulmonary edema can further accelerate alveolar conversion, with the net result being a depletion of the surface-active fraction of surfactant despite normal or high total surfactant pool sizes.

Physiologic Effects of Surfactant in the Preterm Lung

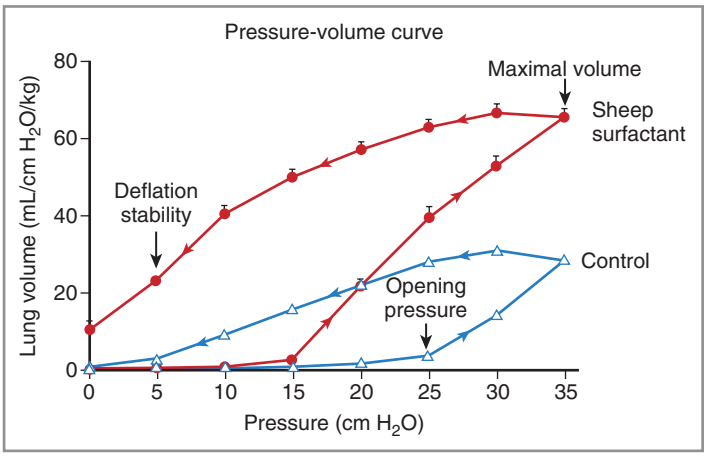
Alveolar Stability



The air-exposed surfaces of alveoli are complex polygonal shapes that are interdependent in that their structures are determined by the shapes and elasticity of neighboring alveoli and airways. The forces acting on the pulmonary microstructure are chest wall elasticity, lung tissue elasticity, and surface tensions of the air-fluid interfaces in the small airways and alveoli. Although the surface tension of surfactant decreases with surface area compression and increases with surface area expansion, the surface area of an alveolus changes very little with tidal breathing. The low surface tensions resulting from surfactant help prevent alveolar collapse and keep interstitial fluid from entering the alveolus. Surfactant also keeps small airways from filling with fluid to cause luminal obstruction.[18] If alveoli collapse or fill with fluid, the shape of adjacent alveoli will change, which may result in regional distortion, overdistention, or collapse. When positive pressure is applied to a surfactant-deficient lung, the more normal alveoli tend to overexpand and the less normal (i.e., less surfactant) alveoli collapse, generating a nonhomogeneously inflated lung (Fig. 62.12).[53] Surfactant treatment can normalize alveolar size.

Pressure-Volume Curves

The effects of surfactant on the preterm surfactant-deficient lung are demonstrated by pressure-volume relationships during quasistatic inflation and deflation (Fig. 62.13).[55] The pressure needed to open a lung unit is related to the radius of curvature and surface tension of the meniscus of fluid in the airspace leading to the lung unit. In the collapsed or fluid-filled lung, there are different units with different radii. The units with larger radii and lower surface tensions "pop" open first because, with partial expansion, the radius increases and the forces needed to finish opening the unit decrease. The movement of fluid with high surface tensions in the airways causes very high sheer forces that can disrupt the airway epithelium.[33] Preterm surfactant-deficient rabbit lungs do not begin to inflate until pressures exceed 25 cm H_2O. With surfactant treatment, the fluid menisci in the airways have lower surface tensions that decrease the opening pressure from about 25 to 15 cm H_2O in this example with preterm rabbit lungs. The subsequent inflation is more uniform as more units open at lower pressures, resulting in less epithelial injury and overdistention of the open units.



A particularly important effect of surfactant on the surfactant-deficient lung is the increase in maximal volume

• **Fig. 62.13** Pressure-volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated preterm rabbit lungs. The control lungs are from 27-day preterm rabbits. Surfactant deficiency is indicated by the high opening pressure, the low maximal volume at a distending pressure of 35 cm H_2O, and the lack of deflation stability at low pressures on deflation. In contrast, treatment of 27-day preterm rabbits with a natural surfactant alters the pressure-volume relationships. (From Creasy RK, et al., eds. *Creasy & Resnik's maternal-fetal medicine*. 6th ed. Philadelphia: Elsevier; 2009:201.)

at maximal pressure. In the example in Fig. 62.13, maximal volume at 35 cm H_2O is increased about 2.5-fold by surfactant treatment to a volume that is similar to that achieved in a term newborn rabbit lung. The opening pressures for many distal lung units in the surfactant-deficient lung exceed 35 cm H_2O and exceed the rupture pressure of the preterm lung. This volume difference resulting from surfactant treatment is lung volume that improves gas exchange, because it is primarily alveolar gas volume. Lung volume recruitment is achieved rapidly with surfactant treatment. Another important effect of surfactant is the stabilization of the lung on deflation. The surfactant-deficient lung collapses at low transpulmonary pressures, whereas the surfactant-treated lung retains about 40% of the lung volume on deflation to 5 cm H_2O, which is the static volume equivalent of functional residual capacity.

Dynamic lung mechanics also are altered by surfactant treatments. Time constants for deflation increase, resulting in less effective lung emptying. The clinical correlate is that a surfactant treatment may increase the FRC of infants with RDS by two mechanisms: the improved deflation stability and the longer expiratory time constant. The consistent initial response of infants with RDS to surfactant treatments is a rapid improvement in oxygenation, whereas improvements in P_{CO_2}, compliance, and, therefore, ventilatory support variables tend to change more gradually. Improved oxygenation without changes in ventilation results from the acute increase in lung volumes following surfactant treatments.

Lung Maturation

Surfactant Appearance With Development

Lamellar bodies first appear within type II cells by 20-24 weeks' gestation in the human fetus, and the amount of saturated phosphatidylcholine increases in lung tissue to term. This early presence of surfactant within human fetal lung tissue is consistent with the clinical experience that some infants born as early as 23 weeks' gestation have little lung disease. Lung maturity as defined by the absence of RDS in the human fetus is generally present after 35 weeks' normal gestation. Therefore a 12-week window of "early maturation" is possible for the human, at least in part because the surfactant synthetic and storage machinery is inducible in the human early in gestation.

The tests for fetal lung maturation depend on surfactant components in amniotic fluid reflecting the status of surfactant in the fetal lung. The lung secretes fetal lung fluid and any surfactant released into that lung fluid. The flow of fluid out of the lung is the episodic balance between fetal swallowing and loss of fetal lung fluid to the amniotic cavity. The amniotic fluid can be characterized as the fetal cesspool, containing all fetal excretions as well as desquamated cells and other biologic matter.[12] Tests of lung maturation depend on the flow of fetal lung fluid into the amniotic fluid being sufficient to change amniotic fluid composition in a timely manner relative to the fetal lung maturation. A remarkable aspect of the human fetus is the extraordinary inducibility of lung maturation at early gestational ages.

Tests of lung maturation with amniotic fluid have been developed to identify fetuses with early lung maturation. These tests include the L/S ratio of lecithin to sphingomyelin, measurements of phosphatidylglyceral as a relatively unique component of surfactant, assessments of surface activity by bubble stability test, measurements of lamellar body numbers, and several commercial tests. Obstetric practice seldom uses lung maturation tests currently, because decisions about delivery are based on clinical assessments of the mother and fetus. If preterm delivery is likely then antenatal corticosteroids are used routinely. However, amniotic fluid can in theory be used to assess the maturational status of multiple fetal organ systems using protein or mRNA analysis. New tests of fetal studies based on amniotic fluid may become of value clinically.[35,58]

Induced Lung Maturation

The incidence of RDS needs to be interpreted within the context of maturational phenomena that occur spontaneously in the preterm. Most infants destined to deliver at term do not have mature lungs until about 36 weeks'

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

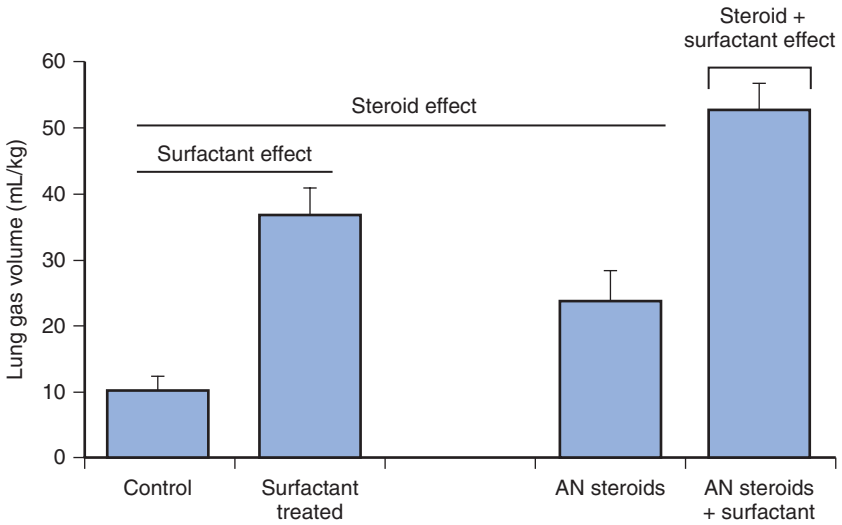
gestational age. Although the incidence of RDS in clinical practice increases as gestational age decreases, the incidence of RDS is not easily defined because of variable definitions and the effect of different clinical care strategies on the diagnosis of RDS. For example, from 1997-2002, the NICHD Neonatal Research Network defined RDS as the need for oxygen and some ventilatory support, plus a compatible chest roentgenogram. With this definition, the incidence of RDS for infants less than 1 kg was 63%.[19] For 2003-2007, the definition was changed to the use of supplemental oxygen for more than 6 hours, and 95% of similar infants now had a diagnosis of RDS.[64] In contrast, only about 50% of infants with birth gestations less than 28 weeks that are initially supported with CPAP have sufficient RDS to receive surfactant.[4] If the use of surfactant is a surrogate for significant RDS, then many very early gestation infants did not have severe RDS. Biologically, this indicates that induced lung maturation is frequent. This spontaneous early lung maturation in the human fetus is believed to result from stress-induced maturation events that can be maternal, placental, or fetal in origin. However, despite fetal stress, fetal growth restriction or preeclampsia do not induce lung maturation.

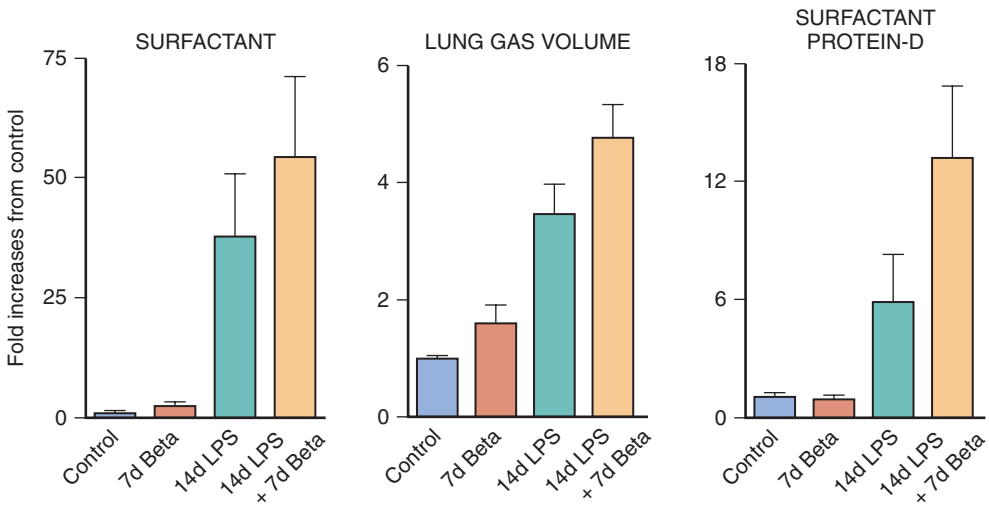
The changing epidemiology of RDS results in part from the more frequent use of antenatal glucocorticoids and a change in obstetric practices to delay preterm delivery as long as possible. Numerous clinical trials have documented that maternal corticosteroid treatments decrease the incidence of RDS by about 50%, and those infants with RDS tend to have less severe disease. Chronic infection and fetal exposure to inflammation and histologic chorioamnionitis are frequent in those pregnancies with preterm labor between 22 and 30 weeks' gestation[21] and are associated with a decreased incidence of RDS. In experimental models, bacterial endotoxin, the proinflammatory cytokine interleukin-1 (IL-1), or fetal exposure to live ureaplasma induce lung maturation when given by intra-amniotic injection.[39] Fetal proinflammatory exposures induce striking increases in surfactant and improvements in postnatal lung function after preterm delivery of lambs without increasing fetal cortisol levels.[40] Therefore fetal exposure to inflammation may have the short-term benefit of decreasing RDS. Prematurity cannot be considered a normal condition. It is useful to think of the infant with RDS as the normal unstressed preterm, whereas the preterm without RDS has experienced a stress sufficient to induce lung maturation.

Glucocorticoids and Lung Maturation



The events resulting in spontaneous early lung maturation in the human have not been well characterized. Explants of human lung at 14-20 weeks' gestational age differentiate in organ culture in the absence of hormonal stimuli, and agents such as corticosteroids and thyroid hormones accelerate maturation.[44] Several agents, such as insulin and transforming growth factor-β, tend to block lung maturation, and androgens delay maturation. Because about half of corticosteroid-treated fetuses do not seem to respond, it is reasonable to propose that fetal lung maturation normally is suppressed in favor of growth. If this suppression is released by stress-related signals, then the lung is susceptible to either endogenously mediated maturational signals or to exogenous effectors. Corticosteroids are one of the categories of agents that can influence lung maturation; however, other agents also can influence lung maturation. The inducing agents can act additively or synergistically in terms of both the timing and the magnitude of the response in experimental models.

The responses of the fetal lung to corticosteroids are multiple and impact many different systems that could influence the clinical outcome.[36] Corticosteroids induce lung structural maturation by increasing the surface area and lung volumes for gas exchange. Type II cell maturation has been noted primarily in vitro. Biochemical markers of maturation include glycogen loss from type II cells, increased fatty acid synthesis, increased β-receptors, and increased choline incorporation into surfactant phosphatidylcholine. In vivo, animals demonstrate improved lung function and survival. Corticosteroid treatment also decreases the tendency of the preterm lung to develop pulmonary edema. The primary effect of corticosteroids on the fetal lung is generally considered to be induction of surfactant synthesis. However, effects on enzymes in the synthetic pathway have not been consistently demonstrated, and surfactant pool sizes do not increase until more than 4 days after maternal glucocorticoid treatments in sheep.[31] Lung function can improve following corticosteroid treatments, even if surfactant is not increased, because of changes in lung structure. In preterm animal models, corticosteroid treatment changes the dose-response curve such that less surfactant is needed to cause larger clinical responses. Because of increased lung volume, corticosteroid-treated fetuses also have improved responses to postnatal surfactant (Fig. 62.14).[27] There are additive or synergistic effects between the corticosteroid-exposed lungs and surfactant treatments.



Antenatal corticosteroid treatment is now the standard of practice for pregnancies at risk of preterm delivery.[56] This therapy is effective and safe, although there is not long-term follow-up data for infants born before 28 weeks' gestation. Repetitive courses of antenatal glucocorticoids have been given at 7- to 10-day intervals, a practice based on the suggestion that the fetal benefit was lost after this interval.[31] Maternal glucocorticoid treatments at 7-day intervals in sheep cause fetal growth restriction but augment lung maturation. Randomized trials in women at risk for preterm delivery demonstrate modest benefit, but there is some concern about longer-term outcomes, especially for infants exposed to four or more antenatal doses of antenatal corticosteroids.[16]

The only other lung maturation strategy that has been extensively evaluated clinically is the combination of corticosteroids and thyrotropin-releasing hormone (TRH). Thyroid axis hormones induce lung maturation and can act synergistically with corticosteroids in vitro. Thyroid

• **Fig. 62.14** Combined effects of corticosteroids and surfactant treatments on lung volumes of ventilated preterm lambs. Fetal sheep were exposed to saline or corticosteroids and then randomized to treatment with surfactant prior to a short period of ventilation. The gas volume of the lung at a static pressure of 40 cm H_2O is given as mL/kg. Both antenatal corticosteroids and surfactant increased the lung gas volumes, and both treatments had a larger effect. AN, Antenatal. (Modified from Ikegami, et al. Corticosteroid and thyrotropin-releasing hormone effects on preterm sheep lung function. *J Appl Physiol.* 1991;70:2268-2278.)

• **Fig. 62.15** Combined responses of the fetal sheep lung to antenatal corticosteroids and intra-amniotic *E. coli* lipopolysaccharide (LPS). Fetal sheep were exposed to maternal betamethasone treatments (Beta) or intra-amniotic LPS as an inflammatory mediator that causes chorioamnionitis at 7- or 14-day intervals before preterm delivery. All values are normalized to a value of 1 for the control. The changes in the amount of surfactant lipids, lung gas volume, and surfactant protein-D were larger with the LPS exposure, and both exposures further increased the markers of lung maturation. (Modified and redrawn from Kuypers, et al. Intra-amniotic LPS and antenatal betamethasone: inflammation and maturation in preterm lamb lungs. *Am J Physiol Lung Cell Mol Physiol.* 2011;302:L380.)

hormones do not cross the human placenta efficiently, but the tripeptide TRH crosses to the fetal circulation and increases fetal thyroid hormone levels. Unfortunately, when evaluated in large randomized controlled trials, TRH demonstrated no benefit and possible risks were identified.[2] Therefore, the use of TRH to supplement antenatal corticosteroid therapy is not recommended.

Intrauterine Infection and Lung Maturation

As noted earlier, fetal exposure to chorioamnionitis also can induce lung maturation. In experimental models, intra-amniotic endotoxin or IL-1 will induce more striking lung maturation than will maternal corticosteroid treatments (Fig. 62.15).[40] The inflammatory mediators trigger lung

maturation by direct contact with the fetal lung and induce a modest lung inflammation/injury response that resolves with large improvements in lung mechanics and increased surfactant lipid and protein pool sizes.[34] Of clinical relevance, the maturational effects of maternal corticosteroids and chorioamnionitis seem to be additive for induced lung maturation.[49] The corticosteroids can suppress inflammation initially, but the inflammatory response is amplified in the fetal sheep at later times, perhaps because corticosteroids mature fetal innate immune responses. In clinical practice, ruptured membranes, a surrogate for chorioamnionitis, are not a contraindication to maternal corticosteroid treatment.[26]

This chapter focuses on the lung. However, maturation of other organs occurs in parallel in most fetuses. Other organs also are sensitive to corticosteroids and other agents. Maternal corticosteroid treatments not only decrease the incidence and severity of RDS but also decrease the incidence of patent ductus arteriosus, intraventricular hemorrhage, and necrotizing enterocolitis and increase kidney tubular function and postnatal blood pressure. Therefore, strategies to optimize maturation of the fetus at risk for preterm delivery target not only the lung but also other organs.

Key Points

- Adequate lung development is essential for survival of the premature infant.
- The surfactant system can have early maturation induced by antenatal corticosteroids.
- Surfactant treatments can improve lung function remarkably.
- The fetal lung responds to inflammation with induced maturation.

Assessment of Neonatal Pulmonary Function

JULIANN M. DI FIORE AND WALDEMAR A. CARLO

Most neonates requiring intensive care present with respiratory symptoms. Although standard techniques for assessing pulmonary function can be applied in a healthy infant, special limitations and problems are encountered in very small or sick neonates. Methods have been developed to evaluate pulmonary function in neonates with suspected abnormalities of the cardiopulmonary system. This section presents a practical and clinical approach to disordered cardiopulmonary function and attempts to help distinguish between heart and lung disease.

Clinical Observations

Five common physical signs relay indirect information regarding pulmonary function: respiratory rate, retractions, nasal flaring, grunting, and cyanosis.

Respiratory Rate

Precise monitoring of respiratory rate is invaluable, as deviations from the normal respiratory patterns have been observed with mechanical pulmonary dysfunction, acid–base imbalances, and arterial blood gas abnormalities. During spontaneous breathing, infants can only achieve successful gas exchange within a limited range of respiratory rates. At low rates, decreased alveolar minute ventilation may occur, while at high rates and corresponding low tidal volumes (V_T), a large proportion of the minute ventilation is wasted in ventilating dead space.

Infants may also adjust the respiratory rate to minimize work of breathing. The total work of breathing consists of elastic and resistive components. The elastic component represents the work required to stretch the lungs and chest wall during a tidal inspiration, and the resistive component is the work required to overcome friction caused by lung tissue movement and gas flow through the airways. Healthy infants rely on tidal volumes of 6-7 mL/kg and approximate respiratory rates of 40-60 breaths per minute. However, during the first hour after birth respiratory rates may be higher, with approximately 50% of healthy newborns having respiratory rates greater than 60 breaths per minute.[40] Newborns with stiff lungs, such as those with respiratory distress syndrome (RDS), attempt to compensate for the increased workload with rapid shallow breathing, whereas patients with increased resistance (e.g., subglottic stenosis) usually exhibit slower and deeper breathing (Fig. 63.1).

Retractions

The neonatal chest wall is extremely compliant, and substernal, subcostal, and intercostal retractions are readily observable even with a relatively minor derangement in lung mechanics. Retractions are caused by negative intrapleural pressure generated by the contraction of the diaphragm and other respiratory muscles and the mechanical properties of the lungs and chest wall. In neonates with respiratory distress, retractions become more apparent as the lungs become stiffer.

Apart from their characteristic appearance in RDS and other pulmonary diseases, severe retractions can signal complications of respiratory disease such as airway obstruction, misplacement of an endotracheal tube, pneumothorax, or atelectasis (see Chapter 64). Decreased retractions in the presence of adequate inspiratory effort suggest that lung compliance and/or resistance is improving.

Nasal Flaring

Nasal flaring is another sign of respiratory distress often observed in infants. The dilation of nostrils produced by contraction of the alae nasi muscles results in a marked reduction in nasal resistance. Because newborns are preferential nose breathers and because nasal resistance contributes substantially to total lung resistance, nasal flaring markedly decreases the work of breathing. Nasal flaring is occasionally observed in the absence of other signs of respiratory distress, particularly during feeding and active sleep.

Activation of other respiratory muscles, such as the genioglossus (tongue) and laryngeal muscles, is also important for optimal function of the upper airway. The genioglossus

Abstract

Most neonates requiring intensive care present with respiratory symptoms. Although standard techniques for assessing pulmonary function can be applied in a healthy infant, special limitations and problems are encountered in very small or sick neonates. Methods have been developed to evaluate pulmonary function in neonates with suspected abnormalities of the cardiopulmonary system. These include physical signs that relay indirect information (i.e., respiratory rate, retractions, nasal flaring, grunting, and cyanosis), cardiovascular assessment (i.e., blood gas measurements, end tidal or transcutaneous CO_2, and pulse oximetry), and physiologic measurements (i.e., radiographic evaluation, lung volume, and respiratory mechanics). Used in combination, these methods can be valuable tools in optimizing oxygenation and CO_2 elimination while using the lowest possible level of respiratory support to minimize lung injury and improve long-term outcomes.

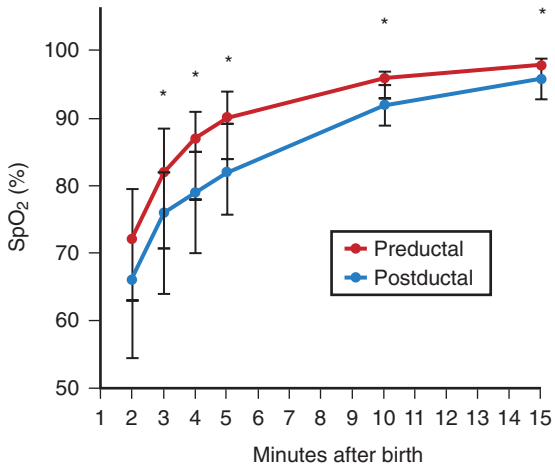
muscle protrudes the tongue and, in part, maintains pharyngeal patency, whereas the laryngeal muscles move the vocal cords and regulate airflow, particularly during expiration.



Grunting

With normal breathing, the vocal cords abduct to enhance inspiratory flow. In some respiratory disorders and with initiation of air breathing after birth, neonates attempt to close (adduct) their vocal cords during the initial phase of expiration, holding gas in the lungs and producing an elevated transpulmonary pressure in the absence of airflow. The elevated pressure and corresponding increased lung volume result in enhancement of the ventilation–perfusion ratio ($\dot{V}/\dot{Q}$). During the last part of the expiratory phase, gas is expelled from the lungs against partially closed vocal cords, causing an audible grunt.

Grunting may be either intermittent or continuous, depending on the severity of lung disease. Grunting can maintain functional residual capacity (FRC) and partial pressure of arterial oxygen (Pa_{O_2}) equivalent to the application of continuous distending pressure. Because endotracheal intubation abolishes grunting, maintenance of lung volume with positive end-expiratory pressure (PEEP) is important following intubation.

Cyanosis

Central cyanosis, best observed by examining the tongue and oral mucosa, is an important indicator of impaired gas exchange. Clinical detection of cyanosis depends on the

• **Fig. 63.2** A rapid postnatal rise in oxygenation occurs during the normal fetal to neonatal transition. total amount of desaturated hemoglobin. Thus, patients with anemia may have a low Pa_{O_2} without clinically detectable cyanosis, and patients with polycythemia may be clinically cyanotic despite a normal Pa_{O_2}. Peripheral cyanosis may be normal in neonates but also occurs in situations of decreased cardiac output. The clinical features of cyanosis and their significance are discussed in detail in Part 12, The Cardiovascular System.

Cardiovascular Assessment

Blood Gas Measurements

Maintaining optimal gas exchange is the primary function of the lung. Thus, pulmonary evaluations should include blood gas estimates in addition to measurements of pulmonary mechanics. Both invasive and noninvasive blood gas measurements are available in the neonatal population. Invasive blood gas measurements are the optimal mode for accurate measures of oxygen and carbon dioxide, whereas noninvasive measurements are ideal for continuous documentation of the rapid changes that occur in this population. These rapid changes in blood gas values begin with the initiation of the first breath after normal delivery, resulting in a rapid fall in Pa_{CO_2} within minutes of birth. During this time, Pa_{O_2} rises quickly to levels of 60-90 mm Hg, although some degree of mismatching of $\dot{V}/\dot{Q}$ is evident during the first day after birth. This is believed to be the result of intracardiac and pulmonary right-to-left shunting. Data in larger groups of infants have characterized the increase in oxygenation following birth by way of pulse oximetry, allowing for further differentiation between preductal and postductal levels (Fig. 63.2).[48] (See also Chapter 33.) The speed with which pulmonary ventilation and perfusion are uniformly distributed is an indication of the neonate's remarkable capacity for maintaining homeostasis.

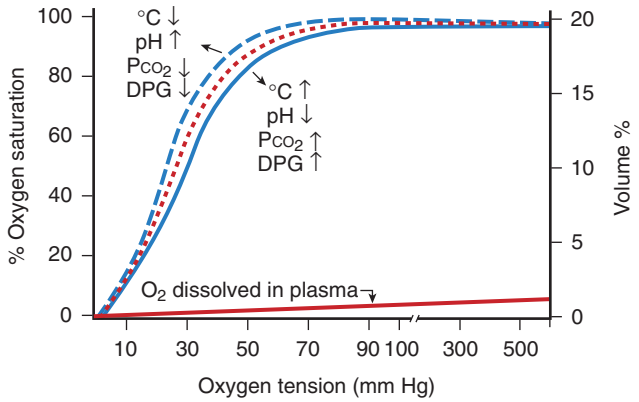
During the early weeks of postnatal life, preterm infants are exceptionally unstable, requiring close monitoring of blood gas status. Pulse oximetry and blood gas measurements are the most widely used clinical methods for assessing pulmonary function in neonates and form the basis for diagnosis and management of cardiorespiratory disease.

Invasive Blood Gas Measurements

Partial Pressure of Alveolar Oxygen and Carbon Dioxide

Changes in partial pressure of alveolar oxygen (P_{AO_2}) and P_{ACO_2} can identify disordered pulmonary function in various clinical situations. P_{AO_2} and P_{ACO_2} values depend on the composition and volume of alveolar gas, the composition and volume of the mixed venous blood, and the mechanisms of pulmonary gas exchange impairment. Alveolar gas composition can be obtained from the equation

$$P_{AO_2} = P_{IO_2} - \frac{P_{ACO_2}}{R}\left[F_{IO_2} + \frac{1 - F_{IO_2}}{R}\right]$$



where P_{IO_2} is partial pressure of inspired oxygen ($P_{IO_2} = F_{IO_2} \times$ [barometric pressure − water vapor pressure]). At sea level, barometric pressure is 760 mm Hg; at 100% humidity, water vapor pressure is 47 mm Hg. P_{ACO_2} is the partial pressure of alveolar carbon dioxide, and R is the respiratory quotient (usually 0.8). The mechanisms of pulmonary gas exchange impairment include $\dot{V}/\dot{Q}$ mismatch, shunt, hypoventilation, and diffusion limitation. Appropriate matching of the alveolar gas with the mixed venous blood yields optimal gas exchange. Mixed venous blood composition and volumes are determined by the arterial blood gas content, cardiac output, oxygen consumption, and carbon dioxide production.

Techniques of blood gas determination in infants with RDS are discussed in Chapter 64. Gas exchange during assisted ventilation is discussed in Chapter 65. Acid–base physiology is discussed in Chapter 92.

Partial Pressure of Arterial Oxygen

Depending on the efficacy of gas exchange, the alveolar oxygen partial pressure (tension) tends to equilibrate with the mixed venous blood, resulting in the P_{aO_2}, which determines the degree of oxygen saturation of hemoglobin. In addition to its chemical combination with hemoglobin, oxygen is also dissolved in plasma and red blood cells (RBCs). Most of the oxygen in whole blood is bound to hemoglobin (measured clinically as oxygen saturation), whereas the amount of dissolved oxygen is only a small fraction of the total quantity carried in whole blood.

The quantity of oxygen bound to hemoglobin depends on the P_{aO_2} and the oxygen dissociation curve (Fig. 63.3). The blood is almost completely saturated at a P_{aO_2} of 90-100 mm Hg. The flattening of the upper portion of the S-shaped dissociation curve makes it virtually impossible to estimate oxygen tension greater than 60-80 mm Hg by using arterial oxygen saturation alone. The dissociation curve of fetal hemoglobin (compared with adult hemoglobin) is shifted to the left, and at any P_{aO_2} less than 100 mm Hg, fetal blood binds more oxygen. The shift appears to be the result of the lower affinity of fetal hemoglobin for 2,3-diphosphoglycerate. Note that pH, P_{aCO_2}, temperature, and diphosphoglycerate (DPG) content influence the position of the dissociation curve.

• **Fig. 63.3** Factors shifting the oxygen dissociation curve of hemoglobin. (Fetal hemoglobin is shifted to the left.) DPG, Diphosphoglycerate.

Arterial oxygen content (C_{aO_2}) is the sum of hemoglobin-bound and dissolved oxygen, as described by the following equation:

$$C_{aO_2} = (1.37 \times Hb \times S_{aO_2}) + (0.003 \times P_{aO_2})$$

where the arterial oxygen content is in mL/100 mL of blood, 1.37 is the approximate amount of oxygen (in milliliters) bound to 1 g of hemoglobin at 100% saturation, Hb is hemoglobin concentration (g/100 mL), S_{aO_2} is the percentage of hemoglobin bound to oxygen, and 0.003 is the solubility factor of oxygen in plasma (mL/mm Hg). In this equation, the first term ($1.37 \times Hb \times S_{aO_2}$) is the amount of oxygen bound to hemoglobin. The second term ($0.003 \times P_{aO_2}$) is the amount of oxygen dissolved in plasma and red blood cells.

Most of the oxygen in the blood is carried by hemoglobin. For example, if an infant has a P_{aO_2} of 80 mm Hg, an S_{aO_2} of 99%, and a hemoglobin concentration of 15 g/100 mL, C_{aO_2} is the sum of oxygen bound to hemoglobin ($[1.37 \times 15 \times 99]/100 = 20.3$ mL) plus the oxygen dissolved in plasma ($0.003 \times 80 = 0.24$ mL). In this example, just over 1% of oxygen in blood is dissolved in plasma and almost 99% is carried by hemoglobin.

The partial pressure of oxygen in arterial blood not only depends on the ability of the lungs to transfer oxygen as determined by alveolar ventilation but also is largely influenced by the $\dot{V}/\dot{Q}$. For normal gas exchange, the ventilation and perfusion should be proportional. The ratio should be very close to 1:1; that is, for every milliliter of gas that passes the alveoli, there should be a proportional volume of blood in the pulmonary capillary bed. If the $\dot{V}/\dot{Q}$ is decreased (as in RDS), only partial oxygenation and CO_2

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

removal from the mixed venous blood will occur. Oxygen supplementation can largely overcome the hypoxemia when the $\dot{V}/\dot{Q}$ is decreased. If the $\dot{V}/\dot{Q}$ is high, as in overventilation, partial pressure of oxygen is increased slightly.

The mechanism of shunting becomes evident when blood bypasses the alveoli, as occurs in congenital cyanotic heart disease, persistent pulmonary hypertension, or atelectasis. Oxygen supplementation does not prevent the hypoxemia produced by such a shunt. Hypoventilation (e.g., caused by apnea) is a common cause of hypoxemia. Diffusion limitation can affect oxygenation slightly, but this mechanism is not a common cause of severe hypoxemia in neonates. Hypoxemia caused by either hypoventilation or diffusion limitation usually can be treated easily with oxygen supplementation.

Three indexes can be used to estimate the degree of oxygenation derangement (see Chapter 70). The *arterial–alveolar oxygen tension ratio* (PaO_2/PAO_2 or a/AO_2 ratio) has no units, decreases with worsening oxygenation, and can be obtained from the equation

$$P(a/A)O_2 = \frac{P_aO_2}{PiO_2 - \frac{PACO_2}{R}\left[FiO_2 + \left(\frac{1 - FiO_2}{R}\right)\right]}$$

where R is the respiratory quotient. Because $[FiO_2 + (1 - FiO_2)/R]$ approximates 1.0, and $PACO_2$ approximates $PaCO_2$, the equation can be simplified as follows:

$$P(a/A)O_2 \sim \frac{PaO_2}{PiO_2 - \frac{PaCO_2}{R}}$$
