In a retrospective review of the short-term outcomes of 116 pregnancies that underwent 457 transfusions in Scotland from 1993-2004, the rate of intrauterine death as a complication of the procedure was 2.3% for 1993-1998 and 0.8% for 1999-2004.[36] Eight infants (6.9%) were delivered by emergency cesarean as a result of a complication during the intrauterine transfusion. The survival rate of neonates from birth to discharge was 97.4%. The majority of the neonates were delivered by cesarean or vaginally at 35 weeks. Roughly 33% of neonates required some type of respiratory support following delivery. Sixteen of the neonates had an exchange transfusion following delivery, with the number of exchanges ranging from 1-4. At least one top-up transfusion was required in 54% of the neonates, with one infant requiring nine transfusions.

The short-term neonatal outcomes of intrauterine transfusion are generally very good. In the Netherlands study, pregnancies complicated by hydrops, pregnancies in which the first transfusion was undertaken at less than 20 weeks, and alloimmunization secondary to Kell had poorer outcomes. In the cohort from Scotland, there was minimal procedural loss, a low rate of emergency cesarean deliveries because of procedural complications, and no more than the expected rate of respiratory support needed secondary to gestational age of delivery at 35 weeks. All neonates were treated with phototherapy, and 16 needed exchange transfusions, primarily those who underwent an emergency delivery because of procedural problems with the intrauterine transfusions.

Long Term

More information is now becoming available on the long-term outcome of fetuses who receive intrauterine transfusions. Previously, this information had been very limited because of the small size of the studies, length of follow-up, lack of controls, and unclear criteria used to evaluate development of the child. The publication of the LOTUS study provided much-needed additional information on long-term effects of fetuses undergoing this procedure.[32]

The LOTUS study evaluated the neurodevelopment of children with hemolytic disease treated with an intrauterine transfusion. Two hundred and ninety-one children were evaluated at a median age of 8.2 years. Cerebral palsy was detected in 2.1%, severe developmental delay in 3.1%, and bilateral deafness in 1%. The overall incidence of neurodevelopmental impairment was 4.8% (14/291). The only risk factor that could be linked with neurodevelopmental delay was severe fetal HF.

The very high rate of intact survival in these at-risk pregnancies complicated by severe anemia is reassuring and confirms the relative safety of the treatment with intrauterine transfusions even in the fetus with severe hemolytic disease, including HF.

Atypical Antigens

As the incidence of Rh disease has decreased with the administration of anti-D immunoglobulin, the incidence of alloimmunization caused by other red blood cell antigens has increased. This rise is because there are no screening programs for women who are negative for these other atypical antigens that have the potential for causing hemolytic disease.

The greatest risk factor for isoimmunization of the other red blood cell antigens is a prior blood transfusion but it can also occur after a maternal fetal hemorrhage during pregnancy. Fortunately, most of the antibodies produced against these antigens are of the IgM type, do not cross the placenta, and therefore do not result in hemolytic disease of the newborn. Because of the rarity of many of these atypical antigens, there is a paucity of evidence supporting specific management algorithms. Critical titers at which time additional surveillance is undertaken are also not well established. Box 23.2 outlines a partial list of antibodies associated with HDN.

The most troublesome of the atypical antigens is the Kell antigen, which is highly immunogenic. After the reactions that occur with ABO and Rh blood groups, the Kell antigen is the most immunogenic. There are 25 Kell antigens encoded by a single gene on the 7th chromosome, with the "K" antigen being the most clinically significant. The pathophysiology of the hemolytic disease of the newborn is different from that seen with ABO and Rh sensitization.

• BOX 23.2 Partial List of Antibodies Associated With Hemolytic Disease of the Fetus and the Newborn

Requiring Fetal Evaluation

- Rhesus: E, C, c, D (C, E, e usually associated with mild disease but may be additive to D)
- Kell: K (especially K1 and K2) can cause moderate to severe disease
- Duffy: Fy^a
- Kidd: Jk^a
- MNSs: M, S, s, U, Mi^a
- MSS: Mt^a
- Diego: Di^a, Di^b, ELO, Wr^a, Wr^b mild to severe (infrequently) disease
- P: PP_{1pk} mild to severe disease
- Public antigens: Yt^a moderate to severe
- En^a moderate
- Co^a severe
- Private antigens: Biles moderate
- Good severe
- Heibel moderate
- Radin moderate
- $Wright^a$ severe
- Zd moderate

Others (Infrequently Associated With Severe Disease)

- Coa, Co3, Ena, Far, MUT, Mur, Mv, sD, Lu^a, Lu^b, Vw, Mur, Hil, Hut, JFV, JONES, Kg, MAM, REIT, Rd, Ce, Cw, Cx, ce, Dw, Ew, Evans, G, Goa7, Hr, Hro, JAL, HOFM, LOCR, Riv, Rh29, Rh32, Rh42, Rh46, Js^a, Js^b, Kp^a, Kp^b, K11, K22, Ku, Ul^a, STEM, Tar, HJK

The Kell IgG antibodies cause destruction of erythroid precursors by macrophages in the fetal liver and can result in severe fetal anemia.[14]

Fortunately, 91% of the population is Kell negative and only 5% of the population will form Kell antibodies after a transfusion, making the disorder relatively rare. Assessment of the father's genotype, if paternity is certain, is initially undertaken because if he is Kell negative, the pregnancy is not affected and no further workup is needed. In Kell alloimmunization, early suppression of fetal RBC synthesis results in less bilirubin being released during hemolysis. Because of this, serial amniocentesis for ΔOD450 titers is not reliable or could even be misleading and should not be used. Results have suggested that MCA-PSV with a cutoff greater than 1.5 is highly predictive of severe fetal anemia as it is in the prediction of fetal anemia in Rh-D-negative mothers and should be routinely used in management.[53]

Other antibodies that have been infrequently linked with severe disease include Colton, Diego, Duffy, and MNS. Those associated with mild disease include Dombrock, Duffy, Kidd, and Gerbich. Surveillance is done with MCA-PSV using the threshold of greater than 1.5 for the diagnosis of fetal anemia.

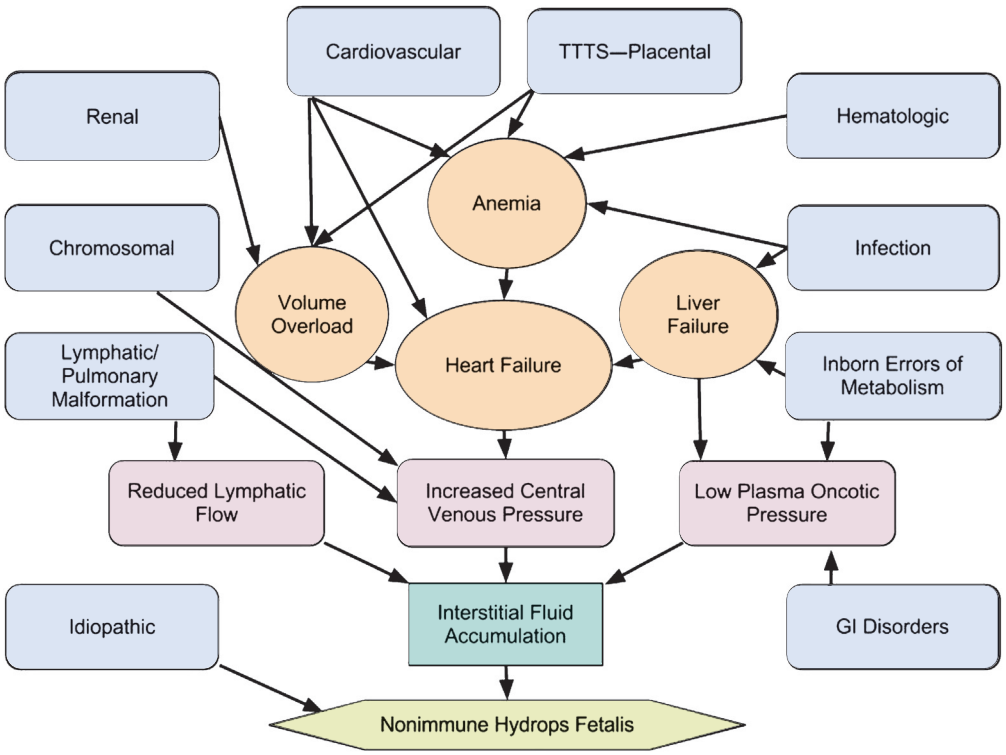
Nonimmune Hydrops Fetalis

Although the incidence of HF has remained stable in the range of 1/1500 to 1/3800 births since the development of Rh immunoglobulin, up to 90% of cases of HF are now the result of nonimmune etiologies. Nonimmune hydrops fetalis (NIHF) defines hydrops in those fetuses whose mothers are Rh positive or that results from a nonimmune cause.[35,41,51]

Although improvements in ultrasound technology have allowed earlier diagnosis and improved understanding of underlying conditions, unfortunately the prognosis for NIHF neonates remains poor, with perinatal mortality (PNM) rates ranging from 50%-90%.[35] Maternal complications associated with NIHF include pre-eclampsia, mirror syndrome, and increased cesarean rates when NIHF is diagnosed in the antepartum period.[3,27]

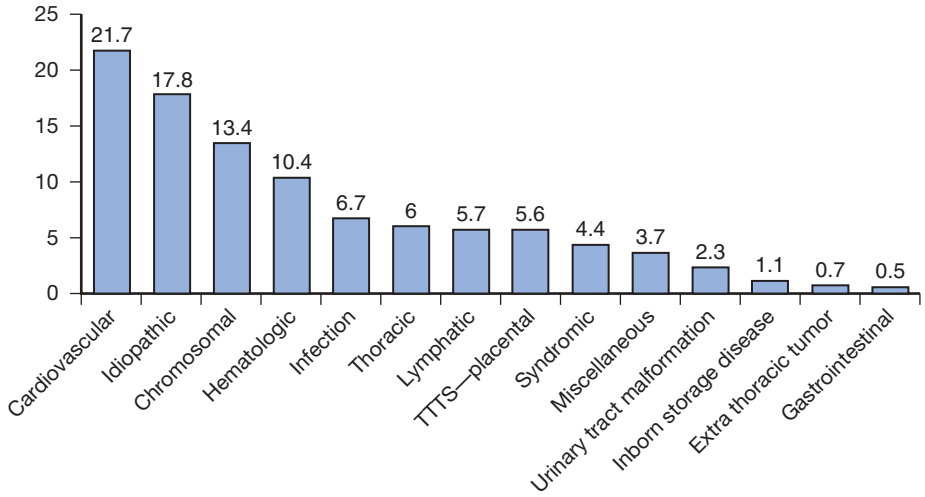
Diagnosis

After ruling out fetal hydrops owing to red blood cell alloimmunization, NIHF is defined by the same ultrasonographic presence of excessive fetal fluid in two or more of the following spaces: abdominal ascites, pleural effusion, pericardial effusion, skin edema, polyhydramnios, or placentomegaly (see Table 23.1). Unlike alloimmunization, there is not a specific screening test for the multiple etiologies of NIHF, and often this diagnosis is made incidentally after a mother undergoes an ultrasound for another indication (e.g., polyhydramnios, standard fetal evaluations).



Pathophysiology

Hydrops occurs when interstitial fluid production and lymphatic return becomes imbalanced, leading to fluid accumulation in interstitial spaces within the fetus. This can result from a myriad of conditions, including those that cause reduced lymphatic flow (e.g., pulmonary masses or lymphatic malformations), lower plasma oncotic pressure (e.g., gastrointestinal anomalies, inborn errors of metabolism, liver failure), or increased central venous pressure (e.g., chromosomal abnormalities, heart failure caused by volume overload or anemia, compensatory hypoxia) (Fig. 23.3). Nonimmune hydrops fetalis rarely resolves spontaneously and, in general, carries a worse prognosis the earlier in pregnancy it is diagnosed.[2]



Differential Diagnosis/Etiology

Just as the pathophysiology of NIHF can result from several different pathways, the conditions or anomalies that lead to these pathophysiologic changes are vast. Fig. 23.4 summarizes 14 separate etiologies most commonly associated with NIHF and the respective percentage for which a cause is identified.[2] Within each of these categories, specific diagnoses or anomalies are further summarized in Table 23.4. In sum, greater than 100 conditions, although many are very

rare, have been associated with the ultimate finding and diagnosis of NIHF.

Antepartum Evaluation

The clinical presentation of fetuses can vary depending on the underlying condition and the gestational age at which it is identified. A common finding in NIHF diagnosed before 20 weeks is a cystic hygroma, often associated with chromosomal anomalies. Common chromosomal abnormalities include Turner syndrome (45 XO) as well as trisomies 21, 18, and 13.[45] In intrathoracic masses, restrictive fetal swallowing often causes polyhydramnios, resulting in uterine size measuring larger than gestational age and prompting ultrasound evaluation.[58] Once identified, antepartum evaluation focusing on identification of the underlying cause includes a detailed history (personal and family) often with the assistance of a genetics counselor, targeted ultrasound, fetal echocardiography, middle cerebral artery Doppler peak systolic velocity (MCA-PSV) analysis, laboratory testing including evaluation of recent viral exposures, and sometimes diagnostic invasive testing. Table 23.5 summarizes the components of a full antenatal evaluation of NIHF.

TABLE 23.4 Principal Diagnoses Associated With Nonimmune Hydrops Fetalis

Cardiovascular (21%)

Structural

- Hypoplasias (left or right heart)
- AV canal defect
- Single ventricle
- Transposition of great arteries
- Septal defects (VSD/ASD)
- Tetralogy of Fallot
- Ebstein anomaly
- Ductus arteriosus closure
- Truncus arteriosus
- Valvular (stenosis/insufficiency)

Arrythmias

- Atrial (flutter/tachyarrhythmia)
- Wolff-Parkinson-White
- Supraventricular tachycardia
- Long QT interval
- Heart block

Cardiomyopathy

- Tumors
- Neoplasias
- Myopathies
- Cardiosplenic syndromes

Infection (6.7%)

- Cytomegalovirus
- Parvovirus B19
- Syphilis
- Herpes simplex
- Rubella
- Coxsackievirus
- Leptospirosis
- Trypanosoma cruzi

Inborn Storage Disease (1.1%)

- Gaucher disease
- GM1 gangliosidosis
- Sialidosis
- Mucopolysaccharide (MPS) IVA
- Mucolipidosis type I+II
- Galactosialidosis

Idiopathic (17.8%)

Chromosomal (13.4%)

Trisomy

- 21
- 18
- 13

Monosomy

- 45, X
- 45, X (mosaic)

Duplications

- 18 q +
- 11p

Deletions

- 13 q –
- 17 q –

Triploidy

Thoracic/Extrathoracic Mass/Lymphatic (12.4%)

Mass Effect

- Diaphragmatic hernia
- Congenital pulmonary adenomatoid malformation
- Intrathoracic mass
- Pulmonary sequestration
- Chylothorax
- Airway obstruction
- Pulmonary lymphangiectasia
- Bronchogenic cyst

Skeletal Dysplasias

- Thanatophoric dysplasia
- Short rib polydactyly
- Hypophosphatasia
- Osteogenesis imperfecta
- Achondrogenesis
- Camptomelic dysplasia
- Lethal chondroplasia

TTTS-Placental (5.6%)

Twin

- TTTS
- Acardiac twin

Placental

- Umbilical vein thrombosis
- Umbilical cord angiomyxoma
- True cord knot
- Chorionic vein thrombosis
- Rare placenta disorders

Hematologic (10.4%)

- Alpha-thalassemia
- Fetomaternal hemorrhage
- Glucose-6-phosphate deficiency
- Leukemia
- Pyruvate kinase deficiency
- Red blood cell aplasias

Gastrointestinal (0.5%)

- Duodenal atresia
- Duodenal diverticulum
- Jejunoileal atresia
- Volvulus
- Imperforate anus
- Meconium peritonitis
- Intestinal malrotation
- Intestinal duplication
- Hepatic fibrosis
- Cholestasis
- Biliary atresia
- Hepatic vascular malformations
- Hepatitis
- Hepatic necrosis
- Liver tumor or cysts

Syndromic/Miscellaneous (8.1%)

- Noonan syndrome
- Arthrogryposis
- Multiple pterygium syndrome
- Neu-Laxova syndrome
- Pena-Shokeir syndrome
- Myotonic dystrophy
- Saldino-Noonan syndrome
- Francois syndrome, type III
- Familial nuchal bleb
- Elejalde syndrome
- Thoracoabdominal syndrome
- Lymphedema-distichiasis syndrome

Urinary Tract Malformation (2.3%)

- Urethral stenosis
- Urethral atresia
- Posterior urethral valve
- Finnish type nephrosis
- Edwards (prune belly) syndrome

ASD, Atrial septal defect; AV, arteriovenous; TTTS, twin–twin transfusion syndrome; VSD, ventricular septal defect.

Management

Depending on gestational age at the time of diagnosis and whether a cause for NIHF can be identified, various management options may include termination of pregnancy, invasive therapeutic intervention, or conservative management, including supportive care and monitoring of the mother and fetus. Fetal surveillance may include frequent nonstress testing or biophysical profiles on a weekly or twice-weekly basis. Because early delivery and neonatal compromise often occur, early consultation with relevant subspecialists (e.g., neonatologists, pediatric surgeons, or pediatric

TABLE 23.5 Antenatal Evaluation of Nonimmune Hydrops Fetalis

Noninvasive Testing

Maternal History (Consider Genetics Counselor)

- Age, parity, gestational age
- Hereditary or metabolic diseases, anemia
- Recent infections or contacts
- Medication use

Maternal Laboratory Evaluation

- Complete blood cell count
- Blood type, Rh, indirect Coombs antibody screen
- Viral titers: parvovirus B19, toxoplasmosis, congenital syphilis, rubella, cytomegalovirus, herpes simplex
- Aneuploidy screening—integrated, sequential, quad, or triple screen, cell-free fetal DNA in maternal serum
- Metabolic studies, autoimmune screening, electrophoresis (if indicated)

Fetal Echocardiography

- Cardiac malformations
- Arrhythmias

Ultrasonography

- Anatomic abnormalities (cystic hygromas, thoracic masses)
- Evaluate extent of edema and/or effusions (cardiac displacement, lung hypoplasia)
- Middle cerebral artery Doppler to rule out anemia

Amniocentesis

- Karyotype
- Viral culture or PCR
- Lung maturity

Invasive Fetal Testing

Fetal Blood Sampling

- Karyotype
- Complete blood cell count, type
- Hemoglobin electrophoresis
- Viral culture or PCR
- Metabolic testing

Fetal Effusion Sampling

- Viral culture or PCR
- Protein count
- Cell count and cytology (lymphocytes)

PCR, Polymerase chain reaction.

cardiologists) is often warranted. If delivery is thought to be imminent, inpatient surveillance with the administration of antenatal corticosteroids may be indicated.

Maternal risks of conservative management include a condition known as mirror syndrome (Ballantyne syndrome).[40] If this occurs, the mother begins to demonstrate similar findings of the fetus, including generalized maternal edema, often with pulmonary involvement, thus "mirroring" the edema of the hydropic fetus and placenta. Although the pathogenesis of this condition is unknown, it is thought that the hydropic placenta causes a systemic inflammatory response as a result of increased shedding of trophoblastic debris into maternal blood.[26]

In some cases, invasive fetal therapeutic interventions may be considered. Conditions such as diaphragmatic hernia, congenital pulmonary adenomatoid malformations, or extralobar pulmonary sequestration may benefit from in utero surgery. Although paracentesis or thoracentesis may be informative for diagnostic purposes, the fluid removed from the fetal body cavity often reaccumulates in a short period of time. In these cases, shunt placement is sometimes considered, with some notable improvement in survival.

Delivery may be indicated if there is evidence of maternal mirror syndrome. Other indications for delivery include gestational age greater than 34 weeks, mature fetal lung profile, or persistent biophysical profiles of less than 6. Cesarean delivery should be reserved for routine obstetrical indications (Table 23.6). Traumatic delivery because of severe soft tissue edema often occurs; however, this risk is not negated by cesarean delivery. Given the increased frequency of nonreassuring fetal testing and labor dystocia, however, the likelihood of cesarean delivery in NIHF is increased.

TABLE 23.6 Management of Nonimmune Hydrops Fetalis

Conservative Management	Invasive Management
• Fetal surveillance—NST, BPP weekly or twice weekly • Serial growth ultrasound	• Shunt placement • Surgical repair when indicated
Hospitalize If	**Indications for Delivery**
• Fetal skin thickening • Pericardial effusion • Nonreactive NST • BPP <6 • Subjective decreased fetal movement • Anticipated imminent delivery • Administer antenatal corticosteroids	• Gestational age >34 weeks • Mature fetal lung profile • Persistent BPP <6 • Maternal compromise (mirror syndrome)

BPP, Biophysical profile; NST, nonstress test.

Prognosis

Overall survival of a fetus diagnosed with NIHF remains poor. This is largely related to the underlying etiology of

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

the condition. If a structural defect is identified, or if no underlying cause is identified, the perinatal mortality rate approaches 100%. In general, PMN rates are worse when NIHF is identified early in pregnancy (<24 weeks) and, conversely, when identified, delivery and neonatal treatments may be beneficial and improve mortality. Certainly the risks associated with prematurity compound the already tenuous status of a fetus with NIHF. Given the rareness of this entity, recurrence risk is also rare, especially when the cause is something other than a hereditary factor.

Summary

Hydrops fetalis, whether from immune or nonimmune causes, represents a large spectrum of rare disorders and conditions resulting in the common pathophysiologic outcome of heart failure and interstitial fluid accumulation in the fetus. Given the seriousness of many of the underlying conditions, perinatal morbidity and mortality remain exceedingly high. Although the prognosis of IHF remains positive in those fetuses who receive intrauterine blood transfusions, treatment in NIHF is often conservative, with increased surveillance of fetal well-being but minimal improvement in short- or long-term neonatal outcomes. Invasive fetal treatment, however, is associated with improved survival in select conditions causing NIHF. All pregnancies should undergo screening for Rh alloimmunization with maternal blood typing and antibody screening. Despite improvements in technology and testing, a certain diagnosis in NIHF occurs only in approximately 67% of cases. Minimizing maternal complications such as mirror syndrome and determining the most appropriate timing for delivery remain challenging in this high-risk pregnancy population.

Key Points

- Hydrops fetalis is defined as excessive fetal fluid in two or more spaces. It can result from immune and nonimmune etiologies.
- Immune hydrops fetalis are due to blood group antigens that can form antibodies and lead to significant hemolytic disease of the newborn.
- Immune hydrops fetalis has significantly decreased after the routine implementation of Rh immunoglobulin prophylaxis with anti-D immune globulin, Rhogam.
- Fetal anemia can be predicted with Doppler flow studies by the peak systolic velocity of the middle cerebral artery and can guide the need for fetal intravascular transfusion.
- Nonimmune hydrops fetalis differential diagnosis should include chromosomal anomalies, recent viral infections, and evaluation of fetal structural anomalies with ultrasound.
- Overall prognosis is dependent on the underlying etiology. Consultation with maternal fetal medicine and neonatology with delivery in a facility capable for intervention.

Amniotic Fluid Volume

PAMELA M. SIMMONS AND EVERETT F. MAGANN

Amniotic fluid surrounds the developing embryo throughout gestation, protecting the fetus and umbilical cord from trauma while allowing mobility to facilitate structural growth and development. The underlying forces that regulate amniotic fluid are exceedingly complex and dynamic, synchronizing volumes within relatively narrow ranges and providing an indirect measure of fetal well-being. Understanding the pathways of water and solute exchange provides the physiologic basis of the pathologic conditions of oligohydramnios and polyhydramnios.

Amniotic Fluid Dynamics

Several pathways for movement of amniotic fluid and solutes exist, including fetal swallowing, urination, pulmonary secretions, intramembranous movement between fetal blood and the placenta, and transmembranous movement across the amnion and chorion.[30] To understand how variations in amniotic fluid volume can affect the fetus, we must first understand fluid dynamics.

Composition

Amniotic fluid contains 98%-99% water, with its solute composition changing throughout gestation. In early pregnancy, the factors that affect amniotic fluid volume are not well known. What is known is that the osmolarity of amniotic fluid and maternal plasma are similar, suggesting that amniotic fluid is a transudate of maternal plasma originating from either placental surfaces or coming through fetal skin.[4] The fetal skin remains nonkeratinized until week 22-25, allowing it to act as a membrane through which amniotic fluid can readily pass.[63] As the fetal skin becomes keratinized and renal function matures, the hypotonic fetal urine causes the amniotic fluid osmolality to decline from 290 mOsm/kg in the first trimester to approximately 255 mOsm/kg near term.[11] Conversely, concentrations of creatinine, urea, and uric acid from the fetal urine increase progressively in the amniotic fluid. Low concentrations of proteins (principally albumin) are found in late pregnancy and provide a minor source of nutrition for the developing fetus. Near term, the amniotic fluid contains increased particulate matter from desquamated fetal skin and gastrointestinal cells, hair, vernix caseosa, stem cells, and occasionally meconium.

Production and Regulation

Surface exchange is the main component of fluid dynamics in early pregnancy before skin keratinization. Beyond 24 weeks, the surfaces in the mouth and nose can additionally act to exchange fluid, but this is not considered a major source of amniotic fluid volume regulation.[12] A fundamental source of amniotic fluid, particularly in the second half of pregnancy, is the fetal renal system. This is evidenced by the almost complete lack of amniotic fluid in fetuses with renal agenesis or bladder outlet obstructions. Secretions of the respiratory tract, fetal swallowing, and transport within and across the fetal membranes also contribute to amniotic fluid volume (Fig. 24.1).

Confirmation of a functioning renal system first starts around 8-11 weeks, when urine is initially observed in the fetal bladder. The dilute urine that is produced is thought to cause the observed drop in osmolality and sodium concentration in the amniotic fluid that persists until delivery.[4] As pregnancy advances, urinary byproducts are observed at two to three times the concentration found in fetal plasma.[32] Estimates of fetal urine output have been made by three-dimensional (3D) measurements of bladder volume at timed intervals and have been found to range from 7-70 mL/hour from 24 weeks until delivery in two separate studies.[43,80] Fetal urine production is characteristically decreased in pregnancies with abnormalities of placental function that result in intrauterine growth restriction (IUGR).[100] However, no correlation is observed between fetal weight and urine production in normal pregnancies. In normal pregnancies, low fetal urine output is not associated with lower Apgar scores, pH less than 7.25, or late decelerations in labor.[100]

Fluid is excreted from the fetal pulmonary system. Approximately 300-400 mL of fluid is secreted per day, driven by chloride ion exchange across the pulmonary epithelium.[11] It has been demonstrated in fetal sheep by Brace et al. that half of secreted lung fluid enters the amniotic fluid, and the other half is swallowed upon exiting the trachea.[10] Amniotic fluid is prevented from entering the lungs by the closed larynx, producing a new efflux of fluid

Abstract

Amniotic fluid surrounds and protects the developing fetus during pregnancy, and its volume is from surface exchange in early pregnancy and the fetal renal system in later pregnancy. The assessment of amniotic fluid volume (AFV) can be done precisely by dye-dilution techniques or measured at the time of cesarean delivery. The dye-dilution techniques require an amniocentesis, are invasive, time consuming, and require laboratory support, and the measurement at cesarean can only be done and delivery, making that technique impractical for the serial assessment of AFV. Because of these limitations AFV is estimated by ultrasound. The current techniques to estimate AFV include the subjective assessment, and the objective assessments using the amniotic fluid index (AFI) and the single deepest pocket technique (SDP). These ultrasound estimates of the AFV correlate well with normal (dye-determined or directly measured) volumes but poorly with true oligohydramnios and polyhydramnios. The use of color Doppler in estimating AFV does not help in identifying true oligohydramnios but instead labels more normal fluid volumes as oligohydramniotic. The use of the statistical method, quantile regression, is the best method to identify what is a normal AFV across gestation. In twin pregnancies, the amniotic fluid volume is best estimated using the SDP technique. The SDP technique compared to the AFI is the superior technique to use in antenatal testing to evaluate AFV in singletons. Polyhydramnios is seen with fetal anomalies, maternal diabetes, fetal macrosomia, immune and nonimmune fetal hydrops, or fetal infection, or may be idiopathic. The best ultrasound measurement to identify polyhydramnios is uncertain.

from the fetal lungs.[28] This was confirmed in an investigation by Liley et al. in which the intra-amniotic injection of contrast media resulted in, with the exception of a few cases, undetectable contrast in the fetal or neonatal lung.[2] The net amount of lung fluid entering the fetal amniotic fluid is approximately 150-200 mL per day. As further evidence of secreted lung fluid being found in amniotic fluid, the phospholipids found in amniotic fluid, which are produced by pulmonary cells, are found in the amniotic fluid. Although meconium staining is not infrequent, with rates in the literature of 7%-27% based on the population, meconium aspiration past the trachea is rare, less than 1%-5%, and is usually associated with accompanying neonatal hypoxia.[3,27] Rarely, the aspiration of amniotic fluid uncontaminated by meconium has been reported as a cause of neonatal death confirmed at autopsy.[8,37]

Analogous to renal agenesis being associated with low amniotic fluid, disruption in fetal swallowing is associated with excess amniotic fluid volume. The human fetus demonstrates swallowing around the same time that urine production begins, at 8-11 weeks,[70] and the swallowed volume increases with gestational age. The ovine model has been used historically to approximate human fetal development.[4] Studies evaluating the volume of amniotic fluid swallowed by the fetus were done primarily in sheep models and were found to range between 210 and 1085 mL/day.[83,96] Ovine studies have also shown that the amount of amniotic fluid swallowed daily in late gestation is correlated with the amniotic fluid volume, suggesting that the fetus can react and attempt to regulate its amniotic fluid surroundings. This attempted regulation is not thought to be a major controller of volume,[9] although the fetus is able to modulate its swallowing. In primate studies, esophageal ligation initially resulted in polyhydramnios, but the polyhydramnios did not persist across gestation, and at the time of delivery the amniotic fluid volume was normal.[69] Observations of swallowed amniotic fluid volume in near-term fetuses range from 210-840 mL per day (average 565 mL). This volume is equivalent to 5%-10% of the fetal body weight.[31]

Excess fluid not removed by fetal swallowing is reabsorbed via an intramembranous pathway. More specifically, this is the reabsorption of fluid and solutes from the amniotic compartment to the fetal blood via the amnion.[5] This pathway is capable of absorbing large quantities of fluid. As the fluid requirements of the fetus increase with increasing gestation, water flow from the amniotic cavity to the fetal circulation via the fetal membranes increases up to 400 mL/day.[67] This is thought to be regulated at least partially by aquaporins found in the human chorioamniotic membranes and the placenta. Aquaporins are small (26- to 34-kDa) cell membrane proteins, which regulate water flux across the cell membranes, have been found to be adaptive to abnormal amniotic fluid levels, and may represent a possible future therapeutic target for abnormal amniotic fluid volume regulation.[22,39,102] The osmotic gradient between the amniotic fluid and fetal blood also drives fluids and solutes from the amniotic fluid into the fetal blood.[32] The flow of solutes and fluid, although bidirectional, is not necessarily equal.[4,26] Vascular endothelial growth factor (VEGF) may also have an impact on intramembranous absorption of fluid.

Transmembranous movement of amniotic fluid describes the transport of water and solutes from the maternal circulation to the amniotic compartment via the placenta.[5] Overall, this has been found to be an insignificant contribution to amniotic fluid dynamics.[30]

Measurement of Amniotic Fluid Volume

The evaluation of amniotic fluid volume is important during the routine ultrasound evaluation of the fetus, because variation above or below normal is associated with increased perinatal morbidity and mortality.[18,19] Amniotic fluid volume can be measured directly at the time of cesarean delivery (with corrections made for blood contamination)[35] or by dye-dilution techniques using para-amino hippurate.[61] The direct measurement can only be done on a single occasion at the time of cesarean delivery, making it impractical for serial assessments of amniotic fluid volume, and the dye-dilution technique is invasive (requires an amniocentesis), necessitates laboratory support to calculate the amniotic fluid volume, and is also impractical for the clinical determination of amniotic fluid volume.[35] The relative accuracy of this indicator dilution technique has been validated by comparing the actual amniotic fluid volume measured at cesarean delivery with the determined by dye-dilution technique, showing only a 7% difference between the dye-determined and direct-measurement volumes (r = .99, P <.001).[57,65] Magnetic resonance imaging has also been evaluated as a means for estimating amniotic fluid volume[101]; however, this is an impractical approach to everyday screening. Although the aforementioned techniques to measure amniotic fluid volume are accurate, they

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

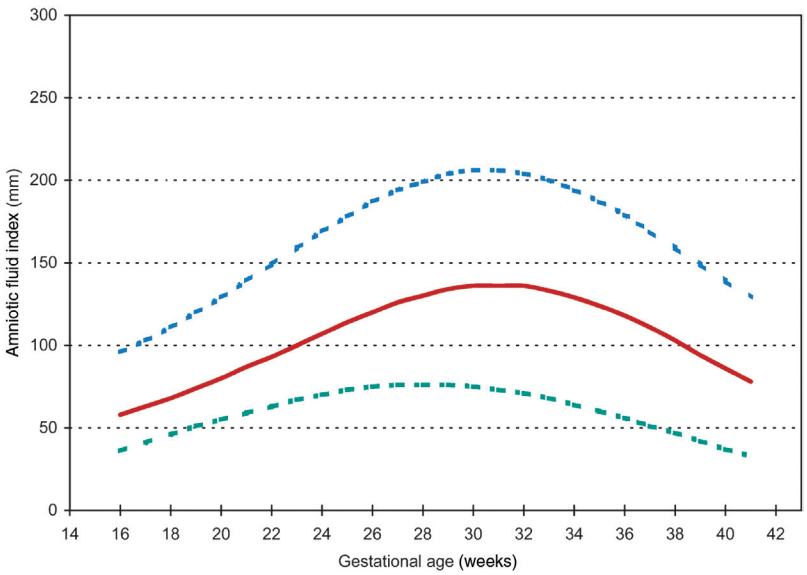
are time consuming, cumbersome, and may require laboratory support; therefore, the volumes are usually estimated by ultrasound.

Sonographic techniques to estimate amniotic fluid volume include subjective (qualitative) estimation and semiquantitative methods: measurement of maximum vertical or single deepest pocket (SDP) and the amniotic fluid index (AFI). Advantages of sonographic estimates include that they are simple to perform; easy to teach to residents, midwives, and nurses; and are reproducible. In a study comparing all three measurements in singleton pregnancies with dye-dilution technique across different operator experiences, the accuracy of subjective and objective (sonographic) estimates was not affected by operator experience and was similarly accurate in identifying normal amniotic fluid volume. The disadvantage is that they are two-dimensional (2D) representations of a complex, 3D structure with limited significance relative to clinical outcome. Although each has been studied extensively, no technique is universally considered superior at predicting perinatal outcome. In the same study, the accuracy of estimates of all three techniques ranged from 65%-70%, and the three sonographic estimates were similar, ranging from 59%-67%. Alarmingly, none of the techniques were accurate in the identification of abnormal volumes (oligohydramnios, or low amniotic fluid, and polyhydramnios, or high amniotic fluid). The accuracy in the identification of normal volumes in twin pregnancies was dismal, ranging from 7%-29%.[54]

Subjective Estimation

Subjective estimation of amniotic fluid is based on the overall sonographic visual impression of the amniotic fluid volume by an experienced sonographer, established by visualizing echolucent pockets between the fetal parts and uterine wall without measurements. Qualitative estimation of the fluid is characterized as normal, increased, reduced, or absent.



Amniotic Fluid Index Measurement

Amniotic fluid index is the summation of the vertical diameter of the largest pocket in each of the four quadrants, as proposed by Phelan and Rutherford.[82] It uses the maternal umbilicus as the central reference point and requires the transducer to be oriented in the longitudinal axis of the maternal abdomen and be kept perpendicular to the floor during scanning. The AFI correlates closely with actual amniotic fluid volume as determined by dye-dilution techniques for normal fluid volume, although it loses its predictive value at the upper and lower ends of the extreme. Moore and Cayle established the mean and outer boundaries (5th and 95th percentiles, respectively) for the AFI from 16-42 weeks' gestation in a study of 791 normal pregnancies.[71] Magann et al. also established 5th-95th percentiles, respectively, as 4.2-14.9 cm for AFI at gestational age 37-41 weeks.[48,62] Both can be seen in Fig. 24.2. The mean AFI is approximately 12-14 cm throughout most of pregnancy, declining after 33 weeks. Above the 95th percentile is approximately 20 cm and below the 5th percentile is approximately 7 cm. The absolute maximum normal AFI is less than 24 or 25 cm. Typical limits for amniotic fluid assessment by AFI are defined in Table 24.1.

TABLE 24.1 Diagnostic Categories by Measurement of the Amniotic Fluid Index

Amniotic Fluid Volume	AFI Value	Patients
Polyhydramnios	≥25 cm	2%
Normal	>8 to <25 cm	76%
Moderate oligohydramnios	≥5 to ≤8 cm	20%
Severe oligohydramnios	<5 cm	2%

SDP, Single deepest pocket.
Data from Chamberlain PF, et al. Ultrasound evaluation of amniotic fluid volume: I. The relationship of marginal and decreased amniotic fluid volumes to perinatal outcomes. *Am J Obstet Gynecol.* 1984;150:245.

Single Deepest Pocket or Maximal Vertical Pocket

The single deepest vertical pocket, as originally described by Chamberlain,[40] is simply found by identifying the largest pocket of amniotic fluid after a global assessment and taking the largest vertical measurement with a horizontal measurement of 1 cm. At gestational age 37-41 weeks, the 5th-95th percentile was 2.3-6 cm for SDP according to nomograms by Magann et al.[62] Typical limits for amniotic fluid assessment by SDP are shown in Table 24.2.

Comparing Amniotic Fluid Assessment Techniques

As stated, the ideal test for sonographic assessment of amniotic fluid volume has not been firmly established. The ideal semiquantitative sonographic technique should be one that correctly identifies the patients at risk for adverse outcome. Amniotic fluid index, SDP, and a two-diameter pocket (horizontal x vertical measurements in cm^2) were compared in a study of 50 normal pregnancies between the gestational ages of 14 and 41 weeks. The prevalence of oligohydramnios as defined by AFI less than or equal to 5 cm, SDP less than 2 cm, or two-diameter pocket less than 15 cm^2 were significantly different (P <.0001) for the three techniques (8%, 1%, and 30%, respectively). The prevalence of polyhydramnios as defined by AFI greater than 24 cm, SDP greater than 8 cm, or two-diameter pocket greater than 50 cm^2 was also diagnosed with significantly different frequencies (P <.0001) (0%, 0.7%, and 3%, respectively).[62] Outcome was not assessed in this study.

Subsequently, two prospective randomized trials comparing the use of SDP versus AFI during modified biophysical profiles in complicated pregnancies were performed. Chauhan and colleagues studied 1080 women and found that AFI identified oligohydramnios in 17% of pregnancies compared with 10% identified in SDP-assessed pregnancies (P = .002).[20] However, there was no difference in delivery mode, NICU admission, umbilical artery pH, or Apgar score. Magann and colleagues had similar findings, showing oligohydramnios was identified in twice as many patients using AFI as compared with SDP in 537 pregnancies (38% vs. 17%, P <.001), resulting in a doubling of inductions of labor (30% vs. 15%, P <.001) and cesarean sections for fetal distress (13% vs. 7%, P <.05).[58] There was, however, no improvement of perinatal outcome. This was confirmed in two meta-analyses comparing the measurement of AFI to SDP.[51,74] Neither sonographic test was superior to the other. Both poorly identified abnormal volumes when compared with dye-determined or directly measured amniotic fluid volume. However, AFI overdiagnosed clinically insignificant oligohydramnios, leading to more intervention without a difference in outcome, suggesting that the single deepest pocket may be a superior sonographic assessment for antenatal testing of the at-risk pregnancy.[74]

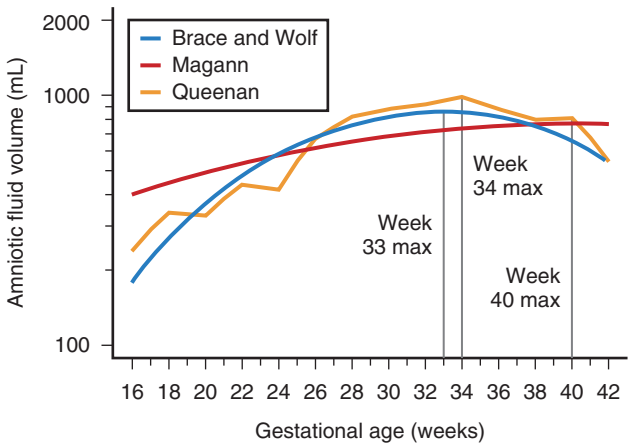
Use of color Doppler has not been shown to aid in identification of pregnancies with adverse outcomes. Using dye-determined volume as the benchmark, Magann et al. compared grayscale ultrasonography to Doppler color ultrasonography and found that Doppler not only overdiagnosed oligohydramnios but labeled 37% of women with normal AFV as having oligohydramnios.[49]

Other Techniques

Sahin et al. attempted to apply the Cavalieri method, a mathematical approximation of volumes, to estimate amniotic fluid volume.[86] Their results correlated with concurrent AFI measurements, and although this is a promising theory, it is complicated to perform and has not been correlated with pregnancy outcome or a directly measured volume.

Three-dimensional ultrasound technology has found relevance in the evaluation of the fetus; however, it has not yet found application in the assessment of amniotic fluid. There has been only one attempt to assess third-trimester amniotic fluid volume with 3D ultrasonography. It was concluded that 3D volume datasets are reliable for determining volume; however, it was determined subjectively by the sonographer based on five volume acquisitions and compared with the value obtained during the 2D ultrasound; there was no attempt at calculating a volume based on a gold standard.[15] Interestingly, in the first trimester, growth charts have been developed for gestational sac volume and embryonic volume, the ratio of which correlates positively with gestational age.[85] Clinical applications for this data have not yet been developed, but normal versus abnormal early pregnancies are being investigated to determine if these parameters can help predict early adverse outcomes such as miscarriage.

Normal Volume and the Singleton Pregnancy



Gravid women accumulate approximately 6 L of additional fluid volume during pregnancy. Most of this fluid is associated with the conceptus: 2800 mL in the fetus, 400 mL in the placenta, and 700-800 mL of amniotic fluid.[87] The

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

remainder of the fluid is associated with the maternal uterus (800 mL), breasts (500 mL), and maternal blood volume expansion (850 mL).[87] Throughout gestation, amniotic fluid volume is highly regulated, gradually increasing in the first trimester, stabilizing in the second trimester, and decreasing late in the third trimester while remaining in a relatively narrow range of volumes.

Normality can be defined in two ways. Mathematically it can represent the majority of the population as expressed by area under the curve in a Gaussian distributed population. Typically the lower and upper 5% are excluded as "abnormal." Normality can also be defined in terms of outcome. Undesired outcomes are tracked, and measurements associated with these outcomes are defined as "abnormal." This second definition is more clinically useful but much more difficult to define.

Amniotic fluid volume has been defined in both these manners. The 5th and 95th percentiles have been defined for AFI, SDP, and dye-determined techniques across gestational ages, as fluid has been found to vary significantly throughout pregnancy. Nomograms for amniotic fluid in normal pregnancies were developed by Queenan et al. in 1972 by dye-determined methods,[84] Brace and Wolfe by dye-dilution and direct measurement,[11] and Magann et al. by dye-dilution and direct measurement. (Fig. 24.3).[48,62] Two of these studies showed that amniotic fluid volume increases steadily in early gestation and remains relatively stable between 22 and 38 weeks, averaging 750-800 mL. Thereafter, amniotic fluid declines by 8% per week, with a mean volume of approximately 500 mL at 40-42 weeks. The third nomogram found that amniotic fluid volume continues to increase throughout gestation, confirming a mean volume of approximately 800 mL at term.[48] A more recent publication evaluated 1,190 normal amniotic fluid volumes (by dye-dilution and direct measurement) across gestation, comparing four statistical methods to construct gestational age-specific reference intervals for amniotic fluid. The investigators determined that quantile regression because of its flexibility and robustness, especially when data is sparse, is the preferred statistical technique to construct gestational age-specific reference for normal amniotic fluid volume (Table 24.3).[77]

• **Fig. 24.3** Comparison of normal amniotic fluid volumes (dye-determined or directly measured) across gestation. (Adapted from Magann EF, Sandlin AT, Ounpraseuth ST. Amniotic fluid and the clinical relevance of the sonographically estimated amniotic fluid volume: oligohydramnios. *J Ultrasound Med.* 2011;30:1573-1585; Brace RA, Wolf EJ. Normal amniotic fluid volume changes throughout pregnancy. *Am J Obstet Gynecol.* 1989;161:382-388; and Queenan JT, Thompson W, Whitfield CR, Shah SI. Amniotic fluid volumes in normal pregnancies. *Am J Obstet Gynecol.* 1972;114:34-38.)

A study of more than 15,000 patients done by Shanks et al. showed that AFI less than the 5th percentile versus a cutoff of 5 cm better predicts fetuses at risk for newborn intensive care (NICU) admission,[89] although this study has been criticized for its retrospective design and the variable intervals between the time the measurement was obtained and the time of delivery. Additionally, an investigation of 291 pregnancies with dye-determined volumes in which the third and fifth percentiles of the AFI were assessed to determine if either of these percentiles was superior to the fixed cutoff of less than 5 for the AFI to detect the 75 pregnancies with oligohydramnios, discovered that both the percentiles (third and fifth) and the fixed cutoff (<5) poorly identified oligohydramnios, but neither was superior to the other.[56]

Twins and Amniotic Fluid

Multifetal pregnancies are at a higher risk of perinatal morbidity and mortality than singleton pregnancies. When evaluating the health of the amniotic fluid in twin pregnancies, singleton growth curves currently provide the best predictors of adverse outcomes, and the evaluation of fluid with singleton nomograms is frequently being used. This approach appears reasonable because in the only evaluation of volume in third-trimester diamniotic twin pregnancies, the amniotic fluid volume, or each sac, was similar to that of normal singleton pregnancies.[64] Morin and Lim performed a literature review with the Diagnostic Imaging Committee of the Society of Obstetricians and Gynaecologists of Canada and suggest that the SDP should be used in each sac with standard definitions for singleton pregnancies, although they state that there is not enough evidence to suggest that one method is more predictive than the others of adverse pregnancy outcome.[72] The AFI has been used to estimate amniotic fluid volume in twins; however, when using the summated AFI (measurement of all four quadrants as is done in singletons but without taking membrane placement into consideration), the measurement poorly predicts dye-determined oligohydramnios and polyhydramnios.[1]

In a single prospective observational study of 299 diamniotic twin pregnancies, SDP was found to be constant between 17 and 37 weeks, with an increase in fetal labor intolerance and neonatal morbidity in twin pregnancies with polyhydramnios. Alternate fixed cutoffs of less than 2.2 cm for a low amniotic fluid volume and greater than 7.5 cm for a high amniotic fluid volume were suggested

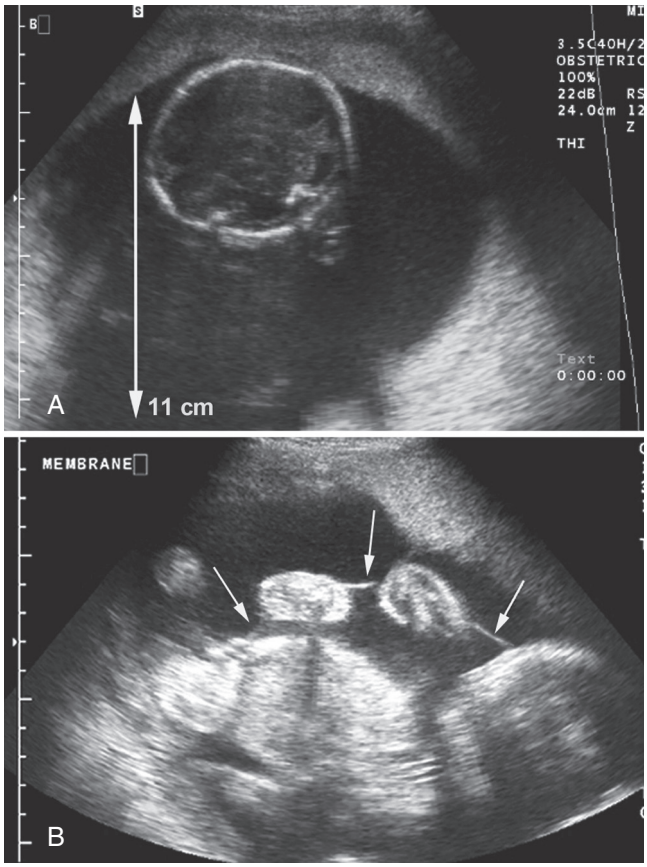
in diamniotic twin pregnancies to identify pregnancies at risk for adverse intrapartum and neonatal outcomes (Table 24.4).[57]

Hernandez et al. performed a retrospective review of 1951 twin pregnancies, both dichorionic and monochorionic, with twin–twin transfusion syndrome excluded.[33] Polyhydramnios was identified in 18% of pregnancies, defined as mild (SDP 8–9.9 cm), moderate (SDP 10–11.9 cm), and severe (SDP ≥12 cm). Pregnancy outcomes were reviewed, and polyhydramnios was not associated with preterm delivery, fetal growth restriction, NICU admission, or neonatal death in either twin. The incidence of major anomalies became more common in increasing polyhydramnios in both monochorionic and dichorionic pregnancies with a prevalence of almost 20% in severe polyhydramnios. Severe polyhydramnios was significantly associated with stillbirth in monochorionic pregnancies (27%, $P < .001$).

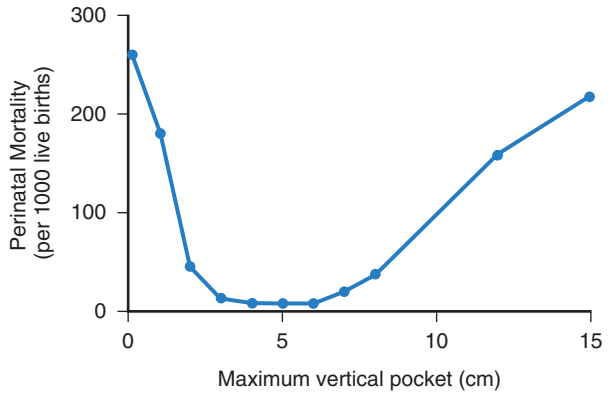
Assessing relative amniotic fluid volume in twin pregnancies is also important because disparity in amniotic fluid volume is a significant component of twin oligohydramnios-polyhydramnios sequence (TOPS), of which twin–twin transfusion syndrome (TTTS) is the extreme endpoint. Twin–twin transfusion syndrome carries with it a three- to fivefold increase in mortality and morbidity.[93] It is often uncovered with ultrasound evidence of discordant fetal weights and amniotic fluid in monochorionic/diamniotic twins, although it has been documented in monochorionic/monoamniotic pregnancies.[92] It may also present sonographically as a "stuck twin," with the fetus appearing to be suspended to the uterine wall with no intervening membrane visible, or there may be tightly adhered membranes that make a fetus appear wrapped in plastic wrap (Fig. 24.4). It is recommended that evaluation for twin–twin transfusion in these pregnancies should begin in the second trimester with weekly surveillance if discordant and evaluation every 2 weeks for concordant pregnancies.[17]

Abnormalities of Amniotic Fluid Volume and Their Management



Deviation of amniotic fluid volume outside the normal range is associated with increased pregnancy loss. As early as the first trimester, low gestational sac fluid volume is predictive of increased rates of spontaneous abortion, 94% versus 8% in patients with normal sac size.[14] In the second and third trimesters, departure above or below normal volumes increases the perinatal mortality (PNM) rate (Fig. 24.5). When diagnosis was made in the third trimester, patients fared better, although there was still a 15% PNM rate.

Oligohydramnios



Oligohydramnios has been defined as an amniotic fluid volume that is less than 200 mL[35] or 500 mL[23] and occurs in 1%-2% of pregnancies. It is sonographically defined as an SDP less than 2 cm, AFI less than 5 cm, or a subjectively low volume. Borderline fluid has been defined as an AFI between 5 and 8 cm or 5 and 10 cm and has been associated with fetal malformations if diagnosed at age 24 and 34 weeks.[52,81]

Low amniotic fluid can be caused by underproduction or loss or can be idiopathic. Underproduction can be the result of absent or dysfunctional kidneys, urinary tract obstruction, uteroplacental insufficiency, maternal medications, or maternal dehydration. Loss is caused by rupture of membranes. Box 24.1 lists conditions associated with oligohydramnios. The clinical management of oligohydramnios should be directed toward diagnosing and alleviating remediable underlying conditions. Appropriate work-up for this abnormality is a review of the maternal history for evidence of rupture, anatomic evaluation of the renal system and bladder, and assessment of placental function and fetal growth and pulmonary status.

The membranes surrounding this twin are not visible on ultrasound examination. **B,** Note the tightly adherent membranes (*arrows*) in the donor twin sac.

• **Fig. 24.5** Perinatal mortality rate related to maximum vertical pocket (MVP) measurements in centimeters. Note the increased perinatal mortality with MVP less than 2 or greater than 8 cm. (Adapted from Harman CR. Amniotic fluid abnormalities. *Semin Perinatol.* 2008;32:288.)

Clinical Implications

Oligohydramnios increases perinatal morbidity with increased rates of IUGR (fetal weight less than the 10th percentile for gestational age, or abdominal circumference less than the 2.5th percentile), meconium-stained amniotic fluid, fetal labor intolerance, and low Apgar scores. Regardless of the etiology, fetuses in pregnancies complicated by oligohydramnios are at increased risk of adverse outcomes in the form of cord accidents, fetal lung hypoplasia, and, if in the first and second trimesters, malformations and contractures.[78] Oligohydramnios was retrospectively evaluated in 7582 fetuses in high-risk pregnancies with normal anatomy. Perinatal mortality was 11% in these pregnancies versus 0.2% in pregnancies with normal fluid based on SDP. Borderline fluid of SDP 1-2 cm was associated with an increased mortality at 3.7%.[18]

There are conflicting data that contend that the most significant risk to the normal fetus with incidental oligohydramnios is iatrogenic prematurity resulting from the subsequent rush to delivery.[68] Low amniotic fluid volume as determined by dye-dilution along with IUGR has been associated with NICU admission (OR 11.1) but no other measures of infant morbidity.[59]

Etiology

In a series by Shenker and colleagues, the most common cause of oligohydramnios was premature rupture of

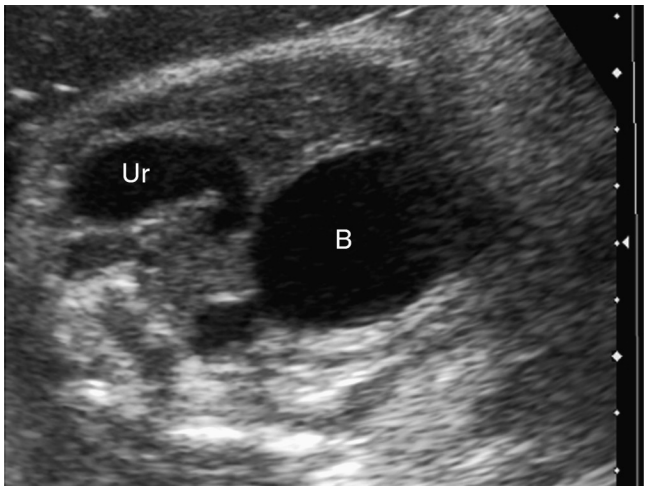
• BOX 24.1 Principal Diagnoses Associated With Oligohydramnios

Fetal

- Chromosomal abnormalities
- Congenital anomalies
  - Genitourinary (renal agenesis, polycystic or multicystic dysplastic kidneys, ureteral or urethral obstruction)
- Intrauterine growth restriction
- Intrauterine fetal demise
- Postmaturity
- Premature rupture of membranes (occult or overt)
  - Preterm
  - Prolonged

Maternal

- Uteroplacental insufficiency
  - Autoimmune condition
  - Antiphospholipid antibodies, collagen vascular disease
  - Maternal hypertension
  - Nephropathy
  - Diabetic vasculopathy
  - Maternal hypovolemia
  - Preeclampsia/pregnancy-induced hypertension
- Medications
  - Prostaglandin synthetase inhibitors
  - Angiotensin-converting enzyme inhibitors



Placental

- Chronic abruption
- Placental crowding in multiple gestation
- Twin–twin transfusion
- Placental infarction

Idiopathic

• **Fig. 24.6** Posterior urethral valve syndrome. Male fetus with "keyhole" bladder on ultrasound. Note large bladder (*B*) and dilated ureter (*Ur*).

membranes (PROM) (50%), followed by IUGR (18%) and congenital anomalies (14%).[90] Shipp and associates noted a bimodal distribution of severe oligohydramnios, with congenital abnormalities accounting for 51% of cases occurring at 13-21 weeks' gestation, but only 22.1% at 34-42 weeks. In this series, urinary tract malformations accounted for 58.7% of all anomalies seen, with aneuploidy accounting for 4% of severe oligohydramniotic patients.[91] Genitourinary malformations associated with oligohydramnios include renal agenesis, cystic dysplasia of the kidneys, and obstructive uropathies, including posterior urethral valve syndrome. The sonographic appearance of posterior urethral valves with megacystis is shown in Fig. 24.6. Late diagnosis of oligohydramnios in pregnancies with normal anatomy has also been found to be associated with undiagnosed renal anomalies up to 9.8% of the time.[44]

Maternal use of certain medications can lead to development of oligohydramnios. Prostaglandin synthetase inhibitors (e.g., indomethacin, ibuprofen, sulindac), which are used to inhibit labor, reduce polyhydramnios, and relieve pain, also reduce the fetal glomerular filtration rate, resulting in decreased fetal urine output and oligohydramnios in up to 70% of patients. They may also decrease uteroplacental perfusion and prematurely cause closure of the ductus arteriosus. Although these effects are reversible, patients maintained on indomethacin for more than 72 hours should be evaluated with semiweekly amniotic fluid assessments and fetal echocardiography to assess the ductal flow. Angiotensin-converting enzyme (ACE) inhibitors have also been implicated as causing oligohydramnios, presumably secondary to severe fetal hypotension, reducing renal blood flow. Angiotensin-converting enzyme inhibitors are associated with producing prolonged neonatal anuria, renal anomalies, ossification defects in the fetal skull, and death; therefore, they are contraindicated in pregnancy.

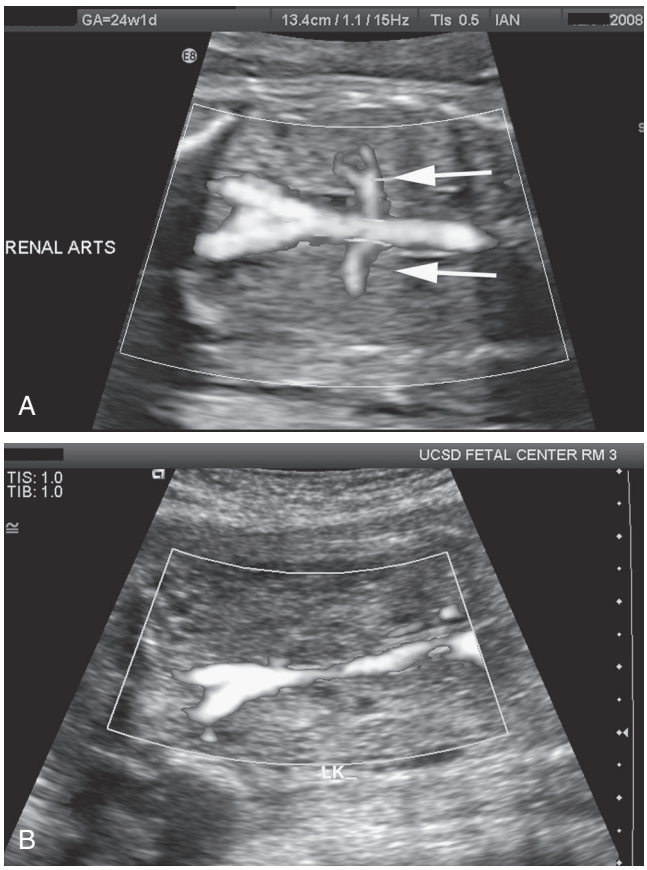
Diagnostic Evaluation

Rule Out Ruptured Membranes

A sterile speculum examination should be performed on any patient suspected of having PROM. If amniotic fluid is grossly present in the posterior vagina, the diagnosis of PROM is confirmed. If only a small amount of fluid is present, it should be tested with Nitrazine paper to detect the alkaline pH of amniotic fluid. A sample should also be applied to a slide and allowed to dry. Sodium chloride in the amniotic fluid crystalizes in a "ferning" pattern, confirming the diagnosis. Cervical mucus, when applied to a slide and allowed to dry, also can create a crystalized pattern, so care should be taken to avoid collection of cervical mucus. Frequently these examinations are negative or equivocal for reasons such as chronic leakage or contaminating blood or semen, making it difficult to conclusively diagnose chronic fluid leakage. If a normal-sized fetal bladder is observed on ultrasound with concomitant severe oligohydramnios, the likelihood of PROM is high. Injection of indigo carmine diluted in sterile saline into the amniotic sac with an amniocentesis needle after placement of a tampon in the vagina can confirm the diagnosis of PROM in cases that are difficult to detect. Patients should be warned that if the fetus delivers within a few days of injection, the baby may be stained blue. Methylene blue dye has been reported to cause methemoglobinemia and hemolysis and, therefore, should not be used. Pyridium has also been reportedly used; however, the orange to red hue of the stained fluid is difficult to distinguish from bodily fluids.

Monoclonal antibodies to detect placental α-microglobulin-1 (PAMG-1) in the vagina can be used to confirm PROM. In clinical testing, the test kit AmniSure (AmniSure International LCC, Cambridge, MA) was shown to be highly sensitive (98.7%) and specific (87.5%) at detecting even minute amounts of PAMG-1 in the vagina.[42] However, false-positive results can occur if there is bleeding; false-negative results are possible if the sample is taken more than 12 hours after presumed PROM.

A group of 31 women with rupture before 24 weeks' gestation was followed for outcomes based on SDP greater than or less than 1 cm (severe oligohydramnios). The group with SDP greater than 1 cm was associated with a longer latency to a live birth in 60% of pregnancies compared to 8.3% in the group with SDP less than 1 cm. The remainder of outcomes, such as sepsis, chorioamnionitis, and abruption, was not statistically different among groups.[94] A separate study found that AFI was a poor predictor of survival in pregnancies with preterm PROM between 16 and 24 weeks.[36]



Assess Fetal Anatomy

A careful ultrasound examination with anatomic survey should be performed in cases of oligohydramnios to rule out congenital anomalies, particularly because renal and ureteral anomalies are the most common anatomic cause of severe oligohydramnios in the absence of ruptured membranes.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

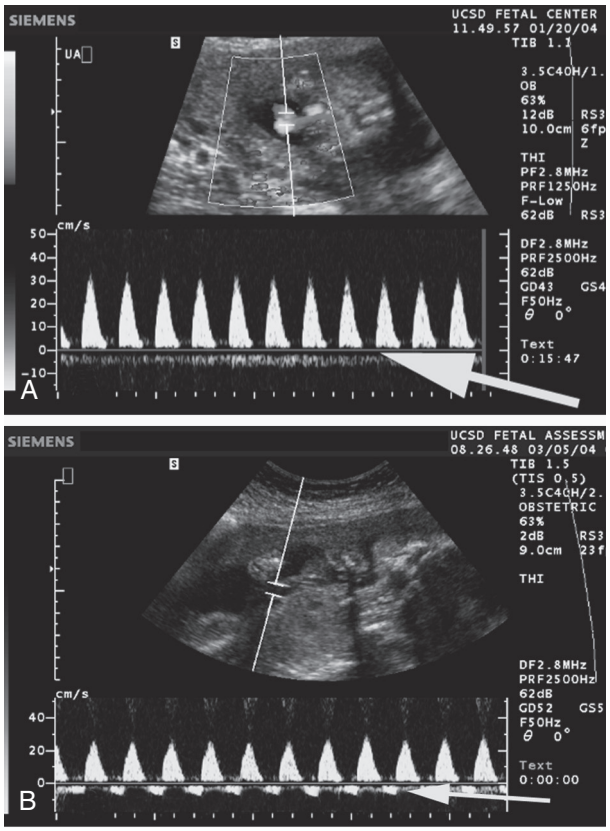
The fetal urinary system should be thoroughly evaluated, paying close attention to the renal parenchyma, dimensions of the renal pelvis, and morphologic features of the fetal urinary bladder. Cardiac, skeletal, and central nervous system anomalies may coexist with primary renal anomalies and should be investigated. Chromosomal abnormalities (i.e., trisomies 18 and 21) can also present with renal anomalies, so evaluation for other signs of aneuploidy should be included and genetic amniocentesis or maternal blood for fetal cell-free DNA considered. Interestingly, isolated renal anomalies do not increase the risk of aneuploidy. With bilateral renal agenesis, virtual anhydramnios is present from 16 weeks onward. With anhydramnios, it is difficult to adequately document whether the fetal kidneys are present. In addition, the fetal adrenals can become hypertrophied and resemble renal structures. To aid in the identification of renal agenesis, Doppler imaging (Fig. 24.7) may be necessary to document the absence of renal arteries to conclusively prove renal agenesis. Transabdominal infusion of normal saline into the amniotic cavity has also been used as an adjunct in midtrimester evaluation of suspected renal agenesis. In a series by Fisk and colleagues, suspected fetal anomalies were confirmed in 90% of patients using amnioinfusion to better visualize fetal structures.[28] However, 13% of the etiologic diagnoses were changed as a result of information obtained at amnioinfusion, including the finding of kidneys in some cases of suspected renal agenesis. Aspiration of a small amount of the fluid instilled during amnioinfusion has also been used for chromosomal analysis with a 70% success rate.

Conversely, polycystic renal disease and obstructive uropathy (e.g., ureteropelvic junction obstruction) are more readily apparent but may not become evident until the late second trimester. Fortunately, unilateral renal agenesis or polycystic kidney disease rarely causes significant decreases in amniotic fluid. Magnetic resonance imaging can also be useful for assessing anatomy not well seen on ultrasound.

• **Fig. 24.7** Bilateral renal agenesis. **A**, Doppler image of normal renal arteries (*arrows*) at 24 weeks' gestation. **B**, Power Doppler image of fetal abdominal aorta and its bifurcation at 20 weeks' gestation, demonstrating bilateral absence of renal arteries. Note absence of amniotic fluid.

Assess Fetal Growth

Chronic poor placental function owing to maternal autoimmune disease, hypertension, or vasculopathy can lead to fetal growth restriction and oligohydramnios. Therefore, if PROM and congenital anomalies are excluded, IUGR resulting from uteroplacental insufficiency should be considered. In general, uteroplacental insufficiency results in asymmetric IUGR, with the fetal abdomen lagging behind the fetal head growth. However, long-standing growth restriction can produce a more symmetric picture. Early-onset symmetric IUGR is more likely to be caused by aneuploidy or congenital anomaly.



In cases of IUGR related to placental insufficiency, Doppler studies of uterine and umbilical blood flow may reveal patterns of high resistance. Absent or reverse end-diastolic flow patterns in the umbilical artery are associated with higher perinatal mortality and are demonstrated in Fig. 24.8. The fetal middle cerebral artery (MCA) can also be interrogated via Doppler and can show increased amplitude of diastolic flow as a marker of fetal hypoxia and cerebral vasodilation. Management of abnormal Doppler studies is dependent on gestational age. Pulsatility of the MCA and abnormal ductus venosus flow are late findings of fetal compromise and are indications for delivery.

In patients with IUGR with oligohydramnios, intensive fetal monitoring and hospitalization should be initiated, because the risks of fetal asphyxia and death are high. Monitoring should be continued in patients diagnosed between 26 and 32 weeks' gestation. Corticosteroids for lung maturity should be considered. Amniocentesis to assess lung maturity should be considered after 32 weeks; however, with severe oligohydramnios, this can be technically challenging. Delivery should be undertaken if the lungs are mature or if there is evidence of a deteriorating fetal status.

Assess Fetal Pulmonary Status

Prolonged oligohydramnios can result in pulmonary hypoplasia, which is associated with a high perinatal mortality. Inhibition of fetal breathing, lack of a trophic function of amniotic fluid within the airways, and simple mechanical compression of the chest are proposed as causes of pulmonary hypoplasia; however, the precise pathophysiology remains unclear.

• **Fig. 24.8** Doppler umbilical artery velocimetry. **A,** Absent end-diastolic flow. Note the umbilical artery flow velocity waveform returns to zero following each fetal heart beat (*large arrow*). **B,** Reverse end-diastolic flow. Here the waveform extends below the zero line (negative flow) between the fetal heartbeats (*small arrow*).

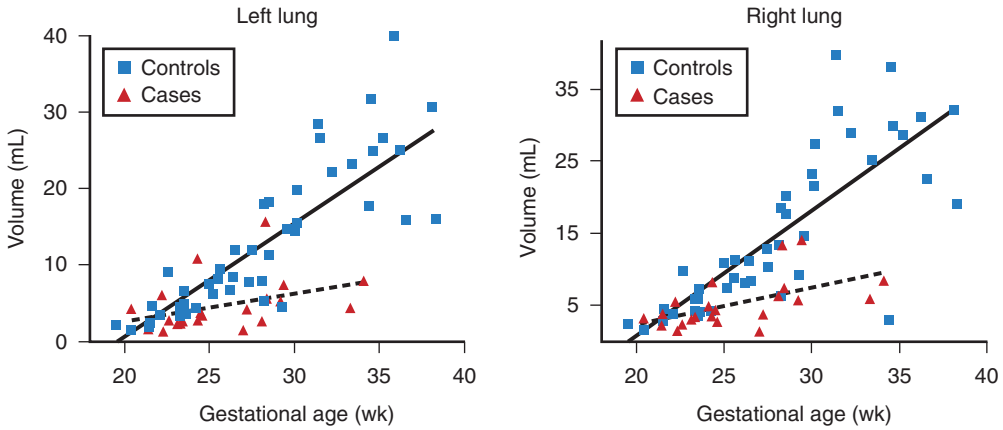
The risk of developing pulmonary hypoplasia is greatest if oligohydramnios is prolonged and occurs during the canalicular phase of alveolar proliferation, from 16-26 weeks of gestation.[98] Improved survival is seen if there is a persistence of a fluid pocket of at least 2 cm between 20 and 25 weeks of gestation (30% survival if the pocket is <2 cm; 98% if the pocket is ≥2 cm). The estimated probability of developing pulmonary hypoplasia with severe oligohydramnios in the second trimester is illustrated in Fig. 24.9.

Several sonographic techniques have been proposed for predicting pulmonary hypoplasia, including measuring lung length and chest circumference, or evaluation of biometric ratios (e.g., thoracic-to-abdominal circumference or thoracic circumference-to-femur length). D'Alton and colleagues found a thoracic-to-abdominal circumference ratio of less than 0.08 in severe oligohydramnios virtually 100% predictive of lethal pulmonary hypoplasia.[21] Sonographically, this would have the appearance of a "bell-shaped" chest, which by itself is concerning for pulmonary hypoplasia.

Vintzileos and coworkers reviewed six current sonographic parameters for predicting pulmonary hypoplasia and found that the highest sensitivity (85%) and specificity (85%) were achieved by calculating the lung area ratio[99]:

• **Fig. 24.9** Estimated probability of development of pulmonary hypoplasia by gestational age in severe oligohydramnios (<2 cm maximum vertical pocket). *Solid line* indicates probability curve. *Dashed line* illustrates 50% probability at approximately 25 weeks' gestation. (From Vergani P, et al. Risk factors for pulmonary hypoplasia in second-trimester premature rupture of membranes. *Am J Obstet Gynecol.* 1994;170:1359.)

$$\frac{(\text{chest area} - \text{cardiac area}) \times 100}{\text{chest area}}$$



The normal lung area ratio should be greater than 66% with the heart occupying less than one-third of the fetal chest. Compared with 2D imaging techniques, 3D lung volumes have higher sensitivity (94%) but similar specificity (82%) in diagnosis of pulmonary hypoplasia. Fig. 24.10 shows total fetal lung volumes for a set of controls and cases with pulmonary hypoplasia using 3D ultrasound. Studies using magnetic resonance imaging are promising; however, nomograms for development have not been standardized.

Treatment

The management of oligohydramnios depends on the severity of the condition, the underlying cause, and the gestational age of the patient. If discovered at term, induction of labor would be a reasonable option. There is a single randomized trial evaluating induction versus expectant management in 54 patients with oligohydramnios beyond 40 weeks.[73] No difference was found in mode of delivery or neonatal Apgar score or cord blood pH.[24] However, in more than 500 maternal-fetal medicine members surveyed, 92% would recommend induction without documented lung maturity before 39 weeks, and 35% before 37 weeks, even though only one-third of respondents felt induction would decrease adverse outcomes.[88] If expectant management is chosen, there is no consensus on what fetal monitoring is best, or even if fetal monitoring is necessary; however, the use of Doppler monitoring in pregnancies thought to be at risk of placental insufficiency has shown benefit. Consistent maternal oral hydration should be encouraged.

Before term, the discovery of oligohydramnios should initiate a comprehensive sonographic evaluation if that

• **Fig. 24.10** Scatter dot plot and regression lines of left and right lung volumes for cases with pulmonary hypoplasia (▲) and controls without pulmonary hypoplasia (■), including serial scans. (Data from Vergani P, et al. Two- or three-dimension ultrasonography: which is the best predictor of pulmonary hypoplasia? *Prenat Diagn.* 2010;30(9):834-838.)

assessment has not already been undertaken, focusing on the renal system and bladder as well as fetal growth and placental function. Chromosomal analysis can be offered to patients, and premature rupture of the membranes should be excluded. Antepartum nonstress testing or biophysical profiles along with Doppler flow studies may be useful, particularly in those pregnancies with isolated oligohydramnios and all other testing reassuring of fetal well-being in avoiding delivery of a preterm fetus or an induction in a term fetus with an unfavorable cervix.

The patient with PROM should be delivered if there is evidence of infection; otherwise, the patient can be managed expectantly with hospitalized bed rest and observation until the fetus reaches 34 weeks or has abnormal antenatal testing. Antibiotics should be administered to prolong latency and corticosteroids given to enhance lung maturity. Most deliver within a week, but those who do not can potentially remain pregnant for several weeks.

Maternal Hydration

Idiopathic oligohydramnios has been found to be responsive to maternal hydration with no difference in IV versus oral hydration acutely or long term.[55,79] The effect, however, is short-lived without continued efforts at hydration.[66] Women also placed in the left-lateral position at rest have been found to have an increase in AFI.[97] It is notable that none of the preceding studies evaluated clinically important outcomes. Maternal hydration, therefore, has a limited clinical application and may help in cases in which adequate amniotic fluid assists in outcome, such as external cephalic versions or amniocentesis.

Amnioinfusion

Prophylactic transcervical amnioinfusion has been shown to reduce the cesarean section rates when used in patients before being induced for oligohydramnios at term. Presumably this effect is achieved by reducing cord compression during labor. However, potential complications from amnioinfusion, including uterine overdistention, hypertonus, infection, and amniotic fluid embolism warrant using this modality with cautious, close monitoring. Amnioinfusion as a treatment for meconium-stained amniotic fluid is no longer recommended.

In severe second-trimester oligohydramnios, serial transabdominal amnioinfusion has been advocated as a therapeutic procedure to prevent pulmonary hypoplasia and improve outcomes. However, in Fisk and colleagues' limited series of nine patients,[28] only 33% of neonates survived. In Locatelli and associates' study of 49 women with PROM before 26 weeks, 36 underwent serial amnioinfusion.[47] They were successful in maintaining the maximum vertical pocket greater than 2 cm in 11 patients, which significantly improved perinatal outcomes: pulmonary hypoplasia was reduced from 62%-10% with no abnormal neurologic outcomes. Other small series similarly report decreased pulmonary hypoplasia, better neurologic outcomes, and overall improved survival with serial amnioinfusions.

Tissue Sealants

Application of various compounds to seal ruptured membranes has been tried since 1979. Compounds used for treating preterm PROM include platelets with thrombin or cryoprecipitate, fibrin sealants to occlude the cervical canal, gelatin plugs, synthetic hydrogels, collagen plugs, and blood patches. These treatments have been associated with poor outcomes, including fetal bradycardia and death, and remain investigational, although a few successes have been reported in repairing the amniotomy made at the time of fetal surgery. The utility in the use of tissue sealants is problematic in pregnancies complicated by preterm PROM, because the reason for the rupture is infection in a number of these pregnancies, and the use of a tissue sealant would not be appropriate in the management of these pregnancies. More study is needed before recommendations can be made for preterm PROM.

Polyhydramnios

Polyhydramnios has been defined as an amniotic fluid volume of greater than 2000 mL[60] and occurs in 1%-3% of pregnancies. By ultrasound techniques, it has been estimated as an SDP greater than 8 cm, AFI greater than 24 or 25 cm or an amniotic fluid volume above the 95th percentile for gestational age, or a subjectively high volume of fluid. Patients with polyhydramnios may present with increased uterine fundal height, dyspnea, edema, and increased weight.

Elevated amniotic fluid can result from decreased absorption, overproduction, or be idiopathic. Decreased absorption typically results from a failure of fetal swallowing from etiologies such as tracheal atresia, tracheal or bowel obstruction, or neurologic abnormalities such as anencephaly. Chromosomal abnormalities,[13] nonimmune hydrops, and diabetes are also recognized reasons for polyhydramnios. The diagnostic workup for polyhydramnios includes an assessment for diabetes, syphilis, Rh isoimmunization, or atypical antibodies that might lead to hemolytic disease of the newborn, fetal or placental (chorioangioma) abnormalities, and work-up for infection if there has been a recent exposure or maternal history suggestive of a recent infection.

Clinical Implications

Retrospective reviews of pregnancies with polyhydramnios show an association with macrosomia, premature births, nonreactive nonstress tests, perinatal morbidity, and congenital anomalies in high-risk pregnancies with polyhydramnios.[76] One hundred eighteen pregnancies with polyhydramnios as defined by SDP greater than 8 cm with a normal fetal anatomic scan, 75-g glucose test, and TORCH serology were studied retrospectively by Abele et al.[1] Eleven of those pregnancies had postnatal abnormalities identified, with the majority being gastrointestinal atresia. In a study of 788 infants with polyhydramnios, the rate of congenital malformations was 2.3% compared with 0.13% in those with normal amniotic fluid. Those with no major congenital malformation diagnosed were at risk for the development of respiratory distress and hypoglycemia.[45]

Etiology

The prevalence of polyhydramnios is 1%-2% with 50%-60% of those pregnancies being idiopathic. Because the major pathway for removal of amniotic fluid is swallowing, it follows that congenital anomalies that interfere with swallowing or intestinal absorption (e.g., duodenal atresia) are the most common causes of polyhydramnios. The prevalence of congenital anomalies correlates with the severity of polyhydramnios, with a 2.6 times greater incidence of anomalies in severe polyhydramnios (75%) than in mild polyhydramnios (29%).[25]

Polyhydramnios has also been linked to maternal pregestational and gestational diabetes and fetal macrosomia.

• BOX 24.2 Principal Diagnoses Associated With Polyhydramnios

Fetal

- Chromosomal abnormalities
- Congenital anomalies
  - Gastrointestinal (duodenal or esophageal atresia, tracheoesophageal fistula, gastroschisis, omphalocele, diaphragmatic hernia)
  - Craniofacial (anencephaly, holoprosencephaly, hydrocephaly, micrognathia, cleft palate)
  - Pulmonary (congenital pulmonary airway malformation, chylothorax)
  - Cardiac (malformations, arrhythmias)
  - Skeletal dysplasias
- Fetal hydrops (immune or nonimmune)
- Anemia (fetomaternal hemorrhage, parvovirus infection, isoimmunization, thalassemia)
- Neuromuscular disorders (myotonic dystrophy, Pena-Shokeir)
- Neoplasias (teratomas, hemangiomas)
- Constitutional macrosomia

Maternal

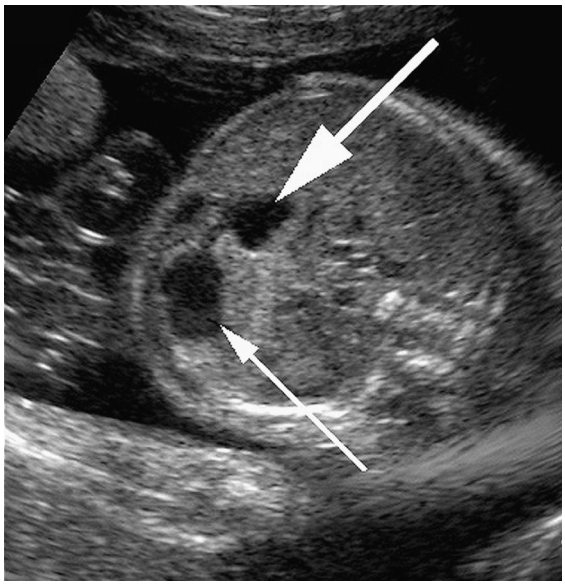
- Diabetes mellitus
  - Gestational diabetes
  - Adult-onset (type 2) diabetes

Placental

- Chorioangioma
- Twin–twin transfusion

Idiopathic

Adapted from Phelan JP, Martin GI. Polyhydramnios: fetal and neonatal implications. *Clin Perinatol.* 1989;16:987; Hill LM, et al. Polyhydramnios: ultrasonically detected prevalence and neonatal outcome. *Obstet Gynecol.* 1987;69:21; Ben-Chetrit A, et al. Hydramnios in the third trimester of pregnancy: a change in the distribution of accompanying anomalies as a result of early ultrasonographic prenatal diagnosis. *Am J Obstet Gynecol.* 1990;162:1344.)



Increased fetal urination in mothers with adult-onset or gestational diabetes accounts for nearly 15% of cases of polyhydramnios.[34] Isolated polyhydramnios has not been found to be a strong independent predictor of gestational diabetes. Aneuploidy is reported in 3%-13% of pregnancies associated with polyhydramnios.[34] Development of the Rh immunoglobulin to prevent immune hydrops fetalis resulting from Rh isoimmunization (see Chapter 23) has decreased the incidence of polyhydramnios due to this condition. Box 24.2 lists conditions associated with polyhydramnios.

Diagnostic Evaluation

Assess Fetal Anatomy

A detailed sonographic evaluation should be performed to assess the fetus for possible congenital anomalies, paying particular attention to the gastrointestinal system for abnormalities that impair fetal swallowing and absorption of the fluid. With proximal obstruction (e.g., esophageal atresia,

• **Fig. 24.11** Duodenal atresia. Note the characteristic double bubble sign within the fetal abdomen, illustrating the fluid-filled stomach (*small arrow*) and duodenum (*large arrow*) on this transverse view of the fetal abdomen.

tracheoesophageal fistula, or esophageal compression from diaphragmatic hernia or lung mass), the usual stomach "bubble" is absent. Conversely with distal obstruction, multiple cystic structures may be seen in the fetal abdomen. For example, duodenal atresia produces a characteristic "double bubble" appearance (Fig. 24.11). Decreased fetal swallowing, which may result in polyhydramnios, is associated with anencephaly, trisomy 18, trisomy 21, muscular dystrophies, fetal akinesia, and skeletal dysplasias. If polyhydramnios is present with a growth-restricted fetus, or if markers of aneuploidy are seen, evaluation for chromosomal abnormalities should be undertaken. Close surveillance is important in the pregnancy with polyhydramnios and IUGR because of the increased risk of perinatal mortality, neonatal morbidity, and neonatal mortality.[25]

Sonographic signs of fluid overload (i.e., hydrops fetalis), including ascites, pleural effusion, pericardial effusion, and skin edema, should be assessed. Polyhydramnios in hydrops fetalis may be the first presenting sign, prompting further evaluation for erythroblastosis fetalis or nonimmune hydrops.

In anatomically normal fetuses with otherwise unexplained polyhydramnios, diabetes should be suspected, particularly if there is fetal macrosomia or asymmetrically larger fetal abdominal circumference. These patients should be evaluated with a glucose tolerance test and treated accordingly. Polyhydramnios in diabetes is associated with increased perinatal morbidity and mortality beyond that of the diabetes itself.

Currently, the best technique, AFI versus SDP, to estimate polyhydramnios is uncertain. In oligohydramnios, the AFI and SDP do not label pregnancies as having oligohydramnios similarly. Magann et al. observed that in 72% of pregnancies with an AFI <5, the SDP remained normal.[53] The Cochrane review[75] concluded the SDP was superior to the AFI in antenatal testing, because the AFI increased the pregnancies diagnosed with oligohydramnios, leading to more interventions without an improvement in perinatal outcomes. With the use of the AFI and SDP in labeling pregnancies as having polyhydramnios, an overlabeling with the SDP to classify a pregnancy at having polyhydramnios has been observed. Does the use of the SDP lead to an increased number of pregnancies being labeled as having polyhydramnios without an improvement in perinatal outcomes? Future investigations are needed.

Treatment

If nonlethal congenital anomalies are uncovered, appropriate pediatric specialists should be consulted for postnatal treatment. In patients with idiopathic mild polyhydramnios (AFI of 24-40 cm), the perinatal outcome should be no different than that in patients with normal amniotic fluid volume, other than large-for-gestational-age babies (>4000 g at birth). Uterine overdistention, however, may stimulate preterm uterine contractions, and labor may ensue. These patients are at a significantly high risk for PROM and cord prolapse. They should be counseled on the signs and symptoms of preterm labor. If polyhydramnios is discovered at an early gestation, antenatal testing should be initiated at 24 weeks' gestation, although there is no consensus on what type of testing should be begun or at what interval. This can be left to the discretion of the physician. The patient should be assessed for early cervical changes if she is contracting or otherwise symptomatic. In women with severe polyhydramnios (AFI >40 cm), amnioreduction or prostaglandin inhibitors should be considered for those with significant maternal complications (difficulty breathing). There are no recommendations for induction of labor if discovered at term.

Amnioreduction

Removal of excess amniotic fluid may prolong pregnancy and reduce maternal dyspnea from the overdistended uterus in patients with severe polyhydramnios. Calderyo-Barcia and coworkers demonstrated that amnioreduction reduces the baseline tonus and contractility of the uterus by using transabdominal intrauterine pressure transducers in cases of polyhydramnios[16]; however, amniotic fluid invariably returns, making serial amnioreduction necessary. In a series by Leung and colleagues, 134 rapid amnioreduction procedures were performed on 74 patients with a maximum vertical pocket greater than 10 cm using higher flow rates (≈100 mL/min).[46] The most common reported indication for the amnioreduction was TTTS, and repeated procedures were required in 64% of cases. However, a single amnioreduction was sufficient in 70% of patients without TTTS. Complications of amnioreduction include PROM, preterm labor, abruption, fetal bradycardia, infection, and maternal hypoproteinemia.

Prostaglandin Synthetase Inhibitors

Indomethacin reduces amniotic fluid volume by stimulating fetal vasopressin release, which has an antidiuretic effect on fetal urine production. Indomethacin is also postulated to enhance fluid reabsorption by the fetal lungs and increase transmembranous absorption of excessive amniotic fluid back to the maternal circulation. The dosing of indomethacin is generally 25 mg orally every 6 hours but can range up to 100 mg every 4-8 hours, depending on the severity of polyhydramnios and clinical response. Treatment should be discontinued once the fluid is reduced by one-third to one-half of its original volume, or when the AFI is less than 20 cm. Indomethacin is effective in reducing the amniotic fluid volume in more than 90% of cases of polyhydramnios, but complications during treatment include premature closure of the ductus arteriosus, renal complications, and necrotizing enterocolitis. Chronic ductal closure in utero can produce fetal hydrops and persistent pulmonary hypertension in the neonate. The risk of ductal constriction is 5% at 27 weeks and increases to almost 50% by 32 weeks; therefore, indomethacin treatment should be discontinued before 32 weeks to avoid iatrogenic side effects. Complications linked with indomethacin use can be minimized if the total dose of indomethacin is less than 200 mg per day and the therapy is discontinued after 48 hours of therapy.

Sulindac, a prostaglandin inhibitor sometimes used for preterm labor symptoms, has incidentally been shown to also reduce amniotic fluid volume. It has a purported advantage of less ductal closure but has not been investigated prospectively for treatment of polyhydramnios.

Close Surveillance

Idiopathic polyhydramnios, in a review of the existing literature, has been linked with a twofold to fivefold increase in the risk of perinatal mortality.[50] The ideal management of idiopathic polyhydramnios is unknown. One proposed management scheme is to do serial antenatal testing, and as long as those assessments are reassuring, then delivery probably does not need to occur before term.[95] If the idiopathic polyhydramnios resolves before term, the question of the pregnancy remaining at increased risk for perinatal mortality is also unknown.

Management of Fluid Abnormalities in Multifetal Pregnancies

Management of abnormal amniotic fluid volume in twin pregnancies does not vary much from singleton pregnancies with the single exception of twin–twin transfusion syndrome. Pregnancies with polyhydramnios-oligohydramnios sequence or those with diagnosed twin–twin transfusion syndrome should be referred to maternal-fetal medicine for evaluation and potential treatment as indicated. Laser therapy is being used with increased frequency in monochorionic diamniotic twin pregnancies complicated by twin–twin transfusion syndrome. Recommended surveillance is assessments of amniotic fluid volume every 2 weeks beginning at 16 weeks and continuing throughout the pregnancy. Surveillance recommendations for twin pregnancies are amniotic fluid assessments and growth scans every 4 weeks. The diagnosis of abnormal amniotic fluid in monoamniotic twins does not alter management of the pregnancy, as antenatal testing should begin at viability and delivery planned early.[38,95] The discovery of abnormal fluid volumes may prompt earlier evaluation of causes such as twin–twin transfusion syndrome, IUGR, and congenital anomalies. Dichorionic/diamniotic twin pregnancies should be treated as described for singleton pregnancies. In pregnancies in which polyhydramnios is found in both sacs, or in a single shared amnion, fluid reduction may be necessary for maternal comfort, and preterm labor may be encountered more frequently.[6]

The Future

Amniotic fluid also harbors fetal cells for chromosomal analysis and multiple proteins, some of which have clinical significance such as alpha-fetoprotein, phosphatidylglycerol, and interleukin-6. Amniotic fluid is now being evaluated by complex methods, such as capillary electrophoresis for early predictors of outcomes such as macrosomia and maternal gestational diabetes.[7,29] Amnion and amniotic fluid are also being used to harvest embryonic stem cells for research in all arenas of medicine, including cancer research.[41] Amniotic fluid is not only the nectar that supports a healthy pregnancy, it is a clue to maternal and fetal disease and possibly the gateway to future therapy.

Key Points

- Fetal contributions to amniotic fluid include fetal urine, lung fluid, and removal by fetal swallowing.
- Ultrasound assessments of amniotic fluid volume include amniotic fluid index and single deepest pocket.
- Both oligohydramnios and polyhydramnios may have maternal, placental, or fetal etiologies and require close monitoring for fetal well-being.

Perinatal Infections and Chorioamnionitis

RICHARD POLIN AND TARA M. RANDIS

Definitions and Epidemiology

Chorioamnionitis (or intra-amniotic infection) is a major cause of fetal, neonatal, and maternal morbidity and mortality. There are strong associations between chorioamnionitis and maternal morbidity,[57] preterm birth,[46] early-onset neonatal sepsis,[67] bronchopulmonary dysplasia,[35] retinopathy of prematurity,[13,63] and diffuse white matter injury.[3] The literature supporting these associations has been inconsistent, largely because of lack of precision in the diagnosis of chorioamnionitis. Potential sites of microbial invasion include the choriodecidual space (between maternal tissues and the fetal membranes), the fetal membranes, the placenta, the amniotic fluid, the umbilical cord, and the fetus (Fig. 25.1).[28] When characteristic clinical signs are present, the condition is usually termed clinical chorioamnionitis. However, histologic chorioamnionitis (inflammation of the chorion and amnion) is three times as common as clinical chorioamnionitis confirmed by amniotic fluid culture.[17] Two main varieties of chorioamnionitis can be identified, acute chorioamnionitis and subclinical chorioamnionitis.[28] They differ in their clinical manifestations, microbiology, and risk to the fetus (Fig. 25.2). Although acute chorioamnionitis is strongly associated with early-onset sepsis, the subclinical variety may contribute to the risk of chronic lung disease and brain injury.[29,45]

Chorioamnionitis complicates 1%-4% of all pregnancies; though, the reported incidence varies widely based upon gestational age and diagnostic criteria used.[72] The prevalence of histologic chorioamnionitis ranges from 50%-70% in very low–birth weight infants to 10%-15% for infants born at term gestation. Approximately 30% of women with preterm labor and intact membranes exhibit histologic chorioamnionitis, as do 80% of women with preterm, premature rupture of membranes (PPROM). Histologic chorioamnionitis almost always represents an ascending infection of organisms colonizing the maternal birth canal. Histologic acute chorioamnionitis represents the inflammatory response of the mother and fetus to the presence of microorganisms (usually bacterial or fungal) in the amniotic cavity. Acute chorioamnionitis cannot occur before the fusion of the amnion and chorion (≈11 weeks' gestation) and is rare before 20 weeks of gestation. Before that time, a chronic choriodeciduitis can develop, which is subclinical and has been linked to an increased incidence of preterm birth, chronic lung disease, and periventricular leukomalacia. It is controversial whether the choriodeciduitis represents an infectious process or a maternal immune response to fetal antigens.[41]

As noted, histologic chorioamnionitis is three times as common as clinical chorioamnionitis, and only about two-thirds of women with suspected clinical chorioamnionitis have evidence of placental inflammation. Part of the difficulty of identifying women with chorioamnionitis is that microbial invasion of the amniotic cavity (MIAC) can be chronic and clinically silent. Furthermore, histologic chorioamnionitis can occur with negative cultures from amniotic fluid. Some of these "negative cultures" can be explained by the fastidiousness of the microorganisms found in amniotic fluid and the difficulty in recovering them using standard culture techniques. Others result from sterile inflammation, in which an immune process caused by maternal antifetal rejection leads to the infiltration of maternal lymphocytes, plasma cells, and/or macrophages.[41] Histologic chorioamnionitis has been associated with intra-amniotic infection in 72% of cases of preterm birth. However, the likelihood of neonatal sepsis in women with histologic or clinical chorioamnionitis varies dramatically with gestational age (Table 25.1).[66]

Risk Factors

Epidemiologic investigations have demonstrated several factors associated with the development of clinical chorioamnionitis, including maternal colonization with group B streptococcus (GBS), GBS bacteriuria, nulliparity, the use of internal monitoring devices, meconium-stained amniotic fluid, serial vaginal digital examinations, duration of active labor, and duration of membrane rupture.[4,58,64] Importantly, meconium-stained amniotic fluid is not only a risk factor

Abstract

Chorioamnionitis (or intra-amniotic infection) is a major cause of fetal, neonatal, and maternal morbidity and mortality. Exposure to intrauterine inflammation increases the risk of preterm birth and the risk of long-term morbidities, including cerebral palsy, bronchopulmonary dysplasia, and retinopathy of prematurity. Administration of broad-spectrum antibiotics and prompt delivery of the fetus in the setting of acute clinical chorioamnionitis reduce both fetal and maternal morbidity. The development of more rigorous diagnostic criteria may better identify those women and fetuses most likely to benefit from antimicrobial treatment and reduce unnecessary, potentially harmful antibiotic exposure. Novel interventions to disrupt inflammatory signaling cascades in utero are greatly needed.

for chorioamnionitis but also may be a consequence of fetal stress secondary to intra-amniotic infection. There are some data to suggest that women diagnosed with chorioamnionitis during their first pregnancy are at increased risk for developing chorioamnionitis in subsequent pregnancies,[14] indicating a persistent predisposing condition or particular underlying host susceptibility. Recent gene association studies have identified single nucleotide polymorphisms in immunoregulatory genes that may influence susceptibility to chorioamnionitis.[38,52] The presence of abnormal cervicovaginal flora (e.g., bacterial vaginosis, aerobic vaginitis) during the first trimester is associated with adverse pregnancy outcomes, including early preterm birth and miscarriage and MIAC,[18,19,36] although discrete evidence linking the presence of abnormal flora of the lower genital tract with the development of acute clinical chorioamnionitis is lacking. Rather, it is hypothesized that these vaginal microbes ascend into the intrauterine cavity and induce

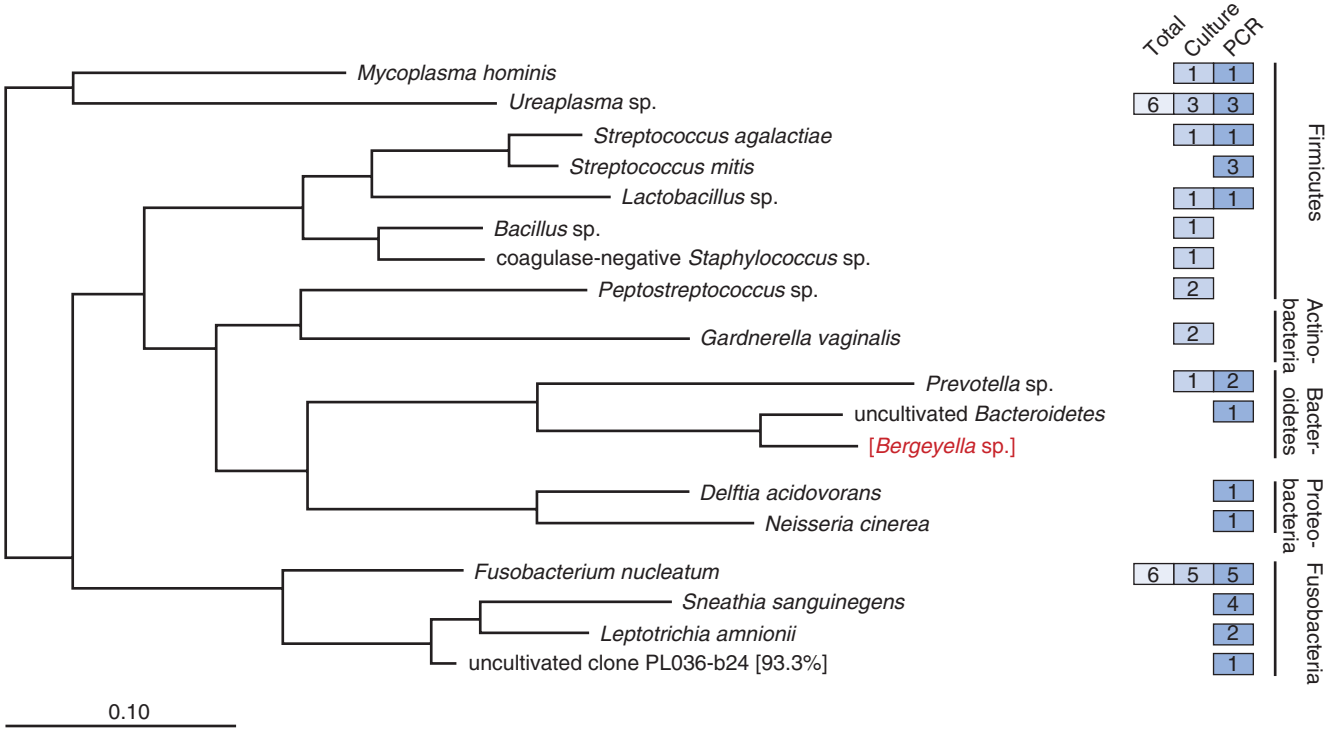
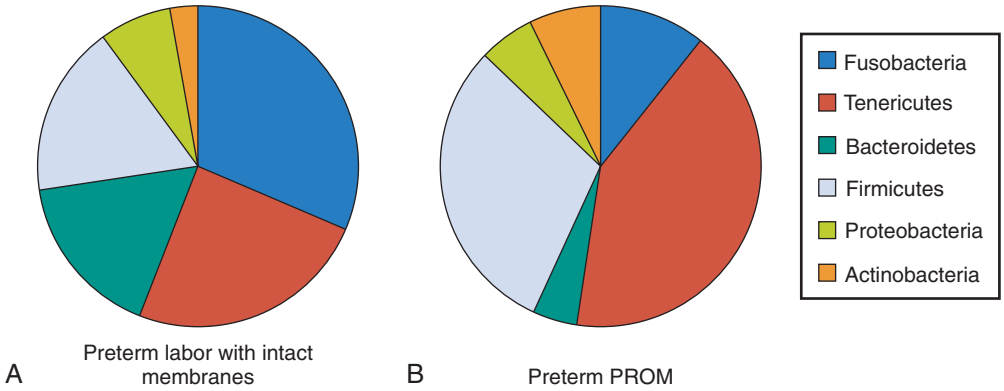
a subclinical, chronic inflammatory response that in turn predisposes to preterm rupture of membranes and/or the onset of preterm labor.



Microbiology

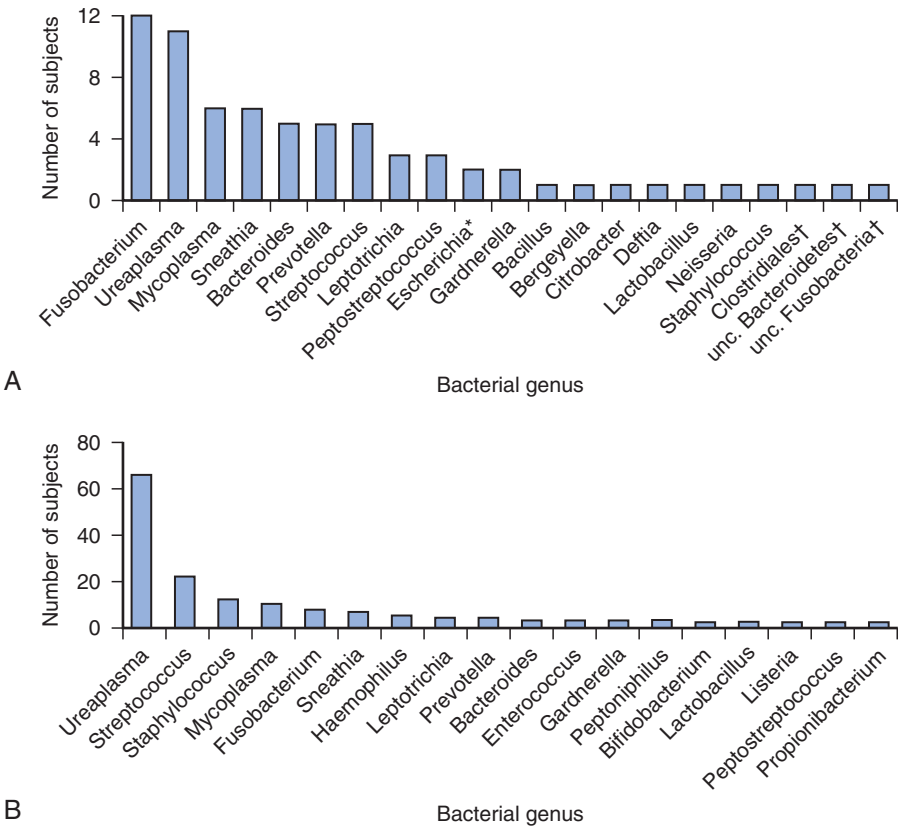
Chorioamnionitis is almost always polymicrobial. Using culture-based techniques, *Ureaplasma urealyticum* and *Mycoplasma hominis* are the most common organisms recovered (47% and 30%, respectively) in culture-proved chorioamnionitis.[72] Other cultivable organisms include anaerobes, such as *Gardnerella vaginalis* (25%) and *Bacteroides* (30%), and aerobes, including GBS (15%) and *Escherichia coli* (8%).[72]

Broad-range PCR has been used to identify the kinds of microorganisms found in the amniotic fluid of women with preterm labor or PPROM. Several conclusions are evident: (1) PCR-based techniques identify 30%-50% more organisms than culture-based methods; (2) five phyla are commonly represented (Fig. 25.3); and (3) the patterns of microorganisms in amniotic fluid in women with preterm labor and intact membranes are different from those found in amniotic fluid samples from women with PPROM (Figs. 25.4 and 25.5).[18] However, given the high sensitivity of PCR, the increased likelihood of detecting DNA from nonviable or environmental contaminants makes the clinical significance of this microbial diversity somewhat uncertain. Studies of the association of MIAC (using PCR-based techniques) with fetal inflammation or perinatal outcomes noted statistically significant associations with elevated concentrations of inflammatory mediators in amniotic fluid and increased rates of histologic chorioamnionitis[53] and preterm delivery.[20]



Diagnosis

Confirmation of intrauterine infection and/or inflammation requires amniotic fluid sampling and/or placental pathology. Therefore, in the vast majority of cases, the diagnosis is made using clinical criteria. The classic definition requires maternal fever (≥100.4°F or 38°C) plus two other findings, including maternal leukocytosis, maternal and fetal tachycardia, uterine tenderness, and foul-smelling or purulent amniotic fluid.[25] Individual clinical criteria have variable sensitivity and generally low specificity for



• **Fig. 25.3** Microbial diversity. Amniotic fluid specimens collected from 166 women in preterm labor with intact membranes were examined for the presence of microorganisms by both culture and polymerase chain reaction (PCR) techniques. The phylogeny of the 17 bacterial taxa identified based in a maximum likelihood algorithm is depicted. Shaded boxes indicate the number of subjects who were positive for a given taxon by culture or PCR (some samples were polymicrobial). For most individual taxa in which neither method detected all positive subjects, the total number is shown in the lightest colored box. A 99% sequence similarity cutoff threshold was used for phylotype assignment, which was based on 621 unambiguous nucleotide positions. *Bergeyella* sp. (bracketed) is included as a reference species only and was not detected in the study population. A single fungal species, *Candida albicans*, was detected by culture in *1*, subject, and by PCR in *2*, data not shown. (From DiGiulio DB, Romero R, Amogan HP, et al. Microbial prevalence, diversity and abundance in amniotic fluid during preterm labor: a molecular and culture-based investigation. *PLoS One.* 2008;3:e3056.)

Data obtained from studies using broad-range polymerase chain reaction (PCR) methods to assay amniotic fluid in the setting of either preterm labor with intact membranes, **A**, or of preterm premature rupture of the membranes (PPROM), **B**. (Data from DiGiulio DB. Diversity of microbes in amniotic fluid. *Semin Fetal Neonatal Med.* 2012;17:2-11.)

• **Fig. 25.5** Genus-level rank abundance curves of bacterial prevalence in amniotic fluid as determined by polymerase chain reaction (PCR). **A**, All 21 taxa reported in studies of women in preterm labor with intact membranes. **B**, The 18 taxa that were detected in two or more subjects in studies of women with preterm premature rupture of membranes. *Two subjects with *Escherichia* spp. were positive by both PCR and culture; in both cases *Escherichia* assignment is based on culture findings because the 16s ribosomal DNA gene is unreliable for differentiating between the genera *Escherichia* and *Shigella*. †Denotes the taxa that could not be classified to genus-level resolution because of current limitations of reference sequence databases. (Data from DiGiulio DB. Diversity of microbes in amniotic fluid. *Semin Fetal Neonatal Med.* 2012;17:2-11.)

chorioamnionitis, with little improvement in diagnostic accuracy when used in combination (Table 25.2).[54,72]

In 2016, a new descriptive term, intrauterine inflammation or infection or both (Triple I), was proposed by a panel of experts in an attempt to better define this clinical entity and to reflect the current understanding of pathophysiology, whereby inflammation does not always equal infection.[31] Suspected Triple I may be diagnosed in the presence of maternal intrapartum fever without a clear source, plus one or more of the following: maternal leukocytosis, purulent cervical drainage, or fetal tachycardia. Whether this new terminology and criteria become incorporated into routine clinical practice remains to be seen.

Maternal fever can occur as a result of intrauterine or extrauterine causes. Epidural anesthesia is associated with an increased risk of fever during labor with a relative risk of 3.34 (CI 2.63-4.23).[5,59] The general belief is that the fever associated with an epidural is noninfectious in origin; however, fever may be more likely to occur when placental inflammation is present. Fever following placement of an epidural can occur within 1 hour but almost always within 4-6 hours. It is noteworthy that fever induces an inflammatory response

TABLE 25.2 Clinical and Amniotic Fluid Laboratory Diagnosis of Chorioamnionitis

Test	Result Suggesting Chorioamnionitis	Comments
Clinical Parameters		**Generally Nonspecific**
Fever	Temperature >100.4°F twice or >101°F once	95%-100% sensitive
Maternal tachycardia	>100/min	50%-80% sensitive
Fetal tachycardia	>160/min	40%-70% sensitive
Fundal tenderness	Tenderness on palpation	4%-25% sensitive
Vaginal discharge	Foul-smelling discharge	5%-22% sensitive
Amniotic Fluid Parameters		
Culture	Microbial growth	Diagnostic gold standard
Gram stain	Bacteria or white blood cells (>6 per high power field)	24% sensitive, 99% specific
Glucose level	<15 mg/dL	Affected by maternal hyperglycemia 57% sensitive, 74% specific
IL-6	>7.9 ng/mL	81% sensitive, 75% specific
Matrix metalloproteinase	Positive result	90% sensitive, 80% specific
White blood cell count	>30/cubic mm	57% sensitive, 78% specific
Leukocyte esterase	Positive (dipsticks)	85%-91% sensitive, 95%-100% specific

Data from Tita AT, Andrews WW. Diagnosis and management of clinical chorioamnionitis. *Clin Perinatol.* 2010;37:339-354.

in the mother, manifested by increased interleukin-6 levels. Epidural anesthesia also affects the body's thermoregulatory mechanisms by decreasing heat dissipation via sweating.

Laboratory testing may be helpful in confirming or excluding the diagnosis of chorioamnionitis, particularly when the diagnosis is uncertain. Leukocytosis has been described in 70%-90% of patients with clinical chorioamnionitis. In the absence of other signs and symptoms, isolated leukocytosis is of limited value. A number of amniotic fluid markers have been studied for the diagnosis of chorioamnionitis. These include culture, Gram stain, glucose levels, white blood cell counts, leukocyte esterase, DAMPs (damage-associated molecular patterns), soluble Toll-like receptors, matrix metalloproteinase, cytokines (e.g., TNF-α, interleukins-6 and -8, matrix metalloproteinase-8) and qualitative assessment of amniotic proteins (proteomics).[12,49] Proteomics is the characterization of the patterns of proteins and peptides in complex biologic samples (e.g., amniotic fluid). Using a newly developed technology (SELDI-TOF mass spectrometry), Buhimschi et al. demonstrated that the severity of chorioamnionitis and funisitis were significantly associated with the degree of intra-amniotic inflammation and time to delivery.[66] The development of rapid, noninvasive assays to measure biomarkers associated with MIAC in cervicovaginal fluid specimens holds promise for future diagnostics.[15]

The histopathologic findings of chorioamnionitis are well characterized and involve both maternal and fetal immune systems.[51] The initial inflammatory response occurs within 6-12 hours, is maternal in origin, and is manifested by an infiltration of neutrophils on the undersurface of the chorionic plate (acute subchorionitis). The next site of involvement occurs at the trophoblast layer of the membranous chorion (acute chorionitis). Over the next 12 to 36 hours, there is spread to the adjacent chorion and amnion (chorioamnionitis). If the infectious process is prolonged (36-48 hours) necrotizing chorioamnionitis (stage 3 acute chorioamnionitis) can result. Fetal vasculitis is an indication of a fetal inflammatory response and represents diapedesis and transmigration of fetal cells across the vessel wall in response to chemotactic agents. In preterm pregnancies, the fetal responses first appear in the chorionic plate (chorionic vasculitis), whereas in term pregnancies they are first evident in the umbilical vein (umbilical phlebitis). Stage 1 fetal inflammatory responses are characterized by neutrophils in the chorionic vessels and/or umbilical vein vasculitis; stage 2 is reached when neutrophils enter the wall of the umbilical artery (umbilical arteritis). With increasing duration of inflammation, neutrophils migrate out of the umbilical artery and vein and enter Wharton jelly to assume an arclike distribution (stage 3). Funisitis is a general term signifying inflammation of the umbilical artery and vein. It is important to distinguish umbilical arteritis from umbilical phlebitis, because the former is associated with increased concentrations of circulating fetal cytokines, whereas the latter is not. It is noteworthy that the majority of neutrophils in both the amniotic fluid and airspaces of the newborn's lungs are fetal in origin.

Pathogenesis

Microorganisms typically invade the intrauterine space by ascending through the cervix from the lower genital tract. Retrograde migration from the abdominal cavity through the fallopian tubes, hematogenous spread through the placenta, and iatrogenic introduction via amniocentesis or chorionic villus sampling are additional mechanisms by which organisms gain access to the uterine cavity.[27]

During pregnancy, the cervical mucus plug, fetal membranes, and placenta function to protect the developing fetus from invading bacteria. The cervical mucus plug is particularly important, because it is not only an anatomic barrier but also contains numerous antibacterial peptides with bactericidal activity against potential pathogens that commonly colonize the vaginal tissues.[30] It is generally believed that once organisms gain access to the intrauterine space, they reside and replicate in the choriodecidual space before entering the amniotic fluid.[56] However, data suggest an initial intra-amniotic entry of bacteria through a restricted cervical region of membranes.[42] After replication in the amniotic cavity, microorganisms then invade the amnion and its connective tissue and progress into the chorion and decidua.

Stimulation of the innate immune response first occurs when the pathogen-associated molecular patterns of invading microorganisms are recognized by pattern recognition receptors (toll-like receptors [TLRs], NOD-like receptors (NLRs]) expressed by host epithelial cells, circulating immune cells, and perhaps most important, placental trophoblast cells.[1,32] Once stimulated, these receptors induce a cascade of proinflammatory signaling, including stimulation of Myd88 (TLRs) and inflammasome (NLRs) pathways. Subsequent production of various cytokines, chemokines, matrix-degrading enzymes, prostaglandins, and other mediators leads to inflammatory cell infiltrate, membrane rupture, cervical ripening, and in some cases the onset of labor.[2,55] Experimental evidence from animal models of intrauterine infection suggests the specific inflammatory pathway leading to the induction of preterm labor is dependent on the particular TLR activated (determined by the nature of infecting agent), as well as the route of infection (ascending versus systemic).[69] The cascade of events leading to preterm labor in the setting of intrauterine infection may be considered an adaptive host response to maintain maternal reproductive fitness.[55] This defense mechanism may also impart a survival advantage for the fetus as a means to escape a hostile intrauterine environment.

As mentioned, bacterial invasion of the amniotic cavity may be chronic, existing for several weeks without clinical symptoms. This is particularly true in infections with *Ureaplasma* spp.[55] Several investigators have documented amniotic fluid cultures positive for *Ureaplasma* in asymptomatic women undergoing genetic amniocenteses at 16-20 weeks' gestation.[68] Despite a lack of overt symptomatology, a significant portion of these women exhibited a robust inflammatory response as measured by expression of inflammatory cytokines in the amniotic fluid and subsequently went on to experience adverse pregnancy outcomes (fetal loss, preterm birth) compared with those women with sterile cultures. In fact, there is ample evidence to suggest that *Ureaplasma* spp., traditionally considered to be of relatively low virulence, may evoke a more intense host inflammatory response as compared with other pathogens associated with chorioamnionitis.[47]

Treatment

Obstetric Management

Administration of broad-spectrum antibiotics and prompt delivery of the fetus in the setting of acute clinical chorioamnionitis reduces both fetal and maternal morbidity.[26] Cesarean delivery should be performed only for standard obstetric indications, because there is no evidence it improves neonatal outcomes in the setting of chorioamnionitis and may only increase maternal complications.[22] Ampicillin and gentamicin are the most commonly prescribed antimicrobials for intra-amniotic infection, although there are no randomized trials comparing the efficacy of various antibiotic regimens. The optimal duration of therapy is unknown; however, intrapartum treatment should not be continued automatically postpartum, and the decision to extend the duration of antimicrobial therapy should be based on risk factors for postpartum endometritis.[16] It is worth noting that standard antibiotic regimens used to treat chorioamnionitis do not provide coverage against *Mycoplasma* and *Ureaplasma* spp., the most common organisms associated with intra-amniotic infection. Although there are a limited number of case reports describing reduced adverse pregnancy outcomes following treatment of documented amniotic fluid infection with genital mycoplasmas,[62] evidence for empiric therapy in the setting of acute clinical chorioamnionitis is lacking. This may reflect the differential microbial etiology of subclinical versus clinical chorioamnionitis. If cesarean delivery is performed, clindamycin (or metronidazole) is often added for anaerobic coverage.

The administration of antenatal corticosteroids to enhance fetal lung maturity in the setting of chorioamnionitis is controversial, because it is believed that the immunosuppressive effects of steroids may exacerbate maternal or neonatal infectious complications. Although randomized clinical trials addressing this issue are lacking, there are observational data to suggest that antenatal steroids may actually reduce neonatal morbidity, including severe intraventricular hemorrhage and periventricular leukomalacia in the presence of chorioamnionitis.[7]

Given that PPROM and preterm labor may be the consequence of occult intra-amniotic infection, it has been hypothesized that antimicrobial therapy may be beneficial in these circumstances despite the absence of overt signs of infection. A meta-analysis reaffirmed that administration of antibiotics and expectant management of women with PPROM is associated with a reduction in chorioamnionitis,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

prolongation of pregnancy, and decreased neonatal morbidities (early-onset sepsis, need for supplemental oxygen, abnormal cerebral ultrasound scans), but was not associated with a significant reduction in perinatal mortality.[39] Furthermore, the use of antenatal antibiotics in particular circumstances may be harmful. The administration of co-amoxiclav (ampicillin/clavulanic acid) in women with PPROM or preterm labor with intact membranes was associated with an increased risk for necrotizing enterocolitis in neonates. In addition, the use of both erythromycin and co-amoxiclav antibiotics for women with preterm labor and intact membranes was associated with an unexpected increase in the incidence of cerebral palsy at a 7-year follow-up evaluation.[40]

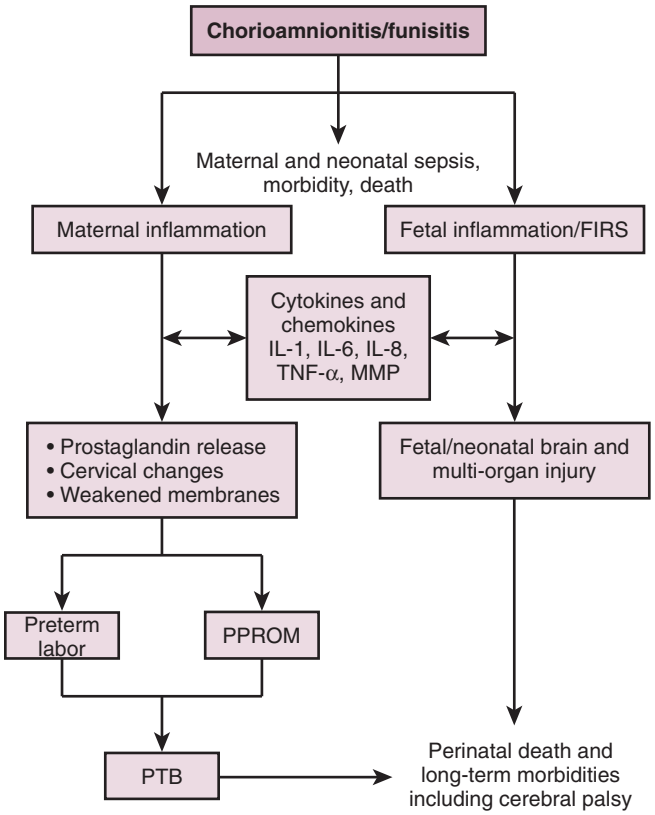
Management of the Exposed Infant

Most recent guidelines from the Centers for Disease Control and the American Academy of Pediatrics Committee on the Fetus and Newborn recommend that all healthy-appearing newborns born to women with a diagnosis of chorioamnionitis undergo a limited diagnostic evaluation and receive empiric antibiotic therapy until early-onset sepsis can be ruled out.[50,74]

There is growing evidence to suggest that close observation, rather than empiric antibiotic therapy, is the preferred strategy for the management of asymptomatic full-term infants exposed to chorioamnionitis.[10,34] The risk of sepsis in this population is exceedingly low given that the incidence of early-onset sepsis has declined dramatically over the last two decades (due to widespread implementation of intrapartum prophylaxis for mothers colonized with GBS and the treatment of women with chorioamnionitis with antibiotics during labor). This substantially increases the number of healthy term newborns who would need to receive antibiotics to prevent one case of sepsis.[76] Because the risk of EOS in infants born to women with chorioamnionitis is strongly dependent on gestational age, it remains prudent to empirically treat chorioamnionitis-exposed preterm infants.

Because the diagnosis of clinical chorioamnionitis is often made when fever is the only manifestation of an intrauterine infection, many infants may be unnecessarily exposed to broad-spectrum antibiotic therapy. Complicating this issue is the increased incidence of fever in women receiving epidural anesthesia.[59] Therefore, if fever is the sole manifestation of suspected chorioamnionitis, consultation with the obstetric provider is recommended to determine the level of clinical suspicion before routinely treating asymptomatic infants.

Outcomes



Chorioamnionitis can adversely affect the mother and her unborn infant. In pregnant women, it is associated with a twofold increase in abnormal progression of labor, an increased risk of cesarean section, postpartum hemorrhage, poor cervical dilation, and placental abruption. Surgical complications after cesarean section such as endometritis, pelvic abscess, wound infection, thromboembolism, and bacteremia are also more common in women with chorioamnionitis. The effects of intrauterine infection on the fetus depend on the duration and timing of the inflammatory process. Acute chorioamnionitis is an important risk factor for early-onset neonatal sepsis. Chronic infections, however, are often subclinical and have been associated with a wide variety of organ injury, including the brain (periventricular leukomalacia), lung (bronchopulmonary dysplasia), eye (retinopathy of prematurity), intestine (necrotizing enterocolitis), and thymus (involution and a change in cellular composition).[23] Chorioamnionitis, especially with a fetal inflammatory component, has also been associated with hemodynamic instability in the preterm newborn infant.

Chorioamnionitis is considered an important cause of preterm birth; microbiologic data suggest that up to 25% of preterm births are caused by an intrauterine infection. The evidence linking infection and preterm labor is as follows: (1) intrauterine infection (or exposure to microbial products) in experimental animals results in preterm delivery; (2) extrauterine maternal infections (e.g., pyelonephritis) are associated with preterm labor; (3) subclinical intrauterine infections are associated with preterm labor and birth; (4) patients with evidence of intrauterine inflammation (e.g., increased amniotic fluid cytokines or matrix metalloproteinases) in the midtrimester are at increased risk for preterm delivery; (5) in experimental animal models, antibiotic treatment of intrauterine infections can prevent prematurity; (6) treatment of asymptomatic bacteriuria prevents prematurity; (7) administration of antibiotics to women with preterm premature rupture of membranes prolongs gestation; (8) microorganisms can be cultured from the placenta in a high percentage of women presenting with preterm labor; and (9) polymorphonuclear infiltrations in the placenta are associated with spontaneous preterm birth. A possible mechanism for infection-associated preterm birth is shown in Fig. 25.6.[72]

Acute chorioamnionitis is a risk factor for neonatal sepsis.[76] That is not surprising given that chorioamnionitis is a key step in the pathway of most ascending infections causing early-onset sepsis. Among infants greater than or equal to 37 weeks' gestation with proven early-onset sepsis owing to *E. coli* or group B streptococcus, clinical chorioamnionitis was documented in the medical record about one-third of the time, and histologic chorioamnionitis was documented in 90%.[66] Importantly, the risk of EOS in infants born to women with chorioamnionitis is inversely correlated with gestational age. Reported rates of confirmed EOS in infants born at ≥35 weeks' gestation to mothers with clinical chorioamnionitis range from 0.47%-1.24%.[9,33,43] In contrast, rates of EOS in exposed moderate and extremely preterm infants are 5-10 times higher.[24,48,65]

Despite a large body of evidence, many studies have not shown a relationship with intrauterine infection, brain injury, and respiratory outcomes. Some of the controversy likely results from lack of precision in the definition of

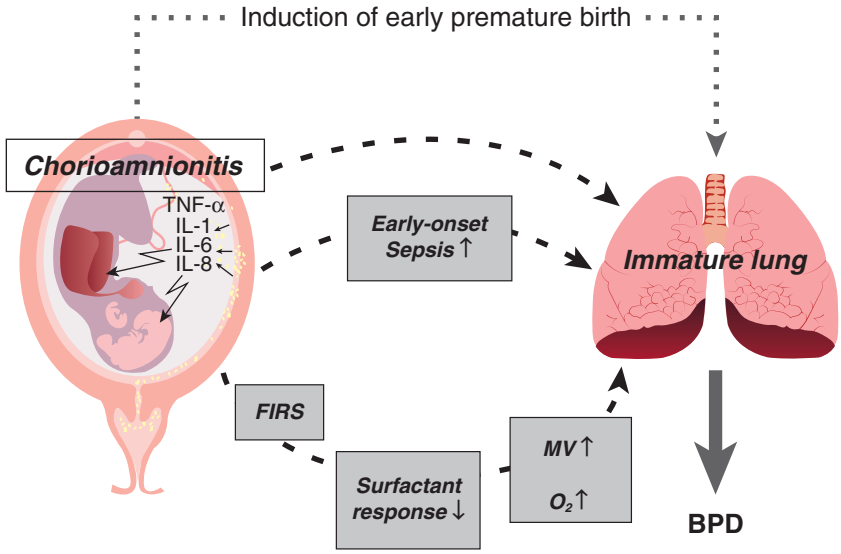
• **Fig. 25.6** Pathogenesis of chorioamnionitis: maternal and fetal response and complications. FIRS, Fetal inflammatory response syndrome; PPROM, preterm premature rupture of membranes; PTB, preterm birth. (From Tita AT, Andrews WW. Diagnosis and management of clinical chorioamnionitis. *Clin Perinatol.* 2010;37:339-354.)

chorioamnionitis and whether a fetal inflammatory response is also present. It is worth emphasizing that chorioamnionitis without evidence of fetal inflammation is unlikely to cause fetal or neonatal injury. Furthermore, the adverse effects on the newborn infant may simply be the result of preterm birth and the host of postnatal complications that affect preterm infants (e.g., respiratory distress syndrome, necrotizing enterocolitis, or intraventricular hemorrhage).



The association with antenatal inflammation and chronic lung disease is indirect and based on a number of experimental observations. In 1996, Watterberg concluded that chorioamnionitis decreased the risk of respiratory distress syndrome but increased the likelihood of bronchopulmonary dysplasia (BPD).[75] However, those data came from an era when antenatal steroids were used infrequently. In contrast, Van Marter et al. demonstrated a reduced risk of BPD in infants born to women with chorioamnionitis, but an increased risk of bronchopulmonary dysplasia in infants born from an infected intrauterine environment who were mechanically ventilated.[73] There appears to be a protective effect of antenatal inflammation on the incidence of respiratory distress syndrome, which is consistent with animal data demonstrating that both bacterial cell wall products (e.g., lipopolysaccharide) and inflammatory mediators (IL-6) accelerate surfactant production.[11,70] Been et al. demonstrated that infants born to women with histologic chorioamnionitis and a fetal vasculitis weaned from oxygen and mechanical ventilation more slowly and exhibited a decreased response to exogenous surfactant.[8] That group of infants was more likely to develop bronchopulmonary dysplasia. This study supports the importance of the additive effects of inflammation and mechanical ventilation on the risk of bronchopulmonary dysplasia. This "multiple hit model," in which both antenatal (chorioamnionitis) and postnatal factors (sepsis, surfactant production and function, mechanical ventilation) modulate the risk for bronchopulmonary dysplasia, is supported by most recent epidemiologic studies and data from experimental animal models (Fig. 25.7).[6,29,37,71]

The relationship between clinical chorioamnionitis and white matter disease is also controversial. In many studies, but not all, cytokine levels are increased in the cord blood of infants who develop periventricular leukomalacia.[78] Postmortem immunohistochemical studies on the brains of preterm infants noted an increased expression of cytokines in the periventricular region of infants with periventricular leukomalacia compared with those without evidence of brain injury.[77] More recent meta-analyses' data have noted significant associations between histologic and clinical chorioamnionitis with the risk of cerebral palsy.[60,61] However, individual studies have not been consistent in those findings. Data most supportive of that relationship have come from the ELGAN study, in which nearly 900 placentas were cultured and biopsied following the delivery of extremely low–birth weight infants.[44] Histologic chorioamnionitis was associated with ventriculomegaly and diparetic cerebral palsy. The recovery of any aerobic or anaerobic organism from the placenta significantly increased the odds ratios for both these outcomes as well as the presence of echolucent lesions on head ultrasound. Furthermore, the investigators were able to demonstrate a dose-response relationship between the number of species recovered and the risk of these morbidities.

Areas for Future Investigation

Despite improved understanding of the pathogenic mechanism by which intrauterine infection leads to adverse pregnancy outcomes, research efforts over the past few decades have yielded little in the way of effective clinical strategies for the prevention and management of intrauterine infection. The development of more rigorous diagnostic criteria may better identify those women and fetuses most likely to benefit from antimicrobial treatment and reduce unnecessary, potentially harmful antibiotic exposure. The development of sepsis calculators that combine a rigorous assessment of intrapartum risk factors together with clinical presentation, like that proposed by Puopolo and Escobar, may better identify neonates most at risk for early-onset sepsis and reduce the number of healthy infants exposed to unnecessary antimicrobial therapy.[21] Continued exploration of the protective role of a healthy vaginal

• **Fig. 25.7** The role of chorioamnionitis in the development of bronchopulmonary dysplasia. Chorioamnionitis induces early preterm delivery of an infant with immature lungs, the major risk factor for bronchopulmonary dysplasia (BPD). Exposure to intra-amniotic inflammatory mediators renders the lung susceptible for further postnatal injuries. Chorioamnionitis with accompanying systemic fetal inflammatory response (FIRS) is known to reduce the response to exogenous surfactant administration, leading to an increased need for mechanical ventilation (MV) and supplemental oxygen (O_2). (From Thomas W, Speer CP. Chorioamnionitis is essential in the evolution of bronchopulmonary dysplasia–the case in favour. *Paediatr Respir Rev.* 2014;15(1):49-52.)

microbiome, mechanisms of abnormal colonization of the lower genital tract, and characterization of maternal/fetal immune responses to specific pathogens may help to identify those women most at risk for infectious complications of pregnancy and open the door for novel preventive strategies. Finally, exploration of potential anti-inflammatory therapies to reduce infection-related morbidities in both the mother and infant is warranted.

Key Points

- Intra-amniotic infection most frequently results from ascension of pathogens from the lower genital tract, eliciting variable inflammatory responses in both the mother and fetus.
- Exposure to intrauterine inflammation increases the risk of preterm birth and increases the risk of long-term morbidities, including cerebral palsy, bronchopulmonary dysplasia, and retinopathy of prematurity.
- Administration of intrapartum antibiotics to mothers with chorioamnionitis decreases the risk of neonatal sepsis and postpartum maternal infections. However, novel interventions to disrupt inflammatory signaling cascades *in utero* are greatly needed.

Placental Pathology

RAYMOND W. REDLINE

The placenta has two opposing functions. It is the sole source of sustenance for the fetus and its sole protection against noxious external influences. It can be argued that no evaluation of a sick neonate is complete without knowing the status of the organ that has accompanied it through the preceding gestation. The specific "value added" by placental examination can be summarized under five overlapping headings:

1. Identification of immediately treatable processes: elevated risk of neonatal sepsis (histologic chorioamnionitis with fetal inflammatory response), specific infections (CMV cytomegalovirus, candida, syphilis, listeria), retained placenta, metabolic storage diseases, placental malignancies
2. Determination of the underlying cause of adverse outcomes: subclassifies preterm delivery, fetal growth restriction, and stillbirth into pathophysiologically homogenous phenotypes
3. Estimation of recurrence risk: different patterns of placental injury have distinct and widely disparate rates of recurrence varying from 0%-70%
4. Guidance for future care path(s): screening for predisposing maternal diseases, genetic testing, high-risk referral, enhanced antenatal surveillance, initiation of antenatal therapy, elective early delivery
5. Quality assurance and risk management: separating perceived from actual pathology (e.g., chorioamnionitis, abruption), uncovering subacute and chronic disorders predisposing to neonatal encephalopathy, seizures, stroke, or cerebral palsy

This chapter is not a comprehensive review of placental pathology; the reader is referred to five general references.[4,11,22,25,48] Rather, it addresses three topics: (1) the optimal use of the pathology service to obtain useful information; (2) an explanation of specific patterns of placental injury; and (3) clinicopathologic correlation (i.e., which lesions are seen in which clinical situations).

Optimal Use of Pathology Service

Because not all placentas are submitted to pathology, every obstetric service should have a specific list of situations in which a placental examination is indicated. Box 26.1 provides a list compiled by the College of American Pathologists in collaboration with a panel of neonatologists and obstetricians.[27] Because many sick neonates are transported from other hospitals, there should be a policy to ensure a timely placental examination. The best solution is to bring the placenta along with the neonate to the tertiary care center. For various reasons, the transport of the tissue specimen itself is sometimes impractical. In these cases, the slides and pathology report from the referring hospital should be requested and reviewed by the pathologist at the hospital where the neonate is to be treated. Whenever possible, placentas should be refrigerated immediately after delivery and sent without fixative to the pathology laboratory. Specimens maintained in this fashion remain useful for at least 7 days after delivery. When refrigeration within 1-2 hours of delivery is impossible, placentas should be immersed in 2-3 volumes of formalin; placentas can remain in formalin for an indefinite period before examination by the pathologist.

An informed evaluation of the placenta requires that the pathologist be aware of the clinical situation. Some mechanism, usually a form, must be established to convey this information. A proper balance should be struck between a totally open-ended form and a tedious checklist. Fig. 26.1 is an example of a form that may be useful.

Placental diagnosis requires very few special studies. Even bacterial cultures in cases of suspected chorioamnionitis rarely provide useful information beyond that which is available from placental histology and the infant's blood culture. Fungal stains of the cord and membranes may occasionally be useful for neonatal management. In certain situations, a placental karyotype may be of interest, because some data suggest that occasional cases of intrauterine fetal demise and idiopathic fetal growth restriction (FGR) may be explained on the basis of chromosomal anomalies confined to placental tissues (confined placental mosaicism).[19]

Structure, Function, and Pathologic Reaction Patterns

Overview

At the simplest level, the placenta is nothing more than fetal blood vessels and surrounding connective tissue enveloped

Abstract

Placental pathology is an important tool for the understanding and management of disorders leading to premature delivery and birth asphyxia. Best practices include prompt submission with adequate history and timely reporting with clinical correlation. Both clinicians and pathologists need to have a thorough understanding of placental biology and the major patterns of placental injury. A successful placental pathology service will facilitate specific diagnosis, immediate management, and future genetic counseling to reduce the risk of recurrence.

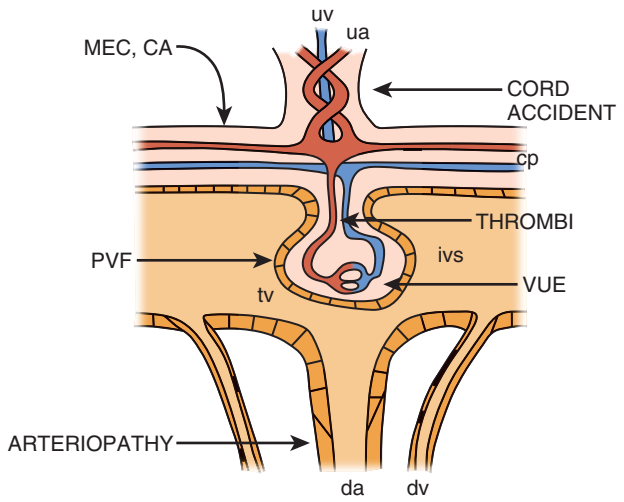
• BOX 26.1 Placental Submission Guidelines

Indications for Submission (College of American Pathologists Practice Guideline 1997): Developed by a task force of pathologists, obstetricians, and neonatologists. Indications separated into three groups as listed below.

Maternal

- Delivery at less than 37 weeks or more than 42 weeks (accepted alternative is <34 weeks)
- Systemic disorders with concern for mother or infant (hypertension, diabetes, other)
- Peripartum fever or infection
- Unexplained or excessive third-trimester bleeding
- Unexplained or recurrent pregnancy complications
- Invasive procedures with suspected placental injury
- Thick or viscid meconium
- Severe oligohydramnios/polyhydramnios

Fetal and Neonatal



- Stillbirth or neonatal death
- NICU admission
- SGA or LGA (<10th or >90th percentile for gestational age)
- Birth depression: pH less than 7.0; Apgar score at 5 minutes less than 7; assisted ventilation greater than 10 minutes; hematocrit less than 35 mg/dL
- Neonatal seizures
- Suspected infection or sepsis
- Hydrops fetalis
- Multiple gestation (accepted alternative is all fused placentas, same-sex twins, or discordant fetal growth)

Significant Gross Placental Abnormalities

- Structural abnormalities of the placental disk or membranes
- Suspected abnormal size or weight for gestational age
- Umbilical cord abnormalities (e.g., long/short/hypercoiled/abnormal insertion/single artery)

LGA, large for gestational age; SGA, small for gestational age.

by a continuous layer of epithelium known as *trophoblast* and sitting in a pool of maternal blood called the *intervillous space*; the latter being continuously filled and drained by maternal uterine arteries and veins (Fig. 26.2). The same unit of structure is repeated in an attenuated form in the placental membranes. Early in pregnancy, the fetal vasculature and maternal intervillous space involute in that portion of the gestational sac destined to become the membranes, leaving a tough shell of fetal connective tissue and the placental trophoblast in contact with the maternal uterus. An understanding of each of these anatomic compartments and

• **Fig. 26.2** Schematic diagram of a functional unit in the placenta, with sites and patterns of injury indicated by arrows. Deoxygenated fetal blood enters the placenta via umbilical arteries (*ua*) and flows through the chorionic plate (*cp*) and stem villous arteries before entering terminal villi (*tv*). Flow into capillaries is regulated by stem villous arterioles. Postcapillary venules combine to form stem villous and chorionic plate veins, which drain into a single umbilical vein (*uv*) that carries oxygenated blood to the fetus. Maternal blood enters the intervillous space (*ivs*) via decidual arteries (*da*) lined with the trophoblast (*hatched lines*) and drains through unmodified decidual veins (*dv*). Decidual arteriopathy restricts maternal perfusion of the intervillous space. Perivillous fibrin (*PVF*) coats the villous trophoblast (*hatched lines*), preventing gas exchange. Villitis of unknown etiology (*VUE*) expands the villous stroma, increasing the diffusion distance. A cord accident compresses the umbilical vessels, causing a global decrease in fetoplacental circulation. Meconium (*MEC*) and chorioamnionitis (*CA*) may decrease villous perfusion by damaging fetal vessels in the chorionic plate. Segmental fetal vascular malperfusion (*THROMBI*) similarly decreases the distal fetal vascular bed.

their reaction patterns in abnormal pregnancies provides the basis for understanding placental pathology.

Considering the fetal circulation first, the *fetal stromal-vascular* portion of the placenta is supplied by a pair of umbilical arteries and drained by a single umbilical vein. Because there is an arterial anastomosis near the umbilical cord insertion site, the fetus is not handicapped if one of the arteries is occluded or absent (single umbilical artery). The vein is the sole supply of oxygenated placental blood for the fetus. It also has the thinnest wall and is the easiest of the three umbilical vessels to collapse. Large chorionic plate arteries and veins branching off from the umbilical vessels transmit blood through the proximal stem villi to the distal villous units, where gas exchange occurs. Decreased flow secondary to fetal malperfusion of these vessels leads to luminal occlusion (fibromuscular sclerosis) and involution of the distal vascular bed (avascular villi).[43] These changes are global in the placentas of stillborn fetuses and focal in live-born infants with occlusive placental thrombi. Each distal villous unit consists of a central mature intermediate villus and surrounding terminal villi. Mature intermediate villi contain arterioles that directly regulate flow to the distal villous capillary bed. Distal villous capillaries may occasionally rupture, leading to fetomaternal hemorrhage, but an

efficient mechanism for villous repair and re-epithelialization usually restricts the amount of lost fetal blood.[34]

Adequate perfusion of the *maternal uterine-trophoblastic* portion of the placenta depends on pregnancy-related increases in maternal intravascular blood volume and decreases in vascular tone. Chronic medical conditions such as renal disease, essential hypertension, and collagen vascular disease can lead to maternal malperfusion by interfering with these systemic accommodations to pregnancy.[21] To ensure adequate perfusion of the intervillous space, the human placenta has evolved a mechanism for remodeling and enlarging uteroplacental arteries.[39] The placental trophoblast grows down the lumen of these vessels, invades the vascular wall, and replaces the smooth muscle layer with a noncontractile layer of fibrinoid matrix. Failure to execute this sequence because of superficial implantation compromises perfusion, leaves the uteroplacental vessels susceptible to spasm, degeneration, and rupture, and is believed to play an important role in the pathogenesis of preeclampsia, abruptio placentae, and some cases of FGR.[6]

Intervening between the fetal and maternal circulations is the villous trophoblast. This barrier consists of a syncytial layer of terminally differentiated trophoblast specialized for gas exchange (syncytiotrophoblast) plus a few widely spaced underlying trophoblast stem cells (cytotrophoblast). In late gestation, the syncytiotrophoblast and its basement membrane fuse with the basement membrane of peripheral villous capillaries to form vasculosyncytial membranes that facilitate gas exchange. Term or near-term placentas that lack adequate vasculosyncytial membranes are at increased risk for stillbirth (sometimes called "delayed maturation").[53] Turnover of villous trophoblast is accomplished via the formation of syncytial knots, which are later released into the systemic circulation as a new trophoblast is generated. Syncytial knots form in excess of their rate of release into the intervillous circulation in placentas affected by maternal malperfusion, leading to a stereotypical histologic appearance that is easily detectable by placental examination (sometimes called "accelerated maturation").[30] It is important that maternal blood contact a nonadhesive surface to prevent activation of the coagulation system. Studies indicate that the anionic phospholipid binding protein annexin-V plays an important role in preventing the assembly of active coagulation factor complexes on the trophoblast cell membrane.[40] Antiphospholipid antibodies have been shown to displace annexin-V from the cell surface, accounting for pathology resembling preeclampsia in some affected pregnancies. Altered anticoagulant mechanisms in the intervillous space may also play a role in a poorly understood placental lesion with a very high recurrence rate known as massive perivillous fibrin deposition ("maternal floor infarction"). This lesion is characterized by an accumulation of fibrin and trophoblast-derived extracellular matrix material that surrounds terminal villi, compromising intervillous circulation and gas exchange (Fig. 26.3A).[29]

Although the two circulations are usually distinct, flow-related trauma can break down the barrier between them, leading to either fetomaternal hemorrhage or entry of maternal cells into fetal tissues. When maternal inflammatory cells cross the trophoblastic barrier, they may participate in a graft-versus-host–type response against fetal antigens in the villi. This process, known as villitis of unknown etiology (VUE), is discussed in more detail in the following.

The final placental compartment is the fluid-filled sac of membranes, which must rupture to allow vaginal delivery. Theoretically, membranes may rupture prematurely for one of two reasons: increased luminal pressure or decreased structural integrity. Increased pressure can be caused by premature contractions, cervical dilation, or polyhydramnios. Structural integrity may be compromised by trauma, inflammatory responses associated with ascending bacterial

• **Fig. 26.3** Histologic patterns of placental injury. **A,** Massive perivillous fibrin deposition. Fibrin and fibrinoid matrix encase the terminal villi. **B,** Chronic maternal vascular malperfusion (accelerated villous maturation). Numerous aggregates of syncytiotrophoblastic nuclei (syncytial knots) surround immature villi of reduced size for gestational age. **C,** Segmental fetal vascular malperfusion. Avascular villi (*lower right*) resulting from upstream vascular occlusion. **D,** Villitis of unknown etiology (*VUE*). Maternal T lymphocytes in the fetal villous stroma (*lower right*) lead to edema and fibrosis, which increase the diffusion distance between the maternal and fetal circulations.

infection, or ischemic necrosis caused by maternal vascular compromise. The amniotic fluid contained within the sac is predominantly derived from fetal urine, and changes in fluid volume (oligohydramnios or polyhydramnios) often reflect altered fetal fluid balance. For example, maternal malperfusion can lead to fetal hypovolemia, oliguria, and subsequent oligohydramnios.[25] Significant oligohydramnios has been associated with umbilical cord compression, limb deformities, and failure of adequate lung growth.[26,28,31]

Placental membranes can also incorporate various exogenous substances suspended in the amniotic fluid, some of which, such as meconium and bacterial cell wall constituents (e.g., lipopolysaccharide), may damage the membranes and the underlying fetal vessels.[3,17] Another exogenous substance sometimes found in the membranes is hemosiderin, which can be an indicator of chronic abruption.[33]

Maternal Uterine-Trophoblastic Lesions

Muscularized maternal arteries supplying the intervillous space are susceptible to stenosis, occlusion, or rupture. Stenosis leads to chronic maternal malperfusion, which is characterized by low placental weight, increased syncytial knotting, intervillous fibrin deposition, and villous agglutination, particularly in the "watershed zones" between spiral arteries (see Fig. 26.3*B*).[21,44] Total occlusion of these arteries causes villous infarction. Although experimental studies have shown that 20%-25% of villous parenchyma can be infarcted without acute fetal compromise,[11] these studies fail to account for the impaired status of the remaining placenta in these disorders.

Rupture of the maternal arteries (abruptio placenta) may be attributed to trauma occasionally but more commonly represents ischemia-reperfusion injury with secondary rupture of the injured vascular wall. The common association of abruption with vasoactive drugs such as nicotine, and especially cocaine, is consistent with this pathogenesis.[1,32] Because muscular arteries are incompletely remodeled in preeclampsia, abruptio placenta is especially frequent in this disorder. Chronic abruption can also occur and manifests pathologically as organizing marginal blood clots, chorioamnionic hemosiderin deposition, and placental circumvallation.[33] Most evidence to date suggests that chronic abruption represents venous rather than arterial hemorrhage.

Fetal Stromal-Vascular Lesions

Fetal vessels within the umbilical cord are protected from compression by the cord matrix, a hydrated gel known as Wharton's jelly. Several processes lessen this protection: decreased hydration of the matrix secondary to maternal malperfusion; torsion of cord vessels owing to excessive coiling; and insertion of the cord vessels into the membranes, leaving them exposed to trauma.[41] The critical parameters for deciding whether a putative cord lesion is significant include thrombosis, necrosis, or hemorrhage at the proposed site of occlusion, and histologic differences in venous dilatation or cord structure proximal and distal to this site.

Large vessels in the chorionic plate and stem villi may occasionally undergo thrombotic occlusion (fetal vascular malperfusion, segmental type, see Fig. 26.3*C*).[43] Factors predisposing to thrombosis are similar to those reported in other organs, including inflammation (villitis of unknown etiology or chorioamnionitis), toxic damage (prolonged meconium exposure), stasis (chronic umbilical cord obstruction, fetal congestive heart failure), inherited predispositions to clotting (protein C and S deficiencies, maternal antiphospholipid antibodies, factor V Leiden), hyperviscosity (fetal polycythemia), and specific maternal diseases (e.g., diabetes mellitus, platelet disorders). Villi downstream from the occlusive thrombi become avascular and hyalinized. Consequences of fetal vascular malperfusion include a reduction in the size of the fetal vascular bed available for gas exchange, coexistent thromboembolic disease in the fetus, and (in rare cases) fetal consumptive coagulopathy with disseminated intravascular coagulation or thrombocytopenia.

Fetal arterioles in mature intermediate villi regulate placental resistance to fetal blood flow, the parameter evaluated in clinical pulsed-flow Doppler studies. Obliteration, stenosis, or spasm of these arterioles can have a profound impact on gas exchange.[13] These arterioles have been found to be numerically decreased in autosomal trisomies[51] and either obliterated or stenosed in patients with severe FGR.[10,13] A large proportion of placentas with these fetal arteriolar changes also show clinical and pathologic evidence of chronic maternal malperfusion.

Fetal capillaries in the terminal villi can sustain microvascular damage leading to leakage of fluid (villous edema) or blood (villous stromal hemorrhage).[13,31] Both lesions have been shown to be associated with adverse outcomes in very premature infants.[12,46] Frank rupture of these capillaries causes placental intervillous thrombi and, in some cases, hypovolemia, fetal anemia, and a compensatory increase in circulating, nucleated red blood cells (massive fetomaternal hemorrhage).[7,20] Finally, the capillary bed of distal villi can undergo adaptive angiogenesis (chorangiosis) in response to hypoxia. Chorangiosis is defined by a significant proportion of terminal villi having 10 or more capillary cross-sections, and has been associated with VUE, meconium staining, diabetes, and congenital anomalies.[2]

Inflammatory and Infectious Lesions

Acute chorioamnionitis is usually caused by cervicovaginal bacteria that either overwhelm normal cervical host defense mechanisms or gain access to the amnionic cavity after rupture of membranes.[42] The inflammatory response to bacterial infection is predominantly neutrophilic and generally involves the membranes and chorionic plate but not the chorionic villi. Acute chorioamnionitis is the most common cause of preterm labor.[15] However, few delivered infants are

septic at birth, attesting to the effectiveness of the placenta as a protective barrier.

Histologic features can help determine the duration of infection in chorioamnionitis.[42] In the initial stages (<6 hours), maternal neutrophils enter the membranous chorion and underside of the chorionic plate (acute chorionitis). Later, maternal neutrophils infiltrate the entire chorionic plate and the full thickness of the membranes (6-24 hours). A concomitant fetal neutrophilic response, as manifested by transmigration across the fetal vessel walls, begins in the chorionic plate (fetal inflammatory response in chorionic vessels) and the umbilical vein (umbilical phlebitis) and is followed by involvement of the umbilical arteries (umbilical arteritis). Changes that occur later, such as fetal neutrophils infiltrating the umbilical cord stroma (perivasculitis) and necrosis of the amnion (necrotizing chorioamnionitis), suggest infection of greater than 24 hours duration. Finally, perivascular umbilical arcs of calcific debris, glycoprotein, and neovascularization (subnecrotizing funisitis) or a histiocytic component (subacute chorioamnionitis) suggest prolonged infection of days to weeks in duration.[35]

Infants with subnecrotizing funisitis or subacute chorioamnionitis are at increased risk for chronic lung disease. Data suggest that a severe fetal inflammatory response in chorioamnionitis may be a risk factor for severe neonatal morbidities, including bronchopulmonary dysplasia, necrotizing enterocolitis, cranial ultrasound abnormalities, and long-term neurologic impairment.[14,46,49]

The described patterns are typical for most bacteria. Unusual patterns that can suggest specific organisms are neutrophilic exudates involving the villi and intervillous space (suggestive of *Listeria monocytogenes*)[9] and microabscesses on the external surface of the umbilical cord (suggestive of *Candida albicans*).[38]

Chronic placentitis is caused by organisms that enter the villi via the maternal bloodstream. The hallmark of chronic placentitis is destructive, diffuse villitis with fibrosis and calcification.[25] Although villous inflammation is generally emphasized, these infections also involve the chorion, decidua, and other placental regions. This pattern of panplacentitis is caused by organisms of the so-called TORCH group (*Toxoplasma gondii,* rubella virus, cytomegalovirus, and herpes simplex virus), *Treponema pallidum,* other herpesviruses (Epstein-Barr virus, varicella), and a host of other parasitic and protozoan infections not commonly encountered in the United States. Distinct histopathologic features typify specific etiologic agents (e.g., increased Hofbauer cells, periarteritis, and necrotizing umbilical phlebitis in syphilis; villous plasma cells in cytomegalovirus; stromal necrosis and calcification in herpes simplex virus; and umbilical cord pseudocysts in toxoplasmosis).

Two other categories of neonatal infection that cannot be evaluated directly by placental pathology are transplacental and intrapartum infections. Transplacental infections spread to the fetus without affecting the placenta, presumably through breaks in the interhemal barrier (maternofetal transfusion). Important organisms in this category include human immunodeficiency virus (HIV), hepatitis B virus, human parvovirus B19, and enteroviruses. Intrapartum infections are acquired by the fetus during passage through a contaminated birth canal and also spare the placenta. Prominent in this category are venereal pathogens such as *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, and human papillomavirus, and some pathogens associated with neonatal sepsis (e.g., group B streptococci and *Escherichia coli*).

Inflammatory Graft-Versus-Host–Type Lesions

Foci of idiopathic chronic villous inflammation, villitis of unknown etiology (VUE), are common in term placentas (5% of all placentas), whereas chronic infectious placentitis is rare (1-2 per 100 live births).[51] Certain features of VUE differ from infectious placentitis. Villitis of unknown etiology is confined to villi and generally involves only a fraction of the villous tree. The predominant cells in VUE are infiltrating T lymphocytes of maternal origin. Villitis of unknown etiology has a high recurrence risk and tends to occur in older women with previous pregnancies as compared with infectious placentitis, which tends to occur in younger women and rarely recurs because of acquired immunity. For these reasons many experts believe that VUE represents a graft-versus-host–type response related to the genetic differences between the mother and fetus. The chronic villous stromal inflammation associated with VUE causes placental dysfunction by increasing the diffusion distance for gas exchange (see Fig. 26.3*D*). Recent data suggest that another closely related graft-versus-host–type reaction, chronic chorioamnionitis, may play a role in some cases of idiopathic preterm labor.[24]

Developmental and Structural Lesions

A final group of lesions involves abnormalities in placental structure. As with structural abnormalities in infants, these placental lesions can represent either primary maldevelopment or secondary deformation and disruption. The uterine decidua regulates the depth of uterine implantation. Prior surgery or other uterine abnormalities can interfere with normal decidualization, leading to uncontrolled placental growth into or through the uterine wall (*placenta accreta* or *percreta*).[25] A long-held theory has been that growth abnormalities such as bilobation, accessory lobes, peripheral umbilical cord insertions, and placenta previa develop when the placenta migrates away from uterine defects toward sites with a better maternal blood supply, a process termed *trophotropism*.[4] More recent data suggest that these abnormalities may be more closely related to deficient branching of major chorionic vessels and the villous parenchyma they supply.[55]

Placental structural anomalies can also predict deformations or disruptions in the fetus. Placental amniotic bands are associated with fetal amputations.[25] Amnion nodosum, developing secondary to prolonged oligohydramnios, is

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

associated with pulmonary hypoplasia.[31] Placental thrombi can be a harbinger of fetal coagulopathies such as stroke, thrombotic liver disease, renal vein thrombosis, intestinal atresia, or purpura fulminans.[25] Placental vascular anastomoses in monochorionic diamnionic twins can cause circulatory shifts leading to acute hypoxic-ischemic injury or chronic circulatory imbalance leading to twin-to-twin transfusion and discordant fetal growth.[18] Monochorionic monoamnionic twins, although rarely affected by twin-to-twin transfusion, commonly have another placental complication—entangled umbilical cords—which can lead to the death of one or both twins.

Tumors are occasionally found in the placenta. The most common placental tumor is the chorangioma, composed of proliferating fetal blood vessels. Chorangiomas can cause fetal complications by arteriovenous shunting, leading to hydrops fetalis and platelet sequestration, resulting in disseminated intravascular coagulation.[4,25] Choriocarcinomas (malignant trophoblastic tumors) can rarely arise from the villi of second- and third-trimester placentas and metastasize to the fetus.[5] The placenta can also be the site of metastasis for malignant tumors from either the mother (e.g., melanoma, adenocarcinoma) or the fetus (e.g., congenital neuroblastoma, Langerhans cell histiocytosis).

Clinical Correlation

The various anatomic, physiologic, and pathologic reaction patterns discussed above are placed in clinical context by reviewing their relative frequency in common obstetric and neonatal disease syndromes (Box 26.2).

Preterm labor and delivery are most commonly associated with pathologic evidence of acute chorioamnionitis.[15] In many cases, it can be difficult to determine whether infection develops before or after the onset of labor. Because chorioamnionitis generally triggers labor relatively rapidly, most cases that develop after prolonged membrane rupture likely represent secondary infection. Many of the remaining cases of preterm birth fall into three groups: placental abruption, chronic maternal malperfusion, and uterine structural anomalies without associated placental abnormalities (e.g., so-called cervical insufficiency).[52] As mentioned, idiopathic chronic inflammation (chronic chorioamnionitis) also may be implicated in some cases.[24]

Fetal growth restriction may either be constitutional, relating to small maternal size, malnutrition, or an anomalous fetus, or directly caused by placental disease. The most frequent placental causes of fetal growth restriction are chronic maternal vascular malperfusion and VUE.[21,45] Other, less frequent etiologies are fetal vascular malperfusion, massive perivillous fibrin deposition ("maternal floor infarction"), and confined placental chromosomal mosaicism.[19]

Intrauterine fetal demise, particularly at or near term, is often clinically unexplained. Recent studies suggest that placental examination can reveal the underlying cause or causes in up to 60%-70% of cases, much more frequently than autopsy.[23] One important group at increased risk of stillbirth are fetuses with clinical entanglements or pathologic lesions of the umbilical cord. These lesions can be diagnosed by using specific pathologic criteria.[36] Another distinct group at risk are infants whose placentas have decreased vasculosyncytial membranes (delayed villous maturation), leading to decreased placental reserve and susceptibility to transient hypoxic events.[53] The prototype for this subgroup is the infant of a diabetic mother. A less common but important cause of stillbirth is massive fetomaternal hemorrhage, which is manifested in the placenta by intervillous thrombi and increased circulating nucleated red blood cells.[7,20] Chronic fetomaternal hemorrhage and its accompanying anemia can cause congestive heart failure and hydrops fetalis. Other forms of hydrops fetalis causing stillbirth that can be identified by placental examination include infections such as human parvovirus B19, toxoplasmosis, and syphilis. Finally, a large proportion of stillbirths is associated with underlying FGR. These cases are characterized

• BOX 26.2 Clinicopathologic Correlation

Preterm Labor
- Acute chorioamnionitis (infectious)
- Abruption (acute or chronic)
- Chronic maternal vascular malperfusion ("accelerated maturation")
- Chronic chorioamnionitis (graft-versus-host type)

Fetal Growth Restriction
- Chronic maternal vascular malperfusion
- Villitis of unknown etiology
- Perivillous fibrin deposition
- Fetal vascular malperfusion
- Confined placental chromosomal mosaicism

Intrauterine Fetal Demise
- Delayed villous maturation
- Massive fetomaternal hemorrhage
- Umbilical cord accident
- Multiple or severe placental lesions

Hypoxic-Ischemic Encephalopathy
- Abruptio placentae or uterine rupture
- Umbilical cord accident
- Rupture of fetal vessels

Cerebral Palsy (Preterm)
- Severe villous edema
- Chorionic vessel thrombi
- Multiple placental lesions

Cerebral Palsy (Term)
- Segmental fetal vascular malperfusion
- VUE with stem vessel obliteration
- Severe fetal chorioamnionitis
- Meconium-associated vascular necrosis
- Multiple placental lesions

VUE, Villitis of unknown etiology.

pathologically by severe examples of one or more than one of the processes discussed in the preceding paragraph.[8]

Central nervous system injury has been associated with several placental lesions. White matter damage, periventricular hemorrhagic infarction, and cerebral palsy in preterm infants have been linked to severe villous edema, chorionic vessel thrombi associated with histologic chorioamnionitis, and multiple placental lesions.[46] Hypoxic-ischemic encephalopathy and cerebral palsy in term infants can follow acute birth asphyxia, recurrent intermittent hypoxia, or chronic uteroplacental disease.[49] Placental findings associated with birth asphyxia include abruptio placentae, occlusive umbilical cord accidents, and rupture of fetal vessels. Recurrent intermittent hypoxia is most often related to clinical or pathologic umbilical cord problems and is commonly accompanied by an increase in circulating nucleated red blood cells in the placenta.[47] The most common chronic uteroplacental lesions associated with brain injury are those affecting large fetal vessels, including segmental fetal vascular malperfusion, villitis of unknown etiology with stem vessel obliteration, severe fetal chorioamnionitis, and meconium-associated vascular necrosis.[50] As is true for the preterm group, term infants with multiple placental lesions are also at very high risk.[49]

Umbilical Cord Coiling

Mechanisms of umbilical cord coiling include contributors from embryonic development, intrinsic properties such as growth of vessels, differential blood flow within arteries, and fetal movements.[37] Hypocoiling, defined as <1 coil/10 cm, has been associated with fetal distress, oligohydramnios, preterm delivery, intrauterine growth restriction, meconium-stained amniotic fluid, fetal heart rate (FHR) alterations, and low cord pH. Horn et al. found association of hypercoiling (>3 coils/cm) and thinning with consecutive constriction of the umbilical vessels (thin cord syndrome) and intrauterine fetal death.[16] Noncoiled umbilical cords are considered a risk factor for poor perinatal outcome and stillbirth.[54]

Summary

The placenta is the link that connects the clinical status of the neonate with underlying maternal and fetal disease processes. Careful evaluation of this organ not only provides useful diagnostic, prognostic, and therapeutic information, but also enhances overall understanding of perinatal biology. Communication among neonatologists, obstetricians, and placental pathologists brings together distinct pieces of a puzzle that none can fully solve alone. Through this process, meaningful explanations of the reasons for adverse perinatal outcomes and their chances of recurrence can be provided for concerned physicians and family members.

Key Points

- Timely examination of the placenta by someone with expertise in perinatal pathology is a critical part of neonatal care.
- Clinical context must be communicated to the pathologist for optimal interpretation.
- Placental lesions may be broadly categorized as maternal vascular, fetal vascular, inflammatory, and other.
- Individual subcategories within these broader categories have distinct significance for immediate care, explaining adverse outcomes and determining recurrence risk.
- Pathologists, neonatologists, obstetricians, and geneticists need to meet periodically to maintain quality of care.

Anesthesia for Labor and Delivery

MCCALLUM R. HOYT

The goal of modern-day obstetric anesthesia practice is to provide the patient with analgesia as she requests it.[57,61] That assumes her choice is appropriate to the labor process and to the current conditions as evaluated by her obstetric provider, and has as little impact on the fetus as possible.[55] Depending on the patient's predilections, labor might be approached with prepared responses to modify pain perception, a plan to use systemic medications or nerve blocks, or some combination of these. How and whether a mother's choice has an impact on fetal well-being and neonatal outcome is the focus of this chapter, which includes a discussion of the newer anesthetic techniques. It also reviews some of the more established pain relief approaches as well as the more popular alternatives currently in vogue.

Labor Pain Characteristics and Challenges

Research has shown that the experience of pain is a complex, subjective, multidimensional response to sensory stimuli.[22] Labor pain in particular has been shown to be more intense than almost any other known pain syndrome.[45] To appreciate the complexity of providing analgesia to the laboring patient and better understand successes and expectations when doing so, a considerably abbreviated and simplistic discussion of pain is in order. A clinically useful classification of pain is to define it as being visceral or somatic. Visceral pain originates from the viscera and is often described as cramping, dull, and steady. Somatic pain is related to nonvisceral structures and is commonly described as sharp, intermittent, and well localized.[9,22] During the dilation phase, or first stage, of labor, visceral pain predominates, arising from mechanical distention of the lower uterine segment and cervical dilation. Somatic pain prevails during the descent phase, or second stage, of labor and is attributed to the distention and traction on pelvic structures surrounding the vagina as well as distention of the pelvic floor and perineum.[9,22]

The challenge when managing labor pain is to understand its very dynamic nature that may require adaptation of pain techniques to adequately manage it. Labor pain evolves rapidly over a relatively short period of time, changing not only in intensity but also from a visceral to a somatic source. To add to the challenge, not all medications are effective for all types of pain. Local anesthetics block nerve conduction and are effective where the nerves responsible for pain transmission are accessible. In labor, the nerves transmitting the pain are well described, and most of them can be reached with some form of nerve block, making this a common choice. On the other hand, opioids are very effective for visceral pain but are of little value for somatic pain.[54] Therefore, systemic opioids can aid a patient reasonably well during the first stage of labor but have little effect if used during the second stage.

Neuraxial analgesia is widely accepted as the most effective and least depressant method of providing pain relief in labor.[61] The term encompasses epidural, spinal, and combined spinal-epidural (CSE) central nervous system blocks that are only administered by those trained in anesthetic methods. With modern-day techniques, dosing can be reduced to such low levels that an analgesic state, which diminishes pain while minimizing the effect on other sensory pathways such as touch and proprioception, is possible and often the goal.[4] The lower doses result in less absorption into the maternal bloodstream, making levels barely or non-detectable. This allows the parturient to experience pain-free labor with minimal side effects to both her and the fetus while still allowing for active participation in the labor process. However, all procedures carry some risk, and as dosing methods can vary across the United States, a fetal or neonatal effect from the medications used can occur.

Despite the proven safety and efficacy of the lower-dose neuraxial techniques, not all parturients wish to use them, nor are there always practitioners available to perform these procedures. Also, not all patients are reasonable candidates for a neuraxial block for a myriad of reasons. As a result, many of the traditional, non-neuraxial approaches for labor pain management are still utilized in obstetric suites, as are some newer alternative therapies.

Techniques That Modify Pain

Although nonpharmacologic techniques do not alter the actual transmission of pain sensation, they attempt to alter the person's perception and response to it, with some measured success. Many of these approaches require preparation

Abstract

Research has shown that the experience of pain is a complex, subjective, multidimensional response to noxious sensory stimuli. Labor pain in particular has been shown to be more intense than almost any other known pain syndrome. The American College of Obstetricians and Gynecologists in their recent "Practice Bulletin on Obstetric Anesthesia and Analgesia" state, "In the absence of a medical contraindication, maternal request is a sufficient medical indication for pain relief during labor." The goal of modern-day obstetric anesthesia practice is to provide the patient with analgesia as she requests it. That assumes her choice is appropriate to the labor process and has as little impact on the fetus as possible. The focus of this chapter is to provide a high-level overview of obstetric anesthesia for the practicing neonatologist or pediatrician and to discuss whether a mother's choice has an impact on fetal well-being and neonatal outcome. It includes a discussion of the newer anesthetic techniques and reviews some of the more established pain relief approaches as well as the more popular alternatives currently in vogue.

beforehand, and their effectiveness is subject to several variables. As a result, studies comparing controlled breathing techniques, hypnosis, and other nonpharmacologic methods to nerve blocks and medications are hard to evaluate.

The assumption held by proponents of alternative pain management techniques and many expectant mothers is that nonpharmacologic techniques to control pain will not have any adverse effect on the neonate and, therefore, are the safest and healthiest choices for themselves and their babies. Clinical studies have not proved this assumption to be true. Although most techniques are as benign as they appear, some can carry unintended consequences if not performed properly, making this pertinent knowledge for the well-informed neonatologist.

Nonpharmacologic Approaches

Natural Childbirth

Natural childbirth is a technique that was first defined by Ferdinand Lamaze in the 1950s and began its popular rise in the 1960s as an alternative to the heavy sedation that was often used at the time. The technique of controlled breathing and focal points to stay in a relaxed state during a contraction is based on the theory that one can modify the sensation of pain and one's response to it. Building upon the popularity of the Lamaze approach to labor pain, the Bradley technique was introduced in the 1970s as a variant and incorporated the woman's partner as her active coach. Today the term *natural childbirth* applies to any controlled breathing technique that the mother uses during labor to cope with pain and avoid pharmacologic methods.

Is natural childbirth an effective way to manage pain during labor? There is some objective evidence that Lamaze training as originally practiced is associated with β-endorphin elevations, which may help alter pain sensation.[19] What is not always appreciated is that incorrect performance can have negative consequences. If the mother deviates from the defined breathing technique and hyperventilates during her contractions, she will lower her P_{CO_2} levels. The maternal hypocapnia and resulting acute alkalosis causes the maternal oxy-hemoglobin curve to shift toward the fetal curve, thereby reducing the release of oxygen to the fetus. It also may reduce umbilical blood flow.[35] If fetal acidosis develops during the first stage of labor, it will worsen during the second stage, especially if that stage exceeds 1 hour.[63] Once hypoxia and a base deficit are present during the second stage of labor, it is difficult to reverse in utero.[63] Obviously, this series of events does not occur in every case, but the fetal tracing associated with this scenario can resemble that of cord compression. Effective analgesic techniques have been shown to improve these conditions if applied before the second stage.[51]

With the popularity of the Internet, patients today are able to find a variety of information about natural childbirth practices without any means to determine if the information presented is accurate. Several factors have come to bear upon modern-day childbirth courses that teach the Lamaze or Bradley techniques and the information that is provided. Couples are no longer willing to take the full course but try to learn the techniques in a matter of hours, if they train at all. This makes it nearly impossible to learn the pain-controlling techniques that Lamaze and Bradley described. Additionally, information provided in courses on available forms of pain relief options is variable, not only due to potential personal biases by the instructor, but also the instructor's knowledge of what is available at the local maternity units. As a result, couples may approach labor with a rigid plan that does not take into consideration informed alternatives for pain management should the fetus show signs of compromise. Unfortunately, a mother who envisions a natural childbirth for her labor often views resorting to any form of analgesia, especially an epidural, as a failure on her part. Studies show that natural childbirth preparation, including training in breathing and relaxation, did not decrease the use of epidural analgesia during labor.[5] Also, mothers who planned for an unmedicated labor but resorted to a neuraxial block frequently experienced longer labors associated with higher pain scores, which may catch them unprepared for the intensity of the process.[32]

Hypnosis

Self-hypnosis for labor and delivery, or hypnobirthing, enjoys a devoted following among those for whom the process has been successful. It requires time for training and practice and is not a choice for those with only a weekend set aside to learn it. There are two main methods of providing hypnosis in the context of pain management for childbirth: hypnotherapy delivered in person by a known practitioner, and self-hypnosis, in which the mother is trained to self-induce a state of altered consciousness. Under such a state, there is less awareness of the environment and an increased susceptibility to suggestion. These may be verbal and nonverbal communications used to achieve specific therapeutic goals.[15] In the context of childbirth, suggestions may focus on increasing feelings of safety, relaxation, and comfort, as well as potentially developing sensations of numbness.[40]

Further studies are warranted to clarify the impact of hypnosis on labor pain as current studies lack randomization, hypnotic methods are not well described, and the study populations are relatively small. A recent Cochrane database review examined 9 trials with a total of 2954. The review authors found hypnosis may reduce the overall use of analgesics but not epidural use. Also, there were no clear differences between women in the hypnosis group and those in the control group with regard to several outcomes: use of pharmacologic pain relief, spontaneous vaginal birth, and satisfaction with pain relief.[40]

Water Birth

The water birth movement holds that submersion for labor, delivery, or both, reduces the sensation of pain. It also holds that birthing from one water environment into another is less stressful for the infant. Unfortunately, there are no

substantive studies supporting this claim. Like most alternative methods, almost everything reported in the literature is anecdotal. A Cochrane database review article indicates that immersion in water during the first stage decreases maternal requests for neuraxial analgesia and can be supported for women at low risk of complications.[12] However, immersion during the second stage of labor needs further investigation. At present, there is no clear evidence whether to support or reject a woman's decision to give birth in water.[12] Questions regarding infection and neonatal outcomes are not addressed, and large collaborative trials are needed to answer these critical issues. A 2004 review article considered three clinical concerns: water aspiration, neonatal/maternal infection, and neonatal/maternal thermoregulation in the practice of water birthing. They also looked at two practical concerns: skills and education of midwives or health professionals assisting the water birth, and emergency procedures in case of maternal collapse. They did not find sufficient evidence to caution women away from this practice.[89]

Acupuncture

This technique has most often been used to address the issue of low back pain during labor and not that of labor pain management in general. In controlled trials, acupuncture has been demonstrated to be beneficial but time consuming and without consistent results.[3] In addition, the study sizes have been small, indicating that more research is needed, although there appears to be no negative effect on the neonate.

Pharmacokinetics, Pharmacodynamics, and the Fetus

There are two classes of drugs commonly used by obstetric providers in modern practice for labor pain management that fall under the scope of this segment. They are opioids for pain relief and sedatives to relax and reduce anxiety. Under emergent surgical conditions, anesthesiologists use other classes of drugs, but these are not reviewed in any detail here. When considering the effect of any medication on the fetus, it is worth noting whether that medication has produced a cerebral effect on the mother. If so, that medication has the properties to cross the lipid blood-brain barrier and likely will cross the placental barrier to reach the fetus as the necessary transport mechanisms are the same.[90] However, the extent to which a fetus is exposed depends on many factors, such as the drug's pharmacokinetic and pharmacodynamic properties, the dose, and the mode of delivery.

Three pharmacologic characteristics are considered when weighing whether or not a medication has the properties to enter the maternal circulation from its primary site of administration and then leave that circulation to cross the placenta (see Chapter 45). These are how much of the drug is in the ionized versus the nonionized state as determined by its pH, whether it has lipophilic or hydrophilic tendencies, and whether it prefers to bind to protein.

A medication that is ionized cannot cross a membrane barrier. A drug's pKa means that 50% of the drug is ionized and 50% is nonionized. Local anesthetics as a class are weak bases (pKa = 7.6-9.1), so at physiologic pH (7.4) more of the drug is in the ionized state. The ratio by which a local anesthetic is ionized in the circulation depends on how much higher the pKa is from 7.4. For instance, a local anesthetic with a pKa of 9.1 is mostly ionized, and more will stay in the maternal circulation than a local anesthetic with a pKa of 7.6. Because only the nonionized portion of a drug will cross a membrane barrier, the amount that crosses will reproportion itself into ionized and nonionized forms once in the fetal circulation. If the fetal pH is lower than the maternal pH because of acidosis, more of the drug converts to the ionized form and cannot return to the maternal circulation. If maternal exposure to the medication persists, more of the drug passes from mother to fetus, and increasing amounts accumulate in the fetal circulation. This phenomenon is called *fetal ion trapping* and has been associated with some of the deleterious effects produced by medications in the compromised fetus.

Of the other pharmacodynamic properties mentioned, drugs that possess lipophilic properties as opposed to hydrophilic are more capable of crossing lipid-rich membranes. Most medications used in obstetrics are lipophilic but to varying degrees. For example, fentanyl and sufentanil are lipophilic opioids, but sufentanil is much more so. As a result, epidural doses of sufentanil more readily leave the epidural space to enter the maternal circulation than fentanyl.

Protein binding is the third important pharmacologic principle. A drug that binds with protein molecules remains in the maternal circulation because when bound, it becomes a bulky molecule. Only the unbound drug is free to cross a membrane and produce an effect. So excluding active transport mechanisms, it is the unbound, nonionized portion of a lipophilic medication that can cross a membrane barrier to produce an effect.

The pharmacokinetic effects of metabolism and elimination are yet another regulator of how much or even whether a drug will exert an effect on the fetal brain. Most medications undergo extensive metabolism into inactive metabolites in the maternal circulation. As a result, very little if any effect may be found. One example of a rapidly metabolized medication is succinylcholine, a depolarizing muscle relaxant. This medication is metabolized to benign metabolites by pseudocholinesterase in the maternal plasma and has a half-life of about 90 seconds. As a result, nothing reaches the fetus. However, if a drug is metabolized into an active metabolite in the maternal system and then crosses into the fetal system, that metabolite can have fetal effects. Such is the case with normeperidine, the active metabolite of meperidine.

A useful measurement that helps estimate fetal medication exposure is the ratio of the umbilical vein drug concentration to the maternal vein (UV:MV). A ratio of 1 (UV:MV = 1) means that the amounts of medication in the

TABLE 27.1 Placental Passage of Commonly Used Anesthetic Medications

Drug	Umbilical Vein to Maternal Vein Ratio (UV:MV)
Induction Agents	
Thiopental	1.08 (range, 0.5-1.5)
Ketamine	0.54 (range, 0.4-0.7)
Propofol	0.7
Etomidate	0.5
Nondepolarizing Neuromuscular Blocking Agents	
Pancuronium	0.19
Vecuronium	0.11
Opioids	
Morphine	0.92
Meperidine	0.81 (may exceed 1.0 after 2-3 hours)
Fentanyl	0.57
Sufentanil	Levels too low to measure in humans
Butorphanol	0.84
Nalbuphine	0.97

Adapted from data from Glosten B. Anesthesia for obstetrics. In: Longnecker DE, et al., eds. *Principles and Practice of Anesthesiology*. 2nd ed. St. Louis: Mosby; 1998.

umbilical vein equal those in the maternal vein. A low ratio means that a small amount has crossed the placenta to reach the umbilical vein. For example, the nondepolarizing muscle relaxants used in general anesthesia are highly ionized, hydrophilic compounds that do not cross the membrane barrier. Their UV:MV ratios tend to be on the order of 0.1. Table 27.1 lists the UV:MV ratios of some common anesthetics.

Even if the umbilical vein levels are significant, they may not be great enough to produce any important neurobehavioral effect, because two more protective barriers exist to shield the fetal brain from medication exposure. Approximately 40%-60% of any medication entering the fetal circulation passes through the liver first and then travels through the inferior vena cava to the heart and into the circulation. The mature or nearly mature fetal liver can metabolize most drugs, and this first pass through the liver buffers the fetal brain from exposure.[26] Additionally, the unique fetal circulation dilutes most of any drug as it travels into the general circulation, and this dilutional effect can be quite protective of the fetal brain.[26]

One final clinical note for the neonatologist: Not only does the dose have an impact on how much medication enters the maternal circulation for eventual fetal distribution, but so does the mode of administration. Although it is obvious that intravenous administration achieves the highest maternal blood levels, all blocks and injections distribute some level of the drug into the maternal circulation, and they differ markedly from one another. From the greatest to the least effect on maternal blood levels, drug administration modes have the following ranking[26]:

Intravenous > Paracervical > Intramuscular > Epidural > Spinal

It should be noted that maternal local anesthetic levels after a spinal delivery are so low as to be clinically irrelevant.

Sedatives

The routine use of heavy sedatives in the active phase of labor has markedly diminished, making it unlikely that a neonatologist will be caring for a neonate with a recent exposure. In modern practice, the primary purpose of sedatives is to help the parturient rest during a prolonged latent phase of labor, but may be administered during a cesarean delivery either to an anxious patient or before the induction of a general anesthetic. Other than in the cesarean delivery scenario, enough time usually passes between administration and delivery so that any significant drug amounts clear the maternal and fetal circulations. The class of medications most often encountered today is benzodiazepines.

Benzodiazepines are most likely used in an acute situation either because of maternal self-administration or from the anesthesia provider during a cesarean section. The two most commonly encountered benzodiazepines are diazepam and midazolam. Midazolam has a low UV:MV ratio, so it does not cross to the fetus well at all, making it essentially without clinical effect when given acutely. The most common use of midazolam is during a cesarean delivery that is unplanned. Given by the anesthesia provider for its excellent anxiolytic properties, it unfortunately causes maternal amnesia that will impair the mother's recall of the delivery if administered beforehand. It is usually reserved for the highly anxious patient, and most providers attempt to delay administration until after delivery. Diazepam is another benzodiazepine that might be encountered. Unfortunately, diazepam has a high UV:MV ratio that reaches 1 within minutes and can increase to 2 within hours.[90] Metabolites are active and can remain in the system for up to 8 days. When given in the intrapartum setting for eclamptic seizures, this medication can cause hypotonia, hypothermia, and respiratory depression in the neonate.[18,44,84] Once thought to cause oral cleft malformations when used chronically during the first trimester, studies do not support this assertion.[72] Regardless, diazepam is not as commonly prescribed by the obstetric provider as it once was, and its use is usually limited to the acute management of maternal seizures. A discussion of other benzodiazepines can be found in any general pharmacologic text.

Barbiturates are used less commonly than before. Phenobarbital is rarely used but remains an option for treatment of partial or generalized tonic-clonic seizures and status epilepticus.[18] Thiopental is an anesthetic induction agent that is no longer available in the United States, making

propofol the most frequently used. The two have similar profiles as far as neonatal effects are concerned.

Opioids

The definition of an opioid is any natural, synthetic, or semisynthetic compound that acts on the same receptors as morphine and produces similar effects. Those agents are known as pure agonists and include morphine, meperidine, and fentanyl. Those that act on only some of the receptors and may even block action on others are known as agonist-antagonists and include nalbuphine and butorphanol. Pure antagonists block action on all receptors and are not considered opioids but can reverse their actions. Naloxone defines this class.

Opioids do not block the transmission of pain but rather stimulate receptors to alter the perception of pain and one's response to that perception. For that reason, opioids are considered incomplete analgesics. There are three known opioid receptor types and a possible fourth on which these drugs act.[54,73] The μ-receptor provides the most complete analgesia but also produces most of the known side effects of opioids such as pruritus, nausea and vomiting, euphoria, dysphoria, and respiratory depression to the point of apnea. The κ-receptor mediates less intense analgesia because of what is known as a "ceiling effect." The dose-response studies performed early in the investigation of medications that stimulate this receptor determined that the curve stopped rising at a particular dose. This flattening of the dose-response curve means that more of the drug does not produce more of an expected effect. This "ceiling effect" holds not only for analgesia but also for respiratory depression. No other side effects appear to be associated with this receptor type. Both the μ- and κ-receptors have been divided into multiple subgroups. The δ-receptor mediates the effects of the endogenous endorphins, especially as they act on the spinal cord. The final receptor, called the σ-receptor, may be responsible for supraspinal effects and little is known about it to date, but research is ongoing.[68] Box 27.1 lists some of the opioids commonly used in labor and their classifications.

Opioids appear to be more effective on visceral pain than somatic pain.[54] As a result, they are more useful during the first stage of labor, which tends to be visceral in nature, than the second stage, which is more somatic.[39] Because all opioids can cross the placenta and produce an effect in the fetus, systemic opioid use has traditionally been limited to the first stage so that the opioid is metabolized from the fetus before delivery. However, not only has the selection of opioids expanded over the years, but also the thoughts on how they can be delivered. Intermittent intravenous administrations are still the mainstay on most units, but intravenous patient-controlled analgesia (IV-PCA) is offered on most obstetric units. Once thought to be taboo because of neonatal opioid-induced depression, studies show that this administration technique can be provided reasonably well.[58,76] However, because of the depressive effects, this method should be reserved for situations in which a regional technique is either not available or contraindicated.

There are several reports in the literature describing the IV-PCA technique with meperidine, fentanyl, alfentanil, and remifentanil.[56,58,76,80] Those neonates whose mothers use this technique should be watched for signs of sedation, respiratory depression, and low oxygen saturation.

Opioid Agonists

Opioid agonists that may be used on the obstetric unit are morphine, meperidine, fentanyl, sufentanil, and remifentanil.[79] Although formerly used, studies have shown that alfentanil is less effective than other opioids, such as fentanyl, for first-stage labor analgesia. In addition, when used in doses of 10 μg/kg in the mother, it can cause severe neonatal respiratory depression.[43] Morphine is the only naturally occurring agonist and, if used at all during labor, is used early. The reason is that not only is it more depressive to the neonate than any other opioid, but it may also depress uterine contractions, making it a questionable choice for labor management.[73]

Meperidine (Demerol) is a synthetic opioid with some very interesting properties. This opioid was one of the most commonly used systemically, but its use has dropped off. There is evidence that it enhances the effacement and dilation of the cervix[47] and has atropine-like properties that can produce tachycardia and myocardial depression in the mother. When injected into the epidural or spinal space, it can produce a block similar to that seen with local anesthetics, making it an option when a patient has a documented allergy to all forms of local anesthetics.[11]

When used to provide systemic analgesia, meperidine is traditionally dosed in such a way as to limit fetal exposure before delivery. The drug's duration of action is 2-4 hours, with a half-life of 3-4.5 hours. Based on that and knowing that intramuscular administration requires about 45 minutes to an hour to absorb and have an effect, meperidine is not given unless delivery is expected within the hour or beyond 3 hours. Unfortunately, estimates of delivery time are an imprecise science, and sometimes the neonate is delivered

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

during peak exposure. Even so, the need for naloxone to reverse the depressive effects is uncommon under this scenario. In any case, it would probably be best to closely observe neonates exposed to this form of analgesia. Meperidine is metabolized to an active metabolite called normeperidine. The fetal liver is capable of metabolizing meperidine into its active metabolite, or it can cross the placenta and accumulate. Its half-life is 15-40 hours, so its neurologic and depressive effects can be evident for some time after delivery.

Several commonly used opioids are analogues of meperidine. They are fentanyl, sufentanil, alfentanil, and remifentanil. Although only fentanyl and sufentanil are used for anesthetic nerve blocks, fentanyl, alfentanil, and remifentanil have been used systemically in the obstetric setting. All these meperidine analogues are lipid-soluble and can cross the placenta. However, they are rapidly metabolized by the first pass through the liver to inactive metabolites, thereby making any depressive effects uncommon when these drugs are given as intermittent intravenous boluses.[62] Because of its pharmacokinetic properties, remifentanil is so short-acting that it can be used only in a continuous infusion mode. In one study, fentanyl was injected as a maternal intravenous dose of 1 μg/kg just before the start of the cesarean section, and no neonatal depressive effects were detected.[56]

Fentanyl has been used in the IV-PCA format,[48,70] as have alfentanil[48] and remifentanil,[31,56] with mild neonatal depression a common occurrence. This mode of administration is a more acceptable alternative to intermittent injections when anesthetic services are limited or neuraxial blocks are contraindicated. Generally, oxygen supplementation and observation are all that is required for the neonate after such exposure.[32,69]

One final note about the opioid agonists: All of them are associated with the suppression of fetal beat-to-beat variability, which returns to normal as the drug is eliminated, suggesting a causal effect.

Opioid Agonist-Antagonists

All medications in this category stimulate the κ-receptor and thus have a ceiling effect on respiratory depression, as previously described. However, the ceiling effect also applies to analgesic capabilities, making this class of drug limited in its effectiveness. The two most commonly used formulations on obstetric units in the United States are nalbuphine (Nubain) and butorphanol (Stadol). Both produce sedation in the mother and degrade to inactive metabolites, and although both cross the placenta, the fetal effects seem limited.[26,54] However, nalbuphine reduces fetal beat-to-beat variability and can produce a sinusoidal pattern when used.[17]

It is important to note that these two medications are markedly different in how they act on the μ-receptor. Whereas butorphanol has essentially no effect on the μ-receptor, nalbuphine actively blocks it. As a result, it can be used in small doses in lieu of naloxone to counter μ-receptor side effects such as pruritus. The danger with nalbuphine is that it can place an opioid-addicted patient into acute withdrawal at doses commonly used for labor analgesia. It can do the same to the addicted neonate.[26,54] Therefore, caution should be exercised when using this medication if there is any indication of opioid abuse in the mother or if she is in an opioid addiction maintenance program.

Because of the sedative and respiratory depressive effects of these drugs as well as the inability to produce complete analgesia, heavy intrapartum use can lead to a situation in which maternal hyperventilation during a contraction is followed by hypoventilation as the contraction recedes. This condition will produce predictable consequences for maternal oxygen and carbon dioxide levels and shifts in the oxyhemoglobin curve that can end in significant fetal acidosis that begins during the first stage and worsens during the second.[49,51,63]

Opioid Antagonists

The opioid antagonist, naloxone (Narcan), blocks the action of an opioid on all of the receptors and is commonly used to reverse adverse side effects and excessive dosing. It has a short half-life (30-45 minutes), which means that repeated boluses may be necessary at times. Naloxone is not a benign drug and has been known to cause pulmonary edema and cardiac failure in some situations, so caution should be exercised when using it.[54] It crosses the placenta, so it will reverse any opioid effect in the fetus. As with nalbuphine, it is not a medication that should be given to a mother with an opioid addiction or who is in an opioid addiction maintenance program. Not only will it produce withdrawal in the mother but in the addicted fetus as well.[49,54]

Nitrous Oxide

Despite common use in many parts of the world, few centers in the United States offered the inhalational analgesic, nitrous oxide (N_2O). But recently, U.S. institutions have considered its use, and as of 2015, 50 centers in the United States were offering it, with more considering it.[66] Nitrous oxide is a weak analgesic that, when combined with oxygen, can provide some pain relief at subanesthetic levels, making it safe to use. It is unclear exactly how N_2O provides analgesia, but what is clear is that the individual response is variable.[66] This may explain study results. A Cochrane database review examined 26 studies encompassing 2959 women.[33] Despite the studies being judged of poor quality and questionable design, those comparing N_2O against flurane derivatives, such as isoflurane and enflurane (which are not available in the United States), found the flurane derivatives provided better pain relief with fewer side effects. When N_2O was compared against placebo or no analgesia, N_2O provided better pain relief but with more side effects that included nausea, vomiting, dizziness, and drowsiness. Nitrous oxide compared against transcutaneous electrical nerve stimulation (TENS) showed no difference in effectiveness. What has not been measured to any satisfaction

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

is the effect of N_2O on the mother-neonate interaction, breastfeeding, or long-term infant outcomes. Concerns over occupational exposure with N_2O use have not been validated in studies, and with newer equipment having a built-in scavenger system now available, fears are further allayed.[37,66] Nitrous oxide's utility and popularity seems to lie in that it provides a choice to mothers, which in turn may improve satisfaction scores. It is also an option when neuraxial block is contraindicated or not available and does not require anesthesia personnel to provide it.

Obstetric Nerve Blocks

Obstetric nerve blocks are invasive procedures performed by the obstetric provider to achieve analgesia in labor. Only two nerve blocks are used in obstetric practice, and these are for different goals. The paracervical block provides pain relief in the first stage of labor, whereas the pudendal block is used for analgesia during the delivery portion of the second stage.

Paracervical Blocks

The purpose of the paracervical technique is to block pain transmission via the visceral afferent fibers near the dilating cervix. This is achieved by injecting local anesthetic lateral to the cervix at the vaginal fornices. Lidocaine without epinephrine is preferred in the United States because of its relative safety.[71] In the early 1980s, US manufacturers of bupivacaine specifically contraindicated the use of the agent for paracervical blockade because of its risk for maternal cardiotoxicity.[71]

Paracervical block (PCB) was described by Europeans in the early part of the twentieth century and was first reported to be useful in providing labor analgesia in the United States in 1945. The technique became popular in the United States in the early 1960s.[71] Numerous early case series, case reports, and clinical studies demonstrated good first-stage labor anesthesia in approximately 75% of women.[71] However, careful reviews of the early reports also describe a post-blockade fetal bradycardia. Although the bradycardia has been described to be of a short duration and usually without adverse sequelae, fetal deaths have been reported.[71] Some of these deaths resulted from direct injection of local anesthetic into the fetal head, resulting in profound fetal systemic toxicity. Other theories about the etiology of the fetal bradycardia included aortocaval compression caused by maternal positioning for the block, paracervical manipulation, increased uterine activity, and local anesthetic-induced constriction of uterine blood flow in the area adjacent to the nerves blocked.[71]

Paracervical blocks are less commonly performed for labor pain in the United States today. Studies show that parturients receiving paracervical block often continue to receive subsequent analgesia and were less satisfied and less willing to have the same technique again compared against neuraxial techniques.[30] However, a PCB might be useful when neuraxial blocks are not available or contraindicated.[36] Further high-quality studies are needed to confirm the findings, assess other outcomes, and compare local anesthetic nerve blocks with various modalities for pain relief in labor.[52]

Pudendal Blocks

A pudendal block may be used for analgesia in the late stages of labor and is most typically used when an operative delivery with forceps is planned. The pudendal nerves are blocked using a transvaginal approach in which 5-10 mL of local anesthetic is injected at the site of the attachment of the sacrospinous ligament to the ischial spine. A significant potential complication of the procedure is maternal intravascular injection, so aspirations are frequently performed. Despite the avoidance of maternal injection and the typically short interval between injection and delivery, blood levels of the local anesthetic may be found in the neonate for up to 4 hours after delivery. However, studies included in a Cochrane analysis from 2012 found no significant adverse neonatal effects (based on an Apgar score of less than 7 at 5 minutes).[52]

Neuraxial Blocks

Any variety of epidural, spinal, or combination thereof falls under the general term *neuraxial block*. These nerve blocks are performed by an anesthesia provider and are the preferred techniques for cesarean deliveries, because maternal airway management is avoided, sensorium is unimpaired, and little or no medication reaches the fetus. Any manner of neuraxial block is commonly offered to parturients when labor is established. The versatility of these blocks makes them the ideal choice, as how dense the block is or how sparing is determined by which medications are used and in what manner they are dosed. In most laboring situations, only an analgesic state is desired; however, on occasion a denser block more closely resembling an anesthetic is preferred. This technical nuance defines two very different goals for the anesthesia provider. An anesthetic is that method designed to remove all sensation—pain, temperature, touch, vibratory sense, proprioception, and motor ability. The goal of an analgesic is to eliminate only the sensation of pain, leaving all other components intact. Logically, higher doses are more likely to produce the anesthetic state, whereas lower doses may produce only an analgesic state.

Techniques

How the most basic neuraxial blocks are administered has evolved over time to include several variations, of which the combined spinal-epidural and the patient-controlled epidural analgesic are just two. New on the horizon is the automated intermittent bolus approach that uses newer technology to administer boluses to the patient at preset

intervals. It is not the purpose of this section to describe all aspects of these procedures in detail, but neonatologists should be aware of their most fundamental facts. A more in-depth description may be found in any obstetric anesthesia text.

Lumbar Epidurals

Lumbar epidural analgesia is usually initiated in either the sitting or lateral position.[67] To block the necessary nerves that transmit labor pain in the first stage (T10-L2), the back is examined for the L4-5, L3-4, or L2-3 interspaces. A placement at any of these three levels will produce the necessary nerve block. Once the epidural space is identified with the needle, a catheter is inserted through the needle and the needle is removed over the catheter. The catheter is then tested with lidocaine or bupivacaine with or without epinephrine to rule out intrathecal or intravascular catheter placement. Adequate labor analgesia is then established by bolus injection of the selected anesthetic. Analgesia is maintained with any combination of intermittent bolus injections and/or a continuous infusion. There are numerous drug combinations, concentrations, and infusion rates cited in the literature, but the prevalent trend today is to use dilute local anesthetic concentrations most often in combination with a low dose of opioid in an attempt to limit drug amounts while maintaining an analgesic state. Use of lower doses also improves the safety of the technique in that there is less of a chance of a deleterious effect on either the mother or fetus should the catheter migrate into either a vessel or the spinal space. The catheter is removed after delivery when there is no further need for analgesia or anesthesia.

Patient-Controlled Epidural Analgesia (PCEA)

First described for use in labor by Gambling et al. in 1988, PCEA allows the parturient to self-administer boluses of the epidural solution, giving her the ability to accommodate changing analgesic needs as labor progresses.[61] The anesthesia provider adjusts the program settings such as demand bolus, lockout interval, and hourly maximum rate for individual patients. Practices vary on whether a background infusion is used, but when included, will often be set at a lower rate than would be set for a conventional infusion. Patient-controlled epidural analgesia allows better dose-demand matching as labor progresses and has been shown to be associated with up to a 35% reduction in total volume of local anesthetic, especially in the first stage of labor.[61]

Intrathecal Injections (Spinals)

The word *spinal* is often replaced by the more accurate terms *intrathecal* and *subarachnoid* when anesthesia providers discuss this technique. Regardless of which term is used, intrathecal injections most often convey an image of complete paralysis and anesthesia. However, with modern dosing techniques, spinals performed for labor analgesia preserve temperature, touch, proprioception, and even mobility while providing pain relief. The procedure is the same as that described for an epidural with the exception that a smaller, styletted 25- to 27-gauge needle is used and a catheter is not left behind. The stylet is not removed until a "pop" is felt as the needle passes through the dura into the spinal space. Once the stylet is removed and the presence of cerebrospinal fluid (CSF) confirmed, the medication is injected and the needle removed.

Intrathecal injections are associated with the lowest maternal blood levels of all the analgesic methods used, resulting in clinically irrelevant fetal exposure. The most commonly used opioids for the induction of labor analgesia are highly lipophilic and travel to the μ-receptors within the central nervous system. As a result of this spread, maternal somnolence and even respiratory depression have been reported with small doses.[29] Not appropriately managing this maternal complication will have an effect on the fetus, but there is no direct effect on the fetus from the opioid as a result of the intrathecal injection. Although intrathecal opioid injections have been tried as the sole labor analgesic, they are not very effective beyond the first stage, and they may not last long enough for the labor. Additionally, should there be a need for an operative delivery or cesarean section, another anesthetic procedure would be required. To resolve this issue, spinals are now often combined with epidural catheter placements.

Combined Spinal-Epidurals (CSE)

With the CSE technique, both an epidural catheter placement and spinal injection are performed at the same interspace so that only one local skin infiltration is required. The spinal needle may go through or under the epidural needle. When the epidural tip is situated in the epidural space and before the catheter is threaded, the spinal injection is performed. After injection, the spinal needle is removed, the epidural catheter is threaded into the epidural space, and the epidural needle is removed. This procedure allows for a rapid analgesic response (the spinal), with the ability to bolus and infuse through the epidural catheter for longevity. An adaptation is to not administer a dose through the epidural catheter until the intrathecal effects begin to wear off.

Combined spinal-epidural analgesia has become increasingly popular over the past decade. Onset of analgesia is significantly faster with CSE compared with epidural analgesia by a factor of four (2-5 minutes vs. 15-20 minutes).[87] Despite studies that have addressed many of the concerns with the technique, not all anesthesia providers embrace it. However, most agree that there are some parturients for whom it is better suited, such as the rapidly progressing multiparous patient who might not be offered any analgesic otherwise. Despite studies showing that epidural catheters placed during a CSE technique are more likely to function properly,[61] a perceived detriment with the technique is that the epidural catheter is untried. Should a problem arise, anesthesia providers may forgo using the untried catheter and subject the patient to a general anesthetic. Even though the continuous infusion epidural and PCEA techniques have a slower onset of pain relief than a CSE, the epidural

catheter is tested and functioning should there be a change in delivery plans.

Programmed Intermittent Epidural Bolusing

The development of a programmed intermittent epidural bolusing (PIEB) technique for maintenance of epidurals is based on studies suggesting that intermittent boluses, rather than continuous infusions, result in better local anesthetic spread, decrease the need for clinician-assisted epidural supplementation, and produce higher patient satisfaction.[38,88] This may be because the higher driving pressure generated by the bolus through the epidural catheter at programmed intervals results in better dispersion of medication than can be achieved with a steady, slow continuous infusion.[38] The optimal combination of bolus volume and dosing interval has yet to be determined but studies are underway.

Maternal Risks and Benefits With Neuraxial Techniques

Benefits

Every study that compares the analgesic effect achieved with a neuraxial block against any other analgesic technique, whether it is pharmacologic or nonpharmacologic, documents a superior result.[2] When done properly, these blocks allow the mother to relax and conserve her energy for the second stage of labor when she needs enough motor preservation to participate in that process. They also prevent the maternal hyperventilation often seen in response to pain and all the potential sequelae on the fetus associated with falling maternal P_{CO_2} levels.

Although the medications used with an epidural can eventually be found in the maternal circulation, measured blood levels are low. The current trend is to use very dilute local anesthetic concentrations supplemented with small opioid doses to keep maternal blood levels to a minimum. As a result, mothers typically show very little if any systemic effect from the administered medications, and such low maternal levels indicate very limited exposure to the fetus.[26]

Current studies have shown either no change or an increase in uteroplacental blood flow after epidural analgesia, provided hypotension is avoided or promptly treated.[20] Conversely, pain and the stress of labor may release excessive catecholamines into the circulation, which in turn decrease uteroplacental blood flow because of sympathetic stimulation.[42] Pain management with neuraxial analgesia decreases the level of circulating catecholamines and avoids maternal hyperventilation, which can lead to maternal hypocapnia.[2]

Maternal Side Effects

Common side effects of neuraxial analgesia are hypotension, pruritus, and some degree of motor block. Hypotension results from the sympathetic block by the local anesthetic, leading to vasodilation. It is common after any neuraxial block but frequently more severe after a spinal. It is also more common after an anesthetic dose as opposed to an analgesic one. If the hypotension is allowed to persist untreated, it would result in a decrease in uteroplacental perfusion. Thus, it would be below the standard of care not to treat hypotension when it occurs. To avoid hypotension, a fluid bolus is given before or along with the block initiation and after completion, the mother is positioned laterally or in a semi-recumbent position to prevent aortocaval compression. Decreases in blood pressure are treated with fluid boluses or intravenous vasopressors.

Pruritus is more common after spinal analgesia. The cause is unknown, but it is opioid-induced rather than histamine-related, and the incidence and severity are dose-dependent.[87] It is usually self-limited, but if severe, it can be treated with an opioid antagonist such as naloxone or the agonist-antagonist nalbuphine.

Although the goal of an analgesic dose is to avoid a motor block, some level of weakness is likely if a local anesthetic is part of the dosing mixture. As a result, the policy at many institutions is to confine the parturient to bed after the neuraxial block is placed. Although the idea of a "walking epidural" was popular some time ago, studies show that ambulation per se does not alter the labor outcome.[86] Also, most women did not care to get up once they were comfortable. As a result of this, and the fears of potential liability should a fall occur, many providers and institutions have stopped offering this option.

Other irritating side effects occur primarily because of the opioid used. Besides the pruritus, they include nausea, vomiting, sedation, and urinary retention. All are caused by stimulation of the μ-receptor (opioid) and will dissipate with time. The only hazardous opioid-induced side effect is respiratory depression, and although it is rare, health care providers should be alert for its presentation.

Maternal Risks

The anesthetic and nonanesthetic literature is full of discussions of documented as well as theoretical maternal risks resulting from neuraxial blocks. Although some are uncontested, such as epidural hematoma formation or nerve damage, others are quite fantastic, such as a reduction in the IQ of the neonate. The wide-ranging list of maternal risks includes unintentional intrathecal or intravascular injection, prolonged labor of either the first or second stage, backache, nerve damage, infection with possible abscess formation, epidural or subdural hematomas, arachnoiditis, an increased incidence of operative delivery, maternal temperature elevation, a cervical level that can affect respirations, and an impact on the cesarean section rate. Because the risks of backache, nerve damage, infection with possible abscess formation, epidural or subdural hematomas, and arachnoiditis are postdelivery problems, the reader is referred to any obstetric anesthesia text for a full discussion there. The following section considers only the maternal risks that are documented or have undergone scientific scrutiny and pose a potential problem for the fetus or neonate. Of those left, some are significant, whereas others are of questionable clinical significance. Other mentioned "risks"

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

are documented to no longer be associated with neuraxial blocks but are mentioned here because the reader may not be aware of the newer literature.

Cesarean Sections

The effects of neuraxial blocks on the progress of labor, and particularly on the mode of delivery, have generated tremendous controversy. Selection bias confounded many studies, especially those that claimed epidurals increased the incidence of cesarean section. Now studies have determined that there is an association between epidurals and cesarean sections, but not causation.[75] The association occurs because in situations of a prolonged or dysfunctional labor, women are more likely to request epidural analgesia. All agree that dysfunctional labors are prolonged and very painful, and women in dysfunctional labor patterns are more likely to request some form of neuraxial block. However, dysfunctional labors are also associated with a greater cesarean delivery rate.[83] Literature has shown that neuraxial blocks are more frequently requested once a dysfunctional labor pattern is in place, and it is this labor pattern, not the neuraxial block, that places the patient at risk for cesarean delivery.[74]

Labor Prolongation

Prolongation of labor has long been blamed on neuraxial blocks. This claim is still undergoing some debate. Two meta-analyses and a Cochrane review reported no difference in the duration of the first stage of labor in women receiving epidural analgesia versus those receiving systemic opioid analgesia or no analgesia at all.[7] Conversely, a 2004 meta-analysis claimed that epidural analgesia increased the length of first stage of labor by approximately a half hour.[77] One offered explanation of this result involved the frequency of cervical examination in these studies. Full cervical dilation is considered the end point of the first stage of labor. This would only be determined by cervical examination or when the parturient complains of rectal pressure, which is likely to be later in a woman with effective neuraxial analgesia.[7] Thus, exams may be more frequently performed in the presence of an epidural to catch this end point. Clinical trials by Wong and Ohel found that the duration of the first stage of labor was significantly shorter when any form of neuraxial analgesia was administered early in labor.[7] As for the second-stage prolongation, it is generally acknowledged that there is a statistically significant average increase of about 15 minutes in the presence of an epidural.[7,74] Whether that amount of time is clinically relevant is debatable, and newer studies argue there is no prolongation at all, but the studies used for the meta-analysis are small and not of good quality.[82] Several studies suggest that a prolonged second stage of labor does not result in adverse maternal or fetal outcomes provided that the fetal status is reassuring, the mother is well hydrated and has adequate analgesia, and there is progress in descent of the fetal head.[7] Also, whether pushing is initiated immediately upon recognition of full cervical dilation or delayed until descent of the head causes an urge to push can influence the duration of time in second stage. Indeed, studies currently show that when the second stage is allowed to continue, as is more common in nulliparous patients, a vaginal delivery is more likely and the section rate is reduced by about one-half versus adhering to the usual guidelines.[24,25] The American College of Obstetricians and Gynecologists (ACOG) recommends that if an epidural is in place and there are no signs of fetal compromise, the second stage should be allowed to continue until the fetus has descended to a lower fetal station to avoid maternal exhaustion.

Operative Vaginal Deliveries

Neuraxial blocks have been associated with an increased need for operative vaginal deliveries. When studies report on the overall incidence of forceps deliveries and epidurals, there is no question that the incidence increases when an epidural is in place. However, multiple confounding factors contribute to these findings, such as high doses of local anesthetic that will relax pelvic muscles, thereby preventing proper rotation of the fetus for delivery, the method of epidural analgesia maintenance, and obstetric factors.[7] Why an obstetrician chooses a forceps delivery is not always well defined. For example, an obstetrician may request an epidural placement rather than perform a pudendal block if he or she feels that forceps are indicated for delivery. This may occur either because the obstetrician is uncomfortable performing a pudendal block or prefers the superior analgesia an epidural provides. As a result, the birth is recorded as a forceps delivery under an epidural. Impact studies have also been helpful in that they document that the introduction of a new epidural service does not increase the incidence of forceps deliveries for obstetric reasons. This strongly suggests that they have no effect.[27] However, until more well-controlled studies are performed in which the indication for the forceps delivery is documented, it will be difficult to determine precisely what the risk is or even if one actually exists.

Maternal Temperature Elevation

The gradual development of modest hyperthermia observed in laboring women with epidural analgesia is not seen in those electing other forms of analgesia or unmedicated labor.[74] Selection bias confounds the association between epidural analgesia and fever, because women at risk for fever, which may be caused by longer duration of ruptured membranes, longer labor, more frequent cervical examinations, and other interventions, are also more likely to select epidural analgesia.[74] However, even randomized trials have confirmed a higher incidence of hyperthermia in epidural-exposed women, especially nulliparous patients that suggest a causal relationship. The mechanisms of epidural-associated hyperthermia remain incompletely understood.[74] Altered thermoregulation and an antipyretic effect of opioids given to women without epidural analgesia may explain part of the phenomenon, but the most likely etiology is not an infectious one[14] but rather a noninfectious inflammation.[3,78]

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Newer studies are suggesting that a cytokine-induced inflammatory response, as is normal in labor, may be behind this phenomenon, especially interleukin 6.[10,41] The consequences of maternal hyperthermia are diverse. Obstetricians are more likely to intervene surgically in laboring women with temperature elevation, and neonatologists are more likely to evaluate neonates of febrile women for sepsis. Studies that looked at the neonatal results reported that there was no increased incidence of sepsis despite the maternal temperature elevation.[27,14] As a result, many neonatal units have adjusted their policies to require other clinical indications besides maternal temperature before a neonatal sepsis workup is initiated.

Inadvertent Injections and Excessively High Levels

Inadvertent intrathecal or intravascular injections when a neuraxial block is performed can have a serious impact on the fetus. The epidural space is a potential space that is vascular in nature. Possible catheter or needle complications include placement into a vessel or through the dura into the intrathecal space. Unrecognized misplacement with subsequent injection of a large amount of local anesthetic can cause maternal hypotension, seizures, and cardiovascular collapse from an intravascular injection, or paralysis with respiratory compromise that may lead to apnea from an intrathecal injection.[34] When an unrecognized intravascular injection occurs, the acute insult to the fetus appears to be caused by the maternal hypoxia[87] that develops during the seizure or arrest and not the high levels of anesthetic in the maternal system, although some of it is sure to cross over if uteroplacental perfusion is maintained. When a high block happens because of improper dosing or an unrecognized intrathecal injection, maternal respiratory muscles become paralyzed and inadequate respirations, including apnea, can occur. If this condition is not recognized and treated, the maternal arrest will have obvious consequences on the fetus. Fortunately, both of these complications are exceedingly rare and very preventable with attention to good technique.

Benefits and Potential Risks for the Fetus

When investigating different methods of maternal pain relief in labor, neonatal outcome has not always been at the forefront.[64] Unfortunately, many laypersons and some health care providers assume that for every negative maternal effect, there must be an associated negative fetal or neonatal effect. However, the literature does not support such a presumption. Those studies that examine the fetal and neonatal effects typically report on the presence or absence of base excess to determine the recent intrauterine environment, the intrapartum fetal heart rate (FHR), the Apgar scores, and a host of neuroadaptive examinations. These neuroadaptive examinations often require operator training and have varying abilities to determine any prolonged effect on the neonate from an intrapartum event or medication. For example, the Neurologic and Adaptive Capacity Score (NACS) has poor sensitivity to distinguish between intrauterine hypoxia and drug effects in the neonate.[6,28] The following section discusses the effects of neuraxial block on the fetus and neonate as defined by the aforementioned indicators and concludes with a brief review on breastfeeding.

Acid-Base Balance

One of the most notable benefits a fetus gains from a neuraxial block in the mother is that she no longer hyperventilates in response to painful contractions. Maternal hyperventilation in response to pain has long been known to have adverse fetal effects.[64,65] Maternal and fetal CO_2 levels are closely associated, and maternal hypocapnia as a result of hyperventilation leads to a maternal respiratory alkalosis resulting in a left shift in the oxygen dissociation curve. This leads to impaired placental transfer of oxygen to the fetus. Furthermore, a compensatory metabolic acidosis develops in the maternal side and may be conveyed to the fetus, resulting in worsening acidosis and hypoxia as labor progresses. With a functioning neuraxial block in place, these events are less likely to occur, and studies have consistently shown an improved fetal acid-base balance when an epidural is used.[64,65] Literature shows that fetal acid-base status is not only better with epidural than with systemic opioids, it is also better than with no analgesia.[65] Neonatal base excess measurement at delivery is believed to best reflect the intrauterine environment just before delivery, and studies comparing epidurals against systemic medications or alternative, nonpharmacologic labor management methods have documented that neonatal base excess levels stay within normal limits more consistently with epidural use than they do with other techniques.[63] Other findings are that amounts of meconium are less or similar upon delivery, and Apgar scores are comparable or improved when a functioning epidural is in place. These findings further support the idea of a better intrauterine environment and less stress on the fetus with an effective neuraxial block present.

Fetal Heart Rate

An alteration in fetal heart rate, most notably fetal bradycardia, can occur in approximately 10%-12% of those parturients receiving an epidural and has been a long-recognized phenomenon. It can occur within 15-45 minutes after initiation of any form of neuraxial analgesia. It has been hypothesized that as analgesia is established, there is an acute decrease in maternal plasma epinephrine levels. This acute decrease against a less rapid drop in norepinephrine levels results in a temporary imbalance of uterine tocolytic and tocodynamic forces, resulting in uterine hypertonus, decreased uterine perfusion, and ultimately, fetal bradycardia.[87] The bradycardia usually resolves with conservative therapy and is often significant enough to initiate intrauterine resuscitative measures but rarely leads to an early delivery.[8] Apgar scores are typically fine upon delivery.

The use of neuraxial opioids can also produce an effect on the fetal heart rate (FHR). Loss of beat-to-beat variability can be attributed to large doses of neuraxial opioids, but

this side effect is also seen with systemic opioids and agonist-antagonist opioids. A comparison of analgesic techniques shows that FHR changes are more common with systemic medications.[26] More newborns of mothers receiving intravenous versus neuraxial opioids had lower 1-minute Apgar scores and needed naloxone and resuscitation.[64,65] Although studies show that the neuraxial opioid effects on FHR are temporally limited when very high doses are delivered repeatedly to the epidural space, enough can be absorbed systemically by the mother and cross the placenta. This can result in high levels in the neonate at birth and require the use of naloxone. As a result, anesthesia providers should be careful with the timing and use of neuraxial opioids during the second stage of labor.

Breastfeeding

A frequent claim made by those opposed to the use of epidurals is that this mode of pain relief will temporarily or permanently damage the neonate's ability to breastfeed.[81] Precisely how this occurs has never been elucidated, and those proposed hypotheses that seemed plausible have not withstood scientific scrutiny. Studies reporting on the effect of neuraxial medications on breastfeeding have not been randomized, and those purporting to show adverse effects of epidural analgesia received disproportionate publicity.[64,65] One of the most common theories is that medications used in the epidural space enter the maternal circulation, reaching such high levels that enough crosses to the fetus, where it remains in circulation after delivery and produces an adverse effect. The other common hypothesis is that high maternal systemic concentrations from epidural injections seep into the breast milk and affect the neonate. Reynolds reviewed 17 breastfeeding studies, from 1994-2010, looking at the effects of neuraxial blocks on breastfeeding versus other or no analgesia.[64,65] Only two studies showed a dose-related detrimental effect of epidural fentanyl, but these findings were not confirmed by other retrospective studies.[64,65] A Canadian study from 2010 showed that, with good support, a breastfeeding success rate of greater than 95% can be achieved after epidural bupivacaine plus fentanyl, with no discernible dose-related effect.[64,65] Anecdotally, some of the patients who had undergone labor without an epidural were so exhausted after delivery that they were not able to breastfeed, whereas those who had an epidural were alert.

Other studies have not measured levels but examined whether nursing policies that require a different postpartum management of patients with epidurals might have a negative influence on breastfeeding behaviors. These policies were found to minimize early postpartum maternal-infant contact. Furthermore, where early maternal-infant separation is minimized, epidural analgesia was found to have no effects on lactation success.[64,65] Although there are numerous reasons why mothers and neonates do not succeed at breastfeeding, the current peer-reviewed literature does not support the premise that neuraxial techniques have any effect on the abilities of the neonate to do so.[21]

Delivery Modes and Anesthetic Techniques

When a mother presents for labor management, and delivery is not imminent, an important role for the obstetric team is to support whatever pain-relieving choices she makes as long as there is no perceived harm to her or her fetus. However, choices are not always well-informed or circumstances dictate a change in labor management that conflicts with the mother's desires. For instance, the morbidly obese patient who has a difficult airway and a questionable fetal heart rate tracing should not pursue the water birth she planned, but be counseled on oxygen supplementation and placement of a neuraxial block in anticipation of a possible emergency cesarean section. Labor is one of the most dynamic natural events in medicine, and what may begin as a routine process can change very rapidly. As a result, analgesic techniques and management plans need to be adaptable. The following section outlines some of the anesthetic-based considerations the anesthesia provider faces when a spontaneous vaginal delivery is no longer likely.

Operative Vaginal Delivery

Over the past decade, the rate of operative vaginal delivery has significantly decreased.[13,53] There are two types: vacuum extraction and forceps delivery. The choice of instrument is often influenced by clinical circumstances, operator choice, and availability of specific instruments.[52] In the case of a vacuum extraction, it cannot be performed until the head is very low in the pelvis.[13] The extractor is generally a soft, pliable cup and the application is well tolerated by the mother so that additional analgesia is not necessary even if none was used for the labor. Some local anesthetic to the perineum in anticipation of an episiotomy may be all that is required.

Forceps application and delivery generally require some level of analgesia, and often the obstetric provider either requests a neuraxial block or performs a pudendal block. There are four levels of forceps delivery described, but the two most commonly performed are low and outlet forceps deliveries.[53,59] The placement of the forceps blades is very stimulating, and it is only in a dire emergency that an obstetric provider should perform such a delivery without some form of anesthesia in place. A pudendal block is a reasonable choice and can be performed in less time than a spinal or epidural can be administered. However, neuraxial blocks offer more complete pain relief and, in the case of an epidural or combined spinal-epidural, can be extended to a higher level should the forceps attempt fail.

Cesarean Section

Cesarean sections can be performed electively, urgently, or emergently. The form of anesthetic used is dictated by the circumstances. Most anesthesia providers prefer not to use

a general anesthetic because of concerns with the maternal airway and potential aspiration. The incidence of failed intubation among the pregnant population is estimated to be upwards of 8-10 times that of the nonpregnant population. Studies have reported the difficult airway incidence to be between 1 in 238-750 general anesthetics, with 1:250 being the most widely quoted ratio.[60] Several factors contribute to this number. The changes of pregnancy itself as well as altered hormonal influences cause edematous airways resulting from fluid accumulation.[46] Add to this the time spent in labor, especially after many Valsalva maneuvers in the second stage, and what was once a normal airway can become swollen with obscured intubation landmarks and easily obstructed with attempts at intubation. Other changes that contribute to maternal risk during induction include those of the pulmonary system, gastrointestinal system, and body habitus over the course of the pregnancy. These changes and the often-emergent nature of an obstetric procedure may result in failed airway management, with or without aspiration. Airway fatalities have diminished secondary to the decreased use of general anesthesia for obstetric procedures and the use of rescue airway equipment such as supraglottic airway devices and video laryngoscopes.[85] Because of these airway concerns, neuraxial anesthesia is the approach of choice whenever possible for most anesthesia providers.

Neuraxial Anesthesia

In the elective or urgent situation, some form of neuraxial block is the anesthetic of choice, assuming that there are no existing contraindications (Box 27.2). If an epidural is already in place, it is an easy matter to change medications to a more concentrated, faster-onset local anesthetic. Opioids may or may not be added. Attention must still be paid to the dosing technique because moving the patient onto the operating bed may dislodge or shift the epidural catheter; therefore, test doses and aliquoted dosing amounts are still in order. If an epidural block is not in place and the need to proceed with the cesarean section is urgent or emergent, the preferred approach in most units is to perform an intrathecal injection or possibly even a combined spinal-epidural technique. These methods give a faster onset and limit the medication exposure to the fetus. All neuraxial techniques have been shown to result in better neonatal parameters than when a general anesthetic is performed.[1]

• BOX 27.2 Absolute Contraindications to Neuraxial Blocks

- Severe hypotension
  - Hypovolemia
  - Sepsis
  - Hemorrhage
- Infection at the site
- Coagulopathy or thrombocytopenia
- Maternal refusal

General Anesthesia

At what level of surgical urgency a neuraxial block should not be attempted or should be abandoned is always a topic for discussion. That decision should never be made lightly because of issues with the maternal airway, effects of anesthetics on uterine tone, and the potential impact on the fetus.[42] There are absolute contraindications to performing a neuraxial block (see Box 27.2), and when one is present, it directs the decision making. Neonatologists present at a nonelective cesarean section reasonably add the use of general anesthetics to their growing list of potential reasons for neonatal resuscitation. Fortunately, the literature supports the clinical observation that under the conditions of short incision-to-delivery times and with the current pharmacologic developments of short-acting anesthetics, the impact on the neonate is small. Those anesthetic agents that are most commonly used are further discussed.

Before the induction of a general anesthetic, the anesthesia provider usually gives the mother one or more agents to reduce the risk of aspiration, provided circumstances allow. The most commonly used agent is sodium citrate, which is an antacid taken orally just before induction. Other agents that may be given instead of or along with sodium citrate are some form of H_2-blocker, such as ranitidine, and metoclopramide. None of these medications has been shown to have an impact on the fetus.[23]

Because it is only during the induction phase and a short maintenance period to which the fetus is exposed, the anesthetics of concern are the induction agents, a rapid-onset neuromuscular blocker such as succinylcholine, a volatile agent, and perhaps nitrous oxide (N_2O) and occasionally opioids. The previous discussion on general pharmacologic properties and the UV:MV ratio should help gauge the potential impact on the fetus. Table 27.1 shows the UV:MV ratios of several of these drugs. Thiopental is no longer available in the United States, thus, propofol is now the most commonly used induction agent.[50] Ketamine and etomidate have been used as well. All cross the placenta, but there is rarely an effect seen in the neonate because of the first-pass effect through the fetal liver and the dilutional effects from the circulation. Some of propofol's benefits are its short half-life and minimal residual impact. Ketamine is generally reserved for the hemorrhaging or volume-depleted patient, because it is less cardio-depressive and produces a sympathetic response that better maintains the maternal hemodynamic state. Etomidate is generally reserved for patients with cardiac disease. All of these induction agents depress the maternal myocardium but to varying degrees. As a result, intervillous blood flow may initially decrease but will return to baseline as long as maternal blood pressures are monitored and any hypotension is treated.

To intubate and secure the airway in the most rapid manner possible, succinylcholine is the neuromuscular agent of choice, because it has the fastest onset of action. It also has the shortest duration of action as it has a half-life of 90 seconds and is metabolized in the maternal plasma by

pseudocholinesterase to benign metabolites. As a rule, no other neuromuscular blocking agent is needed during the short time from incision to delivery, so the use of succinylcholine alone will have no effect on the fetus. However, there are times when succinylcholine is contraindicated or delivery is delayed and a nondepolarizing neuromuscular blocking agent is required. This is a different class of neuromuscular blocker from succinylcholine, but this class of medications is hydrophilic and highly ionized. As a result, little if any crosses the placenta and again, the fetus is not affected (see Table 27.1).

A volatile agent such as isoflurane or sevoflurane is administered to maintain the anesthetic state, and nitrous oxide may or may not be added. Although these agents pass to the fetus, they rarely have a direct effect unless the time from induction to delivery is prolonged. If more than 15 minutes pass since the induction, the concentrations of these agents in the fetus will equilibrate with the maternal levels, and the neonate will be depressed at delivery. Ventilatory support for a few minutes is generally all that is required as these agents are expelled through the lungs. However, it is more important for the neonatologist to note that if the uterine incision to delivery time exceeds 180 seconds, the neonate will more likely be depressed from a compromised perfusion and less so from these maintenance agents.[16]

Adjuvant Medications

Intravenous opioids or sedatives are usually not administered to the mother before delivery but on occasion it happens. Some patients demand some form of anxiolytic before the cesarean section, and in those cases a small dose of midazolam (Versed) is usual. A small dose (1-2 mg) will not have an impact on the neonate. At other times, the neuraxial block may not be adequate for the cesarean section, because either the epidural catheter is poorly positioned or insufficient time has passed for the level to rise adequately, and the anesthesia provider may administer an opioid such as fentanyl or small doses of ketamine intravenously. These medications have already been discussed, and none has a significant effect on the neonate at the dosages commonly used.

Key Points

- Neuraxial blocks are an ideal choice for labor in which the mother wants both the most effective pain relief and least effect on her baby. Maternal side effects may include hypotension and hyperthermia.
- Nonpharmacologic pain management techniques attempt to alter the patient's perception and response to noxious stimuli. Although studies evaluating the effectiveness of these techniques are small and oftentimes demonstrate inconsistent results, they do not appear to negatively impact the fetus.
- The pain management technique most often employed by the obstetrician outside the blockage of nerve transmission is intravenous injection of medication such as sedatives and opioids, which will cross the placenta and enter the fetal circulation. Impact on the fetus depends on the pharmacokinetic and pharmacodynamic properties of the drug, how much is given, and the timing of administration with delivery.
- Should a general anesthetic be necessary for a delivery, the technique employed assumes a short induction to delivery time, thereby minimizing fetal exposure and use of short-acting medications with minimal to no ability to cross the placenta.

Physical Examination of the Newborn

TOM LISSAUER AND ANNE HANSEN

Immediately after a baby is born, all parents want to know, "Is my baby all right?" A quick initial physical examination of all newborns should be performed in the delivery room to ensure that there are no major anomalies or birth injuries, that the newborn's lips and body appear pink, and that breathing is normal. This primary survey must include a brief look at the entire body. This usually allows the clinician to reassure the parents that their infant looks well and appears normal.

Many serious congenital anomalies will have been identified prenatally, their presence anticipated, and a management plan made before delivery. If the newborn is sufficiently preterm or small for gestational age, has a significant problem diagnosed prenatally or at birth, or is unwell (e.g., respiratory distress), the newborn must be admitted to an intermediate or intensive care nursery.

If not already informed prenatally, the parents will be eager to hear if they have a boy or girl. Rarely, there may be uncertainty about the infant's gender, in which case it is important not to guess but to inform the parents that further evaluation is required before the gender can be determined.

During the first few hours after birth, healthy newborns are usually alert and reactive and will suck at the breast. This behavior provides an initial opportunity for the mother to form a close attachment with her infant and to establish breastfeeding. Medical interference during this time should be kept to a minimum.

Routine Examination

Every infant should undergo a "routine examination of the newborn," a detailed physical examination performed by a trained health care provider, within 24 hours of birth.[2] The objectives of the examination are listed in Box 28.1. The prevalence of the most common significant congenital abnormalities is shown in Table 28.1. Some are detected prenatally, but many are first noted in the delivery room or during the routine examination of the newborn. They are described briefly in this chapter; detailed descriptions are found elsewhere in the book. In some countries, for example, the United Kingdom, health professionals are trained according to a standardized National Neonatal and Infant Physical Examination Screening Programme and results recorded on a standardized checklist in the medical records and Parent Child Health Record.[37]

Preparation

Before approaching the mother and infant, the mother's and infant's medical and nursing records should be reviewed. Relevant items are listed in Box 28.2.

Introduction to the Parents

The health care provider should introduce himself or herself to the mother or, preferably, to both parents and explain the purpose of the examination. It is usually best to start by asking if there are any problems with feeding or any other worries about the infant. Before starting the examination the health care professional must conduct hand hygiene and ensure that the newborn can be examined in a warm, private area with good lighting.

Order of the Examination

The exact sequence in which the newborn is examined is flexible so long as the entire body is examined at some stage. If the newborn is quiet, take the opportunity to listen to the heart and examine the eyes. It is often convenient to start by making general observations of the newborn's appearance, posture, and movements while undressing him; then to conduct the examination from head to foot; then to remove the diaper to examine the genital region, femoral pulses, and hips; and finally to pick him up and turn him over to examine the back and spine and assess tone in the prone position (Fig. 28.1).

Measurements

The infant's growth parameters and gestational age should be noted. The birth weight percentile should be ascertained from the gestation-specific growth chart, using growth charts from the World Health Organization (WHO) or Centers for Disease Control and Prevention (CDC) (www.CDC.gov/growthcharts). The 10th-90th percentile for weight at 40

Abstract

This chapter describes the components of the routine physical exam of the newborn. It covers both normal and abnormal findings and refers the reader to relevant chapters for more in depth coverage where appropriate. After reviewing basic measurements and components of the general appearance of the newborn, it covers the exam from head to toe, ending with the neurologic assessment, behavioral evaluation, assessment of gestational age, limitations of the exam, and the role of the exam in health promotion and discharge planning.

• BOX 28.1 Objectives of Routine Examination of the Newborn

- Detect congenital abnormalities.
- Determine whether any of the wide range of nonacute neonatal problems is present, and initiate their management or reassure the parents.
- Check for potential problems arising from maternal disease, familial disorders, or problems during pregnancy.
- Provide an opportunity for the parents to discuss any questions about their infant.
- Initiate health promotion for the newborn (e.g., breastfeeding, prevention of sudden unexplained infant death syndrome safe transport in cars).
- Ensure an appropriate plan is in place for outpatient monitoring of hyperbilirubinemia.
- Ensure that a follow-up plan is in place for parents with child protection issues, mental health problems, substance abuse, severe learning difficulties, or other social concerns.

TABLE 28.1 Prevalence of Significant Congenital Anomalies

Anomaly	Prevalence Per 1000 Live Births
Congenital heart disease	6-8 (0.8 identified in the first day of life)
Hypospadias	4
Down syndrome	1.3
Talipes equinovarus	1.1
Development of dysplasia of the hip	0.7-1.1 (about 7/1000 have abnormal initial examination)
Cleft lip and palate	0.8
Spina bifida/ anencephaly	0.5

weeks' gestation for a female is 2.7-3.85 kg (mean, 3.2 kg) and male is 2.8-4.0 kg (mean, 3.3 kg). If the infant's gestational age is uncertain, it can be determined (±2 weeks' gestational age) using a standardized scoring scheme. Infants often lose weight over the first few days of life, but a loss of >10% of birth weight is a cause for concern.

The head circumference should be measured with a disposable tape measurer at its maximal occipital frontal circumference and plotted on a gestation-specific growth chart to identify microcephaly or macrocephaly and to serve as a reference for future measurements. However, the measurement can change markedly in the first few days because of molding of the head during delivery. The 10th-90th percentile is 32-35 cm for females and 33-36 cm for males at 40 weeks.

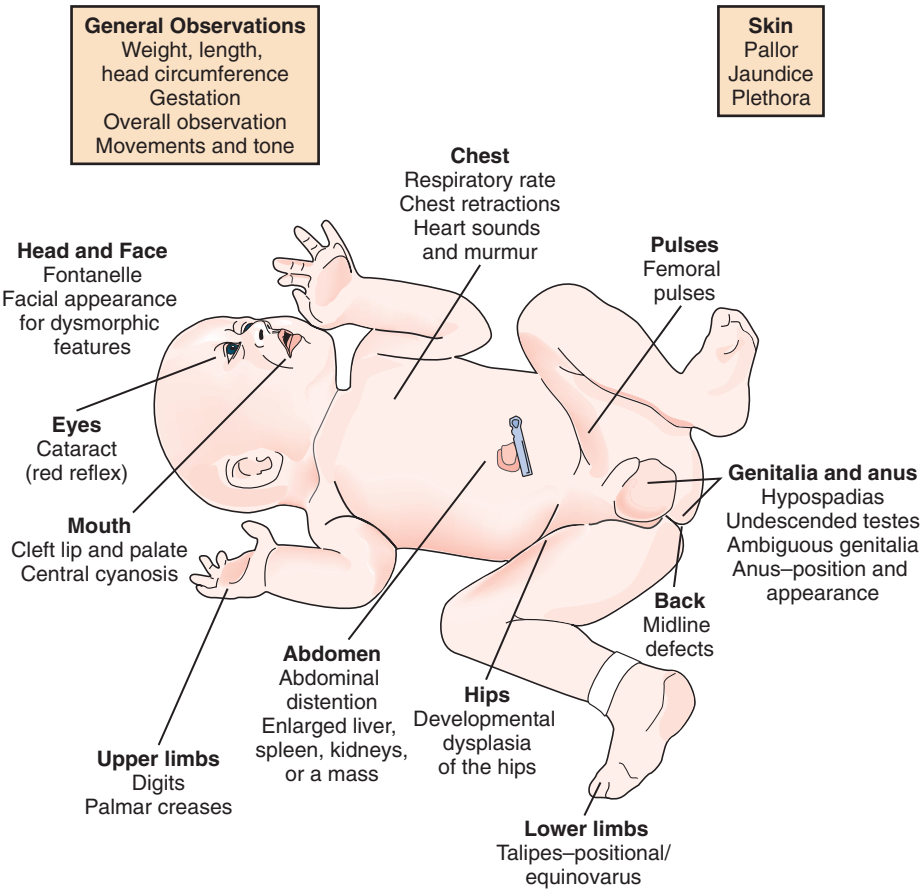
The infant's length may also be recorded, but because the hips and lower legs need to be held extended, unless a length board is used, the length is rarely measured accurately enough to identify short stature or serve as a reliable

• BOX 28.2 Mother's and Infant's Records

Items of Particular Relevance in the Mother's and Infant's Medical and Nursing Records are:

- Maternal age
- Details of previous pregnancies, complications, and any medical problems experienced by those children
- History of maternal disease and medication taken during pregnancy
- Maternal occupation and social background
- History of maternal drug or alcohol abuse, socially high-risk circumstances (e.g., severe learning difficulties, maternal mental health problems, domestic violence, child protection issues, unsatisfactory home conditions)
- Family history of medical problems
- Results of pregnancy screening tests (e.g., blood tests including maternal syphilis and hepatitis B surface antigen, prenatal ultrasound scans)
- Results of special diagnostic procedures (e.g., noninvasive prenatal testing, amniocentesis, chorionic villus sampling)
- Problems during labor and delivery (e.g., prolonged rupture of membranes, maternal fever)
- Infant's condition at birth and if resuscitation was required
- Infant's birth weight
- Infant's gender
- Gestational age and if there is any uncertainty about it
- Any concerns about the infant from nursing staff or parents (e.g., feeding concerns)

reference value when measured routinely. The length of the arms and legs relative to that of the trunk is observed, although short limbs from skeletal dysplasias can be difficult to appreciate in the immediate newborn period.



General Observation of Appearance, Posture, and Movements

Much valuable information can be gleaned by simply observing the newborn. Central cyanosis is best observed on the tongue. If present, it requires urgent investigation. If there is any doubt, the newborn's oxygen saturation should be checked with a pulse oximeter. Polycythemic infants (central hematocrit >65%) sometimes appear cyanotic because of the high concentration of reduced hemoglobin in their blood, even though they are adequately oxygenated. Acrocyanosis, peripheral cyanosis confined to the hands and feet, is common during the first day of life and is of no clinical significance. A blue discoloration of the skin, often with petechiae, can affect the presenting part in a face or breech presentation or the head and neck if the umbilical cord was wrapped around the infant's neck. This can be distinguished from central cyanosis because the tongue remains pink.

Syndromes

The facial appearance is observed. If the face is abnormal, does the newborn have a syndrome? Down syndrome is by far the most common syndrome. The characteristic facies are often difficult to recognize in the immediate neonatal

• **Fig. 28.1** Main features of routine examination of the newborn.

period, especially in preterm infants, but other abnormalities, such as hypotonia, flat occiput, bilateral single palmar creases, and a pronounced sandal gap (an abnormal spacing between the first two toes), can be appreciated at birth. In some cases, the parents will need to be informed of the concern before the results of the chromosome analysis are available.

Many hundreds of syndromes have been described. When the diagnosis is uncertain, a book or computer database should be consulted and advice sought from a clinical geneticist (see Chapter 30).

Assess the face for asymmetry, particularly when crying, to identify facial palsy and asymmetric crying facies. In peripheral facial palsy, babies are unable to wrinkle their forehead or close their eye completely. Most are traumatic and resolve within a few weeks. Asymmetric crying facies is usually due to congenital absence of the depressor anguli oris muscle on one side of the mouth. These infants can wrinkle their foreheads and close their eyes; there is an association with congenital heart disease.

Skin

Inspect the skin for color, texture, rashes, and birthmarks. Cracked, peeling skin is common, especially in post-term infants. The infant may be plethoric from polycythemia or unduly pale from anemia or shock. If there is a concern for polycythemia or anemia, the hemoglobin concentration or hematocrit should be measured. Jaundice within the first 24 hours of birth, unless mild, is most likely to be hemolytic and requires urgent investigation and treatment. It may also be a feature of congenital infection. Manage according to guidelines.

The following newborn skin conditions are benign, self-limited, and do not need any treatment: Neonatal urticaria (erythema toxicum) is a common rash that usually starts on the second or third day of life. It consists of white pinpoint papules at the center of an erythematous base. Eosinophils are present on microscopy. The lesions migrate to different sites, and the rash resolves around the fifth day. Neonatal pustular melanosis is present from birth, contains neutrophils, and is more common in black infants. The top of the pustule is readily removed by wiping, revealing denuded skin, and may easily be mistaken for staphylococcal infection. The denuded skin becomes hyperpigmented and takes several months to fade.

Milia are benign white cysts that may be present on the nose and cheeks from retention of keratin and sebaceous material in the pilaceous follicles. Small white pearls may be visible along the midline of the palate (Epstein pearls). Cysts of the gums (epulis) and on the floor of the mouth (ranula) are mucus-retention cysts.

In harlequin color change, there is longitudinal reddening down one half of the body and a sharply demarcated blanching down the other side. This lasts for a few minutes. It is thought to be due to vasomotor instability.

Mongolian blue spots are blue-black macular discolorations at the base of the spine or on the buttocks. They occasionally also occur on the legs and other parts of the body. They are most common in black or Asian infants and fade slowly over the first few years of life. They are of no clinical significance but are occasionally misdiagnosed as bruises; their presence and distribution at birth should therefore be recorded.

Café au lait spots are common, but more than three may indicate an underlying disorder such as neurofibromatosis type 1 or McCune-Albright syndrome.

Several vascular anomalies can be present at birth, some of which may be of long-term significance. The classification system has changed recently to more accurately reflect two distinct pathologic groups; malformations (errors in vasculogenesis), which may be associated with other anomalies, for example, Sturge-Weber and Klippel-Trénaunay syndromes, and tumors (proliferating endothelium).[35]

Vascular malformations are present at birth. The macular stain of infancy or nevus simplex, previously called "capillary hemangiomas" or "stork bites," are pink macules caused by distention of dermal capillaries and seen on the upper eyelids, the mid forehead, or the nape of the neck. They occur in 40%-60% of infants and gradually fade during the first year, although those on the neck may persist but become covered with hair.

Port-wine stains or "nevus flammeus" are caused by a vascular malformation of capillaries in the dermis. They may be anywhere on the body, are usually unilateral or segmental, and do not cross the midline. The face is a common site, along the distribution of the branches of the trigeminal nerve. They do not fade but grow with the child and become darker. When these lesions are disfiguring, their appearance can be improved using laser therapy.

Vascular malformations may be associated with other anomalies. If the port-wine stain affects the ophthalmic distribution of the trigeminal nerve, it is associated with intracranial vascular anomalies (Sturge-Weber syndrome) in about 10% of cases and, therefore, the infant should be evaluated for glaucoma and brain lesions.

Klippel-Trénaunay syndrome is an uncommon vascular malformation associated with a vascular anomaly typically causing overgrowth of the lower extremities. Larger and more complex lesions can involve the capillaries, veins, arteries, or lymphatics and may require referral to an interdisciplinary vascular anomalies center.[31]

The most common benign tumors of infancy are infantile hemangiomas (strawberry nevus). They are not usually visible at birth but become visible from proliferation of blood vessels in the first few weeks after birth, gradually increase in size until 3-15 months of age, and then slowly regress as they involute. If necessary, *topical* propranolol may be given to hasten their regression. If they cause airway compromise or gastrointestinal bleeding, they may require treatment with *oral* propranolol, sometimes combined with laser therapy. Diffuse liver hemangiomas can cause profound hypothyroidism and, therefore, thyroid function should be followed. Hemangiomas in the distribution of a beard can be associated with airway lesions.

Head

The shape of the head should be noted. It may be asymmetric from the infant's intrauterine position or molded from squeezing through the birth canal. Newborns who have been in the breech position in utero often have a prominent occipital shelf. After cesarean birth without labor the infant's head shape is round and symmetric. The fontanelle and sutures are palpated. The size of the anterior fontanelle is variable. If the fontanelle is tense when the newborn is not crying, this may be from elevated intracranial pressure, and cranial ultrasonography should be performed. A tense fontanelle can also be a sign of meningitis; therefore, a lumbar puncture should also be considered if concerns are raised by the history or physical exam. After delivery, the sagittal suture is often separated and the coronal sutures are overriding. The posterior fontanelle is often open but small. Bruising and abrasions after vacuum or forceps deliveries, from scalp electrodes, or from fetal blood sampling are relatively common (see Chapter 29). A caput succedaneum is bruising and edema of the presenting part of the head. It may extend beyond the margins of the skull bones. A cephalohematoma is caused by bleeding between the periosteum and the skull bone. It is confined within the margins of the skull sutures, usually overlying the parietal bone, and does not cross the midline. These conditions may take several weeks to resolve.

In subgaleal hemorrhage, there is bleeding between the galea aponeurosis and periosteum. Vacuum extraction and coagulopathy are risk factors. The head may have a boggy appearance with anterior displacement of the ears and a "wave sign" if fluid is pushed from one side of the head over to the other. Early recognition and treatment is paramount because of the potential for a large volume of blood loss causing hypovolemic shock.

Craniosynostosis is premature fusion of one or more of the cranial sutures, usually resulting in a markedly asymmetric skull with a palpable ridge along the suture line. It may be isolated, but if more than one suture is involved, it is often part of a syndrome (e.g., Crouzon or Apert syndrome). Because it can restrict brain growth, surgery may be required nonurgently to avoid neurologic impairment and to improve cosmetic outcome.

Eyes

The eyes should be checked both externally and with an ophthalmoscope. The size, slant, and position of the eyes should be noted. A coloboma is a defect in the normal tissue in or around the eye that can involve the lid, cornea,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

iris, retina, or optic disc. Defects internal to the pupil can only be diagnosed by ophthalmologic examination. It may be an isolated abnormality or part of the CHARGE syndrome (*c*oloboma, *h*eart disease, *a*tresia choanae, *r*estriction of growth or development, *g*enitourinary tract abnormality, *e*ar anomalies). The red reflex should be elicited using an ophthalmoscope held about 8 inches from the infant's eyes and focused on the pupil. During this part of the examination the room may need to be darkened. The eyes will usually open if the infant is awake, if the infant's head is supported in the examiner's hand and raised to about 45 degrees, or if the infant is held over the parent's shoulder. If the infant is asleep, the eyelids can be gently opened, although this is often made more difficult by the application of ophthalmic antibiotic ointment and/or swelling of the eyelids, which is common in newborns and resolves during the first few days of life. The red retinal reflex can be seen if the lens is clear but not if it is opaque from a congenital cataract or enlarged and hazy from congenital glaucoma. In dark-skinned infants, the reflex is often more yellow than red. A white pupillary reflex (leukocoria) is an important presentation of retinoblastoma. If the red reflex is abnormal, an ophthalmologist should be consulted directly. Congenital cataract is the most common form of preventable childhood blindness. The American Academy of Pediatrics (AAP) recommends referral to an ophthalmologist for all infants with a family history of significant eye disease regardless of examination findings.

Subconjunctival hemorrhages are common. They occur during delivery and resolve in 1 to 2 weeks. There may also be a mucoid discharge from the eyes in the first few days of life, which resolves spontaneously. If more prolonged, it is often from a blocked or incompletely canalized nasolacrimal duct. The eyelids can be cleansed with clean water. This condition must be contrasted with the erythematous, swollen eyelids with purulent eye discharge seen in conjunctivitis. On the first day of life, gonococcal infection is the most likely etiology of conjunctivitis but is rare in high-income countries. In the United States and many other countries, all infants are given eye prophylaxis against gonococcal conjunctivitis. Conjunctivitis may also be caused by *Chlamydia trachomatis*, but this is rare on the first day, usually presenting on days 5-14 of life.

Ears

The shape, size, and position of the ears are checked. Normally placed ears are positioned so that the top third of the ear is level with a line drawn from the inner to the outer canthus of the eye. Low-set or abnormal ears are characteristic of a number of syndromes. Malformations of the ear may be associated with hearing loss. Skin tags anterior to the ear (preauricular tags) and accessory auricles should be removed by a plastic surgeon. Preauricular tags are usually isolated and benign, but they warrant arranging for a hearing screen[21] if practicing in a setting where universal newborn hearing screens are not performed. Preauricular tags are sometimes associated with other dysmorphic features, renal anomalies, a family history of deafness, or a maternal history of gestational diabetes. When a preauricular tag is associated with other abnormalities or risk factors, a renal ultrasound is recommended.[29] A renal ultrasound examination for an isolated preauricular tag or other minor ear anomaly is no longer recommended.[18]

Congenital ear deformities, in which there is normal development of the ear cartilage but abnormal architecture, may resolve spontaneously, but splinting of the ears in the early neonatal period has been recommended to avoid the need for surgery and improve cosmetic appearance.[27] In some of these patients, surgery is eventually performed.

Mouth and Palate

The mouth is observed for size, position, and symmetry. The palate must be inspected, including posteriorly, to exclude a cleft palate. The whole of the palate needs to be visualized, which may require a flashlight and depression of the tongue. If cleft lip and palate are recognized prenatally, the parents will be forewarned and counseled about the likely appearance and management. When diagnosed at birth, the parents will need to be reassured about the good cosmetic results after surgical repair. Before-and-after photographs of other children are often helpful. Assistance in establishing feeding may be required. The infant will need to be referred to a multidisciplinary craniofacial service.

Micrognathia describes a small mandible and may be associated with glossoptosis and a U-shaped, posterior cleft palate (Robin sequence), which may cause upper airway obstruction and feeding difficulties. It can be syndromic or nonsyndromic.

Neck

Redundant skin over the posterior neck together with a flat occiput is a feature of Down syndrome. A webbed neck is a feature of Turner syndrome, which may also be associated with lymphedema of the feet. A short, webbed neck may indicate abnormalities of the cervical spine (Klippel-Feil syndrome). Cystic hygromas are soft, fluctuant swellings usually in the posterior triangle that transilluminate.

Breathing and Chest

Breathing and chest wall movement are observed. Breathing should be normal, with no signs of respiratory distress (i.e., respiratory rate greater than 60 breaths per minute, retractions of accessory respiratory musculature, flaring of the alae nasi, or grunting). If the breathing is normal, it is rare for significant abnormalities to be detected on auscultation. If the infant has respiratory distress, further evaluation is required immediately. Normal term infants may have periodic breathing with pauses of up to 10 seconds between periods of regular breathing.

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

Breast enlargement can occur in newborns of either sex. A small amount of milk ("witch's milk") may be discharged.

Heart

The normal heart rate is 120-160 beats per minute in term infants but can drop to as low as 85 beats per minute during sleep. The heart sounds should be loudest on the left side of the chest. Heart murmurs can be heard in about 2% of newborns at the routine examination.[1] Most are innocent and originate from a patent ductus arteriosus or tricuspid regurgitation[4] or turbulence generated by the acute angle at the pulmonary artery bifurcation. It can be challenging to differentiate innocent murmurs from those caused by significant heart lesions. Features of innocent and significant murmurs are listed in Box 28.3.

The usefulness of electrocardiograms and chest radiographs in helping to distinguish innocent from significant murmurs is limited. The neonatal electrocardiogram and chest radiograph are difficult to interpret, and these tests have rarely been found to change decisions based on the clinical examination.[24]

If a heart murmur is thought to be significant or cannot confidently be diagnosed as innocent, the infant should be referred directly for echocardiography. The management of infants with an innocent murmur depends on the availability of echocardiography. If echocardiography is readily available, it provides parents with a definitive diagnosis without delay. If echocardiography is not readily available, a follow-up medical examination should be arranged soon after discharge and the parents warned to seek medical assistance if their infant becomes symptomatic with poor feeding, labored breathing, cyanosis, or lethargy. The United States and some other countries have instituted universal oxygen saturation–based screening for critical congenital heart disease.[32]

Femoral pulses are best palpated when the infant is quiet. Pulses feel diminished if there is coarctation of the aorta. Of note, if the ductus arteriosus is still patent, femoral pulses may feel normal even in the setting of a coarctation. If coarctation is suggested clinically, further evidence may be obtained by comparing the systolic blood pressure in the upper and lower extremities. A decrease of more than 20 mm Hg in the legs is significant. Postductal oxygen saturation may be low. If a duct-dependent cardiac lesion is suspected, urgent cardiac consultation is indicated.

Most innocent murmurs disappear in the first year of life, usually in the first 3 months. However, any mention of a heart murmur can create considerable parental anxiety, which sometimes continues for years. This can be minimized by the manner in which the murmur is described to parents.

• BOX 28.3 Features of Neonatal Heart Murmur

Features of an Innocent Murmur

- Soft (grade 1/6 or 2/6) murmur at left sternal edge
- No audible clicks
- Normal pulses
- Otherwise normal vital signs and clinical examination

Features Suggesting a Murmur Is Hemodynamically Significant

- Pansystolic
- Loud (≥ grade 3/6)
- Harsh quality
- Best heard in the upper left sternal edge
- Abnormal second heart sound
- Femoral pulses difficult to feel
- Other abnormality of vital signs or clinical examination

(For recordings of innocent and significant murmurs, see Reference 38.)

Abdomen

Observe for abdominal distention, asymmetry, and signs of umbilical inflammation. For abdominal palpation, the infant must be relaxed. The abdomen is palpated to identify any masses. The liver is normally palpable 1-2 cm below the right costal margin. The spleen tip and kidneys are sometimes palpable; assess for enlargement. If palpation of the abdomen reveals abnormally large renal masses or an enlarged bladder in a male infant, ultrasonography is required urgently to identify urinary outflow obstruction. Most cases of urinary outflow obstruction are now detected on prenatal ultrasound screening, as are other major abnormalities of the kidneys and urinary tract. Although controversial, siblings of children with vesicoureteric reflux have been recommended to be screened for this condition because approximately 27% are also affected.[33]

Umbilical hernias are common, especially in black infants. No treatment is indicated, because they usually resolve within the first few years of life. Observe for a hernia in the inguinal canal. The incidence of inguinal hernias is approximately 4% in term infants and occurs in about 13% of infants born at less than 33 weeks' gestational age. Optimal timing for repair of inguinal hernias in infants remains controversial, as definitive data is lacking. They are commonly repaired prior to discharge home to avoid incarceration of the hernia, but early repair in preterm infants must be balanced against the risk of postoperative apnea and other complications after general anesthesia.[28]

Single umbilical artery occurs in about 0.3% of newborns.[17] It may be identified on prenatal ultrasound scanning. It is associated with an increased risk of adverse perinatal morbidity[34] and mortality,[13] chromosomal abnormalities,[34] and congenital malformations, particularly of the genitourinary and cardiovascular system. A single umbilical artery has been associated with asymptomatic renal anomalies in 2%-10%, but the yield is low from ultrasound screening of the kidneys and urinary tract when this is an isolated finding,[7,11,17,26] and most renal abnormalities identified are transient or mild. The yield is further reduced by routine prenatal ultrasound screening for congenital anomalies of the kidneys and urinary tract. It is probably

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

best reserved for those who also have other anomalies on physical examination.

Genitalia

In boys, the penis is checked for length and the position of the urethral orifice. The penis may appear to be short if buried in suprapubic fat. If less than 2 cm long it meets diagnostic criteria for a micropenis, suggesting congenital hypopituitarism. In hypospadias, the urethral meatus is in an abnormal position, usually on or adjacent to the glans penis, but may be on the penile shaft or perineum. The foreskin is hooded because of ventral foreskin deficiency. Ventral curvature of the shaft of the penis (chordee) may be present. Glandular hypospadias without ventral curvature may not require treatment, but more severe forms require corrective surgery. A specialist opinion should be sought before circumcision, because the foreskin may be required for corrective surgery.

The testis may feel enlarged on palpation; this is usually from a hydrocele, which can be confirmed on transillumination with a bright light. Hydroceles are relatively common in boys and usually resolve spontaneously. Bilateral testes should be palpated and that they have fully descended into the scrotum determined. A testicle is described as undescended if the testis has failed to descend from its embryologic position from the urogenital ridge on the posterior abdominal wall through the inguinal canal to the scrotum. Undescended testes may lie along the normal line of descent but have not reached the scrotum, or they may be ectopic, having deviated from the line of descent. Undescended testes are expected in preterm infants. About 4% of full-term male infants have an undescended testis at birth; by 3 months, about 1% are still undescended, with little reduction thereafter. An undescended testis should be assessed at about 6 weeks of age. If still undescended, referral to a pediatric surgeon or urologist is indicated. If both testes are undescended, the infant should be assessed regarding the possibility that the infant is a virilized female with congenital adrenal hyperplasia or other disorders of sex development.

Neonatal testicular torsion is usually due to prenatal torsion and occurred sometime before delivery. In that situation, the testis is hard, black, and nontender, and is not salvageable because it has already undergone infarction. A pediatric surgeon should be consulted urgently to decide if the torsion occurred recently enough that the testis may be salvaged. Many pediatric urologists will perform surgical fixation of the contralateral testis.

In girls, the clitoris and labia minora are prominent if the infant is preterm but are covered by the labia majora at full term. There may be a white vaginal discharge or small amount of bleeding from maternal hormone withdrawal. There may also be prolapse of a ring of vaginal mucosa. These resolve spontaneously.

The anus is also inspected to check that its position, appearance, and tone are normal and that it is patent.

Passage of urine and meconium should be monitored and recorded; both occur within 24 hours of birth in most term newborns.

Limbs and Hands and Feet

The limbs, hands, and feet are examined for general appearance, symmetry, and posture. Observe for spontaneous movement of all four limbs. Observe for limb reduction defects.

Examination of the hands and feet will identify extra digits (polydactyly), fused digits (syndactyly), or bent digits (clinodactyly). Extra digits are usually connected by a thin skin tag but can be completely attached and contain bone. Extra digits should be removed by a plastic surgeon; many pediatricians tie off thin skin tags with a silk thread, but this may leave a stump of skin. Polydactyly may be familial, but it can also be part of a syndrome.

About 45% of infants with trisomy 21 have single palmar transverse creases. Unilateral single palmar transverse creases are also observed in about 4% of normal infants, but bilateral single palmar creases occur in less than 1% of chromosomally normal infants.

Brachial plexus lesions cause lack of active movement of the affected limb; passive movement is not painful or restricted. The most common is Erb palsy from an upper root palsy (C5, C6, and sometimes C7). The arm is held adducted and internally rotated and pronated with flexion of the wrist, in the "waiter's tip" position. Injury to the lower brachial plexus roots (C8 and T1) results in weakness of the hand flexors of the wrist and fingers, described as a "claw hand," but is rare.

Although most brachial plexus injuries resolve, a significant proportion do not fully recover by 6 months of age. Those that do not recover steadily during the first 2 months of life or are severe should be seen by a specialist, because surgical repair may be indicated. Accompanying respiratory symptoms may be secondary to damage to phrenic nerve roots.

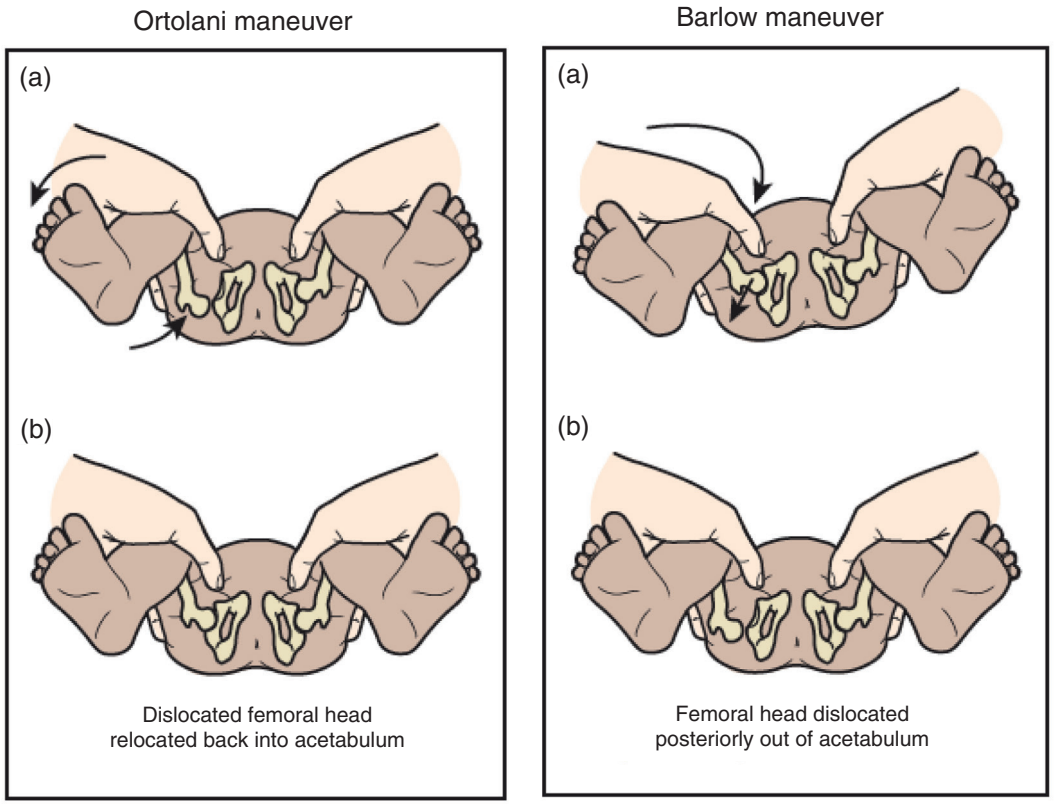
Clavicle fractures most often occur during difficult delivery of the shoulders. In the newborn period it is typically identified because the infant appears to be uncomfortable with decreased movement of the arm on the affected side. After several weeks, it may be diagnosed when a lump is seen or palpated on the clavicle, resulting from callus around the fracture. Clavicular fractures require only supportive care such as mild pain control and pinning the sleeve of the newborn outfit to the contralateral shoulder to provide relative immobilization for comfort. The fracture heals without treatment.

In positional talipes equinovarus, the feet are turned inward from intrauterine compression, commonly associated with oligohydramnios. The foot is of normal size and can be fully abducted and dorsiflexed to the neutral position, and the dorsal surface of the foot can be brought into contact with the anterior lower leg by passive manipulation. If this maneuver can be performed, the parents can be

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

shown passive exercises and no further treatment is required. Feet in the calcaneus valgus position are usually due to positional deformation in utero. It should be possible to dorsiflex the foot to bring its dorsal surface into contact with the anterior lower leg and to achieve normal plantar flexion. If this can be achieved, spontaneous resolution can be expected. With talipes equinovarus, the affected foot may be shorter than normal. The entire foot is inverted and supinated, and the forefoot is adducted. The heel is rotated inward and in plantar flexion. The position of the foot is fixed and cannot be corrected completely. It may be secondary to oligohydramnios, a feature of a malformation syndrome, or of a neuromuscular disorder such as spina bifida. The infant must be referred to a pediatric orthopedic surgeon; early treatment with plaster casting and bracing usually avoids the need for surgery.

Hips



The hips are checked for developmental dysplasia of the hip (DDH). In this condition, on clinical examination in the neonatal period, the hip may be:

- dislocated (subluxated) but reducible, when the posteriorly dislocated femoral head can be returned to the acetabulum, as identified in the Ortolani maneuver.
- dislocatable, when the femoral head is in the acetabulum at rest but is dislocatable posteriorly out of the acetabulum, as identified in the Barlow maneuver.

Other signs of DDH, namely asymmetric thigh or buttock (gluteal) creases, limb length discrepancy, and limited hip abduction are usually only evident beyond the neonatal period; the Ortolani and Barlow tests are usually negative after 3 months of age.

Checking for DDH is best left toward the end of the examination because the procedure is uncomfortable. To successfully perform this examination, the infant must lie supine on a flat, firm surface and be relaxed, because crying or kicking results in tightening of the muscles around the hip.

First, the Ortolani maneuver is performed (Fig. 28.2). The hips and knees are flexed to 90 degrees, and the pelvis is stabilized with one hand. With the other hand, the examiner's index and middle fingers are placed over the greater trochanter and the thumb placed along the middle thigh. The hip is abducted whilst applying gentle upward leverage by lifting the trochanter anteriorly. A dislocated hip will return with a clunk into the acetabulum. This is best felt but can sometimes also be observed. Then the Barlow maneuver is performed (Fig. 28.2). Using the same hand position, the hip is gently adducted while pressure is gently

• **Fig. 28.2** Checking for DDH. In the Ortolani maneuver, on abduction of the hip, the dislocated femoral head is relocated into the acetabulum. In the Barlow maneuver, on adduction of the hip, the femoral head is gently dislocated posteriorly out of the acetabulum.

applied posteriorly. If the hip is dislocatable, the femoral head will be palpated to slide out of the acetabulum.

Little force is required for these procedures; excessive force can damage the hip. During the test, clicks might be elicited but are not of long-term consequence. Any newborn with DDH should be checked for a neuromuscular disorder, and the spine should be examined to exclude spina bifida.

The hips of most infants with an abnormal neonatal hip examination at birth or 2 weeks of age resolve without intervention by 4 weeks of age. The risk for DDH is increased in female infants, in those with a positive family history, and in those with a breech presentation in the third trimester. The risk is also increased in infants with a neuromuscular disorder. The absolute risk for a positive result on routine examination of the newborn is shown in Table 28.2.[22,23]

Back and Spine

The entire back and spine are inspected and palpated for midline and other defects and for curvature of the spine. Spina bifida is often diagnosed prenatally. Affected infants must be referred to a neurosurgical service. A nevus, swelling, or tuft of hair along the spine or middle of the skull requires further evaluation, because it might indicate an underlying abnormality of the vertebrae, spinal cord, or brain. Ultrasound or magnetic resonance imaging delineates the anatomy. Small, blind ending sacrococcygeal dimples are common and harmless. Unusually large dimples, those without a visible base or positioned above the clefts of the buttocks, should be investigated because they might extend into the intraspinal space and place the infant at increased risk for meningitis.[14]

TABLE 28.2 Absolute Risk of Developmental Hip Dysplasia Based on Abnormal Physical Exam of the Newborn

Newborn Characteristics	Risk Per 1000 Newborns

Girls	133

Data from American Academy of Pediatrics. Clinical practice guideline: early detection of developmental dysplasia of the hip. *Pediatrics.* 2000;105:89.

Posture and Muscle Tone

Observe the newborn's posture and tone. Is the infant moving all four limbs fully, and are they held in a normal, flexed position? Do the limbs feel normal on passive movements? Infants who were in an extended breech position in utero sometimes maintain this posture for some days after birth. The newborn is picked up under the arms while supporting the head. A hypotonic newborn will feel as if slipping through one's hands. Most newborns support some of their weight with their feet. When an infant is turned prone, the infant can lift the head to the horizontal position and straighten the back. Hypotonic newborns flop down like a rag doll.

A detailed neurologic examination is required only if an abnormality has been detected. Some pediatricians routinely elicit a Moro reflex, during which sudden head extension causes symmetric extension followed by flexion of all limbs. However, if normal movement of all four limbs has been observed, no further information will be gained from this procedure. Because infants appear to find it unpleasant and parents are often alarmed and upset by it, many pediatricians omit the Moro reflex test from the routine examination.

Concluding the Exam

Most newborns are found to be normal on routine examination. The parents should be reassured that the examination was normal, and any concerns they have about their newborn should be addressed fully. Parents should be informed of any abnormalities detected on examination. This may be upsetting and should be handled with sensitivity by giving a full explanation and allowing time for discussion.

Detailed Neurologic Assessment

If a neurologic concern is raised based on the history, prenatal imaging, physical exam, or postnatal course, a more detailed neurologic assessment should be performed, directed toward the area of concern. The infant's neurologic evaluation combines elements of the standard neurologic examination and a developmental assessment of gestational age[12] (Box 28.4). It also highlights the marked effect of

• BOX 28.4 Neurologic Evaluation

- General appearance
- Level of consciousness
- Head, spine, extremities
- Cranial nerves
- Motor: strength, tone, movements
- Deep tendon reflexes
- Primitive reflexes: Moro, grasp, suck, root
- Autonomic: heart rate pattern, respiratory pattern, bladder function, bowel function

gestational age on neurologic development. With experience, the examiner can accomplish a standard neurologic evaluation with minimal or no discomfort to the infant—an important skill, especially in fragile premature infants.

Level of Alertness

Healthy term newborns cycle between states of alertness. In the preterm, there are cycles of activity and sleep, of regular and irregular respiration, and of the absence or presence of eye movements, but they tend to occur independently rather than in distinct states of alertness. For optimal neurologic examination, a term infant should be alert and not crying. Abnormal levels of consciousness, lethargy, stupor or coma, and hyperalert states can be associated with hypoxic-ischemic encephalopathy and many other congenital or acquired disorders affecting the brain. Hyperalert state can also be due to drug withdrawal. The cry may be abnormal (e.g., high-pitched from cerebral irritation, excessive from drug withdrawal).

Inspection

The physical component of the neurologic examination includes visual inspection and palpation of the head, spine, and extremities. The head is palpated to ascertain the presence of deformities, the position of the skull sutures, and the size and shape of the fontanelles.

The size and shape of the head provide important information regarding the occurrence of an insult to the fetal brain. When fetal brain growth has been compromised, head size is decreased relative to body weight and length. A large head at birth could be due to a wide range of etiologies. If the sutures are widely spaced it could be from raised intracranial pressure, for example, from obstructive hydrocephalus. Postnatally, a rapidly expanding head with widely separated sutures indicates raised intracranial pressure from cerebral edema; epidural or subdural hemorrhage; or acquired, progressive hydrocephalus, which may follow intraventricular hemorrhage in a premature infant.

Cranial Nerves

Despite the inability of the examiner to communicate verbally with the infant, the functions of most of the 12 cranial nerves can be determined in the newborn infant (Table 28.3). Indeed, cranial nerve evaluations can be conducted even in extremely premature infants.

Cranial nerve I (olfactory) is typically not examined given its rare involvement in a disease process and the infant's inability to provide an appropriate response.

Vision (cranial nerve II [optic]) is assessed both subjectively and objectively. Healthy full-term and older premature infants fixate on and track the examiner's face, a red ball, a card with concentric black and white circles presented about 25 cm from the infant's face, or other optokinetic stimuli. Horizontal eye movements are more easily elicited than are vertical eye movements.

The pupillary light reflex also assesses optic nerve integrity. It is a subcortical function and requires an intact efferent limb, specifically the autonomic component of cranial nerve III (oculomotor). Those nerves that subserve extraocular movements include cranial nerves III, IV, and VI (oculomotor, trochlear, and abducens, respectively).

Eye movements in all directions of gaze occur spontaneously or can be induced with oculocephalic maneuvers (doll's eye reflex). The doll's eye reflex is typically elicited with the infant in the supine position by simply turning the

TABLE 28.3 Cranial Nerve Examination

Nerve	Name	Function	Evaluation Method
I	Olfactory (and tract)	Smell	Not tested
II	Optic (and retina)	Visual acuity and fields	Face or red woolen ball or black and white concentric circles
III	Oculomotor response, lid elevation	Extraocular movements; pupillary reflex	Observation of tracking; doll's eye reflex
IV	Trochlear	Extraocular movements	Observation of tracking; doll's eye reflex
V	Trigeminal	Mastication; facial sensation	Corneal and suck reflexes; nasal stimulation
VI	Abducens	Extraocular movements	Observation of tracking; doll's eye reflex
VII	Facial	Facial expression; taste	Nasal stimulation; corneal and sucking reflexes
VIII	Auditory	Hearing; spatial orientation	Sounds and behavioral response
IX	Glossopharyngeal	Swallowing; vocalization	Sucking and swallowing reflex; gag reflex; quality of cry
X	Vagus	Swallowing; vocalization	Sucking and swallowing reflex; gag reflex; quality of cry
XI	Spinal accessory	Head and shoulder movement	Observation
XII	Hypoglossal	Tongue movement	Observation; atrophy; fasciculations

head from one side to the other, whereupon the eyes will deviate in the opposite direction. Vertical eye movements can be ascertained by flexing or extending the head. Alternatively, the infant can be held vertically and rotated clockwise or counterclockwise. The eyes will deviate in the direction opposite the spin. Rotation in the axial plane induces vertical eye movements.

The eyes are observed for the presence or absence of ptosis. Unilateral or bilateral ptosis occurs as a consequence of dysfunction either of cranial nerve III, which innervates the palpebral muscle (upper eyelid only), or of ascending sympathetic nerves, which course through the neck to innervate the tarsal plates (both eyelids). Oculomotor nerve dysfunction producing ptosis is often associated with ipsilateral pupil dilation, whereas sympathetic nerve dysfunction producing ptosis is associated with ipsilateral pupil constriction (Horner syndrome).

Cranial nerve V (trigeminal) has both sensory and motor functions. Corneal and facial sensations can be tested if indicated with a wisp of cotton applied to each cornea to elicit a rapid blink or to the nares to elicit a facial grimace. The motor component of cranial nerve V subserves jaw (mandibular) opening and closure, which are best tested by observing the infant's sucking ability.

Cranial nerve VII (facial) controls all superficial facial movements, including eyelid closure, and taste, which is rarely tested. Facial movements occur spontaneously and are a component of the sucking and rooting reflexes. Tickling the nares with a wisp of cotton should induce facial grimacing, whereupon either unilateral or bilateral facial paresis will become apparent.

Cranial nerve VIII subserves both hearing (auditory) and vestibular functions (see Chapter 59). Hearing is tested either subjectively or objectively, the latter by the evoked otoacoustic emissions or automated auditory brainstem response as used in newborn hearing screening. Subjective testing at crib side can be accomplished with the use of voice, ideally the mother's, or a bell or rattle, observing for a change in heart rate or respirations, and possibly an orienting response. Initially, the sound should be of low intensity, increasing in loudness until a response is obtained. The vestibular component of cranial nerve VIII is not specifically tested other than through its interaction with brainstem pathways that subserve reflex eye movements.

The functions of cranial nerves IX and X (glossopharyngeal and vagus, respectively) are combined to control swallowing function and vocalization. Voluntary motor functions are tested by observing the infant's sucking and swallowing abilities. In addition, the position and movement of the soft palate are observed with a flashlight. Decreased movement of the soft palate or absent gag reflex suggests dysfunction of cranial nerves IX or X. During the oral evaluation, cranial nerve XII (hypoglossal) function is tested by examining the tongue and noting its position, movement, and bulk. Atrophy of the tongue is observed as scalloping of its margins. The presence of tongue fasciculations may be noted, consisting of random, wormlike movements best appreciated along the lateral tongue margins and which may be observed in spinal muscular atrophy. Tongue fasciculations must be distinguished from tremors, the latter consisting of normal rhythmic movements of the structure accentuated by its protrusion during crying.

Cranial nerve XI (spinal accessory) is a pure motor nerve. It innervates the sternocleidomastoid muscle of the neck to produce either lateral or anterior flexion of the head, depending on contraction of one or both muscles. The nerve also innervates the trapezius muscle of the shoulder to produce shoulder elevation. These functions typically are tested by simple observation of head and shoulder movements.

Motor Function

The motor system examination includes tests of skeletal muscle posture, tone, and movement. During the initial period of general observation, the position of the extremities is noted for flexion, extension, or neutral postures. Healthy, full-term infants typically exhibit flexion of the arms at the elbows and of the legs at the knees. Fisting of the hands, including adduction and infolding of the thumbs, is usual. However, there is varied movement of the fingers, including moving the thumb away from the palm. This contrasts with the persistently adducted thumb (cortical thumb) in a tightly fisted hand, with few finger movements seen in infants with cerebral injury genetic disorders or some severe malformations.

Limb position and posturing are relatively symmetric, although the infant manifests spontaneous movements that are often asymmetric and jerky. Limb posture (flexion or extension) is also influenced by the position of the head. If the head is turned to one side, there is often extension of the ipsilateral arm and leg and flexion of the contralateral extremities (asymmetric tonic neck reflex). While prone, the full-term infant maintains a flexed posture of the arms and legs, with resultant elevation of the pelvis as well as hip and knee flexion.

Tone is characteristic of skeletal muscle because of an intrinsic resistance to stretch that can be either active or passive. Muscle at rest resides in a state of partial relaxation, and energy is required for its full contraction. Elongation requires further muscle relaxation and concurrent contraction of the opposing or antagonistic muscle. Thus, normal muscle tone depends on a sophisticated interaction between agonistic and antagonistic muscles, which are influenced by innervating peripheral nerves (sensory and motor) as well as by the central nervous system. Given the strategic role played by skeletal muscle in neurologic function, it is not surprising that alterations in muscle tone represent the clinical hallmark of a variety of neurologic disease processes.

The assessment of muscle tone includes observation of the infant's posture and movement as well as the production of an active or passive range of motion. If feasible, the infant should be suspended in the horizontal plane and the attitude and posture of the head, trunk, and extremities

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

observed. Thereafter, the infant is held in the vertical plane to ascertain the extent and symmetry of flexor tone of the extremities. While the infant lies supine, the upper and lower extremities are extended and flexed to ascertain the presence and extent of resistance. Head control can be determined by lifting the supine infant from the surface by the shoulders.

Increased resistance to passive movement indicates hypertonicity (rigidity, spasticity), whereas reduced resistance and unrestricted movement indicate hypotonicity. In this regard, the neurologic component of the Dubowitz and Ballard scoring systems for determining gestational age largely reflects the maturation of muscle tone in premature infants, from the weak, low tone, and extended posture of very premature infants to the active, flexor tone, and posture of the term infant. Infants who are hypertonic often exhibit an opisthotonic posture related to obligate extension of the back and neck when suspended in either the vertical or horizontal plane because of high tone in axial extensors compared with flexors. Scissoring of the legs might be evident from hypertonia in the hip adductors. In contrast, the hypotonic infant, when held in the vertical plane, tends to slide through the examiner's hands. In the horizontal plane, the infant drapes down from the examiner's hand.

Hypotonia should not be equated with weakness, which is a reduction in muscle strength or power, whether it is partial (paresis) or complete (paraplegia) paralysis. Muscle weakness is ascertained through observation of spontaneous or sensation-induced movements of the extremities. Although muscle hypotonia and weakness often occur together, hypotonia can be seen in the absence of weakness (e.g., cerebellar dysfunction), and weakness can occur when muscle tone is normal or even increased (e.g., spastic paralysis).

Deep Tendon Reflexes

Deep tendon reflexes are elicited as they are for older children and adults. The limb should be positioned in partial flexion and the appropriate tendon tapped with an infant reflex hammer. The head should be maintained in the neutral position to prevent inducing an asymmetric tonic neck response, which produces asymmetric reflex activity. Typically, upper extremity deep tendon reflexes are more difficult to elicit than lower extremity reflexes. In newborn infants, the Achilles tendon is not tapped directly; the reflex is elicited by tapping a thumb positioned on the plantar surface of the partially dorsiflexed foot.

Interpretation of the results of testing deep tendon reflexes is more problematic in neonates than older children but may help to confirm an asymmetric lesion. A few beats of ankle clonus are common and usually normal in the neonatal period if not sustained. Eliciting plantar responses is not worthwhile, because their interpretation is problematic, owing in part to multiple competing reflexes in the foot (plantar grasp, stepping, placing).[16] At this age, the plantar response is usually said to be extensor, but it mainly depends on the location and strength of the stimulus applied; a gentle stimulus will often induce a flexor response.

Developmental Reflexes

The most frequently elicited primitive or developmental reflexes include the rooting, sucking, palmar grasp, and Moro responses. These reflexes are fully developed and strong in the healthy, full-term newborn and typically disappear in the months to follow. Their persistence beyond the anticipated age of disappearance is an indicator of underlying central nervous system dysfunction. Other primitive reflexes include the crossed extension (where a limb withdraws by contracting of the flexor muscles and relaxation of the extensors and the opposite occurs in the other limb), the placing reflex (when there is flexion followed by extension when the infant is held upright and the dorsum of a foot is moved along the under edge of a table), and stepping reactions (when the soles of the feet of an infant held upright touch a flat surface she will take steps by placing one foot in front of the other), all of which make their appearance by 36-38 weeks' postmenstrual age.

Behavioral Evaluation

Behavioral assessment tools, such as the Neonatal Behavioral Assessment Scale (NBAS), the Assessment of Preterm Infants' Behavior (APIB), and the NICU Network Neurobehavioral Scale (NNNS), are formalized screening measures designed to determine neurobehavioral disturbances, identify individual behavioral differentiation and regulation patterns in newborns, or differences among groups of newborns. They are also used to guide referrals for further specialty assessment, care, and interventions, and to support families and caregivers in their understanding of their newborn's individuality. Performing any of the currently utilized assessments requires some degree of training, and in several cases, formal certification. Assessments commonly evaluate movement and postural patterns; muscle tone and strength; activity levels; simple and complex reflex behaviors; sensory functions; social attention and interaction; attention to objects; thresholds to behavioral disorganization; irritability; consolability; state range; and stability including sleep, quality of cry, and habituation or response decrement to repeated stimuli. As an example, for the assessment of consolability, the upset infant's response to different modalities of calming is assessed. It takes longer to console an infant with brain injury than it might a healthy infant. Visual and auditory response decrements are elicited with different stimuli, such as a bright light, and a rattle or bell, respectively. Response decrement is an indicator of cortical inhibitory function. It demonstrates the brain's ability to learn to diminish behavioral responses to repetitive stimuli. Failure to respond initially to the sensory stimulation or a lack of habituation may suggest cortical and/or sensory dysfunction or sedation. A highly reactive, dysregulated neurobehavioral profile may be an indicator of increased risk for

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

neurologic and/or physiologic issues. A milder form of dysregulation may indicate temperament differences. Newborn group studies have also identified ethnocultural background differences in regulation. The timing of assessments depends on infants' medical complexity; ill or infants born preterm require serial assessments to track progress and recovery. The examinations should be performed in the presence of the parents and key caregivers to maximize appreciation of the infant's current strengths and vulnerabilities. In the hands of well-trained specialists, these assessments can be used to guide clinical care decisions and advocate for appropriate outpatient developmental services, as well as to optimize parent understanding of their infant.[8,36]

Assessment of Gestational Age

Formal assessment of gestational age is unnecessary for the routine newborn examination. The best guide to an infant's gestational age is an early antenatal ultrasound evaluation combined with information about the mother's last menstrual period. An evaluation of the clinical methods of assessing gestational age showed that clinical methods had 95% confidence intervals of 17 days, whereas the antenatal ultrasound had 95% confidence intervals of less than 7 days.[30] Clinical assessment is most important for infants whose gestational age is unknown or discrepant with their growth.

Gestational age can be assessed using physical and neurologic criteria, because they progress in an orderly fashion with increasing gestation. Although physical criteria allow distinction of infants with gestational ages older than 34 weeks, neurologic assessments are required to differentiate infants at earlier gestations. A combined scoring system for assessing gestational age was developed by Dubowitz and Dubowitz.[12] Its disadvantage is that it involves assessing 11 physical criteria and 10 neurologic findings. Ballard and colleagues abbreviated it to include 6 neurologic and 6 physical criteria to shorten the time taken. The revised Ballard examination (Fig. 28.3) includes assessment for extremely premature infants and is the most widely used.[5] Regardless of the method used, the assessment of gestational age using physical and neurologic criteria is accurate only to ±2 weeks, with a tendency toward overestimation in extremely premature infants.

The Premature Infant

The neurologic signs in premature infants differ markedly with postmenstrual age. In normal premature newborn infants, pupil responses to light are present, although sluggish, between 28 and 32 weeks' gestation and seldom present before 28 weeks (Table 28.4). Oculocephalic (doll's eye) reflexes are complete and even exaggerated in infants as immature as 24-25 weeks. Corneal and gag reflexes are present in premature infants as is facial grimacing to nasal stimulation.

The newborn's responsiveness to the environment depends not only on the state of health but also on the postmenstrual age. Infants of 25-30 weeks' gestation typically show intermittent arousal with external stimulation, and their waking periods are relatively short when compared with full-term infants. By 31-32 weeks' gestation the premature infant exhibits reasonable alertness during wakeful stages. By term, the infant remains alert for prolonged periods during wakefulness and readily responds to visual, auditory, and tactile stimulation.

A notable difference in the neurologic status of the premature and full-term neonate is that of muscle tone. As indicated by the Dubowitz and Ballard scoring systems for gestational age, the more premature the infant at birth, the greater the muscle hypotonicity (see Fig. 28.3). The hypotonicity is especially apparent when measuring the popliteal and heel-to-ear angles and when executing the scarf sign.

At and before 28 weeks' postmenstrual age, a premature newborn is extremely hypotonic. When held in vertical suspension, the infant does not extend the head, trunk, or

extremities. The maturational change from hypotonia of the small premature infant to the predominantly flexion posture of the full-term infant is manifest first in the legs and later in the arms and head. By 34 gestational weeks, the infant lies in a froglike position while supine; the legs are flexed at the hips and knees, but the arms remain extended and relatively hypotonic. The maturational changes in muscle tone must be taken into account when evaluating newborns of varying gestational ages.

Developmental reflexes appear at specific ages of gestation to become fully developed and strong in the healthy full-term infant (see Table 28.4). The sucking and rooting reflexes do not develop until 33-36 weeks' gestational age. The palmar and plantar grasp responses become apparent at about 28 weeks and are strong by 36 weeks. The Moro reflex appears at 24-26 weeks and evolves through 38 weeks, at which age the entire abduction-adduction response is present.

Interpretation of the Neurologic Examination

Interpreting the findings from a neurologic examination of a newborn infant is difficult, because the interpretation is markedly affected by the infant's postmenstrual and chronologic age as well as the infant's level of alertness. The neurologic examination has been widely studied as a predictor of subsequent neurodevelopmental problems, but it is limited because many abnormal neurologic signs may be transient and significant neurologic abnormalities may take weeks or months to become manifest. Serial examinations are more informative than a single examination.

However, in spite of its limitations in specificity and in predicting prognosis, the neurologic examination is useful when considered in conjunction with a history, with or without neuroimaging, suggestive of a neurologic problem. Neurologic abnormalities that are persistent, severe, or asymmetric place the infant at increased risk of neurodevelopmental problems. The neurologic examination may be helpful in delineating the extent of neurologic deficits (e.g., after hypoxic-ischemic encephalopathy), which also informs management planning. Multiple neurologic abnormalities are more likely to be more significant than isolated abnormalities. Preterm infants who have significant abnormalities on neurologic examination at term are at higher risk of neurodevelopmental problems than those with a normal examination.

Limitations of the Routine Examination

Examination of a newborn in the delivery room and at a routine examination will identify a number of problems, many of which are transient, although some are permanent and significant. However, some significant abnormalities will not be identified. Sometimes this is because of inexperience of the examiner, or the examiner has not managed to overcome the difficulty of performing a satisfactory examination in an unsettled baby (e.g., getting a good view of the eyes and red reflex, hearing a heart murmur, or testing for DDH). However, some significant abnormalities will not be identified, because they will not be evident during the routine physical examination.

Parents might become upset or angry when it becomes evident at a later stage that their child has a significant problem. They need to be made aware that not all abnormalities can be detected at the initial examination. This situation also stresses the importance of clear documentation of the routine examination for future reference. Some of the major limitations of the clinical examination are considered below.

Jaundice

Jaundice usually develops after 24 hours of age, unless caused by hemolysis or congenital infection. Significant jaundice can develop at several days of age even though the infant was not clinically jaundiced only 1 or 2 days earlier (see Chapter 91).

Eye Abnormalities

The outcome for vision following surgery for congenital cataracts is improved if surgery is performed before 8 weeks of age.[9] However, only approximately 35% of congenital cataracts are identified on the routine examination.[20] This demonstrates the difficulty in early recognition of eye abnormalities during the routine examination of the newborn, compounded by the rarity of serious eye conditions, occurring in only 4 per 10,000 live births.[6]

Congenital Heart Disease

About 6-8 infants per 1000 live births have congenital heart disease. There are multiple limitations of the routine examination in identifying significant structural heart disease.

The first is that the newborn examination may be normal when the infant has a significant or even lethal structural heart lesion. At the time of the newborn examination, the pressure in the right side of the heart is still relatively high, and the ductus arteriosus may still be patent. Infants with a ventricular septal defect (the most common congenital heart lesion) or other heart lesions might not have a heart murmur at the routine examination, because the pressure difference between the left and right sides of the heart is insufficient to generate turbulent flow at this stage.

A second reason is that infants with duct-dependent lesions will not present clinically with heart failure, shock, cyanosis, or death until the ductus arteriosus closes days to weeks after birth. Femoral pulses may be palpable at the initial examination because of blood flow through the ductus arteriosus.

An additional limitation is that a heart murmur may be heard, but because most are innocent, it is not always

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

appreciated that the murmur is from a significant heart lesion. Prenatal diagnosis of some severe heart lesions and the increasing availability of echocardiography should reduce, but will not eliminate, failure to identify structural heart lesions before discharge from the hospital.

Pulse oximetry screening assists the detection of ductal-dependent lesions.[15,19,25] The AAP recommends universal screening and recommends further assessment if any of the following criteria are met:[32]

- Any oxygen saturation (SpO_2) is less than 90%.
- Oxygen saturation is less than 95% in both extremities on three measures, each separated by 1 hour.
- There is a greater than 3% absolute difference in oxygen saturation between the right hand and either foot on 3 measures, each separated by 1 hour.

Developmental Dysplasia of the Hip

As a screening test, clinical examination for DDH is problematic. Ideally, all affected infants should be identified in the neonatal period, because early treatment prevents or reduces the need for surgery. However, about 1%-2% of term infants have an abnormal hip examination, but the incidence of DDH is only approximately 1 in 1000 live births; most infants identified clinically have mild instability, which resolves. An additional problem is that a significant proportion of infants who subsequently require surgery are not identified in the neonatal period.

An examiner might fail to identify DDH at the initial examination, because the examination is suboptimal as the infant is not relaxed. However, in some infants with a flat acetabular shelf, the clinical examination may be normal in the neonatal period, but the dysplasia progresses with age.

Two strategies can improve the detection rate of DDH in newborn infants. The hip examination can be performed by pediatric orthopedists, or imaging of the hips can be performed. Ultrasound will identify DDH, including a shallow acetabular shelf. However, ultrasound has a high false-positive rate and is only helpful in the first 5 months of life before femoral head ossification occurs. Alternatively, a hip radiograph will identify DDH but only after 4-6 months of age when the femoral head secondary center of ossification forms.

The evaluation and referral for DDH remains controversial. The American Academy of Orthopedic Surgeons published a guideline in 2014 with a goal of initiating prevention and/or detection of dislocated hips by 6–12 months of age[22]:

- Infants with normal hips should have serial hip exams up to 6 months of age, and those with risk factors (breech presentation, family history, or clinical instability) should have imaging studies before 6 months of age.
- Infants with a positive instability exam should have hip ultrasound imaging before 6 weeks of age to guide the decision to initiate brace treatment.
- Infants over 4 months of age who need hip imaging should have an AP pelvis radiograph instead of ultrasound. The AAP updated the 2000 Clinical Practice Guideline with an AAP Clinical Report in 2016.[23]

Health Promotion

The routine examination is an opportunity to promote preventive health care.

Prevention of Sudden Unexpected Infant Death Syndrome

All parents should be advised that infants should sleep on their backs and that overheating and parental smoking are risk factors. Also, bed sharing and cosleeping should be avoided. Attention to preventive measures has markedly reduced the incidence of sudden unexpected infant deaths in many countries.

Promotion of Breastfeeding

Mothers should be encouraged in, and assisted with, breastfeeding. Lactation consultants are helpful in promoting breastfeeding, especially for mothers of infants who are preterm, ill, or have difficulties with breastfeeding for any other reason.

Hearing, Vision, and Other Screening

Universal hearing screening should be performed per hospital protocol. Children with increased risk for deafness (e.g., family history, malformations of the ear including skin tags and pits) must receive early hearing testing. Infants at increased risk for issues related to vision should be referred to an ophthalmologist. Parents should be given advice about early detection of hearing and vision loss. Other screening tests, including biochemical tests, should be performed according to local guidelines.

Discharge

The discharge physical examination is an opportunity not only to recheck that the infant is well and that any previously identified or ongoing medical issues have been resolved but to also ensure that the mother and infant are ready for discharge. The American Academy of Pediatrics has published details of the criteria that should be met before discharge.[10] These include checking that the infant's vital signs are normal and have been stable for at least 12 hours; that the infant has urinated and passed a stool, completed at least two successful feeds, and has been screened and monitored for sepsis based on maternal risk factors; and that maternal blood test results (hepatitis B surface antigen, HIV, syphilis) have been checked. If the infant is jaundiced, the bilirubin should be measured and a management and follow-up plan should be in place. The importance of immunizations can be emphasized, specifically the hepatitis B vaccine, which is generally given prior to discharge home (see Appendix C).

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

Hearing, blood spot screening, and pulse oximetry screening for critical congenital heart disease should have been performed or arrangements should be in place. A suitable car seat should be available. The AAP recommends that preterm infants be tested for desaturation/respiratory obstruction in a car seat prior to discharge. However, it should be explained that an infant can pass a car seat challenge and still have desaturations in the car seat at another time. Therefore, neonates should be observed while in the car seat and only remain in it for the duration of the trip. It should be explained that a car seat is not designed to be a safe position for infants to sleep once out of the vehicle. The clinician must also ensure that the parents are able to care adequately for their infant and that the infant is going to a suitable environment. Relevant follow-up care for the infant should also be in place. If a term baby is discharged early (<48 hours), a follow-up visit with a health care professional within 48 hours should be in place.

Key Points

A routine physical exam:

- should be performed on every newborn by a trained health care provider within 24 hours of birth,
- should include examination of all parts of the body and measurement of growth parameters,
- should allow minor and major abnormalities to be identified and addressed whether pre- or postnatally diagnosed,
- will not identify all abnormalities, but identification is maximized by specific training of health providers,
- is a time for thoughtful discussion with parents about their concerns, as the birth of a baby is an emotionally charged and vulnerable time for many parents,
- is an opportunity for health promotion and to check that appropriate discharge planning is in place.

Birth Injuries

PREETHA A. PRAZAD, MIRIAM N. RAJPAL, HENRY H. MANGURTEN, AND BHAGYA L. PUPPALA

Birth injuries are those sustained during the birth process, which includes labor and delivery. They may be avoidable, or they may be unavoidable and occur despite skilled and competent obstetric care, as in an especially hard or prolonged labor or with an abnormal presentation. Fetal injuries related to amniocentesis and intrauterine transfusions and neonatal injuries after resuscitation procedures are not considered birth injuries. However, injuries related to the use of intrapartum monitoring of the fetal heart rate and collection of fetal scalp blood for acid-base assessment are included. Factors predisposing the infant to birth injury include macrosomia, prematurity, cephalopelvic disproportion, dystocia, prolonged labor, abnormal presentation, and certain operative deliveries, particularly vacuum extraction. The fetus may also sustain injury, including death, if the mother is involved in a motor vehicle collision.[10] Fetal deaths may occur from maternal cardiovascular instability, uterine rupture, placental abruption, hemorrhage, and direct injury to the fetus. Although usually protected by maternal soft tissues, the uterus, and amniotic fluid, the fetus may be subjected to the same acceleration-deceleration forces as the mother. This may result in full-thickness bowel injury and fulminant disseminated intravascular coagulation. Thus, a thorough physical examination of the infant is critical after a maternal motor vehicle collision to identify any internal injury that may have occurred.

The significance of birth injuries may be assessed by review of mortality data. In 1981, birth injuries ranked sixth among major causes of neonatal death, resulting in 23.8 deaths per 100,000 live births. During the ensuing decade, because of refinements in obstetric techniques and the increased use of cesarean deliveries over difficult vaginal deliveries, a dramatic decline occurred in birth injuries as a cause of neonatal death. Statistics for 1993 revealed a reduction to 3.7 deaths per 100,000 live births; because of the emergence of other conditions, birth injuries ranked 11th among major causes of neonatal death. The most recent figures available (for 2013-2014) identify only 10 leading causes of neonatal and postneonatal death, with no mention of birth injuries.[54]

Despite a reduction in related mortality rates, birth injuries still represent an important source of neonatal morbidity and neonatal intensive care unit admissions. Of particular concern are severe intracranial injuries after operative vaginal delivery (vacuum-assisted and forceps delivery) and failed attempts at operative vaginal delivery.

The clinician should consider the broad spectrum of birth injuries in the differential diagnosis of neonatal clinical disorders. Although many injuries are mild and self-limited, others are serious and potentially lethal. This chapter describes conditions that can be managed by observation only, as well as those that require more aggressive intervention. In addition to assuring timely institution of therapy when indicated, recognition and documentation before discharge from the hospital will help avoid inappropriate suspicion of inflicted injury (child abuse) at a later date.

Injuries to Soft Tissues

Erythema and Abrasions

Erythema and abrasions frequently occur when dystocia has occurred during labor as a result of cephalopelvic disproportion or when forceps have been used during delivery. Injuries caused by dystocia occur over the presenting part; forceps injury occurs at the site of application of the instrument. Forceps injury frequently has a linear configuration across both sides of the face, outlining the position of the forceps. The affected areas should be kept clean to minimize the risk for secondary infection. These lesions usually resolve spontaneously within several days with no specific therapy.

Petechiae

Occasionally petechiae are present on the head, neck, upper portion of the chest, and lower portion of the back at birth after a difficult delivery; they are observed more frequently after breech and precipitous deliveries and tight nuchal cord.

Abstract

Over the last few decades, the number of birth injuries as a cause of neonatal death has dramatically declined as a direct result of improvements in prenatal care and obstetric techniques. However, despite a reduction in related mortality rates, birth injuries still represent a major cause of neonatal morbidity and neonatal intensive care unit admissions. Birth injuries may be avoidable or unavoidable, and they can occur even with skilled and competent obstetric care. Factors that predispose an infant to birth injury include macrosomia, prematurity, cephalopelvic disproportion, dystocia, prolonged labor, abnormal presentation, and certain operative deliveries, particularly vacuum and forceps extraction. The fetus may also sustain injury, including death, secondary to maternal trauma. After a difficult birth, a thorough physical examination of the infant is critical to identify any injury that may have occurred. The clinician should consider the broad spectrum of birth injuries within the differential diagnosis of neonatal clinical disorders. Although many injuries are mild and self-limited, others are serious and potentially lethal. In addition to assuring timely institution of treatment when indicated, recognition and documentation before discharge from the hospital will help avoid inappropriate suspicion of inflicted injury (child abuse) at a later date.

Etiology

Petechiae are probably caused by a sudden increase in intrathoracic and venous pressures during passage of the chest through the birth canal. An infant born with the cord tightly wound around the neck may have petechiae only above the neck.

Differential Diagnosis

Petechiae may be a manifestation of an underlying hemorrhagic disorder. The birth history, early appearance of the petechiae, and absence of bleeding from other sites help to differentiate petechiae caused by increased tissue pressure or trauma from petechiae caused by hemorrhagic disorders (see Chapter 79). The localized distribution of the petechiae, absence of subsequent crops of new lesions, and a normal platelet count exclude neonatal thrombocytopenia. The platelet count also may be low because of infection or disseminated intravascular coagulation. Infections may be clinically distinguished from traumatic petechiae by the presence of other signs and symptoms. Disseminated intravascular coagulation usually is associated with excessive and persistent bleeding from a variety of sites. Petechiae usually are distributed over the entire body when associated with systemic disease.

Treatment

If the petechiae are caused by trauma, neither corticosteroids nor heparin should be used. No specific treatment is necessary.

Prognosis

Traumatic petechiae usually fade within 2 or 3 days.

Ecchymoses

Ecchymoses may occur after traumatic or breech deliveries. The incidence is increased in premature infants, especially after a rapid labor and poorly controlled delivery. When extensive, ecchymoses may reflect blood loss severe enough to cause anemia and, rarely, shock. The reabsorption of blood from an ecchymotic area may result in significant hyperbilirubinemia (Fig. 29.1).

Treatment

No local or systemic therapy is necessary. The rise in serum bilirubin that follows severe bruising may be decreased by the use of phototherapy (see Chapter 91). Ecchymoses rarely result in significant anemia.

Prognosis

The ecchymoses usually resolve spontaneously within 1 week.

Subcutaneous Fat Necrosis

Subcutaneous fat necrosis is a rare form of panniculitis seen mostly in term or post-term infants characterized by well-circumscribed, indurated lesions of the skin and underlying tissue (see Chapter 87).

• **Fig. 29.1** Marked bruising of entire face of a 1490-g female infant born vaginally after face presentation. Less severe ecchymoses were present on extremities. Despite use of phototherapy from the first day, icterus was noted on the third day, and exchange transfusions were required on the fifth and sixth days.

Etiology

Although subcutaneous fat necrosis can occur without any obvious cause, it is most commonly seen in association with perinatal asphyxia. Other etiologic factors that have been implicated include cold exposure, localized skin trauma, obstetric trauma, preeclampsia, gestational diabetes, maternal or fetal risk of thrombosis, maternal cocaine use, hypothermia, prostaglandin E administration, brown fat deficiency, meconium aspiration, sepsis, and intrapartum calcium channel blocker administration. It can also occur as a complication of therapeutic hypothermia for perinatal asphyxia or in newborns undergoing surgical procedures.[34,69] Many affected infants are large and have been delivered by forceps or after a prolonged, difficult labor involving vigorous fetal manipulation. The distribution of the lesions usually is related to the site of trauma, which explains the frequent involvement of shoulders and buttocks. One suggested mechanism of pathogenesis proposes that diminished in utero circulation and mechanical pressure during labor and delivery result in vascular compromise to specific areas, which eventually causes localized fat necrosis. In maternal cocaine use during pregnancy, it has been postulated that cocaine may decrease placental perfusion with subsequent hypoxemia and alteration of the maternal and fetal pituitary-adrenal axes.[12]

Pathology

Histopathologic studies reveal initial endothelial swelling and perivascular inflammation in the subcutaneous tissues. This is followed by necrosis of fat and a dense granulomatous inflammatory infiltrate containing foreign body–type giant cells with needle-shaped crystals resembling cholesterol.

Clinical Manifestations

Necrotic areas usually appear between 6 and 10 days of age but may be noted as early as the second day or as late as the sixth week. They occur on the cheeks, neck, back, shoulders, arms, buttocks, thighs, and feet, with relative sparing of the chest and abdomen. The lesions vary in size from 1-10 cm; rarely, they may be more extensive. They are irregularly shaped, hard, plaquelike, and nonpitting (Fig. 29.2). The overlying skin may be colorless, red, or purple with no local tenderness. The affected areas may be slightly elevated above the adjacent skin; small lesions may be easily movable in all directions. Fever may be seen in a small subset of infants with subcutaneous fat necrosis.

This condition may be associated with hypoglycemia, hypertriglyceridemia, hypercalcemia, nephrocalcinosis, anemia, and thrombocytopenia. Marked symptomatic hypercalcemia may develop in infants with subcutaneous fat necrosis at 3-4 weeks of age; this has been characterized by vomiting, weight loss, anorexia, fever, somnolence, and irritability, with serum calcium levels as high as 17.3 mg/dL. The treatment includes intravenous hydration, calcium-wasting diuretics such as furosemide, potassium citrate to inhibit renal stone formation, and corticosteroids. Successful short-term treatment with bisphosphonates (e.g., pamidronate or etidronate) has been reported to control hypercalcemia.[45] Investigators have suggested extra renal production of 1,25-dihydroxyvitamin D by the granulomatous cells of fat necrosis as a possible mechanism for the hypercalcemia.

• **Fig. 29.2** Subcutaneous fat necrosis in a 2900-g term infant delivered vaginally; pregnancy, labor, and delivery were completely uncomplicated. Note nodular lesion located on right buttock and surrounded by erythema (*darkened area*). (Courtesy of Dr. Rajam Ramamurthy, Cook County Hospital, Chicago.)

Differential Diagnosis

The differential diagnosis includes lipogranulomatosis and sclerema neonatorum, which carry a potentially grave prognosis, and nodular nonsuppurative panniculitis, which is usually associated with fever, hepatosplenomegaly, and tender skin nodules.

Treatment

Most of these lesions require only observation. Surgical management is not indicated, with the exception of extensive ulcerated lesions.

Prognosis

The lesions slowly soften after 6-8 weeks and completely regress within several months. Occasionally minimal residual atrophy, with or without small calcified areas, is observed. Affected infants should be followed closely during the first 6 weeks for potential development of hypercalcemia. It is important to treat this complication without delay to prevent central nervous system (CNS) and renal sequelae.

Lacerations

Accidental lacerations may be inflicted with a scalpel during cesarean section. They usually occur on the scalp, buttocks, and thighs, but they may occur on any part of the body. If the wound is superficial, the edges may be held in apposition with butterfly adhesive strips. Deeper, more freely bleeding wounds should be sutured with the finest material available. Rarely, the amount of blood loss and depth of wound require suturing in the delivery room. After repair, the wound should be left uncovered unless it is in an area of potential soiling, such as the perineal area. Healing is usually rapid, and complications are rarely seen.

Injuries to the Head

Skull

Caput Succedaneum

Caput succedaneum, a frequently observed lesion, is characterized by a vaguely demarcated area of edema over that portion of the scalp that was the presenting part during a vertex delivery.

Etiology

Serum or blood or both accumulate above the periosteum in the presenting part during labor. This extravasation results from the higher pressure of the uterus or vaginal wall on those areas of the fetal head that border the caput. Thus, in a left occiput transverse presentation, the caput succedaneum occurs over the upper and posterior aspect of the right parietal bone; in a right-sided presentation, it occurs over the corresponding area of the left parietal bone.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

Clinical Manifestations

The soft swelling is usually a few millimeters thick and may be associated with overlying petechiae, purpura, or ecchymoses. Because of the location external to the periosteum, a caput succedaneum may extend across the midline of the skull and across suture lines. After an especially difficult labor, an extensive caput may obscure various sutures and fontanelles.

Differential Diagnosis

Occasionally, a caput succedaneum may be difficult to distinguish from a cephalhematoma, particularly when the latter occurs bilaterally. Careful palpation usually indicates whether the bleeding is external to the periosteum (caput) or beneath the periosteum (cephalhematoma). Iatrogenic encephalocele is an infrequent complication of vacuum extraction delivery and may present like a caput succedaneum initially. Imaging should be considered in every child with a large caput succedaneum that does not diminish in 48-72 hours or with enlargement of the swelling more than 24 hours after delivery, especially when there are neurologic deficits and hemodynamic instability.[38]

Treatment

Usually no specific treatment is indicated. Rarely, a hemorrhagic caput may result in shock and require blood transfusion.

Prognosis

A caput succedaneum usually resolves within several days.

Cephalhematoma

Cephalhematoma is an infrequently seen subperiosteal collection of blood overlying a cranial bone. The incidence is 0.4%-2.5% of live births, with a higher frequency in infants born to primiparous mothers.

Etiology

A cephalhematoma is caused during labor or delivery by a rupture of diploic blood vessels that traverse from skull to periosteum. Repeated buffeting of the fetal skull against the maternal pelvis during a prolonged or difficult labor and mechanical trauma caused by use of forceps and vacuum suction devices in delivery have been implicated. Petrikovsky and associates described seven infants in whom cephalhematoma or caput succedaneum was identified prenatally before onset of labor.[56] Occurrence of premature rupture of membranes in five of the pregnancies suggests an etiology of fetal head compression by the uterine wall, resulting from oligohydramnios subsequent to the ruptured membranes.

Clinical Manifestations

The bleeding is sharply limited by periosteal attachments to the surface of one cranial bone; there is no extension across suture lines. The bleeding usually occurs over one or both parietal bones. Less often, it involves the occipital bones and, very rarely, the frontal bones. The overlying scalp is not discolored. Because subperiosteal bleeding is slow, the swelling may not be apparent for several hours or days after birth. The swelling is often larger on the second or third day, when sharply demarcated boundaries are palpable. The cephalhematoma may feel fluctuant and often is bordered by a slightly elevated ridge of organizing tissue that gives the false sensation of a central bony depression. It may be associated with an underlying linear, nondepressed skull fracture in a small percentage of infants.

Radiographic Manifestations

Radiographic manifestations vary with the age of the cephalhematoma. During the first 2 weeks, bloody fluid results in a shadow of water density. At the end of the second week, bone begins to form under the elevated pericranium at the margins of the hematoma; the entire lesion is progressively overlaid with a complete shell of bone.

Differential Diagnosis

Cephalhematoma must be distinguished from other birth complications such as subgaleal hematoma, caput succedaneum, vacuum caput, leptomeningeal cyst, or congenital anomalies such as meningoceles. It may be differentiated from caput succedaneum by (1) its sharp periosteal limitations to one bone, (2) the absence of overlying discoloration, (3) the later initial appearance of the swelling, and (4) the longer time before resolution. Cranial meningocele is differentiated from cephalhematoma by pulsations, an increase in pressure during crying, and the demonstration of a bony defect on a radiograph. An occipital cephalhematoma may be confused initially with an occipital meningocele and with cranium bifidum because all occupy the midline position.

Treatment

No therapy is indicated for the uncomplicated cephalhematoma, as more than 80% resolve by gradual hemolysis and resorption in 3-4 weeks. When the hematoma does not resolve spontaneously, it may get organized, and calcification may be seen. It may still get absorbed slowly and often disappears over 3-6 months. Persistent calcification that is not resolved by time may be an indication for surgical excision.[28] Rarely, a massive cephalhematoma may result in blood loss severe enough to require transfusion. Significant hyperkalemia[41] and hyperbilirubinemia may result from resolving hematoma, necessitating appropriate treatment. The most common associated complications are skull fracture and intracranial hemorrhage. Linear fractures do not require specific therapy, but radiographs should be taken at 4-6 weeks to ensure closure and exclude formation of leptomeningeal cysts; depressed fractures require immediate neurosurgical consultation. Routine incision or aspiration of a cephalhematoma is contraindicated because of the risk for introducing infection. Rarely, bacterial infections of cephalhematomas occur, usually in association with septicemia and meningitis. Focal infection should be suspected when a sudden enlargement of a static cephalhematoma

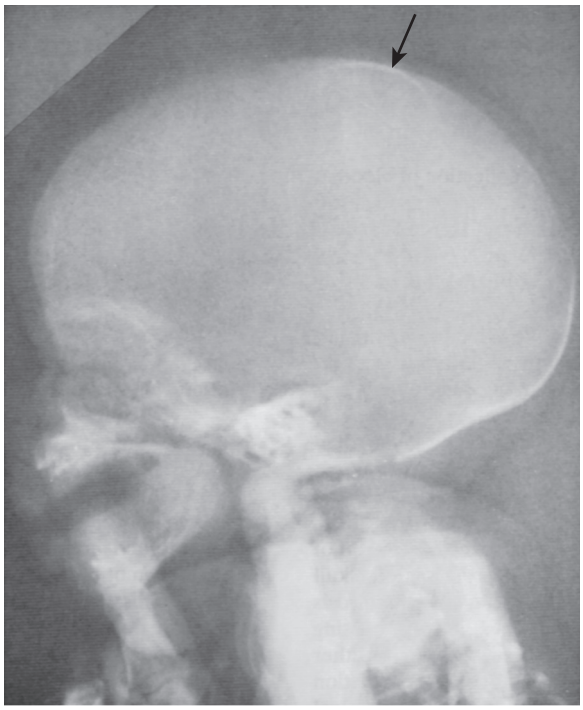
• **Fig. 29.3** Massive, persistently enlarging cephalhematoma in a 13-day-old female infant delivered by midforceps after occiput-posterior presentation. Surgical drainage revealed 300 mL of yellowish material that cultured as *Escherichia coli*.



occurs during the course of a systemic infection, with a relapse of meningitis or sepsis after treatment with antibiotics, or with the development of local signs of infection over the cephalhematoma (Fig. 29.3). Diagnostic aspiration may be indicated. If a local infection is present, surgical drainage and specific antibiotic therapy should be instituted. Osteomyelitis of the underlying skull may be a rare concurrent problem.[50] The diagnosis may be suggested by periosteal elevation and overlying soft tissue swelling on skull radiographs. Additional rare complications that may accompany an infected cephalhematoma and osteomyelitis include venous sinus thrombosis and cerebellar hemorrhage.[13] Magnetic resonance imaging (MRI) may be used to detect these two intracranial complications, whereas computed tomography (CT) is the best imaging modality to identify the permeative bone erosion and destruction of osteomyelitis.[13]

Prognosis

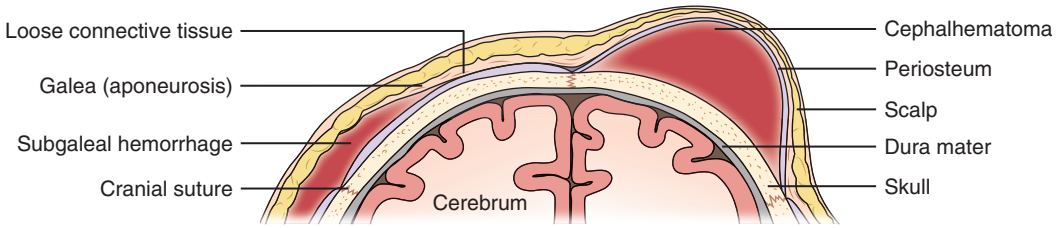
Most cephalhematomas are resorbed within 2 weeks to 3 months, depending on their size. In a few patients, calcium is deposited (Fig. 29.4), causing a bony swelling that may persist for several months and, rarely, up to several years. Radiographic findings persist after the disappearance of clinical signs. The outer table remains thickened as a flat, irregular hyperostosis for several months. Widening of the space between the new shell of bone and the inner table may persist for years; the space originally occupied by the hematoma usually develops into normal diploic bone, but cystlike defects may persist at the sites of the hematoma for months or years. Rarely, a neonatal cephalhematoma may persist into adult life as a symptomless mass, the cephalhematoma deformans of Schüller.

Subgaleal Hemorrhage

Subgaleal hemorrhage is a collection of blood in the soft tissue space between the galea aponeurotica and the

• **Fig. 29.4** Calcified cephalhematoma (*arrow*) in left parietal region of 5-week-old girl. Infant weighed 1410 g at birth and was delivered rapidly because of prolapsed cord. Hard left parietal swelling was detected at 5 weeks by nurses during feeding.

periosteum of the skull (Fig. 29.5). The incidence is about 4 per 10,000 noninstrumented deliveries, with higher incidence after instrumental deliveries. Ng and colleagues have reported an incidence of 64 per 10,000 deliveries when vacuum extraction is performed.[55]



Etiology

The most common predisposing factor is difficult operative vaginal delivery, particularly midforceps delivery and vacuum extraction.[72] The risk for subgaleal hemorrhage may be reduced by use of softer silicone vacuum cups instead of the original rigid metallic ones. The major risk factors include coagulopathies, prematurity, macrosomia, fetal dystocia, precipitous labor, intrapartum hypoxia, male sex, cephalopelvic disproportion, prolonged labor, and nulliparity.

Mechanism of Injury

When vacuum is used, the mechanism of injury is thought to be the vacuum traction pulling the scalp away from stationary bony calvarium, thus avulsing open the subgaleal space and causing the bridging vessels to tear and bleed into the subgaleal space. The loose connective tissue of the subgaleal space is extremely expansive and extends over the entire area of the scalp. The space can accommodate the entire neonatal blood volume (250 mL or more in a term baby), leading to hypovolemic shock, disseminated intravascular coagulation, and multiorgan failure, resulting in death in 25% of the cases.[73]

• **Fig. 29.5** Subgaleal hemorrhage and cephalhematoma.

• **Fig. 29.6** Clinical manifestations of subgaleal hemorrhage. Note anteriorly displaced ear.

Clinical Manifestations

Early manifestations may be limited to pallor, hypotonia, and diffuse swelling of the scalp. The development of a fluctuating mass straddling cranial sutures, fontanelles, or both is highly suggestive of the diagnosis. Because blood accumulates beneath the aponeurotic layer, ecchymotic discoloration of the scalp is a later finding.[27] This is often associated with pitting edema and progressive posterior spread toward the neck and lateral spread around the ears, frequently displacing the ears anteriorly (Fig. 29.6). Periorbital swelling and ecchymosis also are commonly observed. Eventually, hypovolemic shock, multiorgan failure, and signs of cerebral irritation develop. Massive lesions can cause extracranial cerebral compression, which may lead to rapid neurologic decompensation.[5] The clinician should be aware of occasional "silent presentation," in which a fluctuant mass is not apparent initially despite serial clinical examinations.[55] Subgaleal hemorrhage should be considered in infants who show signs of hypoperfusion and falling hematocrit after attempted or successful vacuum delivery even in the absence of a detectable fluctuant mass. Close monitoring is particularly important in those infants who are considered stable enough to allow admission to the normal newborn nursery.

Radiographic Manifestations

Standard radiographs of the skull may identify possible associated fractures. Computed tomography scanning may demonstrate abundant epicranial blood, parieto-occipital bone dehiscence, bone fragmentation, and posterior cerebral interhemispheric densities compatible with subarachnoid hemorrhage.[27]

Differential Diagnosis

In contrast with cephalhematoma, subgaleal hemorrhage is characterized by its more diffuse distribution, more rapid course, significant anemia, signs of central nervous system (CNS) trauma (e.g., hypotonia, lethargy, seizures), and frequent lethal outcome.

Treatment

Prompt restoration of blood volume with fresh frozen plasma or blood is essential. In the presence of continued deterioration, neurosurgery may be considered as a last resort. A bicoronal incision allows for exposure of the subgaleal space. Bipolar cauterization of any bleeding points can then be accomplished, and a drain can be left in the subgaleal space.

Prognosis

Although nearly 25% of infants with subgaleal hemorrhage die, long-term prognosis for survivors is generally good. More experience with aggressive and timely neurosurgical intervention may help to improve outcomes.

Skull Fractures

Fracture of the neonatal skull is uncommon, because the bones of the skull are less mineralized at birth and thus more compressible. In addition, the separation of the bones by membranous sutures usually permits enough alteration in the contour of the head to allow its passage through the birth canal without injury.

Etiology

Skull fractures usually follow a forceps delivery or a prolonged, difficult labor with repeated forceful contact of the fetal skull against the maternal symphysis pubis, sacral promontory, fifth lumbar vertebrae, or ischial spine. They have also been described after vacuum-assisted vaginal delivery.[33] Most of the fractures are linear. Depressed fractures are associated with forceps application. However, they may occur spontaneously after cesarean section or vaginal delivery without forceps. Factors that also have been implicated include pressure on the fetal skull by a maternal bony prominence (e.g., sacral promontory) or uterine fibroid, a fetal hand or foot, or the body part of a twin. Occipital bone fractures usually occur in breech deliveries as a consequence

• **Fig. 29.7** Depressed skull fracture in term male infant delivered after rapid (1-hour) labor. Infant was delivered by occiput-anterior presentation after rotation from occiput-posterior position.

of traction on the hyperextended spine of the infant when the head is fixed in the maternal pelvis.

Clinical Manifestations

Linear fractures over the convexity of the skull frequently are accompanied by soft tissue changes and cephalhematoma. Usually, the infant's behavior is normal unless there is an associated concussion or hemorrhage into the subdural or subarachnoid space. Fractures at the base of the skull with separation of the basal and squamous portions of the occipital bone almost always result in severe hemorrhage caused by disruption of the underlying venous sinuses. The infant may then exhibit shock, neurologic abnormalities, and drainage of bloody cerebrospinal fluid from the ears or nose.

Depressed fractures are visible, palpable indentations in the smooth contour of the skull, similar to dents in a ping-pong ball (Fig. 29.7). The infant may be entirely free of symptoms unless there is an associated intracranial injury.

Radiographic Manifestations

The diagnosis of a simple linear or fissure fracture is seldom made without radiographs in which fractures appear as lines and strips of decreased density. Depressed fractures appear as lines of increased density. On some views, they are manifested by an inward buckling of bone with or without an actual break in continuity. Either type of fracture may be seen on only one view. CT imaging is the optimal diagnostic modality if a skull fracture and possible underlying injury are suspected.

Differential Diagnosis

Occasionally, the fragments of a linear fracture may be widely separated and may simulate an open suture. Conversely, parietal foramina, the interparietal fontanelle, mendosal sutures, and innominate synchondroses may be mistaken for fractures. In addition, normal vascular grooves, "ripple lines" that represent soft tissue folds of the scalp, and lacunar skull may be mistaken for fractures.

Treatment

Uncomplicated linear fractures over the convexity of the skull usually do not require treatment. Fractures at the base of the skull often necessitate blood replacement for severe hemorrhage and shock in addition to other supportive measures. If cerebrospinal fluid rhinorrhea or otorrhea is present, antimicrobial coverage is indicated to prevent secondary infection of the meninges.

Small (<2 cm) "ping-pong" fractures may be observed without surgical treatment. Loeser and associates reported three infants with depressed skull fractures in whom spontaneous elevation of the fractures occurred within 1 day to 3½ months of age.[44] Follow-up at 1-2½ years revealed normal neurologic development in all three.

Several nonsurgical methods have been described for elevation of depressed skull fractures in certain infants:

1. A thumb is placed on opposite margins of the depression, and gentle, firm pressure is exerted toward the middle. After several minutes of continuous pressure, the area of depression gradually disappears.[61]
2. A hand breast pump is applied to the depressed area. Petroleum jelly placed on the pump edges ensures a tighter seal, and gentle suction for several minutes results in elevation of the depressed bone.[64]
3. A vacuum extractor is placed over the depression and a negative pressure of 0.2-0.5 kg/cm^2 is maintained for about 4 minutes.[63]

Because these methods are technically easier and less traumatic, they may be preferable to surgical intervention in a symptom-free infant with an isolated lesion.

Comminuted or large fractures associated with neurologic signs or symptoms should be treated by immediate surgical elevation of the indented segment to prevent underlying cortical injury from pressure. Other indications for surgical elevation include manifestations of cerebrospinal fluid beneath the galea and failure to elevate the fracture by nonsurgical manipulation.

Prognosis

Simple linear fractures usually heal within several months without sequelae.

Basal fractures carry a poor prognosis. When separation of the basal and squamous portions of the occipital bone occurs, the outcome is almost always fatal; surviving infants have an extremely high incidence of neurologic sequelae.

The prognosis for a depressed fracture is usually good when treatment is early and adequate. When therapy is delayed, especially with a large depression, death may occur from pressure on vital areas of the brain. Because the natural history of depressed skull fractures in neonates has not been clearly elucidated, the outcome is uncertain for infants with smaller lesions managed either by simple observation or by surgery after significant delays.

Intracranial Hemorrhage

See Chapter 53.

Face

Facial Nerve Palsy

Facial nerve palsy in the neonate may follow birth injury or rarely may result from agenesis of the facial nerve nucleus. The latter condition occasionally is hereditary but usually is sporadic.

Etiology

Traumatic facial nerve palsy most often follows compression of the peripheral portion of the nerve, either near the stylomastoid foramen through which it emerges or where the nerve traverses the ramus of the mandible. The neonate is vulnerable to these injuries because of the superficial course of the extracranial facial nerves. The nerve may be compressed by forceps, especially when the fetal head has been grasped obliquely. The condition also occurs after spontaneous deliveries in which prolonged pressure was applied by the maternal sacral promontory. Less frequently injury is sustained in utero, often in association with a mandibular deformity, by the persistent position of the fetal foot against the superior ramus of the mandible. An extremely rare cause is the pressure of a uterine tumor on the nerve.

This condition may occur rarely with simultaneous ipsilateral brachial plexus palsy, most likely secondary to compressive forces during delivery.[17] Contributing factors include prolonged second stage of labor and midforceps delivery.

Traumatic facial nerve palsy may follow a contralateral injury to the CNS such as a temporal bone fracture or hemorrhage, tissue destruction, or both to structures within the posterior fossa. This CNS injury is less frequent than peripheral nerve injury.

Clinical Manifestations

Paralysis is usually apparent on the first or second day but may be present at birth. It usually does not increase in severity unless considerable edema occurs over the area of nerve trauma. The type and distribution of paralysis are different in central facial paralysis compared with peripheral paralysis.

Central paralysis is a spastic paralysis limited to the lower half or two-thirds of the contralateral side of the face. The paralyzed side is smooth and full and often appears swollen. The nasolabial fold is obliterated, and the corner of the mouth droops. When the infant cries, the mouth is drawn to the normal side, the wrinkles are deeper on the normal side, and movement of the forehead and eyelid is unaffected. Usually other manifestations of intracranial injury appear, most often a sixth cranial nerve palsy.

Peripheral paralysis is flaccid and, when complete, involves the entire side of the face. When the infant is at rest, the only sign may be a persistently open eyelid on the affected side, caused by paralysis of the orbicular muscle of the eye. With crying, the findings are the same as in a central facial nerve injury, with the addition of a smooth forehead on the involved side. Because the tongue is not involved, feeding is not affected.

A small branch of the nerve may be injured, with involvement of only one group of facial muscles. Paralysis is then limited to the forehead, eyelid, or mouth. Peripheral paralysis caused by nerve injury distal to the geniculate ganglion may be accompanied by a hematotympanum on the same side.

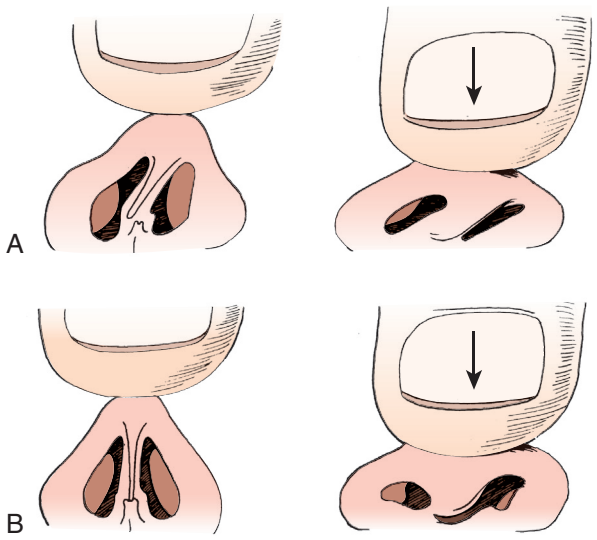
Differential Diagnosis

Central and peripheral facial nerve palsies must be distinguished from nuclear agenesis (Möbius syndrome). The latter frequently results in bilateral facial nerve palsy; the face is expressionless and immobile, suggesting muscle fibrosis. Other cranial nerve palsies and deformities of the ear, palate, tongue, mandible, and other bones may be associated with Möbius syndrome. Congenital absence or hypoplasia of the depressor muscle of the angle of the mouth also may simulate congenital facial palsy and has been associated with an increased incidence of other congenital anomalies.

Treatment

No specific therapy is indicated for most facial palsies. If the paralysis is peripheral and complete, initial treatment should be directed at protecting the cornea with an eye pad and instilling artificial tears every 4 hours. The functional state of the nerve should be followed closely. Falco and colleagues proposed the following comprehensive approach[20]:

1. Distinguish developmental from acquired lesions on the basis of the birth history and a detailed physical examination. Patients thought to have developmental palsy should be examined with radiologic and electrodiagnostic studies and brainstem-evoked response as appropriate.
2. Because of the expected 90% likelihood of complete spontaneous recovery, patients should be observed for 1 year before surgical intervention is considered. If recovery is suggested by physical examination or serial electromyography, observation without surgery may be delayed until the second birthday. Infants who require surgery are best treated with decompression or neuroplasty or both.



Prognosis

Most facial palsies resolve spontaneously within several days; total recovery may require several weeks or months. Electrodiagnostic testing is beneficial in predicting recovery; repeatedly normal nerve excitability indicates a good prognosis, but decreased or absent excitability early in the course suggests a poor outlook. The subsequent appearance of muscle fibrillation potentials indicates nerve degeneration. The prognosis in surgically treated infants worsens with increasing age at treatment.

Fractures and Dislocations of Facial Bones

Facial bone fractures may occur during passage through the birth canal, during forceps application and delivery, and during obstetric manipulation (most often the Mauriceau

• **Fig. 29.8** Result of finger compression, **A**, when nasal septum is dislocated. Normal septal relationship, **B**, results in no nasal deviation with pressure. (Modified from Daily W, et al. Nasal septal dislocation in the newborn. *Mo Med.* 1977;74:381.)

maneuver for delivery of the fetal head in a breech presentation). Manipulation may result in mandibular fractures and mandibular joint damage but is rarely severe enough to cause separation of the symphysis of the mandible. Fracture of the nose may result in early respiratory distress and feeding difficulties. The most frequent nasal injury is dislocation of the cartilaginous part of the septum from the vomerine groove and columella. This may result from intrauterine factors such as a uterine tumor or persistent pressure on the nose by fetal small parts or during delivery from pressure on the nose by the symphysis pubis, sacral promontory, or perineum. The presence of nasal septal dislocation may be differentiated from the more common normal variant of a misshapen nose by a simple compression test in which the tip of the nose is compressed (Fig. 29.8).[15] In the presence of septal dislocation, the nostrils collapse and the deviated septum becomes more apparent; in the normal nose, no nasal deviation occurs with compression.

Infants who sustain nasal trauma during the birth process may demonstrate stridor and cyanosis, even in the absence of septal dislocation. Miller and coworkers noted high nasal resistance in three such infants, only one of whom was found to have septal dislocation.[51] The authors postulated the presence of edema and narrowed nasal passages from compression forces on the midface during delivery. The problem may be exaggerated by repeated nasal suctioning or transnasal bronchoscopy. These procedures and oral feeding should be avoided until the infant re-establishes normal nasal ventilation. Pulse oximetry measurements are useful in monitoring these infants.

Treatment

Fractures of the maxilla, lacrimal bones, and nose warrant immediate attention, because they unite quickly, with fixation in 7-10 days. Nasal trauma may require surgery. While waiting, the pediatrician should provide an oral airway to relieve respiratory distress. Fractures of the septal cartilage also may be reduced by simple manual remolding, but most are associated with hematomas that should be promptly incised and drained. The surgeon can visualize the deformity with an infant nasal speculum, place a septal elevator in the nose, and guide the septal cartilage into the vomerine groove; an audible and palpable click indicates return of the septum into position. For simple nasal positional deformity with no evidence of respiratory distress, steri-strip method (tapes are applied from the septal pyramid/vomer junction anchored to the cheek to straighten the columella and widen the nasal aperture) may be attempted for a few days unless septal dislocation is identified soon after birth.[74]

Early reduction and immobilization are advised for a displaced fracture of the mandible because rapid, firm union may occur as early as 10-14 days. Usually, adequate alignment can be achieved with an acrylic mandibular splint and circum-mandibular wires, which are maintained in place for 3 weeks. In more severe cases with canting of the mandibular alveolar ridge, perialveolar wires below the infraorbital rims have been used with excellent results. This procedure can prevent canted occlusion and possible facial asymmetry as the child grows, thus avoiding later extensive and costly reconstructive surgery.[60]

Prognosis

If the fracture is reduced and fixated within a few days, rapid healing without complication is the usual course. If treatment is inadequate, missed, or delayed, subsequent developmental deformities are common. Ankylosis of the mandible in the second year of life is thought to result from birth trauma to the temporomandibular joint. A young child has been described with unilateral mandibular hypoplasia, which was thought to have resulted from fibrous ankylosis caused by perinatal trauma to the condylar cartilage of the ipsilateral temporomandibular joint.[8] Other deformities may not become apparent until adolescence or young adulthood.

Eyes

See Chapter 95. Mechanical trauma to various regions of the neonatal eye usually occurs during abnormal presentation in dystocia from cephalopelvic disproportion or as a result of inappropriate forceps placement in normal deliveries. Most of the injuries are self-limited and mild and require no specific treatment.

Eyelids

Edema, suffusion, and ecchymoses of the eyelids are common, especially after face and brow presentations or forceps deliveries. Severely swollen lids should be forced open by an ophthalmologist for examination of the eyeball;

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

retractors may be necessary. These findings usually resolve within a week without treatment.

A less common injury is laceration, including disruption of the lacrimal canaliculus. This has been associated with multiple upper-eyelid lacerations, including a full-thickness vertical wound lateral to the punctum and a full-thickness laceration through the lower eyelid with transection of the canaliculus after a low forceps delivery. Microsurgical repair of the lacrimal system and eyelids, including lacrimal intubation with a silicone stent, has been successful. Follow-up at 14 months revealed normal tear drainage with no amblyopia or residual deformity.[32]

An infant has been reported with superficial eyelid lacerations caused by an internal fetal monitoring spiral electrode.[42] At delivery, the electrode was attached to the eyelid. Marked facial edema related to brow presentation apparently obscured the lacerations until 14 hours of age, when much of the edema had resolved. Periorbital edema was believed to have protected the infant from more serious injury to the eyelid and globe.

Lagophthalmos, the inability to close an eyelid, is an occasional finding thought to result from facial nerve injury by forceps pressure. It is usually unilateral. The exposed cornea should be protected by an eye pad and frequent use of methylcellulose drops. The condition usually resolves within a week.

Orbit

Orbital hemorrhage and fracture may follow direct pressure by the apex of one forceps blade, most often in high forceps extractions. In most instances, death occurs immediately. Surviving infants demonstrate traumatic eyelid changes, disturbances of extraocular muscle movements, and exophthalmos. The presence of the latter two findings warrants immediate ophthalmologic consultation. Subsequent management also may require neurosurgical and plastic surgery consultations.

Sympathetic Nervous System

Horner syndrome, resulting from cervical sympathetic nerve trauma, frequently accompanies lower brachial plexus injury. The syndrome consists of miosis, partial ptosis, slight enophthalmos, and anhidrosis of the ipsilateral side of the face. Although small, the pupil reacts to light. The presence of neurologic signs indicating brachial plexus injury helps distinguish this syndrome from intracranial hemorrhage as a cause of anisocoria. Pigmentation of the ipsilateral iris is frequently delayed to several months of age; occasionally, pigmentation never occurs. Resolution of other signs of the syndrome depends on whether the injury to the nerve is transient or permanent.

Subconjunctival Hemorrhage

Subconjunctival hemorrhage, characterized by bright red patches on the bulbar conjunctiva, is a relatively common finding in the neonate. It may be found after a difficult delivery but often is noted after easy, completely uncomplicated deliveries. This finding is considered to result from increased venous pressure in the infant's head and neck, produced by obstruction to venous return consequent to compression of the fetal thorax or abdomen by uterine contractions during labor. If the infant is otherwise well, management consists of reassuring the parents. The blood is usually absorbed within 1-2 weeks. As the blood pigments break down and are absorbed, the color changes from bright red to orange and yellow.

External Ocular Muscles

Injury involving the external ocular muscles may result from direct trauma to the cranial nerve (in the form of compression or surrounding hemorrhages) or from hemorrhage into the muscle sheath, with subsequent fibrosis. The sixth cranial nerve (abducens) is the most frequently injured cranial nerve because of its long intracranial course; the result is paralysis of the lateral rectus muscle. This injury may follow a tentorial laceration with extravasation of a small amount of blood around the intracranial portion of the nerve. The involvement may be mild and transient; internal strabismus noted at birth may resolve gradually within 1-2 months. The seventh cranial nerve may be injured simultaneously with the sixth nerve by compression with forceps. Improvement in lateral gaze of the affected eye may appear within 1-2 months. Alternate patching of either eye in the severely affected infant maintains visual acuity until, with time, maximal improvement has occurred. At 6 months, the degree of nerve regeneration may be evaluated. Some infants subsequently require surgical repair of the strabismus.

Fourth cranial nerve (trochlear) palsy occurs infrequently. It may follow small brainstem hemorrhages with nuclear damage. The affected muscle is the superior oblique, which mainly turns the eye inferiorly and medially. This condition is difficult to identify in the newborn infant. Surgical correction may be necessary later.

Third cranial nerve (oculomotor) palsy, when complete, causes paralysis of the inferior oblique and medial, superior, and inferior rectus muscles. This results in ptosis, a dilated fixed pupil, and outward and downward deviation of the eye, with inability to adduct or elevate up and in, or up and out, or to depress down and out. This palsy also may occur in partial form, with or without pupillary involvement. Partial palsies may recover function spontaneously within several months, whereas complete palsies usually require surgical intervention.

Optic Nerve

The optic nerve may be injured directly by a fracture in the region of the optic canal or from a shearing force on the nerve, with resultant hemorrhage into the nerve sheath. The latter injury seldom is recognized because of the more apparent and severe changes in the sensorium. Occasionally, a fracture through the optic foramen results in formation of callus, which slowly compresses the nerve. A difficult forceps delivery is a frequent preceding event.

Cornea

A diffuse or streaky haziness of the cornea is relatively common. This is usually caused by edema related to the birth process but also may follow use of a silver nitrate solution more concentrated than 1%. The haziness usually disappears in 7-10 days. When it persists, a rupture of the Descemet membrane has probably occurred, usually because of malpositioning of forceps at delivery. The consequence of a ruptured Descemet membrane is a leukoma or diffuse white opacity of the cornea. This results from interstitial damage of the substantia propria by fluids entering through the tear in the membrane. These leukomas are often permanent and, despite patching of the contralateral eye and use of glasses, are accompanied by a high incidence of amblyopia and strabismus.

A ruptured Descemet membrane has been reported after a prolonged delivery in which low forceps were used after unsuccessful attempts at vacuum extraction.[6] Because of significant corneal astigmatism at 2 months of age, a gas-permeable hard contact lens was applied.[68] Patching of the contralateral eye was continued. Assessment of visual acuity at 13 months, with the use of spatial frequency sweep visual-evoked potentials, demonstrated an excellent visual result.

Intraocular Hemorrhage

Trauma at birth may result in retinal hemorrhage, hyphema, or vitreous hemorrhage, with retinal hemorrhage the most common. The cause is most likely compression of the fetal head, resulting in venous congestion. The fetal head is compressed two to four times more forcefully than other fetal parts during the second stage of labor. Retinal hemorrhage is more common in primiparous deliveries and after forceps or vacuum extraction; it is rare after cesarean section. It may occur in normal deliveries. The most common lesion is the flame-shaped or streak hemorrhage found mainly near the disk and sparing the macula and extreme periphery. A majority of cases resolve within 2 weeks with no residual effects. Rarely, hemorrhages may take up to 6 weeks to resolve. It is critical to identify birth-related retinal hemorrhages and document their presence on the infant's chart to avoid subsequent suspicion of child abuse. Retinal hemorrhages may reduce the resolving power of the macula, either bilaterally to produce nystagmus or unilaterally to produce amblyopia, which may not always respond to prolonged covering of the fixing eye with improvement of the amblyopic eye.

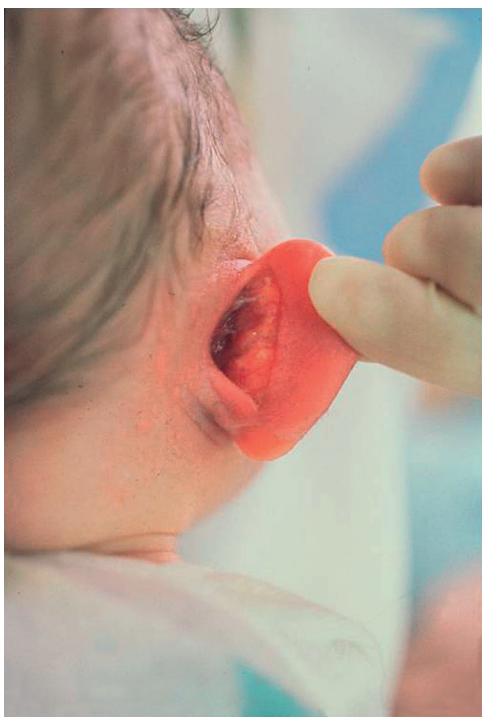
Hyphemas and vitreous hemorrhages usually result from misplacement of forceps and often are associated with ruptures of the Descemet membrane. One infant has been described in whom a hyphema developed in one eye after spontaneous delivery.[58] The hyphema usually is clear of gross blood within 5 days; during this time the infant should be handled gently and fed frequently to minimize crying and agitation. If blood persists or secondary hemorrhage occurs, systemic administration of acetazolamide (diamox) and surgical removal of blood may be necessary.

Vitreous hemorrhage is manifested by large vitreous floaters, blood pigment seen with the slit lamp, and an absent red reflex. The prognosis is guarded; if resolution does not occur in 6-12 months, surgical correction should be considered.

Ears

The proximity of ears to the site of application of forceps makes them susceptible to injury at birth. Most of the injuries are mild and self-limited, but serious injuries may occur because of slipping or misplacement of forceps (Fig. 29.9).

Abrasions and Ecchymoses



Abrasions must be cleansed gently to minimize the risk for secondary infection. Ecchymoses, if extensive and involving other areas of the body, may result in hyperbilirubinemia.

Hematomas

Hematomas of the external ear, if not treated promptly, liquefy slowly and are followed by early organization and development of cauliflower ear. Wide incision and evacuation of the hematoma may be indicated.

Lacerations

Lacerations of the auricle may be repaired by the pediatrician if they are superficial and involve only skin. After

• **Fig. 29.9** Extensive avulsion and laceration of auricle in term infant, resulting from forceful traction of misplaced forceps.

thorough cleansing and draping, the wound edges are sutured with interrupted 6-0 or 7-0 nylon sutures, with exact edge-to-edge approximation. If the laceration involves cartilage, surgical consultation should be obtained because of the tendency toward postoperative perichondritis, which is refractory to treatment and leads to subsequent deformities. A sterile field and more meticulous presurgical preparation are essential. A contour pressure dressing is applied postoperatively.

Vocal Cord Paralysis

Unilateral or bilateral paralysis of the vocal cords related to birth injury is uncommon in the neonate.

Etiology

Unilateral paralysis may be a consequence of excessive traction on the head during a breech delivery or lateral traction with forceps in a cephalic presentation. The recurrent laryngeal branch of the vagus nerve in the neck is injured. The left side is involved more often because of this nerve's lower origin and longer course in the neck. Bilateral paralysis may be caused by peripheral trauma involving both recurrent laryngeal nerves, but more frequently it is caused by a CNS insult such as hypoxia or hemorrhage involving the brainstem. Infants with vocal cord paralysis following instrumental delivery may have associated injuries such as subdural hemorrhage.[22]

Clinical Manifestations

An infant with a unilateral paralysis may be completely free of symptoms when resting quietly, but crying is usually accompanied by hoarseness and mild inspiratory stridor. When associated with difficulty in feeding and clearing secretions, concurrent involvement of the 12th (hypoglossal) cranial nerve should be suspected, particularly if the tongue on the ipsilateral side does not protrude and demonstrates fasciculations. Hypoglossal paralysis also has been described in association with ipsilateral upper brachial plexus injury.[30] Affected infants demonstrate difficulty in sucking, with swelling and immobility of the affected side of the tongue. Bilateral paralysis results in more severe respiratory symptoms. At birth, the infant may have difficulty in establishing and maintaining spontaneous respiration; later, dyspnea, retractions, stridor, cyanosis, or aphonia may develop.

Differential Diagnosis

Unilateral paralysis of the vocal cords must be distinguished from congenital laryngeal malformations that produce neonatal stridor. A history of difficult delivery, especially involving excessive traction on the fetus, may suggest laryngeal paralysis; previously, the diagnosis was confirmed only by direct laryngoscopic examination. The availability of the flexible fiberoptic laryngoscope at the bedside has facilitated earlier diagnosis without disrupting the infant's environment. Serial examinations to monitor progress also can be conducted with ease, because the infant need not be transported to the operating room.

Bilateral paralysis also must be distinguished from a number of causes of respiratory distress in the neonate (see Chapter 66); stridor should suggest the larynx as the site of disturbance. Direct or flexible fiberoptic laryngoscopy is necessary to establish the diagnosis.

Treatment

Infants with unilateral paralysis should be observed closely until there is evidence of improvement. Gentle handling and frequent small feedings aid in keeping the infant quiet and minimizing the risk for aspiration. Bilateral paralysis necessitates immediate tracheal intubation to establish an airway. Tracheostomy is required subsequently in most patients. Laryngoscopic examinations then should be performed at intervals to look for evidence of return of vocal cord function; early extubation may be attempted if complete return occurs within a short time.

Prognosis

Unilateral paralysis usually resolves rapidly without treatment, and complete resolution occurs within 4-6 weeks. Glossolaryngeal paralysis or paresis resulting from birth injury should resolve spontaneously by 6 months of age. Recognition of this subtle condition is important for two reasons. First, its self-limited course is encouraging, thus avoiding needless alarm in the parents with concern about more ominous conditions such as Werdnig-Hoffmann disease. Second, unnecessary invasive and aggressive procedures can be avoided.

The prognosis for bilateral paralysis is more variable. If untreated, a funnel deformity may develop in the lower sternal area; this may appear as early as the 15th day of life. After tracheostomy, a decrease in the severity of the deformity may occur within several weeks. Some affected infants subsequently regain normally shaped chests; others may have residual fixed depressions occasionally severe enough to require surgical correction. The recovery of vocal cord function varies in time and degree. Some infants may show partial recovery within a few months, with several years elapsing before complete movement of the cords is restored. Other infants who have been followed for years show no improvement. Bilateral paralysis of central origin may improve completely if it is caused by cerebral edema or hemorrhage that rapidly resolves.

Injuries to the Neck, Shoulder Girdle, and Chest

Fracture of the Clavicle

See Chapter 97. The clavicle is the most frequently fractured bone during labor and delivery. Most clavicular fractures are of the greenstick type, but occasionally the fracture is complete.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

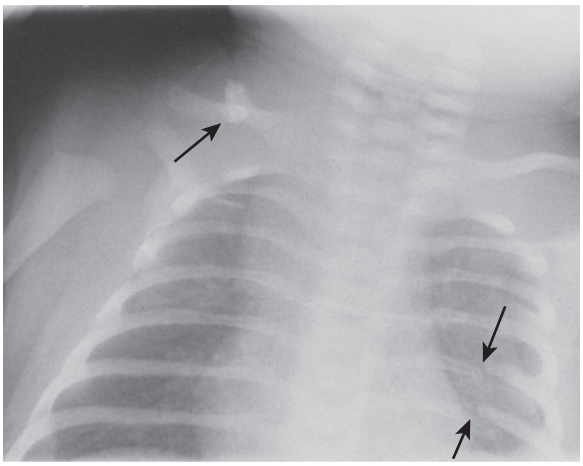
Etiology

The major causes of clavicular fractures are difficult delivery of the shoulders in vertex presentations and extended arms in breech deliveries. Vigorous, forceful manipulation of the arm and shoulder usually has occurred. However, fracture of the clavicle may also occur in infants after apparently normal labor and delivery.[39] It has been suggested that some fetuses may be more vulnerable to spontaneous birth trauma secondary to forces of labor, maternal pelvic anatomy, and in utero fetal position.

Clinical Manifestations

Most often a greenstick fracture is not associated with any signs or symptoms but is first detected after the appearance of an obvious callus at 7-10 days of life. Thus, most neonatal clavicular fractures are diagnosed at discharge or at the first follow-up visit. Complete fractures and some greenstick fractures may be apparent shortly after birth; movement of the arm on the affected side is decreased or absent. Deformity and, occasionally, discoloration may be visible over the fracture site with obliteration of the adjacent supraclavicular depression as a result of sternocleidomastoid muscle spasm. Passive movement of the arm elicits cries of pain from the infant. Palpation reveals tenderness, crepitus, and irregularity along the clavicle. Moro reflex on the involved side is characteristically absent. Radiographs confirm the diagnosis of fracture.

Differential Diagnosis



A similar clinical picture of impaired movement of an arm with an absent Moro reflex may follow fracture of the humerus or brachial palsy. The fracture is confirmed by radiographs; palsy is accompanied by additional clinical findings. Rarely, an infant may present with a congenital pseudoarthrosis of the clavicle, which may be difficult to distinguish from a fracture. Pseudoarthrosis classically appears as a painless lump on the clavicle, with no associated tenderness or limitation of mobility of the shoulder and arm. Radiography reveals disruption of the affected clavicle, with enlargement of the end of the bone. The etiology is uncertain. Recommended treatment options include observation only or surgical excision of the cartilaginous cap at about 4 or 5 years of age, followed by alignment of bone fragments and, if necessary, bone grafting or internal fixation.

Treatment

Therapy is directed toward minimizing the infant's pain. The affected arm and shoulder should be immobilized with the arm abducted more than 60 degrees and the elbow flexed more than 90 degrees. A callus forms, and pain usually subsides by 7-10 days, when immobilization may be discontinued.

Prognosis

The prognosis is excellent, with growth resulting in restoration of normal bone contour after several months.

• **Fig. 29.10** Chest radiograph of a 4905-g girl delivered by midforceps after right shoulder dystocia. On the 11th day, a prominent mass was noted in the right midclavicular region. Radiograph reveals a right midclavicular fracture (*top left arrow*) with slight superior angulation and incidental fractures of left fifth and sixth ribs (*bottom right arrows*). (From Mangurten HH, et al. Incidental rib fractures in a neonate. *Neonat Intensive Care.* 1999;12:15.)

Fracture of Ribs

Rib fractures related to labor and delivery are exceedingly rare.

Etiology

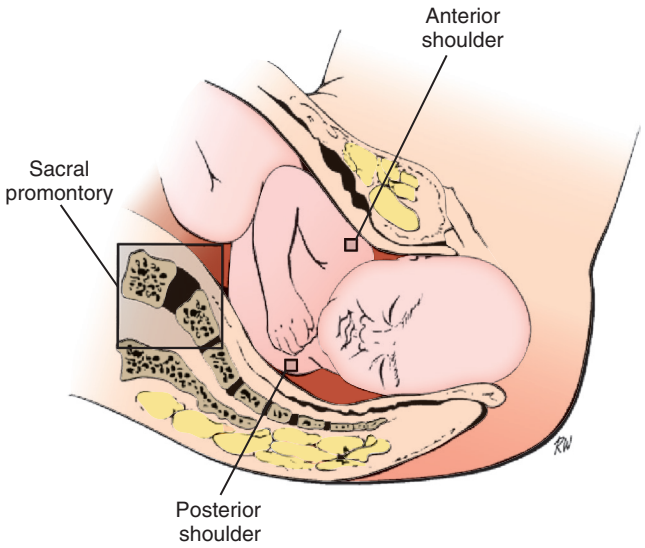
Risk factors are similar to those related to fracture of the clavicle, including macrosomia, a primigravida mother, shoulder dystocia, and delivery by midforceps or vacuum extraction.

Clinical Manifestations

Specific clinical manifestations are often absent, making diagnosis difficult, unless a chest radiograph is obtained for other reasons, including suspected clavicular fracture (Fig. 29.10),[48] respiratory distress, or cyanosis.

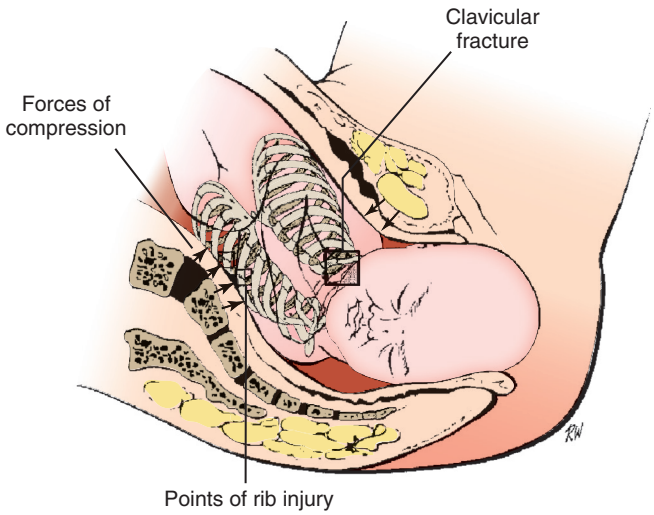
Mechanism of Injury

This injury is initiated when the anterior shoulder is impacted behind the symphysis pubis, with the other shoulder attempting to descend into the posterior compartment of the pelvis (Fig. 29.11).[48] This results in compression forces on the fetal arms and thorax, leading to spontaneous rib fractures on the same side as the posterior shoulder (Fig. 29.12).



Treatment

No specific treatment is required. However, it is extremely important to document this injury immediately after birth to avoid later unwarranted accusation of parents or other caretakers for suspicion of child abuse.



Prognosis

The prognosis is excellent, with spontaneous healing within several months.

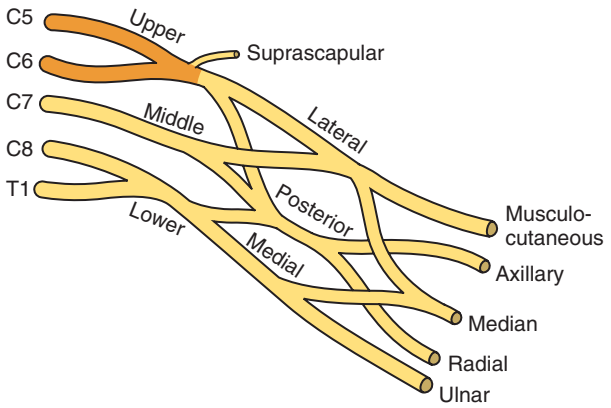
Brachial Palsy

See Chapter 99. Brachial palsy is a paralysis involving the muscles of the upper extremity that follows mechanical trauma to the spinal roots of the fifth cervical through the first thoracic nerves (the brachial plexus) during birth. Three main forms occur, depending on the site of injury:

1. Duchenne-Erb or upper arm paralysis results from injury of the fifth and sixth cervical roots and is by far the most common.
2. Klumpke or lower arm paralysis results from injury of the eighth cervical and first thoracic roots and is extremely rare.
3. Paralysis of the entire arm occurs slightly more often than the Klumpke type.

Etiology



Many cases of brachial palsy follow a prolonged and difficult labor culminating in a traumatic delivery. The affected infant is frequently large, relaxed, and asphyxiated and thereby vulnerable to excessive separation of bony segments, overstretching, and injury to soft tissues. Injury of the fifth and sixth cervical roots may follow a breech presentation with the arms extended over the head; excessive traction on the shoulder in the delivery of the head may result in stretching of the plexus. The same injury may follow lateral traction of the head and neck away from one of the shoulders during an attempt to deliver the shoulders in a vertex presentation, particularly during a vacuum extraction[53] and after shoulder dystocia.[21] More vigorous traction of the same nature results in paralysis of the entire arm. The mechanism for isolated lower arm paralysis is uncertain; it is thought to result from stretching of lower plexus nerves under and against the coracoid process of the scapula during forceful elevation and abduction of the arm. Excessive traction on the trunk during a breech delivery may result in avulsion of the lower roots from the cervical cord. In most patients, the nerve sheath is torn, and the nerve fibers are compressed by the resultant hemorrhage and edema. Less often the nerves are completely ruptured and the ends severed, or the roots are avulsed from the spinal cord with injury to the spinal gray matter.

Some authorities suggest that twisting and extension of the fetal head during the cardinal movements of labor and during delivery contribute to the occurrence of brachial palsy.[62] An increasing number of reports have described "no shoulder" brachial plexus palsy unrelated to excessive traction during delivery.[24] Some experts have suggested an intrauterine insult preceding labor, such as compression by uterine tumors or maternal pelvic bony prominences.[24] One study, which confirmed the well-known association of shoulder dystocia and brachial plexus injury in macrosomic infants, also identified an increased incidence of other malpresentations in low and normal birth weight infants with brachial plexus injury.[25] One report has described an infant with brachial palsy following vaginal delivery with no shoulder dystocia, no delay between delivery of the head and the body, no physician traction during the delivery, and no fundal pressure.[43] A large epidemiologic study revealed that 54% of infants had no identifiable risk factors.[21]

Clinical Manifestations

Clinical manifestations may be understood in relation to depiction of the brachial plexus (Fig. 29.13).[57] The infant with upper arm paralysis holds the affected arm in a characteristic position, reflecting involvement of the shoulder abductors and external rotators, forearm flexors and

• **Fig. 29.13** Simplified schematic diagram of brachial plexus, indicating spinal nerves of origin, trunks, cords, and major peripheral nerves. *Darker area* signifies the portion of the plexus affected in Erb palsy. (Courtesy of Dr. Joseph H. Piatt Jr., St. Christopher's Hospital for Children, Philadelphia.)

supinators, and wrist extensors. The arm is adducted and internally rotated, with extension at the elbow, pronation of the forearm, and flexion of the wrist. When the arm is passively abducted, it falls limply to the side of the body. Moro, biceps, and radial reflexes are absent on the affected side. There may be some sensory deficit on the radial aspect of the arm, but this is difficult to evaluate in the neonate. The grasp reflex is intact. Any signs of respiratory distress may indicate an accompanying ipsilateral phrenic nerve root injury (see Phrenic Nerve Paralysis).

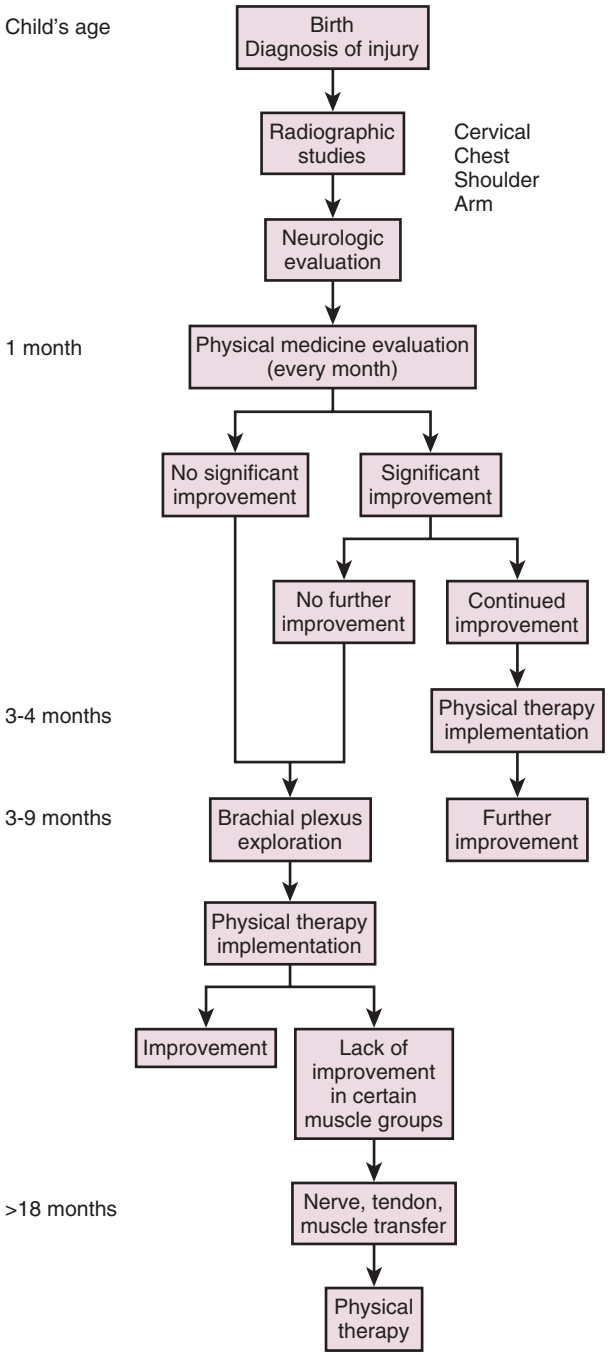
Lower arm paralysis involves the intrinsic muscles of the hand and the long flexors of the wrist and fingers. The hand is paralyzed, and voluntary movements of the wrist cannot be made. The grasp reflex is absent; the deep tendon reflexes are intact. Sensory impairment may be demonstrated along the ulnar side of the forearm and hand. Frequently dependent edema and cyanosis of the hand and trophic changes in the fingernails develop. After some time, there may be flattening and atrophy of the intrinsic hand muscles. Usually an ipsilateral Horner syndrome (ptosis, miosis, and enophthalmos) also is present because of injury involving the cervical sympathetic fibers of the first thoracic root. Often this is associated with delayed pigmentation of the iris, sometimes of more than 1 year's duration.

When the entire arm is paralyzed, it is usually completely motionless, flaccid, and powerless, hanging limply to the side. All reflexes are absent. The sensory deficit may extend almost to the shoulder.

Differential Diagnosis

The presence of a flail arm in a neonate may be caused by cerebral injury or a number of injuries about the shoulder. Cerebral injury is usually associated with other manifestations of CNS injury. A careful radiographic study of the shoulder, including an examination of the lower cervical spine, clavicle, and upper humerus, should be made to exclude tearing of the joint capsule; fracture of the clavicle; and fracture, dislocation, or upper epiphyseal detachment of the humerus. Posterior dislocation of the humeral head may be difficult to identify with standard radiographs. Torode and Donnan have used CT scans to demonstrate that posterior dislocation is more common than previously believed.[71] Hunter and coworkers[36] reported an infant in whom a posterior dislocation was uncertain with standard radiographs. Ultrasonography clearly revealed a posterior dislocation. Because posterior dislocation will complicate resolution of the palsy, ultrasonographic evaluation should be considered early in the management of these infants.

Treatment



The basic principle of treatment historically has been conservative, with initial emphasis on prevention of contractures while awaiting recovery of the brachial plexus. This approach has been replaced by a more comprehensive program that combines initial conservative management with closer follow-up and an earlier decision regarding surgical intervention. This is best represented by the care plan developed by Shenaq and colleagues (Fig. 29.14).[67] This approach is initiated with a thorough and complete physical examination that includes careful palpation of the sternocleidomastoid muscle for contracture or pseudotumor; inspection for fractures of the clavicle, humerus, or ribs; observation for abdominal asymmetry, which could indicate paralysis of the hemidiaphragm; and assessment for ocular asymmetry, which may indicate associated Horner syndrome.

Ancillary investigations, including CT or myelography and MRI, could be helpful in detecting possible avulsions. Electromyography has been unreliable in predicting the extent of damage.

Some infants may demonstrate discomfort because of a painful traumatic neuritis affecting the brachial plexus. If no discomfort is apparent and other lesions as noted earlier are ruled out, early passive range-of-motion exercises, particularly involving the elbow and wrist, should be instituted. Because of shorter nursery stays, the mother should receive early demonstration and written instructions describing these exercises. She should then begin to work with the infant under the guidance of the therapy staff. Exercises include shoulder rotation; elbow flexion and extension; wrist flexion and extension; finger flexion and extension; and thumb abduction, adduction, and opposition. The infant should be reevaluated every month. If improvement in deltoid, biceps, and triceps function has not occurred by the third month of life, functional outcome without surgery is unlikely. Consequently, a decision for surgery should be made by the end of the third month, followed by primary brachial plexus exploration during the fourth month.

Initial surgical intervention beyond 12 months of age at the level of the cervical root alone has resulted in disappointing outcomes. However, when infants referred at this age have been offered a combined cervical root and infraclavicular exploration with neurolysis, graph reconstruction, and nerve transfer of appropriate elements in both

• **Fig. 29.14** Treatment protocol for management of obstetric brachial plexus palsy. (From Shenaq SM, et al. Brachial plexus birth injuries and current management. *Clin Plast Surg.* 1998;25:527.)

anatomic compartments, improved outcomes have been noted. Blaauw and Slooff have reported their experience with transfer of pectoral nerves to the musculocutaneous nerve in 25 patients, 22 of whom had upper root avulsions.[9] Seventeen patients, including one who went to surgery at 3 months of age, had excellent outcomes, five had fair outcomes, and two were considered treatment failures.

The initial surgical therapy may include a team of neurosurgeons, plastic surgeons, and physiatrists who collaborate in the exploration, evaluation, and repair of the injury. This aggressive approach has resulted in up to 90% of patients demonstrating useful function of muscle groups above the elbow. Function below the elbow has been characterized by 50%-70% recovery because of the increased distance required for nerve regeneration.

Prognosis

Continued close follow-up includes serial evaluation of shoulder, elbow, forearm, wrist, finger, and thumb function. Based on the child's progress over time, a decision is made regarding further treatment. Physical therapy is continued until there is no further progress or the deficit is debilitating. For the infant who continues to demonstrate lack of improvement in certain muscle groups, secondary surgical reconstruction is available, with a variety of options depending on the individual deficit.

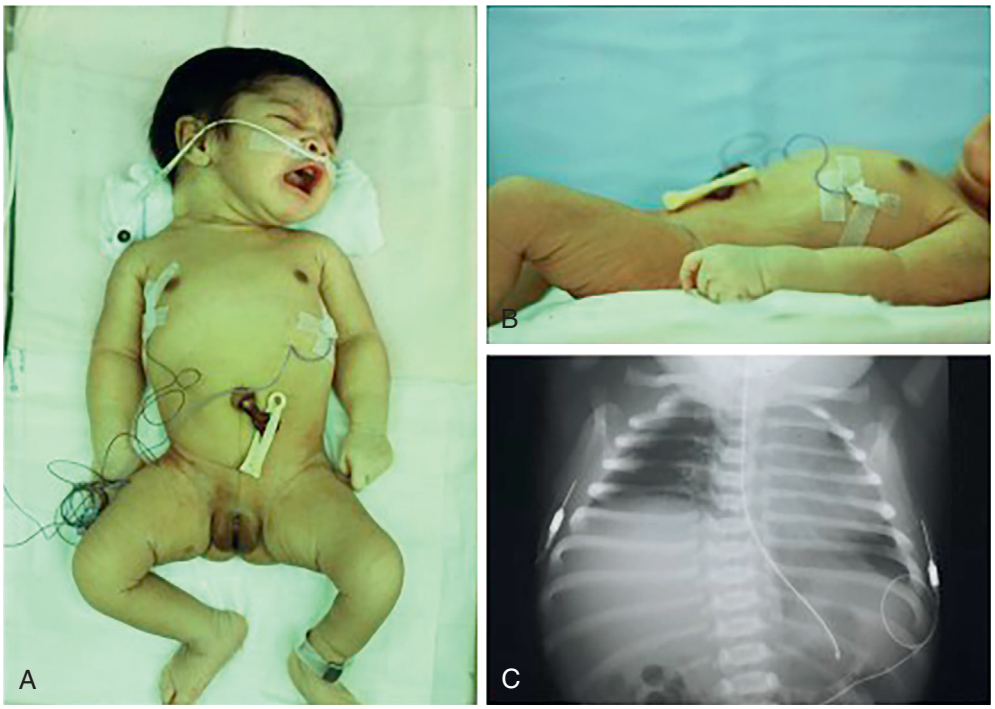
Although most (93%-95%) infants achieve return of function with conservative management, the remainder with persistent deficits may go on to development of long-term severe handicaps of the affected extremity. Early treatment offers significant improvement for about 90% of these children. Referral to centers that have an established rehabilitation program for infants with this condition may be initiated for a timely and successful treatment. In summary, the infant who does not improve spontaneously now has increased hope for recovery owing to advances in microsurgery and nerve transfer techniques.

Phrenic Nerve Paralysis

See Chapter 66. Phrenic nerve paralysis results in diaphragmatic paralysis and rarely occurs as an isolated injury in the neonate. Most injuries are unilateral and are associated with ipsilateral upper brachial plexus palsy.

Etiology

The most common cause is a difficult breech delivery. Lateral hyperextension of the neck results in overstretching or avulsion of the third, fourth, and fifth cervical roots, which supply the phrenic nerve.



Clinical Manifestations

The first sign may be recurrent episodes of cyanosis, usually accompanied by irregular and labored respirations. The respiratory excursions of the involved side of the diaphragm are largely ineffective, and the breathing is therefore almost completely thoracic, so that no bulging of the abdomen occurs with inspiration (Fig. 29.15*A*, B). The thrust of the diaphragm, which often may be felt just under the costal margin on the normal side, is absent on the affected side. Dullness to percussion and diminished breath sounds are found over the affected side. In a severe injury, tachypnea, weak cry, and apneic spells may occur.

Radiographic Manifestations

Radiographs taken during the first few days may show only slight elevation of the affected diaphragm, occasionally so

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

• **Fig. 29.15 A,** Nine-hour-old, 3190-g female infant born after difficult total breech extraction; during delivery, cervix clamped down on head, necessitating extensive tugging and pulling on both arms. Note markedly hyperexpanded chest and classic appearance of both upper extremities in Erb palsy positions. **B,** Lateral view of same infant, demonstrating increased anteroposterior diameter of chest and close-up view of left upper extremity adducted at shoulder, extended at elbow, and pronated and flexed at wrist. **C,** Significant elevation of right hemidiaphragm to level of fifth thoracic vertebra in same infant, compatible with paralysis of right hemidiaphragm. Note significant shifting of heart and mediastinum to the left.

subtle that it may be considered normal. Additional radiographs show the more apparent elevation of the diaphragm, with displacement of the heart and mediastinum to the opposite side (see Fig. 29.15*C*). Frequently, areas of atelectasis appear bilaterally. Early diagnosis can be confirmed by real-time ultrasonographic examination of the diaphragm, which reveals abnormal motion of the affected hemidiaphragm. This procedure provides the added advantage of availability at the bedside. Fluoroscopy should be reserved for equivocal cases. In still questionable cases, diagnosis can be further enhanced by transvenous electrical stimulation of the phrenic nerve.

Differential Diagnosis

Careful physical examination should allow differentiation among CNS, cardiac, and pulmonary causes of neonatal respiratory distress. The diagnosis can be confirmed by fluoroscopy and electrical stimulation of the phrenic nerve.

Treatment

Most infants require only nonspecific medical treatment. The infant should be positioned on the involved side, and oxygen should be administered for cyanosis or hypoxemia. Intravenous fluids may be necessary for the first few days. If the infant begins to show improvement, progressive oral or gavage feedings may be started. Antibiotics are indicated if pneumonia occurs.

Infants with more severe respiratory distress, particularly those with bilateral phrenic nerve palsy, may require assisted ventilation shortly after delivery. de Vries Reilingh and associates have reviewed their experience with 23 infants who incurred phrenic nerve injury as neonates.[18] Infants who had not recovered diaphragmatic function after 30 days of conservative treatment did not demonstrate spontaneous recovery thereafter. Accordingly, these investigators recommend limiting conservative treatment to 1 month, assuming the infant is adequately oxygenated with conventional techniques. The absence of definite improvement after 1 month is considered evidence of disruption of the phrenic nerve, thereby minimizing chances of complete spontaneous recovery. Infants in this category may be considered candidates for plication of the diaphragm or diaphragmatic pacing.

Prognosis

Many infants recover spontaneously. If avulsion of the cervical nerves has occurred, spontaneous recovery is not possible, and in the absence of surgery, the infant is susceptible to pneumonia in the atelectatic lung. Infants treated surgically do well, with no recurrence of pneumonia and no late pulmonary or chest wall complications.

Injury to the Sternocleidomastoid Muscle

Injury to the sternocleidomastoid muscle is designated muscular torticollis, congenital torticollis, or sternocleidomastoid fibroma. Its cause and pathologic features have been controversial.

Etiology

The birth trauma theory suggests that the muscle or fascial sheath is ruptured during a breech or difficult delivery involving hyperextension of the muscle. A hematoma develops and is subsequently invaded by fibrin and fibroblasts with progressive formation of scar tissue and shortening of the muscle. The intrauterine theory postulates abnormal pressure, position, or trauma to the muscle during intrauterine life. Another theory suggests a hereditary defect in the development of the muscle. Others have noted pathologic findings resembling infectious myositis, suggesting an infection in utero or a muscle injured at delivery. Davids and coworkers, based on use of MRI to visualize live infants and cadaver dissections and injection studies, suggest that congenital muscular torticollis results from intrauterine or perinatal compartment syndrome.[16]

In utero or intrapartum positioning of the head and neck in forward flexion, lateral bending, and rotation can result in the ipsilateral sternocleidomastoid muscle kinking on itself. If the kinking continues for a prolonged period in utero, an ischemic injury at the site could develop, followed by subsequent edema and development of a compartment syndrome. Therefore, the mechanism of injury is localized kinking or crush, in contrast to the previously suspected mechanism of stretching or tearing (Fig. 29.16).

• **Fig. 29.16** Algorithm illustrating the Davids study,[16] suggesting that congenital muscular torticollis results from intrauterine or perinatal compartment syndrome.

Clinical Manifestations

A mass in the midportion of the sternocleidomastoid muscle may be evident at birth, although usually it is first noted 10-14 days after birth. It is 1-2 cm in diameter, hard, immobile, fusiform, and well circumscribed; there is no inflammation or overlying discoloration. The mass enlarges during the following 2-4 weeks and then gradually regresses and disappears by age 5-8 months.

A transient torticollis produced by contracture of the involved muscle appears soon after birth. The head tilts toward the involved side, and the chin is somewhat elevated and rotated toward the opposite shoulder. The head cannot be moved passively into normal position. If the deformity persists beyond 3 or 4 years, the skull becomes foreshortened. Flattening of the frontal bone and bulging of the occipital bone occur on the involved side, whereas the contralateral frontal bone bulges and the occiput is flattened. The ipsilateral eyebrow is slanted; the clavicle and shoulder become elevated compared with the opposite normal side, and the ipsilateral mastoid process becomes more prominent. If treatment is not instituted, a lower cervical, upper thoracic scoliosis subsequently develops. Rarely, calcification develops in the affected muscles.

Differential Diagnosis

Careful radiographic examination should be made of the cervical spine and shoulders to rule out Sprengel deformity or Klippel-Feil syndrome, cervical myelodysplasia, and occipitalization of the atlas. In clinically equivocal cases, CT scans may differentiate classic muscular torticollis from other cervical soft tissue lesions that may cause torticollis (e.g., hemangioma, lymphangioma, and teratoma).

Treatment

Treatment should be instituted as early as possible. The involved muscle should be stretched to an overcorrected position by gentle, even, and persistent motion with the infant supine. The head is flexed forward and away from the affected side, and the chin is rotated toward the affected side. The mother can be instructed to repeat this maneuver several times a day. The infant also should be stimulated to turn the head spontaneously toward the affected side; the crib may be positioned so that the infant must turn to the desired position of overcorrection in looking for window light or at a mobile or favorite rattle. During sleep, the infant should be placed on the side of the torticollis; in this position, sandbags should be placed on each side of the infant's body for fixation. An alternative approach involves a helmet that is custom-made for the infant. Rubber straps made of surgical drain tubing attached to the helmet are in turn fixed to the side rails of the crib at night, with appropriate adjustments made to force the infant to sleep on the prominent side of the head. This results in stretching of the shortened sternocleidomastoid muscle.

Ultrasonography may be useful in defining the quantity of normal muscle remnant surrounding the lesion, thereby

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

helping to determine whether the infant requires no treatment at all, conservative stretching, or surgery.[14] Conservative therapy may be continued for 6 months. If the deformity has not been fully corrected, surgery may be considered to prevent permanent skull and cervical spine deformities.

Procedures that have been used include distal tenotomy, muscle lengthening, and excision of the affected muscle. All are followed by some problems. After tenotomy, contractures may recur. Lengthening is difficult because of imprecision in estimating how much elongation will be adequate for subsequent growth. Complete excision deforms the outline of the neck. Akazawa and associates reported favorable results after partial resection between 1 and 5 years of age.[2] This was followed postoperatively with massive cotton bandaging of the neck in the neutral position for 3 weeks. Plaster casts, a brace, and physical therapy were not used.

Prognosis

Most infants treated conservatively show complete recovery within 2-3 months. If surgery is necessary and is performed early, the facial asymmetry will disappear almost entirely. Infants treated before their first birthday have a better outcome than those treated later, regardless of the type of treatment. Nonsurgical treatment after 1 year is rarely successful.

Injuries to the Spine and Spinal Cord

Birth injuries to the vertebral spine and spinal cord are rarely diagnosed. The incidence of spinal cord injury in the neonatal period is 0.14 per 1000 live births. It is not certain whether the low incidence is real, reflecting improved obstetric techniques, or represents a tendency for postmortem examination to overlook spine and spinal cord lesions.

Etiology

Spinal cord injury has been usually reported as a result of excessive traction or torsion placed on the spine during traumatic or instrumented delivery or in association with underlying abnormalities of the cord or surrounding tissues. Ligamental laxity, weak muscles, and incomplete mineralization predispose these infants to these types of injury. Other predisposing factors include malpresentations, dystocia (especially shoulder), prematurity, primiparity, and assisted and precipitous delivery. Few cases of spinal cord injury after atraumatic vaginal delivery are also reported in the literature.[26] The injuries are usually caused by stretching of the cord. However, Hankins reported an infant with lower thoracic spinal cord injury after application of maternal fundal pressure to relieve shoulder dystocia.[31] Magnetic resonance imaging revealed focal spinal cord swelling involving T9 through T12, thought to represent ischemia or infarction caused by a compressive injury. The most common mechanism is forceful longitudinal traction on the trunk while the head is still firmly engaged in the pelvis. When combined with flexion and torsion of the vertebral axis, this becomes a more significant problem. Occasionally, a snap is felt by the obstetrician while traction is exerted. Although cesarean delivery has been recommended as optimal for infants in breech presentation with a hyperextended head, Maekawa and colleagues documented spinal cord injury after cesarean section.[47] In fact, the mother had reported weak fetal movements during the third trimester, which suggests that injury occurred before delivery. Difficulty in delivery of the shoulders in cephalic presentations may result in a similar mechanism of injury. The spinal cord is very delicate and inelastic. Its attachments are the cauda equina below and the roots of the brachial plexus and medulla above. Because the ligaments are elastic and the muscles delicate, the infant's vertebral column may be stretched easily. In addition, the dura is more elastic in the infant than in the adult. Consequently, strong longitudinal traction may be expected to cause elongation of the spinal column and to stretch the spinal cord and its membranes. The possible result is vertebral fracture or dislocation, or both, and cord transection. Most often, hemorrhage and edema produce a physiologic transection. The lower cervical and upper thoracic regions are most often involved, but occasionally the entire length of the spinal canal contains a heavy accumulation of blood.

Clinical Manifestations

Affected infants may follow one of four clinical patterns. Those in the first group often manifest a catastrophic presentation and are either stillborn or in poor condition from birth, with respiratory depression, decreased or absent movement, loss of reflexes, lack of response to painful stimulation, shock, and hypothermia. They deteriorate rapidly; death occurs within several hours, often before neurologic signs are obvious. These infants usually have a high cervical or brainstem lesion.

The second group consists of infants who at birth may appear normal or show signs similar to those of the first group; these infants die after several days. Cardiac function is usually relatively strong. Within hours or days, the central type of respiratory depression that is initially present may be complicated by respiratory distress of pulmonary origin, usually pneumonia. The spinal lesion, usually in the upper or midcervical region, frequently is not recognized for several days, when flaccidity and immobility of the legs are noted. Occasionally, urinary retention may be the first symptom. Paralysis of the abdominal wall is manifested by a relaxation of the abdominal wall and bulging at the flanks when the infant is held upright. The intercostal muscles may be affected if the lesion is high enough. Deep tendon reflexes and spontaneous reflex movements are absent. The infant is constipated. The brachial plexus is involved in about 20% of all cases. The spinal column is usually clinically and radiographically normal.

The third group, with lesions at the seventh cervical to first thoracic vertebra or lower, comprises infants who survive for long periods, some for years. Paraplegia noted at

birth may be transient. The lesion in the cord may be mild and reversible, or it may result in permanent neurologic sequelae with no return of function in the lower cord segments. The skin over the involved part of the body is dry and scaly, predisposing the infant to decubitus ulcers. Muscle atrophy, severe contractures, and bony deformities follow. Bladder distention and constant dribbling persist, and recurring urinary tract infections and pneumonia are common. Within several weeks or months, this clinical picture is replaced by a stage of reflex activity, or paraplegia-in-flexion. This is characterized by return of tone and rigid flexion of the involved extremities, improvement in skin condition with healing of decubitus ulcers, and periodic mass reflex responses consisting of tonic spasms of the extremities, spontaneous micturition, and profuse sweating over the involved part of the body.

Infants in the fourth group have subtle neurologic signs of spasticity thought to represent cerebral palsy. These patients have experienced partial spinal cord injuries and occasional cerebrovascular accidents.

Differential Diagnosis

Differential diagnosis of spinal cord injury in the neonate presenting with flaccid paralysis includes brachial plexopathy, intracranial injury, neuromuscular disease, and a tumor or underlying anomalies of the spinal cord. During the first few weeks of life injuries to the spinal cord may be confused with amyotonia congenita or myelodysplasia associated with spina bifida occulta. The former may be differentiated by the generalized distribution of the weakness and hypotonia and by the presence of normal sensation and sphincter control. The latter is usually associated with some cutaneous lesions over the sacral region such as dimples, angiomas, or abnormal tufts of hair; it is always associated with defects in the spinal lamina. Other conditions less often considered include transverse myelitis and spinal cord tumors, particularly in infants who demonstrate paralysis after an apparently normal labor and delivery. Cerebral hypotonia should be considered in infants who also demonstrate cranial nerve abnormalities, persistent primitive reflexes, and a dull facial appearance, contrasting to the bright, alert facies of the infant with spinal cord trauma. However, the concomitant occurrence of cerebral damage in an infant with spinal cord injury may confound the diagnosis. A final consideration is the infant with bilateral brachial plexus palsy with associated motor and sensory loss, or Horner syndrome; the demonstration of normal lower extremity function should rule out spinal cord injury.

Although somatosensory-evoked potential recording has been used in establishing a diagnosis of spinal cord injury, cervical responses are usually small and can be difficult to detect even in clinically normal infants; in addition, scalp potentials overlying the somatosensory cortex may be absent in normal term neonates. Ultrasonography has been used to evaluate severe spinal cord injury in neonates.[6] The procedure is easily performed at the bedside with no disturbance to the patient. Initial cord edema, hematomyelia, and hemorrhage outside the cord can be assessed. Magnetic resonance imaging provides a direct image of the spinal cord and is the most reliable modality available to evaluate presumptive cervical spinal cord injury in the infant.[52]

Treatment

Treatment is supportive and usually unsatisfactory. The infant affected at birth requires basic resuscitative and supportive measures. Infants who survive present a therapeutic challenge that can be met only by the combined and interested efforts of the pediatrician, neurologist, neurosurgeon, urologist, psychiatrist, orthopedist, nurse, physical therapist, and occupational therapist.

While the infant is reasonably stable, cervical and thoracic spine radiographs should be obtained. In the rare occurrence of vertebral fracture or dislocation or both, immediate neurosurgical consultation is necessary for reduction of the deformity and relief of cord compression, followed by appropriate immobilization. Lumbar puncture in the acute period is of little practical value and may aggravate existing cord damage if the infant is excessively manipulated during the procedure. After several days, however, a persistent spinal fluid block may be demonstrated and may be an indication for exploratory laminectomy at the site of trauma. This possibility should be suspected in an infant with partial paraplegia and negative radiographs.

Prompt and meticulous attention must be given to skin, bladder, and bowel care. The position of paralyzed parts should be changed every 2 hours. Areas of anesthetic skin should be washed, dried, and gently massaged daily. Lambs' wool covers are helpful in preventing pressure necrosis of skin. Benzoin tincture applications help protect the skin in pressure areas. A decubitus ulcer is treated by scrupulous cleansing and complete freedom from weight bearing and friction. An indwelling urethral catheter should be inserted within several hours after severe cord trauma at any level. Repeated instrumentation should be avoided. Cultures of urine should be obtained weekly and as clinically indicated. Antibiotic therapy should be used only in the presence of infection. After several weeks, the infant reaches the stage of paraplegia-in-flexion, and urinary retention usually is replaced by regular episodes of spontaneous voiding. The indwelling catheter may then be removed, and postvoid bladder residuals should be measured. A renal sonogram and a conventional fluoroscopically guided voiding cystourethrogram should be obtained. If there are large postvoid residuals (>10-15 mL) or if the renal sonogram or cystogram shows abnormality, urodynamic studies may be necessary. A high-pressure neurogenic bladder is treated with an anticholinergic agent such as oxybutynin chloride, concurrently with clean intermittent bladder catheterization every 3-4 hours. Treatment of the low-pressure neurogenic bladder requires only clean intermittent catheterization.

Fecal retention also is a common problem, especially after total cord transection. Appropriate dietary balance should aid in keeping the stools soft. Early use of glycerin suppositories at regular intervals encourages automatic defecation. Digital manipulation may be necessary to relieve fecal impaction.

Physical rehabilitation should be instituted early in an attempt to minimize deformity. After several years, orthopedic procedures may still be necessary to correct contractures and bony deformities.

Prognosis

The prognosis varies with the severity of the injury. Most severe injuries result in death shortly after birth. Infants with cord compression from vertebral fractures or dislocations or both may recover with reasonable return of function if prompt neurosurgical removal of the compression is performed. Infants with mild injuries or partial transections may recover with minimal sequelae. Magnetic resonance imaging evidence of hemorrhage in the cervical spinal cord portends a poor neurologic outcome.[52] If MRI reveals extensive edema in multiple spinal cord segments without concurrent hemorrhage, complete recovery is possible. Infants who exhibit complete physiologic cord transection shortly after birth without vertebral fracture or dislocation have an extremely poor outlook for recovery of function. Many die in infancy of ascending urinary tract infection and sepsis. Long-term survivors have been reported to live into their third decade. They are extremely rare, and although they may have normal intelligence and learn to walk with special appliances, these children face the late complications of pain; spasms; autonomic dysfunction; bony deformities; and genitourinary, psychiatric, and school problems.

MacKinnon and colleagues have published an algorithm for predicting outcome in infants with upper cervical spinal cord injury; the algorithm is based on age at first breath and rate of recovery of breathing and limb movements in the first few weeks and months of life.[46] For infants with rapid recovery, the prognosis was clarified by age 3 weeks. Infants who demonstrated very slow or no recovery of breathing or extremity movements by 3 months of age universally had a poor outcome. Patients with intermediate rates of recovery were thought to have an uncertain long-term prognosis at 3 months of age.

Injuries to Intra-Abdominal Organs

Although birth trauma involving intra-abdominal organs is uncommon, it frequently must be considered by the physician who cares for neonates, because deterioration can be fulminant in an undetected lesion, and therapy can be very effective when a lesion is diagnosed early. Intra-abdominal trauma should be suspected in any newborn with shock and abdominal distention or pallor, anemia, and irritability without evidence of external blood loss.

Rupture of the Liver

The liver is the most frequently injured abdominal organ during the birth process. The autopsy incidence of liver injury varies from 0.9%-9.6%.[66]

Etiology

Birth trauma is the most significant factor contributing to liver injury. The condition usually occurs in large infants, infants with hepatomegaly (e.g., infants with erythroblastosis fetalis and infants of diabetic mothers), and infants who underwent breech delivery. Manual pressure on the liver during delivery of the head in a breech presentation is probably a typical mechanism of injury. Prematurity and postmaturity also are thought to predispose the infant to this injury. Other contributing factors include asphyxia and coagulation disorders. Trauma to the liver more often results in subcapsular hematoma than actual laceration of the liver.

Clinical Manifestations

The infant usually appears normal the first 1-3 days but rarely for as long as 7 days. Nonspecific signs related to loss of blood into the hematoma may appear early; they include poor feeding, listlessness, pallor, jaundice, tachypnea, and tachycardia. A mass may be palpable in the right upper quadrant of the abdomen. The hematocrit and hemoglobin values may be stable early in the course, but serial determinations suggest blood loss. These manifestations are followed by sudden circulatory collapse, usually coincident with rupture of the hematoma through the capsule and extravasation of blood into the peritoneal cavity. The abdomen then may be distended, rigid, and dull to percussion, occasionally with a bluish discoloration of the overlying skin, which may extend over the scrotum in male infants. Abdominal radiographs may suggest the diagnosis by revealing liver enlargement, an abnormal course of a nasogastric tube or umbilical venous catheter, or uniform opacity of the abdomen, indicating free intraperitoneal fluid. Although paracentesis can confirm whether the latter indicates free blood in the peritoneal cavity, ultrasonography offers a noninvasive method of diagnosis.[66] Fresh intrahepatic hemorrhage appears echogenic, with possible enlargement of the involved lobe; with involution of the hemorrhage, the lesion becomes more echolucent and may disappear. Computed tomography scan of the abdomen also may assist in establishing a diagnosis of subcapsular hemorrhage without rupture.

Differential Diagnosis

This lesion is one of several that can result in hemoperitoneum; others include trauma to the adrenal glands, kidneys, gastrointestinal tract, and spleen. The presence of a right upper quadrant mass suggests trauma to the liver, but absence of a mass does not rule it out. Abdominal radiography, ultrasonography, and intravenous pyelography may assist in pinpointing the site of trauma, but ultimately a definitive diagnosis can be made only by laparotomy.

Treatment

Immediate management consists of transfusion with packed red blood cells, as well as recognition and correction of any coagulation disorder. The role of surgical intervention is controversial. Hemostasis may be difficult to achieve at surgery. Consequently, blood transfusion and the tamponade of intra-abdominal pressure might be adequate therapy in some infants.

Prognosis

In unrecognized liver trauma with formation of a subcapsular hematoma, shock and death may result if the hematoma ruptures through the capsule, reducing the pressure tamponade and resulting in new bleeding from the liver. Recognition of the possibility of liver rupture in infants with a predisposing birth history, followed by early diagnosis and prompt therapy, should improve the prognosis. Early diagnosis and correction of any existing coagulation disorder also improve the prognosis.

Rupture of the Spleen

Rupture of the spleen in the newborn occurs much less often than rupture of the liver. However, recognition of this condition is equally important because of its similar potential for fulminant shock and death if the diagnosis is delayed.

Etiology

The condition is most common in large infants, infants delivered in breech position, and infants with erythroblastosis fetalis or congenital syphilis in whom the spleen is enlarged and more friable and thereby susceptible to rupture either spontaneously or after minor trauma. An underlying clotting defect also has been implicated. Rupture of the spleen has occurred in normal-sized infants with uneventful deliveries and no underlying disease.[35]

Clinical Manifestations

Clinical signs indicating blood loss and hemoperitoneum are similar to those described for hepatic rupture. The hemoglobin and hematocrit values decrease, and abdominal paracentesis may reveal free blood. Several infants have been described in whom the blood was circumscribed within the leaves of the phrenicosplenic ligament and, therefore, was not clinically detectable. Occasionally, a left upper quadrant mass may be palpable, and radiographs of the abdomen may show medial displacement of the gastric air bubble.

Differential Diagnosis

Rupture of the liver and trauma to the adrenal glands, kidneys, and gastrointestinal tract must be distinguished.

Treatment

Packed red blood cells should be transfused promptly, and any coexisting clotting defect should be corrected. This should be followed by immediate exploratory laparotomy. Every attempt should be made to repair and preserve the spleen to prevent the subsequent increased risk for infection. Packing of the wound surface with Gel Foam® and Surgicel® has been used to stop the oozing of blood.[35] The Gel Foam® and Surgicel® may be removed at a follow-up laparotomy within several days, at which time the spleen may be inspected for rebleeding.

Prognosis

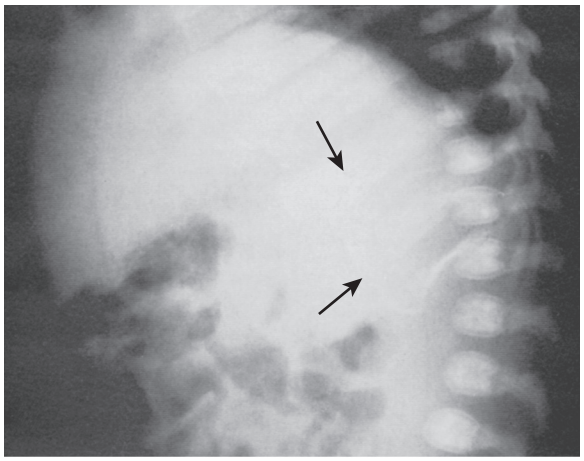
With early recognition and emergency surgery, the survival rate should approach 100%.

Adrenal Hemorrhage

Neonatal adrenal hemorrhage is more common than previously suspected; some autopsy studies have revealed a high incidence of subclinical hemorrhage. Massive hemorrhage is much less common, and the incidence is difficult to determine because the diagnosis is often unsuspected and considered retrospectively only years later, when calcified adrenal glands are unexpectedly found on radiographs or at autopsy.

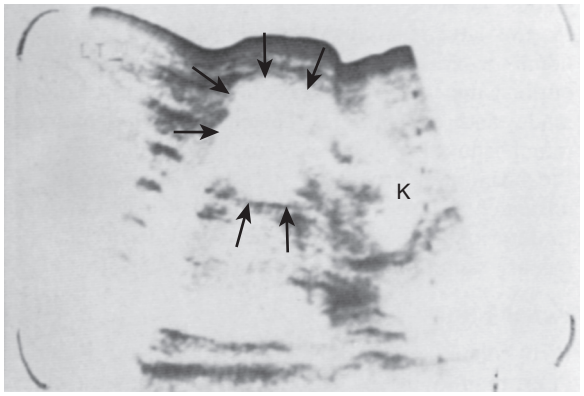
Etiology

The most likely cause is birth trauma; risk factors include macrosomia, diabetes in the mother, breech presentation, congenital syphilis, and dystocia. Placental hemorrhage, anoxia, hemorrhagic disease of the newborn, prematurity, and, more recently, neuroblastoma have been implicated. Pathologic findings vary from unilateral minute areas of bleeding to massive bilateral hemorrhage. The increased size and vascularity of the adrenal gland at birth may predispose it to hemorrhage.



Clinical Manifestations

Signs vary with the degree and extent of hemorrhage. The classic findings are fever, tachypnea out of proportion to the degree of fever, yellowish pallor, cyanosis of the lips and fingertips, a mass in either flank with overlying skin discoloration, and purpura. Findings suggesting adrenal insufficiency include poor feeding, vomiting, diarrhea, obstipation, dehydration, abdominal distention, irritability, hypoglycemia, uremia, rash, listlessness, coma, convulsions, and shock.



Radiographic Manifestations

Initial radiographic manifestations may be limited to widening of the retroperitoneal space with forward displacement of the stomach and duodenum or downward displacement of the intestines or kidneys. In time, calcification may appear. Typically this is rimlike and has been observed as early as the 12th day of life. After several weeks the calcification becomes denser and retracted and assumes the configuration of the adrenal gland (Fig. 29.17). Ultrasonographic examination of the neonate is an excellent adjunctive method of diagnosis. Abdominal ultrasonography performed during the first several days may reveal a

• **Fig. 29.17** Lateral abdominal radiographs of a 5312-g male infant delivered vaginally, with difficulty after shoulder dystocia. At 48 hours, fever, icterus, and slow feeding were noted, and a mass was palpable above the left kidney. At 31 days, there was dense, retracted calcification (*arrows*) that assumed the configuration of the adrenal gland.

• **Fig. 29.18** Sagittal gray-scale abdominal ultrasonographic examination of a 4564-g male infant whose mother had gestational diabetes. Problems included fracture of right clavicle, hyperbilirubinemia requiring three exchange transfusions, and abdominal distention with large left flank mass. Ultrasonographic examination at 14 days demonstrated fluid-filled mass (*arrows*) superior to left kidney (*K*), representing adrenal hemorrhage. (Courtesy of Dr. John C. McFadden, Lutheran General Children's Hospital, Park Ridge, IL.)

solid lesion in the location of the adrenal hemorrhage; this is thought to represent either clot fragmentation or diffuse clotted blood throughout the adrenal gland. If adrenal hemorrhage is suspected, ultrasonographic examination should be repeated at 3- to 5-day intervals. If adrenal hemorrhage has occurred, the lesion will change from a solid to a cystic appearance, coincident with liquefaction, degeneration, and lysis of the clot (Fig. 29.18).

Differential Diagnosis

Adrenal hemorrhage must be distinguished from other causes of abdominal hemorrhage. In addition, when a mass is palpable, the differential diagnosis must include the multiple causes of flank masses in the newborn, such as genitourinary anomaly, Wilms tumor, and neuroblastoma. If the infant is large or the delivery is traumatic or breech, an adrenal hemorrhage is most likely. Neuroblastoma may be distinguished by persistent demonstration of a solid lesion on serial ultrasonographic examinations and by increased excretion of vanillylmandelic acid and other urinary catecholamines in 85%-90% of affected infants. Blood pressure measurements and radiographs also may help to evaluate this possibility.

Treatment

Significant blood loss should be replaced with packed red blood cell transfusion. Suspicion of adrenal insufficiency may warrant the use of intravenous fluids and corticosteroids. The decision for surgical intervention is dictated by the location and degree of hemorrhage. If it appears to be retroperitoneal and limited by the perinephric fascia, some recommend blood replacement and careful observation in the hope of spontaneous control by tamponade; often this approach is successful, and surgery is not necessary. If paracentesis reveals blood or if blood loss exceeds replacement, exploratory laparotomy is indicated. Surgery may involve evacuation of hematoma, vessel ligation, and adrenalectomy with or without nephrectomy. When the hemorrhagic process extends to the peritoneal cavity, peritoneal exploration and evacuation of clots are indicated.

Prognosis

Small hemorrhages are probably often asymptomatic and have no associated significant morbidity, judging from the unexpected discovery of calcified adrenal glands on abdominal radiographs taken for other reasons later in infancy and childhood. If hemoperitoneum or adrenal insufficiency or both develop, the outlook depends on the speed with which diagnosis is made and appropriate therapy instituted. Surviving infants should be followed closely after discharge from the hospital. Adrenal function should be tested with adrenocorticotropic hormone stimulation at a later date to determine whether a normal response occurs in the urinary excretion of 17-hydroxycorticosterone.

Renal Injury

Birth-related injury to the kidneys occurs rarely and less often than injury involving the liver, spleen, or adrenal gland.

Etiology

Factors that predispose an infant to any form of intra-abdominal injury also may affect the kidneys. They include macrosomia, malpresentation (especially breech), and precipitous labor or delivery or both. The potential for renal injury is enhanced by a pre-existing anomaly (e.g., hydronephrosis).

Clinical Manifestations

The infant may demonstrate the same signs of blood loss and hemoperitoneum noted in the other intra-abdominal

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

lesions. More specific signs include ascites, flank mass, and gross hematuria. Radiographs may confirm the presence of ascites and flank mass. Ultrasonographic examination may further define the mass (e.g., presence of cysts) and reveal ascites and retroperitoneal hematoma. Application of a Doppler probe to the renal hilus and the region of the vessels can assist in assessing renal arterial and venous flow. In ambiguous cases, CT scanning may help to clarify ultrasonographic findings.

Differential Diagnosis

Other lesions that cause hematuria must be considered. They include renal tumor with hemorrhage and renal vein thrombosis with infarction.

Treatment

After providing supportive measures similar to those used in other intra-abdominal injuries, the clinician should consider laparotomy. Possible findings at surgery include kidney rupture or transection, renal pedicle avulsion, and kidney necrosis. Use of an intraoperative Doppler probe can determine the status of renal blood flow. If there is no flow, nephrectomy is indicated.

Prognosis

Early recognition of possible renal vascular injury may lead to earlier intervention, with the potential for kidney salvage.

Injuries to the Extremities

Fracture of the Humerus

After the clavicle, the humerus is the bone most often fractured during the birth process.

Etiology

The most common mechanisms responsible are difficult delivery of extended arms in breech presentations and of the shoulders in vertex presentations. Besides traction with simultaneous rotation of the arm, direct pressure on the humerus also is a factor. This may account for the occurrence of fracture of the humerus in spontaneous vertex deliveries. The fractures are usually in the diaphysis. They are often greenstick fractures, although complete fracture with overriding of the fragments occasionally occurs.

Clinical Manifestations

A greenstick fracture may be overlooked until a callus is noted. A complete fracture with marked displacement of fragments presents an obvious deformity that calls attention to the injury. Often the initial manifestation of the fracture is immobility of the affected arm. Palpation reveals tenderness, crepitation, and hypermobility of the fragments. The ipsilateral Moro response is absent. Radiographs confirm the diagnosis.

Differential Diagnosis

The differential diagnosis includes all the previously noted lesions that cause immobility of the arm. An associated brachial plexus injury occasionally occurs.

Treatment

The affected arm should be immobilized in adduction for 2-4 weeks. This may be accomplished by maintaining the arm in a hand-on-hip position with a triangular splint and a Velpeau bandage, strapping the arm to the chest, or application of a cast.

Prognosis

The prognosis is excellent. Healing is associated with marked formation of callus. Moderate overriding and angulation disappear with time because of the excellent remodeling power of infants. Complete union of the fracture fragments usually occurs by 3 weeks. Fair alignment and shortening of less than 1 inch indicate satisfactory closed reduction. Fractures of the long bones in infants always result in epiphyseal stimulation; the closer the fracture to the epiphyseal cartilage, the greater the degree of subsequent overgrowth.

Fracture of the Radius

Fracture of radius is an extremely rare occurrence, reported in a macrosomic infant born after a shoulder dystocia.[70] There was a concurrent midhumeral shaft fracture of the other arm, with lateral displacement of the distal fragment.

Etiology

This injury, because it was a spiral fracture, was thought to have resulted from rotational maneuvers attempted to alleviate the shoulder dystocia. An alternative explanation is compressive forces related to the shoulder dystocia itself; that is, the affected arm could have incurred an extreme degree of direct compression by the overlying symphysis pubis.

Clinical Manifestations

Physical findings were limited to bruising of the affected forearm. However, as in any long bone fracture, if complete with displacement of fragments, additional findings may include swelling, deformity, tenderness, and crepitation.

Treatment

In the presence of bilateral fractures, casts may need to be placed on both arms. If it occurs as an isolated injury, without displacement, a radial fracture can be treated with simple immobilization.

Prognosis

Radiographs at 2 weeks of age revealed a healed radial fracture and marked callus formation around the humeral fracture.

Fracture of the Femur

Although a relatively infrequent injury, fracture of the femur is by far the most common fracture of the lower extremity in the newborn.

Etiology

Fracture of the femur usually follows a breech delivery when the leg is pulled down after the breech is already partially fixed in the pelvic inlet or when the infant is improperly held by one thigh during delivery of the shoulders and arms. Femoral fracture even may occur during cesarean delivery.[3] Infants with congenital hypotonia may be more prone to this injury if their underlying disorder (e.g., severe Werdnig-Hoffmann disease) is associated with decreased muscle bulk at birth. Senanayake and associates reported on an infant who sustained a midtrimester fracture of the femur.[65] No apparent maternal trauma was identified during the pregnancy. The infant was otherwise normal, with no other fractures and no evidence of skeletal dysplasia. Follow-up through age 6 years revealed normal growth, with no additional fractures. The authors were unable to identify an etiology, other than possible "unnoticed maternal trauma." It is critical to document such an occurrence to preclude inappropriate focus on the delivery process as a cause of the fracture. In addition, failure to identify and document the timing of the fracture may lead to subsequent suspicion of child abuse.

Clinical Manifestations

Usually an obvious deformity of the thigh is seen (Fig. 29.19); as a rule, the bone breaks transversely in the upper half or third, where it is relatively thin. Less often, the injury may not be appreciated until several days after delivery when swelling of the thigh is noted; this swelling may be caused by hemorrhage into adjacent muscle. The infant refuses to move the affected leg or cries in pain during passive movement or with palpation over the fracture site.

• **Fig. 29.19** Fullness and obvious deformity of left thigh in 4020-g male infant with Werdnig-Hoffmann disease. Muscle wasting of both lower extremities also is apparent. Radiograph confirmed fracture of proximal third of left femur.

Radiographs almost always show overriding of the fracture fragments.

Treatment

Optimal treatment is traction-suspension of both lower extremities, even if the fracture is unilateral. The legs are immobilized in a spica cast; with Bryant traction, the infant is suspended by the legs from an overhead frame, with the buttocks and lower back just raised off the mattress. The legs are extended and the thighs flexed on the abdomen. The weight of the infant's body is enough to overcome the pull of the thigh muscles and thereby reduce the deformity. The infant is maintained in this position for 3-4 weeks until adequate callus has formed and new bone growth has started. During the treatment period, special attention should be given to careful feeding of the infant and to protection of bandages and casts from soiling with urine and feces.

Prognosis

The prognosis is excellent; complete union and restoration without shortening are expected. Extensive calcification may develop in the areas of surrounding hemorrhage but is resorbed subsequently.

Dislocations

Dislocations caused by birth trauma are rare. Often an apparent dislocation is actually a fracture displaced through an epiphyseal plate. Because the epiphyseal plate is radiolucent, a fracture occurring adjacent to an unmineralized epiphysis gives a radiographic picture simulating a dislocation of the neighboring joint. This type of injury has been termed *pseudodislocation*. Because the humeral and proximal femoral epiphyses are usually not visible on radiographs at birth, a pseudodislocation can occur at the shoulder, elbow, or hip.

Of the true dislocations, those involving the hip and knee are probably not caused by the trauma of the birth process. Most likely, they are either intrauterine positional deformities or true congenital malformations. A true dislocation resulting from birth trauma is that involving the radial head. This has been associated with traumatic breech delivery. Recently, radial head dislocation was reported as a late complication years after brachial plexus palsy.[37] Examination reveals adduction and internal rotation of the affected arm, with pronation of the forearm; Moro response is poor, and palpation reveals lateral and posterior displacement of the radial head. This is confirmed by radiographs. With supination and extension, the radial head can be reduced readily. This should be done promptly, followed by immobilization of the arm in this position in a circular cast for 2-3 weeks. Early recognition and treatment should result in normal growth and function of the elbow.

Bayne and associates illustrated the importance of establishing an early diagnosis when they described a term infant with a swollen, tender elbow after breech delivery.[7]

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Movement produced obvious pain. Radiographs at that time and again at 8 months of age were misinterpreted as normal. At 1 year, an orthopedist diagnosed anteromedial dislocation. Because of several unsuccessful attempts at closed reduction, future osteotomy was required to treat this now permanent deformity.

Epiphyseal Separations

As with dislocations, epiphyseal separations are rare. They occur mostly in primiparity, dystocic deliveries, and breech presentations, especially those requiring manual extraction or version and extraction. Any delivery associated with vigorous pulling may predispose the infant to this injury. The upper femoral and humeral epiphyses are most often involved. Usually on the second day, the soft tissue over the affected epiphysis develops a firm swelling with reddening, crepitus, and tenderness. Active motion is limited, and passive motion is painful. If the injury is in the upper femoral epiphysis, the infant assumes the frog-leg position with external rotation of the leg.

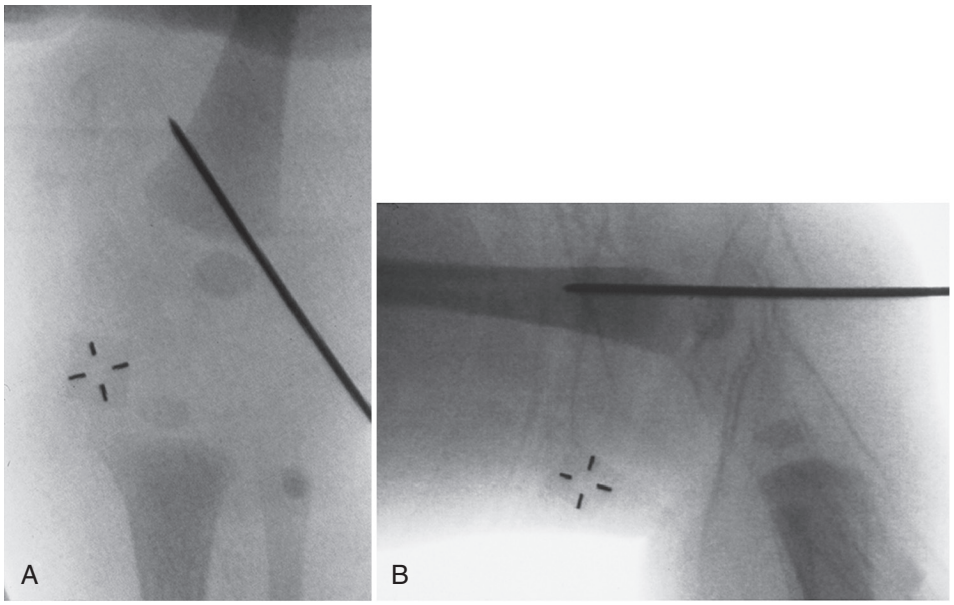
Early radiographs show only soft tissue swelling, with occasional superolateral displacement of the proximal femoral metaphysis. Because the neonatal femoral capital epiphysis is not ossified, this can be mistakenly interpreted as congenital hip dislocation. However, the presence of pain and tenderness would make dislocation unlikely. Besides plain radiographs of the hips, an infant with a history and physical examination compatible with traumatic epiphysiolysis should also undergo ultrasonography before manipulation is attempted. Magnetic resonance imaging may be a better tool for earlier detection. This examination would demonstrate a normal femoroacetabular relationship, in contrast with the abnormal findings in an infant with septic arthritis and congenital hip dislocation. In addition, in the presence of traumatic epiphysiolysis the femoral head and neck would not be continuous, in contrast with the findings of septic arthritis and congenital hip dislocation. Further differentiation between traumatic epiphysiolysis and septic arthritis can be provided by arthrocentesis; in epiphysiolysis, the joint does not contain excess fluid, and what is obtained may be serosanguineous, whereas in septic arthritis, purulent fluid is obtained. After 1-2 weeks, extensive callus appears, confirming the nature of the injury; during the third week, subperiosteal calcification appears.

If possible, treatment should be conservative. Closed reduction and immobilization are indicated within the first few days before rapidly forming fibrous callus prevents mobilization of the epiphysis. The hip is immobilized in the frog-leg position, as in congenital dislocation. Poorly immobilized fragments of the proximal or distal femur (Fig. 29.20) may require temporary fixation with a Kirschner wire (Fig. 29.21).[49] Union usually occurs within 10-15 days. Untreated or poorly treated epiphyseal injuries may result in subsequent growth distortion and permanent deformities such as coxa vara. Mild injuries carry a good prognosis.

• **Fig. 29.20** Radiograph of lower extremities of a 4205-g male delivered precipitously after complete breech presentation. Radiograph demonstrates displaced distal femoral physeal fracture on left (*arrow*) and nondisplaced distal femoral physeal fracture on right (*arrow*). (From Mangurten HH, et al. Neonatal distal femoral physeal fracture requiring closed reduction and pinning. *J Perinatol.* 2005;25:216.)

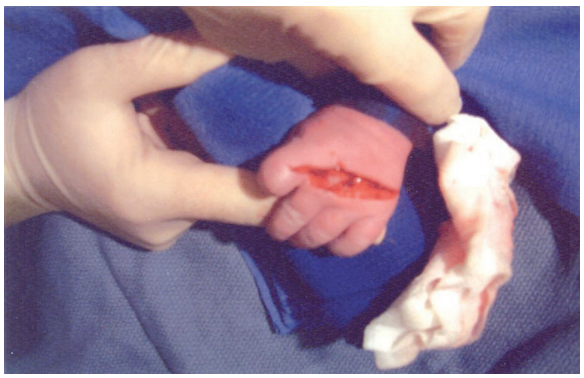
Deep Tendon Injuries

Accidental fetal injury is a serious but underreported complication of emergency cesarean deliveries. Although the most commonly documented injury is superficial skin laceration, deeper and more serious injuries have been described, including amputation of the distal digits and tendon injuries requiring surgical intervention.[1] A prospective study at 13 university centers in the United States revealed an incidence of fetal injury of 1.1% during emergency cesarean section, with skin lacerations accounting for 64% of injuries overall.[4] Neonatal tendon injuries during cesarean section have rarely been reported in the literature.[23] Prazad and associates reported a case of severe multiple extensor tendon lacerations with open metacarpophalangeal joints (Fig. 29.22) sustained at the time of an emergency cesarean delivery.[59]



Risk Factors Associated With Deep Tendon Injury

Several factors associated with increased risk for fetal laceration and fetal injury are emergency cesarean delivery, shortened duration between abdominal skin incision and delivery of infant, type of uterine incision, premature rupture of membranes, abnormal fetal presentation, and active labor.[29]



Management

Even though multiple surgical techniques have been described for adults with the same kind of injury, there is no information available regarding a favorable surgical approach in neonates. Fuller and colleagues described two different methods of extensor tendon repair.[23] Laceration in one finger was closed in a single layer using a full-thickness stitch through the skin and extensor mechanism, and laceration in the second finger was repaired in two layers. Excellent clinical outcome of both fingers was noted after surgery. Kavouksorian and coworkers reported a flexor tendon laceration of the hand that occurred during emergency cesarean delivery with excellent functional results despite delayed primary closure.[40] Prazad and colleagues used immediate (within 3 hours of birth) microsurgical repair at the bedside under local field block anesthesia to achieve an excellent functional outcome at 18 months of age.[59]

• **Fig. 29.22** Laceration extending from index finger to baby finger, with open metacarpophalangeal joints. There were complete extensor tendon lacerations of middle, ring, and baby fingers, with partial laceration of index finger. (From Prazad P, et al. Complication of emergency cesarean section: open metacarpophalangeal disarticulation and complete extensor tendon lacerations of the hand in a neonate. *J Neonat Perinat Med.* 2009;2:131-133.)

Other Peripheral Nerve Injuries

In contrast to the brachial plexus and phrenic and facial nerves, other peripheral nerves are injured less often at birth and usually in association with trauma to the extremity. Radial palsy has occurred after difficult forceps extractions, both from pressure of incorrectly applied forceps and in association with fracture of the arm. Occasionally the palsy occurs later, when the radial nerve is enmeshed within the callus of the healing fracture. Frequently associated subcutaneous fat necrosis overlies the course of the radial nerve along the lateral aspects of the upper arm. The presence of isolated wristdrop with weakness of the wrist, finger, and thumb extensors; skin changes overlying the course of the nerve; and absence of weakness above the elbow distinguish this condition from brachial plexus injury. Palsies of the femoral and sciatic nerves have occurred after breech extractions; sciatic palsy has followed extraction by the foot. Passive range-of-motion exercises are usually the only therapy required. Complete recovery usually occurs within several weeks or months.

Trauma to the Genitalia

Soft tissue injuries involving the external genitalia sometimes occur, especially after breech deliveries and in large infants.

Scrotum and Labia Majora

Edema, ecchymoses, and hematomas can occur in the scrotum and labia majora, especially when they are the presenting parts in a breech presentation. Because the male newborn has a pendulous urethra that is vulnerable to compression or injury, it is possible for significant trauma to occur after a protracted labor in the breech position; the mechanism is believed to be compression of the urethra against a firm structure in the maternal bony pelvis. Rarely, this may cause marked temporary hydronephrosis after delivery. The hydronephrosis usually resolves within 3 days. Because of laxity of the tissues, the degree of swelling and of discoloration occasionally is extreme enough (Fig. 29.23) to evoke considerable concern among the medical and nursing staff, especially regarding deeper involvement (e.g., periurethral hemorrhage and edema), which might hinder

• **Fig. 29.23** Hematoma of scrotum and penis in a 3895-g male infant delivered vaginally after frank breech presentation. Infant voided at 22 hours and regularly thereafter. Swelling diminished appreciably within 5 hours and was gone by third day. Discoloration was greatly diminished by second day.

normal micturition. However, this has not generally been a problem, and frequently these infants void shortly after arriving in the nursery. Spontaneous resolution of edema occurs within 24-48 hours, and resolution of discoloration occurs within 4-5 days. Treatment is not necessary. Secondary ulceration, necrosis, or eschar formation is rare unless an associated underlying condition such as herpes simplex virus infection is present.

Marked scrotal hematoma may simulate testicular torsion, particularly when accompanied by a solid scrotal mass.[19] Because untreated torsion may result in loss of the testis, it is critical to distinguish the two lesions. This may be done by Doppler ultrasonography. If blood flow to the testes is clearly demonstrated, and if the testes appear symmetric in size and echotexture, torsion may essentially be ruled out.

Deeper Structures

Much less often birth trauma may involve the deeper structures of the genitalia. If the tunica vaginalis testis is injured and blood fills its cavity, a hematocele is formed. Absence of transillumination distinguishes this from a hydrocele. If it appears that the infant is in pain, the scrotum may be elevated and cold packs applied. Spontaneous resolution is the usual course.

The testes may be injured, often in association with injury to the epididymis. Usually the involvement is bilateral. The testes may be enlarged, smoothly rounded, and insensitive. The infant may be irritable, with vomiting and poor feeding. Urologic consultation is indicated; occasionally exploration and evacuation of blood are necessary, especially with increasing size of the testes. Severe trauma may result in atrophy or failure of the testes to grow. The occasional finding in older children of a circumscribed fibrous area within the testicular tissue is thought to represent past birth trauma to the gland.

Injuries Related to Intrapartum Fetal Monitoring

Continuous monitoring of the fetal heart rate and the intermittent sampling of fetal scalp blood for determination of acid-base status often are used to monitor the fetus during labor. Thousands of patients have been monitored by these methods (see Chapter 12). The relative infrequency of complications indicates that in experienced hands, these procedures are generally safe. However, certain specific complications have occurred.

Injuries Related to Direct Fetal Heart Rate Monitoring

Direct monitoring of the fetal heart rate during labor depends on application of an electrode to the fetal scalp or other presenting part. Superficial abrasions, lacerations, and hematomas can occur rarely at the site of application of the electrode. These complications require no specific therapy beyond local treatment.

Rarely, abscesses of the scalp may follow application of scalp electrodes. These abscesses usually have been sterile and have required only local treatment. Systemic signs or symptoms require evaluation for possible septicemia.

Lauer and Rimmer reported a potentially more serious complication related to use of a spiral fetal scalp electrode,[42] as noted earlier in this chapter. At delivery, the electrode was noted to be attached to the infant's eyelid, resulting in a superficial laceration. Marked surrounding edema was considered to have protected the infant from more severe injury.

Injuries Related to Fetal Scalp Blood Sampling

Fetal biochemical monitoring requires puncture of the presenting part, usually the scalp, with a 2-mm blade and the collection of blood under direct visualization in a heparinized tube. Major complications that may occur rarely are excessive bleeding and accidental breakage of the blades. The bleeding can be stopped by pressure, but on occasion this requires sutures. Rarely, blood replacement may be required. It is important to obtain a detailed family history of bleeding disorders before initiation of this procedure.

The second major complication has been breakage of the blade within the fetal scalp. Removal soon after delivery is recommended to prevent secondary infection. This is accomplished by use of a magnet attached to a small forceps that probes the puncture site and elicits a click as the blade is attracted to the magnet. On occasion, radiographic localization followed by a small incision is necessary for withdrawal of the blade.

Injuries Related to Trauma During Pregnancy

Trauma to women during pregnancy continues to be a major cause of maternal, fetal, and neonatal mortality and

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

morbidity.[10] The risk of trauma is enhanced by the enlarged size of the gravid uterus, rendering it more exposed to weapons and contact with hard surfaces, putting the developing fetus in close proximity to injury. Trauma unrelated to pregnancy events, which in turn may injure the fetus, may be divided into two major subsets, accidental and intentional. The accidental category most commonly involves automobile accidents in which the woman is the driver, passenger, or pedestrian. In addition, these accidents may result from cycling, falling while horseback riding, or simple falls. The intentional category usually results from criminal intent, resulting in shooting, stabbing, or blunt trauma to the abdomen. Fetal head injuries have been reported after violent insertion of a blunt object through the vagina with an intention to terminate the pregnancy. These may result in skull fractures and intraventricular hemorrhage leading to premature labor and fetal morbidity and mortality. Gunshot wounds, in particular, during pregnancy may result in devastating effects on both mother and fetus throughout gestation. Not only may mother and fetus sustain significant organ damage from gunshot wounds, but also the extent of the physical maternal injury may dictate preterm delivery (Fig. 29.24). Prognosis usually is worse in the fetus than the mother. In a review of 119 cases of gunshot injuries to the uterus, Buchsbaum reported a perinatal mortality rate of 66%.[11] A well-coordinated team of surgeons, obstetricians, and neonatologists providing timely and comprehensive management may improve this outcome.

• **Fig. 29.24** Deep skin wound lateral surface left thigh in 6-hour-old, 845-gm preterm female infant delivered by emergency cesarean birth after mother sustained a gunshot wound to the abdomen.

Key Points

- Birth Injuries may occur despite skilled and competent obstetric care.
- Soft tissue injuries are observed more frequently after instrumental, breech, or precipitous deliveries. Most lesions resolve spontaneously within several days with no specific therapy.
- Subcutaneous fat necrosis is commonly seen in association with perinatal asphyxia and may be associated with hypercalcemia.
- Caput succedaneum may be difficult to distinguish from a cephalhematoma. Careful palpation indicates whether the bleeding is external to the periosteum (caput) or beneath the periosteum (cephalhematoma).
- Subgaleal hemorrhage should be considered in infants who show signs of hypoperfusion and falling hematocrit even in the absence of a detectable fluctuant mass.
- Traumatic facial nerve palsy most often follows compression of the peripheral portion of the nerve by forceps or maternal sacral promontory.
- Fractures of the maxilla, lacrimal bones, and nose may present with respiratory distress and warrant emergent surgical attention.
- It is critical to identify birth-related retinal hemorrhages and to document their presence on the chart to avoid subsequent suspicion of child abuse.
- The clavicle is the most frequently fractured bone during labor and delivery. Greenstick-type clavicular fractures, which occur most frequently, have good outcomes.
- Mechanical trauma to the spinal roots of the fifth cervical through the first thoracic nerves (the brachial plexus) during birth results in brachial palsy. Duchenne-Erb palsy caused by injury of the fifth and sixth cervical roots is by far the most common type.
- Intra-abdominal trauma should be suspected in any newborn with shock and abdominal distention or pallor, anemia, and irritability without evidence of external blood loss.
- Excellent prognosis with complete union and restoration of function is seen after a long bone fracture, which infrequently follows a difficult delivery.

Congenital Anomalies

ANNA L. MITCHELL

Major anomalies are seen in about 2% of newborns, often prompting parental worry and urgent medical intervention soon after birth. In addition, they are a common cause of long-term illness and death. This chapter reviews some of the significant etiologic and epidemiologic aspects of congenital anomalies. It provides an approach to and a framework for the evaluation of the infant with congenital anomalies, with emphasis on conditions that are apparent in the delivery room. More detailed and complete differential diagnoses for each anomaly can be found in other sources.

General Clinical Approach

The neonatologist or perinatologist often is the first person to identify a congenital anomaly and to initiate the necessary medical evaluations. In essence, the clinician observes an abnormal phenotype, which is a term used to describe the identifiable manifestation of a person's genotype, or the genetic constitution of an individual. This observation is followed by the generation of possible causes, which are confirmed or refuted with further testing. Because the underlying defect or genotype is often not known, phenotype in clinical practice refers to a collection of specific traits, physical findings, and the results of medical tests, such as laboratory, pathologic, and radiologic studies.

A congenital anomaly is an internal or external structural defect that is identifiable at birth. Anomalies are deviations from the norm and are classified as major or minor. A major anomaly is a defect that requires significant surgical or cosmetic intervention, such as tetralogy of Fallot or cleft lip and palate, whereas a minor anomaly has no significant surgical or cosmetic importance. The clinician should be aware that minor anomalies often overlap with normal phenotypic variation, so a careful search for specific morphologic patterns is essential. It is important to classify an anomaly as major, minor, or normal because implications differ for both the infant and the family. It is also important to distinguish the concepts of congenital and genetic, terms that are often confused. Congenital merely indicates that the feature is present at birth and can have many genetic and nongenetic causes.

Anomalous external physical features are called dysmorphisms and can be clues to the underlying cause or developmental defect. A useful approach to determining the etiology of a congenital anomaly is to consider whether it represents a malformation, deformation, or disruption of normal development.[65] In a study of 27,145 neonates with congenital anomalies, nearly 98% were caused by an underlying malformation, which is a primary structural defect in tissue formation such as a neural tube defect or a congenital heart defect.[40] A malformation implies an abnormal morphogenesis of the underlying tissue owing to a genetic or teratogenic factor.

In contrast, a deformation results from abnormal mechanical forces acting on otherwise morphologically normal tissues.[1,65] Deformations primarily result from mechanical forces, such as intrauterine constraint, on the growing fetus. A variety of maternal factors can cause fetal constraint, and common examples include breech or other abnormal positioning in utero, oligohydramnios, and uterine anomalies. Clubfoot and altered head shape are frequent anomalies that can result from constraint. Deformations occurring late in gestation often are reversible with changes in position or removal of the force. Observing the position the infant finds most comfortable, along with a careful obstetric history of fetal movement, position, and fluid volume, can be helpful in determining whether an anomaly could have been caused by a deforming force.

A disruption represents the destruction or interruption of intrinsically normal tissue, and it usually affects a body part rather than a specific organ. Vascular occlusion and amniotic bands are common causes of disruptions. Monozygotic twinning and prenatal cocaine exposure are common predisposing factors for disruptions on the basis of vascular interruption.

Malformations may predispose a fetus to additional deformations and multiple anomalies. A neural tube defect, a malformation, causes fetal deformations of hip dislocation and clubfoot, owing to lack of movement below the level of the lesion. If an infant has more than one anomaly, the clinician should then consider whether it is part of a sequence, association, or a known syndrome. Sequence refers to a pattern of multiple anomalies derived from a

single known or presumed cause. An example is the oligohydramnios sequence, often referred to as Potter syndrome, which consists of limb deformations, pulmonary hypoplasia, and Potter facies of a beaked nose, infraorbital creases, and simple ears. These features are due to a lack of amniotic fluid during gestation, secondary to chronic leakage of amniotic fluid or lack of fetal urine (renal agenesis, a malformation).[35,65] Another constellation of anomalies frequently seen by the neonatologist is the Pierre Robin sequence, consisting of micrognathia, cleft palate, and glossoptosis, in which the disproportionately small, malformed mandible causes the tongue to move backward and upward in the oral cavity during development, resulting in a cleft palate and potential airway obstruction.[19,35] In these instances, the key to understanding the underlying cause of the secondary deformation anomalies lies with the primary malformation.

Multiple congenital anomalies in infants can also be seen as part of an association, which refers to a nonrandom occurrence of multiple malformations for which no specific or common etiology has been identified. An example is the VATER (or VACTERL) association, an acronym for a pattern of anomalies consisting of *v*ertebral abnormalities, *a*nal atresia, *c*ardiac anomalies, *t*racheo*e*sophageal fistula, and *r*enal and *r*adial (*l*imb) dysplasia.[12,61] Although several conditions, such as maternal diabetes, are found in conjunction with VATER, a specific genetic link has not been proved. Over time, the genetic cause for some idiopathic associations has been identified, as in the CHARGE association, now known as CHARGE syndrome. The acronym denotes multiple features of the syndrome (*c*oloboma, *h*eart anomalies, choanal *a*tresia, *r*estriction of growth and development, and *g*enital and *e*ar anomalies), and mutations in the *CHD7* gene were found to be causative in over half of affected children, although the exact mechanism for the multiple malformations is not clear at this time.[27] Further, many new genes have been identified for specific syndromes that have been recognized by dysmorphologists as Mendelian traits for many years. In genetic terms, a syndrome refers to a recognized pattern of anomalies with a specific, usually heritable cause, such as the Holt-Oram syndrome, in which radial dysplasia and cardiac defects occur as a consequence of an autosomal dominant *TBX5* gene mutation.[42,62] The Cornelia de Lange syndrome is another example of this forward progress in genetic understanding of recognized malformation syndromes, in which at least five genetic loci, including the *NIPBL* gene, have been identified in patients with growth failure, microcephaly, limb anomalies, and characteristic facial dysmorphisms.[14] It is expected that the discovery of new genetic defects will continue at a rapid pace, improving the diagnostic capability for infants with congenital anomalies in the future.

Although the underlying causes of congenital anomalies are heterogeneous, disruptions and isolated deformations are usually sporadic, with negligible or low recurrence risks. However, congenital malformations can also have more than one cause, often with different possible associated anomalies and different recurrence risks. Cleft lip and palate, for example, can be isolated or can be part of dozens of different syndromes due to monogenic; multifactorial; or complex, chromosomal, or teratogenic causes.[26] The clinician should remember that the search for the underlying cause of a birth defect can be anxiety provoking for parents of newborns with congenital anomalies, as are the implications for future children and other family members. Evaluating the newborn for a pattern of major and minor anomalies will assist the clinician in more efficiently determining the appropriate tests and procedures for diagnosis and management of a congenital anomaly and determining future recurrence risks for family members.

Epidemiology and Etiology

Major Malformations

About 2% of newborn infants have a serious anomaly[22] that has surgical or cosmetic importance (Table 30.1).[6] Most of these infants have a single anomaly, but this proportion is a minimum estimate, because it is based only on the examination of newborn infants; additional anomalies are detected with increasing age.[41] The most common anomalies are structural heart defects, cleft lip and palate, and neural tube defects, occurring in 5-7 per 1000, 1.5 per 1000, and 0.3 per 1000 live births, respectively.[4,6,50,60] Identifying neonates with a major malformation is medically important, because they have a fivefold increase in morbidity and, if identified in the prenatal setting, have a threefold increased risk for death in utero.[32] From a genetic perspective, the etiology of malformations can be divided into broad categories: genetic (multifactorial, single gene [Mendelian], or chromosomal), environmental or teratogenic, and unknown.

Genetic

Complex or Multifactorial

Most congenital malformations (86%) are isolated and not associated with other anomalies.[31] The most common

TABLE 30.1 Birth Defects Among Hospitalized Newborns, 1997-2001

Defect Category	Rate per 10,000
Central nervous system	4.51-8.34
Ear, eye	2.7-7.9
Orofacial	16.22-18.32
Cardiovascular	106.19-110.77
Gastrointestinal	6.3-6.7
Genitourinary	52.04-55.61
Musculoskeletal	10.28-14.15

and familiar birth defects fall into this category, including congenital heart defects, neural tube defects, cleft lip and palate, clubfoot, and congenital hip dysplasia (see Table 30.1). Most isolated malformations are believed to be the consequence of multifactorial inheritance, sometimes called complex inheritance, occurring when one or more genetic susceptibility factors combine with environmental factors and random developmental events.[37] In most cases, multiple genetic components are involved, some with large effects and some with small contributions, the specifics of which continue to be studied. From a public health standpoint, the nongenetic effects have been harder to identify in most cases, although work has begun to link specific gene sequence variants to environmental factors. For example, epidemiologic studies have demonstrated that neural tube defects are associated with many maternal factors, such as hyperthermia, glucose levels, and folate intake.

Single Gene (Mendelian)

Single genes are responsible for causing 0.4% of newborns to have major malformations. The most common mode of Mendelian inheritance for major malformations is autosomal dominant, with a minority of major malformations resulting from autosomal recessive or, rarely, X-linked genes. Limb anomalies, including postaxial polydactyly, syndactyly, and brachydactyly, constitute the most prevalent major localized malformation, and they are frequently the result of a dominant gene. Any type of malformation, however, may be under the control of a single gene, including multiple anomalies arising in different structures or organ systems. The mechanisms of monogenic malformation disorders are related to the dysfunction of the gene or disruption of the developmental pathway. For example, autosomal recessive Smith-Lemli-Opitz syndrome, characterized by genital abnormalities, syndactyly of the second and third toes, ptosis, wide alveolar ridges, hypotonia, inverted nipples, and abnormal fat distribution, has been found to be caused by a deficiency of the enzyme 7-dehydrocholesterol reductase in the cholesterol biosynthesis pathway.[5,34] Since the genetic cause of this disorder was identified, other single gene disorders of cholesterol biosynthesis have been identified that result in multiple congenital anomalies.[52] Although a biochemical or molecular basis increasingly is being recognized for different malformations, specific diagnosis still relies heavily on the family history and clinical evaluation.

Chromosomal

About 0.2% of newborns have a major malformation as a result of a chromosomal disorder, amounting for 10% of all the major congenital malformations (Table 30.2; see Chapter 10). The most prevalent malformation syndrome caused by an abnormal chromosomal constitution in newborns is Down syndrome, or trisomy 21, which occurs in about 1 in 660 births.[33] The other common trisomies are trisomy 18 and trisomy 13, each occurring in about 1 in 10,000 births. All three autosomal trisomies, and the sex chromosome aneuploidies, 47,XXY and 47,XXX, occur more frequently with increased maternal age.

TABLE 30.2 Etiology of Human Congenital Malformations

Etiology	Malformed Live Births (%)
Environmental	**10**
Maternal conditions *Alcoholism, diabetes, endocrinopathies, phenylketonuria, smoking, nutritional problems*	4
Infectious agents *Rubella, toxoplasmosis, syphilis, herpes simplex, cytomegalovirus, varicella, Venezuelan equine encephalitis*	3

Chemicals, Drugs, Radiation, Hyperthermia	<1
Genetic	15-25
Single gene disorders Chromosomal abnormalities	
Unknown	65-75
Polygenic/multifactorial (gene-environment interactions) "Spontaneous" errors of development Other unknowns	

Modified from Brent RL. Addressing environmentally caused human birth defects. *Pediatr Rev*. 2001;22:153.

It is important to note, however, that although about 0.6% of newborns have chromosomal anomalies, the abnormalities are not detectable by physical examination at birth in 66% of these infants.[33] Included among these early phenotypically undetectable chromosomal anomalies are common aneuploidies of the sex chromosomes, such as 47,XXY (Klinefelter syndrome) and 47,XXX. Neonates with these sex chromosome disorders may not have obvious malformations in the newborn period, because the phenotype may develop over time.

In contrast, Turner syndrome (45,X) is present in 1 in 5000 female births, is often detected prenatally, and has a phenotype in a proportion at birth.

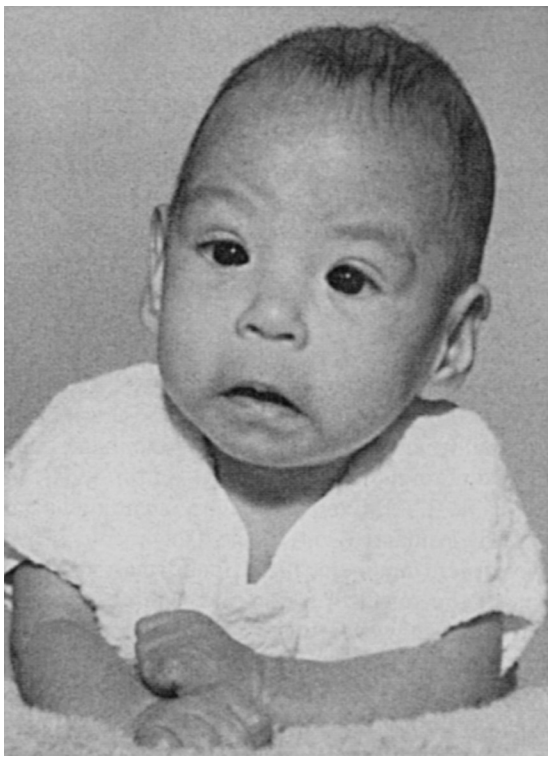
Many other types of chromosomal aberrations have been identified using standard karyotype and newer genomic technologies. In addition to detecting the gain or loss of a single chromosome, routine chromosome banding techniques can identify many translocations, inversions, ring chromosomes, marker chromosomes, and deletions.[58] However, not all deletions are detectable by routine or

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

even high-resolution (prometaphase) cytogenetic analysis, so that additional methodologies such as fluorescence in situ hybridization (FISH) or comprehensive genomic technologies should be considered. FISH uses fluorescently labeled DNA probes that identify deletions in specific locations on the chromosome metaphase spread, such as those associated with conditions as 22q11 deletion syndrome/ velocardiofacial/ DiGeorge syndrome and Williams syndrome (long arm of chromosome 7).[25]

Newer genomic technologies simultaneously examine the entire structure of the chromosomes.[15] Chromosomal microarray analysis targets known microdeletion syndromes, subtelomeres, and pericentric regions, and is more sensitive than routine karyotype analysis. When the microarray is done with single nucleotide polymorphism (SNP) analysis, regions of the genome that lack heterozygosity can be identified. This may suggest uniparental disomy or consanguinity, which may be contributing to the child's features. In a relatively short period of time, array analysis has revolutionized the diagnosis of neonates and children with multiple anomalies or developmental delay.[15] In an analysis of 1176 cases evaluated by a clinical genetics laboratory, 9.8% had pathogenic chromosomal imbalances identified by comparative genomic hybridization (CGH) array, compared with 2% using routine karyotyping.[51] Other studies have shown that infants with multiple congenital anomalies may have a higher rate of imbalances. Lu et al. showed that 17% of 444 neonates with a variety of malformations had clinically significant aneuploidies found on microarray analysis.[38] Furthermore, new microdeletion syndromes of developmental delay and multiple malformations have been identified, which suggests that whole genome analysis technologies of the future will improve diagnosis and expand our knowledge of clinically significant areas of the genome.[63]

Whole exome sequencing (WES) is a novel technology that allows for evaluation of the entire coding region of the genome, estimated to be 2%-3% of the total genomic material. This testing methodology is estimated to provide a genetic etiology for 24%-47% of fetuses with anomalies.[23,69]



However, karyotype remains the appropriate first-line test for suspected aneuploidy (trisomies 21, 18, and 13, and Turner and Klinefelter syndromes) and in cases of ambiguous genitalia because of the rapid turnaround time and lower cost.

Environmental Exposure and Teratogens

A teratogen is anything external to the fetus that causes a structural or functional disability in prenatal or postnatal life (see Chapter 14). Teratogens can be drugs and chemicals, altered metabolic states in the mother, infectious agents, or mechanical forces. Known teratogenic factors cause only 5%-10% of congenital anomalies despite the ever-expanding list of potential teratogens in our increasingly chemical environment (see Table 30.2).[8] Before one can attribute malformations to a teratogenic agent, there must be one anomaly, only a few specific anomalies, or a recognizable pattern of anomalies found to occur at increased incidence over the background risk in infants exposed at the appropriate developmental stage (usually 2-12 weeks of gestation). With only a few exceptions, teratogenic agents do not affect every exposed infant, which is probably related to genetic susceptibility factors. Dose and timing of exposure also alter the potential of a specific teratogenic agent. To assess for specific drug teratogenic effects, multiple resources are available.[29]

Although beyond the scope of this chapter, pharmaceutical agents and environmental toxins are well documented to alter the development of the fetus.[59] Although many drugs have teratogenic potential, the clinician should be aware of the teratogenic effect of some commonly used drugs and exposures. Alcohol is thought to be the most common teratogen to which a fetus may be exposed. Chronic maternal alcohol use during pregnancy is associated with increased perinatal mortality and intrauterine growth restriction, as well as congenital anomalies such as cardiac defects, microcephaly, short palpebral fissures, and other anomalies (Fig. 30.1). Long-term effects include intellectual disability and behavioral problems. Alcohol carries serious risks when it is used almost at any time during pregnancy in sufficient quantities, because the central nervous system continues to develop throughout pregnancy. For this reason it is recommended that women avoid alcohol, even in small amounts, throughout their pregnancies (see Chapter 46).

Anticonvulsants are a common category of teratogens to which a fetus is likely to be exposed. Although the

medical literature is somewhat controversial, clinical geneticists, dysmorphologists, and clinical teratologists generally identify a variable but recognizable pattern of anomalies and developmental defects that occur at a significantly increased frequency among fetuses exposed to older classes of anticonvulsants. Studies have implied that newer classes of antiepileptic medications may not have the same effect on the developing fetus, although the clinician should be cautious in interpreting these studies.[68]

Some altered metabolic states in the mother also are known to have teratogenic potential. One of the most common is maternal diabetes mellitus. Infants of diabetic mothers are at two to three times the risk for congenital heart defects, caudal regression and sacral dysgenesis, and central nervous system abnormalities.[18] In this population, there is about a threefold increase of congenital anomalies over those in the general population. The risk for congenital anomalies appears to be lower in offspring of diabetic mothers with better control of blood glucose, but this is not absolute, and factors other than blood glucose levels are thought to play a role in teratogenesis (see Chapters 18 and 86). Another example is untreated maternal phenylketonuria, in which the elevated levels of phenylalanine cause microcephaly, growth delay, and cardiac and neurologic abnormalities in the developing fetus.

Congenital anomalies also may be associated with certain infections during pregnancy. The most common and best understood infections are represented by the acronym TORCH, which stands for *t*oxoplasmosis, *o*ther agents (including syphilis), *r*ubella, *c*ytomegalovirus, and *h*erpes simplex. Although the sequelae of these infections may not be apparent until later, the clinician should consider these congenital infections in neonates with intrauterine growth restriction, microcephaly, chorioretinitis, intracranial calcification, microphthalmia, cataracts, or hearing loss. Confirmation of the specific diagnosis should be made by antibody studies and other evaluations such as ophthalmic examination and imaging studies.

Unknown

About 66% of major malformations have no recognized etiology, if one includes those of presumed polygenic and multifactorial etiology (see Table 30.2).[8] It is presumed that specific genetic or environmental causes of these congenital anomalies will be identified in the future as medical knowledge about the underlying biology of embryonic development and the technology for identifying gene-environment interaction improves. For example, folic acid supplementation has been recognized to decrease the risk for neural tube defects, thus implicating folic acid deficiency in the etiology of these anomalies.[3]

Anomalies in Aborted Fetuses

Spontaneously aborted fetuses have a higher incidence and severity of malformations than do newborns,[32] which presumably represents a higher lethality of some developmental abnormalities. As in newborns, common anomalies, such as neural tube defects and cleft lip or palate, are also frequent in aborted fetuses, although these may be more severe. Other malformations, such as cloacal exstrophy, are relatively rare in newborns but are comparatively common in aborted fetuses.

In addition to these localized and single anomalies, multiple congenital anomalies commonly occur together in aborted fetuses, including well-recognized syndromes that are caused by single genes and chromosomal abnormalities (Table 30.3).[13] It is estimated that about half of all pregnancy losses before 20 weeks of gestation have an underlying chromosomal abnormality. These losses include unrecognized early pregnancies and fetuses without an obvious structural anomaly. In this context, the most common single chromosomal abnormality is 45,X, followed by triploidy. Both conditions are more common in aborted fetuses than in newborns. The trisomies as a group account for more than

50% of all chromosomally abnormal pregnancy losses. The most frequent trisomy, accounting for almost one-third of all trisomies, is trisomy 16, which is not found in newborns, because it is lethal to the fetus.[32,70] Trisomy 21, the most common trisomy in newborns, occurs in less than 10% of all recognized trisomic conceptions. Unbalanced translocations account for 2%-4% of all chromosomally abnormal fetuses and are three to six times more frequent in aborted fetuses than in newborns. As with neonates, newer genomic technologies examining the chromosomes for small areas of genomic imbalance have shown an increased number of previously unrecognized deletions or amplifications of genetic material in fetuses with congenital anomalies. Analysis of DNA from the fetus's parents could be helpful in determining whether the chromosomal microarray finding was diagnostic of the congenital anomaly.

Minor Anomalies and Phenotypic Variants

Although major malformations often are easy to identify, minor anomalies are, by nature, more subtle and may not be appreciated unless they are specifically sought. It should be noted that 15%-20% of healthy newborns will have a minor anomaly, so their presence alone is not necessarily indicative of a more serious problem. However, these minor anomalies may be part of a characteristic pattern of malformations and thus may provide clues to a diagnosis. Also, their occurrence may be an indication of the presence of a more serious anomaly. It is estimated that the presence of a single minor anomaly is associated with a 3% risk of having a major malformation, while having three or more minor anomalies is associated with a 20% risk of a major malformation.[2,9]

Minor anomalies are most frequent in areas of complex and variable features, such as the face and distal extremities (Table 30.4).[39] Among the most common features are lack of a helical fold of the pinna and complete or incomplete single transverse palmar crease patterns. Typical single transverse palmar crease occurs in almost 3% of normal newborns, but it appears in 45% of individuals with trisomy 21.[35]

Among the most frequent phenotypic variants, those present in 4% or more of the population, are a folded-over helix of the pinna and cerulean spots in blacks and Asians (Table 30.5).[39] Before attributing medical significance to an apparent minor anomaly or phenotypic variation, it is useful to determine whether the anomaly is present in other family members or whether it is frequent in the patient's ethnic group. It is common for isolated minor anomalies such as syndactyly of the second and third toes to be familial.

Racial and Ethnic Differences

The prevalence of congenital malformations varies among different racial and ethnic groups. This variation is most likely the consequence of differing genetic predispositions and variable environmental factors operating in diverse areas. Table 30.6 shows the prevalence of common major congenital malformations in white Americans, African Americans, and Chinese.[16,50] It is of interest that certain anomalies are especially common in a particular race, such as postaxial polydactyly in African Americans and hypospadias and clubfoot in white Americans. Minor malformations may show an equally striking racial predisposition. Brushfield spots are common in white Americans but are rare in African Americans. Umbilical hernias, however, are common in African-American infants but are relatively infrequent in white American infants. The widely varying frequencies of various traits in different races may make the determination of whether any given characteristic is considered to be a minor anomaly or a phenotypic variant strongly dependent on the race of the patient being studied.

TABLE 30.4 Common Minor Malformations in Newborns (Frequency Greater Than 1:1000)

Minor Malformation	Newborns (%)
Craniofacial	
Borderline micrognathia	0.32
Eye	
Inner epicanthal folds	0.42
Ear	
Lack of helical fold	3.52
Posteriorly rotated pinna	0.25

One of the best examples is cerulean spots, which occur in almost 50% of African-American or Asian infants but in only 0.2% of white infants.[39] Ethnic differences have also been noted for the Hispanic population, in whom there is a higher prevalence of neural tube defects, gastroschisis, and trisomy 21.[50]

Evaluation

Every infant with a congenital anomaly should have a thorough diagnostic evaluation; without one, accurate information about the natural history of the condition and the recurrence risk for similarly affected future children cannot be provided.[20] In addition, parents usually are intensely interested in why the anomaly occurred and often harbor inappropriate guilt concerning the cause.

When a child is born with one or more anomalies, a number of considerations should guide the physician in the evaluation. The most critical factors to be considered are the detailed prenatal and family histories, the dysmorphic physical examination (including careful observation and measurements of growth parameters and individual features), and the use of appropriate diagnostic tests and evaluations, particularly if there is more than one anomaly. It is important to assess whether the malformation is isolated or part of a constellation of anomalies. It is also essential to identify whether there are other major or minor anomalies, including perhaps unapparent internal malformations, and to recognize well-described patterns of malformations.[10,35] The severity of an anomaly can sometimes be helpful in identifying whether it may be associated with other anomalies and in predicting the prognosis for the infant. Consultation with other specialists, such as a medical geneticist, who have expertise in the evaluation of neonates with congenital anomalies may be required.

Patient and Family History

The evaluation of an infant with congenital anomalies begins with detailed medical, prenatal, and family histories. The important goal is to identify a possible genetic predisposition, environmental factor, or other clue to the cause of the anomalies. It is useful to begin with the pregnancy to document fetal movement and vigor, complications, illnesses, maternal use of any medications, or possible exposure to teratogens, as well as the timing of all complications and exposures (see Chapter 14). In particular, information about previous prenatal ultrasound findings; maternal serum screening; and results of noninvasive prenatal screening (NIPS), amniocentesis, or chorionic villus sampling (if any) should be reviewed. The extent of smoking and alcohol

consumption should be determined, and every mother should be asked about illicit drug use.

To identify other potentially affected family members and obtain clues to an etiology, a detailed three- to four-generation family history, charted in a concise manner in the form of a pedigree, should be constructed, using squares for male and circles for female members. Horizontal lines indicate genetic union, and vertical lines indicate genetic descent. All abortions and stillbirths should be noted. A question always should be specifically asked about possible parental consanguinity. A simple way to inquire is to ask if the families of the affected child's parents are related in any way. If so, the charting should indicate the exact relationships. The presence of other relatives with congenital anomalies of any type or with growth or developmental abnormalities should be recorded along with other pertinent information, such as the maternal and paternal ages and the nature of the anomaly. Family photographs are often very useful in clarifying questions of possible unusual facial features. The pedigree should, at a minimum, include all siblings and parents of the proband as well as aunts, uncles, cousins, and grandparents. In the case of possible dominant or X-linked disorders, a more extensive pedigree may be needed.[67]

Physical Examination

The goal of the physical examination (see Chapter 28) of an infant with congenital anomalies is to determine whether an anomaly is isolated or to detect a recognizable pattern of malformations so that a specific etiologic determination can be made. In addition, careful attention must be directed not only to an exact description of the major anomalies but also to apparent minor anomalies or variations. Distinctive physical features may become clues in identifying the cause of multiple congenital anomalies; therefore a detailed inspection of various features of external anatomy and measurement of them when appropriate should be performed. The overall body size measurements of length, weight, and head circumference should be compared with gestational norms. Normal measurements of many face and body characteristics can be found in a number of resources.[28,35] Objective description of anomalous features allows for appropriate use of resources or consultants. In this section, an outline of this external examination is presented by region or structure, and certain helpful points, as well as aspects of the differential diagnosis, are discussed. Greater detail in regard to examination and abnormalities of various organ systems is given in other relevant chapters in this book. The reader also is referred to various resources in which the anomalies and syndromes mentioned in this section are discussed at length.[1,30,35,65]

Skin

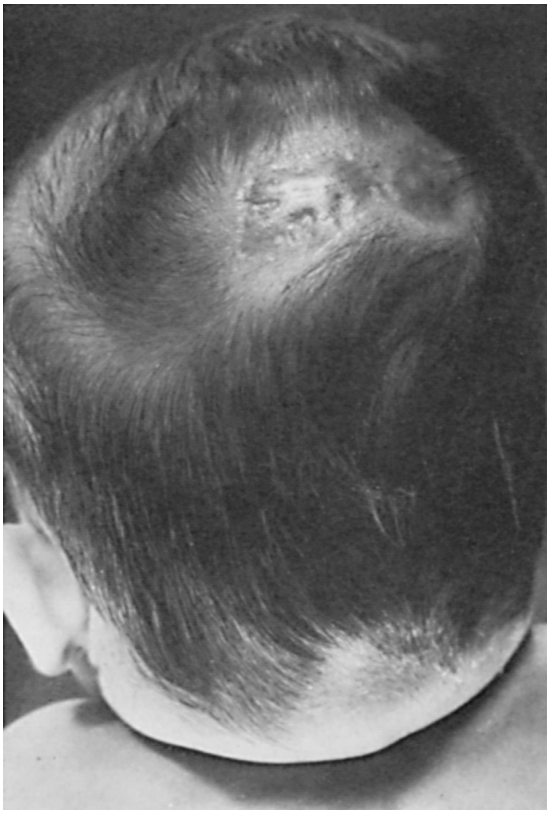
Normal infant skin, particularly when exposed to cold temperatures, shows a marbling pattern termed cutis marmorata or livedo reticularis (see Chapter 94). In rare instances, this pattern may be unusually prominent and familial, inherited as an autosomal dominant trait. A similar prominent pattern may occur in those with trisomy 21, hypothyroidism, or Cornelia de Lange syndrome.

A variety of lesions with altered pigmentation may provide useful clues to a diagnosis. Café-au-lait spots are characteristic of neurofibromatosis, but they also occur in other conditions and may be isolated, especially in darkly pigmented infants. Hypopigmented macules may be the earliest manifestation of tuberous sclerosis in the young infant. Multiple irregular pigmented lesions arranged in whorls are suggestive of incontinentia pigmenti, but this disorder usually presents initially with a vesicular rash. An angiomatous patch over one side of the face may be an isolated anomaly or part of Sturge-Weber syndrome. More than one skin hemangioma should raise suspicion of internal vascular lesions.

Generalized edema may obscure many minor anomalies, making diagnosis difficult. Turner syndrome, trisomy 21, and Noonan syndrome should be considered in newborns with generalized edema. The texture of the skin also can assist the clinician with a syndromic diagnosis, because thick or coarse skin is characteristic of Costello syndrome, and abnormal distribution of fatty tissue can be seen in congenital disorders of glycosylation.

Hair

The relative sparseness or prominence of body hair should be noted. Sparse hair is characteristic of an ectodermal dysplasia, but it does occur in other syndromes, such as cartilage-hair hypoplasia and oculodentodigital syndrome. Generalized hirsutism is typical of Cornelia de Lange syndrome, fetal hydantoin syndrome, and fetal alcohol syndrome, but it also may occur in those with trisomy 18. It also may be an ethnic (Hispanic, Middle Eastern, American Indian) or familial characteristic.



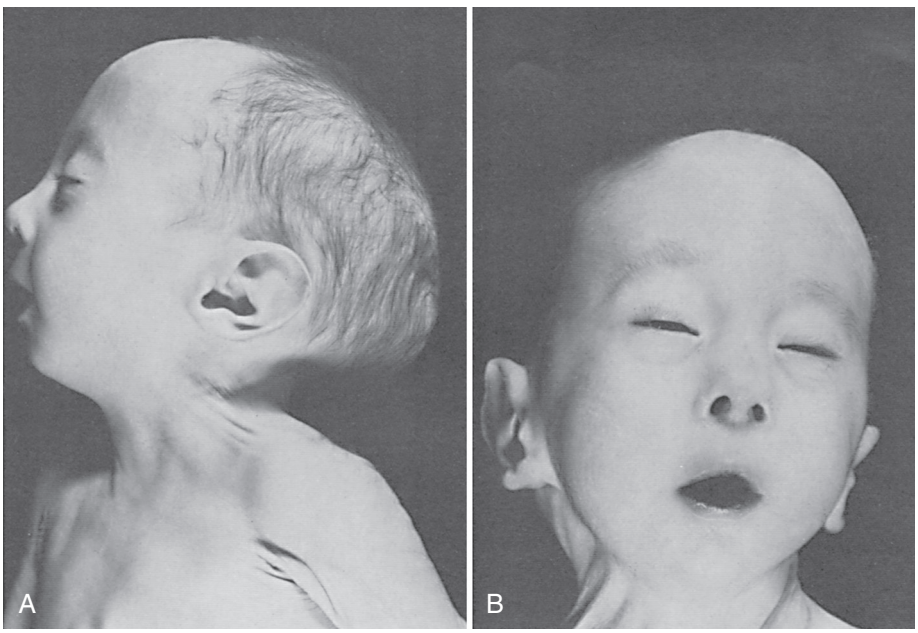
Abnormal scalp hair patterns may reflect underlying brain abnormalities. In microcephaly, there may be a lack of the normal parietal whorl, or the whorl may be displaced more centrally or posteriorly. In addition, the frontal hair may show a prominent upsweep. A low posterior hairline occurs with a short or webbed neck, as in Turner syndrome and Noonan syndrome. Punched-out scalp lesions in the parietal occipital area (aplasia cutis congenita) are typical of trisomy 13 or may be seen in isolation and may be familial (Fig. 30.2).

Head

The size of the head, measured by the maximal head circumference, and the sizes of the anterior and other fontanelles should be compared with those of appropriate standards (see Chapter 57). Head size varies with age, sex, and racial group and correlates with body size. Macrocephaly as an isolated anomaly often is familial and inherited in an autosomal dominant fashion; therefore, determining the head circumferences of the parents is helpful. However, macrocephaly may be a manifestation of several disorders, including

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

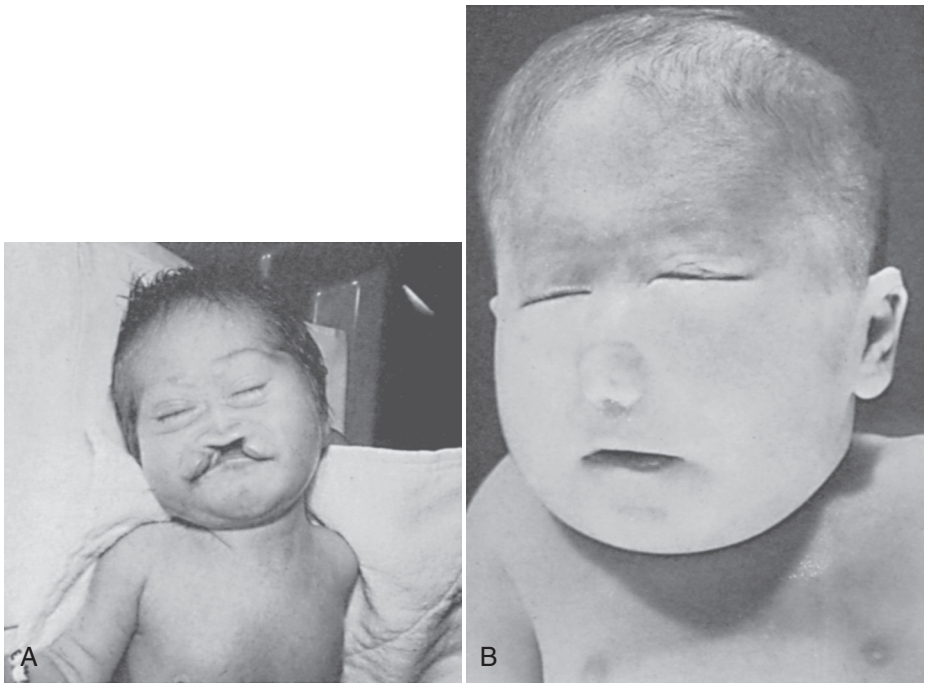
hydrocephaly and various conditions affecting the skeletal system such as achondroplasia, or overgrowth syndromes such as the PTEN hamartoma tumor syndrome. Microcephaly can also be familial, either autosomal dominant, or recessive, but it is more commonly a manifestation of many syndromes that result in intellectual disability. Large fontanelles occur in hypothyroidism, in trisomies 21, 18, and 13, in peroxisomal disorders like Zellweger syndrome, and in many bone disorders such as hypophosphatasia and cleidocranial dysostosis. A small anterior fontanelle may be a sign of failure of normal brain growth.



• **Fig. 30.2** Scalp lesions in trisomy 13.

The normal shape of the head may vary from an increase in the anteroposterior diameter (dolichocephaly) to a decrease in this dimension (brachycephaly). Premature infants and those with trisomy 18 characteristically have dolichocephaly (Fig. 30.3), and hypotonic infants often develop dolichocephaly over time, but either type of head shape may be of familial or racial origin. Many Asian and American Indian infants, for example, have strikingly brachycephalic heads.

Premature fusion of cranial sutures (craniosynostosis) results in an abnormal configuration in head shape. Various types occur depending on the sutures involved (see Chapter 57). Torticollis or abnormal mechanical forces in utero can cause asymmetric head shape (plagiocephaly). A common anomaly in head shape is frontal bossing, which is frequent in some skeletal dysplasias such as achondroplasia and in some cases of hydrocephaly.



Face

The face is composed of a series of structures, each demonstrating considerable normal variation and providing a distinctive and unique appearance to every human. Because examination of the face is both complex and important to establishing an etiology of anomalies, a systematic approach is necessary. It is never sufficient merely to describe the face as "unusual," nor appropriate to describe the face as "funny looking." Specific abnormalities should be analyzed and quantified, when appropriate, even though an overall gestalt impression may suggest a diagnosis in some cases. Recall that lack of resemblance to other family members may be an indicator of an underlying condition.

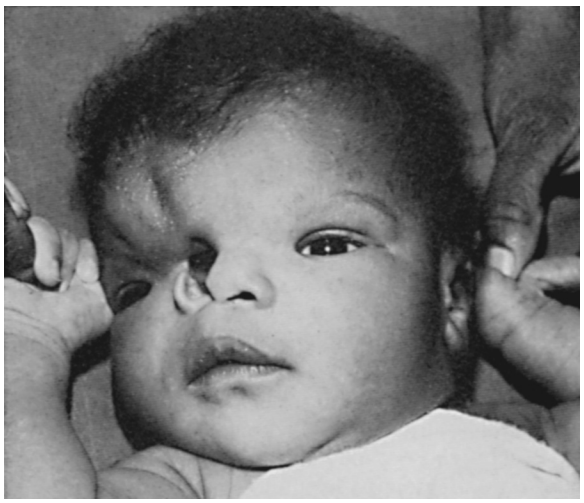
• **Fig. 30.4** Trisomy 13. **A,** Note anomalous midline facial development with hypotelorism, midline cleft lip, and lack of a nose. **B,** Note hypotelorism and abnormal nose.

Eyes

Hypotelorism occurs when the eyes are unusually close together; hypertelorism occurs when the eyes are too far apart. Clinically, hypotelorism and hypertelorism are defined by the interpupillary distance, which may be estimated in a relaxed patient by measuring between the midpoints of the pupils. It is usually impossible to measure the interpupillary distance of a newborn; therefore, two other relevant and useful measurements that are easier to obtain are the inner canthal distance and the outer canthal distance. Telecanthus is an increase in the inner canthal distance, and it may occur in the absence of hypertelorism, such as in Waardenburg syndrome type I. There are other factors that may create an illusion of hypertelorism, such as epicanthal folds and a flat nasal bridge; therefore, a subjective impression should always be confirmed by measurement of all three distances, if possible. From the prognostic and diagnostic points of view, it is important to identify hypotelorism, because often it is associated with holoprosencephaly, a major malformation of the central nervous system that can be associated with severe disturbance of brain function and early death. Holoprosencephaly can be isolated or can be part of trisomy 13 (Fig. 30.4) or occasionally other syndromes. Hypertelorism, however, occurs in a number of syndromes such as frontonasal dysplasia, and even when it is severe, it is less likely to be related to an underlying brain malformation. Comparison with parents' eye distances is important. Figs. 30.5 and 30.6 illustrate hypertelorism with midline facial anomalies.

Epicanthal folds are a feature of normal fetal development, and they may be present in normal infants. They are characteristic in trisomy 21 (Fig. 30.7*A, B*), but they occur in many other malformation syndromes, especially in those that include a flat nasal bridge.

• **Fig. 30.5** Frontonasal dysplasia with hypertelorism and bifid nose.



Normally, an imaginary line through the inner and outer canthi should be perpendicular to the sagittal plane of the face. An upward slant to the palpebral fissure is seen in trisomy 21 (see Fig. 30.7*A, B*), and a downward slant is seen in mandibulofacial dysostosis (see Fig. 30.7*C*) and Noonan

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

syndrome. Both types of slant can be part of a number of other syndromes.

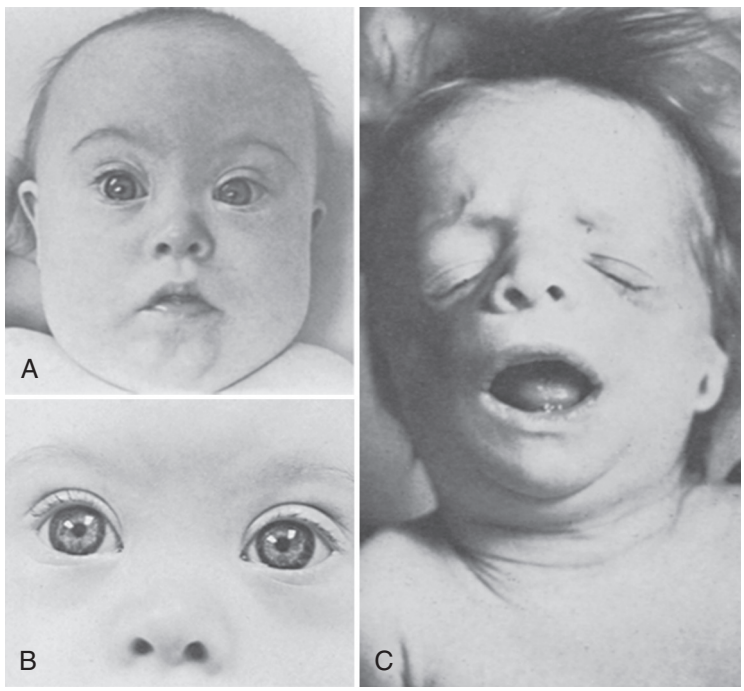
Palpebral fissure length is measured from the inner canthus to the outer canthus. Short palpebral fissures may occur in association with other ocular anomalies, such as microphthalmia, and they are characteristic of syndromes such as fetal alcohol syndrome (see Fig. 30.1) and trisomy 18 (see Fig. 30.3*B*).

A coloboma is a developmental defect in the normal continuity of a structure, and it often is used in reference to the eye. Colobomas may involve the eyelid margin, as those seen in Treacher Collins syndrome (see Fig. 30.7*C*), or the iris and retina, as those seen in CHARGE syndrome.

• **Fig. 30.6** Frontonasal dysplasia with nasal cleft.

Identification of a coloboma should lead to a formal ophthalmic evaluation.

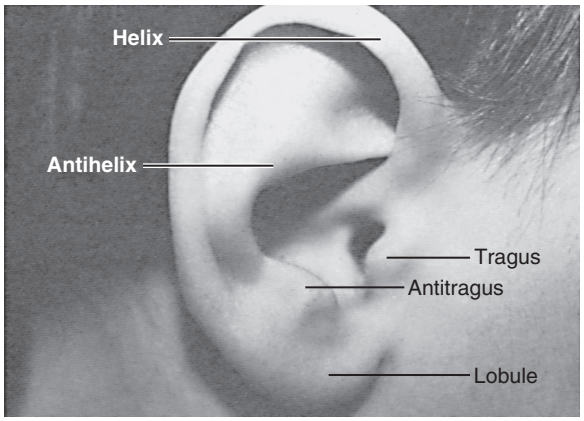
Synophrys, or fusion of the eyebrows in the midline, is common in hirsute infants, and it may also be familial in some instances. The Cornelia de Lange syndrome is strongly associated with synophrys.



Anomalies of the internal eye structure are discussed in Chapter 95.

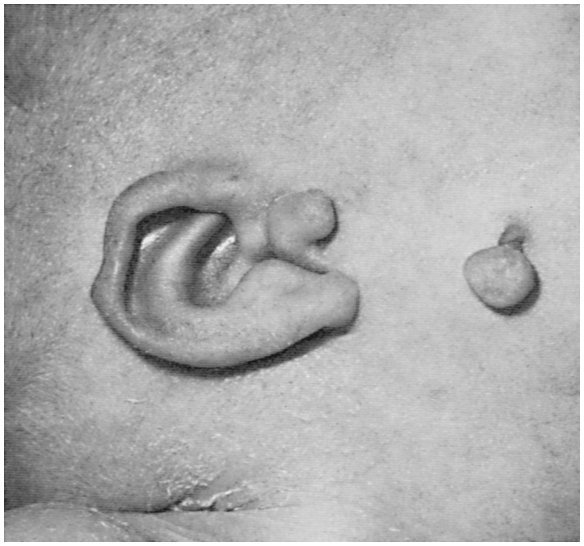
Ears

The external ear, or pinna, commonly shows great variation that can be identified by a number of anatomic landmarks. These should be described and measured when evaluating the anomalous ear. These landmarks include the helix, antihelix, tragus, antitragus, external meatus, and lobule (Fig. 30.8). If the ears appear to be large or small, they should be measured by obtaining the maximal length of the pinna from the lobule to the superior margin of the helix. Preauricular tags or pits may be isolated or associated with other abnormalities of the pinna (Fig. 30.9).



The ears are low set when the helix joins the head below a horizontal plane passing through the outer canthus perpendicular to the vertical axis of the head (Fig. 30.10). It is critical that this condition be assessed with the head in vertical alignment with the body because any posterior rotation of the head can create an illusion of low-set ears. In most instances, the relative placement of the ears is more a function of head shape and jaw size than of an intrinsic anomaly of the ear.

When the vertical axis of the ear deviates more than 10 degrees from the vertical axis of the head, the ears are



• **Fig. 30.7** **A,** Trisomy 21. Note epicanthal folds and upslant of eyes. **B,** Enlargement of eyes of patient in (**A**). Note Brushfield spots on irides. **C,** Mandibulofacial dysostosis (Treacher Collins syndrome) with down-slanting eyes. Note coloboma, or notch, in left eyelid.

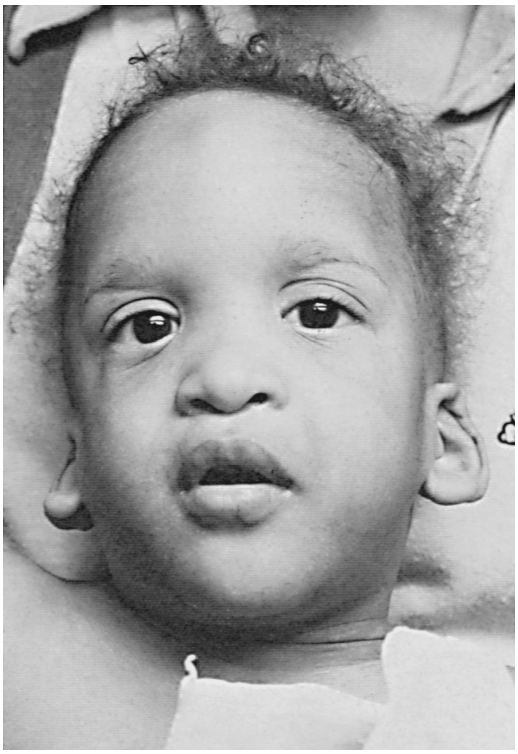
• **Fig. 30.8** Normal pinna and its landmarks.

• **Fig. 30.9** Preauricular tags with malformed pinna.

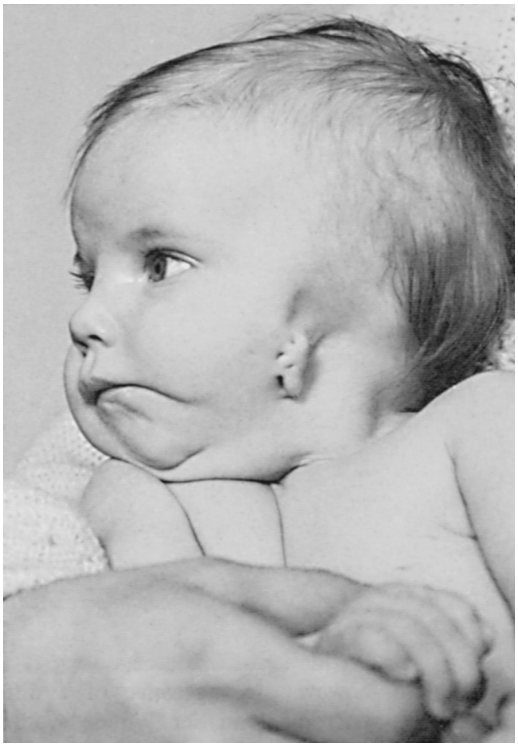
• **Fig. 30.10** Normal pinna and its orientation with respect to eyes.

• **Fig. 30.11** Abnormal pinna that is low set and posteriorly rotated in patient with Smith-Lemli-Opitz syndrome.



posteriorly rotated. This anomaly often is associated with low-set ears and represents a lag in the normal ascent of the ear during development (Figs. 30.11 and 30.12). Care should be taken when examining neonates in the intensive care unit because tape used to secure intubation or nasogastric tubes can give the false impression of posteriorly rotated ears.

Any significant abnormality of the external ear may be an indication of additional anomalies of the middle or inner ear and may be associated with hearing loss; therefore, an early hearing assessment is indicated in such cases (see Chapter 59). Fig. 30.13 illustrates a patient with hemifacial microsomia, whose findings include a severely malformed pinna and an absent ear canal. This is one condition in which an early hearing assessment is essential because hearing loss is likely.



Nose

The nose, like the external ear, shows great individual variation, but certain alterations in shape are frequent in malformation syndromes involving the face. The nose may be unusually thin with hypoplastic alae nasi, as in Hallermann-Streiff syndrome, or it may be unusually broad, as in frontonasal dysplasia (see Fig. 30.5). A depressed nasal bridge with an upturned nose occurs in many skeletal dysplasias, such as achondroplasia. When the depression is severe, the nostrils may appear to be anteverted and the nose may appear to be shortened. A hypoplastic nose is often syndromic, and a nose with a single nostril is highly suggestive of holoprosencephaly (see Fig. 30.4).

• **Fig. 30.12** Facial view of patient in Fig. 30.11.

• **Fig. 30.13** Hemifacial microsomia showing mandibular hypoplasia, severely malformed pinna, and absent ear canal.

Mouth

The mouth is a complex structure with component parts that require separate evaluation (see Chapter 68). The size and shape of the mouth may be altered. A small mouth, or microstomia, should be noted; it occurs in trisomy 18 (see Fig. 30.3). Macrostomia, a large mouth, should be noted as well; it may be present in such conditions as mandibulofacial dysostosis (see Fig. 30.7*C*). Severe macrostomia may result from a lateral facial cleft. The corners of the mouth may be downturned, as in Prader-Willi syndrome and other conditions with hypotonia. An asymmetric face during crying occurs with congenital deficiency in the depressor anguli oris muscle on one side, and this may be associated with other abnormalities, such as hemifacial microsomia and 22q11deletion/velocardiofacial/DiGeorge syndrome.

• **Fig. 30.14** Prominent alveolar ridges in patient with Smith-Lemli-Opitz syndrome.

Prominent, full lips occur in various syndromes, including Williams syndrome. A thin upper lip may be seen in Cornelia de Lange syndrome and in fetal alcohol syndrome (see Fig. 30.1).

A cleft upper lip is usually lateral, as in the common multifactorial cleft lip (or palate) anomaly, occurring in the position of one of the philtral ridges. The presence of pits in the lower lip associated with a cleft lip or palate, however, is suggestive of Van der Woude syndrome, which is inherited in an autosomal dominant manner. A median cleft lip is very suggestive of holoprosencephaly (see Fig. 30.4*A*). In fact, there are many diverse syndromes with cleft lip or palate that are important to identify, because they may have other associated malformations and relatively high genetic risks for recurrence. Therefore, it is particularly important to evaluate the infant with cleft lip or palate carefully for evidence of other malformations to give accurate recurrence risk and prognostic information to the family.

Isolated cleft palate is different genetically from cleft lip.[53] Mild forms of cleft palate are represented by submucosal clefts, pharyngeal incompetence with nasal speech (velopharyngeal insufficiency), and bifid uvula. A high arched palate may occur normally, but it is also a feature of many syndromes, especially if hypotonia or another long-standing neurologic abnormality is present. Hypertrophied alveolar ridges are apparent in the palate along the inner margin of the teeth, and they are suggestive of Smith-Lemli-Opitz syndrome (Fig. 30.14) if seen in an infant.

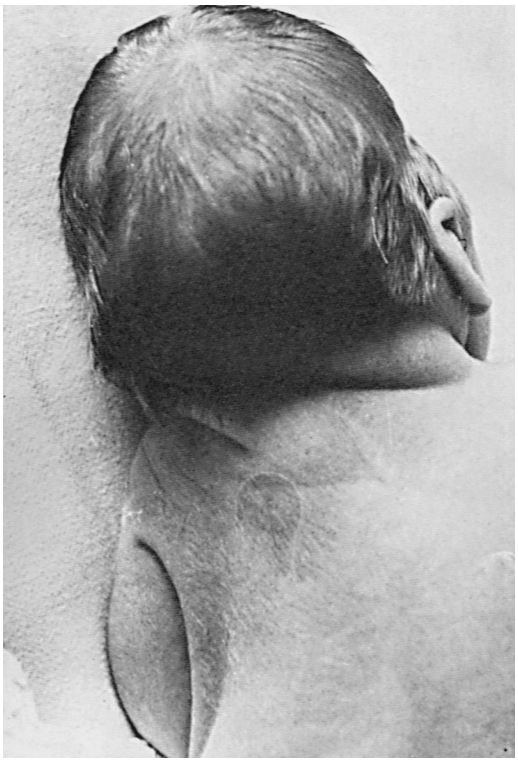
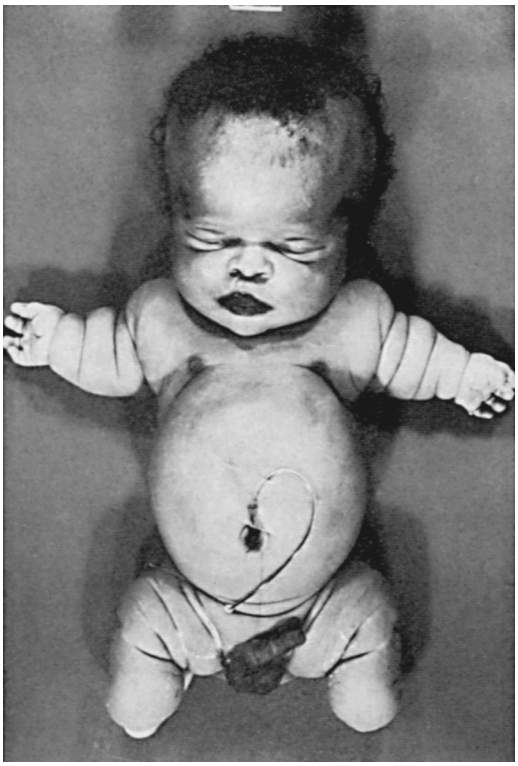
• **Fig. 30.15** Micrognathia in Pierre Robin sequence.

Macroglossia may be relative, as in the Pierre Robin malformation sequence, in which the primary abnormality is mandibular hypoplasia. In other cases, such as hypothyroidism, Beckwith-Wiedemann syndrome, and trisomy 21, the tongue protrudes and is enlarged. A cleft or irregular tongue or oral frenula occurs in various syndromes, such as the orofaciodigital syndromes.



The lower portion of the mouth is formed by the mandible, which in young infants is relatively small. An excessively small mandible is termed *micrognathia*, which is a feature of many syndromes. It is a characteristic of the Pierre Robin sequence, which consists of the triad of micrognathia, glossoptosis, and a U-shaped cleft palate, as opposed to the common V-shaped cleft. A typical patient is shown in Fig. 30.15. The Pierre Robin sequence may be part of a syndrome, such as Stickler syndrome (hereditary arthro-ophthalmopathy), and thus other anomalies and a family history must be sought. In other syndromes, the maxilla likewise may be hypoplastic, decreasing the prominence of the upper cheeks (malar hypoplasia).

Neck



The neck may be short, and limitation of rotation should raise the suspicion of fusion of cervical vertebrae, as in a Klippel-Feil anomaly. Excessive skinfolds are characteristic of Turner syndrome (Fig. 30.16), Noonan syndrome, and trisomy 21. In these examples, the excess nuchal skin often represents resolution of a cystic hygroma that was present prenatally.

Chest

The thoracic cage may be unusually small as part of a skeletal dysplasia, such as thanatophoric dysplasia (Fig. 30.17) or Jeune asphyxiating thoracic dystrophy. The sternum itself may be unusually short, which is typical in trisomy 18, or it may be altered in shape, as is seen in pectus excavatum

• **Fig. 30.16** Excess skinfolds of the neck in patient with Turner syndrome.

• **Fig. 30.17** Thanatophoric dwarfism. Note short limbs and narrow thoracic cage.

or pectus carinatum. The latter anomalies are commonly seen in a variety of skeletal dysplasias and connective tissue disorders (see Chapter 66).

Abdomen

Hypoplasia of the abdominal musculature may occur in association with intrauterine bladder outlet obstruction and other anomalies of the urogenital system. It results in a characteristic prune-belly appearance in Eagle Barrett syndrome (see Chapter 93). An omphalocele, in which abdominal contents protrude through the umbilical opening, may be part of Beckwith-Wiedemann syndrome (see Chapter 86) or chromosomal abnormalities such as trisomy 13. Gastroschisis, however, is usually an isolated disruption in which the abdominal contents protrude through the periumbilical abdominal wall. Anomalies of a more minor nature, such as inguinal or umbilical hernias, occur in normal infants, but they are more frequent in various syndromes, particularly in connective tissue disorders (see Chapter 84).

Anus

Imperforate or displaced anus may be isolated or may occur as the mildest expression of a caudal regression sequence, in which other anomalies such as sacral dysgenesis are seen. It is most commonly part of a constellation of anomalies, such as the VATER or VACTERL association. It also can be seen in a number of chromosomal abnormalities or as part of diabetic embryopathy (see Chapter 84).

Genitalia

Hypogenitalism can be seen in association with hypotonia in Prader-Willi syndrome or with low-set dysplastic ears, syndactyly of the toes, and thickened alveolar ridges in Smith-Lemli-Opitz syndrome. Genital ambiguity is associated with renal anomalies and an increased risk for Wilms tumor in Denys-Drash syndrome. Virilization may be associated with 21-hydroxylase deficiency, which requires urgent management of adrenal insufficiency (see Chapter 89).

Spine

Among the most common congenital anomalies are the neural tube defects, which involve abnormalities of the central nervous system along with defects in the associated bony structures. Minor external anomalies, particularly of the lower spine, include unusual pigmentary lesions, hair tufts, dimples, and sinuses. Some of these changes, such as hair tufts and sinuses above the gluteal cleft, may be an indication of a more significant deeper anomaly and require further evaluation, such as magnetic resonance imaging (see Chapter 58).

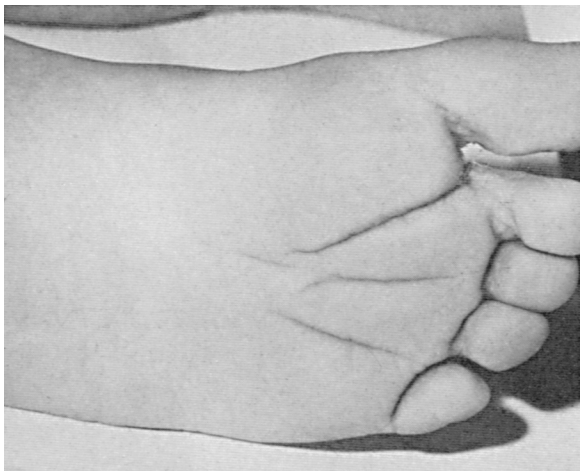
Extremities

Extremities may be relatively long, as occur in Marfan syndrome or homocystinuria, or unusually short, as occur in a diverse group of skeletal dysplasias, the most common being achondroplasia. A simple guide to evaluating relative extremity length is to determine where the fingertips are in relation to the thighs when the upper extremities are adducted alongside the body. In the normal infant, the fingertips fall below the hip joint in the midthigh region. When the upper extremities are short, they align with the hip joint or above (see Fig. 30.17); when they are relatively long, they may reach the knees. A more precise and useful bedside measurement is to determine the ratio of the upper segment to the lower segment. The distance from the pubis to the heel with the leg fully extended constitutes the lower segment. By subtracting the lower segment measurement from the total length, one obtains the upper segment. In normal newborns, the ratio of the upper segment to the lower segment is about 1.7, and the ratio decreases with age to about 1.0 in the adult. A high ratio suggests relative shortening of the extremities, and a low ratio implies either unusually long extremities or a foreshortened trunk, as may occur in spondyloepiphyseal dysplasia.

Paired extremities may be asymmetric in either length or overall size, suggesting either atrophy of one or hypertrophy of the other. The distinction may be difficult to make at times, although it is often evident if an extremity is unusually large or excessively small. Hypertrophy of limbs may be a manifestation of Beckwith-Wiedemann syndrome or Klippel-Trénaunay-Weber syndrome. Isolated hemiatrophy may occur with long-standing corticospinal tract damage as well, as in Russell-Silver syndrome. It is important to identify hemihyperplasia, because individuals with this finding are at increased risk for intra-abdominal tumors, such as Wilms tumor, and thus require close monitoring throughout infancy and childhood.

Foreshortening of long bones leads to various limb abnormalities, depending on the segments involved. A number of terms have been used to describe such anomalies. Rhizomelia denotes proximal shortening of the limbs, such as those in achondroplasia. Mesomelia refers to shortening of the middle segment, and acromelia refers to relative shortening of the hands or feet. A shortened forearm with secondary prominence of skinfolds in a newborn with thanatophoric dysplasia is shown in Fig. 30.18.

The hands and feet have epidermal ridges and creases forming a variety of configurations. Normally, there are two deep transverse palmar creases that do not completely cross the palm. In various conditions, such as trisomy 21, there may instead be a single transverse palmar crease. Single palmar creases may be completely transverse across the palm or may be bridged or incomplete (Fig. 30.19A, B). They may become more apparent when the palm is slightly flexed. A single phalangeal crease on the fifth finger, instead of the normal two, occurs as a consequence of a hypoplastic middle phalanx and results in clinodactyly (incurving of the digit). This is frequently seen in trisomy 21 (see Fig. 30.19*C*) and in a number of other conditions.



The foot also has ridge patterns. A sandal pattern of deep furrows is typical of mosaic trisomy 8 (Fig. 30.20). Fig. 30.21 illustrates the increased separation of the first and second toes and a prominent interdigital furrow in trisomy 21.

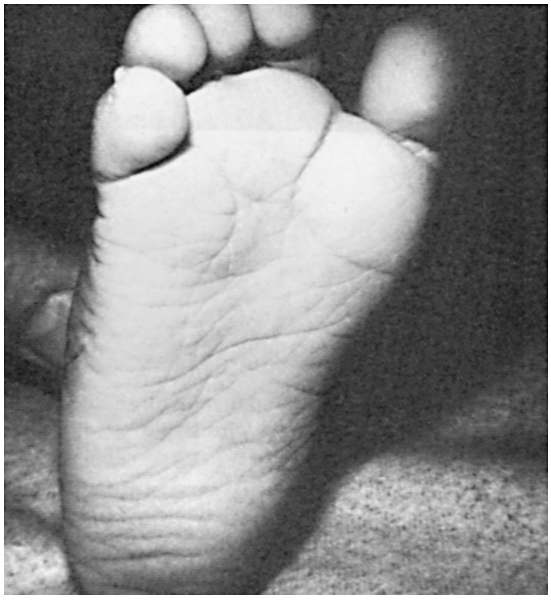
Historically, dermatoglyphics, the study of configurations of the characteristic ridge patterns of the volar surfaces of the skin, was sometimes used to aid in the diagnosis of the newborn with congenital anomalies. The scope of this subject is beyond that of this chapter, and the reader is referred to other sources.[54]

The hands and feet may be enlarged as a result of lymphedema. This is characteristic of infants with Turner or Noonan syndrome, in which the dorsum of the hands and feet may have a puffy appearance (Fig. 30.22). Congenital lymphedema can also be an autosomal dominantly inherited condition with variable expressivity.



Rocker-bottom feet (Fig. 30.23) is a term used to describe a prominent heel and a loss of the normal concave longitudinal arch of the sole. This feature is common in trisomy 18 and other syndromes.

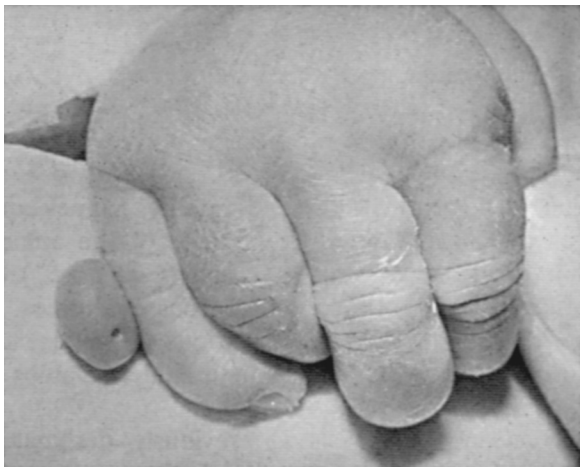
• **Fig. 30.22** Dorsal edema of feet in patient with Turner syndrome.

• **Fig. 30.23** Trisomy 18. Note right hydrocele and rocker-bottom feet.

Significant anomalies of the underlying structure produce alterations in the normal form of the hands and feet. Such abnormalities may be classified into the following categories: absence deformities, polydactyly, syndactyly, brachydactyly, arachnodactyly, and contracture deformities (see Chapter 99).

Absence anomalies are of various types, and the etiology and possible associated malformations vary with the type.

• **Fig. 30.24** Postaxial polydactyly.



Congenital absence of an entire hand is termed acheiria, and absence of both hands and feet is acheiropodia. Ectrodactyly refers to a partial or total absence of the distal segments of a hand or foot, with the proximal segments of the limbs more or less normal. All such anomalies are examples of terminal transverse defects and may occur sporadically or as part of a syndrome. The term ectrodactyly is frequently misused for the lobster-claw anomaly, which is best described as split hand/split foot. In this anomaly, the central rays are deficient, and there is often fusion of the remaining digits. Split hand/split foot may be seen in isolation, when it is of autosomal dominant origin, or it may be seen with other anomalies.

It is useful to determine whether the defects involve primarily the radial, or preaxial, side of the limb or the ulnar, or postaxial, side. For example, blood dyscrasias such as Fanconi anemia and the thrombocytopenia-absent radius syndrome (TAR) commonly involve radial deficiency (see Chapter 79).

Polydactyly refers to partial or complete supernumerary digits and is one of the most common limb malformations. Postaxial polydactyly is more frequent than preaxial, particularly in African Americans (Fig. 30.24). As an isolated anomaly, polydactyly may be inherited as an autosomal dominant trait. It also may be a manifestation of a multiple malformation syndrome. Postaxial polydactyly may occur in a variety of syndromes, including trisomy 13 (Fig. 30.25), chondroectodermal dysplasia, Meckel-Gruber syndrome, and Bardet-Biedl syndrome. Preaxial polydactyly is characteristic of Carpenter syndrome and Majewski short rib-polydactyly syndrome.

Syndactyly refers to fusion of digits; it is usually cutaneous, but it may involve bone. Minimal syndactyly of the second and third toes is common in normal newborns. More extensive syndactyly is shown in Fig. 30.26 and can be seen in trisomy 21 and Smith-Lemli-Opitz syndrome. As an isolated anomaly, different clinical types may be distinguished, but each of them is inherited as an autosomal dominant trait with variable expressivity and incomplete penetrance.

• **Fig. 30.25** Postaxial polydactyly in trisomy 13.

• **Fig. 30.26** Syndactyly between second and third toes.

Extensive syndactyly often is part of a syndrome, and typical examples include some of the craniosynostosis conditions, such as Apert and Pfeiffer syndromes.

Brachydactyly refers to shortening of one or more digits owing to anomalous development of any of the phalanges, metacarpals, or metatarsals. Various clinical types may be distinguished, but most isolated forms of brachydactyly are inherited in an autosomal dominant fashion. Brachydactyly is also a component of numerous disorders, including skeletal dysplasias such as achondroplasia and syndromes such as Albright hereditary osteodystrophy and trisomy 21 (see Fig. 30.19*C*).

Arachnodactyly refers to unusually long, spiderlike digits, and it is characteristic but not invariable in Marfan syndrome and homocystinuria. The appearance of brachydactyly and arachnodactyly can be confirmed by measuring and determining the ratio of middle finger to total hand length, which is normally about 0.43 in the newborn.

A variety of congenital joint deformities involving the limbs may occur. Arthrogryposis, multiple congenital contractures, is most often sporadic and may be associated with oligohydramnios or may be the result of some underlying neuromuscular abnormality, such as spinal muscular atrophy. Talipes equinovarus or calcaneovalgus deformities of the ankle are common isolated joint contractures (see Chapter 99). Contractures also may occur in numerous syndromes. Joint hypermobility is frequent in various connective tissue disorders, such as Marfan and Ehlers-Danlos syndromes, and can also be seen in a number of multiple anomaly syndromes such as Kabuki syndrome.

• **Fig. 30.27** Trisomy 18. Note characteristic clinodactyly of second, fourth, and fifth fingers.

Clinodactyly, as discussed previously, designates an incurving of a digit, most commonly of the fifth finger. This condition is frequent in trisomy 21 and other syndromes (see Fig. 30.19*C*). A characteristic clinodactyly involving the fourth and fifth fingers radially and second finger in an ulnar direction occurs in trisomy 18 (Fig. 30.27) or, less often, in trisomy 13.

Camptodactyly is irreducible flexion of the digits. In the hand, it usually involves the fifth finger, but it may affect other fingers as well. Isolated camptodactyly may be inherited as an autosomal dominant trait. Camptodactyly also may be part of a syndrome such as trisomy 8, trisomy 10q, and Freeman-Sheldon syndrome.

Evaluation of the Stillborn

Evaluation of the stillborn is essential to the diagnostic workup and is similar to that of the live-born infant. If this important function is not adequately performed, the family is left with little understanding of the nature and etiology of the anomaly, the recurrence risk, and methods of preventing future occurrences. Further, the grieving process, a natural consequence of fetal loss, can be more difficult without an understanding of the cause of the loss. In addition to the obvious role of the pathologist to learn as much as possible from the examination of the aborted fetus, the clinician is essential in encouraging the family to allow fetal evaluation and to allow the pathologist to conduct it. The clinician also should direct additional testing and meet with the family when the evaluation is complete to ensure that the family receives medical and genetic counseling. These

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

evaluations are generally done by the perinatologist or neonatologist, and it is reasonable to assume that before 20 weeks of gestation, responsibility of pregnancy loss evaluation rests with the perinatologist, and after this date, it falls to the neonatologist.

Pregnancy loss before 20 weeks occurs in at least 12%-15% of all pregnancies. When the loss occurs after 20 weeks, it is usually called stillbirth[13,46,55,66] and occurs in 1%-2% of pregnancies. It is optimal for each hospital to develop a protocol for evaluating fetal loss, including which fetuses to study and which evaluations are appropriate.[47] A thorough surface examination by the clinician is useful to identify minor anomalies that may not be apparent to the pathologist as rigor mortis sets in. If indicated, a sample of blood or skin should be obtained as soon as possible under sterile conditions for chromosome analysis and possible chromosomal microarray, because karyotypic abnormalities are seen in 6%-13% of stillbirths.[36,49] Skin can be placed in viral culture media or sterile saline and sent to the laboratory for fibroblast culture. Cells from the fetal side of the placenta may grow when macerated fetal tissue may not. Examination of the stillborn and the placenta by the pathologist may identify internal anomalies that lead to a definitive diagnosis.

Diagnostic Testing and Indications

Once a thorough history has been taken and a physical examination has been performed, the clinician should identify those features that are most unique to the neonate. Sometimes a pattern is readily recognized, such as trisomy 21 in a child with an atrioventricular canal, hypotonia, palpebral fissures that slant upward, small squared ears, and fifth finger clinodactyly. However, a review of reference texts often is required to determine whether the findings represent a previously recognized malformation syndrome.[11,35] A clinical geneticist may be especially helpful at this point.

The following laboratory and imaging studies may be indicated to aid in making an accurate diagnosis. In many cases, a diagnosis does not become apparent until later in life as the physical features change and other structural or functional abnormalities become apparent.[41] Parents should be counseled about this possibility and that even though a diagnosis may not be apparent, the findings may well have a genetic basis and recurrence in future pregnancies is possible.

General Studies

In a newborn with one or more obvious major malformations or with multiple minor anomalies, imaging studies are often indicated to identify other anomalies. Whether or not other significant anomalies are identified, these studies will further describe the phenotype of the affected neonate. Detection of major anomalies involving the brain, heart, and kidneys is particularly important for diagnostic purposes, and it also may allow for more appropriate management and more accurate prognostication. Echocardiography is useful because congenital heart defects are among the most common major malformations with specific indications for genetic testing (Table 30.7). Ultrasonography of the head and abdomen is useful to screen for major structural anomalies of the brain, kidneys, and liver. Head ultrasonography is a crude study for brain abnormalities, and if brain abnormalities are suspected, more definitive procedures such as magnetic resonance imaging are indicated. Newborns with skull abnormalities, short stature, or foreshortened long bones should have a skeletal survey to evaluate for skeletal dysplasias.

Ophthalmology evaluation also can be useful in diagnosing the neonate with congenital anomalies, especially if brain malformations or neurologic abnormalities are present. This evaluation also should be performed if small genitalia are present in a male infant (septo-optic dysplasia) or if features of the CHARGE syndrome are present.

The neonate with ambiguous genitalia requires a battery of tests, including chromosome analysis (see Genetic Laboratory Studies) to determine genotypic sex, pelvic ultrasonography to identify internal genitalia, and endocrine testing (17-OH progesterone, testosterone, luteinizing hormone, follicle-stimulating hormone). It is best to defer assignment of sex until many of these tests have been performed and a urologist has evaluated the newborn. This is an emotional crisis for the family. Every neonatal unit should have a plan in place to treat sex determination as a medical emergency. A psychologist is an essential member of the team to assist the family in dealing with the uncertainty and complexity of decision making (see Chapter 89).

The value of the postmortem examination cannot be overemphasized. A thorough evaluation by an experienced pathologist can yield findings that would not be identified otherwise and that may lead to a definitive diagnosis and thus information about recurrence risk and possible prenatal testing in future pregnancies. The role of the clinician is to educate the family about the importance of such an evaluation. If the family is reluctant to agree to a full autopsy, a partial exam focused on chest and abdomen can be useful.

Genetic Laboratory Studies

Table 30.7 shows typical cytogenetic, molecular, and biochemical tests performed on neonates with congenital anomalies.[24] Genetic analysis is indicated in all newborns with ambiguous genitalia, two or more major anomalies, multiple minor anomalies, or growth restriction in association with anomalies. Such studies should be performed, even if a prenatal chromosome analysis had normal findings, because of improvements in resolution in identifying small deletions or amplifications. Chromosomal microarray (CMA) is considered the first line genetic test in neonates with multiple anomalies.[45] It allows for the detection of deletions and duplications too small to be seen in a high-resolution chromosome analysis. Depending on the study

TABLE 30.7 Genetic Diagnostic Tests Commonly Used in Newborn Medicine

Indication*	Condition	Approach
Hypotonia	Myotonic dystrophy	Targeted mutation analysis of trinucleotide repeat
	Spinal muscular atrophy	Deletion analysis of exon 7 in *SMN1* gene
	Prader-Willi syndrome	Methylation studies of chromosome 15
	Congenital disorders of glycosylation	Analysis of serum transferrin glycoforms
Multiple anomalies	CHARGE syndrome	Gene sequencing of *CHD7*
	Noonan syndrome	Sequencing of seven genes in the Ras pathway: *PTPN11*, *KRAS*, *RAF1*, *SOS1*, *NRAS*, *BRAF*, and *MAP2K1*
	Microdeletion syndromes	Chromosome microarray
Abnormal genitalia, isolated or with other anomalies	Camptomelic dysplasia	Gene sequencing of *SOX9*
	WAGR or Denys-Drash	Gene sequencing of *LIT1*
Ambiguous genitalia	Congenital adrenal hyperplasia	17-OH progesterone
	Smith-Lemli-Opitz syndrome	7-Dehyrocholesterol
	45,X/46,XY	Karyotype
Small infant or dwarfism	Achondroplasia, hypochondroplasia, thanatophoric dysplasia	Targeted sequencing of *FGFR3*
Pierre Robin sequence	Stickler syndrome	Genetic sequencing of *COL11A1*, *COL11A2*, or *COL2A1*
	22q11 deletion/velocardiofacial/ DiGeorge syndrome	FISH 22q11 deletion probe or microarray
Congenital Heart Disease		
Conotruncal defects	22q11 deletion/velocardiofacial/ DiGeorge syndrome	FISH 22q11 deletion probe
Supravalvular aortic stenosis	Williams syndrome	FISH for *ELN* gene deletion
Coarctation of aorta	Turner syndrome	Karyotype
Pulmonic stenosis	Noonan syndrome	Sequencing of eight genes in the Ras pathway: *PTPN11*, *SOS1*, *RAF1*, *RIT1*, *KRAS*, *NRAS*, *BRAF*, *MAP2K1*

*This list is not exhaustive, and the appropriate genetic test for all these indications is dependent on the phenotype of the neonate. WAGR, Wilms tumor, aniridia, genitourinary anomalies, intellectual disability.
Adapted from Goodin K. Advances in genetic testing and applications in newborn medicine. *NeoReviews* 2008;9:282; and Slavotinek AM. Novel microdeletion syndromes detected by chromosome microarrays. *Hum Genet*. 2008;124:1.

population, CMA is able to identify an additional 5%-10% of cases with genomic imbalance compared with routine karyotyping.[15,38] However, CMA can also identify deletions or duplications known as copy number variants that may or may not be associated with the phenotype of the neonate.[56] Thus, care must be taken when interpreting the CMA results. Parental samples are recommended to determine whether the copy number variant occurred de novo or is inherited from a normal parent and is unlikely to cause the anomaly in question.

Fluorescence in situ hybridization testing can be ordered if there is a high level of suspicion for a known microdeletion syndrome not detectable by routine cytogenetic analysis, such as 22q11 deletion/velocardiofacial/DiGeorge syndrome or Williams syndrome. Testing with FISH has shown that a significant number of neonates with conotruncal heart defects have a 22q11 microdeletion, so this testing is indicated in all patients with truncus arteriosus, interrupted aortic arch, and tetralogy of Fallot. Conditions with known cardiovascular associations are listed in Table 30.8.

When a syndrome or syndromes are suspected in the differential diagnosis, molecular genetic analysis of specific genes should be considered. Molecular gene-based testing has become a useful tool in diagnosing the newborn with congenital anomalies, because the number of genes identified to cause malformation has increased. For example, in those infants with unexplained hypotonia and contractures, DNA testing may identify an expansion in the myotonic dystrophy gene or mutations in the spinal muscular atrophy gene. Fifty percent of infants with Pierre Robin sequence will have an identifiable genetic cause such as mutations in the collagen genes (*COL11A1*, *COL11A2*, or *COL2A1*) causing the autosomal dominant Stickler syndrome, or deletion in 22q11 causing velocardiofacial/DiGeorge syndrome.[19]

The medical sequencing technology should be understood by the ordering clinician because some molecular tests examine the most frequent sequence variants and other methods sequence the entire coding regions of the causative gene. Thus, a targeted test could miss a true causative mutation in a particular patient. Further, sequence variants of unclear pathogenicity have been commonly identified across the genome, so care should be taken when correlating a putative mutation with the phenotype.

TABLE 30.8 Major Chromosomal and Inherited Syndromes Associated With Heart Defects

Syndrome	Cardiac Defects	Noncardiac Features
Trisomy 13	ASD, PDA, VSD	Microcephaly; cutis aplasia; holoprosencephaly; cleft lip; microphthalmia; low-set ears; micrognathia; hypotonia; polydactyly; rocker bottom feet; cryptorchidism
Trisomy 18	ASD, ECD, PDA, TOF, VSD	Intrauterine growth restriction; microcephaly; prominent occiput; micrognathia; cleft lip/palate; low-set ears; clenched hands with fingers 1 and 4 overlapping 2 and 3; rocker bottom feet; cryptorchidism; short sternum; pectus carinatum
Trisomy 21	ECD, VSD, ASD	Brachycephaly; epicanthal folds; small ears; upslanting palpebral fissures; transverse palmar crease; protruding tongue; excess nuchal skin; hypotonia; duodenal atresia
CHARGE	TOF, ECD aortic arch anomalies	Coloboma; choanal atresia; cranial nerve dysfunction; ear abnormalities; Mondini defect of the cochlea; absent or hypoplastic semicircular canals; developmental delay; growth deficiency; genital hypoplasia
Deletion 22q11 (DiGeorge, velocardiofacial)	IAA, TF, VSD, truncus arteriosus	Hypocalcemia; palatal abnormalities; immune deficiency; significant feeding and swallowing problems; constipation with or without structural gastrointestinal anomalies; renal anomalies; hearing loss (both conductive and sensorineural)
Holt-Oram	ASD, VSD, COA	Upper-extremity malformations involving radial, thenar, or carpal bones; cardiac conduction defects
Kartagener	Dextrocardia	Situs inversus; bronchiectasis; asplenia; conductive hearing loss
Loeys-Dietz	Aortic dilatation and/or rupture, MVP	Hypertelorism; craniosynostosis; cleft palate/bifid uvula; pectus excavatum or pectus carinatum; scoliosis; joint laxity; arachnodactyly; talipes equinovarus; velvety and translucent skin; easy bruising; widened, atrophic scars
Marfan	Aortic dilatation, MVP, TVP, pulmonary artery dilatation (proximal)	Arachnodactyly; pectus deformity; hyperextensible joints; high arched palate; ectopia lentis
Neurofibromatosis	PS, aortic dilatation, MVP, HCM[36]	Café au lait spots; axillary/inguinal freckling; Lisch nodules; cutaneous neurofibromas; anteriolateral tibial bowing
Noonan	PS, HCM[12,33]	Short, broad neck; low hairline; coagulation defects; pectus deformity; scoliosis; cryptorchidism; lymphatic dysplasia; ptosis; low-set, posteriorly rotated ears
Smith-Lemli-Opitz	TAPVC, AV canal	Prenatal and postnatal growth restriction; microcephaly; underdeveloped external genitalia in males/hypospadias; postaxial polydactyly; 2-3 syndactyly of the toes; poor suck, irritability; failure to thrive; temporal narrowing; epicanthal folds; broad nasal bridge; short nasal root; anteverted nares; cleft palate; low-set, posteriorly rotated ears; micrognathia
Thrombocytopenia-absent radius (TAR)	ASD, TOF[16]	Thrombocytopenia; bilateral absent radii with thumbs present; long bone abnormalities
Turner syndrome	AS, COA, HLHS[70]	Broad chest; short, broad neck; lymphedema; hyperconvex nails
Williams syndrome	SVAS, branch pulmonary artery stenosis[10]	Hypercalcemia; feeding difficulties; failure to thrive; fullness of mouth and eyes; hypotonia; hyperextensible joints; hypertension; hypercalciuria

AS, Aortic stenosis; ASD, secundum atrial septal defect; AV, atrioventricular; COA, coarctation of the aorta; ECD, endocardial cushion defect; HCM, hypertrophic cardiomyopathy; HLHS, hypoplastic left heart syndrome; IAA, interrupted aortic arch; MVP, mitral valve prolapse; PDA, patent ductus arteriosus; PS, pulmonary valve stenosis; SVAS, supravalvular aortic stenosis; TAPVC, total anomalous pulmonary venous connection; TGA, transposition of the great arteries; TOF, tetralogy of Fallot; TVP, tricuspid valve prolapse; VSD, ventricular septal defect.

With advances in technology, it is now possible to sequence the entire coding region (exome) or genome of an individual. Whole exome sequencing (WES) is most powerful when DNA samples from both parents are included for analysis, referred to as an exome trio. This testing methodology identified an etiology for the anomalies for 36% of the 140 babies with multiple anomalies who underwent analysis.[21] Other series reporting on results focused on the high-risk NICU population with abnormal neurologic findings have reported identifying a care changing diagnosis in up to 50% of patients.[44,57] As the process of data interpretation improves, the diagnostic yield of WES should continue to increase, making it more informative in the evaluation of the neonate with multiple anomalies.

Biochemical testing for many metabolic malformation syndromes is also possible. Metabolic conditions were traditionally thought of as not being associated with congenital anomalies, but this concept is changing. A definitive diagnosis of multiple malformation Smith-Lemli-Opitz syndrome can be made by obtaining a low serum cholesterol level and an elevated 7-dehydrocholesterol level.[48] Congenital disorders of glycosylation, a group of autosomal recessive disorders with a wide variety of abnormalities, are diagnosed by serum transferrin glycoform analysis.[64] Presumably many other conditions with congenital anomalies will be found to have a biochemical basis, which will allow for more definitive diagnoses and appropriate management strategies (see Table 30.7).

Genetic Counseling

Genetic counseling should be provided at some point to all parents of children with major malformations or multiple anomalies. Genetic counseling is a communication process during which families are informed about the abnormalities present in the affected individual, with medical and genetic knowledge discussed in practical language. It is most often provided by genetic counselors, who typically work with medical geneticists. Genetic counselors are individuals with master's degrees who have been specifically trained to understand genetic disorders and congenital anomalies and to help families with the psychological and emotional adaptation to having a family member with a serious and chronic problem. Medical geneticists are physicians who have received special training in genetic counseling and in the diagnosis and management of genetic disorders and birth defects.

Genetic counseling for congenital anomalies should include a description of the abnormality, the natural history, associated abnormalities, and prognosis for the disorder. The etiology of the abnormality (if known), whether genetic or nongenetic, is explained in such a manner that the family can understand. The family also is given reassurance that the condition in the affected individual is not the fault of any individual, and information about recurrence risk is provided. Analysis of the pedigree can then identify family members who are at increased risk for being affected or having affected offspring. These relatives should also learn about the disorder and receive an explanation of the reproductive options available for the condition, particularly the prenatal and preimplantation technologies, complications, and accuracy. Assistance should be offered in reaching a decision about prenatal or postnatal testing. Information about appropriate community services and family support organizations also is offered.[67]

Educational Resources and Support Organizations

With almost universal access to the Internet, the number of educational resources for clinicians and families about genetic conditions has increased greatly, from clinical description to chromosomal and molecular databases.[7,24] The National Library of Medicine's National Center for Biotechnology Information hosts several gene-specific websites that are particularly relevant for the neonatologist or perinatologist who is evaluating an infant with congenital anomalies.[45a] Gene Reviews provides a detailed description of many single-gene disorders and gives information about clinical genetic testing availability and interpretation, also providing current lists of resources for families.[45b] An excellent reference for all single-gene conditions is the Online Mendelian Inheritance in Man.[43] Because most congenital anomalies and genetic disorders are relatively rare, usually occurring with a frequency of 1 in 1000 or less, family support organizations have been developed to help combat the isolation and grief felt by families who have or have had an affected child. These groups usually offer support and empathy and serve as a clearinghouse for information about the disorder and its management. Often they have a newsletter for members that describes helpful coping mechanisms and keeps families updated on relevant resources and research. With the increased use of social media, many support groups have Facebook pages that allow members another method of communication.

Such organizations often have been started by, and are usually staffed by, parents of affected individuals or by affected individuals themselves. As a result, they vary greatly both in the format and content of what they offer and in the accuracy of the information they distribute. Organizations for more frequent disorders, such as trisomy 21, are usually large and professionally run; offer educational forums, such as an annual conference and lay literature; keep listings of resources locally and nationally; and may even offer grant funding for research on the disorder. Smaller organizations for less common conditions may serve primarily a social and support function. Because of this variability in the knowledge of support organizations and the resultant uncertainty concerning the accuracy of information provided, it is advisable for the physician to become familiar with an organization and its functions before referring a family.

The Genetic Alliance (http://www.geneticalliance.org/, accessed March 17, 2018) provides information services

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

for individuals and disease-specific organizations. The alliance supplies contact information and data about the organizations. Another group, the National Organization for Rare Disorders (http://www.rarediseases.org/, accessed March 17, 2018), functions as a clearinghouse for information on genetic disorders; it will send a summary of this information written for lay individuals for a small fee, will match families, and will make medical referrals, if appropriate. The March of Dimes (http://www.marchofdimes.com/, accessed March 17, 2018) provides excellent lay information about specific genetic disorders. Genetics Home Reference (https://ghr.nlm.nih.gov/, accessed March 17, 2018) provides basic information about genes and genetics, as well as information about genetic disorders.

Acknowledgments

The author and editors gratefully acknowledge the contributions of Suzanne Cassidy, Louanne Hudgins, Aditi Parikh, and Georgia Wiesner to previous editions of this chapter, portions of which remain unchanged.

Key Points

- It is the role of the neonatologist to direct the evaluation of the newborn or stillborn with congenital anomalies.
- Diagnostic testing and evaluations, along with consultation of references and specialists in the field, such as medical geneticists and dysmorphologists, may be helpful.
- The goal is to identify the etiology to improve medical management and to provide accurate information on prognosis and recurrence risk that can be shared with the family.

Overview and Initial Management of Delivery Room Resuscitation

JAY P. GOLDSMITH

The transition from fetus to neonate represents a series of rapid and dramatic physiologic changes during which the placenta is replaced by the lungs as the primary organ of gas exchange. Although this transition goes smoothly most of the time, in approximately 10% of births the active intervention of a skilled individual or team is necessary to ensure that the newborn receives the appropriate assistance to assume independent existence as quickly as possible.[70,72] The need for full resuscitation, including chest compressions and/or medication administration, is relatively rare, occurring in approximately 1-2 per 1000 live births.[48] For these severely depressed newborns and for extremely premature infants, to avoid or minimize injury, the process of resuscitation during the first hour of life requires excellent communication, cognitive knowledge, skilled technical providers, and behaviors that are integral to a collaborative team effort.

Although certain episodes of fetal asphyxia cannot be prevented, there are many circumstances in which, in the immediate neonatal period, a prompt and skilled resuscitation may prevent death or ameliorate lifelong adverse sequelae. Newborns who require medication and/or chest compression in the first few minutes after birth usually have significant fetal acidemia, inadequate ventilation after birth, or both.[48] Because the need for significant intervention cannot always be predicted, the American Heart Association (AHA)/American Academy of Pediatrics (AAP) *Textbook on Neonatal Resuscitation* and the *Guidelines for Perinatal Care* have advised: "At every delivery, there should be at least one individual whose primary responsibility is the infant and who is capable of initiating resuscitation, including positive pressure ventilation."[4,70] The *Guidelines* also suggest that "the identification and resuscitation of a distressed neonate requires an organized plan of action" and that hospitals should assure the competency and periodic credentialing of individuals who perform these tasks.[4]

In the past three decades, neonatal resuscitation has been the subject of extensive research and review. The evidence evaluation process of the International Liaison Committee on Resuscitation (ILCOR) provides rigorously developed evidence-based guidelines based on the available medical science to inform the best approach to neonatal resuscitation.[72] Although many elements of a resuscitation sequence have been agreed upon, debate and discussion regarding certain aspects of the process continue.[14,67] Moreover, the ILCOR guidelines are a Consensus of Science and Treatment Recommendations (CoSTaR) document, and each national resuscitation council may modify the treatment recommendations based on its members' own deliberations of the science and what is deemed appropriate for its country. Thus, despite one international scientific document, there are often significant differences among the recommendations for performing neonatal resuscitation among various countries.[52]

Research continues to search for answers to many difficult questions. The US guidelines (e.g., Neonatal Resuscitation Program), updated every 5-6 years by the AAP and the AHA,[70] are essentially derived from the ILCOR CoSTaR document, which is usually published the preceding year.[72] These recommendations represent the best distillation of the available science at the time of their publication as viewed by the AAP Neonatal Resuscitation Program Steering Committee and should serve as the foundation for any resuscitation program or algorithm in the United States. This chapter presents the current guidelines for neonatal resuscitation and reviews the evolving science in this area to provide an appreciation of common and controversial questions and a basis for understanding conflicting views.

Fetus

In utero, the fetus depends on the placenta for gas exchange. Despite a Pao_2 of 20-30 mm Hg, the normal fetus carries on essential metabolism and is not hypoxic. The tissues receive adequate amounts of oxygen, and anaerobic metabolic pathways are not usually used. Adequate oxygen delivery is accomplished with an adaptive process primarily involving the architecture of the circulatory system, the characteristics of fetal hemoglobin, and the rate of perfusion of fetal organs.

Abstract

Neonatal resuscitation has been the subject of extensive research over the last three decades, resulting in evidence-based guidelines that are revised every 5-6 years. The transition from fetal to neonatal gas exchange requires many cardiopulmonary physiologic changes, which may be impaired by a variety of intrauterine and/or intrapartum events leading to neonatal depression at birth requiring skillful resuscitation. Someone capable of beginning resuscitation should be at every delivery; in some cases, the need for resuscitation may be anticipated and a team of appropriately trained individuals should be ready to begin the initial steps. The clinical condition of the newly born infant, evolving Apgar scores, and umbilical cord blood gases will inform the resuscitation team of the need for and the extent of resuscitation required. Initial steps should include provisions for the maintenance of normal temperature, clearing the airway, and beginning positive pressure ventilation if adequate breathing does not result from appropriate stimulation.

The placenta has the lowest resistance in the circulatory system of the fetus and preferentially receives blood from the systemic circulation. Approximately 40% of the total cardiac output of the fetus flows through the placenta. Blood in the umbilical artery leaving the fetus travelling back to the placenta has a P_{O_2} of 15-25 mm Hg.[37] In humans, umbilical venous blood returning from the placenta to the fetus obtained by percutaneous umbilical vein sampling has a P_{O_2} normally 20-40 mm Hg, but it may range up to 45 mm Hg.[42] When the umbilical venous blood is mixed with venous return from the fetus, the resultant P_{O_2} is lower. Although the arterial oxygen tension of the fetus is low compared with postnatal values, the high affinity of fetal hemoglobin for oxygen shifts the oxyhemoglobin curve to the left, resulting in only mildly diminished oxygen content of the blood.

Several adaptive and anatomic mechanisms help keep fetal tissue well perfused and oxygenated despite low oxygen tension. When the umbilical vein enters the abdomen of the fetus, the stream splits, with slightly more than half of the blood flowing through the ductus venosus into the inferior vena cava. The remaining blood perfuses portions of the liver. The umbilical venous return entering the inferior vena cava tends to stream and does not completely mix with less oxygenated blood entering the inferior vena cava from below. In the right atrium, the crista dividens splits the inferior vena cava stream so that oxygenated blood from the umbilical vein flows through the foramen ovale into the left side of the heart. The less oxygenated blood returning from the fetal body flows into the right ventricle (Fig. 31.1).

In the fetus, blood flow through the lungs is diminished because of the high resistance of the fetal pulmonary circuit, the open ductus arteriosus, and the lower resistance of the systemic and placental circuits. Nearly 90% of the right ventricular output crosses the ductus arteriosus and enters the aorta, bypassing the lungs. With little return from the pulmonary veins, oxygen in the umbilical venous blood crossing the foramen ovale into the left atrium is only slightly diluted. The most highly oxygenated blood perfuses the brain and heart through the carotid and coronary arteries before its oxygen concentration is decreased by blood entering the aorta through the ductus arteriosus.

Another adaptive mechanism keeping the fetal tissues oxygenated is the rate of perfusion. Fetal tissues are perfused with blood at a higher rate than in the adult. The increased delivery of blood compensates for the low oxygen saturation (Sp_{O_2}) in the fetus and the higher oxygen affinity of fetal hemoglobin. Finally, the fetus (except during labor) has less of an oxygen demand than the newborn. Because thermoregulation is unnecessary and respiratory effort is limited, two significant processes that consume oxygen in the newborn are either eliminated or markedly diminished in the fetus.

The P_{CO_2} of the fetus is slightly higher than adult levels. The normal umbilical venous P_{CO_2} is 35-45 mm Hg. Elimination of carbon dioxide from the fetus is enhanced by maternal hyperventilation and relative hypocarbia during pregnancy. Because of the lower P_{CO_2} of maternal blood, a gradient is created favoring the transfer of carbon dioxide across the placenta from fetal to maternal blood (Bohr effect).

• **Fig. 31.1** Fetal circulation.

The low fetal P_{O_2} contributes to the flow characteristics of the fetal circulation by helping to keep the pulmonary vascular resistance (PVR) high. The ductus arteriosus remains patent because of fetal production of prostaglandins and a relatively low P_{O_2}.

The fetus maintains metabolic homeostasis despite low oxygen tensions because of these adaptive and anatomic characteristics. However, any significant compromise of fetal gas exchange before labor (e.g., intrauterine growth restriction, placental abnormalities) or during the intrapartum period or lack of effective transition at birth quickly results in asphyxia, consisting of hypoxia, elevated P_{CO_2}, and metabolic acidosis.

Transition at Birth

The circumstances and process of delivery contribute to the condition of the infant at birth. A cesarean section done

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

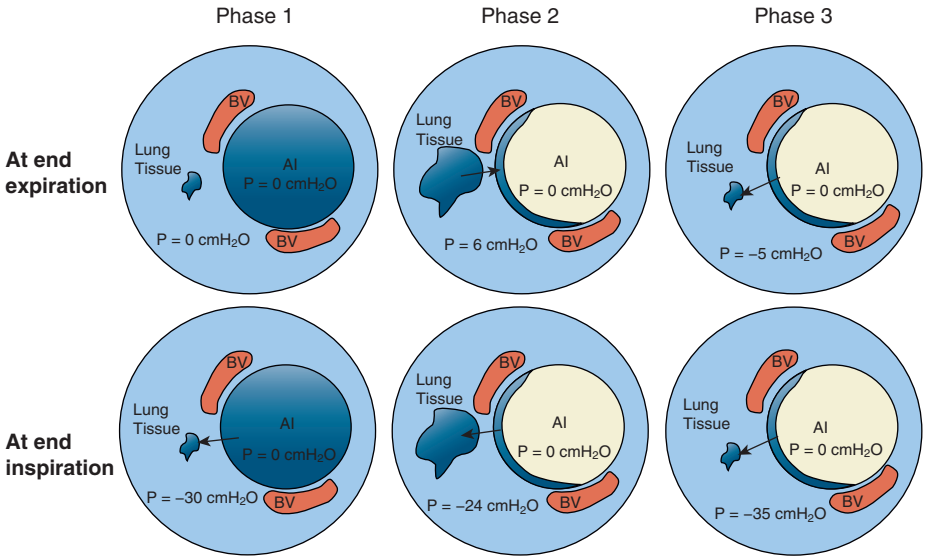
before the onset of labor has a different physiologic effect on the process of transition than the standard labor process. Delivery of a multiple gestation and anesthesia administered to the mother may also be significant contributing factors. The labor process causes mild hypoxia and acidosis. With each contraction, uterine blood flow decreases, with a resulting decrease in placental perfusion and a temporary impairment of transplacental gas exchange resulting over time in a mild metabolic acidosis; this is accompanied by transient hypoxia and hypercapnia. The intermittent nature of normal labor permits the fetus to "recover" between each contraction; however, the effect is cumulative and may be exacerbated with an abnormal labor contraction pattern. Throughout a normal labor, the fetus undergoes a progressive but slow reduction in P_{O_2}, some increase in P_{CO_2}, a decrease in pH, and the accumulation of a mild metabolic acidosis.[11] The normal fetus enters labor with a base excess of –2 mmol/L; with uncomplicated progression of labor to vaginal delivery, the base excess will be reduced by an additional 3-4 mmol/L.[11,54] In the normal circumstance, these changes are not significant enough to depress the infant and prevent normal transition from intrauterine to postnatal existence.

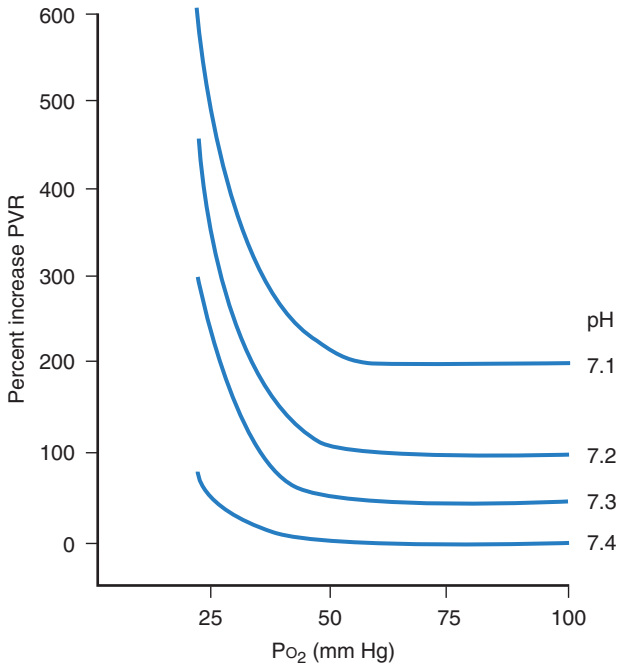
With birth, the neonate must establish the lungs as the site of gas exchange; the circulation, which in the fetus shunted blood away from the lungs, must now fully perfuse the pulmonary vasculature. Postnatal breathing is on a continuum with in utero breathing movements that are well established but intermittent in the term fetus.[47] Clamping of the cord at birth stimulates peripheral and central chemoreceptors, and in conjunction with tactile and thermal stimulation, results in an increased systemic blood pressure. This combination of events is usually enough stimulation for a noncompromised infant to begin breathing. The American College of Obstetricians and Gynecologists (ACOG) now recommends delayed cord clamping for 30-60 seconds in vigorous term and preterm infants to increase blood volume, decrease need for inotropic support, and reduce several complications of prematurity. However, if the placental circulation is not intact (i.e., abruptio placenta) or the newborn needs immediate resuscitation, immediate cord clamping should be considered or care should be individualized.[15,50]

The clearance of lung fluid after birth is the result of multiple processes and only minimally caused by the "thoracic squeeze" during passage through the birth canal. A few days before a normal term vaginal delivery, the fetal production of lung fluid slows, and alveolar fluid volume decreases.[9] The process of labor is a powerful stimulus for the clearance of lung fluid, and that transfer of fluid from the air spaces is predominantly a process of active transport into the interstitium and drainage through the pulmonary circulation, with some fluid exiting through lymphatic drainage.[28] Although started before labor and influenced by the increasing levels of endogenous catecholamines, the process accelerates immediately after birth.



The first few breaths must facilitate clearance of fluid from the lungs and establish a functional residual capacity (FRC).[62,63,69] The first breath of a spontaneously breathing term infant is generally characterized by short inspirations each followed by prolonged expiratory phases. Although the peak inspiratory pressure may be as high as −50 cm H_2O to −100 cm H_2O, the opening pressures are very low. That is, gas begins to enter the lungs at very low pressures, usually less than −5 cm H_2O pressure. Very high expiratory pressures are also generated; these pressures generally exceed the inspiratory pressure. This expiratory pressure, probably generated against a partially closed glottis, drives the liquid in the lung peripherally, increasing the FRC over the first several breaths with multiple inspiratory efforts. In a vigorous, spontaneously breathing, vaginally delivered infant, a significant FRC develops with the first several breaths. However, the depressed neonate may need assistance with establishing an FRC. A three-phase process proposed by Hooper et al. suggests that initial resuscitation of an apneic newly born baby should begin with a sustained inflation to aerate the lung followed by positive end expiratory pressure to maintain the FRC (see Chapter 32) (Fig. 31.2).[26,39] However, sustained inflations at birth are not recommended at this time by the Neonatal Resuscitation Program (NRP).[70]

Expansion of the lungs is a stimulus for surfactant release, which reduces alveolar surface tension, increases compliance, and helps maintain a stable FRC. Simultaneously, the act of ventilation alone reduces PVR. Ventilation leads to a decrease in P_{CO_2} and an increase in pH and P_{O_2}, also causing a decrease in PVR.[13] The administration of oxygen is not necessary to produce this drop in PVR. In a study of lambs, Lakshminrusimha and colleagues showed that PVR decreased nearly as much (72%) in the first 30 minutes after birth with air resuscitation as with 100% oxygen.[31] By 60-90 minutes after birth, the decrease in PVR in the air group had reached the same level as the 100% oxygen group. Fig. 31.3 illustrates the relationships between pH, P_{O_2}, and PVR.[55] Clearance of lung fluid, establishment of FRC, and a decrease in PVR with an increase in pulmonary blood flow facilitate postnatal ventilation and oxygenation.



With the onset of ventilation, the fetal circulatory system assumes the adult pattern. Coincident with clamping of the cord, the low-resistance placenta is removed from the systemic circuit, and systemic blood pressure increases. This increase in systemic pressure, coupled with the decrease in PVR and in pulmonary artery pressure, decreases the right-to-left shunt through the ductus arteriosus. The increase in Pa_{O_2} further stimulates functional closure of the ductus arteriosus. With ductal shunting diminished, pulmonary artery blood flow increases, resulting in increased pulmonary venous return to the left atrium and increased pressure in the left atrium. When the left atrial pressure exceeds right atrial pressure, the foramen ovale functionally closes.

An uncomplicated transition from fetal to newborn status is characterized by loss of fetal lung fluid, secretion of surfactant, establishment of FRC, decrease in PVR, increased systemic pressure after removal of the low-resistance placenta from the systemic circuit, functional closure of two shunts (ductus arteriosus and foramen ovale), and increase

in pulmonary artery blood flow. In most circumstances, the mild metabolic acidosis associated with labor is insufficient to interfere with this process. Regardless of the mode of birth, the transition may be significantly altered by various antepartum or intrapartum events, resulting in cardiorespiratory depression, asphyxia, or both. Infants who are very premature are especially vulnerable to these untoward events.

Causes of Depression and Asphyxia

A newborn may be compromised because of problems initiated in utero with the mother, the placenta, or the fetus itself (Box 31.1). A process initiated in utero may extend into the neonatal period, preventing a normal transition. An asphyxial process also may be neonatal in origin; that is, the infant seems well until required to breathe on his or her own.

Maternal causes of fetal compromise may be related to decreased uterine blood flow, which decreases the amount of oxygen transported to the placenta. Diminished uterine blood flow may result from maternal hypotension (such as hypovolemia, allergic reaction, or as a result of drugs used to treat hypertension), regional anesthesia, eclampsia, or abnormal uterine contractions. Problems with the placenta, such as chronic structural abnormalities, infarcts, premature separation, edema, or inflammatory changes may impair gas exchange. The fetus also may be compromised because of fetal problems related to cord compression, such as nuchal cord, prolapse, or a breech presentation with cord compression by the aftercoming head, or by intrinsic fetal problems such as anemia or congenital abnormalities. In some cases, inflation of the lung occurs normally, but there may be a deficiency in oxygen-carrying capacity, as in severe hypovolemia from acute hemorrhage or fetal-maternal transfusion, or there may be inadequate cardiac output from numerous causes. A neonate may not have adequate ventilation after delivery because of many problems, including asphyxia, drug-induced central nervous system (CNS) depression, CNS anomalies or injury, spinal cord injury, mechanical obstruction of the airways, congenital facial or airway deformities, immaturity, pneumonia, or congenital anomalies.

• BOX 31.1 Factors Associated with Neonatal Depression and Asphyxia

Antepartum Risk Factors

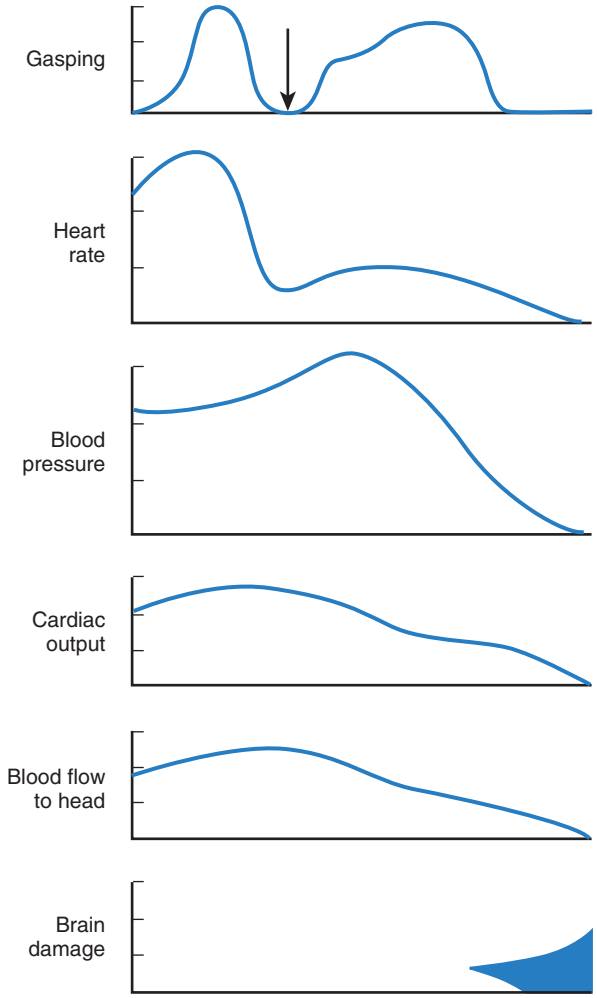
- Maternal diabetes
- Pregnancy-induced hypertension
- Chronic hypertension
- Chronic maternal illness
- Cardiovascular
- Thyroid
- Neurologic
- Pulmonary
- Renal
- Anemia or isoimmunization
- Previous fetal or neonatal death
- Bleeding in second or third trimester
- Maternal infection
- Polyhydramnios
- Oligohydramnios
- Premature rupture of membranes
- Post-term gestation
- Multiple gestation
- Size-dates discrepancy
- Drug therapy
- Lithium carbonate
- Magnesium
- Adrenergic blocking drugs
- Selective serotonin reuptake inhibitor antidepressants
- Maternal substance abuse
- Fetal malformation
- Diminished fetal activity
- No prenatal care
- Age <16 or >35 years

Intrapartum Risk Factors

- Emergency cesarean section
- Forceps or vacuum-assisted delivery
- Breech or other abnormal presentation
- Premature labor
- Precipitous labor
- Chorioamnionitis
- Prolonged rupture of membranes (>18 hours before delivery)
- Prolonged labor (>24 hours)
- Prolonged second stage of labor (>3 hours)
- Fetal bradycardia
- Nonreassuring fetal heart rate patterns
- Use of general anesthesia
- Uterine tetany
- Narcotics given to mother within 4 hours of delivery
- Meconium-stained amniotic fluid
- Prolapsed cord
- Abruptio placentae
- Placenta previa

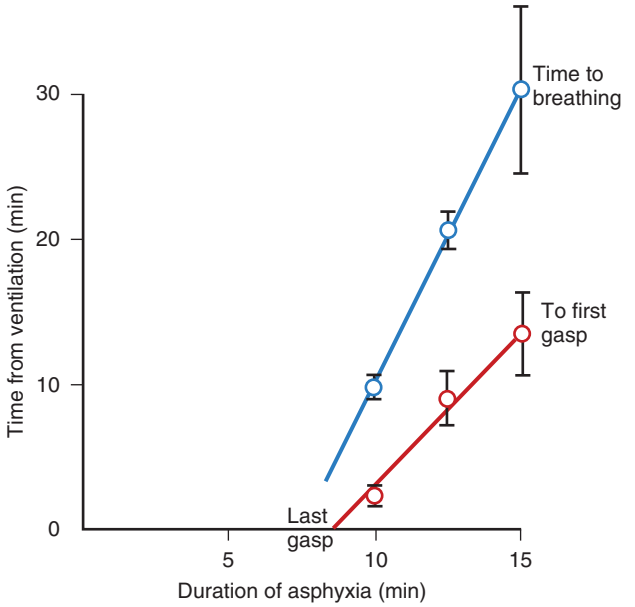
Finally, there are some circumstances in which the infant may initiate breathing only to diminish markedly or stop breathing soon after birth. Examples include extreme prematurity with inadequate ventilatory support after birth, drug-induced depression in which the stimuli surrounding birth initially overcome the depression, congenital diaphragmatic hernia (CDH), and spontaneous pneumothorax.

Response to Asphyxia



The goal with any depressed or asphyxiated infant, whether the process is initiated in the fetal or the neonatal period, is to reverse the ongoing events as soon as possible and avoid death or permanent injury. An understanding of the response of the fetus or neonate to asphyxia forms the basis of the resuscitative process.

Intrapartum asphyxia can be divided into two major types: acute near-total asphyxia and partial prolonged asphyxia. Acute near-total asphyxia has an abrupt onset, usually lasts 5-30 minutes, and causes complete or near-complete cessation of blood flow to the fetus. Etiologies include maternal cardiac arrest, uterine rupture, complete placental abruption, and severe cord compression. Partial prolonged asphyxia occurs more slowly over one to many hours and usually results from various causes of uteroplacental insufficiency. When a fetus or neonate is subjected to partial prolonged asphyxia, the classic "diving" reflex occurs; this is simply an attempt either to accentuate or restore a fetal type of circulation. Hypoxia and acidosis, regardless of their duration, increase vasoconstriction of the pulmonary vasculature (see Fig. 31.3).[55] The increase in PVR results in a decline in pulmonary blood flow, decreasing left atrial return, which lowers left atrial pressure. The decline in left atrial pressure increases right-to-left shunting across the foramen ovale. In the fetus, this shunting directs the most highly oxygenated blood coming from the placenta to the left side of the heart. In a neonate with no placenta, this shunting merely bypasses the lungs, perpetuating a vicious cycle of hypoxia, more acidosis, and more shunting. In acute near-total asphyxia, there may not be time for the diving reflex to have a physiologic effect; in contrast to partial prolonged asphyxia, there may not be significant multisystem organ damage from shunting of blood away from the kidneys, liver, bones, and other organs not essential to the immediate preservation of life.



In the fetus and the neonate, the increase in noncerebral peripheral resistance during prolonged asphyxia results in a redistribution of blood flow, with increased flow to the head, heart, and adrenal glands, and decreased flow to organs not vital to immediate survival. Although the oxygen content of the blood is low, during the early stages of asphyxia the amount of oxygen brought to the head and heart is maximized by the maintenance of cardiac output and the increased flow to these organs.[43] The increased peripheral resistance sustains blood pressure early in asphyxia. The blood pressure remains at reasonable levels as long as the myocardium is able to maintain cardiac output. As the asphyxia progresses and hypoxia and acidosis worsen, the myocardium fails, and cardiac output and blood pressure decrease.[20,43]

Hypoxic cardiomyopathy is the intermediary step to significant brain and other organ damage in partial prolonged asphyxia.[51] The asphyxiated newborn will usually be born with little muscle tone, apnea, and a low heart rate. However, most healthy babies are born with a heart rate less

• **Fig. 31.4** Schematic diagram of changes associated with asphyxia. Arrow indicates point of primary apnea. (Modified from Dawes GS. *Fetal and neonatal physiology*. Chicago: Year Book Medical; 1968:149; Phibbs RH. Delivery room management of the newborn. In: Avery G, ed. *Neonatology.* 3rd ed. Philadelphia: Lippincott; 1987:215.)

• **Fig. 31.5** Time from ventilation to first gasp and to rhythmic breathing in newborn monkeys asphyxiated for 10, 12.5, and 15 minutes at 30°C. (Data from Adamsons K, et al. Resuscitation by positive pressure ventilation and tris-hydroxymethylaminomethane of rhesus monkeys asphyxiated at birth. *J Pediatr.* 1964;65:807.)

than 100 beats/min, and the clinician should use other signs of significant acidosis (i.e., hypotonia, apnea) to determine which baby needs immediate resuscitation. The resuscitation algorithm of children and adults emphasizes interventions to promote the return of spontaneous circulation and does not apply in newborns; the provision of adequate ventilation is the mainstay of neonatal resuscitation with the goals to reverse the bradycardia and restore adequate circulation. Superimposed on these circulatory and hemodynamic changes is a characteristic change in respiratory pattern. Initially, there are gasping respirations (which may occur in utero). With continuing asphyxia, respirations cease in what is known as primary apnea. If the asphyxia is not corrected, the infant again begins to gasp irregularly, and the respirations cease (secondary apnea) unless effective positive pressure ventilation (PPV) and successful resuscitation occur (Fig. 31.4).[17]

Primary apnea usually responds to the cessation of the asphyxiating insult and stimulation. Secondary apnea is usually accompanied by severe metabolic acidemia and requires much more vigorous resuscitation for the newborn to recover. The longer the asphyxia has gone on, the longer it takes for the onset of spontaneous ventilation to occur after PPV is started (Fig. 31.5).[1] Asphyxia may begin before birth, and the infant may pass through any or all of these stages of the asphyxial cascade in utero. It may be difficult to determine at birth how far the asphyxial episode has progressed. With any depressed infant, it is essential to assume that the infant is in secondary apnea, and resuscitation should be initiated without delay. The goal of resuscitation, although not always attainable, is to initiate interventions in a timely and effective manner so that the insults of hypoxia, ischemia, and acidosis are reversed before they cause permanent injury (Box 31.2).

Preparation for Resuscitation

The strategic elements in preparing for resuscitation are anticipation of the problem, provision of adequate equipment, and presence of trained personnel. The turmoil that sometimes occurs with resuscitation of an infant, especially an unexpected resuscitation, is primarily caused by late notification, inadequate or unavailable equipment, or staff members who are unskilled or have difficulty coordinating their activities. In most cases, appropriate preparation and timely notification of a high-risk delivery can ameliorate many of these problems. The training of personnel using simulation has been shown to be an effective preparation for the teamwork and communication needed in the emergent situation of a neonatal resuscitation.[57,66] Some units have designed a scripted protocol of care for each provider at an anticipated difficult resuscitation (i.e., delivery of an

extremely low birth weight infant) to facilitate an orderly response with assigned responsibilities and optimal use of time during the first "golden hour" of life.[5] Periodic training should include cognitive learning and technical and behavioral skills to conduct a resuscitation appropriately. The availability of adequate models to practice technical skills (e.g., intubation, catheter placement) can be a major impediment in the training of personnel for the rare full resuscitation. New high-fidelity manikins now available provide much greater realism and anatomic fidelity to solve this problem in training but are expensive and require a skilled instructor.[40] However, the decreased opportunities for the practice of technical skills on live neonates in both training programs and daily practice make the acquisition and continued mastery of these skills a continuing challenge for all neonatal providers.[19] Moreover, the most recent guidelines suggest that for retention of necessary skills, neonatal resuscitation task training should occur more frequently than every 2 years.[72]

Communication between the obstetric and neonatal teams is essential to the graded response needed for neonatal resuscitation. In some situations, a single competent person is appropriate to the clinical situation. At other times, a full resuscitation team of three or more skilled providers may be necessary. When time allows, a careful review of the antepartum and intrapartum history can identify many problems that put a mother at risk of delivering a depressed or asphyxiated infant (see Box 31.1) and determine the composition of the resuscitation team. Even an emergency call for assistance to the neonatal team should include pertinent information. Using the acronym *HANDS* may be helpful to highlight the most important data: *H* for hemorrhage, *A* for amniotic fluid (clear or meconium-stained), *N* for number of infants expected, *D* for dates (gestational age), and *S* for fetal monitoring strip (category I, II, or III).

Identifying a high-risk situation before delivery of the infant provides time for adequate preparation and gathering the appropriate personnel in the delivery room. Because of modern obstetric techniques and anesthesia, it is no longer necessary to consider a repeat cesarean section as a high-risk delivery because this form of delivery carries no greater risk than a vertex vaginal delivery at term.[33] Only if the cesarean section involves a premature infant, fetal distress, or other complications is there any cause for added concern. It is impossible to identify every infant who may need assistance. At every delivery, equipment and personnel should be available in case of unanticipated neonatal depression.

Adequate Equipment

Whenever an infant is delivered, appropriate equipment must be close at hand and in good working order. An area in or near the delivery room should be designated as the resuscitation area, and provisions should be made for adequate space, heat (radiant warmer), blended oxygen, and suction. Supplies and drugs as specified in the resuscitation guidelines should be placed in a code cart or bag or attached to a wall board for easy access.[70] These supplies should be routinely checked by hospital personnel and rechecked for completeness and good working order (e.g., laryngoscope light works) before an anticipated resuscitation. A delay in effective resuscitation may occur if someone needs to leave the delivery room during the procedure to obtain an essential piece of equipment. When expecting an extremely depressed infant (e.g., terminal bradycardia resulting in an emergency cesarean section), it may be appropriate to prepare the umbilical catheter and draw up epinephrine *before* delivery.

Adequate Personnel

Individuals vested with the responsibility of resuscitating infants should be adequately trained, readily available, and capable of working together as a team. Having trained personnel readily available means having someone present at every delivery who has the skill required to initiate resuscitation, with other available staff close at hand in case they are needed. This person does not have to be a physician but should be able to recognize the need for resuscitation and perform the initial steps, including the initiation of positive pressure ventilation. The hospital is responsible to ensure the competence of these personnel in the same way a surgeon is credentialed to perform certain operations.[4] At least two, if not three, people are needed to carry out a full resuscitation. Adequate training involves more than simply going through a course and receiving a certificate of completion. The neonatal resuscitation program of the

AHA/AAP and similar courses are simply starting points.[70] These programs do not ensure competence or qualify one to assume independent responsibility.

Finally, the personnel available to the delivery room should be capable of working together as a team. If staff are skilled at carrying out their responsibilities and can anticipate each other's needs, the tension inherent in any resuscitation can be reduced, and the process will go much more smoothly. The use of simulation training using manikins and the holding of mock code drills on an ongoing basis help to maintain skills and develop coordination among staff.[40,57]

Apgar Score

The Apgar score is a tool that can be used objectively to define the state of an infant at given times after birth, traditionally at 1 minute and 5 minutes (Table 31.1).[3,6] The Apgar score should not be used as the primary indicator for resuscitation, because it is not normally assigned until 1 minute of age. As noted, asphyxia may begin in utero and continue into the neonatal period. To minimize the chances of adverse sequelae, one should begin resuscitation as soon as there is evidence that the infant is unable to establish ventilation sufficient to maintain an adequate heart rate. Waiting until a 1-minute Apgar score is assigned before initiating resuscitation only delays potential therapies. An Apgar score at 1 minute of 0-3 often indicates the presence of secondary apnea. Infants who fail to achieve an Apgar score of 7 by 5 minutes of age should have repeated Apgar scores every 5 minutes until the score is at least 7.[3] Steps taken during the resuscitation and the resulting Apgar scores should become part of the medical record (Table 31.2).[3]

Umbilical Cord Blood Gases

Umbilical cord blood analysis for high-risk deliveries (i.e., low 5-minute Apgar score, severe intrauterine growth restriction, fetal heart rate tracing abnormalities, intrapartum fever, multiple gestation pregnancies, and cesarean deliveries for fetal distress) is currently recommended by ACOG.[41] The arterial cord gas can be a valuable representation of the fetal acid-base state prior to delivery.[10,24] Adverse neurologic sequelae have been associated with a low arterial cord pH.[34] Using both the arterial and venous cord values, the clinician may be able to determine the intrapartum events leading to neonatal depression.[10,29] Severe acidosis in a cord blood gas may inform the resuscitation and determine triage of the newborn to the appropriate postresuscitation care.[30] An arterial cord pH less than 7.0 and a base excess greater than −16 have been used as criteria for therapeutic hypothermia in the treatment of intrapartum asphyxia.[27,46,59,60]

If only one cord blood gas is reported, it may be from the umbilical vein, as this vessel is larger and more easily sampled.[24,49] One clue that a single gas sample is of venous origin is the PaO_2 value. If the reported PaO_2 is >31 mm Hg, it is highly likely to be a venous sample.[49]

In the ideal situation, both arterial and venous umbilical cord blood will be sampled for blood gas analysis.[7,71] The umbilical artery pH should be at least 0.02 units lower than the vein.[24] The normal umbilical arterial pCO_2 is usually more than 4 mm Hg greater than the vein.[24] Therefore, if two cord gases are reported and the A-V difference is 0.02 units or less in the pH and <4 mm Hg in the pCO_2, then the two results are likely from the same vessel.[24] Normal umbilical cord blood gases are shown in Table 31.3.[49]

Elements of a Resuscitation

A resuscitation can be viewed as a series of elements. The process is not a linear set of steps in which one marches inexorably from one point to another. Rather, it involves an evaluation of the infant's condition, a decision based on that evaluation, and action.[35] These steps are repeated until the process is concluded. Fig. 31.6 provides an overview of the resuscitation process.[70]

Virtually all infants undergo the initial steps. Most infants requiring active resuscitation respond to appropriately administered PPV.[48] All infants, whether they require only the initial steps or a complete resuscitation, are entitled to a skilled and timely response, regardless of who is performing the resuscitation. Parents may be present while perinatal care is being provided to neonates, including procedures, resuscitation, and stabilization. Parents should be informed about and involved in the care of their infants within the principles of family-centered care.[23]

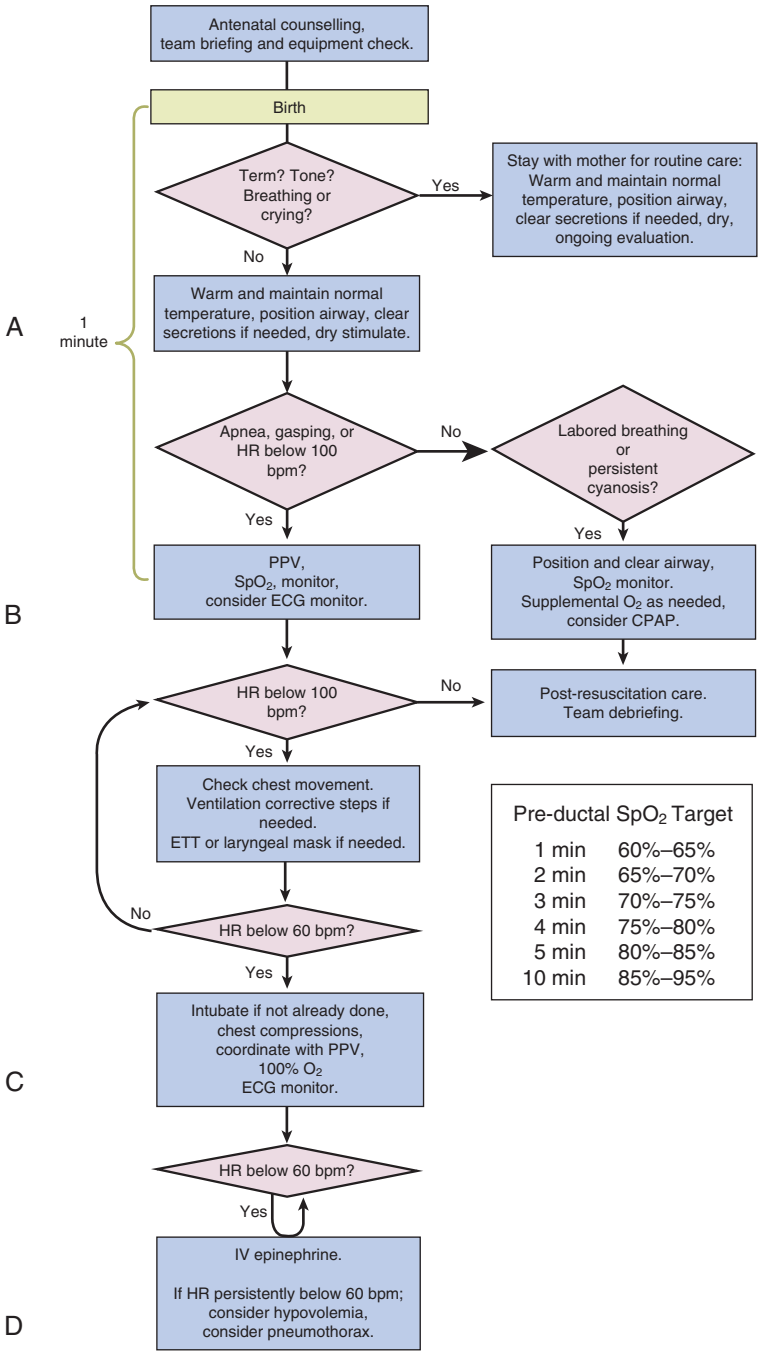
	Venous Cord Blood, Normal Range (Mean ± 2SD)	Arterial Cord Blood, Normal Range (Mean ± 2SD)
pH	7.25-7.45	7.18-7.38
pCO_2 (mm Hg)	26.8-49.2	32.2-65.8
pO_2 (mm Hg)	17.2-40.8	5.6-30.8
HCO_3^-	15.8-24.2	17-27
Base excess (BE)	0 to –8	0 to –8

Pomerance JJ. *Interpreting umbilical cord blood gases*. 2nd ed. Glendora, CA: BNMG; 2012.
Data are mean values ±2 standard deviations (SD).
*Base excess, estimated from data.
**1 kPa = 7.50 mmHg; 1 mmHg = 0.133 kPa
Note: "Normal" is arbitrarily defined as the mean ±2 times the standard deviation (approximately 95.4% of a normally distributed population).



Initial Quick Overview

Most infants are vigorous, cry at birth, and breathe easily thereafter. However, there may be a delay of 30 seconds or more before a healthy baby takes a first breath. Many times, parents prefer that the infant go to the mother immediately after birth rather than be placed on a warmer and put through the "initial steps" in resuscitation. In most circumstances, a healthy and vigorous infant does not require suctioning after delivery. With appropriate triaging and oversight, most newborns can be given directly to the mother for bonding and initiation of breastfeeding immediately after birth without compromising their care.

A rapid initial assessment that provides the information necessary to triage the infant appropriately is required. If the infant has not passed meconium in utero, is term, is breathing easily, has good tone, and appears normal and vigorous, it is appropriate to hand the child to the mother for skin-to-skin contact immediately after birth. As the mother holds the infant, a light blanket may be provided to prevent rapid evaporative heat loss while covering the infant in such a way as to be able to observe the infant for signs of distress. During this process, a trained observer should be able to see the infant's nose and mouth, and the head should be turned to one side.[21] If the infant has passed meconium in utero, is preterm, is not breathing easily, has diminished tone, or does not appear normal and vigorous, the infant should be placed on a radiant warmer until a more thorough assessment of the infant can be done.

Although the following steps apply to any infant who is not term, healthy, and vigorous at birth, there are several caveats. An initial evaluation should be done but may take

• **Fig. 31.6** Overview of resuscitation in the delivery room. ETT, Endotracheal tube; HR, heart rate; PPV, positive pressure ventilation. (From Weiner GM, ed. *Textbook of neonatal resuscitation*. 7th ed. Elk Grove Village, IL: American Academy of Pediatrics, American Heart Association; 2016.)

longer than 30 seconds.[58] The median heart rate in healthy term and preterm infants is <100 bpm and may take up to 2 minutes to rise to 140 bpm.[18] Evaluation of color at birth is usually not helpful in determining the status of a newborn, because it usually takes several minutes for even a healthy term infant to achieve SpO_2 greater than 90% and "become pink" (see Chapter 33).[44,56] Therefore, the clinician must evaluate the newly born infant carefully, looking at all aspects of well-being and recognize the normal processes of transition.

Initial Steps

If resuscitation is deemed necessary, the initial steps are to place the infant in a "sniffing" position, which will facilitate opening the airway. If needed, secretions can be cleared with a bulb syringe and the infant is dried, unless very preterm, in which case a plastic wrap is used to maintain temperature. The infant is then stimulated to breathe and observed before starting the next steps.

Thermal Management

The fetus maintains a body temperature about 0.5° higher than maternal temperature. Through the accumulation of brown fat late in gestation, the term newborn is able to activate thermogenesis by stimuli of oxygenation, ventilation, and oxidative metabolism via various hormonal intermediaries. The lack of brown fat accumulation in preterm infants and the sequelae of asphyxia in term infants put these newborns at significant disadvantage in thermoregulation postdelivery.[25] Delivery rooms are kept at a level of thermal comfort for the adults working in them. The neonate with a very large surface area-to-mass ratio is susceptible to cold stress; this is especially true for depressed infants with poor perfusion and extremely low birth weight infants. Unintentional hypothermia in neonates has been associated with metabolic acidosis, increased oxygen consumption, and increased mortality, especially in very preterm infants.[36] For very low birth weight infants, one large cohort study revealed a 28% increase in mortality for each 1°C decrease in neonatal intensive care unit admission temperature.[32]

Studies have shown that >30% of infants with extremely low birth weight (<1000 g) become hypothermic with standard warming techniques in the delivery room.[8,36,67] Because this population makes up less than 1% of all deliveries, special preparations should be made for these infants by prewarming the delivery room or an adjacent resuscitation area to 75°F-78°F and using a radiant warmer and food-grade plastic wrap to keep the infant warm after birth.[36,67,68,70] Other strategies may include prewarmed blankets, hats, exothermic mattresses, and using warmed, humidified air/oxygen for ventilation.[61] Care must be taken not to overheat an infant, since animal studies have shown that hyperthermia is synergistic with asphyxia in worsening cerebral injury.[72]

For a term nondistressed newborn, the infant should be placed skin-to-skin with the mother or in the microenvironment of a preheated radiant warmer immediately after birth. Newborns who do not qualify for routine care should be placed in warm blankets and quickly moved to a preheated radiant warmer set at 100% power. The infant should be thoroughly dried, and the wet blankets should be promptly removed to avoid evaporative heat loss. These simple measures can minimize the decrease in core temperature that the term infant experiences at birth.[38] Preventing excessive heat loss can become especially important with a preterm infant or an infant who is asphyxiated and hypoxic. Because hypoxia blunts the normal response to cold, a hypoxic infant undergoes a greater than normal decline in core temperature if not thermally protected.[12] Recovery from acidosis also is delayed by hypothermia (see Chapter 35).[2]

Clearing the Airway

Previously, it was recommended that the airway should be cleared with the use of a bulb syringe or a suction catheter. However, if the newborn is vigorous and born through clear amniotic fluid, this procedure is not necessary,[22] and stimulation of the posterior portion of the pharynx may induce bradycardia.[16] If the infant has excessive secretions, a bulb syringe may be used to clear first the mouth and then the nose ("m" before "n"). An infant exposed to meconium in the amniotic fluid represents a special circumstance (discussed in Chapter 34).

Monitoring

Heart rate may be evaluated by palpation of a peripheral pulse or the umbilical cord. However, studies have shown that these measurements are not reliable.[18] If the resuscitation team is expecting a significantly depressed baby or a very low birth weight infant who probably needs help in transition, attaching ECG leads to monitor heart rate can be done early in the resuscitation process. Use of a pulse oximeter to guide treatment is also suggested by the NRP.[72] There may be a delay of 1-2 minutes after attaching the pulse oximeter until accurate readings of both heart rate and oxygen saturation are obtained. If the baby has poor perfusion or a very low heart rate, the pulse oximeter may not give accurate readings.

Tactile Stimulation and Assessment

Usually the act of drying the infant is enough tactile stimulation to initiate respiration. An infant in primary apnea will generally respond to these gentle measures. All babies will be cyanotic at birth and blow-by oxygen is not indicated. If the infant does not breathe after tactile stimulation, gentle flicking the soles of the feet or rubbing the infant's back may be enough additional stimulation to elicit regular respirations. After initial steps, if assessment fails to elicit a vigorous response, the baby should be assumed to be in secondary apnea, and PPV should be quickly initiated. Positive pressure ventilation may be given initially to term and late-preterm infants with air (21% Fio_2). Continued and more vigorous tactile stimulation is not useful and may be harmful if ineffective maneuvers allow the baby to remain hypoxic and acidotic. The decisions from this point revolve around the response of the infant—primarily heart rate and respirations.

Free-Flow Oxygen

Over the past several years, there has been considerable discussion and research on the use of oxygen in neonatal resuscitation (see Chapter 33).[53,64,65] Previously, the *Textbook of Neonatal Resuscitation* recommended that free-flow oxygen be used if the newborn remained cyanotic after 30 seconds of initial steps (drying, warmth) and evaluation, or if PPV was needed. This recommendation has been revised based on numerous studies. The current recommendation is to use pulse oximetry if resuscitation is anticipated, when positive pressure ventilation is given, and if central cyanosis persists after 5-10 minutes. Resuscitation for full-term infants should begin with room air (21% oxygen at sea level), and oxygen should be given if necessary and titrated according to the interquartile range of healthy term

TABLE 31.4 Target Preductal Oxygen Saturations for Newborn Infants in the First 10 Minutes of Life

1 min	60%-65%
2 min	65%-70%
3 min	70%-75%
4 min	75%-80%
5 min	80%-85%
10 min	85%-90%

From Weiner GM, ed. *Textbook of neonatal resuscitation*. 7th ed. Elk Grove Village, IL: American Academy of Pediatrics, American Heart Association; 2016, 48.

newborns after vaginal birth at sea level (Table 31.4). If chest compressions, medication, or both are needed, 100% oxygen is recommended (see Fig. 31.6).[70,72] Current recommendations advise against the routine use of oxygen for transient cyanosis and the avoidance of high concentrations of oxygen whenever possible.[64,65]

If the infant is spontaneously breathing, and the heart rate is greater than 100 beats/min, but the infant remains cyanotic for >5 minutes after birth, oxygen may be administered through a free-flow system until it can be shown that the oxygen concentration can be reduced (arterial oxygen saturation, SaO_2 >85%) or that lowering the concentration makes no difference (cyanotic heart disease). Studies of normal term newborns have shown that it may take 6 minutes or longer for infants to reach SaO_2 greater than 90%, and many clinicians believe the use of oxygen should be restricted unless the baby remains bradycardic.[56] A high concentration of oxygen can be obtained with an oxygen mask (with escape holes) held firmly over the face or an oxygen tube cupped in the hand. A flow-inflating bag (but not a self-inflating bag) is capable of delivering high concentrations of blow-by oxygen.[70] The use of high concentrations of oxygen is not usually necessary and hyperoxia should be avoided, especially in a preterm infant.

It is best to heat and humidify the oxygen. During an emergency, cold, dry oxygen may be given for a short time; however, if free-flow oxygen is to be continued for any period, it should be heated and humidified and given through wide-bore tubing. An oxygen blender and oximeter are useful in determining the amount of oxygen the infant requires. It is recommended that all hospitals should be capable of blending oxygen in the delivery room and using pulse oximetry in this area.[70] After suctioning and tactile stimulation, if the respirations are gasping or are insufficient to sustain the heart rate at greater than 100 beats/min, PPV must be initiated.

Preterm infants must be resuscitated with modest elevations (30%) of oxygen, as research has shown that resuscitation with 21% oxygen is unlikely to be successful (see Chapter 33).[45]

Key Points

- At birth, the newborn must establish the lung as the organ of gas exchange, and this may require the assistance of a skilled resuscitation team.
- A neonate may not have adequate ventilation after delivery because of many problems, including asphyxia, drug-induced central nervous system (CNS) depression, CNS anomalies or injury, spinal cord injury, mechanical obstruction of the airways, congenital facial or airway deformities, immaturity, pneumonia, systemic infection, or congenital anomalies.
- The strategic elements in preparing for resuscitation are anticipation of the problem, provision of adequate equipment, and presence of trained personnel.
- The need for and the extent of resuscitation required will be determined by the clinical condition of the newly born infant, umbilical cord blood gases, and evolving Apgar scores.
- In most resuscitations, following the algorithm provided by the Neonatal Resuscitation Program will guide the team in the appropriate series of steps to revive a depressed or acidemic newborn.

Role of Positive Pressure Ventilation in Neonatal Resuscitation

LOUISE OWEN AND PETER DAVIS

Newborn babies who do not spontaneously breathe at birth require support to safely make the transition to extra-uterine life. Over the past 20 years, guidelines for those providing care to these infants have been developed.[52] However, the evidence available to guide initial respiratory support remains limited, reflecting the challenges associated with conducting research in the delivery room.

The crucial steps in the adaption to extra-uterine life involve the transition from liquid-filled to air-filled lungs, and the establishment of functional residual capacity (FRC). These changes normally occur in the first minutes after birth and include an increase in pulmonary blood flow and the onset of regular respiration. Lung aeration and the development of an FRC facilitate gas exchange, leading to an increase in heart rate. If an infant does not quickly establish effective respiration, assistance is immediately required. Typically, this is a brief need for basic respiratory support only,[39] unless there is abnormal anatomy, significant fetal acidemia, or if ineffective respiratory support is given. Preterm infants have additional requirements at birth; although most preterm infants breathe and cry,[45] very preterm infants are still likely to need support to effectively establish and maintain FRC. Preterm lungs are delicate, and lung injury can occur with just a few positive pressure inflations.[73] This has led to a shift in emphasis in preterm stabilization toward a gentle, supportive approach to augment rather than override their efforts and to minimize lung injury.

Normal Transition and Initial Spontaneous Breathing

In healthy, newborn term infants, normal transition is characterized by repeated, short, deep inspirations, each followed by a prolonged expiratory phase through a partially closed glottis (crying). The inspiratory efforts generate large negative trans-pulmonary pressures, typically −50 cm H_2O to −100 cm H_2O, such that the high-resistance liquid filling the infant's airways is driven distally, moving the air-liquid interface toward the distal airways.

Detailed imaging of rabbit lungs demonstrates that initial lung aeration depends on the generation of this trans-pulmonary pressure, with consequent stepwise increases in FRC over three to five repeated inspiratory efforts. More volume is inspired than expired with each breath, which overcomes small losses in FRC between inspiratory efforts as lung liquid moves back into airways.[20] The lung liquid then moves into the interstitial tissue and is cleared over the following hours.

Prolonged expiration through a partially closed glottis with simultaneous abdominal muscle contraction pressurizes the chest, further pushing back the air-liquid interface; this is called expiratory braking (Fig. 32.1). Recordings of the first breaths in preterm infants have also shown that they use crying and expiratory braking to facilitate lung recruitment and development of FRC[80] (Fig. 32.2).

Delayed Transition and Need for Respiratory Support

Some infants do not breathe or have ineffective breathing at birth. Guidelines recommend initial steps of umbilical cord clamping, warming, drying and stimulating the baby, and opening, and in some cases clearing, the airway.[52] They stipulate that positive pressure support should be commenced by 60 seconds of age if the baby remains apneic, has irregular or gasping respirations, or has a heart rate less than 100 beats/min (bpm).[52] However, following these recommendations may not always be straightforward.

- Healthy babies may not take their first breath immediately after birth; there may be a delay of 30 seconds or longer.
- In practice, initial evaluation often takes longer than 60 seconds.[64]

Abstract

Newborn babies who do not spontaneously breathe at birth require immediate support to successfully transition to extra-uterine life. Positive pressure ventilation (PPV) must be applied; this is a critical skill to master, but it is difficult to learn and apply. This chapter covers the indications, techniques and equipment needed to support newborns who do not establish adequate spontaneous breathing. This chapter discusses why transition may be delayed; it identifies the key indicators for assessing the condition of newborns. It explores the basics of PPV, how to generate PPV, and how to choose an interface to deliver it. The chapter discusses assessment of the effectiveness of PPV, how to apply PPV from the first breath, and the practicalities of endotracheal intubation. Most infants breathe at birth and need no support; preterm infants usually breathe, but often need support. Infants who do not establish regular respiration require PPV, typically given using a face-mask and a self-inflating bag. These are the devices of choice in resource limited settings; T-piece resuscitators are the device of choice for stabilizing preterm infants. Effective PPV should result in a rapid increase in heart rate. Ineffective PPV, or poor technique, results in clinical compromise and may cause lung damage. Endotracheal intubation should be considered if resuscitation is prolonged or the infant remains bradycardic. Most newborns do not need assistance at birth. When assistance is required it is needed promptly, applied with appropriate equipment and technique. Acquisition of this skill is critically important.

• **Fig. 32.1** Example of crying in a term infant at birth. There is a large inspiration (*1*), followed by crying, seen as high-frequency interruptions to the expiratory flow wave lasting more than 2 seconds (*2*), followed immediately by the next inspiration (*3*). The software resets the volume trace at end inspiration and end expiration. (Adapted from te Pas AB et al. Breathing patterns in preterm and term infants immediately after birth. *Pediatr Res*. 2009;65:352.)

• **Fig. 32.2** Example of expiratory braking in a preterm infant on continuous positive airway pressure (CPAP), just after birth. There is a short, large inspiration (*1*) followed by a 2-second period without any flow (*2*), then a short, quick expiration (*3*), immediately followed by the next inspiration (*4*), without any postexpiratory pause. The software resets the volume at end expiration. (Adapted from te Pas AB et al. Spontaneous breathing patterns of very preterm infants treated with continuous positive airway pressure at birth. *Pediatr Res*. 2008;64:281.)

- In healthy term and preterm babies, the median heart rate at one minute is <100 bpm, rising to ~140 bpm by 2 minutes of age.[10]
- Clinical assessment of heart rate at birth, either by palpation or auscultation, is intermittent and inaccurate.[26]
- Assessment of a newborn's color is subjective and unreliable.[44] Although assessment of color is not used in the most recent resuscitation guidelines, it remains part of the Apgar assessment.

These factors make assessment at birth, and the decision whether to intervene, more complex. If decisions are made too early, unnecessary interventions may be applied. Whereas, if decisions are delayed, there may be further cardiorespiratory compromise. It may be helpful to be aware that:

- Accurate measurements of oxygen saturation (SpO_2) and heart rate can be obtained by about 90 seconds using pulse oximetry,[9] and heart rate values may be seen within 1 minute using electrocardiography.[28]
- The key sign of an infant's condition in the minutes after birth, and response during stabilization, is the heart rate.
- An infant who has good tone is unlikely to be severely hypoxic.

Basics of Positive Pressure Support

When an infant fails to establish spontaneous breathing after birth, the caregiver must commence positive pressure support. Typically, this is initially applied using a face mask and a pressure-generating device. If the infant is breathing but has not completely established regular, effective breathing, continuous positive airway pressure (CPAP) may aid inflation of the lungs and establishment of FRC. CPAP helps establish and maintain end expiratory lung volume, reduce alveolar collapse, and decrease work of breathing. It aids lung expansion and helps to conserve surfactant. CPAP also improves oxygenation, lung compliance, and ventilation-perfusion mismatch.[1] However, an infant who has no respiratory effort, or who is bradycardic, will require positive pressure ventilation (PPV). Ideally, PPV should be given along with positive end expiratory pressure (PEEP), although not all resuscitation devices are capable of delivering PEEP (Table 32.1). Studies in intubated preterm animals have demonstrated that the addition of PEEP to PPV results in more rapid acquisition of FRC, improved oxygenation and lung compliance, and decreased lung injury.[74] PEEP is recommended for the resuscitation of preterm infants,[52] although clinical trials have failed to show

a significant difference in the proportion of infants requiring intubation in the delivery room,[13] or in SpO_2 at 5 minutes of age[8] when PEEP was added. Use of PEEP during stabilization of preterm infants in the delivery room in major units in the UK and Canada is now reported to be higher than 75%.[12,75]

Endotracheal intubation should be considered for infants who have an ongoing need for PPV and those who remain bradycardic and/or hypoxic in spite of adequate mask PPV. The management of preterm infants who require ongoing respiratory support has evolved over the last decade, moving away from immediate intubation and surfactant administration toward continuing CPAP support with either rescue intubation or surfactant treatment if certain criteria are met, or surfactant administration without endotracheal intubation plus ongoing CPAP. Meta-analysis of trials that compared immediate intubation with CPAP found a reduction in the combined outcome of death or bronchopulmonary dysplasia in the CPAP group, without any difference in pneumothorax risk.[70] Both options may be appropriate, however, international guidelines now recommend initial CPAP for spontaneously breathing preterm infants with respiratory distress rather than routine intubation.[52] As a gentler approach to early respiratory support has become more popular, more preterm infants are likely to be supported by CPAP in the delivery room.

Application of Noninvasive Positive Pressure Support

How to Generate Positive Pressure

Various devices are available for generating positive pressure in the delivery room. The choice of device may be made based on availability of a gas supply, the skills of the resuscitator, the desire to deliver sustained inflations, PEEP and CPAP, and on local preferences. A European survey reported that centers typically use more than one device, with self-inflating bags (SIB) being most commonly used (85%),[59] whereas a recent Japanese survey reported flow-inflating bags (FIB) to be most commonly used (63%).[21]

Self-Inflating Bags (SIB)

Self-inflating bags (Fig. 32.3*A1* and *A2*) re-expand after compression. These are the only devices that can be used without a gas supply; they have been shown to be an effective method for reducing mortality from birth asphyxia in resource-limited areas.[17] Their use is an integral part of the international Helping Babies Breathe program.[42]

Several types and sizes of SIB exist. The smallest sizes, ~240 mL, are most appropriate for newborns. The peak pressure delivered by an SIB depends on how hard and fast the bag is squeezed. SIBs usually incorporate a valve, which limits the maximum deliverable pressure. The valve can be manually overridden to deliver higher pressures but can be inadvertently overridden if the SIB is squeezed very hard or very fast. Pressures greater than 100 cm H_2O have been reported, resulting in very high delivered volumes, >20 mL/kg. The more fingers used to squeeze the bag, the more pressure is generated[2]; for most resuscitations, a gentle squeeze with a finger and thumb is all that is required. Many studies, including Bassani et al., have shown that it is difficult to give consistent peak pressures when using an SIB, particularly if an operator is inexperienced.[61] Manometers attached to the SIB help improve the consistency of peak pressure delivery,[57] and newer "upright" designs of SIB have been shown to provide more consistent volume and pressure delivery,[41] even with novice operators.[86] If a PEEP valve is attached to an SIB, some PEEP can be delivered. However, it is difficult to achieve the desired PEEP, and delivered PEEP is rate dependent.[31] PEEP levels decay quickly between inflations,[40] although newer models are

better.[85] Different brands of SIB have different capacities to deliver a sustained inflation[87]; closing the pressure relief valve improves the ability to perform sustained inflation.[4] It is not possible to deliver CPAP using an SIB, therefore, it may not be the optimal device for stabilizing preterm infants.

Flow-Inflating Bags (FIB)

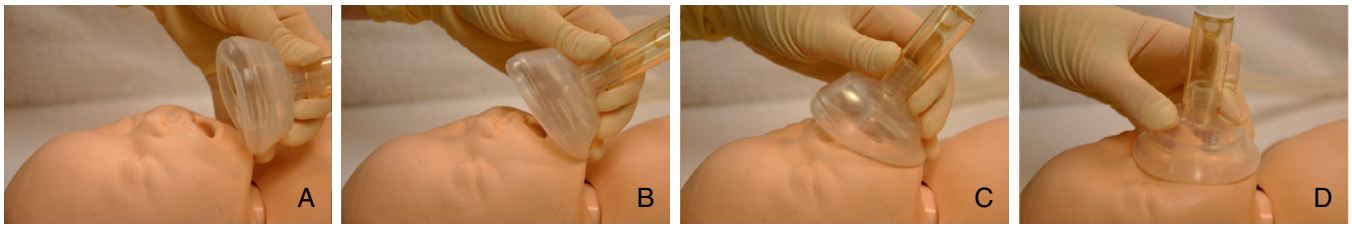
A flow-inflating bag (see Fig. 32.3*B*) needs a continuous gas supply, something which may not always be readily available. The delivered pressure and tidal volume depend on how hard the bag is squeezed. A pressure-limiting valve can be attached to prevent high pressure being inadvertently delivered. PEEP can be delivered with an FIB by controlling the rate of gas escaping from the back of the bag during expiration. This technique requires experience as it can inadvertently lead to dangerously high PEEP. It is difficult to consistently deliver both the desired PEEP and peak pressures with a flow-inflating bag,[3,7] and many operators find the flow-inflating bag more difficult to use than the SIB. A sustained inflation can be delivered by a skilled operator, but the pressure achieved is more variable than that delivered using a T-piece.[32] It is very difficult to deliver CPAP with an FIB.

T-Piece Devices

T-piece devices (see Fig. 32.3*C*) also require a continuous gas supply, again something that may not be available in resource-limited settings. The gas flow, and an internal valve, generate the set peak pressure and set PEEP. The peak pressure is achieved by occluding the hole in the top/side of the T-piece with a finger. When the hole is open, PEEP or CPAP is delivered. Inflation time depends on how long the hole is occluded.

T-pieces are easy to use and are preferred by both experienced and inexperienced operators.[23] In manikin studies, the T-piece device delivers peak and PEEP pressures more accurately and consistently than other devices, resulting in more stable tidal volume delivery,[60] even with inexperienced operators.[61]

Although facemask leak is common during positive pressure ventilation, leak has less detrimental effect on pressure and volume delivery when using a T-piece, compared with an SIB.[18] Randomized studies of infants requiring PPV at birth have shown less need for intubation,[79,84] less supplemental oxygen, and shorter duration of PPV when using a T-piece compared with an SIB,[84] but no difference in proportion of infants with heart rate >100 bpm at 2 minutes of life[79] or other longer-term outcomes.



Occlusion of the hole on the T-piece allows delivery of a consistent, sustained inflation of any duration or pressure.[32] Likewise, the T-piece is capable of delivering consistent CPAP,[60] and, therefore, may be the optimal device for providing respiratory support for preterm infants at birth.[23] However, care needs to be taken if gas flow is increased during T-piece PPV as increased flow increases the delivered pressures, particularly PEEP.[81] Additionally, as set PEEP is increased in some T-piece systems, the resistance and imposed work of breathing can increase.[11]

Other Options for Providing Positive Pressure

Positive pressure support can be delivered using a neonatal ventilator; this delivers accurate peak and PEEP pressures, and may allow both synchronization of inflation with the infant's own efforts and tidal volume measurement.[90] CPAP can also be continuously delivered. Other methods of providing respiratory support have been tried and are under investigation, such as use of nasal high flow.[58]

In the resource-limited setting, no devices may be available to generate positive pressure support, so mouth-to-mask[37] and mouth-to-tube[83] ventilation may be used. Both are preferable to mouth-to-mouth resuscitation, but both still carry some risk of infection.

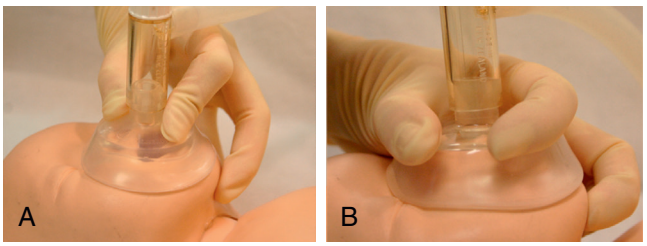
In summary, there are advantages and pitfalls with all these devices (see Table 32.1). With the possible exception of a ventilator, no device provides information on perhaps the most important parameter—the tidal volume being delivered. Novel resuscitation devices and simple delivery room monitors that accurately measure and display delivered tidal volume are currently being developed and tested but are not in general clinical use. Whichever device is used, providers need to be trained in how to set up, use, and troubleshoot the equipment.



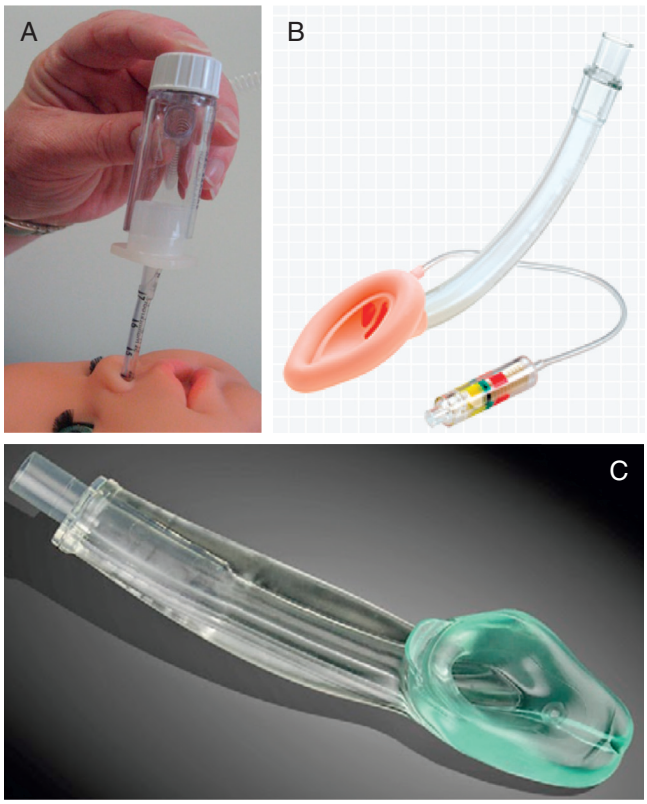
Choosing an Interface to Deliver Positive Pressure

Positive pressure may be delivered via face mask, nasal tube, nasal cannulae, laryngeal masks, and endotracheal tubes.

Face Masks

Use of a face mask requires a good seal between the mask and the infant's face,[96] but this is difficult to achieve and maintain; leak and pressure loss leading to reduced tidal volume delivery is common. Round, cushion-rimmed masks are used more commonly than anatomically shaped, triangular masks,[43] and there is conflicting evidence as to whether leak is greater with one type or the other. Newer masks being tested may help to overcome this.[36] It is, however, clear that mask leak is common in the delivery room and is frequently large and troublesome.[68]

A face mask should seal around the mouth and nose but not cover the eyes or overlap the chin. Several makes and sizes of round face masks are available, but many commonly used brands may be too large for very preterm infants.[49] Accurate positioning and mask hold are required to minimize mask leak. An accurate position can be obtained when the correctly sized mask is rolled upward onto the face from a finger placed on the chin tip (Fig. 32.4); this technique reduces leak.[95] The optimal hold for a mask varies with the brand of mask being used; for example, two commonly used brands shown to have similar leak in the delivery room.[5] With the Laerdal mask (Laerdal Medical, Stavanger, Norway), equal pressure should be applied to the top flat portion of the mask, with the thumb and index finger where the silicone is thickest, to obtain the best seal (Fig. 32.5*A*).[95] The fingers should not encroach onto the skirt of the mask as this causes the rim to kink.[38] In contrast, when using the Fisher & Paykel round masks (Fisher & Paykel Healthcare, Auckland, New Zealand), the thumb and index finger should form a "C" shape (as in the "OK" hand gesture) placed around the top flat portion of the mask, applying an even distribution of pressure to the outer edge of the mask to provide the best seal (see Fig. 32.5*B*).[95] Initial education and regular retraining are important for the maintenance of this important skill.[95]



• **Fig. 32.5** **A,** Round Laerdal mask: the "two-point top hold" provides the best mask seal. **B,** Fisher & Paykel round mask: the "OK rim hold" provides the best seal. (Photographs courtesy of Fiona Wood and Colin Morley.)

Typically, operators using a T-piece and face mask with a neonatal manikin have 40%-60% mask leak, although this can be reduced with training[95] and by using a two-handed mask hold technique.[89] Despite large and variable mask leaks, the desired pressure may still be achieved.[18] Unfortunately, neither the delivered pressure nor the amount of chest rise seen correlates well with the delivered tidal volume.[68] Variable leaks may result in some tidal volumes that are too low and others that are dangerously large.[68,77] Concern over large face mask leak may lead the provider to apply excessive pressure to the mask[65] and, therefore, to the face and head of the infant.[92] This pressure may obstruct the airway[14] by distorting the nose and altering the position of the mouth and chin; obstruction occurs in 25%-75 % of preterm mask resuscitations.[14,67] Although inefficient mask ventilation may not achieve adequate pressure and tidal volume, there may still be some benefit due to stimulation of Head's paradoxical reflex. This reflex generates a large inspiratory effort in response to a small inflation. The response may assist with the first effective inspiratory volume during newborn transition, even if mask ventilation fails to adequately inflate the lungs.

Single Nasal Tube and Bi-Nasal Prongs

Alternative interfaces include a single nasal tube (Fig. 32.6*A*), binasal prongs, and nasal cannulae. To ensure minimal leak

when the nasal route is used, it may be necessary to close the mouth, and when a single nasal tube is used, it may also be necessary to occlude the contralateral nostril.

A randomized controlled trial comparing a single nasal tube with a round cushion-rimmed face mask showed no difference in measures of effectiveness of resuscitation of preterm infants, including intubation in the delivery room, or in short- or long-term respiratory outcomes.[27] The authors subsequently reported more leak and obstruction with the nasal prong and less overall tidal volume delivery.[91] Therefore, a nasal tube may be a useful alternative to a face mask, but there is no evidence for its superiority. Observational reports exist of nasal prongs[50] and nasal cannulae[58] being used to stabilize preterm infants in the delivery room, but neither have been subjected to randomized trials.

Assessing the Effectiveness of Non-Invasive Positive Pressure Ventilation

It is important to be able to accurately assess whether the support being given is effective. However, clinical assessments of color change[44] and heart rate[26] are imprecise and inaccurate. Pulse oximeters provide rapid, continuous, accurate displays of heart rate and oxygenation and are now recommended for use in babies requiring assistance in the delivery room. Clinicians are poor at assessing mask leak, chest rise, and delivered tidal volume.[68] A respiratory function monitor can assist with assessment of leak and adequate tidal volume delivery.[29,71] However, these monitors are not readily available in the delivery room. A colorimetric carbon dioxide (CO_2) detector or quantitative end-tidal carbon dioxide monitor may help to determine whether there is gas exchange occurring during mask ventilation,[34] but neither have been shown to improve short-term clinical outcomes.[33] Most recently, cerebral oxygenation using near-infrared spectroscopy has been used in the delivery room to give additional information on the effectiveness of resuscitation.[53]

Laryngeal Mask Airway

Laryngeal mask airways are supraglottic airways (SGA) commonly used during anesthesia. SGAs consist of a soft elliptical mask with an inflatable, or gel rim, and a flexible airway tube (see Figs. 32.6*B* and *C*). The mask is inserted into the infant's mouth using the index finger, such that the mask covers the laryngeal opening, and the rim conforms to the contours of the hypopharynx, occluding the esophagus. The inflatable rim can be expanded via a small balloon. The airway tube can be attached to any resuscitation device. Various sizes and reusable and disposable versions are commercially available. An SGA may be helpful for infants with congenital anomalies involving the mouth, lip, palate, or other upper airway anomalies where endotracheal intubation is difficult. It may also be a useful technique where resources, training, and clinical experience are lacking. Almost all SGA insertions are successful at the first attempt and within 10 seconds.[97] Several studies have assessed the effectiveness of PPV delivered by SGA in term and near-term infants, and international guidelines now recommend that an LMA be used in these infants if mask ventilation is unsuccessful and endotracheal intubation is not possible.[52] Most recently, studies have assessed SGA use in more preterm infants for the delivery of surfactant with promising results.[54,62] However, there are currently no SGA devices small enough for infants <1500 g.

Endotracheal Tube

There are no absolute criteria for tracheal intubation after birth. Indications vary depending on gestational age, degree of respiratory effort, response to noninvasive ventilation, and the skill and experience of the resuscitator. International guidelines suggest intubation is considered at several stages:

- if the heart rate is <100 bpm after 30 seconds of effective positive pressure ventilation,[51]
- if non-invasive ventilation does not increase the heart rate, or
- if the infant continues to be apneic despite adequate ventilation.

It is also recommended if mask ventilation is prolonged or ineffective, or there are congenital anomalies affecting transition. Infants without a detectable heartbeat, and who are very hypotonic, should be intubated and ventilated as

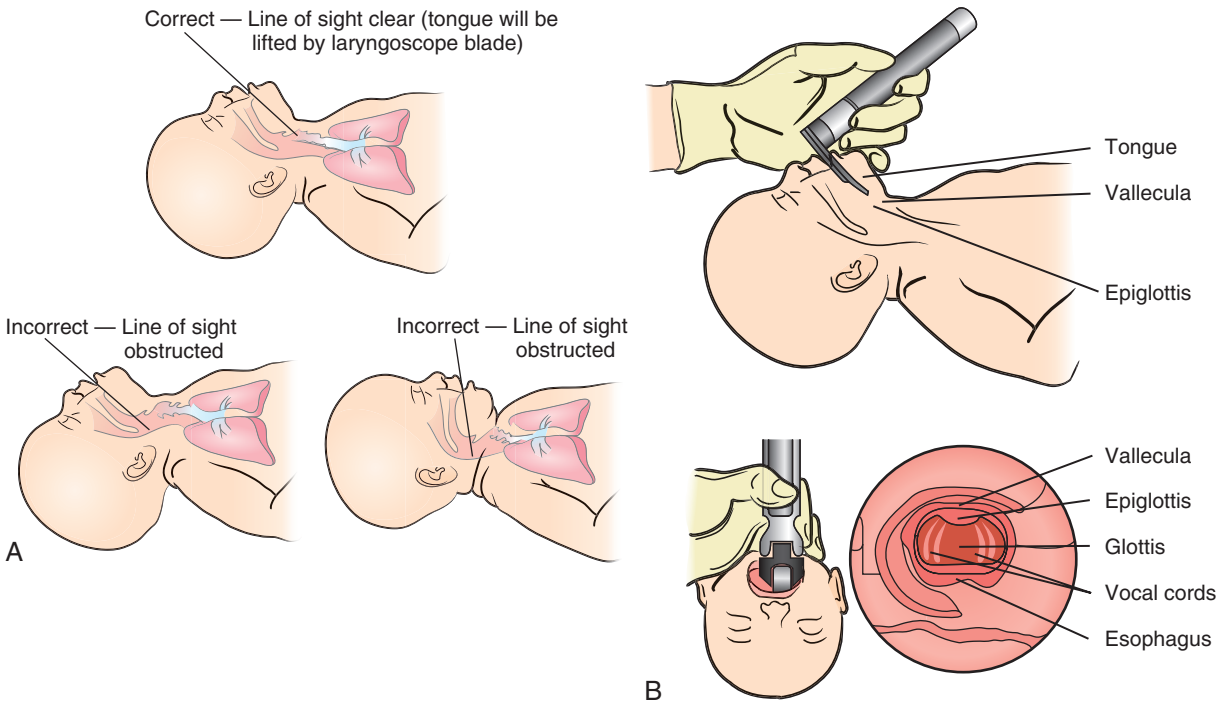
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

soon as possible. For infants <29 weeks who are spontaneously breathing and who have respiratory distress requiring respiratory support in the delivery room, international guidelines now suggest initial use of CPAP in preference to routine intubation.[52]



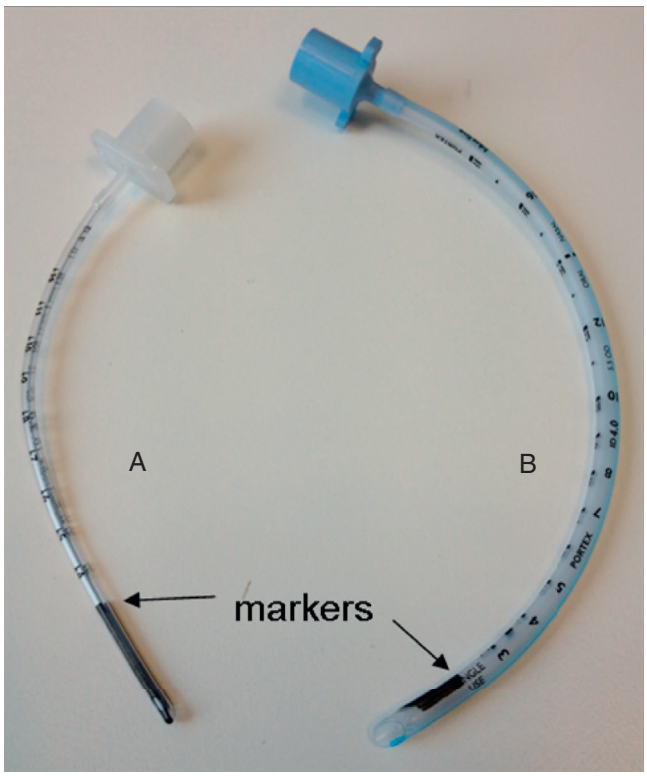
Neonatal intubation is a difficult skill to acquire and maintain. Fewer infants are now intubated and skills are declining. Although experienced operators are successful more than 85% of the time, junior trainees are successful in less than half of attempts.[46] Success can be increased by techniques such as use of videolaryngoscopy,[48] but less experienced operators still take longer to perform intubations. Successful intubations frequently take longer than the recommended 30 seconds, and infants often become bradycardic and deteriorate during intubation attempts.[46] Neonatal endotracheal tubes are uncuffed and usually straight. Some providers use a stylet inside the endotracheal tube, although there is no evidence that this reduces the duration or improves the rate of successful intubation.[47]

Intubation Procedure

Prior to endotracheal intubation, all necessary equipment should be assembled, a team and team leader identified, their roles delineated, and an escalation plan made for the possibility of intubation not initially being successful. The suggested items are outlined in Box 32.1. The infant should be placed supine in a "sniffing position" (Fig. 32.7*A*), avoiding both flexion and hyperextension of the neck, which make the glottis hard to visualize. The tip of the laryngoscope blade should be advanced over the tongue to the vallecula, or over the top of the epiglottis, and elevated gently to reveal the vocal cords (see Fig. 32.7*B*). The laryngoscope should support the tongue toward the left side of the mouth to have adequate space to see the larynx and pass the endotracheal tube (ETT). If the laryngoscope blade is

• BOX 32.1 Equipment Required for Endotracheal Intubation

1. Shoulder roll to facilitate optimal head position
2. Pressure delivery device (T-piece, self-inflating bag, or flow-inflating bag; manometer and PEEP valves optional)
3. Neonatal face masks—preterm and term infant sizes
4. Laryngoscope with blades (straight blade, Miller size number 00, 0 for preterm, and number 1 for term infant)
5. Straight endotracheal tubes (2.5, 3.0, 3.5, 4.0 mm internal diameter); with a standard curve, radio-opaque, and with marks to indicate depth of insertion
6. Endotracheal tube stylet (optional)
7. Magill neonatal forceps (if nasal intubation)
8. Sterile scissors
9. Neonatal stethoscope
10. Exhaled CO_2 detector
11. Air and oxygen supply; oxygen flow meter with air blender
12. Pulse oximeter for measuring heart rate and oxygen saturation
13. Suction apparatus and suction catheters (5, 6, 8, and 10 French sizes)
14. Equipment to secure endotracheal tube; appropriate adhesive tape to attach tube to face



• Fig. 32.7 A, Effects of flexion and hyperextension on ability to visualize the glottis. **B,** Correct view of glottis in preparation for intubation. advanced too far, the tip will be in the lower pharynx, and the larynx will not be visible. Gentle cricoid pressure may be helpful in bringing the larynx into view.

The endotracheal tube should be inserted to the level of the tube marker, so that it is visible just above the larynx (Fig. 32.8). The ETT should be secured with the appropriate centimeter side mark located at the upper lip (Table 32.2). This level is estimated as 6.0 cm plus the infant's weight in kilograms. If a stylet is used to assist with ETT insertion, care must be taken not to allow the stylet to protrude beyond the tip of the ETT and damage the trachea. When removing a stylet from a correctly placed ETT, care must be taken not to dislodge the tube. If a nasal intubation is being performed, McGill forceps may be required to advance the ETT through the vocal cords.

• **Fig. 32.8** Endotracheal tubes showing depth markers at the tip. **A,** Size 2.0 endotracheal tube (Mallinckrodt Medical, Athlone, Ireland). **B,** Size 4.0 endotracheal tube. (Portex endotracheal tube, Smiths Medical, Ohio.)

The position of the endotracheal tube in the trachea must always be verified. The best clinical indicator of correct placement is a prompt increase in heart rate. Correct positioning can be verified by visualizing the tube passing through the vocal cords, listening to both axillae with a stethoscope, observing misting inside the ETT during expiration, and observing chest movements during inflations. However, none of these methods are absolute confirmation. Use of an end-tidal CO_2 detector on the endotracheal tube connector is now recommended to verify correct tube placement quickly.[51] Colorimetric CO_2 detectors can rapidly demonstrate CO_2 in the expired ETT gas more quickly than changes in heart rate and oxygen saturations are seen.[66] However, they can give a false negative result when very low tidal volumes are being delivered[15] and false positive results when contaminated by adrenaline and surfactant.[22] Respiratory function monitors can provide a quicker indication of correct ETT placement than clinical assessment and expired CO_2 detectors.[72] When insertion is verified, correct depth of ETT insertion should be assessed by checking the measurement on the tube at the lips and by assessing symmetric chest movement and with chest radiography.

Applying Positive Pressure Support

When delivering positive pressure ventilation the clinician aims to provide effective ventilation for adequate gas exchange, without causing lung injury. It has been well documented that lung injury can be caused by lung overdistention (volutrauma),[24] excessive pressure (barotrauma), and by repeated alveolar collapse and re-expansion (atelectrauma). Studies in preterm animals have shown that lung injury can occur within the first few positive pressure inflations, resulting in an inflammatory response within a few minutes.[19] Therefore, knowledge about the causes and prevention of lung injury during ventilation of preterm

TABLE 32.2 Guidelines for Endotracheal Tube Sizes and Depth of Insertion

Weight (g)	Gestation (wk)	Endotracheal Tube Size (mm ID)	Orotracheal Tube Length (cm) from Upper Lip	Nasotracheal Tube Length (cm) from Nasal Flare
500-750	<26	2.5	6.5	7.5
750-1000	<28	2.5	6.5-7.0	7.5-8.0
1000-2000	28-34	3.0	7.0-8.0	8.0-9.0
2000-3000	34-38	3.0 / 3.5	8.0-9.0	9.0-10.0
>3000	>38	3.5 / 4.0	>9.0	>10.0

Depth can be calculated as weight (in kg) +6 cm for oral intubation, or weight (in kg) +7 cm for nasal intubation.

infants should be applied from birth. Actions to prevent lung injury include facilitating formation and maintenance of FRC, avoiding large tidal volumes that can easily and inadvertently be delivered with currently available resuscitation equipment,[77] and avoiding repeated lung collapse and re-expansion.

Very premature infants are especially vulnerable to the interventions applied in the first minutes after birth.[93] Therefore, as most preterm infants spontaneously breathe soon after birth, they may manage with CPAP alone, which is likely to cause less lung damage than routinely intubating them and applying positive pressure ventilation.[25] For infants who do not breathe or who require more than CPAP support, a gentle ventilatory strategy needs to be applied.

The First Breaths

The long initial inspirations, followed by prolonged expirations through a partially closed glottis that are seen in spontaneously breathing infants at birth, led researchers to question whether longer initial positive pressure inflations would be beneficial in infants without adequate spontaneous breathing. In anesthetized, intubated, preterm animal models, sustained inflation at modest pressure leads to rapid lung aeration without overexpansion, immediate development of appropriate FRC, and uniformly aerated lungs[82] without serious side effects.[76] Alternative strategies such as serial increases in applied PEEP may also have similar benefits.[88]

The optimal pressure and duration of a sustained inflation in preterm infants is unknown, and the effects of variable face mask leak, intermittent spontaneous breathing, and potential closure of the glottis make the standardization of applying a sustained inflation difficult. Randomized trials of sustained inflation for resuscitation in preterm infants have produced mixed results; meta-analysis showed less need for intubation in the delivery room but no effect on longer-term outcomes when sustained inflation was compared with standard PPV.[69] The current recommendation is for sustained inflation not to be used routinely and to limit its use to within randomized clinical trials.[52]

Peak Inflation Pressures and Tidal Volumes

Tidal volumes are not usually measured in the delivery room; therefore, clinicians must use peak pressure and clinical judgment of chest rise as a proxy for volume delivery. Neither of these provide reliable guidance regarding volume delivery.[56,68] However, they remain the most practical methods of targeting delivered volume given the equipment currently available. The actual delivered volume depends on multiple factors—the infant's spontaneous breathing effort, lung compliance, mask leak, obstruction at the mouth and nose, and the resuscitation device used. This means that tidal volumes delivered during PPV are variable and usually much higher than those generated during spontaneous breathing.[30] Animal studies have shown that high tidal volumes given soon after birth result in reduced oxygenation, increased need for ventilatory support, and instability of cerebral blood flow that increases the risk of brain injury.[55] The ideal target volumes for ventilation of term and preterm infants remain uncertain. Avoidance of tidal volumes greater than 8 mL/kg appears reasonable.[78] Development and testing of inexpensive, reliable, and accurate techniques to measure and display tidal volume is an important priority in neonatal resuscitation.

In the absence of tidal volume monitoring devices, clinicians rely on set peak pressure and clinical signs to deliver safe and effective ventilation. Typically, pressures in the range of 20-30 cm H_2O are suggested as initial settings[51,94] and have been shown to produce reasonable tidal volumes. Infants who make no respiratory effort may require higher pressures initially. As the lungs aerate and become more compliant, pressure may need to be reduced.[35] A rising heart rate is a good sign that effective ventilation is being delivered.[51]

Positive End Expiratory Pressure

The lungs of preterm infants are immature, surfactant-deficient, partially liquid-filled, and prone to collapse at end expiration. The beneficial effects of a continuous distending pressure include:

- splinting the airways open
- facilitating lung fluid clearance
- increased lung expansion and promoting the formation and retention of a residual lung volume at end expiration, preventing alveolar collapse
- conserving surfactant
- reducing ventilation-perfusion mismatch and right-to-left shunting
- improving oxygenation
- improving lung compliance
- reducing airway resistance by dilating the larynx and airways
- reducing upper airway occlusion by decreasing upper airway resistance and increasing the pharyngeal cross-sectional area
- reducing the work of breathing
- stabilizing the respiratory pattern
- stabilizing the chest wall and counteracting paradoxical movements

PEEP protects against lung injury and distal airway collapse at end expiration, while improving lung compliance, oxygenation, and accumulation of FRC. Whether or not an initial sustained inflation is given, animal studies have shown that without PEEP, no FRC is established[74] or maintained.[82] After an inflation without PEEP, lung volume is lost, airways collapse, and the infant becomes at risk of atelectrauma during the following inflations.[6]

There are few randomized studies in premature infants examining the use of PEEP at birth. Those that have been published failed to show a significant benefit over PPV without PEEP in terms of short-term respiratory

outcomes.[8,13] International guidelines suggest that PEEP is likely to be beneficial during positive pressure support of preterm infants, and if it is available it should be used.[51]

It is not possible to predict a single optimal PEEP level for all infants; however, infants with the highest oxygen requirements usually have the smallest FRC and may benefit from higher PEEP. Guidelines recommend the use of PEEP of 5 cm H_2O in the delivery room.[52] Trials of different levels of PEEP during resuscitation of human infants at birth are required.

Inflation Rate and Duration

There is little evidence on which to base the optimal inflation rate. Rates of 40-60 per minute are recommended and match the typical respiratory rates of healthy newborns. In an infant who has some respiratory effort, it is likely that manual inflations will sometimes be asynchronous with spontaneous breaths. This may lead to ineffective resuscitation, inadvertent high pressures, and increased risk of injury such as pneumothorax.[16] The duration of each inflation may, following the initial inflations, be best timed to reflect spontaneous inspiratory times of newborn infants to last approximately 0.3 seconds.

Gas Flow

It is rarely necessary to change the gas flow above the standard 8-10 L/minute during a resuscitation. Alteration of gas flow may not affect pressure or volume delivery when using a self-inflating or flow-inflating bag. Increasing gas flow above recommended rates during T-piece ventilation increases leak; it also increases the PEEP without increasing the peak pressure, resulting in lower delivered tidal volumes.[63,81]

Key Points

- Most full-term and late preterm infants breathe at birth and need no assistance to transition to extrauterine life.
- Infants who do not establish regular respiration require prompt respiratory support.
- Effective mask ventilation should result in a rapid increase in heart rate.
- Excessive tidal volume may cause lung damage especially to preterm infants.
- Endotracheal intubation should be considered if resuscitation is prolonged or the infant remains bradycardic.

Oxygen Therapy in Neonatal Resuscitation

MAXIMO VENTO

Use of Oxygen in Perinatal Asphyxia and Resuscitation

Oxidative Stress: Pathophysiologic Background

Perinatal asphyxia is a devastating disorder that affects roughly 2% of newborn babies in industrialized countries, but constitutes one of the leading causes of early neonatal death in nonindustrialized countries.[26] Both ischemia and hypoxia reduce oxygen and glucose supply to neurons leading to ATP depletion and inactivation of ATP-depending ion pumps, causing intracellular accumulation of Na^{+} (cell swelling), of ionic Ca^{++} (increased free radical formation and oxidative stress/damage), and inhibition of neurotransmitters' recaptation at the synaptic cleft causing hyperexcitability. Altogether these pathophysiologic circumstances will not only lead to cell necrosis but will collectively predispose tissue to reoxygenation injury.[12] During hypoxia, limited oxygen availability decreases oxidative phosphorylation, resulting in a failure to resynthesize energy-rich phosphates, including adenosine 5′-triphosphate (ATP) and phosphocreatine, resulting in an accumulation of purine derivatives, especially hypoxanthine. The tissue concentration of these metabolites is directly dependent on the intensity and prolongation of hypoxia[22] (Fig. 33.1). Upon resuscitation, restoration of oxygen and glucose supply may salvage neurons, but it will also activate the transformation of xanthine dehydrogenase in xanthine oxidase leading to the generation of a burst of oxygen and nitrogen free radicals that will trigger apoptotic and proinflammatory pathways, thus expanding the initial neuronal damage.[39] Moreover, in the endothelium, ischemia promotes expression of certain proinflammatory gene products (e.g., leukocyte adhesion molecules, cytokines) and bioactive agents (e.g., endothelin, thromboxane A_2) while repressing other "protective" gene products (e.g., prostacyclin, nitric oxide). Ischemia induces a proinflammatory state that increases tissue vulnerability to further injury on reperfusion.[16]

Reperfusion and reoxygenation of ischemic tissues result in the formation of toxic reactive oxygen species, including superoxide anions ($\bullet O_2^-$), hydrogen peroxide (H_2O_2), hydroxyl radicals (•OH), and nitrogen reactive species, especially peroxynitrite (•ONOO-). Under physiologic conditions, hypoxanthine accumulated during the ischemia is further oxidized by xanthine dehydrogenase to uric acid in the cells containing this enzyme. However, during prolonged ischemia, xanthine dehydrogenase is converted to xanthine oxidase by specific proteases. Of note, xanthine oxidase uses oxygen as a substrate and during hypoxia-ischemia is unable to catalyze the conversion of hypoxanthine (resulting in the buildup of excess tissue levels of hypoxanthine). When oxygen is reintroduced during resuscitation, conversion of the excess hypoxanthine by xanthine oxidase results in the formation of reactive oxygen species, especially anion superoxide. Moreover, in the presence of nitric oxide, both superoxide and nitric oxide will combine in the formation of reactive nitrogen species, especially peroxynitrite. In tissues rich in ferrous iron such as the brain, Fenton chemistry will ensue, leading to the formation of the highly reactive hydroxyl radical. Interestingly, xanthine oxidase in humans is mainly restricted to the liver and intestine. It has been shown, however, that xanthine oxidase leaks out into the blood after hypoxia and hypotension, and the hypoxanthine-xanthine oxidase system may be detrimental in all parts of the body. Many other oxygen radical–generating systems are presently well described.[48]

Reactive oxygen species and reactive nitrogen species are potent oxidizing and reducing agents that directly damage cellular structures. They are able to peroxidize membranes, structural proteins and enzymes, and nucleic acids. In addition, they are known to be extremely important regulators of intracellular signaling pathways that modulate DNA and RNA synthesis, protein synthesis, and enzyme activation, and directly influence the cell.[19] Increasingly, the concept of redox code has acquired more relevance. The redox code defines the positioning of nicotinamide adenine dinucleotide (NAD, NADP), thiol/disulfide (GSH/GSSG; CysSH/

Abstract

Fetal to neonatal transition causes an increased supply of oxygen to tissue, a burst of oxygen free radicals, and subsequently a physiologic oxidative stress. Healthy term newborn babies are readily prepared to overcome this circumstance. However, in asphyxiated babies, prolonged hypoxia and ischemia lead to a pathologic oxidative stress that overcoming newborn infants' defenses may cause damage to brain, myocardium, and other organs. Therefore, it is recommended that resuscitation is started with room air, and oxygen supplementation when needed should be under strict pulse oximeter control. Preterm babies are especially vulnerable to oxygen-derived damage because of the immaturity of the antioxidant system. Therefore, it has been recommended in the recent 2015 ILCOR guidelines that the initial inspired fraction of oxygen (FIO_2) for these babies should be 0.3 and titrated according to evolving pulse oximetry and heart rate, trying to adjust saturation to the American Heart Association (AHA) recommended ranges. However, recent studies have shown that babies that are supplemented with lower initial FIO_2 and do not achieve saturations of 85% or are kept with heart rates <100 bpm at 5 minutes after birth are more prone to develop intraventricular hemorrhage or have increased mortality. It is not known if these babies are already born with some in utero handicap, or it is because they are not supplied with enough oxygen. Adequately powered and designed randomized controlled trials are necessary to find an answer to this conundrum.

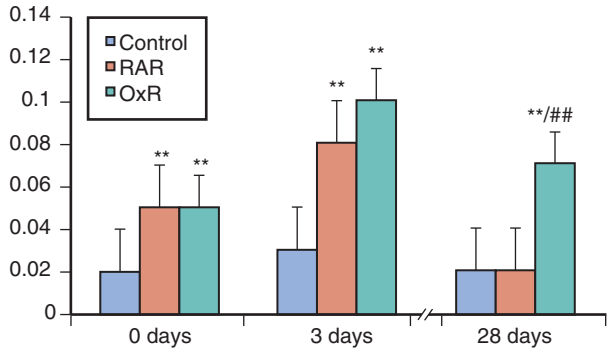
• **Fig. 33.1** During hypoxia, adenosine triphosphate (ATP) is exhausted, and complete rebuilding is not achieved. Purine derivatives (e.g., hypoxanthine) accumulate. During reoxygenation, specific proteases transform xanthine reductase ($X_{REDUCTASE}$) into xanthine oxidase ($X_{OXIDASE}$), which uses oxygen as a substrate, generating a burst of reactive oxygen species such as superoxide anion ($O_2^{\bullet-}$), hydrogen peroxide (H_2O_2), and hydroxyl radical (O·). In the presence of ferrous iron (Fe^{++}), Fenton chemistry generates great amounts of superoxide anion. Superoxide anion easily combines with abundant nitric oxide (NO), generating peroxynitrite (NOO·), an extremely aggressive nitrogen free radical. Free radicals are capable of damaging nearby molecules and organelles but also act as signaling molecules causing changes in gene expression, promoting inflammation, altering immune response, and inducing apoptosis.

CysS-S), and other redox systems as well as the thiol redox proteome as common elements for biologic processes. These control elements are functionally organized in redox circuits, which are controlled by central nodes constituted by sulfur/disulfide couples. These circuits function independently and are highly responsive for redox conditions, thus signaling and regulating biologic processes. The code is present in an oxygen-dependent life. Activation and deactivation cycles involving oxygen and hydrogen peroxide contribute to spatiotemporal organization for differentiation, development, and adaptation to the environment.[18]

A vast array of enzymatic and nonenzymatic antioxidants has evolved in biologic systems to protect cellular structures against the deleterious action of free radicals. Antioxidant enzymes catalytically remove reactive oxygen species (ROS), thereby decreasing ROS reactivity, and protect proteins through the use of chaperones, transition metal-containing proteins (transferrin, ferritin, ceruloplasmin), and low molecular weight compounds that purposely function as oxidizing or reducing agents to maintain intracellular redox stability.[19]

Clinically, antioxidant enzymes that have been most widely studied are the superoxide dismutases, catalases, and glutathione peroxidase. The most relevant nonenzymatic cytoplasmic antioxidant is reduced glutathione (GSH), a tripeptide (γ-glutamyl-cysteinyl-glycine). Hence, two molecules of GSH establishing a disulfide bond form oxidized glutathione and release one electron that is accepted by a free radical to stabilize the outer atomic shell. Thiol-disulfide strategy is extremely important in maintaining the reducing state in the cytoplasm and the cell redox status, essential for cell reproduction and maturation. Other systems to detoxify hydrogen peroxide in mitochondria and other organelles include glutaredoxin, thioredoxin, thioredoxin reductase, and the peroxiredoxins. Other enzymes with antioxidant and signaling functions are heme oxygenases (HO-1 and HO-2). HO-1 removes heme, a pro-oxidant, and generates biliverdin, an antioxidant, releasing iron and carbon monoxide. Finally, nonenzymatic antioxidants such as reduced glutathione, vitamin C, vitamin E, and β-carotene also function to protect cells from damaging effects of ROS.[54]

Oxidative stress in a biologic system is defined as the imbalance of pro-oxidants and antioxidants in favor of pro-oxidants.[15] Different biomarkers of oxidative stress have been used in biology and medicine. An indirect way of measuring oxidative stress is the detection of increased activity of antioxidant enzymes, such as superoxide dismutase, catalase, glutathione peroxidase, or glutathione redox cycle enzymes. Another measure is to analyze the oxidized form



Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

of a nonenzymatic molecule such as oxidized glutathione. An increased concentration of oxidized glutathione or a decreased ratio of reduced to oxidized glutathione may indirectly reflect a pro-oxidant status.[43]

For clinical purposes, the most widely employed markers of oxidative stress are those derived from the oxidant alteration of biologic molecules that convey the following characteristics: being chemically stable, reproducible, and easily measurable in biologic fluids. Urinary markers of oxidative stress are extremely valuable in neonatology, because urine sampling is readily available, allowing serial measurements without the need of supplementary blood sampling. In recent studies, reliable high performance liquid chromatography coupled to tandem mass spectrometry methods has been validated in the urine of newborn infants.[7] Hence, protein oxidation can be readily measured, analyzing phenylalanine oxidation by the action of hydroxyl radicals that leads to the formation of ortho-tyrosine (O-tyr) and meta-tyrosine. In addition, the action of hypochlorous acid and peroxynitrite upon phenylalanine produces byproducts such as chlor-tyrosine and nitro-tyrosine that reflect inflammatory processes and nitrosative stress respectively.[47] Hydroxyl radical aggression upon DNA can be assessed analyzing urinary concentration of oxidized guanidine bases.[21] The byproducts 8-hydroxyguanine (8-oxo-Gua) and its 2′-deoxynucleoside equivalent 7,8-dihydro-2′-deoxyguanosine (8-oxo-dG) are highly mutagenic. Urinary elimination of 8-oxo-Gua and 8-oxo-dG perfectly reflects nuclear attack by hydroxyl radicals.[8] In experiments performed in a piglet model of hypoxia and reoxygenation, urinary elimination of metabolites O-tyr and 8-oxo-dG correlated significantly with the amount of oxygen used on reoxygenation.[44] Lipid oxidation, especially arachidonic (isoprostanes, isofurans), docosahexanoic (neuroprostanes, neurofurans), and adrenic (di-homo isoprostanes) acids perfectly reflect damage to neuronal membranes and lipid components in gray and white matter respectively. Hence, F2-isoprostanes and isofurans, which are non-cyclooxygenase oxidative derivatives of arachidonic acid, are considered at present the most reliable markers of lipid peroxidation. These compounds are chemically stable, formed *in vivo*, present in all organic fluids and tissues, and are not affected by dietary content of lipids. Isofurans reflect oxidation in a high oxygen atmosphere and isoprostanes in a normoxic environment. In addition, byproducts derived from the oxidation of docosahexanoic acid such as neuroprostanes and neurofurans have also been considered very valuable biomarkers, especially related to oxidative damage of neuronal membranes, and adrenic acid reflects white matter damage by oxygen free radicals.[2,6,45]

Oxidative Stress: Differences Between Resuscitation With 100% Oxygen and Room Air

In the absence of severe lung disease or cyanotic congenital heart disease, resuscitation with 100% oxygen has been shown to cause supra-physiologic arterial partial pressures of oxygen in the newly born infant. By contrast, resuscitation with room air increases the Pao_2 to physiologic levels only (i.e., approximately 70-80 mm Hg). Biomarkers of oxidative stress such as oxidized glutathione or antioxidant enzyme activity are significantly increased in patients receiving excessive oxygen. Thus, newborn infants resuscitated with pure oxygen exhibit higher oxidative stress after resuscitation than infants recovered with room air.[50] Conspicuously, oxidative stress derived from resuscitation with pure oxygen may cause a long-lasting pro-oxidant status. Hence, in newborn babies resuscitated with 100% oxygen, oxidative stress was detected 4 weeks after birth. These infants had a decreased ratio of total blood reduced (GSH) to oxidized (GSSG) glutathione and oxidized DNA bases in urine at 1 month of life. No such effect has been observed in infants resuscitated with room air (Fig. 33.2).[49]

• **Fig. 33.2** Ratio of oxidized glutathione to reduced glutathione in asphyxiated newborns resuscitated with room air (RAR) or 100% oxygen (OxR) determined at 0 (birth), 3, and 28 days of life. ** $p < .01$ versus control; $p < .01$ versus RAR.

Hyperoxemia has also been associated with a series of negative side effects, including increased oxygen consumption and metabolic rate, increased activation of leukocytes and endothelial cells, and increased formation of reactive oxygen species and reactive nitrogen species.[16] Prolonged vasoconstriction of cerebral arteries has also been shown. In a study involving premature infants younger than 33 weeks' gestational age at 24 hours, cerebral blood flow was reduced by 20% in infants given 80% oxygen compared with infants for whom room air was used. This finding is in line with studies in newborn rats showing that the use of 100% oxygen for resuscitation reduces cerebral blood flow compared with room air resuscitation.[14]

Room Air versus Pure Oxygen for Resuscitation of the Newborn

Traditionally, postnatal resuscitation in the delivery room had been performed with 100% oxygen.[1] However, in 1998, the Resair 2 trial showed that it was feasible to resuscitate depressed newborn infants with room air.[36] Thereafter, a series of clinical studies summarized in an updated

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

review and meta-analysis has shown not only the suitability of room air for the resuscitation of the depressed term neonate but also a series of advantages, among which the most relevant is a decrease in mortality.[38,39]

Animal Studies

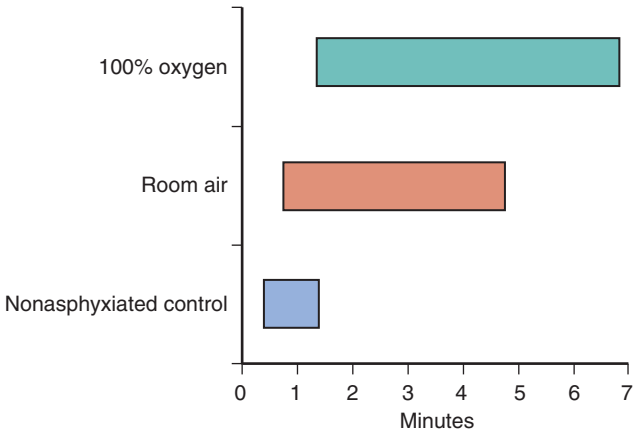
Animal studies have shown that after a period of severe hypoxia, physiologic functions such as blood pressure and blood flow to various organs, including the brain, are restored equally efficiently with 21% and 100% oxygen. Evoked potentials and biochemical indicators such as base deficit and hypoxanthine are restored efficiently using room air for resuscitation. Furthermore, experimental studies have also clearly shown that using 21% instead of 100% oxygen offers significant additional advantages. Hence, the use of high oxygen concentrations is not only toxic for the lungs but also for several other organs such as the heart, liver, and brain. In a review, the most relevant findings in animal models of hypoxia and reoxygenation with 21% versus 100% have been detailed.[40] Thus, extracellular glycerol concentration from the striatum was significantly higher in hypoxic piglets resuscitated with pure oxygen as compared with those resuscitated with air. Moreover, in a mouse model, hyperoxia after hypoxic-ischemic brain injury increased secondary neuronal injury and interfered with myelination. Matrix metalloproteinases, which reflect tissue damage and repair, were measured in lung, liver, heart, and brain of hypoxic piglets recovered with 100% versus 21% oxygen. Remarkably, the use of elevated oxygen concentration caused a significant increase of metalloproteinases in all analyzed tissues.[14] The H_2O_2 concentration in leukocytes from the sagittal sinus increased significantly in newborn hypoxic piglets resuscitated with 100% oxygen, in contrast to piglets given 21% oxygen. The nitric oxide concentration in the brain also tended to become higher if pure oxygen was used compared with ambient air for resuscitation of piglets. The stage might be set for a higher production of reactive nitrogen species and peroxynitrite if 100% oxygen is used.[20,23,24]

There are also clear indications that resuscitation with 100% oxygen augments inflammatory processes in the myocardium and the brain more than 21% oxygen. In a study using cord occlusion of fetal lambs, resuscitation with room air restored blood pressure as fast as when using 21% oxygen. In the cortex and subcortical area, significantly higher levels of proinflammatory cytokines and activities of Toll-like receptors 2 and 4 were found in animals given 100% oxygen.[28]

Some animal studies have shown that cerebral brain microflow is reestablished faster with 100% oxygen. One study in newborn mice found that 100% versus 21% oxygen gave faster cerebral blood flow restoration and poorer short-term and improved long-term recovery.[34] In another study, the slower normalization of cerebral blood flow in animals resuscitated with room air versus animals resuscitated with 100% oxygen almost disappeared, however, if moderate hypercapnia was present. In birth asphyxia, hypercapnia always coincides with hypoxia. Hypercapnia might seem to be an important factor in reestablishing brain blood flow after asphyxia. As mentioned earlier, other studies have shown that 100% oxygen during normocapnia, in contrast to the use of 21% oxygen, reduces cerebral blood flow.[14]

Oxygen is a pulmonary vasodilator, but studies performed in animal models of hypoxia reoxygenation have shown that hyperoxia blunts vasodilator activity of oxygen probably mediated by the generation of reactive oxygen species, especially H_2O_2 in the mitochondrial matrix. H_2O_2 diffuses to the cytoplasm, activating phosphodiesterase 5 (PDE5), which, acting upon the vascular smooth muscle cells, degrades cGMP thus inhibiting nitric oxide–mediated vasorelaxation and favoring persistent vasoconstriction. Remarkably, resuscitation with 100% oxygen of term fetal lambs asphyxiated by cord occlusion initially induced a decrease in pulmonary vascular resistance (PVR) and subsequent increase in pulmonary blood flow. Nonetheless, subsequent values (between 2 and 30 min) for PVR did not differ between lambs resuscitated with air or 100% oxygen. Interestingly, the increased pulmonary artery contractility induced by 100% oxygen was reversed when superoxide anions were scavenged. Hence, the use of 100% oxygen increases partial pressure of oxygen in the pulmonary artery, yet it does not enhance oxygen uptake by lung tissue, does not decrease pulmonary vascular resistance, and does not increase systemic oxygen extraction ratios. Furthermore, 100% oxygen also induces oxidative stress and increases pulmonary artery contractility, thus favoring pulmonary hypertension.[25,26] Animal studies have also shown that even in meconium aspiration, resuscitation with room air is as efficient as resuscitation with 100% oxygen, provided that a sufficient tidal volume is given.[46]

The results from animal studies quite overwhelmingly indicate that room air resuscitation is, in most cases, beneficial when compared with the use of 100% oxygen. Still there might be clinical conditions such as prematurity with primary lung disease when limited initial supplemental oxygen should be added.



Clinical Data

Several clinical studies have been conducted, aiming to evaluate the efficacy of resuscitation with ambient air compared with pure oxygen. Ten studies including 2133 newborns have been included in randomized or pseudo-randomized studies investigating any differences between infants resuscitated with 21% oxygen and 100% oxygen.[38] Results of these studies indicate that Apgar scores are more depressed, at least at 5 minutes of age, in newborns resuscitated with 100% oxygen compared with 21% oxygen; this is probably because newborns given oxygen take their first breath and cry significantly later than newborns given room air. As shown in a newborn rat model, initiation of diaphragmatic contractility and spontaneous respiration after hypoxia

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

is directly influenced by the oxygen concentration used upon reoxygenation.[3] Normal, nonasphyxiated newborns delivered vaginally or by cesarean section initiate the first cry almost immediately after birth and attain a sustained pattern of respiration within the first 30 seconds of life. Hypoxic and acidotic-asphyxiated infants do not initiate breathing spontaneously, however, and may require positive pressure ventilation. The duration of the resuscitation period directly correlates with the severity of asphyxia and the efficiency of the resuscitation procedure. Furthermore, onset of respiration was delayed in infants given 100% oxygen compared with infants given room air. Hence, time to first cry in infants resuscitated with room air ranged from 0.6-4.5 minutes, whereas infants resuscitated with 100% oxygen took 1.2-7 minutes to the first cry (Fig. 33.3). Another study of the duration of resuscitation until asphyxiated infants were able to sustain a spontaneous and regular pattern of breathing revealed that infants resuscitated with room air also needed less time (5.3 ± 1.5 minutes) than infants resuscitated with 100% oxygen (6.8 ± 1.2 minutes) to establish a regular respiration.[49,50,51]

An updated review and meta-analysis indicate that neonatal mortality is reduced 30% in the room air group. If we translate this data to the worldwide incidence of severe neonatal depression, this intervention could potentially save approximately 250,000 lives annually.[38,39] Remarkably, systematic review showed neonatal mortality of 12.8% in the 100% oxygen group versus 8.2% in the room air group, giving a relative risk (RR) of 0.69 (95% confidence interval [CI] 0.54-0.88) for neonatal mortality in infants given 21% oxygen. Number needed to treat is 25. These dramatic results raise several questions, first about the quality of the studies included and second, regarding what was the cause of death in these infants. The studies represent a mixture of blinded and unblinded, multicenter and single-center studies from many countries. Most of the infants were recruited from countries with poor resources. When analyzing separately the children from industrialized countries enrolled in six strictly randomized trials, a significant reduction of 2.8% (from 3.9%-1.1%) in neonatal mortality rate was still found (RR 0.32, 95% CI 0.12-0.84) in favor of the infants resuscitated with ambient air.[38]

• **Fig. 33.3** Time to first cry in asphyxiated newborns resuscitated with room air or 100% oxygen.

The causes of death can be mainly, but not exclusively, attributed to asphyxia. If oxidative stress is induced in infants resuscitated with pure oxygen, this may lead to alterations of cell function and physiology that place the infant at increased risk. This situation is illustrated in one study finding significantly higher troponin and *N*-acetylglucosaminidase in infants resuscitated with 100% oxygen compared with 21% oxygen, indicating more damage to the myocardium and kidney in the infants exposed to pure oxygen.[51] There was also a trend toward a reduction of severe hypoxic-ischemic encephalopathy stage 2 and 3 in the room air–resuscitated infants compared with 100% oxygen–resuscitated infants (RR 0.88, 95% CI 0.72-1.08).[38]

In newborns needing intervention at birth, with an Apgar score of less than 6 at 1 minute and given room air by bag and mask, the median SpO_2 at 1 minute of age was 65%, with 10th-90th percentiles ranging from 43%-80%. At 3 and 5 minutes, the corresponding figures are 85% (60%-90%) and 90% (73%-95%). The infants randomly assigned to pure oxygen did not have higher SaO_2 values over the first 10 minutes of life.[37]

Follow-up of 414 children aged 12-24 months and resuscitated with 21% versus 100% O_2 after birth were analyzed. Of note, none of these studies were designed to perform long-term follow-up as an outcome; nonetheless, final results indicated that no significant difference was found between groups regarding neurodevelopmental outcome. However, given the heterogeneous design of these studies, estimates are imprecise and warrant further study to draw conclusions.[41]

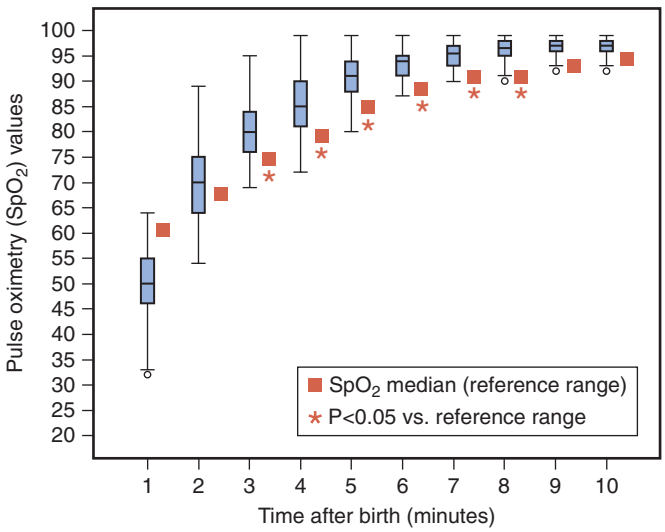
Oxygen Supplementation in the Delivery Room in Extremely Low Gestational Age Neonates

Mortality of neonates of extremely low gestational age (≤28 weeks' gestation) has substantially decreased in recent decades; however, morbidity, especially in the lower gestational age segment, remains high. Among neonates of extremely low gestational age, 70% may need some type of positive pressure ventilation in the delivery room.[55] In animal experiments, ventilation with high tidal volumes in the first minutes of life cause structural changes in the lung, predisposing to chronic lung disease.[17] Moreover, oxygen in excess upon resuscitation causes oxidative damage, especially in patients with an immature antioxidant defense system predisposing to chronic lung disease.[48,52] The feasibility of resuscitating extremely preterm infants with low initial FIO_2 has been approached in different studies. The use of room air was unsuccessful in achieving target saturations and heart rate in a significant number of very preterm infants who needed to be switched to 100% oxygen.[56] Contrarily, resuscitation with an initial FIO_2 of 0.3 was significantly more successful in achieving postnatal stabilization with less

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

oxygen exposure.[13,52] In both studies, very preterm infants achieved Spo_2 of 75% at 5 minutes after birth, and Spo_2 of 85% at 8-10 minutes. In 2014, a meta-analysis by Saugstad et al., including randomized trials (RCT) comparing higher (60%-100%) versus lower (21%-30%) initial oxygen in 677 preterm infants ≤32 weeks' gestation showed no differences in morbidity but a trend toward lower mortality in the lower oxygen group. It was concluded that preterm infants could be initially stabilized with Fio_2 of 0.21-0.3.[42] A survey among neonatologists from 25 countries in 2016 showed that only a small minority would resuscitate with an initial high supplemental oxygen.[29] However, Oei et al. published results of the largest RCT, comparing the effects of resuscitation with room air versus 100% oxygen in 289 preterm infants <32 weeks' gestation, targeting an SpO_2 65%-95% by 5 minutes and 85%-95% until admission. Mortality in the subgroup of babies <29 weeks' gestation was 16.2% in the room air group and 6% in the 100% oxygen group. Although statistically marginal, results emphasized the urgent need for larger RCTs.[30] In addition, the Canadian Neonatal Network published a retrospective cohort study comparing infants ≤27 weeks' gestation before and after 2006 when the policy regarding initial Fio_2 for preterm infants in the delivery room was changed from 100% to <100% oxygen and titration according to SpO_2. Adjusted OR (AOR) for the primary outcome of severe neurologic injury or death was higher in the lower oxygen group (AOR 1.36; 95% CI 1.11-1.66) and in those resuscitated with room air (AOR 1.33; 95% CI 1.04-1.69), when compared with 100% oxygen. The investigators cautioned about the consequences of a policy of initial stabilization with lower oxygen in very preterm infants compared to starting with 100% oxygen.[35] However, since both of these studies were simultaneously published with the 2015 ILCOR treatment recommendations, they were not included in the 2015 ILCOR final statements. In 2016, in a systematic review and meta-analysis of outcomes of randomized controlled trials in infants ≤28 6/7 weeks' gestation randomized to resuscitation with low (≤0.3) versus high (≥0.6) fraction of inspired oxygen (Fio_2) at delivery, main outcomes were death in hospital, bronchopulmonary dysplasia (BPD), retinopathy of prematurity (ROP) (>grade 2), intraventricular hemorrhage (IVH) (>grade 2), patent ductus arteriosus (PDA), and necrotizing enterocolitis (NEC) (>stage 2 of Bell). No differences in BPD, ROP, PDA, and NEC, and overall mortality were found.[31] Furthermore, a study in 2017 has analyzed the association of SpO_2 at 5 min after birth and clinical outcomes in preterm infants ≤32 weeks' gestation.[32] Data from 768 infants ≤32 weeks' gestation from 8 randomized control trials of lower (≤0.3) versus higher (≥0.6) initial Fio_2 were analyzed. The study aimed to establish a relationship between SpO_2 at 5 minutes, death, and IVH >grade 3. Interestingly, only 23% of the 706 patients met the SpO_2 targets at 5 minutes, and 46% did not reach SpO_2 80%. Pooled data showed decreased likelihood of reaching SpO_2 80% if resuscitation was initiated with Fio_2 <0.3 ($p<0.05$); moreover, SpO_2 <80% was associated with lower heart rates and with IVH ($p<0.05$). Of note, bradycardia (HR <100 bpm) at 5 minutes increased the risk of death ($p<0.05$). Taken altogether, and after accounting for confounders including gestation, birth weight, and bradycardia at 5 minutes, risk of death was significantly increased with time taken to reach SpO_2 80%. These findings could be explained because insufficient oxygen was provided or because inability of infants to respond to resuscitation is a reflection of the infant's *in utero* status.[32]

Boronat et al. have published in 2016 the only follow-up study from preterm infants randomized to an initial FIO_2 of 0.3 versus 0.6.[4] A total of 206 infants <32 weeks' gestation representing 81.4% of the total recruited in two studies completed follow-up at 24 months. No differences in perinatal characteristics, oxidative stress, or morbidities during the neonatal period were found. Moreover, no differences of mortality at hospital discharge or when follow-up was completed were found between groups. Remarkably, no differences regarding Bayley III scale scores (motor, cognitive, and language composites), neurosensorial handicaps, cerebral palsy, or language skills between groups were found.[4]



Oxygen Saturation Nomogram

Dawson, Kamlin, and Vento separately enrolled in three prospective observational studies 468 healthy newly born infants with gestational ages ranging from 25-42 weeks not needing any type of intervention in the delivery room after birth and until stabilization. SpO_2 was measured using preductal pulse oximetry and retrieved from the first minute after birth using state-of-the-art monitors set at maximum sensitivity attached to the right wrist. Thereafter, the three data sets were assembled into a graph that represents a reference range for SpO_2 for normal babies <42 weeks' gestation in the first 10 minutes after birth. Interestingly, it was shown that enrolled babies needed a median of 7.9 (interquartile range [IQR]: 5.0-10.0) minutes to reach SpO_2 >90% (Fig. 33.4).[9] Moreover, preterm infants needed significantly more time to reach this saturation. Hence, time needed to achieve SpO_2 stabilization was inversely proportional to gestational age.[9] In addition, a nomogram for heart rate also revealed different timing for stabilization in term and preterm infants.[10] At present, Dawson's oxygen saturation nomogram represents the best estimate of the most appropriate SpO_2 targets for term, but especially for preterm infants, during the first minutes of life.[11] Interestingly, preterm infants on continuous positive airway pressure and room air achieved targeted saturations reflected in the nomogram significantly earlier than those breathing spontaneously (see Fig. 33.4).[53]

Room Air versus 100% Oxygen—or Something Else

In 2010, the ILCOR guidelines clearly established the use of air as initial gas admixture to resuscitate depressed

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• **Fig. 33.4** *Red squares* represent oxygen saturation as measured by preductal pulse oximetry (SpO_2) in neonates with a gestational age ranging from 25-42 weeks' gestation who did not receive active resuscitation after birth. *Blue squares* represent SpO_2 of preterm babies (<32 weeks' gestation) who received respiratory support with continuous positive airway pressure and air immediately after birth. (Data from Dawson JA, et al[9] and Vento M, et al.[53])

newly born term infants. Moreover, if recovery is not successful, increased oxygen concentrations should always be used guided by pulse oximetry.[33] However, there is a discrepancy between the American Heart Association's (AHA) algorithm and the European Resuscitation Council (ERC) regarding SpO_2 targets for term infants. Hence, while the AHA recommends SpO_2 ranges at 1, 2, 3, 4, 5, and 10 minutes after birth of 60%-65%, 65%-70%, 70%-75%, 75%-80%, 80%-85%, and 85%-90%, respectively, the ERC recommends starting oxygen at an SpO_2 of 60%, 70%, 80%, 85%, and 90%, respectively, at 2, 3, 4, 5, and 10 minutes after birth. The differences between recommendations are based on the percentiles chosen as safety references to avoid hyperoxia and hypoxia, which have not yet been determined in randomized controlled trials.[11]

The use of supplemental oxygen to stabilize very preterm infants is still a matter of debate among neonatologists. In the last few years, a series of studies have shown that it is preterm infants ≤28 weeks' gestation who are at the center of the debate. Prolongation for more than 5 minutes of hypoxemia (SpO_2 <80%), and especially bradycardia (HR <100 bpm), seems to increase the probability of death and/or IVH. However, it is not clear if preterm infants do not reach these saturation and heart rate targets because they are already compromised *in utero* or because they are not adequately ventilated or oxygen supplementation is too low. The only means to solve this conundrum is to launch adequately designed and powered studies addressing this relevant issue. However, until more data are available, starting with 30% oxygen and trying to achieve SaO_2 of 85% within 5 minutes is recommended. In those cases, where there is no response in the first 3-4 minutes, titration should be performed, increasing more rapidly with higher oxygen increments.

Key Points

- Cellular injury results from biochemical pathways activated by both hypoxia and reoxygenation with oxidative stress determined by prooxidant/antioxidant imbalance.
- Both animal and human studies have documented detrimental physiologic and biochemical consequences of 100% versus 21% oxygen resuscitation. In extremely low gestation infants, initial low supplemental oxygen (e.g., 30%) is frequently needed.
- Available oxygen saturation nomograms provide a useful guide to titrate supplemental oxygen against SpO_2 targets obtained via pulse oximetry, especially in preterm infants.

Chest Compression, Medications, and Special Problems in Neonatal Resuscitation

VISHAL KAPADIA AND MYRA WYCKOFF

Advanced resuscitation in the delivery room is rarely needed as long as effective ventilation is quickly established. When compressions are needed, it is critical to minimize pauses, use the most effective two-thumb method from the head of the bed position, and coordinate with breaths that inflate the lung. In rare cases of profound asphyxia, intravenous epinephrine may be needed to reestablish adequate coronary perfusion pressure. Medical personnel who attend deliveries should practice these rare but vital steps so that when a crisis delivery occurs, they can mobilize additional help rapidly and perform the needed steps with skill without hesitation.

Accurate recording of the events in the delivery room and deliberate team debriefing should be employed to drive constant improvement in management of complex resuscitations.

Importance of Effective Ventilation

Effective positive pressure ventilation (PPV) is the most critical action needed to stabilize a newborn infant that is compromised at delivery. This is because the most likely cause of cardiovascular collapse of a newborn is asphyxia (inadequate gas exchange).[94] When effective ventilation is the primary focus of a newborn resuscitation team, chest compressions and medications are rarely needed. Data from a busy intercity delivery service with a highly trained resuscitation team suggests that chest compressions are provided for 0.1% of all deliveries[67] and chest compressions plus medications in 0.05%.[31] Premature newborns have higher rates of receiving chest compressions than their term counterparts.[1,32]

The most recent Neonatal Resuscitation Program (NRP) guidelines from the American Heart Association and the American Academy of Pediatrics suggest that chest compressions be performed if the heart rate remains less than 60 beats per minute after ventilation that inflates the lungs, as evidenced by chest rise with ventilation breaths.[97] Specific steps to improve ventilation before starting chest compressions should be initiated using the mnemonic algorithm MRSOPA (Table 34.1), which includes checking for a good *m*ask seal, *r*epositioning the infant in the open airway position, *s*uctioning the oropharynx for possible obstructing secretions, *o*pening the mouth so that ventilation attempts are not just through the higher resistance nasal passages, increasing the peak inspiratory *p*ressure of the PPV device, and placing an advanced *a*irway such as a laryngeal mask airway or endotracheal intubation.[94] Thus, if at all possible, the airway should be secured and ventilation provided via an advanced airway before initiation of chest compressions. The increased focus on achieving effective ventilation means that some extra time is allowed to work on the MRSOPA steps before proceeding to chest compressions. Common sense must prevail in the uncommon circumstance when neither a laryngeal mask airway nor endotracheal tube can be placed successfully. In this situation, chest compressions may have to be started while continuing to focus on optimization of mask ventilation. This can be accomplished by observation of adequate chest rise, bilateral auscultation of the lungs, and use of an end-tidal CO_2 ($ETCO_2$) detector. A neonatal pig study of asphyxia-induced asystole found no difference in rates of return of spontaneous circulation when the initial steps of resuscitation (dry, position, suction if needed, and stimulation) were followed by 30 versus 60 seconds of ventilation before compressions were started; however, 90 seconds of ventilation before supporting the circulation with compressions decreased rates of return of spontaneous circulation.[83] There is no evidence regarding optimal length of ventilation before compressions in the situation of severe bradycardia rather than asystole.

TABLE 34.1 Steps to Improve Ventilation Before Starting Chest Compressions (MRSOPA)

M	Mask	Check mask seal
R	Reposition	Position in open airway "sniffing" position
S	Suction	Suction to remove obstructing secretions
O	Open the mouth	Open the mouth to decrease resistance
P	Pressure increase	Increase the peak inspiratory pressure
A	Advanced airway	Place a laryngeal mask airway or intubate

There is no clinical evidence to offer guidance in either circumstance.

Current resuscitation guidelines[68] recommend that initial PPV be provided with 21%-30% oxygen in preterm infants <35 weeks of gestation[65] and with 21% oxygen in the remaining older preterm and term infants.[75] Oxygen supplementation should be guided by pulse oximetry and oxygen saturation per minute-of-life norms; however, when chest compressions are initiated, it is recommended that 100% O_2 be used until the heart rate is stabilized.[97] This recommendation remains controversial, and clinical data for guidance are lacking. Animal studies of profound cardiovascular collapse caused by asphyxia provide mixed results, with some suggesting a protective effect when 100% O_2 is avoided.[45,86] Other studies suggest that 100% O_2 and 21% O_2 are equivalent,[57,82] and still others suggest benefits when 100% O_2 is used.[56,70] Two clinical reports suggest that following asphyxia and resuscitation, newborns who demonstrate early hyperoxia in the neonatal intensive care unit (NICU) have worse neurologic outcomes.[40,72] There are no randomized studies to determine whether hyperoxia is causal for neurologic injury or merely a marker of a more severe asphyxial insult that needed more oxygen for stabilization. The best compromise for the clinician at the present time continues to be to resuscitate with supplemental oxygen when chest compressions are necessary (as ventilation with room air will have already been tried by this point), with weaning of the oxygen as soon as possible once the heart rate is stabilized to limit exposure to hyperoxia.

Chest Compressions

The most common reason for why a newborn fails to successfully transition at birth is lack of gas exchange resulting in simultaneous hypoxia and mixed metabolic and respiratory acidosis, otherwise known as asphyxia.[39] Combined profound hypoxia and acidosis depresses myocardial function and promotes maximal vasodilation. The goal of chest compressions is to mechanically pump the blood through the heart until the myocardium is sufficiently oxygenated to recover spontaneous function. Due to preferential perfusion of the heart and brain during cardiac compressions, greater than 50% of normal cardiac and cerebral blood flow can be achieved through optimized cardiac compressions.[8,9] Improved myocardial perfusion increases the likelihood of faster return of spontaneous circulation, while improved cerebral perfusion positively impacts neurologic outcome.

Chest compressions should be centered over the lower one-third of the sternum to compress most directly over the heart.[27,50,66,69] Compression of the sternum directly over the heart squeezes it against the spine. This increases intrathoracic pressure, which causes blood to be pumped from the heart into the arteries. When the pressure on the sternum is released, venous blood refills the heart and blood flows into the coronary arteries.[94] Chest radiograph studies demonstrate that the center of the infant heart is positioned under the lower third of the sternum the majority of the time.[27,69] Ten pediatric patients (between 1 month and 3 years of age) who sustained cardiac arrest and had arterial pressure monitoring lines in place were monitored during external chest compressions performed by medical providers who were blinded to the blood pressure monitoring.[66] Compressions were provided in random order either at the level of the patient's nipples (midsternum) or over the lower one-third of the sternum above the xiphoid. Each patient served as his or her own control with compressions performed at both locations in random sequence. The performance of compressions over the lower one-third of the sternum resulted in significantly better systolic and mean arterial blood pressures.[66] A more recent study of 63 infants confirmed that location of the left ventricle in 90% of cases was under the lower 1/3 of the sternum using infant CT scan measurements.[50] Although there is one report of CT scan measurements for 75 infants with a mean age of 4.4 ± 3.6 months, which found the heart to be located under the lower 1/4 of the sternum,[102] care must be taken to not be too low on the sternum to avoid dislocation of the xiphoid process, which could lead to liver laceration.[18] Similarly, placement of the compressing thumbs must be centered over the sternal bone so as to not cause rib fractures, which could inhibit critical ventilation via pneumothoraces or a flail chest.

The two-thumb technique in which the hands encircle the chest while the thumbs compress the sternum should be used for neonatal chest compressions.[24] The older, less effective two-finger method is no longer recommended.[68] Evidence from animal models of asphyxia-induced asystole demonstrate that the two-thumb technique generates higher blood pressures than the two-finger technique.[36] This has also been shown in a manikin model with a customized artificial arterial system.[23] Manikin studies demonstrate that the two-thumb technique improves depth of compression, lessens fatigue of the compressor, and results in more consistently accurate thumb placement on the sternum than the two-finger technique.[17,73] Clinical data are limited to a few case reports but also suggest that the two-thumb

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

technique generates better perfusion pressures than the two-finger technique in newborns.[20,88] In the past, the two-finger technique was used primarily as a means of keeping the compressor's arms out of the way while emergent umbilical venous line placement was obtained. With the implementation of the MRSOPA algorithm and securing an advanced airway before initiation of compressions, the compressor can move to the head of the bed once the tube or laryngeal mask is secured and continue the more effective two-thumb technique even while emergent intravenous access is obtained. It is crucial that compressions from the head of the bed never interfere with adequate ventilation and establishment of an advanced airway.

Optimal compression depth for the newborn is believed to be one-third the anterior-posterior (AP) diameter of the chest and thus varies with the size of the baby. Computed tomography images of the chest of neonates and young infants estimate that a compression depth of half the AP diameter might result in internal organ damage but that one-third the AP diameter would lessen this risk while still resulting in enough compression of the heart to generate blood flow.[12,63] Clinical data are limited to a report of six infants who had arterial lines in place after cardiac surgery and subsequent cardiac arrest.[59] Chest compressions were given to a depth of one-third the AP diameter and subsequently one-half the AP diameter. Although a compression depth of one-half the AP diameter resulted in higher mean arterial pressures, this was mainly owing to an effect on systolic blood pressure. Diastolic pressures between the two groups were similar. This is an important distinction, because coronary perfusion pressure is determined by aortic diastolic blood pressure minus the right atrial diastolic blood pressure, so it is the diastolic blood pressure that is most critical.[39] It has also been noted that a compression-to-relaxation ratio with a slightly shorter compression than relaxation phase offers theoretical advantages for blood flow in the very young infant.[21,39] The chest must be allowed to fully recoil before the next compression so that the heart can refill with blood.[52,100]

The best ratio of compressions to ventilations to optimize perfusion and ventilation during neonatal resuscitation is unknown. It is clear from animal models that ventilations in combination with chest compressions result in better outcomes than if resuscitation proceeds with ventilations or compressions alone,[6,7] especially during prolonged resuscitation.[22] Physiologic mathematical modeling suggests that higher compression-to-ventilation ratios would result in underventilation of asphyxiated infants.[3] Such models predict that three to five compressions to one ventilation should be most efficient for newborns. The current NRP guidelines recommend a ratio of three compressions to one ventilation breath such that 90 compressions and 30 breaths per minute are achieved. The medical providers performing the compressions and ventilations should communicate by having the compressor count the cadence out loud as "one and two and three and breathe and."[94] Studies have compared 3:1 to 9:3 compression-to-ventilation ratios[83] and 3:1 to 15:2 ratios[84] in newborn pig models of asystole caused by asphyxia. Although the 15:2 ratio provided more compressions per minute without compromising ventilation as measured by arterial blood gas and generated statistically higher diastolic blood pressures, the diastolic blood pressure was still inadequate until epinephrine was given, and thus there was no difference in the time to stabilize the heart rate. A manikin study of 3:1, 5:1, and 15:2 compression-to-ventilation ratios using the two-thumb technique compared depth of compressions, decay of compression depth over time, compression rates, and breaths delivered over a 2-minute interval.[34] Providers using the 3:1 versus 15:2 ratio achieved a greater depth of compressions as well as more consistent depth over time. The 3:1 ratio delivered the most breaths and fewest compressions, as would be expected. Thus, there is no evidence from human, animal, manikin, or mathematical modeling studies to warrant a change from the current compression-to-ventilation ratio of 3:1. Rescuers may consider using higher ratios (15:2) if the arrest is believed to be of cardiac origin.

Concern that simultaneous compressions and ventilation breaths might impede effective ventilation has led to continued emphasis that compressions and ventilations should be coordinated during neonatal cardiopulmonary resuscitation (CPR), so that they do not interfere with each other. Although studies of asynchronous chest compressions and ventilation (CCaV) show improved minute ventilation, there was no improvement in return of spontaneous circulation (ROSC).[77] CCaV is associated with increased rescuer fatigue and poor quality chest compressions as well as increased left ventricular lactate levels, possibly from trauma or anaerobic metabolism.[10,11,52,85,86] Recently, neonatal animal model studies[54,78] and a randomized feasibility study in a small number of neonates showed shorter time to ROSC with continuous chest compressions during sustained inflation.[76] A larger clinical trial is underway to determine if continuous chest compressions during a sustained inflation results in increased ROSC in neonates receiving CPR.

Strategies for optimizing the quality of the compressions and ventilations with as few interruptions as possible should be considered. NRP currently recommends that the interval between auscultation pauses be at least 1 minute in an effort to decrease interruptions in perfusion.[94] Once compressions are initiated, cardiac monitoring leads should be placed so that pauses for auscultation of heart rate can be minimized.[97] It can take a team 17 seconds to complete the auscultation process during delivery room resuscitation when using a stethoscope.[93] When the cardiac monitor heart rate is greater than 60 beats per minute, it is important to confirm by auscultation that the displayed heart rate is not just pulseless electrical activity.

Quantitative $ETCO_2$ monitoring can serve as a noninvasive tool to eliminate frequent auscultation pauses during CPR. Changes in $ETCO_2$ primarily reflect changes in cardiac

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

output during CPR. A piglet model of asphyxia-induced asystole demonstrated that once effective PPV is provided, $ETCO_2$ plummets to near zero with loss of pulmonary blood flow and then increases slightly with initiation of chest compressions, reflecting some blood being pumped through the lungs by the chest compressions. ROSC correlates with a sudden rise in $ETCO_2$ as the re-established perfusion brings CO_2-laden blood back to the lungs. An $ETCO_2$ greater than 15 mm Hg correlates well with return of an audible heart rate greater than 60 beats per minute in a newborn pig model.[13] A single case report of CPR in a very preterm infant at birth noted ROSC just after $ETCO_2$ reached 12 mm Hg during the resuscitation.[53] Clinical correlate studies are currently underway.

Medications

Epinephrine

When asphyxia is severe enough to cause asystole or agonal bradycardia despite initiation of CPR, the newborn heart is depleted of energy substrate (adenosine triphosphate [ATP]) and can no longer beat effectively. Oxygenated blood must be restored to the coronary circulation, or ROSC with a heart rate greater than 60 beats per minute will not be achieved. During CPR, coronary blood flow occurs exclusively during diastole, presumably because of increased intramyocardial resistance and increased right atrial pressure during chest compressions[44]; therefore, coronary perfusion pressure is determined by the aortic diastolic blood pressure minus the right atrial diastolic blood pressure. Given the profound acidemia and resultant vasodilation induced by severe asphyxia, a vasoconstricting pressor agent such as epinephrine is frequently required to attain sufficient aortic diastolic pressure to improve coronary perfusion during newborn CPR. Consequently, if the heart rate remains less than 60 beats per minute despite 30 seconds of effective positive pressure ventilation (with chest rise), followed by coordinated chest compressions and ventilation, then 0.1-0.3 mL/kg of 1 mg/10 mL epinephrine solution should be given rapidly via the intravenous (IV) route followed by 0.5-1.0 mL of normal saline flush.[97]

Data regarding optimal dosing for intravenous epinephrine during newborn CPR are lacking. Intravenous rather than endotracheal delivery of epinephrine is preferred and mandates that delivery room resuscitation providers be well trained in rapid preparation and placement of umbilical venous catheters.[94] In a newborn lamb model of asphyxia, endotracheal (ET) epinephrine was absorbed slowly compared to IV epinephrine, which resulted in lower plasma concentration and less effectiveness.[91] In addition, the absorption of ET epinephrine was delayed, which increases chances of very high epinephrine levels after multiple doses of ET epinephrine in animals who achieved ROSC. Similarly, a recent retrospective cohort study in newborns who required CPR in the delivery room also noted that only 20% of newborns responded to ETT epinephrine alone even though the recommended ET dose was increased compared to a decade earlier.[4,31] The total dose of epinephrine delivered was higher when any ET epinephrine was given.[31] This might increase risk of arrhythmia or other adverse outcomes due to higher plasma epinephrine levels.

Newborn transitional physiology limits the success of the endotracheal route, because the decreased pulmonary blood flow may be insufficient to transport the drug from the alveoli to the central circulation, pulmonary vasoconstriction from acidosis may impede drug absorption, unresorbed alveolar fluid may dilute the epinephrine, and potential right-to-left intracardiac shunts could bypass the pulmonary circulation altogether. Based on current evidence, once the airway is secured and CPR initiated, immediate attention should be on establishing IV access so that IV epinephrine can be given. The endotracheal route should be used only until IV access is available.[41] However, if the endotracheal route must be tried because of inability to obtain intravenous access, a higher dose (0.5-1.0 mL/kg) of 1 mg/10 mL epinephrine solution may be used in hopes of improving efficacy.[97] Loading endotracheal epinephrine doses in a larger 3- to 5-mL syringe to alert the resuscitation team as for which route the dose is intended can help avoid accidentally giving the higher endotracheal dose through the umbilical line. Successful resuscitation of newborns using the intraosseous route for epinephrine delivery has been reported.[26] A neonatal simulation study found that health care providers could quickly obtain the intraosseous route for delivery of epinephrine.[71] Neonatal resuscitation teams should routinely practice emergent placement of whatever kind of line is used most often at their institution.

At this time, the only other vasopressor that has been studied for use during neonatal CPR is vasopressin. In a newborn piglet asphyxia model, vasopressin improved survival and resulted in lower postresuscitation troponin levels and less hemodynamic compromise compared to epinephrine.[62] This epinephrine alternative needs to be evaluated further before any recommendation can be made.

Volume

Although an asphyxiated infant may be in shock, this is not usually caused by hypovolemia but rather by decreased myocardial function and decreased cardiac output from asphyxia. Most infants who have undergone intrauterine asphyxia and delivery room CPR are not hypovolemic.[28,99] In some circumstances, however, hypovolemic shock is a real possibility (Box 34.1). Shock at birth may be caused by asphyxia, hypovolemia, or sepsis. In addition, most causes of hypovolemic and septic shock result in neonatal asphyxia. Although most severely hypovolemic and septic infants are asphyxiated, most septic or asphyxiated infants are not hypovolemic. Some studies have shown that antepartum asphyxia is associated with increased transfer of blood from the placenta to the fetus before birth, resulting in normal

• BOX 34.1 Causes of Hypovolemia

- Decreased blood return from placenta
- Cord compression resulting in venous, but not arterial, occlusion
- Placental separation compromising placental blood return to the fetus
- Hemorrhage from the fetal side of the placenta
- Fetal-maternal hemorrhage
- Fetal-fetal transfusion
- Incision of the placenta during cesarean delivery
- Velamentous insertion of umbilical cord with fetal arterial rupture

or increased circulating blood volume.[55,101] The difficulty is in distinguishing hypovolemic and septic shock from asphyxial shock that does not involve hypovolemia.

A history of bright red vaginal bleeding just before delivery, a cesarean delivery where the uterine incision had to be made through an anterior placenta, or the finding of a velamentous insertion of the umbilical cord can raise suspicion for acute fetal blood loss. Placental abruption is a major cause of asphyxia but rarely is associated with fetal blood loss unless caused by trauma such as a high-speed motor vehicle accident. The painful bleeding of abruption is almost always maternal blood loss. Maternal fever, fetal tachycardia, and other signs of chorioamnionitis may indicate neonatal sepsis and shock. Volume expanders may be detrimental in an infant who is not hypovolemic, especially one who has experienced hypoxia-induced myocardial dysfunction.[96] Volume expanders should be given in the acute circumstance when, after adequate ventilation and oxygenation have been established, poor capillary filling persists, and there is evidence or suspicion of blood loss with signs of hypovolemia. In an infant in whom the pulse cannot be normalized despite adequate resuscitation, measures including epinephrine and volume expansion should be considered.

In an acute situation, the volume expander of choice is normal saline; although 5% albumin was used in the past, it has no advantage over crystalloid solutions, and there is some evidence of increased risk for subsequent pulmonary edema and, thus, it is no longer included in neonatal resuscitation guidelines.[28] Lactated Ringer's has never been studied in neonatal resuscitation and for simplification of stocking delivery room neonatal resuscitation supplies has been removed from the NRP recommendations.[94] The best volume expander, although rarely immediately available, is whole O-negative blood; this provides volume, oxygen-carrying capacity, and colloid. Infusion of volume expanders should consist of a volume of 10 mL/kg given over 5-10 minutes. In true acute hypovolemia, it is often necessary to repeat this infusion a second or third time. In acute hypovolemia, hematocrit may be misleading since not enough time has passed for equilibration to occur. Therefore, with a history of acute blood loss (i.e., ruptured velamentous cord insertion), volume should be given even in the face of a normal early hematocrit.

Other Drugs

Other drugs such as sodium bicarbonate, naloxone, and pressor agents other than epinephrine are no longer considered resuscitation drugs for the delivery room. They are discussed briefly in the section Immediate Care after Establishing Adequate Ventilation and Circulation.

Intravenous Access

Medications should preferentially be given through an umbilical venous catheter. When an umbilical catheter is used, it should be inserted into the umbilical vein just beneath the skin, approximately 2-4 cm until free flow of blood is obtained when the stopcock is opened to the syringe and the syringe gently aspirated. If the catheter is inserted too high and becomes wedged in the liver, solutions can be infused into the liver, which may cause liver necrosis. The depth of insertion of the catheter is much less in premature infants depending on their weight, and care should be taken not to insert the catheter too far. If a catheter is not prepared and ready, endotracheal administration of epinephrine may occur through the endotracheal tube while the catheter is being prepared, but only as a temporizing measure while IV access is established. It is prudent, however, that when preparing for a "crash" delivery, the catheter should be prepared in advance to minimize the delay in giving epinephrine by the most effective route. Table 34.2 presents an overview of the medications used in delivery room resuscitation, including concentration, dosage, route, and precautions.

When to Discontinue Resuscitation Efforts

If an infant still has no heart rate after 10 minutes of what otherwise appears to be effective resuscitation, resuscitation providers may consider discontinuing their efforts.[97] This does not mean that the resuscitation team must stop at 10 minutes after birth, but rather that after 10 minutes of well-coordinated resuscitation efforts if the newborn is still asystolic, it is appropriate to consider discontinuation. The majority of available data indicate that after 10 minutes of asystole, there are few survivors[33,80,87] and those who do survive frequently have severe disability.[33] Infants with 10-minute Apgar scores of zero but who survived to be admitted to the NICU and entered into a hypothermia clinical trial had better outcomes than those reported in the systematic review by Harrington; however, there was significant selection bias.[42,48] Recent cohort studies of infants with 10-minute Apgar scores of zero who were subsequently treated with hypothermia had ~20%-30% survival with normal development on early assessments.[80] Decisions regarding whether to continue or discontinue resuscitative efforts must be individualized. Variables to be considered

TABLE 34.2 Medications for Neonatal Resuscitation in the Delivery Room

Medication to Administer	Concentration	Syringe for Preparation	Dosage; Route	Weight of Newborn (kg)	Total Dose (mL)	Precautions
Epinephrine	1 mg/10 mL	1 mL	0.1-0.3 mL/kg; IV	1	0.1-0.3	Preferred route; give rapidly
				2	0.2-0.6	
				3	0.3-0.9	
				4	0.4-1.2	
		3 or 5 mL	0.5-1.0 mL/kg; ET	1	0.5-1	5-10 times IV dose; give directly into the ET tube
				2	1-2	
				3	1.5-3	
				4	2-4	
Volume expanders	Normal saline, whole blood	30 mL	10 mL/kg; IV	1	10	Give over 5-10 min
				2	20	
				3	30	
				4	40	

ET, Endotracheal.

may include whether the resuscitation was considered optimal; the availability of advanced neonatal care such as therapeutic hypothermia; the specific circumstances before delivery (e.g., known timing of the insult); and the wishes expressed by the family.[97]

Documentation and Debriefing

A critical member of the neonatal resuscitation team is the recorder, who should document in real time the steps of resuscitation that the team makes and the infant's response. It is not acceptable to write a summary from memory after the fact when the accuracy of the details may be lost. The resuscitation record should be used to debrief the team after every advanced resuscitation to look for opportunities to improve in communication, documentation, resuscitation skills, and knowledge of the algorithm. Some institutions choose to video record delivery room resuscitations for this purpose.

Immediate Care After Establishing Adequate Ventilation and Circulation

Induced Therapeutic Hypothermia

Any newborn who undergoes significant resuscitation efforts in the delivery room should have an umbilical artery cord blood gas to check for fetal acidemia and have a careful neurologic exam. Infants born at ≥36 weeks' gestation with evidence of an acute perinatal event and moderate to severe hypoxic-ischemic encephalopathy should be offered therapeutic hypothermia. Therapeutic hypothermia initiated within 6 hours of birth with cooling to 33.5°C has been shown to reduce mortality and neurologic impairment at 18-month follow-up. The hypothermia treatment should be implemented according to the studied and published protocols, which currently include initiation of cooling within 6 hours following birth, continuation for 72 hours, and slow rewarming over at least 4 hours.[97] Because the goal is initiation of cooling within 6 hours of birth, it is important that all delivery hospitals have such protocols in place or have access to a referral center to which such infants can be sent quickly. Passive cooling before transport has not been studied, and clinical judgment should prevail until further data are available. Hypothermia initiated after 6 hours of birth is not as effective as early hypothermia but appears to confer some benefit for those infants that cannot get to the cooling center in time or for whom moderate/severe encephalopathy was not obvious until after 6 hours of age.[49] The risks and benefits of hypothermia treatment for late preterm infants (33-35 weeks' gestation) with moderate to severe neuroencephalopathy are not clear and trials are currently underway.

Sodium Bicarbonate

There is no evidence either from experimental neonatal animal studies or clinical trials regarding the risks or benefits of sodium bicarbonate on achieving ROSC in the situation of severe bradycardia or asystole. The only randomized trial of sodium bicarbonate infusion in neonates requiring positive-pressure ventilation in the delivery room failed to show any benefit on neurologic outcome or survival.[58] Adult animal models and clinical studies have demonstrated

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

deleterious effects on physiologic end points after administration of sodium bicarbonate during CPR, effects that include depression of myocardial function from the osmolar load with severe acidosis, paradoxic intracellular acidosis, and reduced cerebral blood flow.[2,51] Thus, use of sodium bicarbonate should be discouraged during CPR. Its use in the newborn should be moved to post-resuscitation care in the NICU and guided by arterial blood gas levels or serum chemistries, although even in the NICU there is not clear benefit.[19,43] It should never be given unless there is assurance that adequate ventilation has been achieved or it will paradoxically worsen acidemia because of increased respiratory acidosis. To avoid a sudden increase in osmolality with the risk of intracerebral hemorrhage, the concentration of bicarbonate should be 0.5 mEq/mL and infused slowly.

Naloxone

The most common reason for a newborn to have respiratory depression is asphyxia. Respiratory depression caused by the mother receiving narcotics during labor is quite rare. The appropriate response to respiratory depression, no matter what the cause, is to initiate effective PPV. Rather than give an opiate antagonist such as naloxone in the delivery room, the apneic newborn's respirations should be supported as needed, including placement of an advanced airway if necessary and the infant taken to the NICU. In the NICU, more information can be gathered to rule out other causes of respiratory depression such as shock, sepsis, elevated magnesium levels, or fetal acidemia. If ultimately it is decided that the infant's poor respiratory effort is caused by narcotic depression, then naloxone can be given to the infant with an appropriate intravenous line established and continuous monitoring within the NICU.

Dopamine

Sometimes an infant has experienced enough myocardial compromise that, despite all resuscitative measures, poor cardiac output and hypotension remain. If the infant is not hypovolemic, inotropic support is indicated rather than continued volume expansion in the face of hypoxic cardiomyopathy. In such circumstances, dopamine may be used. At dosages of 10 μg/kg per minute, dopamine has inotropic and alpha-adrenergic effects. At this dose, the increased cardiac output antagonizes the alpha-adrenergic effect, resulting in increased cardiac output with only mild peripheral vasoconstriction. In higher doses, the alpha-adrenergic effect predominates with generalized peripheral vasoconstriction. In low doses of 5 μg/kg per minute, dopamine binds to dopaminergic receptors in the renal, mesenteric, and cerebral arteries, producing vasodilation. Traditionally, dopamine is started at 5 μg/kg per minute, and the dosage is increased as necessary. If the dosage reaches 20 μg/kg per minute without adequate response, it is unlikely that increasing the dose further would make a difference and other vasopressors can be considered.

Prolonged Assisted Ventilation

Some infants need a ventilator after immediate resuscitation. In a severely asphyxiated infant, central nervous system depression may inhibit spontaneous ventilation. The longer the asphyxia lasts, the longer it takes for resumption of spontaneous ventilation. Most infants in this category also have some degree of pulmonary compromise related to asphyxia. Some infants with primary lung disease initially breathe spontaneously; however, these infants subsequently may need assisted ventilation to attain adequate gas exchange. Asphyxia may also affect the type 2 cells of the lung and result in acquired surfactant deficiency. Meconium or blood aspiration or sepsis may also inactivate surfactant, resulting in the need for continued ventilatory support. Whenever an infant is in need of ventilation for more than the immediate resuscitative period, evaluation of blood gases should guide the ventilatory support. Prolonged ventilation by hand is often overzealous, with resultant hypocapnia, or inadequate, leading to respiratory acidosis. Continued ventilation by machine or a T-piece resuscitator gives more uniform ventilation.

Glucose

As soon as possible after stabilization from an asphyxia event, an infusion of glucose at approximately 4-8 mg/kg per minute should be started. Adjustment of the glucose infusion rate depends on repeated measurements of blood glucose levels. The purpose of the glucose is twofold: (1) to provide fuel and (2) to help eliminate the metabolic acidosis. A steady infusion of glucose provides fuel to an infant who has depleted much of his or her glycogen, especially myocardial glycogen, during the asphyxial episode. This infusion helps prevent the hypoglycemia that frequently accompanies asphyxia. Glucose should not be started until the infant is adequately oxygenated and ventilated. Anaerobic metabolism of carbohydrate leads to the formation of additional lactic acid, worsening the acidosis. Hypoglycemia is synergistic with asphyxia in producing brain damage, and failure to provide glucose and monitor levels may result in additional brain injury.[5,74]

Fluids

The urine output of any infant who undergoes an asphyxial episode should be carefully monitored. Acute kidney injury resulting in oliguria is a common complication of asphyxia, and an infant can easily be overloaded with fluid. Fluid should be restricted until there is evidence of adequate urine output. The need to restrict fluid and yet give adequate glucose emphasizes the importance of considering glucose infusion in terms of milligrams of glucose per kilogram of body weight per minute, rather than the amount of 10% glucose to be given. The concentration of infused glucose depends on how much fluid can be given to the infant (see Chapter 92). In addition, potentially

nephrotoxic antibiotics and diuretics should be administered with caution, because poor renal clearance may result in toxic levels.

Feeding

During asphyxia, ischemia of the intestine occurs as a result of vasoconstriction of the mesenteric vessels. Because of the suggested relationship between ischemia of the intestine and necrotizing enterocolitis, it may be prudent to delay enteral feedings in an asphyxiated infant, especially one who is premature (see Chapters 41 and 85).

Other Problems

Other complications of asphyxia that are of concern include hypocalcemia, disseminated intravascular coagulation, seizures, cerebral edema, and intracerebral hemorrhage. These are discussed elsewhere in this text.

Special Problems During Resuscitation

Infants With Very Low Birth Weight and Extremely Premature Infants

Infants born at less than 32 weeks' gestation or less than 1500 g birth weight require special considerations in the delivery room. Most facilities do not have an adjacent NICU to provide a warm and monitored environment immediately for these very fragile infants, so provisions must be made in the delivery room. It has been suggested that simulating the intensive care environment in the delivery room from the moment of birth helps to improve survival and reduce morbidity in this population.[92] The provision of a well-trained and complete resuscitation team at delivery is of critical importance. Unless significant preventative efforts are made, preterm newborns will quickly lose heat in the delivery room by evaporation of amniotic fluid from the baby's body, conduction of heat from the body touching cooler surfaces, convection to cooler surrounding air, and radiation to cooler objects in the vicinity.[98] It is important to prevent hypothermia because for every 1°C below 36°C on admission temperature, mortality increases significantly.[46,47] An important initial preventative step is to increase the ambient temperature of the delivery environment to 73°F-77°F (23-25°C) before delivery occurs. Several randomized trials demonstrate that warming the delivery environment to this level can decrease rates of moderate hypothermia upon NICU admission in preterm infants.[25,38] Polyethylene plastic bags and wraps that prevent evaporative heat loss improve NICU admission temperatures in preterm newborns.[68] Plastic bags do not prevent all hypothermia; thus, additional strategies may be required in the delivery room. Chemically activated thermal mattresses improve temperature stabilization as well.[81] The use of plastic wrap and thermal mattresses in combination can further reduce hypothermia, but caution must be taken to prevent hyperthermia.[60] Covering the preterm newborn head with a plastic[79,89] or wool hat[15] may help as well. Warmed, humidified gases for use during ventilation in the delivery room can also reduce hypothermia in the preterm population[61] (see also Chapter 35).

In preterm infants, delayed cord clamping reduces mortality[29] and is now recommended for at least 30-60 seconds for most preterm infants showing some signs of vigor.[97] Animal studies suggest that inflation of the lung prior to cord clamping may have significant benefits.[35] Randomized trials are underway to compare the impact of initiating resuscitation and positive pressure ventilation before versus after clamping the umbilical cord. Other investigations to examine the risks and benefits of cord milking compared to delayed cord clamping are underway.

The NRP recommends the use of pulse oximetry and blending oxygen in the delivery room to avoid hyperoxia.[97] The avoidance of barovolutrauma during initial ventilatory support may be facilitated by the use of a T-piece resuscitator, the use of an end-tidal CO_2 detector, and the measurement of tidal volumes. Many preterm infants can be placed directly on nasal CPAP and avoid intubation.[30] Less invasive techniques for surfactant administration without intubation are under investigation.[37] For infants who require intubation for stabilization, early administration of surfactant may reduce long-term respiratory morbidity. Many such infants may be managed with an *INSURE* protocol (*IN*tubation, *SUR*factant, *E*xtubation).[30,37]

Meconium Aspiration

If meconium is present in the amniotic fluid, there is a chance that meconium may enter the mouth of the fetus and be aspirated into the lungs. Aspiration of meconium can result in a ball-valve obstruction of the airways, causing gas trapping and pneumothorax. It can also cause a reactive inflammatory process. Because meconium-stained amniotic fluid (MSAF) is frequently associated with asphyxia in newborns, the inability to achieve adequate ventilation combined with the initial asphyxia may result in enough hypoxia and acidosis to maintain the increased resistance of the pulmonary vasculature, resulting in persistent pulmonary hypertension of the newborn.

For many years, in an effort to prevent meconium aspiration syndrome (MAS), a combined obstetrical (suctioning of the oropharynx prior to delivery of the chest) and pediatric (intubation and suctioning of selected infants born through MSAF) procedure was routine practice in the delivery room. As new evidence became available, recommendations changed. Vain and colleagues showed that suctioning the hypopharynx after delivery of the head and before delivery of the shoulders has no effect on the development of MAS.[90] A multicenter randomized study looked at vigorous infants with a gestational age of more than 37 weeks who were born through MSAF of any consistency. In these vigorous infants, intubation and tracheal suctioning did not offer any advantage over expectant management.[95]

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

More recently, routine suctioning of the trachea in nonvigorous infants born through MSAF has been called into question. Indirect and low quality evidence from multiple observational studies was inconclusive regarding benefits of tracheal suction in nonvigorous infants born through MSAF.[68] In 2015 and 2016, two small randomized trials performed in the setting of high incidence of MSAF and MAS found no difference in the incidence of MAS, need for mechanical ventilation and mortality whether or not tracheal suctioning was performed on nonvigorous infants.[16,64]

Routine suctioning of nonvigorous infants may delay initiation of critical ventilation in nonbreathing infants. In addition, intubation can cause harm such as trauma or vagal responses resulting in bradycardia. In the face of any unknown benefit of routine suctioning of nonvigorous infants born through MSAF, and in hopes of avoidance of harm, the International Liaison Committee on Resuscitation recommended to stop routine tracheal suction after the birth of these infants. Instead, emphasis should be placed on initiating ventilation within the first minute if the infant is not breathing or the heart rate is <100/min after the initial steps are completed. Because the presence of MSAF may indicate fetal distress and is associated with increased risk that the infant will need resuscitation, an individual skilled in tracheal intubation should be part of the team present at delivery. If during positive pressure ventilation, even after ventilation corrective measures the chest is not rising and obstruction is suspected, tracheal suction should be performed. If intubation is to be done and meconium removed from the trachea, the best method is to attach an adapter to the endotracheal tube so that suction can be directly applied using regulated wall suction at approximately 100 mm Hg as the tube is withdrawn. The trachea can be reintubated and suctioned again if necessary (see also Chapter 66).

Pneumothorax

A pneumothorax may occur spontaneously and may be the cause of the need for resuscitation. More commonly, pneumothorax is a complication of PPV. Pneumothorax should be suspected in any infant who is improving during a resuscitative effort and then suddenly decompensates. Listening to the infant, one may hear unequal breath sounds and distant heart sounds, which may be shifted from the normal position in the left side of the chest. The affected side of the chest may appear hyperinflated compared with the nonaffected side and move less during ventilation. If the pneumothorax is large enough to obstruct venous return, cardiac output decreases, and the infant becomes hypotensive and eventually bradycardic. When these events occur in an infant who is otherwise stable, pneumothorax is easy to suspect. When pneumothorax occurs early during resuscitation of a severely compromised infant, the signs and symptoms are not as obvious. When immediate intervention in the delivery room is needed, it may be necessary to insert a needle into the thorax before radiographic confirmation, especially if transillumination is not available. The NRP suggests using an 18- or 20-gauge percutaneous catheter and inserting it in the fourth intercostal space in the anterior axillary line or the second intercostal space at the midclavicular line.[94]

Congenital Diaphragmatic Hernia

With the increasing availability of prenatal ultrasound, most infants with congenital diaphragmatic hernia (CDH) are anticipated and can be delivered in a level III or IV center where the appropriate team can attend the delivery. An infant with an undiagnosed CDH is usually in significant respiratory distress at birth, although the diagnosis may not be immediately obvious. The diagnosis may be suspected when there is a scaphoid abdomen and decreased breath sounds, usually on the left side (85%). The situation may be worsened by the use of mask ventilation, which inflates the bowel in the chest and compromises ventilation further.

An infant with CDH may appear similar to an infant with a pneumothorax. To prevent gas from entering the intestines, one should always use an endotracheal tube when ventilating the lungs of an infant with a suspected CDH. An orogastric tube should be inserted as soon as possible to remove air before it passes into the portion of intestine located in the chest. The main focus of management includes gentle ventilation, hemodynamic monitoring, and treatment of pulmonary hypertension followed by surgery[14] (see Chapters 13 and 66).

Erythroblastosis and Hydrops Fetalis

Successful resuscitation of an infant with hydrops fetalis demands preparation of a coordinated team with preassigned responsibilities. The team should be prepared at delivery to perform a partial (or, rarely, complete) exchange transfusion with O-negative packed red blood cells crossmatched against the mother. In addition, team members should be prepared to perform a thoracentesis, paracentesis, and complete resuscitation, including intubation and CPR if needed. In recent years, most infants with hydrops have nonimmune causes. With advanced ultrasound technology, most of these infants are diagnosed in utero, and the delivery and resuscitation can be carefully planned. An infant with hydrops may not only be severely anemic but also is likely to have ascites, pleural effusions, and pulmonary edema. Such infants frequently have had chronic intrauterine and intrapartum asphyxia. Because they are usually premature, respiratory distress syndrome may be an underlying confounding complication.

On delivery, the infant should immediately undergo intubation because of poor lung compliance and the risk of pulmonary edema. High ventilator pressures are often needed, and the use of high-frequency ventilation may be necessary to minimize lung injury. If adequate ventilation cannot be attained (as judged by inability to stabilize the

heart rate), and if there is evidence of fluid in the abdomen or pleural space, paracentesis and/or thoracentesis may be needed. Ultrasonography performed before delivery can help determine in which spaces the fluid resides (pleural, ascitic, or pericardial) and the amount of fluid present. If the abdomen is markedly distended, the paracentesis should be performed first to relieve pressure on the diaphragm; this may need to be followed with a thoracentesis. Although most of these infants initially have a normal blood volume, after a large amount of ascitic and pleural fluid has been removed, some of this fluid may reaccumulate, reducing intravascular volume. Careful attention should be paid to maintain intravascular volume and prevent shock after resuscitation.

A hematocrit obtained immediately at birth determines the need for an exchange transfusion (usually partial) in the delivery room. If the infant is extremely anemic and in need of oxygen-carrying capacity, catheters should be inserted into the umbilical vein and artery to permit a slow isovolemic exchange with packed red blood cells, which results in minimal impact on the already borderline hemodynamic status of the infant. These lines also can be used to monitor central venous pressure and aortic pressure to determine the volume needs of the infant. This is especially important when large amounts of fluid are removed from the thorax or abdomen. Given the complexity of the resuscitation in these cases, the resuscitation team must be of sufficient number and skill to perform these procedures expeditiously and skillfully to achieve optimal outcome (see Chapters 23 and 24).

Screening for Congenital Defects

Two to three percent of infants are born with a congenital anomaly, some of which will require intervention soon after birth (see Chapter 30). If undetected, some of the anomalies may result in life-threatening problems. Immediately after birth, choanal atresia, severe micrognathia, or CDH may result in respiratory distress. Other problems may appear later, such as aspiration caused by esophageal atresia (with esophageal fistula) or a high intestinal obstruction. A rapid screening exam for congenital defects can easily be performed by delivery room staff to help identify many of these defects, along with others that are not life threatening but require prompt recognition and intervention.

Before examining the infant, the team should inquire about the amniotic fluid, placenta, and umbilical cord. Oligohydramnios may be a marker for oligohydramnios sequence (Potter sequence) with pulmonary hypoplasia. These infants also have growth deficiency, Potter facies, and limb positional defects. A significantly short umbilical cord at term (<40 cm) is a sign of fetal akinesia sequence and usually indicates a muscle or central nervous system etiology for the infant's respiratory insufficiency, or may be associated with pulmonary hypoplasia (Pena-Shokeir syndrome). If antenatal sonograms suggest significant postnatal airway obstruction is likely, an EXIT (ex utero intrapartum treatment) procedure may be a consideration for delivery (see Chapter 13).

Physical Examination

A rapid external physical examination identifies obvious abnormalities, such as abnormal facies and limb, abdominal wall, or spinal column defects (see Chapter 28). A close look at the abdomen may reveal a scaphoid abdomen, which is a clue to a CDH. If an umbilical vessel count reveals only two vessels, there is a possibility of other defects, especially involving the genitourinary tract. Because infants are preferential nasal breathers, bilateral choanal atresia results in respiratory difficulty and need for airway stabilization after birth (see Chapter 68). Bilateral choanal atresia can be ruled out quickly if the infant is able to breathe while the mouth is held closed. Some infants with unilateral choanal obstruction appear normal until an examiner closes the mouth and then sequentially obstructs each nostril with a finger. When the patent nostril is obstructed, such infants have difficulty breathing. Choanal atresia is confirmed by the insertion of a soft nasogastric tube into each nostril. If an obstruction is reached within 3-4 cm, choanal atresia is a possibility.

An examination of the mouth may identify a cleft palate. Inserting a nasogastric tube through the mouth may help identify an esophageal atresia or a high intestinal obstruction. If the tube does not reach the stomach, an esophageal atresia, most often associated with a tracheoesophageal fistula, is likely. A few cubic centimeters of air forced through the tube, while listening over the stomach, confirms that the tube is in the stomach. A minute or so spent screening for congenital defects in this way may help to avert many future problems.

Key Points

- Make sure the lungs of the newborn are truly inflated prior to initiation of chest compressions (place advanced airway if possible).
- When compressions are needed, use the two-thumb technique and coordinate with ventilations in a three-compression to one-breath ratio using 100% oxygen.
- Use a cardiac monitor when compressions are needed to help avoid pauses in circulation.
- Use intravenous epinephrine rather than endotracheal if possible.
- Practice advanced resuscitation skills on a frequent basis via simulation.
- Record in real time what is being done during delivery room resuscitation so that you and your team can debrief and look for opportunities for improvement with every delivery.

Thermal Environment of the Intensive Care Nursery

JOHAN ÅGREN

Thermal management of the newborn infant is a cornerstone of neonatal care: The field accommodates important advances in care provision spanning from pioneering studies on chronic cold stress[58] and neonatal incubation to kangaroo mother care,[46] prevention of low admission temperatures,[43] and therapeutic hypothermia. Globally, cold stress remains a contributor to neonatal mortality and morbidity, and the potential impact of optimal thermal care provision on infant health is huge.[38] A basic understanding of the physics and physiology of heat exchange enables the undertaking of adequate measures to reduce heat loss and monitor body temperature, measures that often are simple and easy to apply. Without thermal care, a term 5-kg newborn may quickly and easily become hypothermic, increasing its need for endogenous heat production and posing a risk for cardiorespiratory instability and failure to feed properly, states that may be detrimental to an otherwise healthy or only slightly depressed infant. On the other hand, with adequate preparation, equipment, and training, the body temperature of a 500-g extremely preterm infant can be kept within the normal range, aiding a smooth transition to extrauterine life. In general, adequate thermal management depends at least as much on sound knowledge as on the use of high-tech devices such as incubators and radiant warmers.

Heat Exchange Physics

The Four Modes of Heat Exchange

Direct heat exchange between the infant and its environment occurs through the skin and through the respiratory tract. With use of different techniques, this heat exchange may be calculated and estimated with reasonable accuracy.[26,60] The four modes of heat exchange—convection, radiation, evaporation, and conduction (Box 35.1)—all influence thermal balance, and the relative contribution of each mode changes with maturity, postnatal age, disease state, and care environment. Analysis of the contribution from the different modes of heat exchange makes it straightforward to reduce heat loss in any given situation, minimizing the need for delivery of heat through another route. Together with proper temperature monitoring, such an approach simplifies thermal management and renders individual estimates of heat loss unnecessary.

Heat Exchange at Term Birth

The wet newborn infant will be exposed to moving air and surfaces that have a much lower temperature than that in utero. Unless the infant is wiped dry and covered by a blanket, heat loss through evaporation and radiation to surrounding surfaces of the delivery room will be high and lead to rapid cooling.[22] Heat loss through convection is also significant unless airflow velocity is reduced (e.g., by covering, clothing). As soon as the term or moderately preterm infant is dry, radiant heat loss will dominate.[22]

Evaporative Heat Loss Is Related to Infant Maturity and Ambient Humidity

As loss of fluid also implies loss of heat, evaporative fluid loss is an important component of heat exchange, particularly in extremely preterm infants. A functionally competent skin barrier develops gradually during fetal life.[17] Consequently, the magnitude of water loss through the skin is related to maturity at birth,[55] and the tiniest infants may have evaporative heat losses that are many times higher than those of a term infant under similar environmental conditions (Fig. 35.1).[21] In the preterm infant relatively rapid postnatal skin maturation occurs, leading to decreased evaporative loss over the first postnatal days and weeks (Fig. 35.2).[3,22] This maturation explains the gradual reduction in the environmental temperature needed to obtain thermal balance, even though evaporative heat loss still exceeds radiant heat loss for about a week in the most immature infants (see Fig. 35.2).

Abstract

To establish an adequate thermal environment and maintain normal body temperature is a cornerstone of neonatal care. This chapter reviews key routes of heat exchange, neonatal thermal physiology, modes of care, and treatment recommendations in the area of neonatal thermal management.

Keywords

newborn
hypothermia
heat exchange
evaporation
incubator
radiant warmer
skin-to-skin care

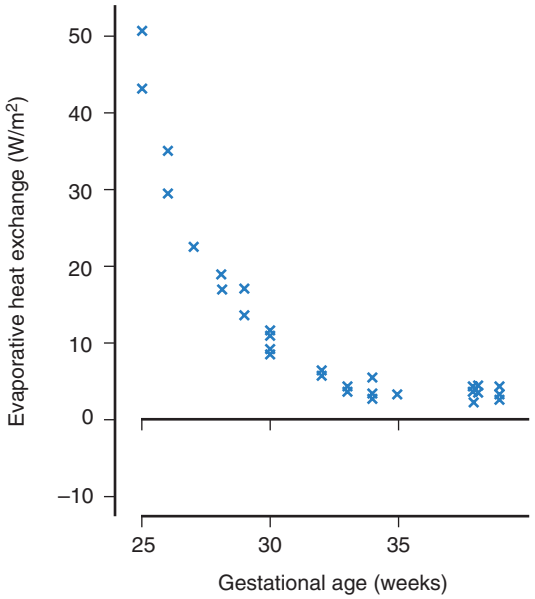
• BOX 35.1 The Modes of Heat Exchange

Convection

- Air movement causes warm air close to the skin to move away, resulting in heat loss.
- The relative magnitude of heat loss through convection is similar in term and preterm infants.
- Convective heat loss is much increased when air velocity is high (forced convection).
- Convective heating is the mode by which modern intensive care incubators operate.
- Convective heat exchange is reduced by any measure that will minimize air movement close to the skin (e.g., limiting incubator porthole opening to one side at a time, providing clothing and/or blankets).

Radiation

- Radiant heat transfer occurs *from* the infant to surrounding cooler surfaces and *to* the infant from radiant heaters and warm-light phototherapy devices.
- The magnitude of heat exchange depends on the temperatures of the surfaces facing the infant and on the body surface area exposed.
- Heat radiation is reduced by clothes, blankets, double incubator walls, heat shields, flexible plastic wrap, and bags.



Evaporation

- Evaporation of fluid from the skin surface implies loss of heat (approximately 2.4 kJ/g water).
- Evaporation is the dominant route for heat loss from the wet neonate in the delivery room but is substantially reduced by immediately wiping the infant dry at birth.
- Very immature infants have poor skin barrier function, leading to large ongoing losses of water and heat for several days to weeks after birth.
- Evaporation is reduced in a high vapor pressure environment.

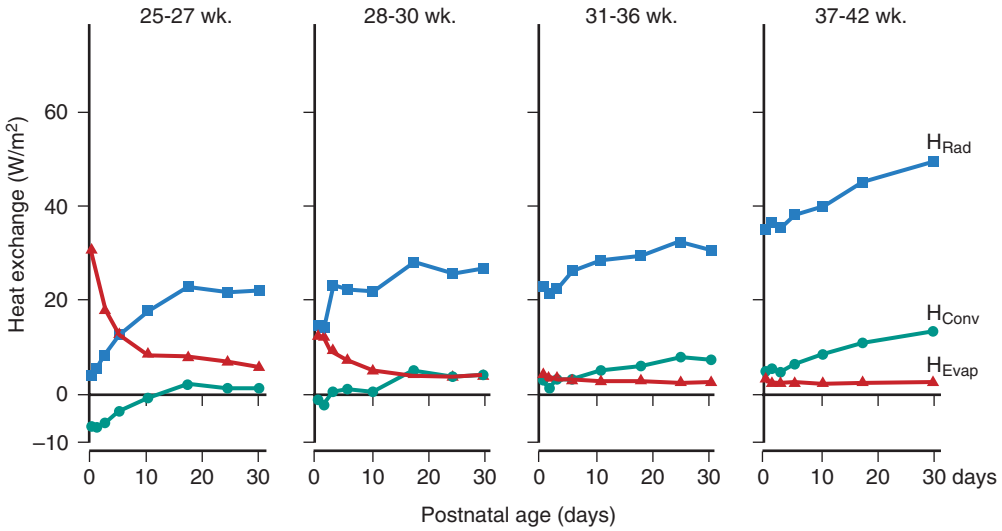
Conduction

- Inadvertent conductive heat loss is negligible in most care situations, because mattresses used in incubators and cots are made of insulating material.
- Care must be taken when using equipment with an active warming function. If switched off, a gel mattress such as those used in some radiant warmer beds and/or an unheated water-filled mattress will be a very effective conductive cooler for any size neonate.
- Conductive cooling is the method by which all systems for hypothermia treatment operate.
- Conductive heat delivery (e.g., heated mattress or skin-to-skin care) is a simple and effective way to rewarm infants and stabilize body temperature.

Evaporative heat losses are inversely related to ambient humidity (Fig. 35.3),[21] and measures to increase the vapor pressure close to the skin thus simplify fluid and thermal management.[54] Note that the impact of postnatal age and ambient humidity on evaporative loss is less clinically important in newborn infants with a gestational age of more than 28-30 weeks[22] and in the extremely preterm infant beyond the first postnatal week.[3]

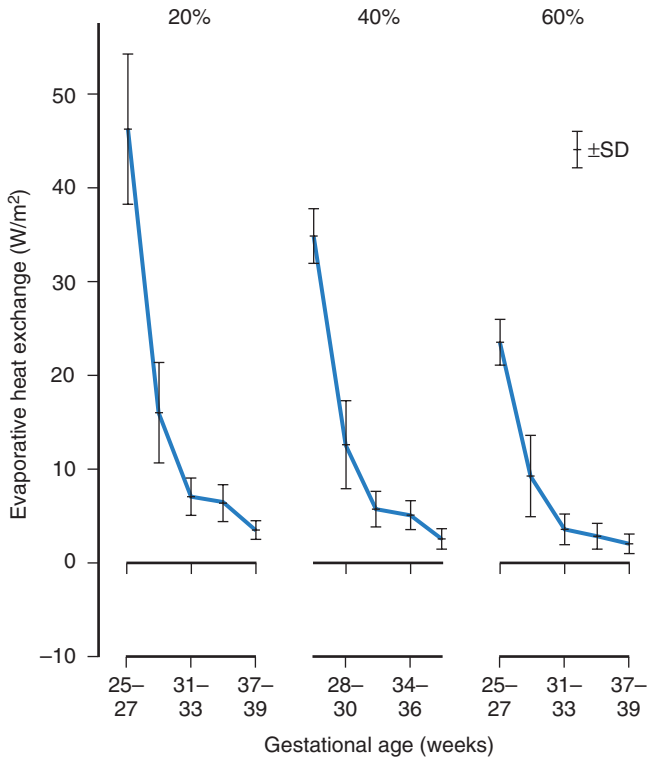
• **Fig. 35.1** Heat exchange through evaporation in relation to gestational age. Measurements from the first day of life during incubator care at an ambient humidity of 50%. (Data from Hammarlund K, et al. Transepidermal water loss in newborn infants. VI. Heat exchange with the environment in relation to gestational age. *Acta Paediatr Scand.* 1982;71(2):191-196.)

Respiratory Loss of Heat



Respiratory water and heat exchange take place by the combined processes of evaporation and convection. These processes occur as the temperature and vapor pressure of the inspired air rapidly equilibrates in the airway. Consequently, the losses are related to air temperature and humidity and directly proportional to the rate of breathing.[53] Provision of a warm and humid environment (e.g., humidified incubator) and/or assisted ventilation with use of adequately warmed and humidified (saturated at ≥37.0°C) gas will reduce respiratory loss of water and heat to a minimum[60] and aid temperature stability.[61] Only in situations in which cold (pressurized) gas is delivered or when ambient temperature and humidity are low, such as during transport in a cold climate, will the heat loss through the airway be of clinical significance.

Thermal Physiology



The Fetal Thermal Equilibrium

The fetus generates heat in the processes of tissue proliferation, metabolism, maintenance of physiologic functions, and muscular movement. From experimental studies, fetal (and neonatal) heat production per unit weight has been demonstrated to be considerably higher than in the adult. Together with heat generated by the uterus and placenta,[51] this results in a temperature gradient between the fetus and the mother of about 0.5°C, with the heat being dissipated mainly via the placental circulation.[51]

• **Fig. 35.4** The main components of the homeostatic thermoregulatory system.

Neonatal Thermoregulation

The exposure to cold, clamping of the umbilical cord, and the general "stress of being born" induce a thermal response. This response is part of a homeostatic system with input (detectors) and output (effectors) that is aimed at preserving body temperature. The main components are schematically depicted in Fig. 35.4.

In the neonate, shivering thermogenesis is nonoperative in the normal to near-normal body temperature range, and a cold-exposed infant thus depends primarily on chemical thermogenesis to avoid hypothermia.[12] Exposure to cold induces a sympathetic surge that acts on receptors in brown fat stores stimulating lipolysis.[12] The presence of the protein thermogenin in brown fat uncouples β-oxidation, resulting in metabolic production of heat instead of adenosine triphosphate. The metabolic rate of a newborn has been observed to increase up to threefold when maximally

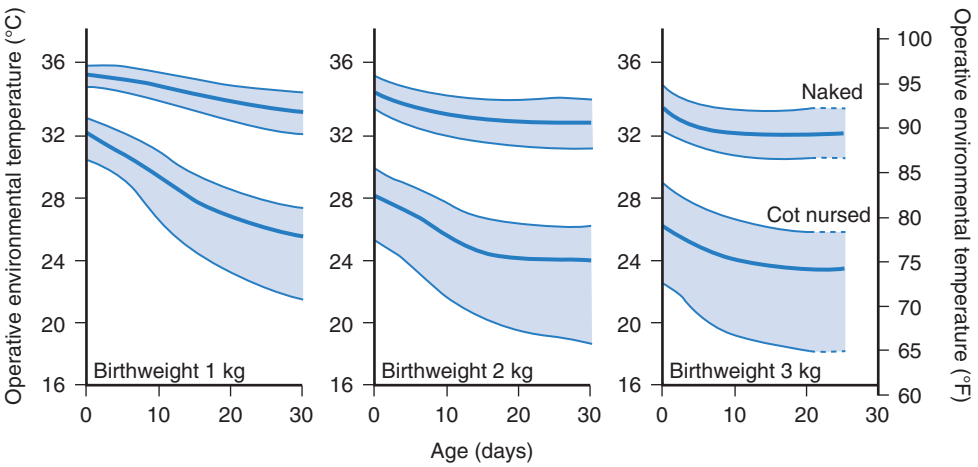
stimulated by cold,[30] but preterm infants have a limited thermogenic capacity due to scarce fat stores and often suboptimal nutritional provision.

The cost of heat production implies that even a slight long-term exposure to cold will increase thermogenesis, consume oxygen and substrate stores, and impact negatively on growth.[63]



Thermoneutrality

The concept of an optimum thermal environment for newborn infants evolved during the 1960s.[28] This "thermoneutral zone" (Fig. 35.5) is defined as the range of temperature within which the infant can maintain a normal body temperature at minimal metabolic rate with use of non-evaporative processes (vasoconstriction, vasodilation, and/or changes in posture) only.[25] Body size has a large impact on the range in which infants can maintain body temperature. Compared with an adult, the newborn infant has both a several times higher body surface per mass ratio and a poorly insulated body shell.[27] Several factors related to the care environment will, to a varying extent, influence the boundaries of the thermoneutral zone (Table 35.1). Outside this range, body temperature might still be maintained at the cost of an increased metabolism, but if the temperature deviates further, inevitable cooling (or warming) will take place. The temperature ranges for each care modality and individual infant may be crudely estimated, and together with proper infant monitoring, such estimates will suffice as a starting point for routine care.

TABLE 35.1 Infant and Environmental Factors and Their Impact on the Heat and/or Temperature Setting Needed to Obtain Thermoneutrality

	Heat/Temperature Setting to Maintain Thermoneutrality
Infant Factor	
Smaller/more immature	Increase
Postnatal age	Decrease
SGA*	Decrease, but to a lesser degree

Overwarming Versus Fever

Overheating activates heat-losing mechanisms such as skin vasodilation (redness/flushing/peripheral warmth) and behavioral changes (the infant assumes spread-eagle posture). Evaporative heat loss increases and overt sweating can be noted in a term infant. The gradient between central and peripheral temperature decreases. With severe heat stress, the infant may become hyperactive and irritable.

In contrast, an infant with fever due to an increase in endogenous heat production presents differently. The febrile infant, at least during the phase of rising temperature, is vasoconstricted as displayed by an increased central-to-peripheral temperature gradient[45] and pale-blue–appearing extremities.

Hypothermia

Different thresholds of the effector response for nonshivering and shivering thermogenesis explain the differences observed between hypothermic adults and neonates. In the range of normal to near-normal body temperature (≥36°C), shivering thermogenesis will be nonoperative in the neonate, and chemical thermogenesis dominates.[12] However, as core temperature is further lowered, shivering may occur. Thus, shivering is exclusively (and not always) seen in the severely cold-stressed (e.g., hypothermia-treated) infant. Therapeutic hypothermia treatment for neuroprotection in neonatal encephalopathy is discussed elsewhere (see Chapter 54), but the methods used are based on conductive heat loss from either the head (cooling cap), or the whole body (cooling mattress). During therapeutic hypothermia, core temperature has to be monitored, because surface temperatures will not adequately reflect core temperature. During cooling, significant set point displacement may occur, explaining why some infants are difficult to warm with the risk of temperature overshoot during rewarming. Therefore, the infant's body temperature needs to be carefully monitored and controlled for several days after termination of the hypothermia treatment. Data obtained from the cooling trials support the notion that it is better to slowly (maximal rate 0.5°C/h) increase core temperature in a hypothermic infant. It seems reasonable to apply similar caution also when rewarming infants who have become hypothermic from other causes, although the optimal speed of rewarming has not been identified.

Temperature Monitoring

Temperature measurements as such do not provide much information on whether the infant is in thermal balance, and there are no methods suitable for routine bedside monitoring of metabolic rate. Therefore, thermal management needs to be based on several sources of information. They include (but are not limited to) trends of continuous or intermittent measurements of central and peripheral body temperature, ambient temperature and humidity, as well as the general appearance and behavioral state of the infant.

Central ("Core") Body Temperature

Several measurement sites serve as estimates of core body temperature. *Direct temperature measurements* make use of a probe inserted into a body cavity (e.g., rectum, esophagus) that is central enough to measure zero temperature gradient versus the body core. Esophageal temperature measurements are technically feasible, represent true core temperature, and are well tolerated by the infant.[59] Esophageal temperature monitoring is recommended when very strict thermal monitoring is needed and body surface measurements are unreliable (i.e., during therapeutic hypothermia). Rectal temperature measurements do not reliably reflect core temperature, pose unnecessary risks of repeated trauma to the rectal mucosa, and their use should be limited.[44]

Core temperature can also be estimated from *indirect temperature measurements* at the body surface by artificial creation of zero temperature gradient, or "zero-heat-flux." By insulation of the measurement probe from the environment, zero-heat-flux will be created between the body core and the probe. Trunk skin temperature measurements (back to mattress, abdomen to mattress, abdomen to insulated pad) rely on this principle and give readings that are very similar to esophageal temperature. Axillary temperature also makes use of zero-heat-flux (insulated by the arm and shoulder) and can be used as a proxy for core temperature when intermittent measurement is deemed sufficient but may be associated with infant discomfort and occasionally differ from esophageal temperature.

What Temperature Should Be Aimed for?

The concept of an easily defined hypothalamic set point for core temperature is relative. Because not only core, but also peripheral sensory input, influences the action of thermoregulation, the optimal core body temperature may indeed vary with maturity/age, care environment, and disease state. Deflections in the set point occur with pyrogen exposure but may also result from exposure to cold and/or warm environment, even for a relatively limited time. Normal human central body temperature is considered to be 37.0 ± 0.5°C, and this is probably also true for the newborn infant.[42,47,48] However, it is evident that seemingly well babies with central temperature kept within this range may still be subjected to cold stress (i.e., display increased metabolic rate due to thermogenesis). Thus, aiming for such a "normal" body temperature might at times be suboptimal in neonatal care. In the preterm infant, the fetal thermal equilibrium has been suggested as also optimal after birth.[8] In fact, to minimize the risk of cold stress when caring for infants with limited thermoregulatory capacity, it has been shown to be adequate to aim for slightly higher core temperatures.

TABLE 35.2 Thermoneutral Central-to-Peripheral Temperature Differences (ΔT) in Low Birth Weight Infants in Relation to Postnatal Age

Infant Group	Postnatal Age (Days)	ΔT (°C)
<750 g	0-5	<0.5*
	6-14	<1*
	>14	1-2*
750 g-1000 g	0-2	<0.5
	3-5	<1
	>6	1-2
1000 g-1500 g	0-2	0-1
	>3	1-2

*Estimated values.

Peripheral Temperature and Central-Peripheral Temperature Difference

Although not considered integral to routine thermal care, peripheral temperature measurements from the sole of the foot might provide additional and valuable information about the thermal state of the infant, particularly if graphed together with core temperature.[40] Cold exposure induces vasoconstriction and a decrease in skin temperature, resulting in an increased central-to-peripheral temperature difference (ΔT), well before a drop in central temperature occurs. Likewise, other causes of vasoconstriction (hypovolemia, sepsis, catecholamine administration) and low cardiac output (hypovolemia, large ductal shunting, and some congenital heart defects) increase ΔT, which could potentially be of value as an early warning sign.[45] However, the optimal ΔT depends on infant maturity, postnatal age, and care environment and is, therefore, not easily defined. Recommended ΔT for very low birth weight and extremely low birth weight infants nursed in incubators are available[39,40] (Table 35.2).

Thermal Aspects of the Care Environment

Convective Thermal Support—Incubator Care

In a modern convectively heated incubator, the warm air is directed so that the walls of the incubator are also kept warm. With a low airflow velocity (<0.1 m/s), the convective heat transfer will depend on the gradient between the skin and the air temperature, and the vapor pressure gradient close to the skin will be maintained, avoiding an increased evaporative heat loss.[9,37] The feature of double wall design reduces the radiant heat loss to the inner walls of the incubator. In a single wall incubator, the "working" temperature in the incubator will be lower than the set air temperature because of the higher radiant loss of heat and thus will require a higher temperature setting, depending on the room temperature. The incubator is controlled thermostatically by air or infant temperature, two modes with distinct advantages and disadvantages.[62]

Infant skin temperature servo control has the advantage of providing a more stable body temperature under changing care conditions. However, if the probe becomes detached, this may lead to overwarming, although usually this is not severe. Also, when using skin servo control, the use of body temperature as a possible signal of disease (hypovolemia, sepsis) has to be replaced by monitoring incubator temperature, which might not be as intuitive. An anterior abdominal skin temperature of 36.5°C has been widely used for servo control of incubator air temperature[18] but may be too low to ensure thermoneutrality in the tiniest and most immature infants.[40] An abdominal skin (or back to mattress) temperature setting of 37.0°C may then be preferable.

Air temperature servo control does not require a probe to be attached but makes it necessary to frequently determine infant temperature, thus adding further to the load of procedures disturbing the infants. For both modes, it is essential that procedures such as intravenous line insertion and/or intubation are performed through the portholes and not through the large front access panel.

Incubator Humidification

Because evaporative loss is related to ambient relative humidity, adding humidification will decrease heat loss; the higher the humidity, the lower the evaporation. However, in most situations, a higher evaporative loss can be compensated for by a higher air temperature (convective gain), and a "too low" incubator humidity will only increase metabolic demand if the infant is nursed below thermoneutral temperature. Thus, a high incubator ambient humidity (70%-90%) is only vital in situations wherein high insensible water loss *per se* complicates fluid management (i.e., in extremely preterm infants during the first postnatal week).[54] In this situation, a high ambient humidity is often needed to maintain normal body temperature even at maximal incubator temperature.[10] An increased risk of pseudomonas infections has been demonstrated with the use of incubator humidification[24] when condensation of vapor on the inner incubator walls occurs, which therefore should be avoided. Also, experimental studies demonstrate that transepidermal water transport is an important signal for stratum corneum formation,[23] and results obtained in extremely preterm infants nursed in incubators at two levels of ambient humidity after the first postnatal week indicate a more rapid barrier formation in infants nursed at a lower relative humidity.[2] However, running incubators entirely without humidification will often result in very low humidity (<15%-20%), promoting large insensible water losses.[16] Although reserving high ambient humidification (70%-90%) for the first postnatal week in the extremely preterm (<28 weeks) infant, a medium level of 40%-50% can be recommended for general incubator care.

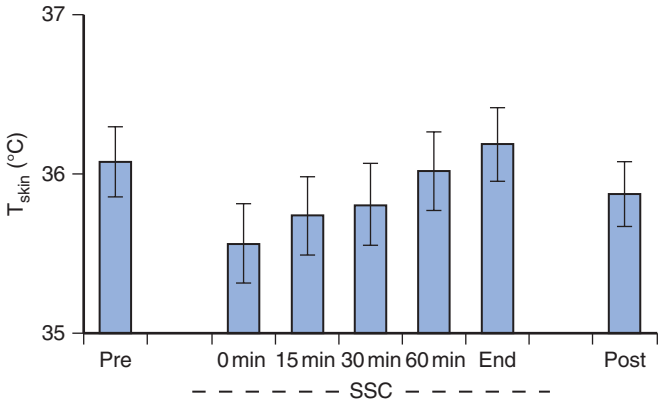
Radiant Thermal Support—Radiant Warmers

Radiant warmers provide excellent accessibility for the care of the newborn infant and have, therefore, become widely used in neonatal intensive care. The high power output of the device explains the effectiveness and speed with which a hypothermic infant can be warmed. However, harmful overheating can rapidly occur unless careful monitoring (preferably continuous) of infant temperature is instituted.[6] Because ambient humidity is low and air velocity at times relatively high, heat loss through evaporation and convection may be extensive but can be compensated for by radiant heat gain.[7,8] An anterior abdominal temperature of 37.0°C is generally recommended for servo control of radiant heat output,[7] at least as a starting point. Unless the warmer is equipped with a warming mattress, the back-to-mattress (zero-heat-flux) temperature can also be used for servo control.



A transparent heat shield positioned over the infant may influence the heat exchange (occurring through convection, evaporation, and radiation) and result in reduced losses of heat.[5] However, such a shield will also disrupt the servo-control mechanism and thus may intervene with thermal control. An alternative is the placement of flexible plastic wrap as a blanket loosely over the infant. This method has proved to result in a more homogenous environment and to reduce insensible water loss and metabolic rate[8] and is used in many institutions. Incubators that can interchangeably be used both as radiant warmers and incubators might at times add flexibility of use and improve thermal management of very preterm infants.[32]

Conductive Thermal Support—Skin-to-Skin Care

Skin-to-skin care (SSC) has been practiced for as long as humanity, long before the concept of kangaroo mother care for preterm infants was introduced. Studies mainly performed in countries with limited resources demonstrate important benefits.[14] In the moderately preterm and low birth weight infant, SSC has proven to enhance physiologic stability[1,11,64] and is recommended.[13] Limited guidelines are also available for use in a high-tech setting.[50] In SSC, the kangaroo position is optimal to enable conductive heat gain through skin-to-skin contact between infant and parent (see also Chapter 36).

Studies in more immature infants have shown that SSC can be safely applied, and without an increase in metabolic rate, as early as during the first week after birth in stable 28- to 30-week infants and from the second week in infants born at a gestational age of 25-27 weeks.[4,41]

In another report,[31] mechanically ventilated extremely preterm (<26 weeks) infants were studied during early SSC (first week of life), demonstrating that ambient air temperature and humidity are lower during SSC compared with incubator care, thus increasing heat loss through convection, radiation, and evaporation. Transfer from the incubator to SSC results in a drop in temperature, but the conductive heat gain during SSC is sufficient to result in a gradual recovery of the infant's temperature (Fig. 35.6).

• **Fig. 35.6** Skin temperatures (T_{skin}) in a group of extremely (22-26 week) preterm infants during early (1st week) skin-to-skin care (SSC). T_{skin} was measured in the incubator before SSC (Pre), during SSC, and after return to the incubator (Post). (Data from Karlsson V, et al. Early skin-to-skin care in extremely preterm infants: thermal balance and care environment. *J Pediatr*. 2012;161(3):422-426.)

Heated Mattresses and Cot Nursing

Conductive thermal support may also be provided by use of a heated mattress. It has been demonstrated that infants as small as 1 kg can be rewarmed and kept warm by placing them on a heated (water-filled) mattress.[63] Heated mattresses are most often used in cots for stable, growing preterm infants and are convenient to use interchangeably with SSC. A heated pad can also be used inside incubators or with radiant warmers. Such a mattress should always be prewarmed and the temperature never set lower than the desired body temperature since this will lead to significant conductive heat loss and may impact negatively on weight gain.[19,29]

Clothing

After the immediate postpartum thermal adaptation (30-60 min), a room temperature of ≥24°C provides a neutral thermal environment for a dressed (clothes, cap, and blanket) term neonate.[35] Indeed, clothing can be expected to reduce all modes of heat exchange and in the relatively stable preterm infant, the use of clothes or a blanket will improve thermal stability during both incubator and radiant warmer care.[33]

Phototherapy

Open phototherapy increases insensible water loss from the skin of the newborn infant.[15] This is mostly an effect of a decrease in relative humidity caused by the increase in ambient temperature, but minute effects have also been

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

demonstrated with cold-light phototherapy.[20] Accordingly, the effect is not observed if the infant is treated in an incubator with controlled environment,[34] and neither fluid nor thermal management should be significantly impacted. In recent years, flexible and portable "phototherapy blankets" have been made available. Such devices work well with most modes of neonatal care, including incubator, radiant warmer, cot nursing, and skin-to-skin care.

Recommendations for Practice

Thermal care benefits from a protocol-driven approach based on guidelines that minimize variation in practice. Such guidelines should specify ranges for normal body and skin temperatures and thermal environment recommendations. They should specify in which situations incubators, radiant warmers, heated mattresses, and skin-to-skin care are applicable, and when to use continuous temperature measurement and infant servo or air control. As incubator settings and operation will differ between types of incubators, it is beneficial if the most vulnerable population can be cared for under uniform environmental conditions (same room and incubator type, for instance) within each neonatal unit, and extra caution should be applied when switching to a different mode of care (e.g., from incubator to SSC). The different modes of care each have their advantages and disadvantages, and a combination of incubation, radiant warmer, and SSC is needed to ensure physiologic stability and early detection of disease and to promote parental involvement. It is not a matter of high- versus low-tech care delivery but rather of finding the best compromise and getting the most out of each mode of care.

Before Birth

The space used for resuscitation should always be ready for instant use. With a prewarmed radiant warmer (and mattress), adequate thermal management of an ill moderately preterm or term neonate is uncomplicated. When needed, the radiant heat output can be instantaneously increased. When available, the heated mattress should be set at 37.0°C. When an extremely preterm infant is awaited, further measures must be undertaken (see Very [28–31 weeks] and Extremely [<28 weeks] Preterm Infants). It is, for many reasons, valuable to meet the parents prior to delivery, time permitting. Specifically, information about thermal care is relatively easy to grasp even in a stressful situation and can as such contribute to a sense of recognition, involvement, and meaningfulness for the parents.

Term and Moderate to Late Preterm (>32 Weeks) Infants

The vigorous term and near-term infant should be carefully wiped, placed on the mother's chest, and covered by a cap and blanket. As long as the delivery room temperature is ≥24°C, these measures will usually suffice to provide thermoneutrality. The term infant may then be continuously cared for skin-to-skin and when not, dressed and placed in a cot. If the infant is low birth weight and/or in the lower range of gestational age, uninterrupted conductive heat support, preferably through skin-to-skin care, is required to maintain thermal balance. If skin-to-skin care cannot be arranged, the low-birth-weight infant must be dressed and placed on a heated mattress or in an incubator. If resuscitation is required, it should be performed under a radiant warmer and the infant placed skin-to-skin with the mother after stabilization.

Globally, most infants will be born in a low-resource setting without access to neonatal care facilities (see Chapter 8). Specifically, thermal care will often have to be provided without high-tech equipment and/or electricity. The principle of wiping the infant dry and establishing continuous skin-to-skin contact with the mother (or other family member) is solid and could, if uniformly applied, be expected to reduce infant mortality.[35,36] If resuscitation is needed, this might be performed without interrupting the skin-to-skin contact or at least by rapidly returning the infant to its natural conductive heat source (i.e., mother) after stabilization.[52]

Very (28-31 Weeks) and Extremely (<28 Weeks) Preterm Infants

At birth, very preterm infants must be cared for under a radiant warmer, preferably equipped with a heated mattress, to ensure adequate thermal balance. The infant should be wiped and placed on dry linen under the radiant warmer for resuscitation and stabilization. In the extremely preterm infant, transepidermal water loss will keep the skin constantly wet. As a consequence, it is not meaningful to dry the infant. This situation is better handled by placing the infant in a transparent plastic bag. This will effectively limit convective heat loss and create a high humidity microclimate close to the skin that will reduce evaporative heat loss.[43] Radiant heat will still be transferred from the warmer to the infant's skin through the plastic bag. This measure has proved to improve thermal care during resuscitation and result in higher NICU admission temperatures.[43] In this vulnerable population, ventilator support should always be provided using humidified gas saturated at body temperature.[56,61] If stabilization takes more than approximately 10 minutes, it is advisable to monitor infant temperature to avoid overwarming. After stabilization, the preterm infant may either be nursed in an incubator or under a radiant warmer. For extremely preterm infants, measures to reduce insensible water and heat loss through the skin are recommended throughout the first week of life. In the incubator, this is accomplished by use of high ambient relative humidity, and under the radiant warmer, by use of a plastic wrap.[57] Skin-to-skin care can provide even the tiniest infant with an excellent care environment but needs to be carefully conducted and should be postponed until the end of the first week in the smallest infants. For these infants, the room

RH, Relative humidity; SSC, skin-to-skin care.

temperature needs to be elevated, preferably to ≥26°C during skin-to-skin care. The parent should wear an open-front shirt, and the infant a diaper and a cap and be wrapped during the transfer. The infant is placed skin-to-skin in the kangaroo position on the parent's chest, monitoring is attached (including thermistor for back skin temperature), and the infant covered by blankets. To minimize cold stress, the sessions of SSC should be at least 1-2 hours, preferably longer, to allow the attainment of a stable microenvironment around the infant and stabilize body temperature. As monitoring of back skin temperature under a blanket will not render zero-heat-flux, a back skin temperature of ≥36.5°C during SSC may be considered thermally neutral (author's unpublished observations). Suggested modes of care and their timing are given in Table 35.3.

During the first 12-24 hours after birth, perturbation of the care environment occurs very frequently. Careful planning and prioritizing among procedures such as weighing, umbilical line insertion, intubation, obtaining chest radiographs, manipulating intravenous lines, repositioning, and suctioning is often helpful, and precautions should be undertaken to prevent heat loss during these procedures.

With increasing postnatal age and body weight, the temperature requirements of the care environment decrease and as infant stability improves, there is less need for constant monitoring of the infant. The infant may eventually be dressed and/or covered and transferred from the incubator (or radiant warmer) to a cot with heated mattress.[19] Weaning from the mattress is usually possible at a body weight of approximately 1600 g.[49] Thermal stability is an important criterion for discharge, and parents should be advised on how to proceed with thermal care at home.

Key Points

- Cold stress and/or hypothermia negatively impacts on vital neonatal outcomes such as survival and growth.
- Heat exchange between the infant and the care environment occurs through convection, radiation, evaporation, and conduction. Their relative contribution and the direction of heat transfer depend on infant maturity, postnatal age, and mode of care.
- Thermal (and fluid) management of the extremely preterm infant is simplified by use of a high humidity micro-environment during the first week(s) of life. This can be accomplished in a highly humidified incubator by use of plastic dressings under a radiant warmer, or by appropriately conducted skin-to-skin care.
- Thermal care benefits from a protocol-driven approach using guidelines that minimize variation in practice. They should specify in which situations incubators, radiant warmers, heated mattresses, and skin-to-skin care should be used, and how to monitor body temperature and what temperature to aim for.

Optimization of the NICU Environment

LIISA LEHTONEN AND ROBERT WHITE

Neurobehavioral Maturation

The expected physiologic environment for a preterm infant would be in utero, floating and moving in warm amniotic fluid, mostly in a flexed position, tasting the amniotic fluid, sensing their mother's movements and circadian rhythm, hearing her voice and sounds from her body but being protected from loud noises, receiving rich amounts of nutrients for optimal growth, and performing gas exchange through the placenta. Full-term newborns demonstrate capabilities they have developed and learned during their fetal life: they recognize their mother's smell and voice and they are ready to crawl to the breast of the mother and start sucking from the breast during the first hour of life. From this time point onwards, the development continues in the physical and emotional closeness with the caregivers and the larger social environment, optimally by getting breast milk directly from the breast for the first months of life.

The neurobehavioral maturation of a preterm infant is based on the genetically programmed development occurring in utero, including highly active axonal and dendritic growth, myelination, synaptogenesis, and proliferation of microglia and astrocytes. This development is modified by environmental influences from a completely different environment, the neonatal intensive care unit, usually for several weeks or months. The experiences provided for the developing brain can either strengthen or weaken the development of specific neural connections, or they can modify the reading of the genetic information by epigenetic mechanisms.[19] The time window during prematurity and early infancy is also the time for unique plasticity, allowing therapeutic interventions to compensate for structural brain injuries. Therefore, the quality of the hospital care has a large potential to affect the long-term developmental outcome of preterm infants. Medical treatments and procedures, medications and nutrition, physical and social environment, and routine infant care can be either nurturing or directly toxic to the brain. Experiences in the NICU environment should be designed to mimic the physiologic, age-appropriate in utero environment.

Depending on their gestational age at birth, preterm infants are born at different developmental stages with a large variation in the degree of immaturity of the central and autonomous nervous systems and sensory functions. Whereas a full-term newborn infant has a well-developed sleep-wake cycle; is capable of reciprocal social interaction, meaningful behaviors and responses to the stimuli from the environment; and has abilities to breastfeed, a preterm infant has an attenuated capacity to regulate his/her behavioral/sleep states and has problems processing or even tolerating a high amount of sensory information. Preterm infants have immature feeding competencies and undifferentiated and/or weak signals about their needs or stress. Their skills for social interaction are immature, especially visual interaction, emphasizing the role of the senses that develop in earlier phases of fetal life.

A preterm infant has especially poor compensatory capacities in response to stressful stimuli, which cannot be completely avoided due to the many inevitable invasive procedures in the neonatal intensive care environment. Therefore, focusing on a developmentally supportive physical and social environment is especially important during prematurity when infants are still developing their capacities to reach a balanced state, i.e., to achieve neurobehavioral organization and to be able to interact with the caregivers. Reciprocity has been shown to be a very strong factor supporting learning in fetal experiments in animal models.

There is extensive animal research and clinical observation over decades by Rene Spitz, James Robertson, Konrad Lorenz, Harry Harlow, and John Bowlby, among others (as reviewed by Sullivan et al.[70]), showing that newborn infants (or offspring in animal models) are biologically preprogrammed to attach to their mother/caregiver, and this attachment process is a prerequisite for normal emotional and cognitive development of the child. The mediating elements for attachment include sensory stimuli provided by the mother and hormonal and metabolic changes both in the mother and infant, making them susceptible for bidirectional bonding.[59] Because mother/caregiver–infant

Abstract

The neurobehavioral development of a preterm infant is modified by environmental influences from the neonatal intensive care unit for several weeks or months. This chapter summarizes research on (1) the development of the behavioral/sleep states and the significance of protecting sleep in preterm infants, (2) the development of the sensory functions and circadian rhythm and their implications on the neonatal care environment, (3) the developing muscle tone and feeding skills, and the prevention of infections from the perspective of NICU environment, (4) the parent–infant interaction in the NICU environment, (5) the assessment methods of the neurobehavioral maturation of preterm infants, and (6) NICU design including research on the single-family room design. This chapter aims to describe how the NICU environment can support neurobehavioral maturation of a preterm infant and the development of parent-premature infant relationship. The goal should be to provide the infant with nurturing stimuli and an opportunity to form a healthy attachment relationship with his/her parents. Single-family rooms bring family members together and provide privacy, individuality, a sense of closeness, peacefulness, and protection, which have been shown to benefit all family members.

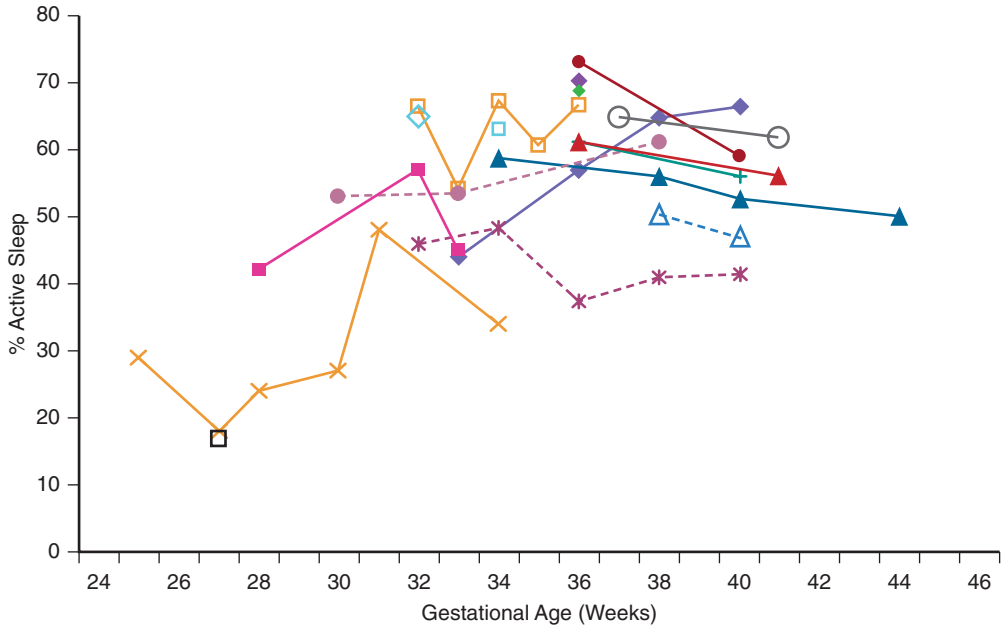
bonding has been shown to be essential to neurobehavioral organization and the long-term outcome in a preterm infant, neonatal care should support parents to be physically and emotionally close to their infant and to enhance sensitive, reciprocal parent–infant interaction. The following paragraphs will describe how the NICU environment can support neurobehavioral maturation of a preterm infant and the development of parent–premature infant relationship.

Behavioral/Sleep States and NICU Environment

The behavioral states of a newborn are commonly classified into six categories, from sleep to crying. The behavioral states of a preterm infant are summarized in Table 36.1. In preterm infants with still immature sleep states, criteria for non–rapid eye movement (NREM) and rapid eye movement (REM) sleep are not always met. Then sleep is classified as indeterminate, which can also occur as a transition between sleep states. Drowsiness can be seen as a transition between sleep and wakefulness, but it can be justified as a behavioral state in preterm infants who spend long time periods in drowsiness. Fussing can be considered as a transition from active wakefulness to crying.

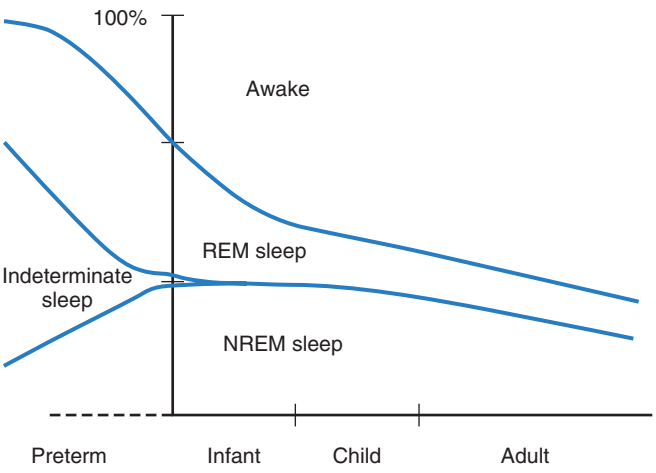
Preterm infants sleep most of the time. When polysomnography is available, electroencephalography (EEG) patterns together with REMs represent the established practice to classify sleep states in preterm infants. From 28 weeks of gestation onward, the concordance between EEG and REMs begins to emerge, defining NREM and REM sleep in preterm infants.[4] In fetuses, because EEG is not available, REMs and body movements are used instead and similarly show the concordance from 28 weeks of gestation onward.[15] A strong biologic basis can be assumed behind the maturation of sleep states, because fetuses and neonates have identical proportions of sleep states at corresponding gestational ages (Fig. 36.1).

By term, the sleep states have developed such that indeterminate sleep has disappeared and it has given space to NREM sleep, which comes ontogenically later than REM sleep. REM sleep is related to more fetal respiratory patterns such as susceptibility to apnea, suggesting that REM sleep is physiologically more immature than NREM sleep. At term, infant sleep has nearly similar proportions of NREM and REM sleep. Sleep states alternate so that one cycle of sleep states lasts for about an hour at term age and becomes longer during childhood. Fig. 36.2 shows the development of the proportions of behavioral states before and after term age.



Sleep, especially REM sleep, is important for normal brain development.[41] Animal experiments have shown that REM sleep deprivation during early development leads to permanent deviations in behavior, to alterations in neurotransmitter responses, and to reduced brain volumes. In addition, REM sleep deprivation abolished the effects of environmental enrichment seen in nondeprived animals, suggesting that REM sleep deprivation might have detrimental effects on the later capacity for learning. In a fetus, endogenous neural cell activity of retinal ganglion cells happens during REM sleep. Cortical processing of auditory stimuli also happens during REM sleep, but not in NREM sleep,[71] supporting the role of REM sleep in auditory learning as well. Furthermore, oxygenation in ventilated extremely preterm infants is most stable during REM and NREM sleep while indeterminate sleep or arousals are associated with more time in hypoxemia.[35]

TABLE 36.1 The Behavioral States of a Preterm Infant



Behavioral State	Characteristics
I. Non–rapid eye movement (NREM) = Quiet sleep = Deep sleep	Eyes closed, no eye movements Regular breathing EEG discontinuous up to 36 weeks of gestation, tracé alternant from 37 weeks of gestation onward High muscle tone, no movements (occasional startles may occur)
II. Rapid eye movement (REM) = Active sleep = Light sleep	Eyes closed (may open briefly), REMs Irregular breathing (variation >20 cycles/minute), sighs EEG continuous Low muscle tone, slow or jerky movements occur (in body/limbs/digits, facial movements, sucking, startles) Brief vocalizations may occur
III. Drowsy	Eyes half open, eyes may be open but not fully alert
IV. Quiet awake	Wide open, bright eyes Breathing usually regular High muscle tone, few movements
V. Active awake	Eyes open and moving, eyes opening and closing Irregular breathing High muscle tone, active gross body movements Vocalization may be present, not crying
VI. Crying	Eyes open or tightly closed Regular, intense cry vocalization during expirations; grimacing face Very high muscle tone, gross body movements

• **Fig. 36.1** The development of the proportion of active sleep in preterm infants (*solid lines*) and in fetuses (*broken lines*), according to the corrected gestational age. Each line represents data from an individual study. The definitions are comparable within each study. (Adapted from Lehtonen L, Martin R. Ontogeny of sleep and awake states in relation to breathing in preterm infants. *Semin Neonatol.* 2004;9(3): 229-238.)

• **Fig. 36.2** The development of the proportion of behavioral states by age.

Based on the research knowledge on the importance of sleep on brain development of a preterm infant, all efforts should be made to develop neonatal care environments and care cultures so that they minimize sleep disturbances. A lot can be done to make the space calmer (Table 36.2). Optimally, families have their own rooms so that alarms and care of other infants do not disturb the infant close by. Infant care can be delivered based on the behavioral states and cues of the infant, not based on a routine time schedule. Invasive procedures should be minimized and noninvasive monitoring prioritized (e.g., transcutaneous CO_2 monitoring instead of blood gases). Medications such as opioids should be minimized as they affect REM sleep.[6] We discuss below the ways to decrease sleep disturbances caused by noise and ambient light.

Awake states can be classified according to behavioral criteria in a full-term infant, but it can be difficult to define wakefulness in very preterm infants. The time spent in a quiet awake state is also short in very preterm infants, but it increases with development. The emergence of an attentive quiet awake state changes the quality of social interaction, as quiet awake state provides a window of opportunity for verbal and visual parent–infant interaction and related learning, and for feeding practices. Multiple internal and external stimuli may disturb preterm infants and may prevent them from reaching an attentive awake state. Therefore, attention is needed to control environmental stimuli and to facilitate infants' self-soothing.

Infants at very early gestational ages cry little despite stressful and even painful intensive care. In one study, ventilator-treated very preterm infants presented crying facies for less than 1% of observation time.[35] Crying in neurologic assessment situations increases after 31 weeks of gestation. The attenuated capacity of preterm infants to produce reactions seen in relation to pain in older infants needs to be remembered when evaluating pain responses in preterm infants. Crying increases in preterm infants after term age, reaching the peak at the average age of 6 weeks of corrected age,[8] when the amount of crying peaks also in full-term infants. Excessive crying has been seen as a sign of poor behavioral regulation, and its role has been studied in predicting later development.[46] Many neurobehavioral assessment tools include infant crying or irritability.

TABLE 36.2 How to Promote Sleep in the NICU Environment

Goal	Methods
Avoid noise	Single-family rooms; technology with no/few auditory alarms at bedside; decibel meters
Avoid bright lights	Indirect, dimmed lighting; protect eyes during procedures
Ensure thermoneutral environment	High enough ambient temperature in the room
Cluster caretaking and procedures to the times when the infant is awake	Infant-centered, individualized care
Minimize heel sticks and other painful/stressful procedures	Consider each heel stick carefully: Is it likely that the infant benefits more from not being disturbed than from the information of the blood test? Use noninvasive monitoring when possible
Minimize the use of opioids	Routine use of nonpharmacologic pain management such as skin-to-skin contact

Sensory Functions and NICU Environment

The developing sensory functions form a basis for interaction between preterm infants, caregivers, and the environment. The age-specific sensory functions determine which modes of interaction are relevant at each age. The onset of sensory functions occurs in the same sequence in all mammals: the first one to occur is tactile function, followed by gustatory and olfactory, vestibular, auditory, and visual functions, suggesting a fundamental importance of this sequence for the development.[59] However, it is also known from animal studies that normal development requires balanced multimodal stimulation.

Tactile Function and Skin-to-Skin Contact

The role of touch is central in very early developmental phases. Although preterm infants need to be carefully protected from unnecessary painful and stressful tactile stimulation, not always completely avoidable in intensive care, there is a vast literature about the benefits of parent–infant skin-to-skin contact (also called kangaroo care). Skin-to-skin contact is a natural interaction mode between the caregiver and a preterm infant when other senses are even more immature. Through skin-to-skin contact the caregiver coregulates infant physiology and behavior. It was shown in a meta-analysis of 124 controlled studies that preterm infants have a lower breathing rate and higher oxygen saturation, less pain symptoms, and better temperature and glucose balance in skin-to-skin contact compared to care in an incubator.[12] Furthermore, the meta-analysis showed that skin-to-skin contact decreases mortality and infections and improves breastfeeding rates and the head growth of preterm infants. Furthermore, skin-to-skin care has been shown to increase vagal tone and to enhance neurobehavioral maturation in preterm infants.[39] Consistently, very preterm infants had more optimal neurobehavioral performance at term age if the neonatal units allowed parents unlimited access and practiced daily skin-to-skin contact compared with the units with less infant-centered care.[43]

Many hormonal mechanisms mediate the neurobehavioral effects and the psychological processes related to skin-to-skin contact. Oxytocin is one of the key hormones facilitating parent–infant relationships. Seven of eight human studies showed a strong association between oxytocin levels and the mother–infant relationship as summarized by Galbally et al.[24] Furthermore, the fundamental biologic role of oxytocin is supported by extensive animal literature, reviewed by Rilling.[58] Breastfeeding, skin-to-skin contact, and infants' social signals stimulate oxytocin secretion in mothers. Oxytocin may promote early interaction by several mechanisms, such as improved face and affect recognition and increased caregiving motivation by activation of the dopaminergic system, the "reward pathway." Maternal behavior is increased by estrogen, which increases the number of oxytocin receptors.

Consistent with reports showing that massage, a type of tactile stimulation, increases growth in preterm infants, an Italian group showed in a randomized study that infant massage 15 minutes three times a day increased blood levels of insulin-like growth factor 1 (IGF-1).[25] In addition, the group receiving massage had accelerated maturation of visual function and EEG. In rat pups, the beneficial effects on vision were blocked by antagonizing IGF-1.

The effects of skin-to-skin care on improved growth might partially be mediated by cholecystokinin (CCK), which enhances digestion and has a calming effect. Preterm infants in skin-to-skin care had a CCK response to tube feeding while tube feeding without skin-to-skin care did not increase CCK levels.[73] Skin-to-skin contact and breastfeeding also decrease cortisol levels in mothers. A care setting supporting parental presence in a NICU improved cortisol synchrony between the mother and the infant.[45]

Most commonly, parent–infant skin-to-skin contact has been implemented during neonatal intensive care and practiced for a few hours daily. Although skin-to-skin contact

• **Fig. 36.3** Four-day-old infant born at 25 weeks' gestation is skin-to-skin with her mother while on the ventilator, receiving tube feedings and parenteral nutrition via a PICC line. Daily skin-to-skin care was started on the second day of life and continued throughout the hospital stay.

has been shown to be safe, even in extremely low gestational age infants from the first week of life[12,28,40] (Fig. 36.3), the beginning is commonly delayed and the average daily duration of skin-to-skin contact in preterm infants remains low in most neonatal units. In a study done in 11 European neonatal units, the duration of skin-to-skin contact was longer in the neonatal units providing an opportunity for the parents to stay overnight in the neonatal unit.[54] Comfortable, reclining chairs or adult beds at the infant bedside can be provided even without family rooms to facilitate longer periods of parent–infant skin-to-skin contact. Flacking and Dykes explored the role of space in neonatal units from the perspective of mother–infant attunement at feeding interaction.[22] The researchers concluded that the bed or chair at bedside signaled the importance of the parents and what was expected of them. When a bed was at bedside, parents were signaled that they were expected to lie in it and that a bed was needed for parent–infant closeness. A chair at bedside conveyed a message that parents were expected to come and stay close to the infant, possibly holding him/her for as long as they could.

The value of early contact in the formation of the mother–infant bond was shown in full-term infants in the landmark study by Klaus et al.[29] in 1972 and has been confirmed later by them and others.[44] There is evidence that early physical contact between a preterm infant and the mother in the delivery room is associated with fewer later behavioral problems at 5 years of age.[33] However, it remains challenging to apply continuous skin-to-skin care for preterm infants right after birth in the delivery room. Poor implementation of early skin-to-skin contact in preterm populations might be defended by safety concerns, but it is more likely that the obstacles are related rather to the care culture and attitudes, which do not sufficiently appreciate the value of mother–infant closeness. The preterm infant is optimally transported to intensive care on the parent's chest, and the mother and her preterm infant are cared for together in the same room throughout the hospital stay (couplet care). Flacking and Dykes concluded in their observational study of four neonatal units that the earlier and the longer a mother can stay with her baby in close proximity, the more she will be attuned to the signals of the baby and assume the role as the primary caregiver.[22]

In addition to tactile stimuli, skin-to-skin contact with a parent provides the infant with other stimuli, including kinesthetic, olfactory, and auditory stimuli, and an interactive dimension associated with the parents' immediate responses to their infant's cues. Some of these elements can be achieved by holding the infant (with clothes on). All caring and gentle touch should be encouraged in all units, even in those that have not yet developed competencies for early and prolonged skin-to-skin contact.

Taste and Smell Functions and Environmental Experiences

Full-term newborn infants show a preference for their own mothers' smell, suggesting learning in utero as maternal dietary flavors are transmitted to the amniotic fluid and recognized as both flavors and odors by the term newborn. Fetuses show behavioral responses to taste as early as 16 weeks of gestation. Olfactory stimuli leading to behavioral responses or cortical blood flow changes have been documented from 28-35 weeks of gestation.[9]

Familiar taste and smell can be used in NICU environment to calm the preterm infant. During tube feeding, drops of maternal breast milk to the tip of the tongue of the infant familiarizes her/him to the taste of maternal breast milk. Smell has been used as a calming method by bringing the mother's smell to the baby in a fabric if the mother herself is not available.[76] Smell might be one beneficial component of mother–infant skin-to-skin contact and is available even without skin-to-skin contact when the infant is held.

Vestibular/Proprioceptive Functions

Newborn babies are carried around by their caregivers for most of the day in many traditional cultures. Better motor development is shown in the infants who are carried in an upright position, facing the caregiver and legs flexed. Rocking is also a common experience provided to young infants. Fetuses are exposed to acceleratory environment when the mother moves, usually for most of the day. The care provided for very preterm infants in incubators is far from these physiologic situations in fetuses and full-term infants. Lying in one flat position easily molds the skull of a preterm infant. It can be hypothesized that the lack of upright position and lack of experiences of acceleratory movements during early development partly explain later problems in motor coordination commonly seen in very preterm infants.[63]

Auditory Functions and Environmental Experiences

Fetal auditory learning is suggested by newborn infants' preference for the voices of their own mothers and to music their mothers have listened to during pregnancy. Auditory function in fetuses develops during pregnancy in an environment in which amniotic fluid and maternal tissues protect the fetus from high-frequency noise. All axon layers of the auditory cortex are found histologically by 25 weeks of gestation, but the density of the axons increases up to 9 months of corrected age, suggesting increasing cortical capacity in processing sounds.

Very preterm infants from 23 weeks of gestation react behaviorally and electrophysiologically to intense auditory signals. Fetuses have been shown to have magnetoelectrographic responses to auditory stimuli from 28 weeks of gestation. Very preterm infants born below 30 weeks of gestation show different auditory evoked potentials compared with older preterm infants when tested at 35 weeks of gestation, suggesting that the development of auditory functions is affected by the neonatal care environment as compared to the intrauterine environment.[10a]

When skin-to-skin contact is practiced, the infant is exposed to the heartbeat and breathing sounds of the parent and also to the parent's voice, which are normal stimuli during fetal life. Parental voice seems, indeed, to be one important stimulus for infant development. A study showed that preterm infants vocalized more actively already at 32 weeks of gestation when the parents were present compared to when the staff were present.[13] Later language development correlated to the amount of adult words these very preterm born infants had heard at 32 weeks of gestation.[14] Consistently, very preterm infants had better language development if their mothers were actively involved in their care compared to low involvement mothers.[37] The infants cared for in a single-family room unit supporting parents' presence had better language development compared to those cared for in an open bay model.[75] Consistently, if preterm infants were cared for in private patient rooms without parents' beds, their language development was more delayed than those cared for in an open unit model.[53]

All these studies support NICU environments where parents are engaged in the care of their infants and where they have a natural (calm, quiet, private) environment to talk (and maybe sing) to and with their infants. The environment should be calm and quiet for the comfort of both the infant and the parents. The parent's voice may have many benefits compared to the unfamiliar voices of the staff members: the parent's voice is familiar to the newborn from the intrauterine environment, and its familiarity strengthens during postnatal time; the parent's voice might include more emotional components; and the parent's talk is likely to be more sensitively tuned to the infant's cues and responses.

It is important and possible to control noise in the neonatal environment. Noise disturbs the developing auditory system and is a source of stress. The noise level of any equipment should be taken into account when making decisions on purchases. Technologies should also be developed better; there are, for example, no incubators with less than 55 dB noise (compared to the hotel room standard of 40 dB). Technologies transmitting alarms to the staff member responsible for the patient can be used to avoid disturbing the patient and parent. In the patient room, visual alarms instead of auditory ones can be prioritized. Single-family rooms prevent infants from being exposed to the noise from alarms and care of other patients. Technologies should also be improved to increase the reliability of signals, and thereby decreasing false alarms, which would be a benefit from both infant and staff perspectives.

Visual Functions and Environmental Experiences

The visual system matures in utero anatomically and functionally, even if fetuses are not exposed to discrete visual stimuli. Endogenous neural cell activity of retinal ganglion cells is an important part of visual system development. Together with sleep cycle organization, the endogenous neural activity concentrates in REM sleep periods. Stimuli disturbing the immature retina or REM sleep might interfere with the development of the visual system. Therefore, exposure to bright lights is one potentially toxic but avoidable environmental stimulus. Extremely preterm infants can already react to bright light. The capability to follow an object emerges at 29-30 weeks of gestation. Although preterm infants have been reported to be ahead of full-term infants in visual tracking at term, delays have been reported in preterm infants compared with full-term infants in many dimensions of visual functioning such as smoothly pursuing eye movements and cortical vision.[38] These delays suggest that the development of visual function is affected by the neonatal care environment as compared to the intrauterine environment. Maturation in vision, eye movements, and cortical vision will continue after term age.

One implication of the research on the development of vision on NICU design is that ambient light should be gentle. The rooms should be designed with indirect ambient lighting with levels adjustable through a range of 10-600 lux. When needed for procedures, the light should be a spotlight directed only to the area in attention, and the eyes of the patient should be covered.

Circadian Rhythm and NICU Environment

Circadian rhythmicity has developed during evolution to adjust life to the rotation of earth. Specific genes have been identified that regulate circadian rhythmicity, yet it is profoundly affected by the sensory environment, especially light. In newborn infants, the shorter (about 3-hour) cycles regulated by feedings dominate and circadian rhythm is not yet established. Wakefulness starts to cluster to daytime during the second month of life, and clear rhythm following the 24-hour day is normally developed by 1 year of age.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

During fetal life, circadian rhythmicity operates quite differently than during the rest of life. The fetus has a well-developed circadian rhythm by the end of the second trimester,[62] probably influenced by multiple maternal stimuli, including physical (movement, body temperature) and hormonal (transplacental melatonin, cortisol) *zeitgebers* (timekeepers). In preterm infants, a circadian rhythm cannot be detected, even though the neural mechanisms to respond to a circadian light stimulus are intact by early in the third trimester. In exploring this phenomenon, one is struck by the absence in the NICU of the circadian stimuli that would be available to the fetus. Body temperature is rigidly servo controlled, touch and kinesthetic stimuli are as likely to occur in the middle of the night as during the day, and access to maternal rhythms of melatonin and cortisol, present in breast milk, is often prevented by administration of breast milk without regard for the time it was expressed or by the use of artificial formula. Even skin-to-skin contact with the mother for several hours a day may not be sufficient to impart circadian information to the preterm infant. Preterm infants may develop a circadian rhythm sooner if exposed to cycled lighting.[26]

Sensory Functions and Pain

Very preterm infants have not yet developed clear behavioral pain responses. The robustness of pain responses (crying, arousal, and facial grimace) increases with development. Even if poorly capable of displaying clear behavioral responses, preterm infants are sensitive to pain. Blood flow changes in the contralateral somatosensory cortex have been shown to be related to a heel stick as early as 25 weeks of gestation, and the blood flow responses are stronger at lower gestational ages compared with more mature preterm infants.[65] Recurrent pain exposure in preterm infants is suggested to delay their growth, alter their brain maturation and the performance in neurobehavioral assessments, and impair their motor and cognitive development.[74]

As both pain and pain medications are potentially harmful for brain development, the optimal solution is to avoid both of them. The care of preterm infants has become less invasive and more gentle, which has been reflected in decreasing rates of neurologic impairments in preterm infants shown in both European and Australian register studies.[61,66] Interestingly, Lester et al. showed in their study about single-family rooms that the infants cared for in a single-family room were exposed to fewer procedures.[36]

Skin-to-skin contact in different forms has been used to alleviate pain and stress in preterm infants.[16] Parents can effectively alleviate the stress/pain behavior of their preterm infant by holding the infant by their warm hands in a flexed position during a painful or stressful procedure.[7]

Muscle Tone, Movements, and Reflexes

Preterm infants typically have lower muscle tone and less coordinated movements than full-term infants. A flexed position maintained most of the time in utero supports infants' self-soothing abilities such as bringing the hand to the mouth (Box 36.1). To provide similar opportunities for preterm infants, special attention in nursing care needs to be paid to supporting a flexed position in a preterm infant both during rest and during handling. Although healthy preterm infants by term can reach the same level in muscle tone, tone distribution, spontaneous movements, and reflex functions as full-term infants, preterm infants present a larger variation in their performance, especially in muscle tone. This variation makes it more difficult to define neurologic normality in preterm infants at term equivalent age than in full-term infants. Preterm infants at term tend to have less flexor limb tone, less head control, and increased hyperexcitability seen in brisk reflexes, strong grasp, startles, and tremors. More tremors are seen in preterm infants born in the lowest gestational weeks.[57]

The flexed position of a preterm infant should be supported in their environment whether it is in an incubator or on a parent's chest, or during rest and handling. It is an open question how much movement (vestibular stimulation) the care environment should offer for a preterm infant and whether a more physiologic upright position could be feasible.

• BOX 36.1 Examples of Behavioral Signs of a Preterm Infant Indicating Stress/Avoidance and Self-Soothing/Approach Behavior

Stress Signs/Avoidance

Abnormal cry (high-pitched, monotonous, weak), irritability
Abrupt behavioral state changes, unable to reach quiet awake state
Gaze aversion, abnormal eye movements
Labored breathing
Yawning, sneezing, hiccoughing
Burping, gagging
Pale, mottled, cyanosis
Startles, tremors
Hypertonia, back arching, fisting

Self-Soothing Behaviors/Approach

Visual fixation
Hand-to-mouth
Sucking on the fist/thumb/fingers
Stroking the face
Crossing arms/legs
Grasping cords/tubes/blanket
Bracing leg(s)
Moving to a flexed posture

Adapted from Boukydis CF, Bigsby R, and Lester BM[11]

Sucking and Swallowing

A fetus swallows amniotic fluid from 12 weeks of gestation in increasing amounts as sucking movements develop as an integral part of age-appropriate neurobehavioral

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

development. Immature sucking patterns with short bursts and long pauses develop into long, rhythmic sucking bursts of 10-30 sucks per burst. To be able to feed orally, a preterm infant must be able to synchronize sucking and swallowing with breathing. Both respiratory stability and sufficient neurobehavioral organization are required for safe and efficient oral feeding. Nonnutritive sucking has been used as an indicator for readiness for oral feeding, but there are no proven feeding readiness instruments to predict the time to full oral feedings. Breastfeeding seems to be easier for preterm infants to coordinate with breathing compared with bottle feeding.[10] Even if respiratory stability requires ventilator support, the first feeding experiences, such as licking/sucking the breast or small drops of milk from a syringe, can be initiated for the infant's pleasure and learning. Occasional infants are capable of starting breastfeeding at 28 weeks of gestation and are able to reach full breastfeeding at 32-33 weeks of gestation.[27] Full oral feeding is reached at an earlier postmenstrual age by infants born at lower gestational age, suggesting that exposure to (breast) feeding enhances learning. Controlled studies have demonstrated that nonnutritive sucking, sensory stimulation, and early initiation of oral feedings enhance the learning of nutritive sucking.[23] In some studies, however, it might be that the experimental settings allow the infants with readiness for feeding to feed earlier than is allowed in many clinical practices at which feeding may be rigidly based on weeks of gestation instead of the infant's individual capacities. Full oral feeding can be achieved by most infants at 34-36 weeks of gestation, and almost all preterm infants are capable of full oral feedings at 38 weeks of gestation, even if the efficacy of feeding increases after infants reach term. The key is to sensitively observe the behavioral state and cues of the infant to see the readiness of the infant to feed.

Environment Supporting Growth

During the period of rapid brain growth, it remains challenging to provide a preterm infant with nutrition comparable to the nutrition provided through the placenta to a fetus during normal pregnancy. The initiation and maintenance of sufficient lactation to enable breastfeeding, when the infant is ready for it, is also a challenge for the mothers of preterm infants. In full-term infants, breastfeeding relates to higher IQ scores as shown in a cluster randomized study design.[31] Both nutrients and the mother–infant closeness and interaction component of breastfeeding are likely to contribute to this effect. Better developmental outcome was found in very preterm infants who were breastfed at discharge despite lower weight gain before term age compared with formula-fed controls.[60] Both the duration of breastfeeding and the amount of breast milk intake during neonatal care have been shown to correlate in a dose-response relationship with developmental outcome in very preterm infants so that 100 mL/kg/day increase in maternal breast milk volume at 4 weeks of age was shown to increase Bayley test language and cognitive scores by 3 points.[75]

The neonatal unit care culture and environment can support breast milk pumping and breastfeeding in many ways. It is important to value breastfeeding as an important moment for mother–infant interaction regardless of the volume of milk produced/ingested. Providing privacy for pumping and breastfeeding is important to many mothers. Breast milk pumps, comfortable chairs and refrigerators in the patient rooms, and easy milk logistics are essential parts of NICU design. Maternal breast milk volumes were shown to be higher in a single-family room neonatal unit compared to earlier open-bay units among mothers of very preterm infants.[75]

Environment Protecting From Infections

If a preterm infant acquires sepsis during the hospital stay, the risk for clinically significant developmental problems doubles as shown in two large follow-up studies.[42,69] Therefore, care routines and design protecting preterm infants from nosocomial infections are important also from the perspective of infant neurodevelopment. Several studies have shown that single-family room design decreases the risk of infections.[17,36] It may be due to better location/availability for hand disinfectants and sinks for handwashing, longer distances between patients, or parents' surveillance and control on staff hand hygiene. Ideally, one patient should stay in the same room throughout the stay as patient logistics affects spreading of bacteria.

Environment Supporting Parent–Infant Interaction

As supported by animal research, the mother/parent is an important regulator of infant physiology, behavior, and development. Separation from the parent produces dysregulation in the offspring's brain functioning and behavior. A controlled study was carried out to reduce mother–preterm infant separation in the era when separation was the hospital routine. The mother's early participation in infant care was shown to improve mother–infant interaction and later cognitive development of the child in a study by Klaus and Kennell in 1982.[30] In a later NICU care context, when it had become routine for parents to visit daily, those infants whose mothers visited less than daily were at higher risk for behavioral problems at 7 years of age.[34] Parents' visitations, as well as the time the parent cuddled their preterm infant, correlated with better neurobehavioral organization during the neonatal period, even in a neonatal environment with low median amounts of parent–infant closeness.[56] Despite the evidence, neonatal care is still often organized in such a way that separation occurs to a significant extent and reducing the obstacles of parent–infant closeness is not prioritized in quality improvement efforts.

Intervention programs have been designed to guide parents and staff more systematically to use the knowledge of infant neurobehavior and infant cues in neonatal care

environments. The main principles of preterm infant behavior, such as the capacity of an infant to show stress signs or avoidance behaviors when overwhelmed or to use self-soothing behaviors and to show approach behaviors (see Box 36.1), can be used by the staff and by the parents. As the staff and parents understand how to adjust the amount of stimulation and interaction to the immediate capacity of their infant, they can help the infant to reach and sustain a quiet awake state, or they can support the infant's sleep. Parents and staff can plan the everyday care of the infants so that it is guided by the individual neurobehavioral signs of the preterm infant to synchronize the care better with the infant's needs. There will be consistency in the style of care when the parents are the primary caregivers and continue to be such after hospital stay at home.

A famous study randomized a group of orphans located in the orphanages in Romania to those who continued their (low-quality) care in the orphanages and those who were provided a foster home. This study showed that essential elements of care supporting later growth and development included sensitivity (child-centered, contingent responses) and positive regard for the child (acceptance, respect, and warmth, including expressions of physical affection).[47,80] Low birth weight infants were shown to be especially sensitive to the quality of care. In the preterm infant, the basis of the parent–infant relationship is formed during neonatal hospital care. Thereby, the engagement of the parents during hospital time modifies the neurobehavioral development of the preterm infant during neonatal care and also throughout childhood by modifying the psychological growth environment of the child.

A Norwegian study using a modified Mother Infant Transaction Program, developed by Achenbach et al.,[1] demonstrated possible mechanisms mediating the long-term neurodevelopmental benefits of parenting programs in NICUs and also the time span needed to judge impact of the program. The Norwegian intervention consisted of 12 sessions provided by a nurse, most of them just prior to discharge, teaching the parents to recognize infants' behavioral cues and to respond sensitively. In addition, one session was designed to reflect the experience during the hospital stay. The intervention influenced parent–infant interaction in the long term: the children in the intervention group showed more joint attention in examiner–child interaction at 12 months of age, the parents showed more nurturing child-rearing attitudes when the child was 12 and 24 months old, and parents' stress related to parenting decreased progressively over years.[32] The children in the intervention group had better cognitive outcome at 5 years of age[49] and fewer behavioral problems reported by the parents (although not by the teachers).[50] The benefits were still seen at 9 years of age. This study suggests that parenting interventions can start a positive trajectory early on and that the effects accumulate over years and are mediated through different dimensions of parent–infant interaction. It is noteworthy that the differences in neurodevelopment were not yet measurable at 2 years of corrected age, similar to Achenbach et al.,[1] showing that the intervention effect on cognition progresses after 24 months of age. Although evidence is accumulating regarding interventions focused on parent–infant relationship (supporting parent participation and more sensitive parenting), conflicting results have been reported. The benefits may not be seen if interventions are carried out in isolation so that the care culture in the neonatal unit counteracts the intervention. The intervention might also be too short-lasting or the follow-up too short to show the possible effects on cognitive development.

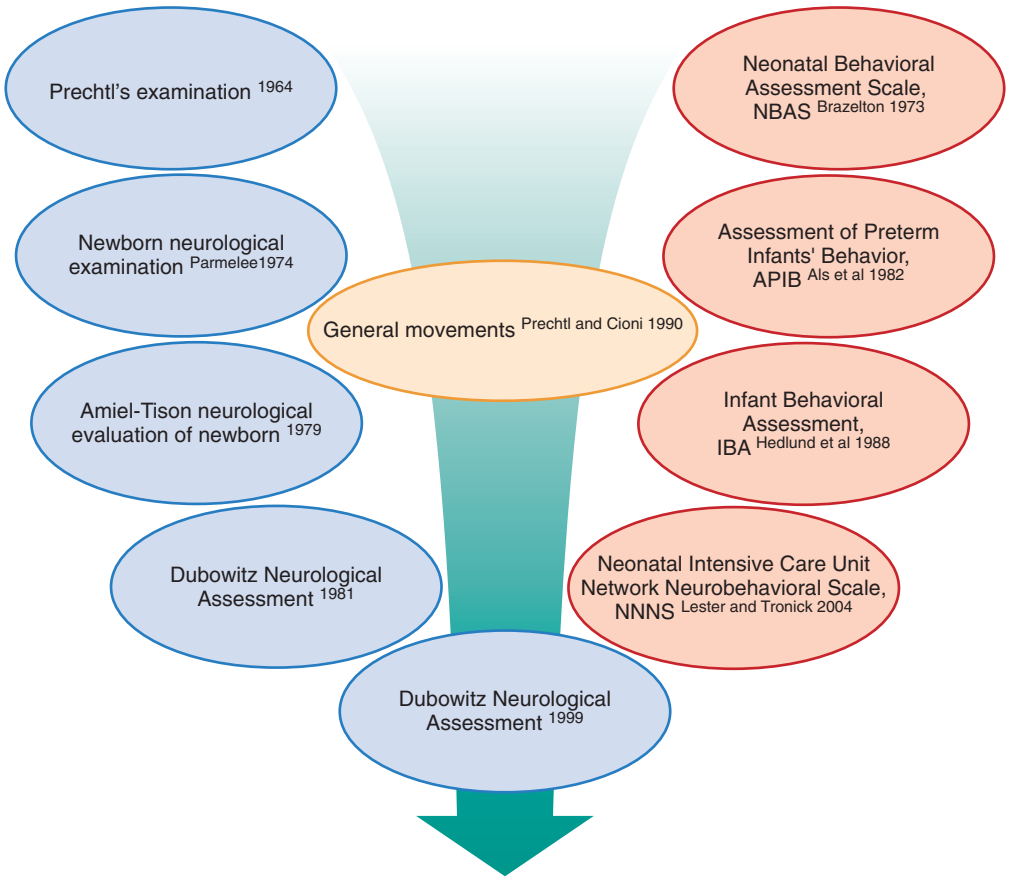
A meta-analysis of early interventions showed that the interventions focusing on the parent–infant relationship had a greater impact on cognitive outcome of the children compared with those that focused on infant development.[67]

One mechanism behind the beneficial effects of parenting interventions may be decreased postpartum depression. Parenting interventions in neonatal units have been shown to decrease maternal depression by as much as 75%–80% compared to controls.[2] Depression is known to be associated with less optimal mother–preterm infant interaction. The high incidence of postpartum depression in the mothers of preterm infants might be partly a result of separation and an undervalued parenting role. Parents' participation in infant care and in decision-making about infant care and skin-to-skin contact during intensive care continued with breastfeeding during convalescent care are safe ways to decrease caregiver–infant separation and to provide the mother a unique role in caregiving.

Several new protocols focusing on supporting parenting in neonatal care units have been published. They include different aspects of developmentally supportive care and different levels of neurobehavioral observations and interpretation of infants' cues with parents. It is important to support parent–child interaction and infant neurobehavioral development from the beginning to make the intervention preventive instead of treating and correcting abnormal development. It will be important to learn which type of intervention, at which time point, and for how long will be needed to effectively support infant neurobehavioral development.

The NICU design can support parents' participation and optimal long-term neurodevelopmental outcomes of preterm infants (see NICU design below). Single-family room units providing the families with better facilities increased mothers' participation in the United States,[36] and the hospital stay shortened by 15 days in the high maternal involvement group.[37] The neurodevelopmental outcome of preterm infants cared for in the single-family room unit were better than those cared for in the traditional open bay unit.[75]

Neurobehavioral Assessment Tools



The assessment of neurobehavioral performance and development is an essential part of the clinical assessment of a preterm infant in neonatal care but can also be used to demonstrate the impact of a change in the NICU design

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

or care culture, or differences between neonatal units. The assessment tools have evolved over decades, reflecting the increase in understanding of the complex, multidimensional neurobehavior of an infant. The assessment methods were developed first for full-term infants and later further adjusted specifically for preterm infants. The history of the development of standardized assessment methods for preterm infants includes, among others, André-Thomas defining active and passive muscle tone and reflexes in newborn infants and Saint-Anne Dargassies showing the maturation of these neurologic functions in preterm infants. This formed the basis for Amiel-Tison's assessment method for newborn infants (1979, 1980). Prechtl (1969), Brazelton (1973), and Parmelee (1976) studied behavioral states, and Prechtl and Cioni (1990) studied general movements of a newborn. Dubowitz and Dubowitz (1981) developed an evaluation method for the neurobehavioral performance of newborn infants based on neurologic functions of the newborn but integrating behavioral measures and spontaneous movements derived from the framework of assessing general movements.

Most methods used today combine neurologic, sensory, and behavioral items with differences in emphasis. The most widely used assessment methods are schematically presented in Fig. 36.4 to emphasize their origin and focus. However, the similarities in their content are greater than the differences. Because behavioral states influence motor and reflex performance, sensory functions, and their interaction, behavioral states need to be taken into account when assessing neurobehavioral development in a preterm infant using any method.

Assessment methods focusing on behavioral performance examine the full range of behavioral states and provide a global view of higher neurologic functions. These methods are well suited to follow recovery of an at-risk infant in neonatal care or to adjust the care of an individual infant based on a differentiated understanding of his/her neurobehavioral maturation and vulnerabilities. When applied systematically, the neurobehavioral assessment of the preterm infant population in a unit can serve as a tool to monitor the effects of quality improvement efforts. Lester et al. showed that preterm infants had better performance in the Neonatal Intensive Care Unit Network Neurobehavioral Scale (NNNS) when cared for in a single-family room unit compared to open bay unit.[36] In Italy, an association between the level of infant-centered care in the unit and neurobehavioral performance of preterm infants was also shown by using the NNNS.[43]

• **Fig. 36.4** The main methods for the assessment of the neurobehavioral development of newborn infants are schematically presented. Those with emphasis on neurologic items are in blue, those with emphasis on behavioral items are in red, and assessment of general movements is in orange.

On the other hand, if the goal is in diagnostics or in defining the infants at risk for long-term neurodevelopmental problems and, therefore, in need of additional support, the structured methods with more specific neurologic items, such as the Dubowitz Scale, or general movements seem to give better predictive value. More important than the method chosen is the systematic application of a standardized assessment. To screen for neurologic diagnoses of a preterm infant in neonatal care, any method is expected to discriminate normal maturational progress of the infant. The strengths and weaknesses of the assessment methods are important to understand, and they differ in the amount of training needed to use them reliably as reviewed by Spittle et al. (2008),[68] El-Dib et al, (2011),[18] and Noble and Boyd (2011).[48] The length of time needed for assessment is also important from a practical point of view. Preterm infants do not tolerate much handling, so it is beneficial if the test is noninvasive. The methods with clear written/illustrated manuals, easily definable variables, and a relatively short time to perform may better suit the realities of everyday clinical settings, whereas those requiring long training, extensive lists of variables, and longer time to perform may better suit research purposes.

If the expected age-appropriate progress in neurobehavioral development is not seen, a concern for underlying neurologic disease or pathology related to prematurity should be raised. The precise prediction of outcome based on the neurobehavioral status of a preterm infant cannot, however, be expected, because preterm infants benefit from their unique brain plasticity, compensating for deficits during the neonatal period. Early information about deviations in neurobehavioral status should be used to optimize care, and the neonatal environment to support neuronal growth and synaptogenesis and to support inherent compensating plasticity.

NICU Design

A renovation or building a new space allows major changes in the neonatal care environment. The planning process can progress according to the phases described in Box 36.2. The key factors to be taken into account in designing the NICU are listed in Box 36.3. Single-family rooms with facilities for the parents to stay throughout the day and night in the patient room of their infant have become more common in different countries. Several benefits related to single-family room NICUs have been discussed above. Controlled studies on single-family room NICUs are summarized in Table 36.3. There are, however, large differences in how this concept is implemented. Particularly, the degree of privacy provided to the families is different in different units: some units rely on technology to monitor the patient while others have transparent walls to the rooms, compromising privacy to maintain visual access to the room. The differences in design should be reported in detail when reporting the outcomes.

Although the benefits of single-family rooms, for example, fewer infections and shorter length of stay,[51] may generate economic savings for the hospital and society, the greatest advantages are likely to be seen in the improved well-being of the infants and satisfaction of the parents and other family members. The benefits for the developing parent–infant relationship and for parents' psychological well-being are likely to mediate the improvement shown in the long-term outcomes of the infants.

Health Care Team Perspectives

New NICU designs and related changes in family-centered care culture are both challenges and opportunities for the health care team of the unit. The challenge for staff is how to adopt a professional role focusing more on facilitation of parenting and to let parents perform infant care routines. The whole health care team needs new skills to negotiate and collaborate with parents as equal partners and to support parenting.[3] In one study, the nurse–parent interaction time per nursing shift increased from 35 minutes to 117 minutes after moving to a single-family room unit.[72] New care culture, together with parents, is likely to bring more meaning and satisfaction to the work of the staff when the child is seen as a part of a larger family context.[5,36] Family members are also in a better position to improve the quality of care. The health care team needs to openly embrace their input.

The health care team members also appreciate the opportunity to collaborate and socialize with their colleagues throughout the workday. A "nursing station" is a space away from the bedside, but within the patient care area, for the health care team to meet and collaborate in a setting that encourages interaction with their colleagues while keeping them informed of the status of their patients through electronic monitoring and communication devices. Charting stations immediately outside the patient rooms do not replace this additional gathering area. Many units have found that a total of 8-12 beds are required for one "nursing station" to have enough persons for a team, as significant time is spent inside the patient rooms. The staff lounge should be attractive and comfortable, and it should be located separate from parents' lounges to allow the staff time off from the close contact with the parents. The staff lounge has its role during pauses, and it does not replace the "nursing station" area facilitating team work.

The layout of the unit significantly dictates distances the staff has to cover. However, the distances are likely longer between the patients in single-family room NICUs. Many hospitals have still succeeded to move from open bay units to single-family room NICUs without increasing the number of staff members.[17]

The optimal physical NICU environment may also be different from staff and infant perspectives. Preterm infants require high ambient temperatures and dimmed lights. The staff might feel more energetic in lower temperature and brighter light. Most night-shift workers are nocturnal while working but diurnal on their days off, leading to stress and sleep deprivation.[21] Although even moderate levels of light at night can suppress melatonin-induced sleepiness and

• BOX 36.2 The Planning Process of a Neonatal Intensive Care Unit

Dream

- Assemble the team. Who are equal partners—and who are not? Disciplines that are not included from the beginning are often given the message that they are not on an equal level in the decision-making process. Most notable in this respect are parents, who are often not included until the "user group" stage.
- Determine the vision. How will the new unit change the culture, attitudes, processes, and lives of the people who are cared for and caregivers there? Recognize that this is a life-defining place for many people who pass through. How can the unit design facilitate the best outcomes for all constituencies?
- Review what you appreciate about your existing unit (e.g., collegiality, visibility, easy communication). Too often, a new unit is built to address the glaring inadequacies of the existing unit but creates new problems of its own, because the benefits of working in close, open quarters are overlooked and, therefore, are not preserved with new strategies.
- Educate your team on change strategies. Building a new unit requires major changes for everyone, and achieving buy-in will be necessary at many points along the way.

Design

- Select an architectural firm, as well as any additional design collaborators (e.g., acoustical engineer, lighting engineer, interior designer).
- Review the advantages and challenges a new location will give you. Typical constraints include financial and space limitations. Finding out about these after the design process is well advanced can be the source of much frustration!
- Develop the functional program together with the multidisciplinary team involved in the whole care process and the representatives of families. Use, for example, Value Stream Mapping to identify the bottle necks and lean fundamentals to optimize the care processes.[55] Identify all discrete areas needed, the amount of space needed for each, and desirable adjacencies and traffic patterns. Make sure you do not leave out areas that you may not have now but should include in a new unit, such as family support spaces, recycling area, and sufficient staff support space. All change is incremental, so spaces that do not exist or are grossly inadequate currently are often the hardest to get right. The tendency is to make the space larger but still inadequate.
- Design the patient room mock-up concurrently with the floor plan. Do not let the geography and space available dictate the ideal room size/layout any more than absolutely necessary.
- Additional activities that are important to initiate early in the design process:
  - Methods for communicating the progress of the design process to all staff for their input and buy-in
  - Planning for the move, especially if interim space will be used during the construction process or if the relationship of the neonatal intensive care unit to the labor, delivery, and recovery area will change
  - Planning for sustainable design/operation. Many of these decisions will need to be made very early in the design process and would be very expensive to introduce later. This will lead to decisions about HVAC systems; floor, wall, cabinetry, and ceiling finishes; power supply and use; and more.
  - New communication systems/strategies for a larger, more private unit (e.g., patient [monitor] to nurse, nurse to nurse)
  - New health care team collaboration/training opportunities/challenges/strategies. Collaboration with parents needs to be in focus (Ahlqvist-Björkroth et al. 2017).
  - New supply access/storage/removal opportunities/challenges/strategies
  - New infection control opportunities/challenges
  - HIPAA/privacy considerations
  - Site visits—a very important component to "get right." Choosing at least a couple of units to visit that have a similar size, acuity, and philosophy is important, but much can be learned from innovative units even if they are much different from your own and even if they are in other parts of the hospital, such as pediatric or adult ICUs or noncritical care facilities.
  - Equipment planning

Build

- Once the design is finalized and the unit is under construction, many months remain to prepare for the dramatic changes in culture and practice that can occur in a new unit. Teams that are already at this stage are advised to review the items in the design stage and focus on any of those that still remain in an early stage or may even have been overlooked until now.

Modified from the work developed for use in the Vermont Oxford Network NICQ 2009 Improvement Collaborative.

improve alertness while reducing the normal night-time temperature decline,[21] attempts to keep the infant's environment dark may make supplemental lighting difficult to provide for caregivers. In addition, with evidence that night-shift workers are at increased risk for cancer[21] and that melatonin may be beneficial in reducing tumor growth, it is impossible to know at present what the ideal lighting environment is for night-shift workers, at least with respect to providing them an optimal work environment while causing the least harm.

Natural daylight and a view to nature have been suggested to improve staff well-being and recovery of adult patients.[64] Similarly, the parents in the unit would benefit from natural daylight and a view to nature. The design of the unit should find a solution to provide those elements for the staff and parents without compromising the infant's environment.

Conclusion

The management of a preterm infant calls for a delicate counterbalance between necessary and sufficient support for the infant's physiology and avoidance of any unnecessary interference with parent–infant interaction. During

• BOX 36.3 Key Factors in Designing the Neonatal Intensive Care Unit[78]

Location
- Close proximity or controlled access to delivery and transport areas
- Controlled access and egress for patient and staff safety

Space Allocation
- Minimum of 120 square feet per bed space, excluding sinks and aisles (165 square feet minimum for single-patient rooms)
- Adequate and easily accessible storage (30 square feet per bed) for supplies and equipment

Access
- At least 4-foot aisles in multibed rooms
- At least 8-foot corridors outside private rooms

Privacy
- Minimum of 8 feet between beds, with provisions for family and speech privacy
- A comfortable reclining chair and/or a hospital bed (head to be adjusted) for the parent for skin-to-skin contact and breastfeeding

Nutrition
- A breastmilk pump for each mother, a comfortable reclining chair for breastmilk pumping, and refrigerator for breastmilk storage

Headwall
- Twenty simultaneously accessible electrical outlets, divided between normal and emergency power circuits
- Three each of compressed air, oxygen, and vacuum outlets, all simultaneously accessible
- Data transmission port

Hand Hygiene
- Hand disinfectant at each patient bed
- Large sinks with hands-free controls within 20 feet of every bed
- Sinks designed to accommodate children and persons in wheelchairs
- Appropriate provision for soap, towel dispensers, and receptacles for trash, recyclables, and biohazardous waste

Surfaces
- Floors[77]—easily cleanable, durable, glare free, and cushioned in patient care areas
- Walls—easily cleanable and durable; sound-absorbent materials can be used where they can be protected from damage; interior design signaling warmth, comfort, and normality
- Ceilings—washable, highly sound-absorbent acoustical tile wherever feasible

Lighting[20]
- Ambient lighting levels adjustable through a range of 10-600 lux
- No direct ambient lighting in patient care areas
- Light sources with suitable spectrum to permit accurate color rendering[17]
- Procedure lighting capable of providing at least 2000 lux at the bed surface and adjustable in both location and intensity
- Daylighting for adult work areas, with appropriate shading and insulation

Acoustics
- Noise control measures to maintain the combination of background and operation sound below a mean level of 45 dB[52]

Heating, Ventilation, and Air Conditioning
- Ambient temperature of 22°-26° C (72°-78° F)
- Relative humidity of 30%-60%
- Minimum of six air exchanges per hour with appropriate filtering; two changes should be with outside air
- Exhaust vents situated to minimize drafts near patient beds and appropriately sized and constructed to minimize noise from airflow

Family Support
- Adequate and welcoming directional and informational signage and parking space
- Lounge, refreshments, restrooms, showers, storage, Wi-Fi
- Overnight rooms if rooming-in is not possible
- Private, quiet space for consultations/grieving
- Lactation area (if sufficient privacy is not available at the bedside)
- Dedicated area at the bedside for infant care, work, and rest

Staff Support
- Lockers, lounge, restrooms, on-call rooms
- Adequate and comfortable charting/work area at each bedside
- Clerical/work areas away from, but easily accessible to, each bedside
- Office/desk space for all disciplines that routinely provide care

Sustainable Design
- Use of materials that are free of substances known to be teratogenic, mutagenic, carcinogenic, or otherwise harmful to human health
- Designs and materials that reduce consumption of energy, cleaning fluids, and nonrenewable resources[79]

the long care process, countless decisions are made and encounters occur in the complex system of neonatal care. Within this care process, all treatment and care practices, and the physical and psychological environment are important in optimizing the neurobehavioral development of a preterm infant. The goal should be to provide the infant nurturing stimuli and an opportunity to form a healthy attachment relationship with his/her parents. Single-family rooms bring family members together and provide privacy, individuality, a sense of closeness, peacefulness, and protection, which have been shown to benefit all family members.

TABLE 36.3 Studies on the Impact of Single-Family Room Design in Neonatal Intensive Care Units on the Infant, Parent, and Staff Outcomes

Author; Year of Publication	Design	Population	Outcome	Finding
Örtenstrand et al.; 2010	RCT	<37 weeks' GA; n = 183 in SFR vs. n = 182 controls	LoS, infant outcomes up to discharge, maternal, and infant salivary cortisol levels	SFR: 5.3 days shorter LoS in infants <37 weeks' GA; 10.1 days shorter if <30 weeks' GA, less BPD (1.6% vs. 6.0%); better mother–infant cortisol synchrony
Domanico et al.; 2011	Prepost	Pair matched NICU infants, mean 34 weeks' GA; n = 75 in SFR after 2008 vs. n = 75 controls	Medical progress, growth, breastfeeding, ambient sound, and light measurements	SFR: Earlier enteral feeds; less apnea; no change in growth; more sustained lactation and discharge with maternal breastmilk
Flacking and Dykes; 2013	Ethnography in 4 neonatal units	2 units in Sweden, 2 units in England	Attuned parent–infant relationship and feeding	Parents' feeling of "ownership" of place and space, at-homeness, privacy, and possibility to follow infant's cues improved parent experience and parent–infant attunement
Lester et al.; 2014	Prepost	<30 weeks' GA; n = 252 in SFR in 2010-2012 vs. n = 151 controls in 2008-2009	Infant, parent, and staff outcomes up to discharge	In SFR: Better weight gain; less procedures; earlier full enteral nutrition; less infections; better neurobehavioral performance at discharge; less maternal stress; better work satisfaction
Lester et al.; 2016	Prepost	<30 weeks' GA; n = 93 in SFR in 2010-2012 vs. n = 123 controls in 2008-2009	Bayley III at 18 months	Nonsignificant developmental difference by unit design, but more maternal involvement improved outcomes in both types of NICUs. SFR did not have adverse effects in low maternal involvement group.
Vohr et al.; 2017	Prepost	<1250 g; n = 297 in SFR in 2010-2011 vs. n = 394 controls in 2007-2009	Breastmilk provision and Bayley III at 18-24 months	SFR: Higher cognitive and language scores; higher rates of human milk provision at 1 and 4 weeks; higher human milk volume at 4 weeks
Toivonen et al.; 2017	Prepost observation study	20 nurses observed both in SFR in 2014-2015 vs. in 2013-2014	Nurse–family interaction time per work shift	SFR: Nurse–family interaction time doubled, nurse–parent interaction time tripled; the increase in nurse–infant interaction time was not statistically significant

These data are based on single-family room design that provides space, facilities, and privacy for parents to stay throughout the day and night close to their infant.
LoS, Length of stay; RCT, randomized controlled trial; SFR, single-family room unit; BPD, bronchopulmonary dysplasia.

Key Points

- The neurobehavioral development of a preterm infant is modified by environmental influences from the neonatal intensive care unit.
- The physiologic sensory environment of a preterm infant that would be in utero includes multimodal sensory inputs and intimate interaction with the mother's activities and physiology.
- Parent–preterm infant closeness and interaction can compensate for many environmental elements that would have been present in utero.
- Undisturbed sleep is shown to be important for brain development.
- Single-family rooms protect preterm infants from noxious stimuli and provide more nurturing stimuli. Single-family rooms also support an opportunity to form a healthy parent–infant attachment relationship by bringing family members together and by providing privacy, individuality, closeness, peacefulness, and protection.

Biomedical Engineering Aspects of Neonatal Cardiorespiratory Monitoring

JULIANN M. DI FIORE

Preterm infants are exceptionally unstable in terms of respiratory control due to both immaturity of the central nervous system and susceptibility to disease and infection. As a result, they exhibit a high incidence of apnea, bradycardia, and desaturation events during the first few months of life.[17,55] Respiratory support including supplemental oxygen, continuous positive airway pressure (CPAP), and mechanical ventilation are ubiquitous in the neonatal intensive care unit (NICU) but with a goal of decreasing duration and level of support to minimize the incidence of chronic lung disease.[71] These treatment decisions are most often based on nursing documentation of apnea, heart rate, and desaturation alarms[8] making bedside cardiorespiratory monitoring an integral part of NICU clinical care.

Because of their small stature and fragile skin, extremely low birth weight (ELBW) infants continue to be a challenge in monitor design with a focus on continuous, accurate, artifact-free recordings obtained in a safe and noninvasive manner. More often than not, monitors are developed for adult patients or older children followed by application in newborns with minimal data demonstrating accuracy and safety. Nevertheless, even a well-designed monitor is only as good as the end user. Therefore, a thorough understanding of bedside monitor functionality is also needed to maintain optimal settings to reduce both nuisance alarms and signal distortion of real events. This chapter includes a description of the principles of operation of cardiorespiratory monitoring modalities, including current and future directions of hemodynamic, blood gas, and respiratory waveform acquisition in the NICU setting.

Hemodynamic Monitoring

Electrocardiogram

Principle of Operation

During each heartbeat, an electrical impulse originates in the sinoatrial node, and is propagated among the muscles of the atrium, through the atrioventricular node, followed by dispersion throughout the ventricles. In summary, the heart can be viewed as a dipole, as excited myocardium is negatively charged with respect to the myocardium at rest. The small alterations in voltage generated by the heart can be measured at the body surface with electrodes placed on the chest. The most common type of electrode used in the NICU is the silver-silver chloride, foil-based, recessed, or floating electrode. Each electrode contains a highly conductive electrolyte gel with a composition that varies by manufacturer. Electrode location is important in acquiring a signal of adequate resolution, especially in neonates with a limited surface area.[3] Multiple probe applications should be avoided to optimize adhesiveness of the electrodes and ECG signal integrity and decrease the chance of skin damage, including high transepidermal water losses,[10] in extremely preterm infants with fragile skin.

The ability of the electrodes to detect small electrical changes with each heartbeat requires the application of a current to the chest wall. The recommendations of acceptable current limits by the American Heart Association (AHA) cover two aspects of electrical safety. The first entails the amount of current allowable in a patient-connected lead that can flow through the myocardium without inducing ventricular fibrillation. The second aspect pertains to the allowable chassis leakage current that flows through the patient to ground. The AHA recommends that currents be limited to 10 μA through patient leads and less than 100 μA, with an optimal level of 10 μA for chassis leakage current.

The initial goal of simple heart rate measurements has expanded to include identification of specific arrhythmias and more complex algorithms of heart rate variability. For example, alterations in spectral indices and prolongation of QT interval have been shown to be associated with prematurity[79] and sudden infant death.[26] In addition, longitudinal regression-based models of abnormal heart rate characteristics associated with systemic infection and inflammation have been shown to reduce infant mortality in VLBW

Abstract

Preterm infants exhibit a high incidence of apnea, bradycardia, and intermittent hypoxemia during early postnatal life. As a result, many preterm infants require respiratory support, including pressure to maintain airway patency and supplemental oxygen to provide adequate gas exchange. With current aggressive weaning protocols, cardiorespiratory monitoring plays a crucial role in documentation of fluctuations in respiration and oxygenation as well as identifying periods of hyperoxemia. Due to the small stature and fragility of very low birth weight infants and accompanying ventilatory instability, the technologies available in the NICU must include noninvasive continuous modes of monitoring heart rate, respiration, and oxygen. This chapter summarizes the strengths and limitations of current modalities used for both acute and longitudinal measures of cardiorespiratory monitoring in the NICU setting.

infants.[46] Although sophisticated mathematical analyses have been predominantly limited to the research arena, development of the ability to detect alterations in heart rate variability in an automated fashion may play a role in future clinical care.

Cardiac Output

Principle of Operation

Application of the Fick principle is considered the gold standard of cardiac output monitoring in a research setting. This method states

$$CO = VO_2/(Ca\text{-}Cv)$$

where VO_2 = oxygen consumption, Ca = oxygen concentration of arterial blood, and Cv = oxygen concentration of mixed venous blood. Although the Fick principle may be accurate, especially in low flow states, precision may be limited by air leakage, cardiopulmonary disease, and enhanced pulmonary oxygen consumption.[15]

Noninvasive methods that are validated in neonates include transcutaneous Doppler, transthoracic echocardiography (TTE), and thoracic electrical impedance. Doppler ultrasound uses an ultrasound beam to measure blood flow velocity. A velocity-time waveform is then produced from spectral analysis of Doppler shifts, caused by moving erythrocytes. The stroke distance can be calculated by the area under the velocity-time waveform. If the cross-sectional area of the vessel is known, cardiac output can be calculated by:

$$\text{Cardiac output} = \text{stroke distance} \times \text{cross-sectional area of the vessel} \times \text{heart rate}$$

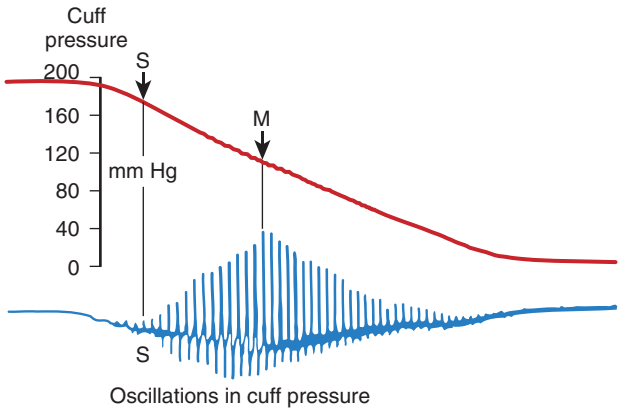
Doppler-based cardiac output measurements can vary widely and should be limited to trend monitoring.[15]

During TTE, measures of left ventricular output, right ventricular output, or superior vena cava flow can be obtained. Validation data with TTE have been limited to transthoracic left ventricular output measures, which have been shown to be comparable with pulmonary artery thermodilution and O_2-Fich methods.[15] A variation of thoracic electrical impedance, electrical velocimetry, includes surface ECG electrodes placed on the forehead, left side of the neck, left mid-axillary line at the level of xiphoid process, and left thigh. During application of a small alternating electrical current through the thorax, changes in voltage are measured during periods of systole and diastole. Stroke volume (SV) is then determined using the following equation:

$$SV = V_{ept} \times \nu_{LVET} \times LVET$$

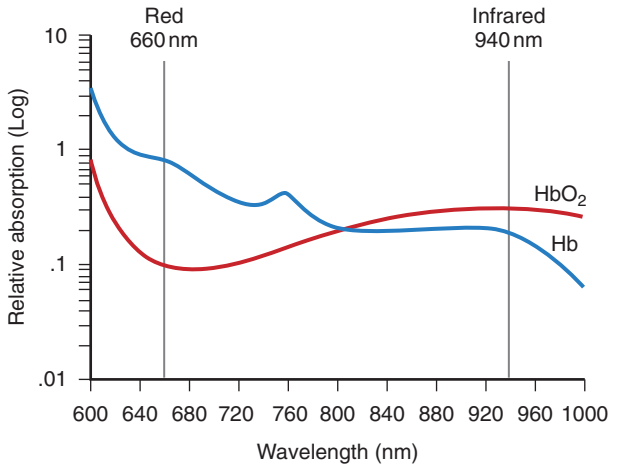
where V_{ept} (mL) = volume of electrically participating tissue derived from body mass and height, ν_{LVET} (s^{-1}) I = ohmic equivalent of mean aortic blood velocity during left ventricular ejection, and LVET (s) = left ventricular ejection time. Data have shown electrical velocimetry as a comparable mode of measuring left ventricular output in neonates when compared with echocardiography,[48] although variation among individuals was seen using both techniques.

Blood Pressure



Principle of Operation

Direct continuous readings from an indwelling arterial line are considered the gold standard for blood pressure monitoring in the neonate. Arterial and venous pressures are usually accessed by a catheter placed in the umbilical vessels. The catheter is then attached to a transducer. The transducer works on the principle that fluid exerts a force on the diaphragm. This force can be converted to a change in voltage and calibrated to a given pressure. The dome must be flushed, making sure there are no bubbles in the circuit; the transducer must be placed at the level of the distal tip of the catheter; and a zero pressure should be established before patient data are acquired.



Indirect blood pressure readings can be acquired through a cuff or inflatable bladder placed around the upper arm or calf. The cuff is inflated to a pressure adequate to cause occlusion of the arterial flow. During deflation of the cuff, measurements of diastolic and systolic blood pressure can be obtained. Mean blood pressure is then defined as the integrated area under the arterial pressure waveform.

The size and placement of the cuff can affect accurate measurements of blood pressure. A cuff that is too narrow or applied loosely may result in falsely high readings. The American Heart Association recommends a cuff width of approximately 40% of the limb circumference. The two modes of indirect blood pressure monitoring include the auscultatory and oscillometry methods. The auscultatory method entails rapid inflation of the cuff, followed by slow deflation while listening for distal Korotkoff sounds with a stethoscope. This method, most commonly used in adults, is limited by the inaudible frequency range of arterial sounds in neonates, intra-observer variability, and disturbance to the patient. The oscillometry method is more often used in newborn intensive care units. In this method, cuff pressure is rapidly inflated to above systolic pressure. As the pressure is slowly released, small pulsations can be detected as the cuff approaches systolic pressure. When the cuff pressure decreases to below systolic pressure the oscillations increase in magnitude because of blood flowing into the artery. Ultimately a maximum oscillation point will be reached, corresponding to mean arterial pressure, followed by a decline as the cuff pressure decreases to baseline (Fig. 37.1). In critically ill premature infants, oscillometric blood pressure measurements have been shown to have good agreement with arterial catheter values, although accuracy is greatly diminished in infants with a mean arterial pressure less than or equal to 30 mm Hg.[72] Although the use of a cuff does not allow for continuous monitoring of blood

pressure, many systems have the ability to provide automated transient readings.

Blood Gas Monitoring

Arterial blood gas sample measurements provide the most accurate estimate of arterial oxygen and carbon dioxide status. However, blood gases are limited by painful and time-consuming procedures, inherent risks including infection and vascular events, and intermittent short-term monitoring of PaO_2 and $Paco_2$. Continuous monitoring of oxygenation and carbon dioxide modalities offer an improved alternative by providing noninvasive, easy-to-use, portable, high-resolution, and fast-response options to alert the clinician to rapid decompensations that often occur in this high-risk infant cohort. Ideally, implementation of these devices in the NICU setting would lead to the ultimate goal of ventilation of the neonate—to stabilize respiration and minimize the use of supplemental oxygen and invasive respiratory support.

Oxygenation

The multitude of diseases associated with prematurity frequently necessitates oxygen therapy as a component of clinical care. Even during periods of supplemental oxygen, severity of illness compounded with immature respiratory control quite often leads to respiratory instability presenting as rapid intermittent hypoxemia events.[20] Therefore, blood gas measurements are useful for estimating baseline levels of oxygenation but cannot quantify short desaturation events that commonly occur in this patient population.[17] As a result, intermittent blood gas sampling is often accompanied by noninvasive continuous pulse oximetry or transcutaneous monitoring.

Pulse Oximetry

"One man's noise is another man's signal."

—SEVERINGHAUS

Principle of Operation

The principle of pulse oximetry is based on the Beer-Lambert law, which states that the concentration of an absorbing substance in solution can be determined by the intensity of the light transmitted through the solution.[68] Applying this concept, pulse oximetry relies on the light absorption characteristics of deoxygenated and oxygenated hemoglobin in the red (600-750 nm wavelength) and infrared (850-1000 nm wavelength) light spectrum ranges, respectively (Fig. 37.2). The oximeter probe comprises two LEDs, each emitting light of a specified wavelength (660 and 940 nm) through the capillary bed of the infant's extremity. A photodiode detector on the opposing side of the electrode measures the intensity of the light passing through the extremity at each wavelength, which is equivalent to the amount absorbed by tissue, and venous and arterial blood. Oxygen saturation values can be extrapolated from this measurement by exploiting the relatively small arterial pulsatile changes, also known as the plethysmogram waveform, with each heartbeat. This is accomplished by measuring the ratio of the transmitted light owing to the arterial pulsatile component (pulsatile) to the transmitted light owing to the constant component of the signal (constant); that is, tissue and baseline blood in tissue (Fig. 37.3). This ratio is calculated separately for both the red and infrared waveform signals. The ratio of the red (pulsatile/constant component at 660 nm) to the infrared signal (pulsatile/constant component at 940 nm) can then be converted to a measure of oxygen saturation.

The advantages of pulse oximetry are ease of use, fast response time, and continuous measures of oxygen saturation. The probe requires no heating or calibration by the user and is routinely placed on the palm of the hand or sole of the foot. In sick infants with intravenous lines or heparin locks precluding access to these extremities, the wrist or ankle have been suggested as an adequate alternate site.[51] Rapid response time and continuous measurement capabilities make oximetry the ideal modality for detection of intermittent hypoxemia, especially in preterm infants.[17]

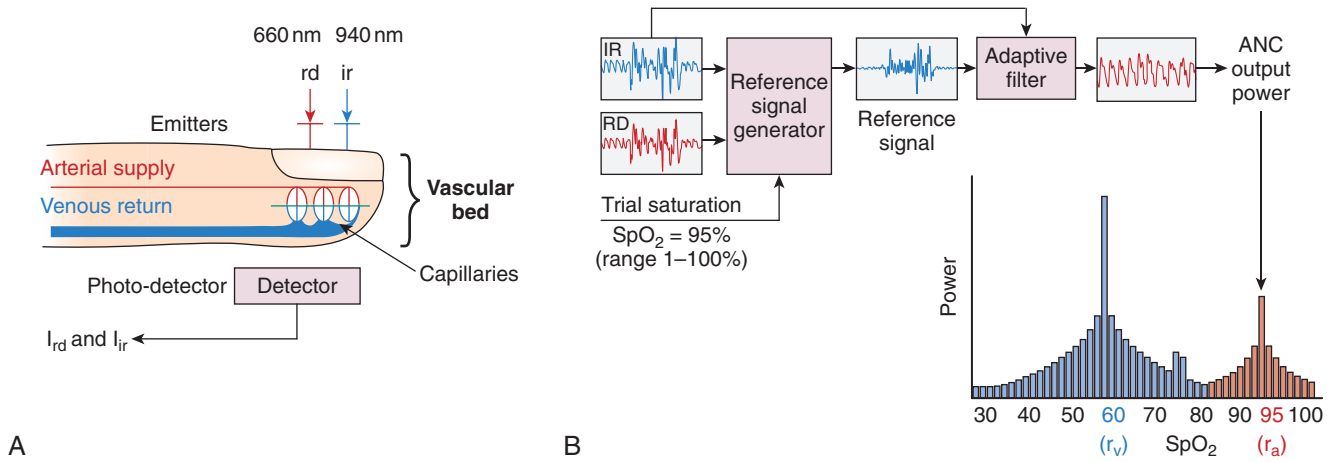
Accuracy of pulse oximetry is dependent on multiple factors, including range of oxygenation, probe position, motion and ambient light interference, low perfusion, skin pigmentation, variations in hemoglobin, and calibration algorithms. Many manufacturers report accuracy of ±2% full scale, but error increases with decreasing SpO_2.[23,60,65] For example, in a study of 1664 preterm infants, overall mean differences between SaO_2 and SpO_2 were −1.84 ± 2.93%, but less than 40% of infants were within 3% of the corresponding SaO_2 when SpO_2 fell below 88%.[60] Improper probe placement and ambient light interference can result in either falsely high or low values of SpO_2.[54,75] Under conditions of excessive ambient light interference, the SpO_2 will trend toward a value of 85%, the SpO_2 value at which the ratio of red to infrared light absorption equals 1, or complete failure to detect SpO_2 with a value of 0%. Direct opposition of the emitter and detector and covering of the extremity can minimize an optical shunt and reduce ambient light interference. Display values of 0% can also occur because of motion artifact, a common occurrence in early model pulse oximeters. Improved filtering algorithms have been shown to minimize loss of signal and accompanying nuisance alarms,[40] the most successful being developed by Masimo Corporation (Irvine, CA).[31,63] The procedure begins with detection of all optical density ratios that correspond to oxygen saturations of 1%-100% and computation of the reference signal for each optical density ratio (Fig. 37.4). The output power of the adaptive noise canceler is measured for each reference signal followed by identification of the appropriate peak in the Discrete Saturation Transformation Algorithm that corresponds to the largest SpO_2 value. The saturation algorithm is independent of recognition of a clean pulse, giving it a distinct advantage over pulse oximetry systems using these criteria as a prerequisite for calculation of arterial oxygen saturation. Additional factors affecting SpO_2 accuracy include dark skin pigmentation and low perfusion (i.e., periods of hypothermia, low cardiac output, or vasoconstriction), which may result in delayed waveform recognition and underestimation of oxygen saturation levels.[54,75]

Differences in SpO_2 values between manufacturers can be attributed to multiple factors. The manufacturer should state whether the instrument is displaying functional or fractional SpO_2[73] where:



$$\text{Functional } SpO_2 = [HbO_2/HbO_2 + RHb)] \times 100$$

$$\text{Fractional } SpO_2 = [HbO_2/(HbO_2 + RHb + MetHb + COHb)] \times 100$$

These values typically differ by 2%, the value equivalent to the levels of COHb, MetHb, and other dysfunctional hemoglobins in healthy, nonsmoking adults. The type of hemoglobin can also contribute to deviations in both

displayed value of SpO_2 and clinical interpretation of oxygen content delivery. In the presence of fetal hemoglobin, because of its high affinity to oxygen, a normally clinically acceptable level of SpO_2 may not translate to adequate oxygen delivery to the tissue. This effect is noted by a left shift in the oxygen dissociation curve.[67] Blood transfusions during the first week of life will reduce the proportion of fetal hemoglobin and should be taken into consideration when oxygen therapy is being regulated.[16] Finally, calibration procedures, including motion artifact algorithms, software versions, and mathematical extrapolations at low ranges of SpO_2 can vary by manufacturer and affect the displayed SpO_2 value. Trials randomizing infants to low oxygen saturation to decrease the incidence of retinopathy of prematurity revealed a flawed calibration artifact in the Masimo SET Radical, resulting in an artificial reduction in saturations of 87%-90% and an increase in higher values of oxygen saturation.[37,70] Revised software implemented in 2009 corrected this bias. Encompassing all of the factors that can affect accuracy, it is not surprising that measures of bias, precision,[66] and event detection[31] have been shown to vary widely among manufacturers.

There are three pulse oximeter settings that directly affect patterns of oxygenation and clinical management—alarm threshold, alarm delay, and waveform averaging time. A high alarm setting of 95% for infants receiving supplemental oxygen is generally accepted to avoid excessive oxygen exposure, although standards for ideal oxygen saturation targets,[69,70] and thus corresponding alarm thresholds, do not yet exist. Low alarm thresholds are much less clear and are based on the individual NICU target focusing on avoidance of both sustained and intermittent periods of hypoxemia. Alarm delays currently range from 0-15 sec depending on the manufacturer. Implementation of a long alarm delay can reduce nuisance alarms, but there is wide variation between clinical practices in both their use and availability. Averaging time is probably the most misunderstood parameter on the pulse oximeter display. Conceptually, a longer averaging time will minimize oscillations in the SpO_2 waveform and reduce nuisance alarms by averaging the current data point with previous values within a specified window (2-16 seconds). However, longer averaging times can erroneously under-report the incidence of short events (<10 seconds) and event severity[24] and falsely over-report the occurrence of prolonged desaturation events (>20 seconds),[76] which is concerning as longer intermittent hypoxemia is more likely to be treated with supplemental oxygen. Therefore, in theory, ideal monitor settings should include a short averaging time to accurately detect the incidence and severity of true desaturation events and a long monitor alarm delay, if needed, to minimize nuisance alarms.

Transcutaneous Monitoring of Oxygen

Principle of Operation

Transcutaneous oxygen tension measurements are based on the principle of oxygen diffusion through the skin. The electrode consists of a platinum cathode and silver reference anode encased in an electrolyte solution that is then separated from the skin by a membrane permeable to oxygen. The electrode is heated, which arterializes the blood in the capillaries underneath the skin and breaks down the stratum corneum barrier, allowing diffusion across the skin surface. The oxygen from the skin sensor reacts with the platinum-silver chloride sensor to create an electrical current, which is converted to partial pressure measurements of oxygen.

Agreement between arterial PaO_2 and PO_2 measured at the skin surface is influenced by multiple factors, including decreased solubility of oxygen in blood owing to heating of the skin, oxygen consumption in the heated skin and inside the electrode,[54] air bubbles under the sensor, insecure seal with the skin, and excessive contact gel. The sensor must be placed in a well-perfused area and properly heated before reliable values can be attained, which may take as long as 15 minutes. An electrode temperature of 44.5°C had been initially suggested with increasing underestimation of $tcPO_2$ as the temperature decreases from 45.0°-43.0°C.[41] However, subsequent studies have used lower temperatures of 44.0[22] and 43.0°C[53] to reduce the risk of burns. Sensor location must be altered intermittently to correct for transient electrode drift and avoid heat-related skin complications. Increased sensitivity has occurred with a time interval of 3-5 hours between sensor relocations in preterm infants during hospitalization[6]; however, even shorter durations of 2 hours have been associated with hyperpigmented macules and prolonged erythema in preterm infants with fragile skin.[27] Longer time intervals of 6-8 hours between site changes in older term and former preterm infants (median age 2.6 months) during home monitoring may put infants at risk for mild skin irritation resulting in slight redness that usually resolves in less than 48 hours.[53] Multiple studies have shown a linear relationship between $PtcO_2$ and PaO_2,[22] but accuracy may differ at low and high levels of PaO_2.[22] Although there are no standard thresholds for pathologically high and low levels of oxygen, Poets et al. showed sensitivities between studies ranging from 68%-100% for hypoxemia (<50 mm Hg) and 71%-92% for hyperoxemia (>80 mm Hg).[54] Given this wide variability in sensitivity, $tcPO_2$ should be used in conjunction with intermittent blood gas sampling to confirm levels of oxygenation and minimize unnecessary supplemental oxygen exposure.

Although $tcPO_2$ monitoring offers the advantage of continuous oxygenation monitoring, it is limited by a slow response time and a reduced period in which reliable data can be acquired. In contrast to pulse oximetry, which can detect immediate arterial changes at the sensor site, $tcPO_2$ monitoring must account for the time needed for oxygen to diffuse through the capillaries and across the sensor membrane.[22] This delay can range from 16-30 seconds.[53] During probe placement, oxygen saturation measurements can be immediately acquired after detection of an adequate plethysmograph waveform with no need for relocation of the probe. In contrast, a delay of approximately 15 minutes

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

needed to heat the transcutaneous probe compounded with multiple site location changes to reduce the risk of burns can lead to a large percentage of the monitoring period without measurements of oxygenation. Given these limitations, pulse oximetry is considered the most widely accepted modality for continuous measures of oxygenation in the neonatal intensive care setting.

Near-Infrared Spectroscopy

"We had discovered the possible existence of an optical window into the body…"

—JOBSIS-VANDERVLIET

Principle of Operation

In contrast to pulse oximetry, which measures arterial oxygenation, near-infrared spectroscopy (NIRS) measures oxygen uptake in the tissue. This technology has been used in a variety of organ systems, with a particular interest in cerebral oxygenation in the preterm infant population. Near-infrared spectroscopy relies on the presence of chromophores, compounds whose absorption of NIR light is dependent on oxygen status, in the tissue. These chromophores include cytochrome aa_3, myoglobin, and the most often studied, hemoglobin. Using light absorption properties of oxyhemoglobin (HbO_2) and deoxyhemoglobin (HHb) in the infrared range (700-1300 nm),[36] near-infrared spectroscopy measures the difference between the oxygen delivered and the oxygen extracted by the tissue. This measurement is also known as regional oxygen saturation (rSO_2) where:

$$rSO_2 = HbO_2/(HbO_2 + HHb)$$

The basic concept of NIRS entails a probe placed on one temple of the infant's head with a laser or light-emitting diode (LED) probe as a source of NIR wavelength transmission. The lasers/LEDs are pulsed in sequential order where multiple photodetectors, attached to the opposite temple, collect the transmitted light photons that are not absorbed in the tissue. An additional reference signal is used to correct for light reflected from the skin, laser drift, and skin coloration. By measuring the difference between the amount of light transmitted through the deep tissue and the surface path, NIRS values can estimate the amount of spectral absorption that occurs in the tissue bed. Spatial resolution is currently limited to approximately 1 cm^2 with several layers of tissue, including skin, skull surface vasculature, and gray matter in one two-dimensional sample. The current primary target area is restricted to the surface of the cortex, because access to deeper brain structures would require lasers of increased intensity and risk of damage to brain tissue.[2] Near-infrared spectroscopy values have been shown to correlate with cerebral venous saturation[77] with improved precision with increased tissue homogeneity.[1] However, overall comparability and reproducibility of different NIRS devices remains poor.[52] This may be because of manufacturer-specific variations in design that include the source of monochromatic light, the number and specific wavelengths used, the frequency of light cycling, and the frequency at which the signals are updated for digital display. Modifications in sensor geometry[35] and adjustments for the variability in arterial blood pressure[29] may have promise in improving precision.

Interpretation of absolute measurements of rSO_2 is still the subject of ongoing research. Average cerebral oxygen saturation values of 77.9% ± 8.5% have been recorded in healthy term newborns,[5] but levels have been shown to be dependent on both gestational and postnatal age.[38] Although normative data are lacking in normal healthy preterm infants, a close correlation has been shown between cerebral oxygenation, as measured by NIRS, and oxygen saturation via pulse oximetry.[7] This correlation is reduced in preterm infants with respiratory disease. There has been some suggestion that alterations in neonatal cerebral oxygenation may be associated with clinical outcomes such as intraventricular hemorrhage, cognitive impairment, and mortality, while others have shown no relationship with any clinical characteristics.[38] Therefore, the role of NIRS in identifying etiologies of brain injury has yet to be determined, and more extensive research is needed before NIRS can be routinely used in the clinical neonatal setting.

Carbon Dioxide

The presence of hypocarbia or hypercarbia has been implicated with a wide range of neonatal morbidities, including chronic lung disease, intraventricular hemorrhage, and neurodevelopmental impairment.[21,44,49] For this reason, maintenance of normocarbia and avoidance of extreme levels of arterial CO_2 is imperative in preterm infants. During periods of respiratory instability in which extreme oscillations in $PaCO_2$ can occur, arterial or indwelling catheters are not adequate. Under these conditions, continuous measurements of end-tidal or transcutaneous CO_2 monitoring have become increasingly popular in the intensive care unit.

End-Tidal Carbon Dioxide Monitoring

Principle of Operation

End-tidal CO_2 monitoring originally used mass spectroscopy to estimate CO_2 from samples of exhaled gas. Because of improvements in technology allowing for portable devices, infrared spectroscopy is now the method of choice. Infrared spectroscopy is based on the principle that CO_2 molecules absorb light in the infrared wavelength of 4.26 μm. Light is transmitted through the sample using an infrared emitter with light absorption measured with photodetectors. The amount of light absorbed in the given IR spectrum is then proportional to the concentration of CO_2.

Capnography sensor designs fall into two categories: sidestream and mainstream. *Sidestream systems* require constant aspiration of expired gas, which may result in underestimation of CO_2 readings in preterm infants with low tidal volumes. This incidence may be reduced with

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

the development of microstream technology, which uses a refined spectrum of discrete wavelengths, allowing for extremely small sample cells (15 μL) and a correspondingly lower sample rate of 50 mL/min.[14] The advantage of the sidestream system is it can be used on both spontaneously breathing and intubated patients. During intubation, sampling of gas at the distal end of the endotracheal tube is recommended to improve accuracy, although both proximal and distal measurements of $PetCO_2$ have been shown to provide acceptable estimates of $PaCO_2$ in healthy infants.[33] Accuracy may be affected by water vapor or secretions occluding the adapter or condensation on the photo detector. This is eliminated by vertical positioning or the use of Nafion tubing, a semipermeable polymer that allows water to pass through and evaporate. *Mainstream systems* rely on gas passing through a wide chamber, or cuvette, placed in-line with the patient circuit. As opposed to a remote device with sidestream systems, a miniature IR optical system is placed directly over the chamber. This allows for an instantaneous measurement of less than 500 msec. However, it is limited to intubated patients or patients with a closed circuit, that is, a sealed nasal/oral mask. Erroneous values caused by water condensation are reduced by slight heating of the cuvette. Additional factors that can contribute to measurement error for both sidestream and mainstream systems include temperature dependence, miscalibration, drift, noise, and pressure effects from the sampling system.[56]

In addition to instrumental design, the accuracy of end-tidal CO_2 monitoring is dependent on patient characteristics. $PetCO_2$ has been shown to accurately estimate alveolar CO_2 in healthy newborns,[28] but the agreement is poor and negatively influenced by the presence and severity of pulmonary disease[74] and inadequate gas exchange caused by atelectasis. Neonates have small tidal volumes and high respiratory rates, which often result in wide variations in end-tidal CO_2 values and underestimation of true alveolar gas, making it a prohibitive modality for estimating CO_2 during high-frequency oscillatory ventilation. Despite a poor correlation in ventilated preterm infants and its lower precision compared with transcutaneous monitoring,[61] its ability to detect extreme low and high CO_2 levels[42] may be of use for trending or screening patients for abnormal arterial CO_2 values.

Disposable colorimetric end-tidal CO_2 detectors are an efficient method of verifying correct endotracheal tube placement.[78] When placed between the ventilator and endotracheal tube, the pH-sensitive chemical indicator (metacresol purple) changes from purple to yellow when exposed to expired CO_2. The minimum and maximum CO_2 concentrations needed to establish a color change are 0.54% (0.5 kPa) and 2%-5% (2-5 kPa), respectively. Because neonatal extubation failure can have devastating consequences, calorimetric detectors can play a significant role in the intensive care unit. However, this device cannot detect hypocarbia, hypercarbia, right main-stem bronchus intubation, or oropharyngeal placement in spontaneous breathing patients.[45]

Transcutaneous Monitoring of Carbon Dioxide

"The fluids are invited by the warmth to the surface, and the functions of the skin are encouraged."

—ABERNATHY, 1793

Principle of Operation

Transcutaneous carbon dioxide tension measurements are based on the principle of CO_2 diffusion through the skin. The sensor consists of a pH-sensitive glass electrode with an adjacent silver chloride reference anode covered by a hydrophobic membrane permeable to carbon dioxide and separated by a sodium bicarbonate electrolyte solution. Changes in pH are measured as carbon dioxide from the skin diffuses through the electrode membrane. These changes are then converted to corresponding PCO_2 values. Preliminary data showed a linear correlation between $tcPCO_2$ and $PaCO_2$ with unheated electrodes. This was followed by a heated (44°C) electrode design that improved both the correlation between $PaCO_2$ and $tcPCO_2$[30] and the response time.

Data assessing the relationship between $PaCO_2$ and $tcPCO_2$ in infants have shown a wide variation in both slope and intercept values. These discrepancies were attributed to electrode calibration procedures and variations in electrode temperature that ranged from 42°C-44°C.[32] Additional data by Martin et al. demonstrated a progressive increase in the difference between $tcPCO_2$ and $PaCO_2$ as $PaCO_2$ increased ($tcPCO_2 - PaCO_2$, 5 ± 4 mm Hg and 9 ± 6 mm Hg in normocapnia and hypercapnia respectively).[43] These data suggest that as $PaCO_2$ increases, there may be an imbalance between CO_2 production and removal. It should also be noted that in contrast to $tcPO_2$, which underestimates PaO_2 in infants with chronic lung disease, $tcPCO_2$ has been shown to overestimate $PaCO_2$ under similar conditions.[59] This can be attributed to multiple factors, including metabolic events in the skin, circulatory disturbances that permit gas to accumulate in the tissues, the anaerobic heating coefficient of blood, and increased CO_2 tension with higher electrode temperature.

The determination of $tcPCO_2$ or end-tidal CO_2 monitoring should include the discussion of the risk/benefit ratio for each patient. The use of heated $tcPCO_2$ electrodes entails a risk of skin damage caused by burns that can be avoided by repeated repositioning of the sensor. This can be a serious limitation when considering low birth weight infants with fragile skin. In contrast, transcutaneous CO_2 detectors have been shown to be accurate during high-frequency oscillatory ventilation.[4] This alternative mode of noninvasive CO_2 monitoring may be a reasonable screening tool for preterm infants with small tidal volumes and during periods of rapid breathing where end-tidal CO_2 may underestimate $PaCO_2$. Regardless of the modality chosen, clinical care should include comparisons with blood gas values, especially during periods of relative hypercapnia.

Respiratory Monitoring

"I've got to keep breathing. It'll be my worst business mistake if I don't."

—STEVE MARTIN

Respiratory instability in the preterm infant can be attributed to immaturity of the central nervous system and a highly compliant chest wall, resulting in both central and obstructive apnea. During normal respiration, the diaphragm contracts, expanding the thorax in conjunction with activation of accessory muscles that stabilize the rib cage and maintain upper airway patency. Because of the highly compliant chest wall of the preterm infant, any loss of accessory muscle tone, including intercostals stabilizing the rib cage or hypoglossus maintaining upper airway patency, may result in instability and retraction of the rib cage in response to negative pressure generated by the diaphragm during inspiration. As a result, asynchronous or paradoxic chest wall movements will occur with partial airway obstruction, which is a common respiratory pattern in the preterm infant, particularly during rapid eye movement sleep. During extreme occasions, total airway obstruction may occur, presenting as asynchronous chest wall and abdominal efforts and no corresponding airflow. Respiratory pauses may also arise because of decreased central respiratory drive, as can occur during periods of periodic breathing and spontaneous central apnea. Therefore, ideal respiratory monitoring should have the ability to detect both central and obstructive apnea.

Flow Sensors

Principle of Operation

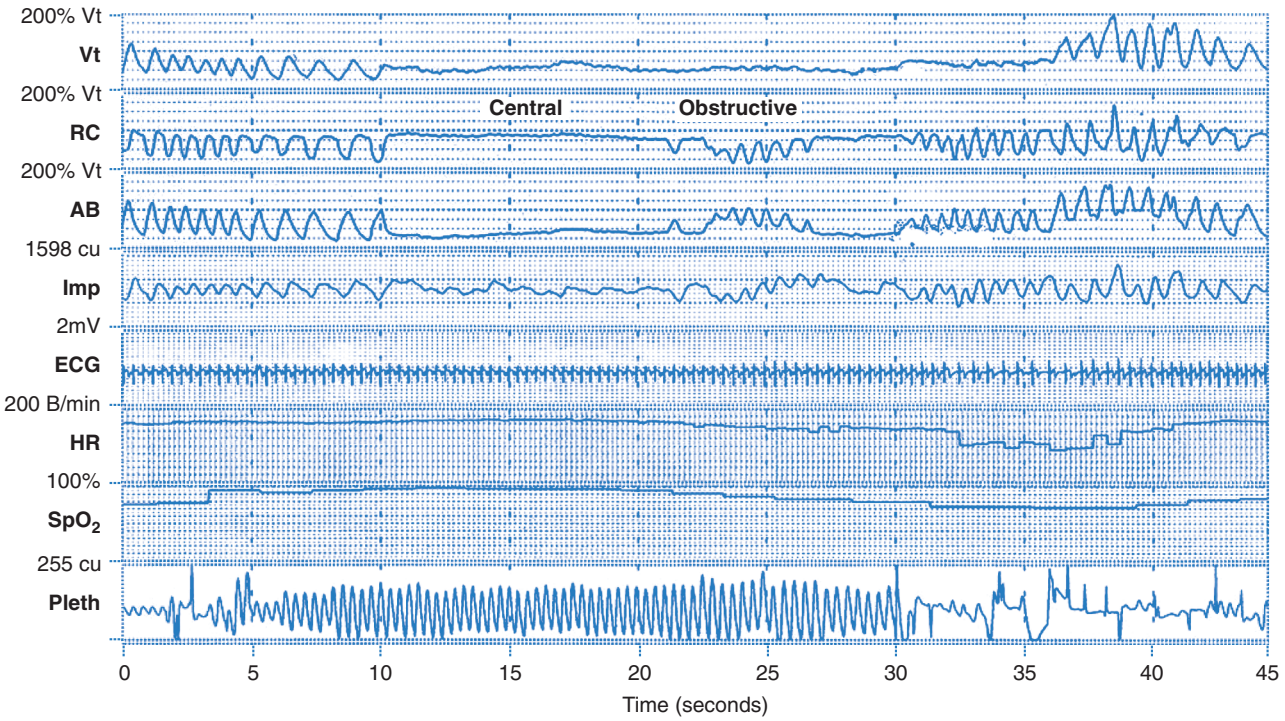
The pneumotachometer is considered the gold standard for measuring flow and volume and is most often used during mechanical ventilation and calculations of respiratory mechanics. There are two types of pneumotachometers, *fixed orifice* and *laminar flow*. The fixed orifice design consists of a fixed orifice placed within the tubular attachment placed in the airway. The differential pressure is measured across the fixed orifice, which is proportional to the square of the flow rate. This mathematical relationship can then be used to calculate a given flow. The laminar flow design consists of a simple compartment containing a resistive element, usually consisting of a mesh screen or capillary network. The pressure drop across the resistive element is linearly related to the flow passing through the compartment and can be calibrated accordingly. The range in which there is a linear relationship between pressure and flow will be dependent on the design of the device, including the length, width, and type of resistive element used. To maintain precision, all flow must pass through the device, which may be problematic during mechanical ventilation in preterm infants with a high occurrence of endotracheal tube leaks. During spontaneous respiration, the pneumotachometer must be incorporated into a nasal/oral mask. To minimize the effect of the mask on the respiratory pattern, the mask design should include minimal dead space, the ability to flush the mask to reduce CO_2 retention, and low resistance to minimize work of breathing.

Pneumotachometer use in the clinical setting has been limited to pulmonary function measurements in spontaneously breathing patients, incorporated into a sealed nasal/oral mask, or tidal volume measurements when attached to the endotracheal tube in mechanically ventilated patients. During these periods, the device may add a significant resistive load, especially in severely ill ELBW infants. As a result, many companies have replaced the pneumotachometer with the hot-wire anemometer for volume measurements during mechanical ventilation. The hot-wire anemometer includes a heated element placed in the airway circuit. As flow passes, the sensor is cooled. The system delivers an electrical current to maintain the default sensor temperature. The amount of current needed to maintain the sensor temperature can be calibrated to a given flow. If bidirectional flow is desired, a second wire can be placed in the system. Accurate measurements of flow may be compromised if secretions accumulate on the heated element. However, because of its high-frequency response, proven accuracy, and minimal resistive load, hot-wire anemometer is a promising modality for measurements of respiration in the preterm infant, including periods of high-frequency oscillatory ventilation.[64]

Although the pneumotachometer and hot-wire anemometer give quantifiable measurements of flow and volume, additional devices such as thermistor/thermocouple sensors and end-tidal CO_2 can display qualitative estimates. The relationship between peak-to-peak amplitude of the thermistor signal and actual measures of flow has been shown to be nonlinear and frequency dependent.[25] There is also minimal correlation between $PetCO_2$ and actual measures of volume. Therefore the implementation of thermistor or $PetCO_2$ monitoring is limited to the sleep lab, where, used in conjunction with chest wall motion sensors, it can be used to identify the presence or absence of flow associated with central and obstructive apnea.

Chest Wall Motion Sensors

Principle of Operation



Impedance technology is the most widely used modality for measuring respiration in the hospital setting. With two electrodes placed on either side of the chest above and below the insertion of the diaphragm, impedance monitoring measures changes in electrical impedance across the thorax that occur during a breath. Specific placement of electrodes for optimal signal quality can vary between infants. This modality is based on the principle that air has a much higher level of impedance when compared with tissue. During inspiration, there is a decrease in conductivity (and corresponding increase in impedance), owing to both an increase

in gas volume of the chest in relation to the fluid volume and increased length of the conductance path with chest wall expansion. Using a high-frequency current of greater than 25 kHz, the same electrodes used for measuring ECG can be used for detection of respiratory efforts. The ECG waveform is filtered out by manufacturer-based signal processing algorithms, thus eliminating this potential source of noise artifact. However, changes in thoracic blood volume may be falsely identified as a breath. In addition, as air moves from one compartment to the other during periods of obstruction, impedance monitoring cannot distinguish obstructive efforts from normal respiration (Fig. 37.5).

Respiratory inductance plethysmography (RIP) has been used extensively in both clinical research and pulmonary function lab settings. It is currently not used at the bedside but could be a promising alternative choice for respiratory monitoring. As with impedance, it is a noninvasive method of measuring respiration with two bands wrapped around the chest wall and abdominal areas. Each band contains a sinusoidal inductance coil with a small AC current that travels through the coil, as opposed to through the chest wall, as occurs with impedance. Respiratory inductance plethysmography relies on the principle that a current applied through a loop of wire generates a magnetic field (Faraday's law) and that a change in the area enclosed by the loop generates an opposing current directly proportional to the change in area (Lenz's law). Thus, as the chest wall expands, the coil in the band elongates, altering the magnetic properties, or inductance, of the band. The strength of this modality is the presentation of respiration as a two-dimensional model. Thus, obstructive apnea will present as asynchronous, 180-degree out-of-phase movements between the rib cage and abdomen as air flows from one compartment to the other. With the addition of a software algorithm to calibrate the rib cage and abdominal waveforms, a semiquantitative volume waveform can be acquired,[62] giving RIP the ability to identify obstructive apnea without the need for an oral/nasal flow sensor (see Fig. 37.5).

Respiratory inductance monitoring has been used extensively in infant-related research protocols, including the multicenter collaborative home infant monitoring (CHIME) study.[58] Given that RIP technology uses rib cage and abdominal excursions to measure ventilation, studies have examined the effect of body position and chest wall asynchrony on RIP accuracy. Brooks et al. found good overall agreement between RIP and tidal volume measurements via pneumotachograph in preterm infants that was not significantly affected by body position, chest wall asynchrony, or

• **Fig. 37.5** An example of an apnea with both central and obstructive components as detected by impedance and respiratory inductance plethysmography (RIP) technologies. Both modalities have the capability of identifying a central respiratory pause as noted by minimal baseline activity on the impedance channel (*Imp*) and RIP channels (*AB*, abdomen; *RC*, rib cage; *Vt*, semiquantitative volume). During periods of complete airway obstruction, Imp presents a respiratory oscillation, thereby missing the event. In contrast, RIP-based channels reveal a flat baseline on the Vt channel in conjunction with asynchronous chest wall motion on the RC and AB channels. (From Neuman MR, et al. Cardiopulmonary monitoring at home: the CHIME monitor. *Physiol Meas.* 2001;22:267-286. http://www.ncbi.nlm.nih.gov/pubmed/11411239. respiratory rate.[9] However, RIP is a semiquantitative estimate of tidal volume and can vary with pneumotachograph values on a breath-by-breath basis. Even with this limitation, RIP technology has the advantage over impedance in its ability to distinguish central from obstructive apnea but has yet to make its way into clinical bedside monitoring.

Future Directions

The need for advanced diagnostic systems, including cardiorespiratory monitors, in neonatal care continues to expand. This growth should incorporate the development of safe and effective devices for use in the NICU and a collaborative research and testing effort among the biomedical engineering disciplines.[57] Areas in which improvements are needed include the development of "smart alarms" for cardiorespiratory monitoring, education of personnel pertaining to the use of equipment, automated signal quality assessment, and electronic storage of longitudinal waveforms. The implementation of more sophisticated algorithms should be countered by a less complex user interface.

As physicians continue to be bombarded with physiologic data from bedside monitors, current clinical practice uses only a fraction of the information available for patient care. Pulse oximetry waveform extrapolation is limited to simple values of baseline oxygen saturation and time in various target ranges. Future exploitation of this waveform alone may include identification of subtle pathologic SpO_2 waveform patterns[19] and the use of automated feedback controllers[13] to avoid high-risk patterns of oxygenation and improve time in any given oxygen saturation target range. Implementation of electronic servers for storage of continuous cardiorespiratory waveforms and application of sophisticated mathematical algorithms (e.g., stochastic modeling, spectral and wavelet analysis) to longitudinal datasets to identify early patterns of cardiorespiratory instability[11,50] associated with morbidity[12,18,47] is currently limited to research protocols. The major challenge for development and application of high-risk predictive models to the clinical setting requires large-scale centralized and automated storage of waveforms and development of integrated systems incorporating multiple physiologic parameters from electronic patient database records while protecting patient confidentiality. Current trials are attempting to meet this challenge by reducing this vast amount of data into a comprehensible parameter that is useful for clinical practice.

Key Points

- Continuous cardiorespiratory monitoring plays a crucial role in stabilizing oxygenation and ventilation in preterm infants.
- NICU protocols of oxygen and carbon dioxide monitoring must include a practical balance between accuracy and noninvasive acquisition.
- Alteration of monitor settings can affect patterns of oxygenation, including artifact and signal distortion of real events.
- Current clinical practice uses only a fraction of the information available from bedside monitors for patient care.

Diagnostic Imaging of the Neonate

SHEILA C. BERLIN

Introduction

Diagnostic imaging is integral to the evaluation of neonates with medical and surgical conditions. Understanding the advantages and shortcomings of available imaging modalities as well as the most recent practice patterns facilitates selection of appropriate imaging. This chapter begins with a brief introduction to the benefits and potential hazards of relevant imaging modalities; the remainder of the chapter reviews the imaging approach to common neonatal disease according to organ system. This discussion highlights normal anatomy and the spectrum of imaging appearances of common neonatal pathology.

Radiography, Fluoroscopy, and Computed Tomography

Because a large number of radiographs may be performed in critically ill neonates, attention has been drawn to the potential cancer risk from cumulative doses of ionizing radiation in medical imaging. The radiation dose of a portable chest radiograph is approximately 0.02 mSv; this is a very small fraction of the 3 mSv of annual natural background radiation to which the average individual is exposed. Commonly performed fluoroscopy procedures in the newborn, such as an upper gastrointestinal series, contrast enema, or voiding cystourethrogram, can be performed at doses between 0.5 and 2.0 mSv in infants. Although performed far less frequently, computed tomography (CT) is also performed at low radiation doses; most head and body CT scans can be performed at a dose less than 2 mSv. Current literature indicates that the risk of a future cancer from low dose radiation (below 100 mSv for serial exams) is "too low to be detectable and likely nonexistent."[1] In the absence of data confirming a causal relationship between low dose radiation from medical imaging and cancer, parents and providers should be reassured that the benefits of a medically necessary exam far exceed any potential future cancer risk.[25] Even so, current recommendations endorse performing only medically necessary exams and limiting radiation exposure to doses that are "as low as reasonably achievable."[30] Such steps include using patient size–based tube current and tube voltage, attention to patient positioning, artifact removal, and beam collimation.

Infants requiring a CT scan of the brain or body are typically scanned without sedation, because scan times are usually less than 5-10 seconds. Iodine-based intravenous contrast may be administered to evaluate for cardiovascular abnormalities, neoplasm, or infectious disease. In the absence of known renal failure, neonates show no increased risk for renal toxicity after receiving iodinated intravenous contrast material.[9] A distinct disadvantage of CT imaging is the lack of portability. Because CT equipment requires room shielding, a relatively large footprint, and is highly sensitive to small fluctuations in temperature and humidity, patients must travel to the radiology department's CT suite for imaging.

Ultrasound

Following radiography, sonography is the most common imaging examination performed in the neonate. Ultrasound is particularly suitable for newborns because of its low cost, accessibility, portability, lack of ionizing radiation, and absence of known health risks. There is no need for patient sedation, and technologists can easily capture both static and cine images that include characterization of flow dynamics with color and spectral Doppler. High-quality sonographic images are dependent upon the skill of the technologist in identifying optimal sonographic windows and in the appropriate selection of ultrasound probes of varying frequencies. Because sound waves travel poorly through air and calcified bone, sonographic evaluation of anatomy can be limited if obscured by gas-filled bowel, aerated lung, and overlying bones. Another disadvantage of ultrasound is the relatively low spatial resolution relative to CT and MRI.

MRI

While ultrasound remains the screening modality of choice in the prenatal period, magnetic resonance (MR) imaging has become a valuable adjunct to identify at-risk infants who may benefit from in utero intervention as well as to prepare for optimal perinatal management. In the postnatal period, MR imaging can provide vital detailed information that ultrasound and CT cannot—particularly in the diagnosis of traumatic or anoxic brain injury and congenital anomalies. Gadolinium-based intravenous contrast may be used without risk of renal toxicity in infants without known renal

failure.[9] Despite scan times that may exceed 30 minutes, the majority of infants under three months of age can be scanned without sedation using the "feed and swaddle" technique.[27] The most significant barrier to MR use is the need to travel to the radiology department MR suite, frequently not in close proximity to the NICU. New dedicated infant-sized MR scanners designed to be housed in the NICU may offer a solution to the risks of transport and minimize the disruption of care for critically ill neonates.[28]

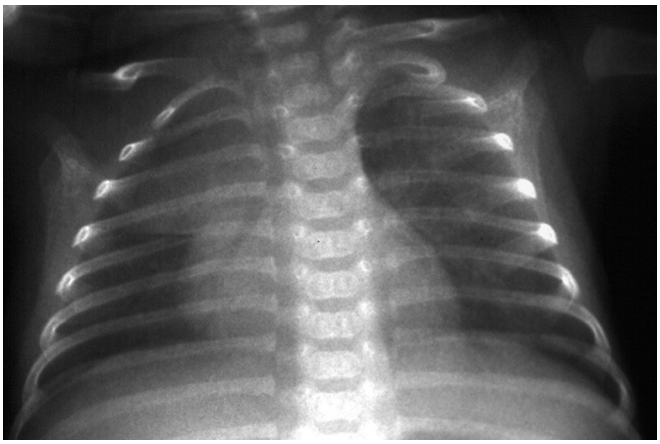
Scintigraphy

Nuclear medicine contributes to the care of newborns with congenital anomalies, infection, and neoplasm. The radiopharmaceuticals used are nonallergenic and show no toxic effects. The radiation dose for most exams is between 0.6 mSv and 5.5 mSv, in the range of CT imaging. Although most studies require that the patient remain still for a relatively long period of time, most neonates can be imaged without sedation. As with CT and US, these exams require patient transport to the nuclear medicine suite of the radiology department.

Chest

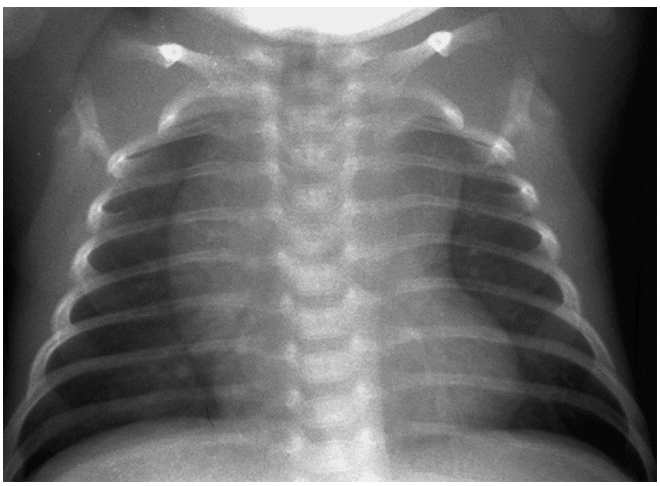
Respiratory distress is the most common indication for imaging in the newborn. The chest radiograph (CXR) plays an important role in the assessment of cardiopulmonary pathology in the neonate and young infant and is usually the initial examination of choice.

Portable chest radiographs are obtained in the anteroposterior (AP) view with the infant lying supine. The arms should be extended away from the body or above the head, and the thighs should be immobilized. With proper positioning, the radiograph should demonstrate symmetry of the clavicles and ribs and a midline appearance of the superior mediastinum. It is important to ensure proper patient positioning because a rotation-distorted image may obscure or mimic cardiac and pulmonary pathology. Further, leads and electrodes may also compromise image quality by obscuring regions of critical importance such as tube and line placement or small air leaks.



Additional imaging modalities can be used to evaluate specific neonatal chest abnormalities. Sonography is useful in the assessment of diaphragmatic motion, pleural fluid, and catheter complications. Cross-sectional imaging with CT or MRI is useful for surgical and medical treatment planning of more complex thoracic conditions. Specifically, CT is the study of choice to evaluate parenchymal and mediastinal lesions. Both CT and MR are useful in the evaluation of complex congenital heart conditions.

Evaluating a Normal Chest



Familiarity with the normal appearance of the newborn chest radiograph improves recognition of pathologic changes. Normal lungs appear primarily radiolucent and symmetric in volume. The pulmonary vessels are seen as branching, linear shadows that taper in size as they extend from the hilum to the lung periphery. Normal vessels decrease in size and number in the lateral half of the lung and are not visualized in the lung periphery. Normally collapsed, the pleural space is visualized only when it is distended from fluid, air, or pleural thickening. The heart borders should be distinct and the diaphragm should be outlined clearly against aerated lung. The normal cardiac diameter on an AP radiograph should be less than 60% of the thoracic diameter. The normal thymus is visible in most newborns. Extremely variable in size and shape, it is composed of two asymmetric lobes and may therefore have an asymmetric appearance in chest radiography (Fig. 38.1). The "wavy" undulations of the lateral borders often silhouette a portion of the heart and can give the appearance of the cardiomegaly (Fig. 38.2).

Catheters, Tubes, and Lines

The positions of the endotracheal tube, enteric tube, and the various arterial and venous catheters should be evaluated

• **Fig. 38.1** Normal thymus. Anteroposterior chest radiograph demonstrates an asymmetrically enlarged right lobe of the thymus.

• **Fig. 38.2** Normal thymus. Anteroposterior chest radiograph demonstrates a symmetrically enlarged thymus resulting in a widened mediastinum.

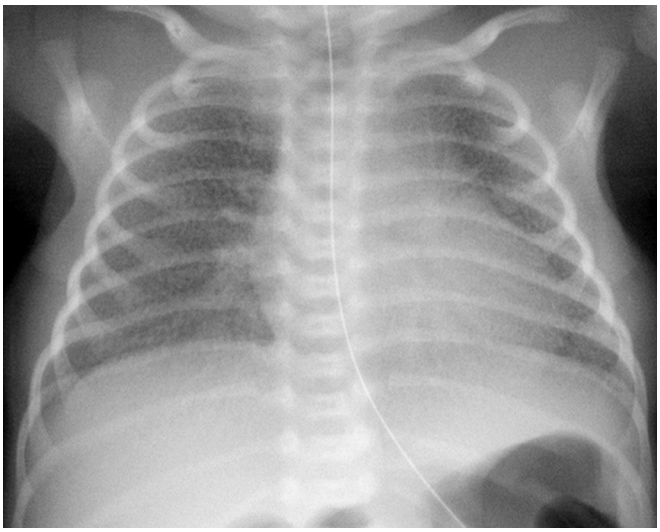
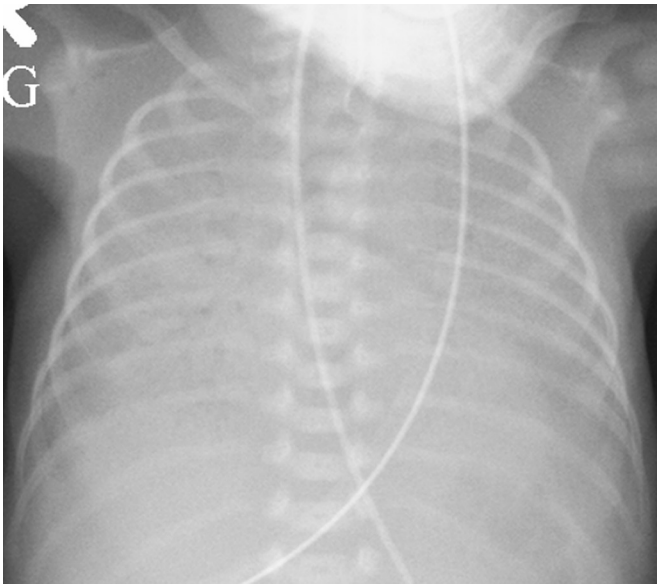
on all neonatal radiographs, as malpositioning may lead to complications. The endotracheal tube tip should overlie in the trachea between the medial ends of the clavicles and the carina. Intubation of the right mainstem bronchus is the most common site of tube malposition. The enteric tube should terminate in the stomach body, beyond the gastroesophageal junction.

Umbilical catheters can be easily identified by their characteristic paths. The umbilical venous catheter (UVC) courses superiorly and gradually posteriorly within the umbilical vein to intersect the left portal vein, continuing through the ductus venosus, left or middle hepatic vein, and then into the inferior vena cava (IVC). Its tip should be directed superiorly, ending at the right atrial/inferior vena cava (RA/IVC) junction. Malposition of the UVC within the liver is the most common complication and may result in portal vein thrombosis or portal hypertension. The umbilical arterial catheter (UAC) first extends inferiorly and posteriorly to the junction of the umbilical artery and internal iliac artery. The catheter then turns superiorly to course through the common iliac artery and aorta. The tip of the UAC should also be directed superiorly, lying below the ductus arteriosus and above or below the visceral arteries. The UAC, therefore, may be placed in a high position, ending between T6 and T10, or in a low position ending between L3 and L5. Malposition of the UAC may result in thrombosis of the aortic branches and possible ischemic injury.



The position of percutaneously placed catheters, including peripheral inserted central venous catheters (PICC lines) and extracorporeal membrane oxygenation (ECMO) catheters, must also be documented. The tip of an upper extremity PICC line should lie within the superior vena cava (SVC) or at the RA/SVC junction. A lower extremity PICC line should end between the 9th and 12th ribs. Extracorporeal membrane oxygenation therapy is reserved for neonates with severe, reversible respiratory failure not responding to conventional treatment and may use a venous and an arterial catheter or a dual lumen venous catheter. The venous catheter is inserted through the right internal jugular vein and ends in the RA. The arterial catheter is inserted into the common carotid artery and ends near the origin of the innominate artery. Complications of all vascular catheters include malposition, thrombosis, perforation, or infection.

Respiratory Disease: Medically Treated

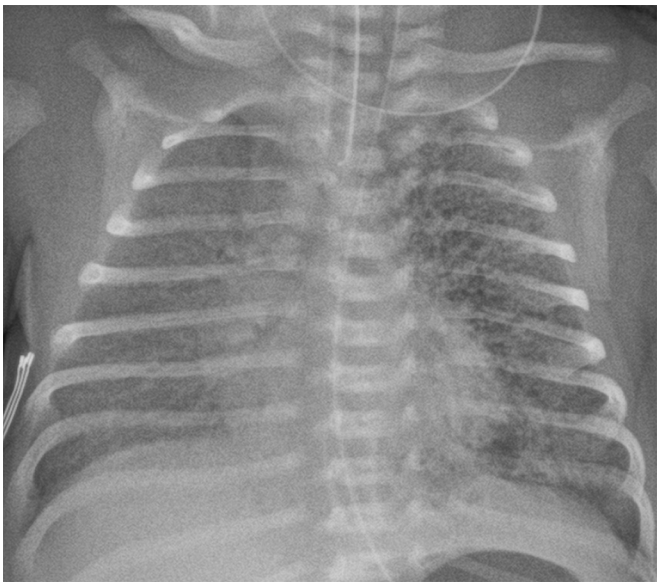


Respiratory Distress Syndrome

Respiratory distress syndrome (RDS) from surfactant deficiency is the most common cause of respiratory distress and a leading cause of morbidity in the premature infant. The prematurity of type II pneumocytes results in an inadequate production of surfactant. This triggers a cascade of responses leading to decreased alveolar distensibility, capillary leak edema, noncompliant lungs, and respiratory distress.

The typical radiographic appearance of RDS reflects generalized alveolar collapse and shows a finely granular or ground-glass pattern with diminished lung volumes. The severity of radiographic disease is variable and usually correlates with the severity of clinical disease. Mild radiographic disease is characterized by a finely granular pattern that allows visualization of normal vessels (Fig. 38.3), whereas severe disease results in loss of defined heart borders and diaphragm (Fig. 38.4). Peripheral air bronchograms may be seen with severe disease because of air in the bronchi being visualized against a background of alveolar collapse. The distribution of disease is usually diffuse and symmetric; however, patchy or asymmetric disease may be seen. The

• **Fig. 38.3** Moderate surfactant deficiency disease. Anteroposterior chest radiograph demonstrates a fine granular pattern. The heart borders, vessels, and diaphragm are well seen.



• **Fig. 38.4** Severe surfactant deficiency disease. Anteroposterior chest radiograph demonstrates diffuse ground-glass opacities. The heart borders and diaphragm are silhouetted.

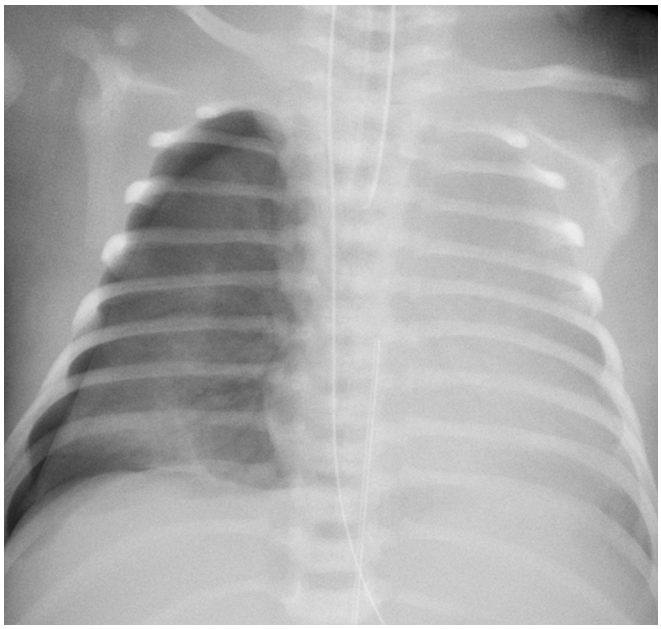
radiographic changes associated with RDS are often seen immediately after birth but can also develop over the first 6-12 hours of life. The radiographic abnormalities related to uncomplicated RDS should resolve by the time the neonate is 3-4 days old or sooner if surfactant therapy is given. Severe RDS on the initial radiograph in the first few hours of life has been proposed as predictive of continuous positive airway pressure failure in extremely low birth weight infants.[56] New diffuse worsening of bilateral opacities in the lungs may be seen with pulmonary edema or pulmonary hemorrhage. Sudden increase in focal opacity usually indicates atelectasis.

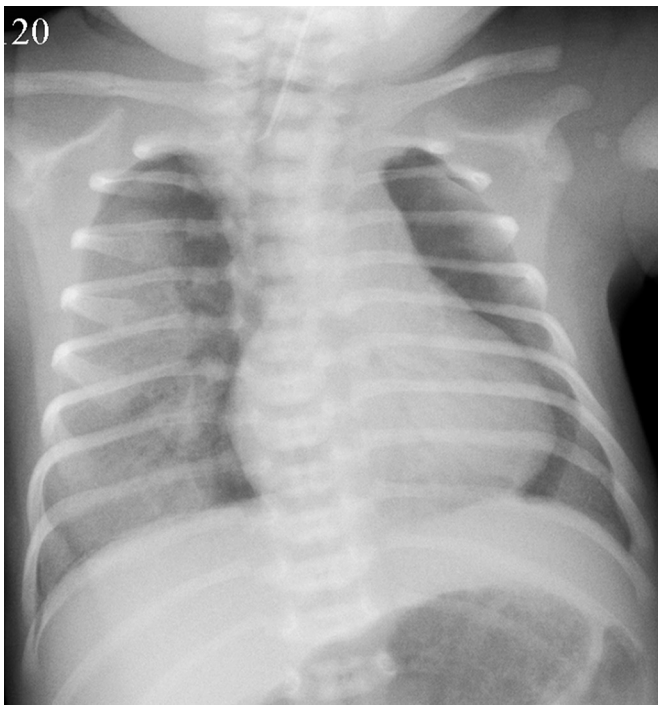
Chest radiography can be used to help assess the effectiveness of surfactant replacement therapy in infants with RDS. Lung ultrasound has also been proposed as a technique to differentiate RDS from transient tachypnea and possible need for surfactant therapy.[68] Typically, improvement in the appearance of the lungs is rapid and uniform after surfactant administration. In 80%-90% of neonates treated with surfactant, improvement occurs in one or both lungs. When there is a partial response, the improvement may be asymmetric or even restricted to one lung. Explanations for asymmetric radiographic improvement following surfactant therapy include (1) maldistribution of surfactant, (2) insufficient surfactant, and (3) regional differences in lung aeration before surfactant treatment. The absence of radiographic improvement after surfactant administration is a poor prognostic sign and suggests a diagnosis other than surfactant deficiency. Surfactant-related pulmonary hemorrhage may mimic RDS with focal or diffuse alveolar parenchymal disease.

Complications can result from the high distending pressures of mechanical ventilation that may be required in the treatment of RDS. Alveolar rupture from overdistention results in pulmonary interstitial emphysema (PIE). The radiographic appearance of PIE includes small, rounded or linear lucencies representing interstitial air coursing along the bronchovascular sheaths (Fig. 38.5). These meandering radiolucencies may be diffuse or localized. Larger focal air collections (pseudocysts) may also form in the interstitium of the lung. Pulmonary interstitial emphysema can dissect into the mediastinum or the pleural space, resulting in a pneumomediastinum or pneumothorax. Radiographic signs of pneumomediastinum include (1) lateral displacement of the mediastinal pleura; (2) continuous diaphragm sign; and (3) superior elevation of the thymus, which is referred to as the *spinnaker sail sign* or *angel wings* (Fig. 38.6). Radiographic findings of pneumothorax include (1) increased lucency, (2) identification of the visceral pleural line (Fig. 38.7), (3) increased sharpness of the adjacent mediastinal border or hemidiaphragm, and (4) visualization of a deep costophrenic sulcus. Pneumothoraces may be seen bilaterally (Fig. 38.8). Lateral decubitus or cross-table lateral radiographs can be useful in the detection of small pneumothoraces. Large pneumothoraces can produce tension, resulting in contralateral shift of mediastinal structures and depression or eversion of the ipsilateral hemidiaphragm.

• **Fig. 38.5** Pulmonary interstitial emphysema. Anteroposterior chest radiograph shows multiple rounded lucencies throughout the left lung secondary to interstitial emphysema.



• **Fig. 38.6** Pneumomediastinum. Anteroposterior chest radiograph shows superior displacement of the thymus (thymic sail sign).



Neonatal Pneumonia

Most neonatal pneumonias are of bacterial origin, including streptococci, *Staphylococcus aureus*, and *Escherichia coli*. These infections may be acquired in utero, during delivery, or after birth. Infection typically disseminates widely throughout the lungs because of incomplete formation of the interlobar fissures at this age. First described with group B streptococcus pneumonia, diffuse granular or ground-glass opacities are often seen and are indistinguishable from RDS. Alternatively, coarse nodularity or a streaky, hazy appearance of the lungs may be seen. The presence of

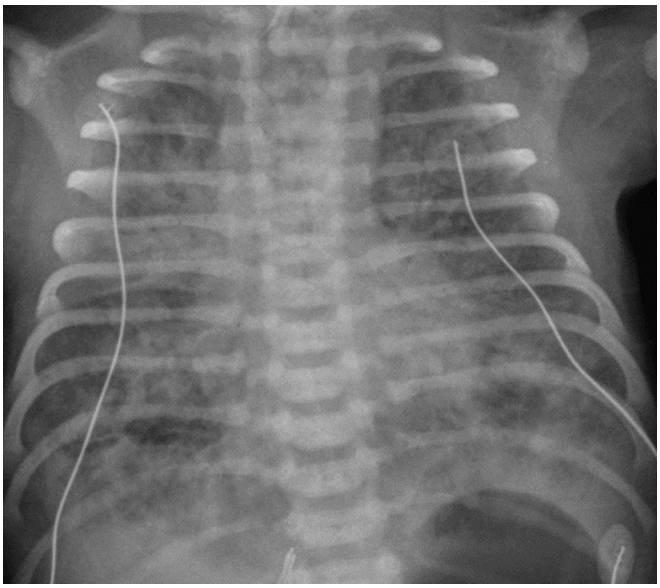
• **Fig. 38.7** Right pneumothorax. Anteroposterior chest radiograph. The visceral pleura and a deep right costophrenic sulcus are seen laterally; increased thoracic lucency is seen medially. Note there is complete opacification of the left hemithorax.



• **Fig. 38.8** Bilateral pneumothoraces. Anteroposterior chest radiograph shows increased thoracic lucency seen medially with increased sharpness of the mediastinal borders.

pleural fluid should raise the suspicion of bacterial infection, because effusions are uncommon in RDS or viral pneumonia.[24]

Transient Tachypnea of the Newborn

Transient tachypnea of the newborn (TTN) is associated with retained lung fluid that may be associated with precipitous delivery or cesarean section. Typically a clinical diagnosis, TTN has a varied and nonspecific appearance. The radiograph may appear normal or show streaky, perihilar opacities and hyperinflation. Small pleural effusions may also be seen. A normal heart size with TTN helps distinguish retained fluid from pulmonary edema or heart failure. The radiographic and clinical findings of TTN have a benign course, usually resolving within the first 24-48 hours of life.

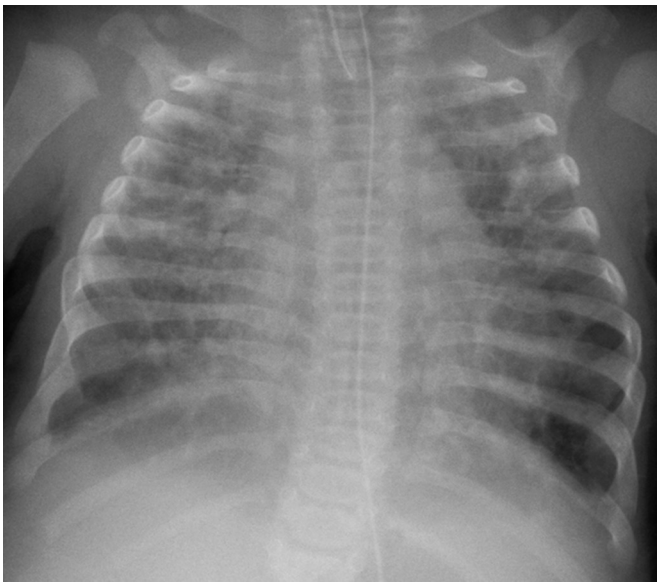
• **Fig. 38.9** Meconium aspiration. Anteroposterior chest radiograph demonstrates coarse, patchy opacities throughout both lungs.

Meconium Aspiration Syndrome

The expulsion of meconium before birth is often related to fetal distress leading to a hypoxia-induced vagal response. It typically occurs in full-term or postmature infants. Fetal aspiration of meconium causes obstruction of small airways with associated atelectasis and air trapping. Radiographic findings of meconium aspiration syndrome are seen within the first few hours of birth and include coarse, patchy, or nodular opacities and segmental hyperinflation (Fig. 38.9). The distribution of disease is bilateral and often asymmetric. Complications include chemical pneumonitis, surfactant inactivation, pulmonary hypertension, and air-leak phenomena such as pneumothorax and pneumomediastinum. Pleural effusion may be present.

Pulmonary Hemorrhage

Pulmonary hemorrhage in infants may result from hypoxia-induced capillary damage. In premature infants whose RDS is resolving and pulmonary vasorelaxation occurring, the resultant pulmonary overcirculation from a PDA may cause pulmonary hemorrhage. In addition to PDA, periventricular leukomalacia and seizures are known associations with pulmonary hemorrhage.[61] In intubated patients, the diagnosis is usually established by detecting blood in the endotracheal tube. The radiographic appearance of pulmonary



Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

hemorrhage is variable and nonspecific: small amounts of hemorrhage may not be visible, but more extensive hemorrhage results in focal or diffuse ground-glass opacities. Findings may mimic pneumonia or pulmonary edema. The radiographic changes from a single episode of pulmonary hemorrhage are usually transient, resolving within 24-48 hours.

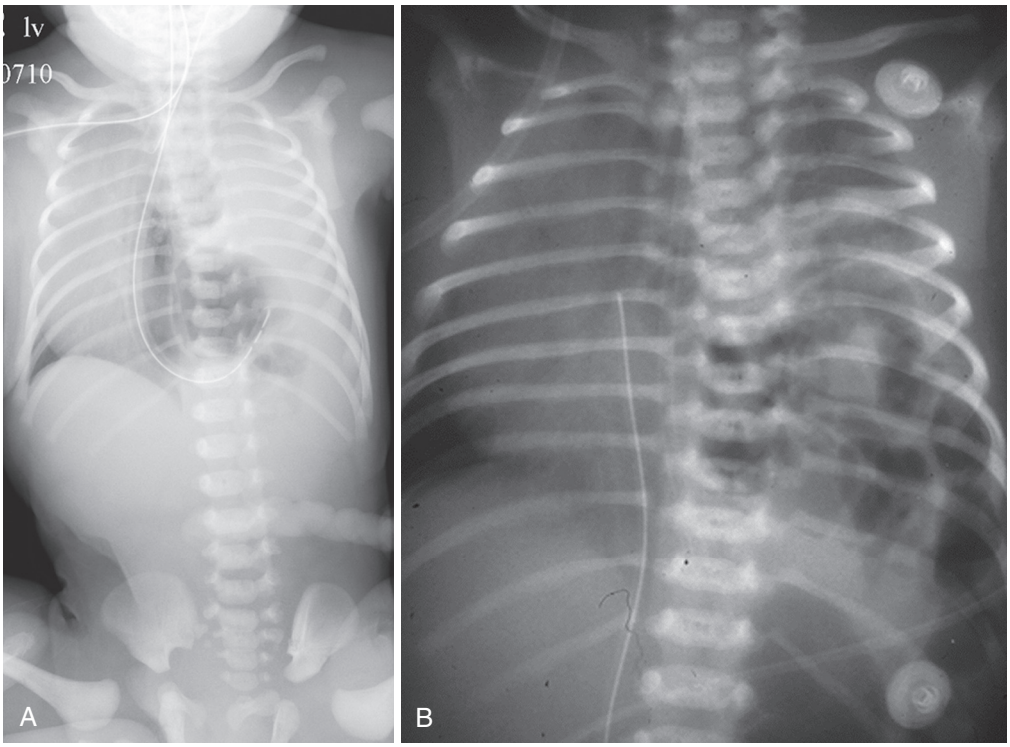
Bronchopulmonary Dysplasia

Chronic lung disease in the premature infant, known as bronchopulmonary dysplasia (BPD), is most often seen in very low birth weight infants. Bronchopulmonary dysplasia is also seen in higher birth weight infants following prolonged mechanical ventilation for conditions including neonatal pneumonia, meconium aspiration, and congenital cardiac disorders. The definitions of BPD are evolving and include both clinical and physiologic criteria.[20,37,64] Pathologically, BPD is considered to be part of the group of alveolar growth abnormalities and can be recognized on imaging. Because BPD is the result of injury and repair of the immature developing lung, the pathologic and radiologic findings are affected by changes in therapy and the degree of prematurity of the infant. Bronchopulmonary dysplasia was originally described as airway injury, obstruction, inflammation, and parenchymal fibrosis. Chest radiograph findings of the later stages of BPD included hyperinflated lungs, asymmetric, coarse, patchy opacities, and cystic emphysematous changes.[2,32]

The widespread adoption of antenatal glucocorticoid administration, postnatal surfactant therapy, and refinement of assisted ventilation have decreased lung injury from oxygen toxicity and barotrauma.[22,40] Bronchopulmonary dysplasia is now rarely seen among infants of gestational age greater than 30 weeks or birth weight over 1200 grams. Modern therapies have also allowed an increased survival of very low birth weight infants. Despite the absence of prior severe RDS or barotrauma, these less mature infants often have a more insidious development of BPD, known as the "new" BPD. Arrested lung development leading to decreased alveolar and microvascular growth is thought to contribute to this condition. Radiographic and CT findings range from near normal to disordered lung architecture with hyperlucent areas, linear and subpleural opacities, and bullae typical of chronic lung disease (Fig. 38.10)[6,22,43] (see Chapter 69).

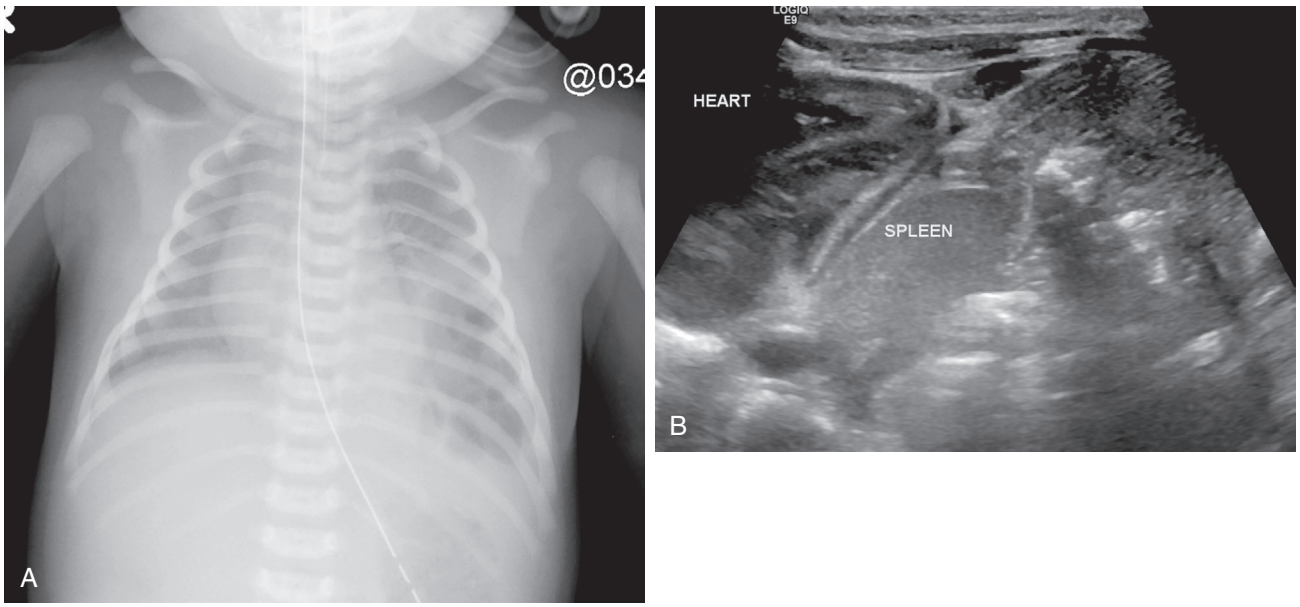
• **Fig. 38.10** Bronchopulmonary dysplasia. Anteroposterior chest radiograph shows diffuse, coarse parenchymal opacities.

Respiratory Disease: Surgically Treated



Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) is a complex life-threatening lesion caused by defective fusion of the pleuroperitoneal membranes during embryologic development. Patent pleuroperitoneal canals located posterolaterally are known as the foramina of Bochdalek. Bowel and solid organs may herniate through the foramen into the hemithorax, most commonly on the left side. At birth, the herniated bowel loops may be fluid-filled, making radiographic diagnosis difficult. Eventually, gas-filled bowel loops are seen in the thorax with a paucity of bowel loops in the abdomen (Fig. 38.11). The ipsilateral lung is almost universally hypoplastic, and there is usually contralateral shift of the mediastinum, resulting in contralateral lung hypoplasia. However, partial aeration of the ipsilateral lung with a smaller hernia may also occur and may be difficult to distinguish from complete eventration (Fig. 38.12). In such cases, ultrasound can be used to evaluate for continuity of the hemidiaphragm. Prenatal sonography and fetal MRI (Fig. 38.13) allow early diagnosis and may predict neonatal survival by evaluating the degree of pulmonary hypoplasia and defining associated anomalies.[58]



Congenital Pulmonary Airway Malformations

Congenital pulmonary airway malformations (CPAMs), previously known as congenital cystic adenomatoid malformations (CCAMs), are a group of congenital, hamartomatous cystic, and noncystic lung masses characterized by overgrowth of the primary bronchioles and a proximal communication with a defective bronchial tree.[11,38,39,66] The new terminology has been recommended because not all lesions are cystic and only one is adenomatoid. Stocker updated the classification system to include five types (0-4) based on cyst size and similarity to segments of the developing bronchial tree and air spaces: *Type 0* is acinar dysplasia of tracheal or bronchial origin and is incompatible with life. *Type 1*, the most common, has a single or multiple large cysts (>2 cm) of bronchial or bronchiolar origin; *type 2* has a single or multiple small cysts (≤2 cm) of bronchiolar origin; *type 3* is predominantly solid with microcysts (<0.5 cm) of bronchiolar-alveolar duct origin; and *type 4*, characterized by large air-filled cysts, has a distal acinar origin and is indistinguishable from pleuropulmonary blastoma on imaging. Congenital pulmonary airway malformation can also be

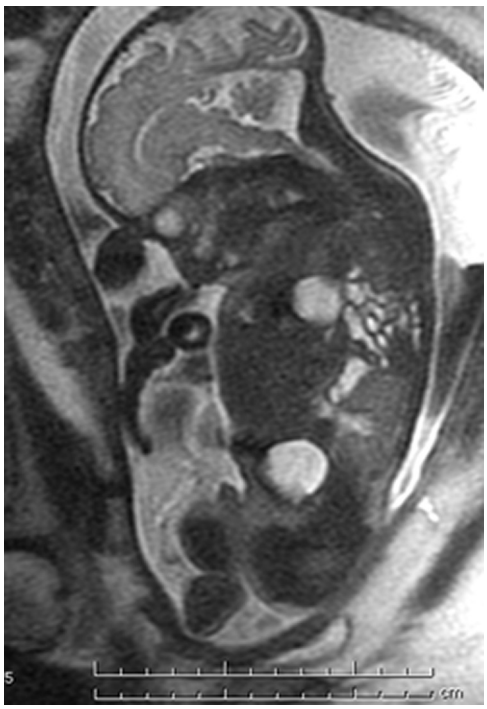
• **Fig. 38.11** Congenital diaphragmatic hernia. **A,** Anteroposterior radiograph shows a gas-filled stomach and central bowel loops in an otherwise opacified left hemithorax. **B,** Left hemithorax shows gas-filled bowel loops. There is a mediastinal shift from left to right in both cases.

• **Fig. 38.12** Congenital diaphragmatic hernia. **A,** Anteroposterior radiograph shows gas-filled bowel in the lower left hemithorax with preserved aeration of a portion of the left lung. **B,** Sagittal sonographic image shows herniation of spleen into the chest.



seen in association with other foregut anomalies, most commonly pulmonary sequestration.[11]

Prenatal sonography and fetal MRI classifies CPAMs mainly based on the presence of macrocysts or microcysts.[21] At birth, chest radiography and CT may show a range of findings from large single or multiple air-filled cystic structures to solid lesions that resemble consolidation (Fig. 38.14*A* and *B*). Because of the association of CPAMs with sequestration, precise vascular mapping is essential. Ultrasound may be useful in identifying an abnormal vascular systemic supply typical of sequestration (see Fig. 38.14*C*). However, CT angiography with 2D and 3D reconstructions provides the most accurate assessment of the lung parenchymal and vascular anatomy of these lesions.

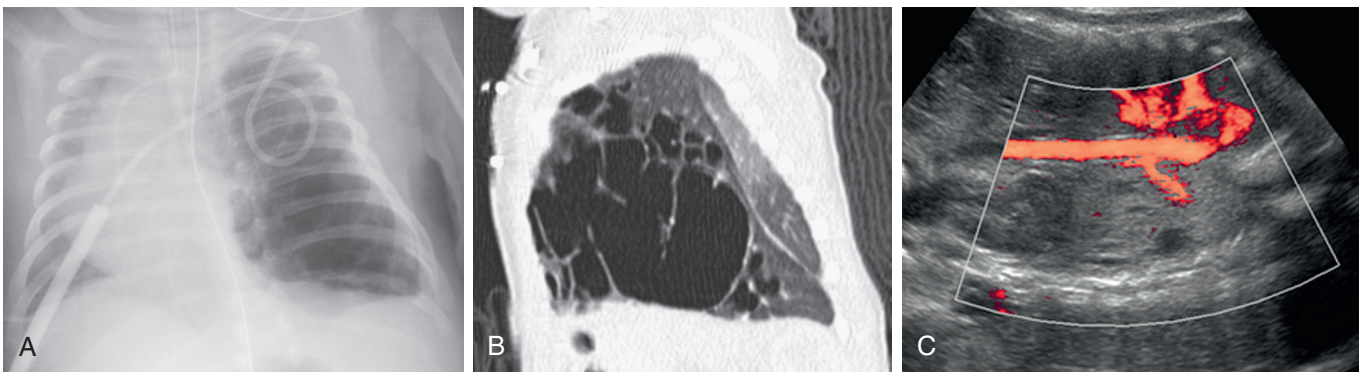
Congenital Lobar Overinflation

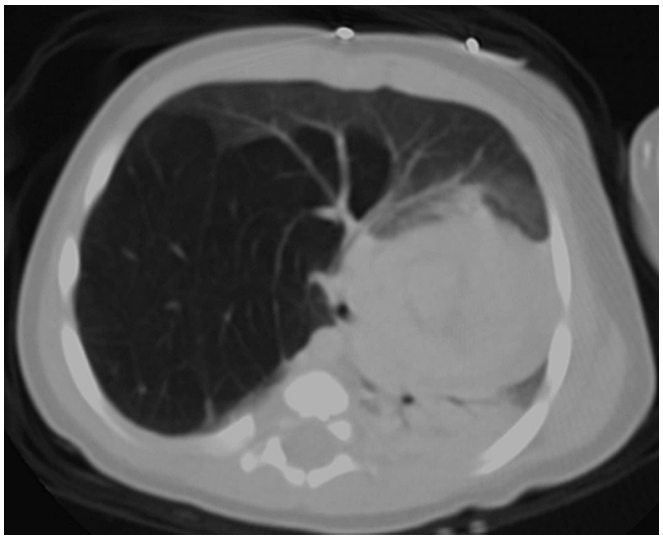
Congenital lobar overinflation (CLO) or emphysema is a condition characterized by progressive overinflation of one or more pulmonary lobes. This may be caused by intrinsic bronchial narrowing from weak or absent bronchial cartilage or may be caused by extrinsic bronchial narrowing from mass effect of adjacent structures. The collapsed bronchus can result in one-way valve obstruction causing air trapping and progressive distention of the distal airways in the affected lobe.[11,39] Congenital lobar overinflation most commonly affects the left upper lobe, followed by the right middle lobe and the right upper lobe. At birth, the involved lobe may be radiographically opaque because of retained lung fluid. When the fluid clears, imaging demonstrates progressively increased volume, hyperlucency, and attenuated vascular markings of the involved lobe with compression of the remaining ipsilateral lung and mediastinal shift (Fig. 38.15).[11] CT more precisely characterizes these findings and can distinguish multilobar involvement. CT is also helpful in excluding causes of extrinsic bronchial compression such as vascular anomalies or mediastinal masses (see Chapter 66).



• **Fig. 38.13** Congenital diaphragmatic hernia. Sagittal fetal MRI shows multiple fluid-filled bowel loops and stomach in the left hemithorax.

Esophageal Atresia and Tracheoesophageal Fistula

The pairing of the terms esophageal atresia and tracheoesophageal fistula (TEF) describes a disorder in formation and separation of the primitive foregut and esophagus. A spectrum of malformations is noted, ranging from esophageal atresia (with or without a proximal or distal tracheoesophageal fistula) to a tracheoesophageal fistula without esophageal atresia. The most common type, involving proximal esophageal atresia with a distal tracheoesophageal fistula, accounts for more than 80% of cases. With this type, a blind-ending, air-filled proximal esophageal pouch is noted on a chest radiograph (Fig. 38.16). The presence of a distal fistula is supported by air in the gastrointestinal tract. An esophagram can be performed to evaluate for a fistulous tract. Tracheoesophageal fistula is associated with multisystem abnormalities in approximately one-third of cases, including vertebral, cardiac, renal, and limb anomalies as well as other gastrointestinal tract atresias. All infants with a tracheoesophageal abnormality should undergo additional imaging evaluation to assess for associated anomalies.



Heart

Cardiac disease in infants is usually congenital in origin. Chest radiography rarely leads to a specific diagnosis and is primarily used to exclude pulmonary conditions as a cause of respiratory distress. Echocardiography, the primary initial imaging modality, may incompletely define extracardiac

• **Fig. 38.14** Congenital pulmonary airway malformation. **A,** Anteroposterior chest radiograph demonstrates a multicystic mass in the left lung, resulting in mediastinal shift and compression of the right lung. **B,** Sagittal chest CT shows a large parenchymal multicystic mass anteriorly in the left lung. **C,** Longitudinal Doppler color fetal sonography demonstrates systemic supply from the aorta to a lung mass, representing a hybrid lesion.

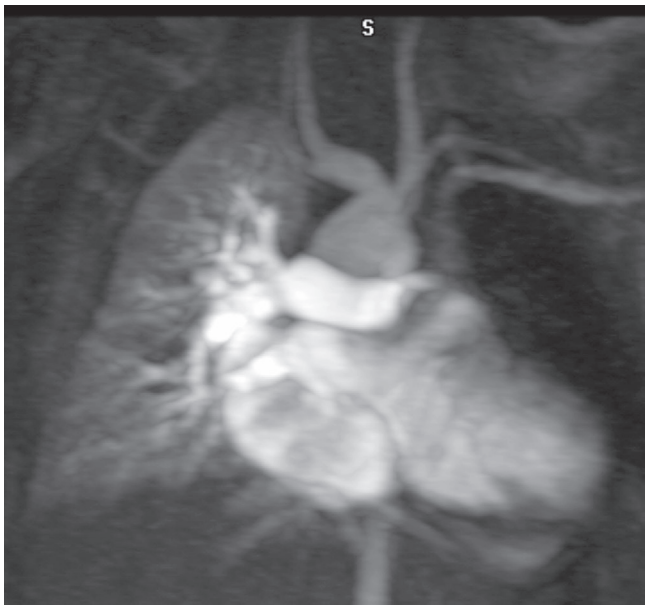
vasculature and associated airway involvement. CT angiography (CTA) and cardiac MRI (CMRI) complement echocardiography by illustrating these important structures as well as providing functional information.

Great variability in cardiac size is found in congenital heart anomalies. Cardiomegaly is present in neonates with large left-to-right shunts, Ebstein anomaly, hypoplastic left heart syndrome, and cardiomyopathy. Alternatively, cardiomegaly may be seen transiently in the absence of cardiac

• **Fig. 38.17** 3D CT angiogram shows a double aortic arch with mirror image branching; the dominant right arch is larger than the left.



disease with hypoglycemia, hypocalcemia, severe anemia, or in infants of diabetic mothers. Enlargement of specific cardiac chambers cannot be accurately assessed by chest radiography.

In cyanotic congenital heart disease, the caliber of the pulmonary arteries is reduced, the hila appear small, and the lungs may appear more lucent. However, it is difficult to differentiate normal from small pulmonary vessels by chest radiography. Persistent pulmonary hypertension may mimic cyanotic congenital heart disease, both clinically and radiographically, because of cardiomegaly and pulmonary oligemia.

Radiography is useful in diagnosing increased pulmonary arterial vascularity associated with large left-to-right shunts seen in infants with patent ductus arteriosus, ventricular septal defect, atrial septal defect, and endocardial cushion defect. Increased pulmonary arterial vascularity becomes visible on a CXR when the ratio of left-to-right shunt is greater than 3:1. Increased branching linear shadows will be seen in the perihilar region, and vascular markings will be seen in the periphery of the lung fields. The pulmonary arterial vascularity usually appears normal with shunts of a lesser degree (see Chapter 72).

CT is particularly useful in evaluation of aortic arch anomalies (coarctation of the aorta, interrupted aortic arch, and vascular ring or sling) (Fig. 38.17), pulmonary artery anomalies (pulmonary artery stenosis and aorticopulmonary collaterals), anomalies of pulmonary venous return (anomalous pulmonary venous return and pulmonary vein stenosis), coronary artery anomalies, extracardiac anatomy (pericardial masses, airway compression and parenchymal

• **Fig. 38.18** Postoperative CMRI shows persistent severe left pulmonary artery (LPA) stenosis in infant with tetralogy of Fallot; no flow is seen to the left lung from the LPA.

disease), and postoperative evaluation after surgery.[23] Indications for CMRI include: cardiac chamber volume, mass, and functional analysis; cardiac morphologic analysis in complex congenital heart disease; soft tissue characterization of cardiac masses and tumors; hemodynamic analysis of pulmonary to systemic blood flow, ejection fraction, and valvular stenosis and regurgitation; and postoperative assessment (Fig. 38.18).[23]

Gastrointestinal Tract

Intestinal obstruction is the most common abdominal emergency in the newborn period. Neonatal obstruction is typically characterized as high, occurring proximal to the distal ileum, or low, involving the distal ileum or colon.[63] The clinical presentation of infants with high and low intestinal obstruction may overlap with symptoms of abdominal distention, vomiting, and poor feeding. Low obstructions are often characterized by failure to pass meconium.

Abdominal radiographs are the initial imaging examination of choice to distinguish between high and low intestinal obstructions. Radiographs in infants with high intestinal obstruction typically show few dilated bowel loops (Fig. 38.19), whereas radiographs in infants with low obstruction show many dilated bowel loops (Fig. 38.20). When bowel obstruction is present, the dilated bowel loops become elongated and are stacked in a parallel configuration. The distinction between high and low intestinal obstruction dictates the type of imaging that the infant may need. With a high obstruction, the upper gastrointestinal series (UGI) is the examination of choice. Infants with a suspected low obstruction are typically evaluated with a water-soluble contrast enema.[29]

• **Fig. 38.19** High intestinal obstruction. Supine abdominal radiograph demonstrates a few dilated proximal small bowel loops and absence of distal bowel gas.

• **Fig. 38.20** Low intestinal obstruction. Supine abdominal radiograph demonstrates multiple dilated bowel loops.

As with all radiologic examinations, proper positioning is important because even a small degree of patient rotation may distort anatomic landmarks.

High Intestinal Obstruction

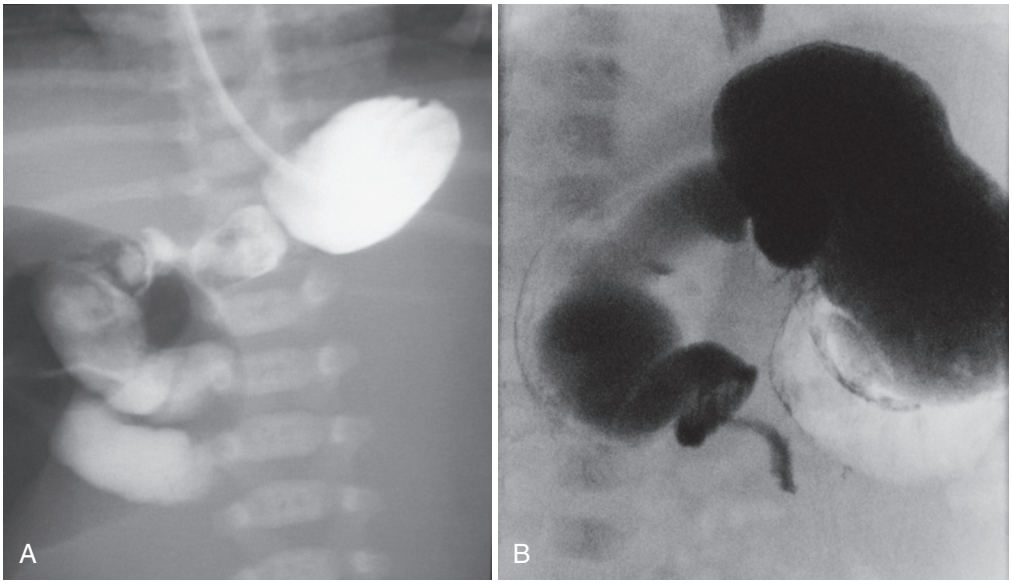
Midgut Malrotation

Midgut malrotation is the most important cause of upper intestinal obstruction. Abnormal in utero rotation of the

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

midgut results in abnormal mesenteric fixation and a short mesenteric base that may allow twisting of the bowel and mesentery around the axis of the superior mesenteric artery. Midgut volvulus can lead to vascular compromise, bowel ischemia, and necrosis. Most infants with malrotation present with bilious vomiting. Up to 75% of patients present in the first month of life.[55] Bilious vomiting in an infant should be considered a potential surgical emergency and, in the absence of another defined cause, evaluation for midgut malrotation should be performed.

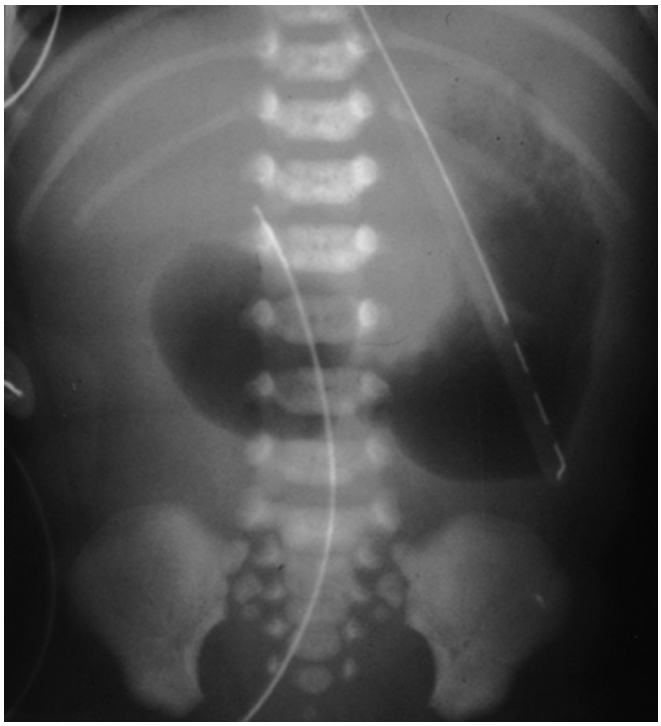
The diagnosis of midgut malrotation by imaging is challenging and the findings variable.[5,55] The abdominal radiographic findings may be normal in infants with malrotation. A high obstruction pattern may be seen in the setting of abnormal peritoneal attachments (Ladd bands) or midgut volvulus. Dilatation of multiple bowel loops may indicate volvulus-induced ischemia. The diagnostic examination of choice is the UGI. The location of the duodenum seen on this study is predictive of the mesenteric attachment. Normally, the third portion of the duodenum (D3) courses posteriorly in the retroperitoneum, crossing the midline to reach the duodenal-jejunal junction (DJJ). This junction is normally located to the left of midline and at the level of the pyloric channel. An abnormal course of the duodenum and abnormal location of the DJJ is diagnostic of midgut malrotation (Fig. 38.21A). A spiral or corkscrew appearance of the duodenum and jejunum indicates midgut volvulus (Fig. 38.21*B*). The wrapping of the superior mesenteric artery around the superior mesenteric vein, known as the "whirlpool sign," is specific for the diagnosis of midgut volvulus.[47,57]



Cross-sectional imaging with sonography or CT has been proposed as an alternative method to diagnose midgut malrotation by identifying the anatomic location of D3 and its relationship to the superior mesenteric vessels. However, a normal retroperitoneal position of D3 does not exclude malrotation, and the relationship of the mesenteric vessels is highly variable and unreliable.[59] Because of the lack of sensitivity or specificity of cross-sectional imaging, UGI remains the gold standard for diagnosing.

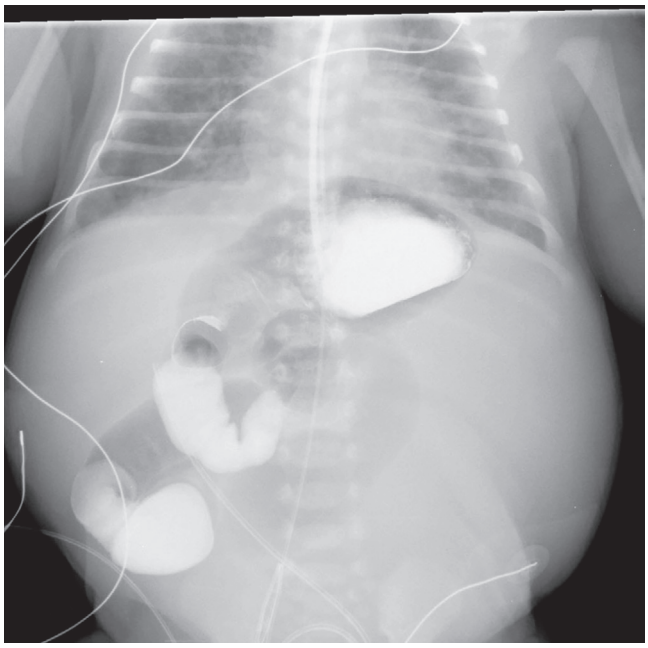
Duodenal Atresia

Duodenal atresia is the most common cause of high intestinal obstruction in the newborn. It occurs more commonly than duodenal stenosis or web and results from congenital failure of recanalization of the duodenum during embryologic development. Because the majority of cases occur distal to the ampulla, infants often present with bilious vomiting. Associated abnormalities include Down syndrome, congenital heart disease, and other gastrointestinal anomalies. Abdominal radiography typically shows gastric distention and a dilated duodenal bulb referred to as the *double bubble* sign (Fig. 38.22). These findings are diagnostic for duodenal atresia, and when they are present, no further study is necessary.[63]



Jejunal Atresia

Jejunal atresia results from an ischemic injury to the developing small intestine. The injury may result from a primary vascular accident or a mechanical obstruction, such as an in utero volvulus. Newborns with jejunal atresia present with bilious emesis and abdominal distention. Abdominal radiographs typically demonstrate dilated small bowel loops that may contain air-fluid levels indicative of a mid–small bowel obstruction. A *triple bubble* sign may be seen, characterized by dilation of the stomach, duodenum, and



• **Fig. 38.21** Midgut malrotation. Spot film from an upper gastrointestinal series shows (A) an abnormal location of the duodenal-jejunal junction and (B) midgut volvulus with partial obstruction and corkscrew appearance of the duodenum.

• **Fig. 38.22** Duodenal atresia. Supine abdominal radiograph demonstrates a "double bubble," representing a dilated stomach and duodenum.

• **Fig. 38.23** Jejunal atresia. Supine abdominal radiograph shows barium opacification of the stomach, duodenum, and proximal jejunum with no distal gas.

proximal jejunum. UGI will show obstruction in the proximal jejunum (Fig. 38.23). Since there may be additional sites of atresia in these patients, contrast enema is usually performed prior to surgical repair to define the anatomy of the distal bowel.[63]

• **Fig. 38.24** Hirschsprung disease. Lateral view from a contrast enema demonstrates a transition zone. The more proximal colon is dilated, whereas the caliber of the distal, aganglionic segment is mildly contracted.

Low Intestinal Obstruction

Hirschsprung Disease

Hirschsprung disease (HD) is characterized by the absence of distal enteric ganglion cells. This is caused by an arrest of the craniocaudal migration of neural crest cells during embryologic development, resulting in a failure of normal colorectal relaxation and functional obstruction. Most infants present in the first six weeks of life with abdominal distention, constipation, vomiting, and occasionally diarrhea. The condition is more common in male than female infants. Abdominal radiographic findings in HD are usually nonspecific with variable dilation of bowel and frequent absence of air in the rectum.

The diagnostic imaging examination of choice in patients with suspected HD is a water-soluble contrast enema. A contrast enema may also be therapeutic since the water-soluble contrast promotes the passage of meconium. A small, soft catheter should be used without inflation of a catheter balloon so as not to obscure a transition zone. The lateral view best demonstrates the transition zone between normal, dilated proximal colon and the contracted aganglionic distal segment (Fig. 38.24). The transition zone is most commonly located in the rectosigmoid region. Tubular filling defects may be noted in the colon, representing meconium or stool. The affected aganglionic segment always includes the rectum and extends proximally to involve a variable length of colon without skip areas. Although contrast enema is diagnostic in the majority of patients, the

transition point identified by imaging does not always correlate with the pathologic extent of aganglionic colon.[31]

Approximately 5% of patients have total colonic aganglionosis and demonstrate a diffusely small-caliber colon (microcolon) without a transition zone. As some infants have a normal contrast enema, a rectal biopsy should be performed in patients where there is a high clinical suspicion for HD.

Functional Immaturity of the Colon

Functional immaturity of the colon, also known as *meconium plug syndrome* or *small left-colon syndrome*, is a benign transient functional obstruction of the colon seen in the newborn period. It is thought to be associated with immaturity of the myenteric plexus ganglia. There is an increased incidence with a history of maternal diabetes mellitus, preeclampsia treated with magnesium sulfate, and prematurity. Functional immaturity of the colon is the most common diagnosis in newborns who fail to pass meconium in the first 48 hours.[63] Abdominal radiography shows a low bowel obstruction with or without air-fluid levels. Water-soluble contrast enema shows tubular filling defects representing meconium plugs. The caliber of the colon is variable; it may be normal in its entirety, or there may be a dilated proximal colon with a small-caliber left colon distal to the level of the splenic flexure and a normal caliber rectum (Fig. 38.25). The diagnostic contrast enema is often also therapeutic in these patients, as it helps to evacuate residual meconium, and resolving the obstruction.

Meconium Ileus

Meconium ileus is caused by abnormal meconium inspissation in the distal ileum and is the earliest clinical manifestation of cystic fibrosis.[63] The abnormally thick meconium in these infants results in a distal small bowel obstruction. Meconium ileus may be complicated by in utero volvulus or perforation with peritonitis. Abdominal radiography demonstrates multiple dilated small bowel loops often without air fluid levels. A "soap bubble" appearance of rounded foci of gas may be noted in the right side of the abdomen. Calcified meconium resulting from meconium peritonitis can be seen in the abdomen and scrotum. Water-soluble contrast enema should be performed in infants suspected of having meconium ileus. The enema typically demonstrates a microcolon (Fig. 38.26). The contrast enema may have a therapeutic effect in some infants, particularly if contrast refluxes into the distal ileum filled with inspissated meconium.[63]

Ileal Atresia

Ileal atresia may be caused by a vascular accident similar to jejunal atresia or may result from other gastrointestinal anomalies such as meconium ileus. Abdominal radiographs in neonates with ileal atresia usually show a low intestinal obstruction pattern. Contrast enema demonstrates an unused microcolon and may be diagnostic if reflux of contrast into the distal ileum demonstrates the level of the atresia.

Anorectal Malformation

Anorectal malformations (ARM) result from improper descent of the hindgut and are associated with vertebral,

• **Fig. 38.25** Small left colon syndrome. Contrast enema demonstrates a small-caliber descending colon. Multiple filling defects throughout the colon are caused by meconium plugs.

• **Fig. 38.26** Meconium ileus with microcolon. Contrast enema demonstrates a microcolon. Filling defects in the terminal ileum are caused by inspissated meconium.

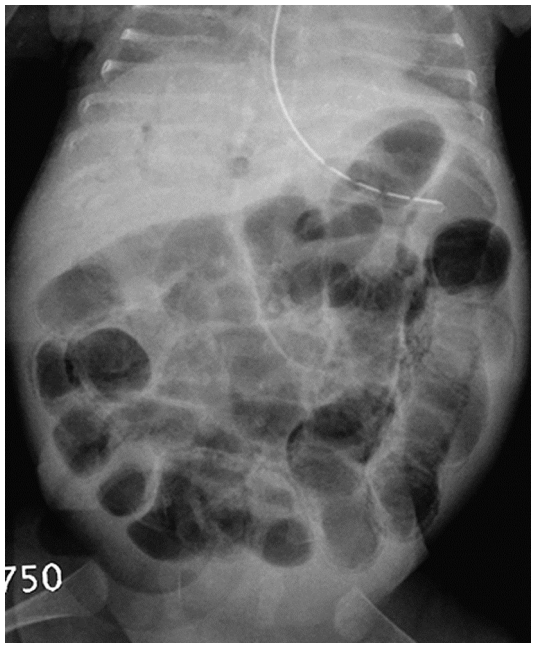
cardiac, renal, and limb anomalies. The level of obstruction is characterized as high or low if the obstruction is above or below the puborectalis sling. In the infant with an ARM, imaging plays a significant role in treatment planning.[3] Radiographs of the chest, spine, and pelvis may show osseous anomalies. Perineal ultrasound is used to evaluate the location of the distal pouch in patients suspected of having a high type. Distal contrast study is helpful in patients with intermediate to high ARM who have undergone colostomy as this defines the location of the rectum and can demonstrate fistulae. Pelvic MR can also define the location of the rectal pouch as well as the size, morphology, and degree of development of the sphincteric muscles prior to surgical repair.[59a]

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC), seen predominantly in premature infants, is the most common acquired gastrointestinal emergency in the neonatal intensive care unit. Infants usually present with abdominal distention, abdominal tenderness, feeding disturbance, and guaiac-positive stools.

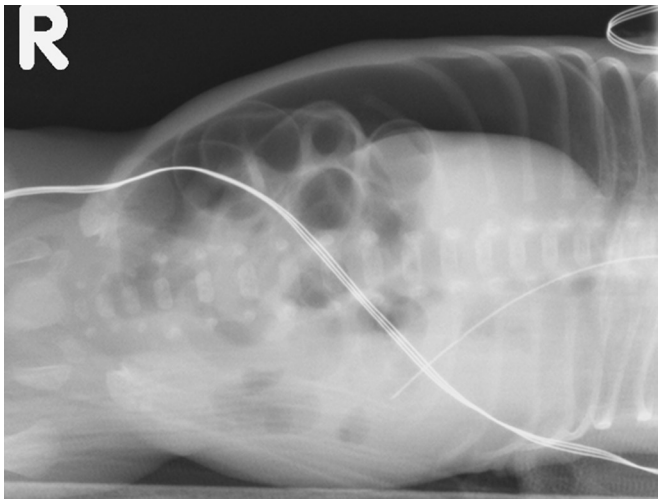
Abdominal radiography plays an important role in the diagnosis of NEC. Early radiographic findings of NEC are nonspecific and include bowel dilation and rounded or elongated loops. Focal or asymmetric distribution of fixed bowel dilation may be seen. As the disease progresses, the intramural gas—specific for pneumatosis intestinalis—is seen.



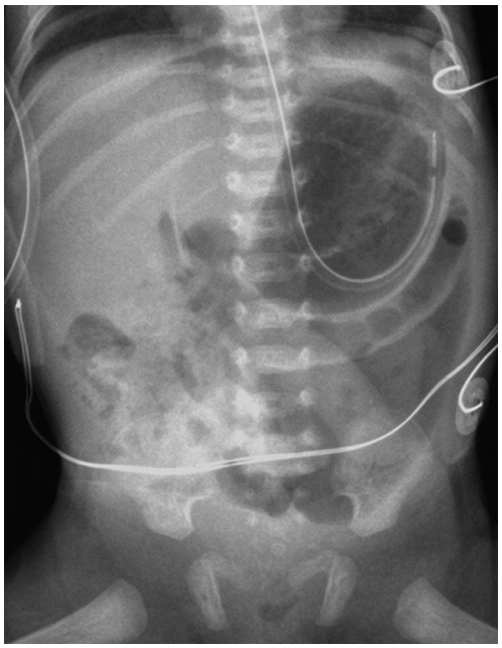
Radiographically, pneumatosis intestinalis appears as a "bubbly" pattern or as curvilinear lucencies (Fig. 38.27). This can be difficult to differentiate from stool. Pneumatosis is most commonly seen in the right lower quadrant. Intramural gas may extend into the veins of the bowel wall and then into the portal venous system. Portal venous gas is seen in the porta hepatis as branching, linear lucencies overlying the liver (Fig. 38.28) and is typically a later finding in more severe cases of NEC. Like intramural gas, this finding may be transient and may not correlate with severity of clinical disease.

Once the diagnosis of NEC is established, serial imaging is performed to evaluate for the complication of bowel perforation. A cross-table lateral radiograph or left lateral decubitus radiograph of the abdomen (left side down) is performed to assess for free intraperitoneal air (Fig. 38.29). Free air collects in the least dependent portion of the abdomen and is seen as lucencies between bowel loops just beneath the abdominal wall or as collections of gas between the liver and adjacent bowel wall. On the supine view, large amounts of peritoneal air give rise to the "football" sign, where air outlines the superior abdomen with the falciform ligament, creating the appearance of the lacing of a football (Fig. 38.30).

Sonography has been used in the evaluation of NEC.[53] Pneumatosis intestinalis is seen as fixed hyperechoic foci in a thickened, ill-defined bowel wall that has abnormal vascularity. Portal venous gas is seen as intraluminal echogenic foci within the liver (Fig. 38.31). The presence of focal peritoneal fluid collections or free peritoneal fluid containing internal echoes correlates with bowel perforation and abscess formation or peritonitis.



• **Fig. 38.27** Necrotizing enterocolitis (NEC) with pneumatosis intestinalis. Supine abdominal radiograph demonstrates dilated bowel and diffuse bubbly and curvilinear lucencies.



• **Fig. 38.28** Necrotizing enterocolitis (NEC) with portal venous air. Supine abdominal radiograph demonstrates linear lucencies overlying the liver representing portal air. Also note dilated bowel and diffuse pneumatosis intestinalis.

• **Fig. 38.29** Pneumoperitoneum. Left lateral decubitus view of the abdomen demonstrates a large extraluminal air collection.

• **Fig. 38.30** Pneumoperitoneum. Anteroposterior view of the abdomen shows a large rounded collection of extraluminal air in the upper abdomen (football sign).

• **Fig. 38.31** Portal venous air. Sonogram of the liver demonstrates multiple echogenic foci within the liver, representing portal venous gas.

• **Fig. 38.32** Colonic stricture after necrotizing enterocolitis (NEC). Image from a contrast enema examination demonstrates focal narrowing at the splenic flexure, representing a focal stricture.

A delayed complication of NEC is bowel stricture, representing the sequela of necrotic areas of bowel wall. Strictures occur in 20%-30% of survivors of NEC. Strictures may be single or multiple and are usually located in the colon at the level of the splenic flexure. Water-soluble contrast enema is useful for identifying these sites of focal narrowing (Fig. 38.32) (see Chapter 85).

Hepatobiliary Tract

Biliary Atresia

The underlying abnormality in biliary atresia is obliteration of the extrahepatic biliary tree with progressive obliteration of portions of the intrahepatic biliary tree. Biliary atresia is associated with other abnormalities, including choledochal cyst, polysplenia, preduodenal portal vein, cardiac and pulmonary malformations, azygous continuation of the inferior vena cava, and malrotation.[4,33,51] Infants present with jaundice soon after birth. A frequent clinical challenge is to differentiate biliary atresia from idiopathic neonatal hepatitis as both present with conjugated hyperbilirubinemia. The principal difference between the two entities is that there is patency of the biliary tree in infants with idiopathic neonatal hepatitis.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

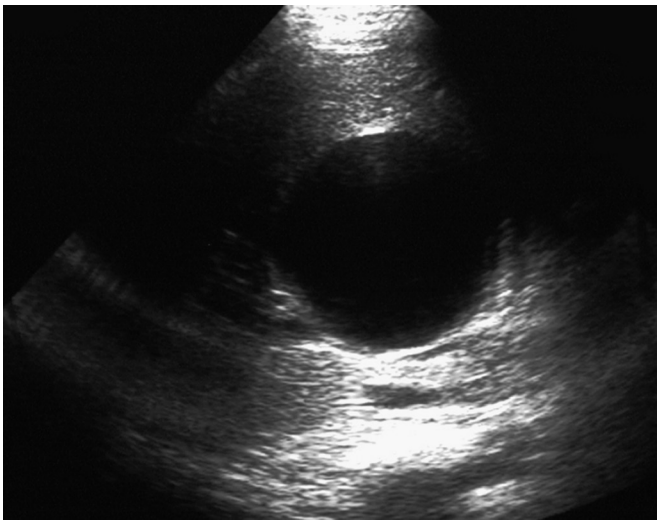
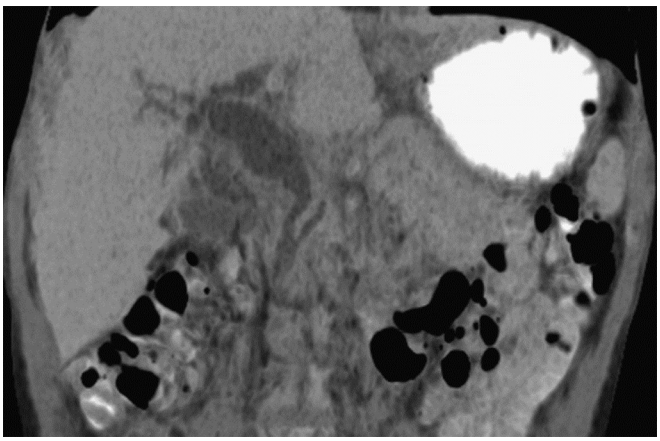
Sonography is the initial imaging examination for neonatal conjugated (direct) hyperbilirubinemia, as it can identify alternative etiologies such as choledochal cyst, biliary sludge, and cholelithiasis. The most specific sonographic finding for biliary atresia is the triangular cord sign.[51] This thickening of the anterior wall of the right portal vein represents the fibrous remnant of the bile duct within the hepatic hilum. The gallbladder is not identified in approximately 80% of patients and is usually small, with an abnormal shape and abnormal wall in the remainder.[7] Hepatic parenchymal echogenicity may also be abnormal. When the gallbladder is present, sonography performed before and after oral feeding can help differentiate biliary atresia from idiopathic neonatal hepatitis. In biliary atresia, the gallbladder is not affected by oral feeding, whereas contraction of the gallbladder is seen in idiopathic neonatal hepatitis.[51] However, in most cases of biliary atresia, the sonographic findings are nonspecific.



Hepatobiliary scintigraphy is a highly sensitive examination used to diagnose biliary atresia.[33,41] The infant is pretreated with phenobarbital to enhance hepatocellular function and improve specificity. Gastrointestinal excretion of the administered isotope excludes biliary atresia, whereas lack of excretion of isotope by 24 hours is highly suggestive of the condition (see Chapter 91).

Choledochal Cyst



A choledochal cyst represents cystic dilation of the extrahepatic or intrahepatic biliary tree and is a rare cause of neonatal cholestatic jaundice.[34] Biliary atresia should always be ruled out in these infants given the association of these entities and similar clinical presentations.[51] Choledochal cysts are classified on the basis of their location, morphology, and the number of cysts. The most widely used classification system is by Todani and colleagues.[60] Ultrasound is the initial imaging method used to evaluate the size and location of the cyst and to evaluate for additional cystic changes of the biliary tree. The sonographic appearance includes a focal, rounded, thin-walled cyst (Fig. 38.33); fusiform dilation of the common bile duct; or cystic segments of the intrahepatic biliary tree (Fig. 38.34). Magnetic resonance cholangiography is now the gold standard for the evaluation of choledochal cysts, as these images confirm the biliary origin of the cyst and assist with preoperative planning.

Cholelithiasis

Approximately 10% of all cases of gallstones in children occur in the first 6 months of life. Neonatal cholelithiasis is associated with total parenteral nutrition, furosemide therapy, dehydration, infection, hemolytic anemia, and short-gut syndrome. Neonates who undergo parenteral nutrition are at greatest risk, and gallstones have been reported in up to 40% of such infants. The typical sonographic appearance of a gallstone is a rounded, mobile, echogenic focus within the gallbladder.

• **Fig. 38.33** Choledochal cyst. Transverse sonogram through the porta hepatis demonstrates focal cystic dilation of the biliary tree.

• **Fig. 38.34** Choledochal cyst. Coronal cross-sectional image of the liver shows fusiform dilation of the biliary tree.

Hepatic Calcifications

Isolated hepatic calcifications are relatively common in the fetal liver during prenatal sonography and may persist in the neonatal period. Neonatal calcifications may be solitary or multiple and are usually idiopathic. Intrauterine infections such as cytomegalovirus, toxoplasmosis, rubella, herpes, syphilis, and varicella can result in both hepatic calcifications and ascites. Hepatic calcifications can also be seen in congenital malformations and aneuploidy. Subcapsular calcifications may be caused by emboli from the portal or hepatic veins. These may result from umbilical venous catheter complications.[54] Perihepatic calcifications may be secondary to meconium peritonitis.

Liver Tumors

Benign liver tumors are more common than malignant liver tumors in the neonate. The most common benign tumors are hemangiomas and hemangioendotheliomas. Often first

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

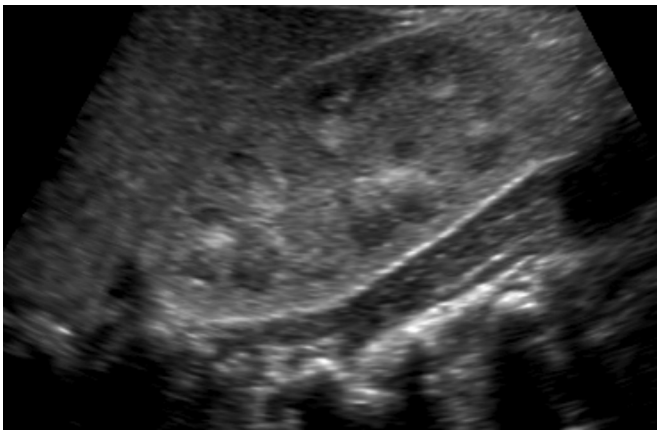
diagnosed by sonography, MRI is the imaging examination of choice for optimal characterization of these lesions. They appear hypointense on T1-weighted images and hyperintense on T2-weighted images with avid centripetal contrast enhancement. Infantile hemangioma cells test positive for the glucose transporter protein isoform 1 (GLUT-1). They undergo a rapid proliferative phase followed by a slow involuting phase.[16] Primary malignant hepatic neoplasms are unusual in infants. Hepatoblastoma, the most common malignant neoplasm, may appear as either a solitary mass or a multifocal or infiltrative lesion. The most common metastatic tumor of the liver is neuroblastoma. Computed tomography or MRI are used to evaluate these tumors.

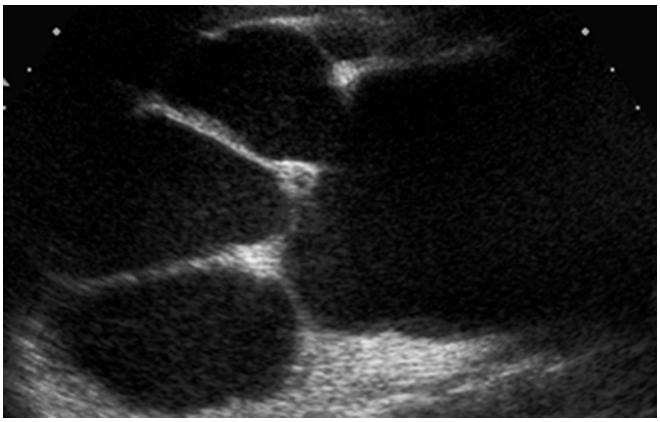
Urinary Tract

Sonography is the imaging examination of choice for the initial evaluation of suspected urinary tract abnormalities in infants. The neonatal kidney typically demonstrates increased parenchymal echogenicity because of the relatively high number of glomeruli and the increased cellularity. Therefore, the renal parenchyma is often isoechoic or hyperechoic relative to the liver and spleen. The increased parenchymal echogenicity persists until age 3-4 months. The neonatal kidney also demonstrates prominent, hypoechoic pyramids because of the larger medullary volume present. This finding may persist until 1 year of age and should not be confused with a dilated collecting system.



Small amounts of fluid may be seen in the renal pelvis of infants in the absence of urinary tract pathology. It is generally accepted that fluid in the renal pelvis and an AP diameter of the renal pelvis of less than 5 mm are normal findings.[19] A renal pelvic diameter of 5-9 mm is characterized as mild pyelectasis and may be associated with a small amount of fluid in the calices. These findings have been reported in 6% of normal neonates and usually resolve over the first year of life. Therefore, neonates with a renal pelvic diameter of less than 10 mm are not at increased risk for urinary tract disease and do not require further follow-up. If the renal pelvic diameter is greater than 10 mm, the infant should be evaluated for possible obstructive uropathy. The Urinary Tract Dilatation (UTD) Classification System—developed by consensus among urology, nephrology, and radiology societies—is recommended to standardize the description of the severity of both fetal and postnatal collecting system dilatation.[46]

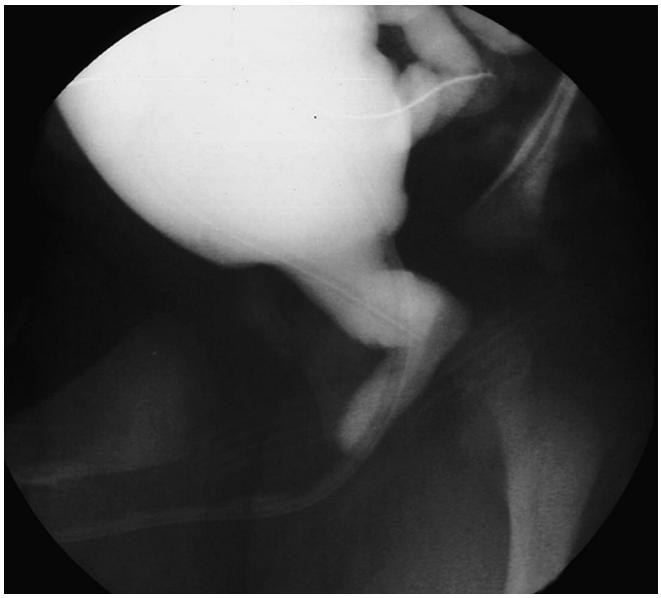
The normal neonatal kidney may also demonstrate transient increased echogenicity of the medullary pyramids at birth (Fig. 38.35). This finding is usually diffuse and bilateral and resolves within 10 days.[17]



Obstructive Uropathy

The most common cause of urinary tract obstruction and flank mass in infants is ureteropelvic junction (UPJ) obstruction. Theoretical causes of UPJ obstruction include an abnormal smooth muscle arrangement or abnormal innervation of the proximal ureter, fibrous scar, or a crossing vessel at the UPJ.[49] Ureteropelvic junction obstruction is commonly identified on prenatal imaging, but infants may also present after birth with a palpable abdominal mass. Sonography is the initial diagnostic examination in children with suspected UPJ obstruction. The sonographic findings include a dilated intrarenal collecting system without ureteral dilation (Fig. 38.36). The obstruction is bilateral in one-fourth to one-third of patients. Although the diagnosis of UPJ obstruction can be made with a high degree of certainty with sonography, renal scintigraphy is needed to quantify the degree of obstruction and to determine renal function. Scintigraphic findings in UPJ obstruction include progressive increase in radionuclide activity within the renal collecting system and delayed excretion. Since ureteropelvic junction obstruction may be associated with vesicoureteral reflux, the imaging evaluation of infants with the condition should include a voiding cystourethrogram (VCUG).

Posterior urethral valves (PUV) are the most common cause of lower urinary tract obstruction and the leading cause of end-stage renal disease in boys. The valves represent obstructive folds or urethral tissue at the level of the prostatic urethra.[10,42] While the diagnosis is also often



• **Fig. 38.35** Transient increased medullary echogenicity of the newborn. Longitudinal view through the kidney demonstrates increased medullary echogenicity. The distribution is bilateral and symmetric.

• **Fig. 38.36** Ureteropelvic junction obstruction. Longitudinal view through the right kidney demonstrates marked dilation of the intrarenal collecting system. The ureter was not dilated.

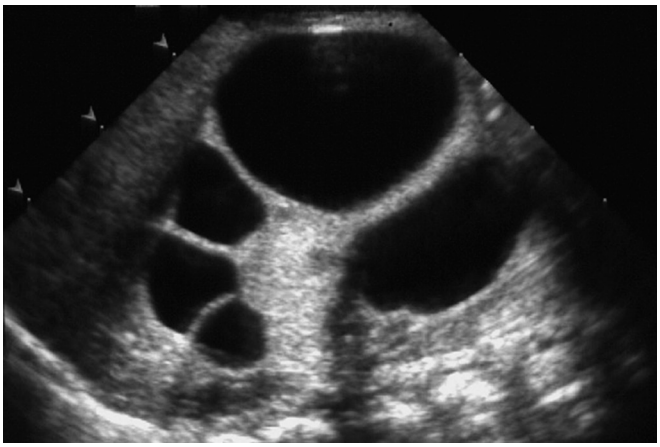
• **Fig. 38.37** Posterior urethral valves. Lateral image from a voiding cystourethrogram shows a dilated posterior urethra and a small-caliber anterior urethra.



made at prenatal imaging, some infants present after birth with a palpable abdominal mass voiding abnormalities or urinary tract infection. Initial findings include bilateral hydroureteronephrosis and a dilated bladder with a thick, trabeculated wall. If abnormal, the renal parenchyma may show dysplastic changes, including increased echogenicity of the renal parenchyma, loss of corticomedullary differentiation, and small peripheral cortical cysts. The diagnosis of PUV is confirmed on a VCUG that demonstrates a dilated posterior urethra and diminution of the urethral caliber distal to the valves (Fig. 38.37).[10] There may be associated vesicoureteral reflux.

Multicystic Dysplastic Kidney

Multicystic dysplastic kidney (MCDK) results from an insult in early embryologic development that leads to pelvic infundibular atresia.[44,49] Infants with multicystic dysplastic kidney usually present with a unilateral palpable flank mass. The sonographic criteria for diagnosing an MCDK include multiple noncommunicating cysts of variable size and absence of renal parenchyma or collecting system (Fig. 38.38). Rarely, the MCDK appears as a single large cyst. Up to 50% of patients have a coexistent contralateral renal abnormality such as UPJ obstruction or vesicoureteral reflux. The natural history of an MCDK is a gradual decrease in the number and size of the cysts over several months or years as the cyst fluid resorbs.

Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease (ARPKD) is an inherited disorder characterized by nephromegaly,

• **Fig. 38.38** Multicystic dysplastic kidney. Longitudinal view of the right kidney demonstrates multiple cysts of varying sizes that do not communicate with one another.

• **Fig. 38.39** Autosomal recessive polycystic kidney disease. Longitudinal view through the kidney demonstrates renal enlargement and lack of normal renal architecture. Note numerous small cysts diffusely.

microscopic or macroscopic cystic dilation of the renal collecting system, and periportal hepatic fibrosis. Infants with ARPKD typically present with large palpable abdominal masses or renal insufficiency. The characteristic sonographic appearance is that of symmetric markedly enlarged, hyperechoic kidneys. The increased echogenicity results from the multiple acoustical interfaces associated with cystic dilation of the renal collecting ducts (Fig. 38.39).[16] High-resolution sonographic equipment may also allow visualization of tiny macroscopic cystic structures.[62] A hypoechoic rim may be noted along the periphery of the kidney, representing compressed normal renal cortex.

Renal Vein Thrombosis

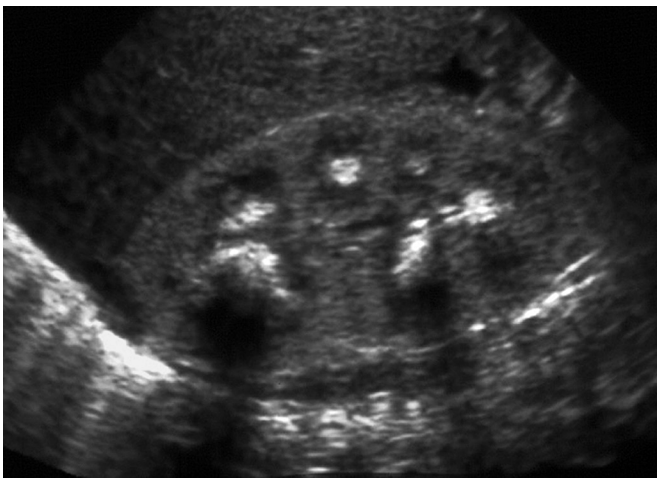
Renal vein thrombosis (RVT) in neonates has traditionally been associated with hemoconcentration caused by dehydration, sepsis, or maternal diabetes mellitus. This entity has become relatively infrequent. RVT is thought to begin in the small intrarenal veins and progress to the

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

hilum; thrombus within the main renal vein may not be present.[13,35] Renal vein thrombosis may also be seen in infants who develop inferior vena caval thrombi associated with an indwelling catheter. The clinical presentation of RVT includes a palpable mass, renal insufficiency, hematuria, or hypertension. In the acute period, enlargement of the involved kidney, diffuse increase in parenchymal echogenicity with echogenic striations, and loss of corticomedullary differentiation are typically seen. Over the next several weeks, the renal parenchymal echogenicity of the involved kidney becomes heterogeneous and renal size decreases. Doppler examination may show diminished perfusion and high-resistance arterial flow with reversal of diastolic flow.

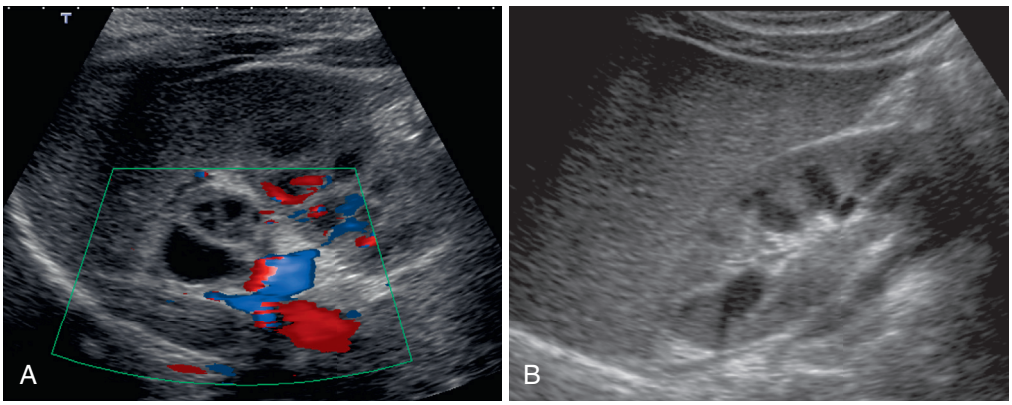
Nephrocalcinosis

Nephrocalcinosis refers to the deposition of calcium in the renal parenchyma, most commonly in the medullary pyramids. Most cases of medullary nephrocalcinosis in neonates are the result of increased calcium excretion related to furosemide therapy. This entity may also be seen in association with hypervitaminosis D and distal renal tubular acidosis. Nephrocalcinosis associated with furosemide therapy gradually resolves after the medication is stopped.



Sonography is used to diagnose and monitor the evolution of the disease. Initial findings include increased echogenicity without acoustic shadowing in the normally hypoechoic renal pyramids (Fig. 38.40). Medullary nephrocalcinosis is typically seen diffusely throughout both kidneys.

Adrenal Glands

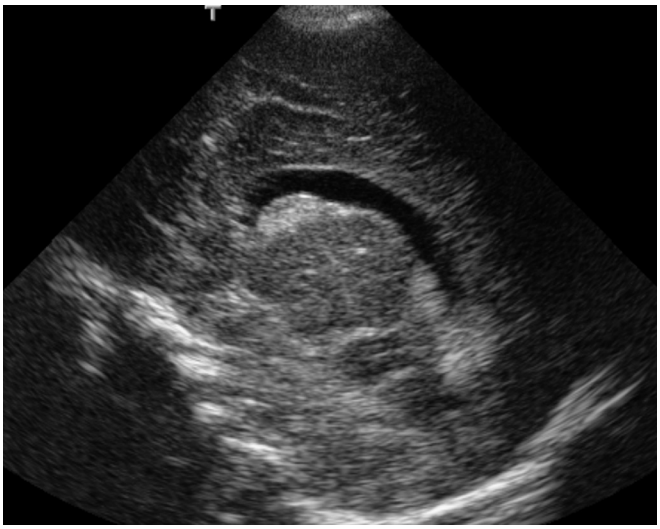


Adrenal Hemorrhage

Adrenal hemorrhage is the most common cause of a neonatal adrenal mass. Right-sided hemorrhage occurs far more commonly than left-sided hemorrhage, possibly owing to the shorter right adrenal vein. Neonates are at increased risk for adrenal hemorrhage because of the relatively large size and increased vascularity of the gland in this age group. Conditions associated with adrenal hemorrhage include perinatal asphyxia, sepsis, coagulation disorders, hypotension, and surgery. Although unilateral involvement is more common, clinical manifestations are typically seen only when there is diffuse, bilateral gland involvement, resulting in adrenal cortical insufficiency.

Sonography is the examination of choice to evaluate for suspected adrenal hemorrhage. The sonographic appearance of adrenal hemorrhage is that of an oval or triangular solid mass of variable echotexture. There may be focal or diffuse involvement of one or both adrenal limbs. Adrenal calcifications may develop weeks to months after the hemorrhage. Large adrenal hemorrhages may be difficult to differentiate from a tumor, particularly if calcification is already present. In such cases, follow-up sonographic images show a gradual decrease in size over 1-2 weeks (Fig. 38.41).[49]

• **Fig. 38.40** Medullary nephrocalcinosis. Longitudinal view sonography through the right kidney demonstrates increased medullary echogenicity with posterior acoustic shadowing.



• **Fig. 38.41** Adrenal hemorrhage. **A,** Doppler color sonography demonstrates a nonvascular cystic adrenal mass. **B,** Three weeks follow-up sonography demonstrates a normal right kidney and complete involution of the mass, indicative of resolution of adrenal hemorrhage.

• **Fig. 38.43** Grade 1 intraventricular hemorrhage. Sagittal view through the lateral ventricle demonstrates a subependymal hemorrhage.

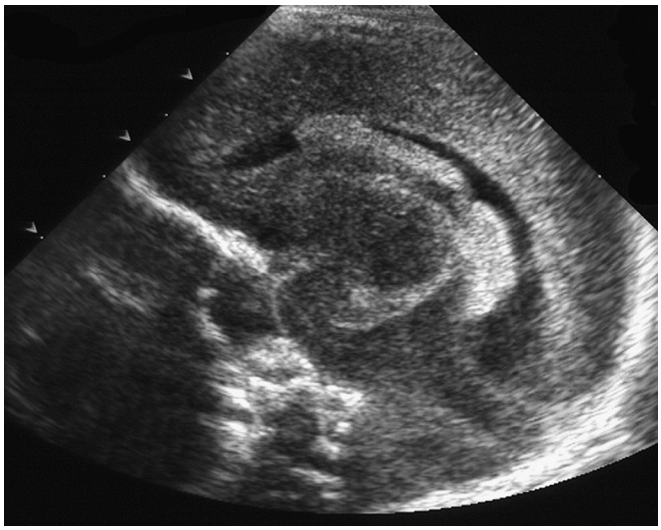
Neuroblastoma

Neuroblastoma is the most common neonatal neoplasm and may present in the prenatal or neonatal period. While perinatal neuroblastoma most often arises from the adrenal gland, a primary lesion can arise from any site in the sympathetic chain. Sonography is usually the initial imaging examination of choice and demonstrates a solid or cystic suprarenal mass that may contain calcifications.[49] CT or MRI offers more precise characterization of the organ of origin and is required for staging (Fig. 38.42). Magnetic resonance imaging can be useful to assess intraspinal extension.[16] Iodine 123 (^{123}I) metaiodobenzylguanidine (MIBG) is the first-line functional imaging agent used with uptake seen in 90% of neuroblastomas. ^{123}I-MIBG identifies both the primary tumor and sites of metastatic disease. The addition of single photon emission computed tomography to ^{123}I-MIBG improves characterization of uptake.[52]

Brain

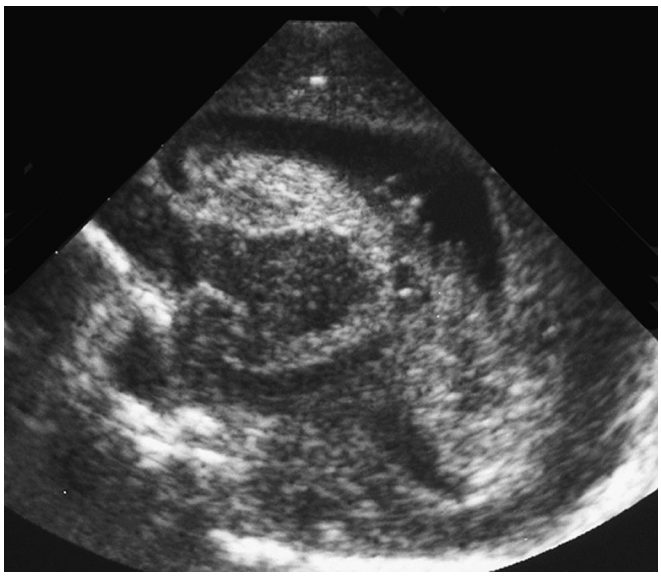
Sonography is the primary means of evaluating intracranial pathology in infants. The most frequent indication for cranial ultrasound is to evaluate for germinal matrix hemorrhage in premature infants.[67] Sonography is performed at the bedside through the anterior and posterior fontanelles with a high-frequency sector transducer. Doppler ultrasound offers effective screening of large intracranial arteries and veins for sinovenous thrombosis and vascular malformations. Evaluation of parenchymal, subarachnoid, and subdural abnormalities are limited on sonographic examination and are better characterized with MRI or CT. In addition, MRI provides detailed anatomic information about the brain and its vasculature.

Germinal Matrix Hemorrhage



Germinal matrix hemorrhage (GMH) is seen primarily in premature infants. Infants at highest risk are those with a gestational age of less than 32 weeks or a birth weight of less than 1500 grams. Most hemorrhages occur by the first week of life. The site of origin for GMH is the caudothalamic groove, an area bordered by the ventricular surface of the caudate nucleus and the thalamus. This extremely vascular area is composed of fragile thin-walled blood vessels with little surrounding connective tissue. Conditions associated with increased intracranial blood flow in the premature infant may result in intracranial hemorrhage.

The traditional classification system for GMH is based on the presence of subependymal and intraventricular hemorrhage, ventriculomegaly, and parenchymal abnormalities (see Chapter 53). Grade 1 is subependymal hemorrhage only; grade 2 is subependymal and intraventricular hemorrhage; grade 3 is subependymal and intraventricular hemorrhage with ventriculomegaly; and grade 4 is periventricular hemorrhagic infarction. Periventricular infarcts are thought to be caused by compression of the periventricular veins by the subependymal hemorrhage.



At sonography, a grade 1 hemorrhage appears as a subependymal echogenic focus inferolateral to the frontal horn of the lateral ventricle (Fig. 38.43). If the subependymal hemorrhage is large, it may efface the ipsilateral lateral ventricle. In grade 2 hemorrhage, blood is seen as echogenic material within the nondilated lateral ventricle (Fig. 38.44). In grade 3 hemorrhage, the intraventricular hemorrhage expands the ventricle, resulting in ventriculomegaly (Fig. 38.45). Grade 4 hemorrhage is characterized by additional echogenic periventricular abnormalities representing hemorrhagic venous infarct (Fig. 38.46).[63] The grade of the germinal matrix hemorrhage has been shown to affect neurodevelopmental outcome. The developmental outcome in infants with grades 3 and 4 hemorrhage is worse than those with grades 1 and 2 for whom the bleeds may not be prognostically significant.[48]

Ventriculomegaly is a frequent sequelae of intraventricular GMH that results from obliterative arachnoiditis or intraventricular obstruction from clot or debris. The

• **Fig. 38.44** Grade 2 intraventricular hemorrhage. Sagittal view through the lateral ventricle demonstrates hemorrhage within the right lateral ventricle.

• **Fig. 38.45** Grade 3 intraventricular hemorrhage. Sagittal view through the lateral ventricle demonstrates intraventricular hemorrhage and ventriculomegaly.

ventriculomegaly may develop soon after the GMH or may be delayed by several weeks. Typically, the trigones and occipital horns of the lateral ventricles dilate before the frontal horns, and the lateral ventricles may dilate alone or to a greater degree than the third and fourth ventricles. Serial sonographic evaluation is performed in infants with GMH to evaluate for developing hydrocephalus, which may require shunting if progressive.

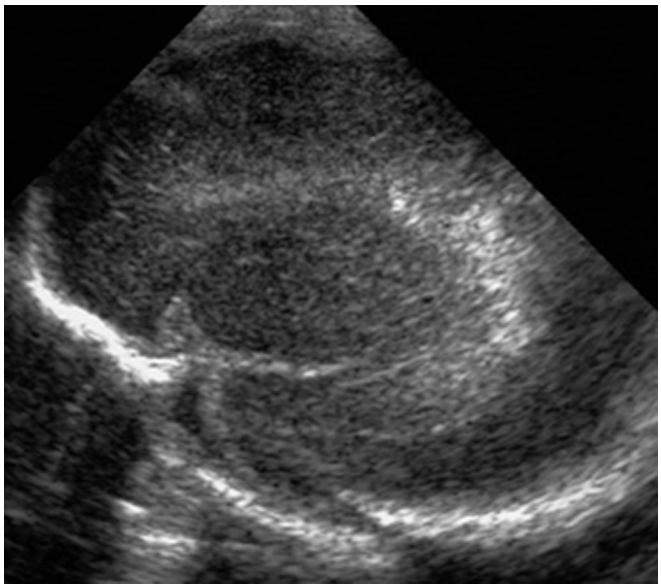
Periventricular Leukomalacia

Periventricular leukomalacia (PVL) represents infarction of deep white matter adjacent to the trigones and frontal horns of the lateral ventricles in premature infants. Infants with

• **Fig. 38.46** Grade 4 intraventricular hemorrhage. Coronal view through the lateral ventricles shows a large intraventricular hemorrhage on the right and adjacent echogenic parenchymal abnormality, representing a hemorrhagic infarct.

PVL may also have intraventricular hemorrhage. Cranial ultrasound performed soon after the infarction is most often normal. The earliest sonographic abnormality is increased periventricular echogenicity (Fig. 38.47). With progression of disease, cavitation may occur, resulting in parenchymal cystic areas (Fig. 38.48). These areas may communicate with the ipsilateral lateral ventricle.[14] Magnetic resonance imaging is the most sensitive imaging modality for the assessment of PVL.[12] Peritrigonal areas of hyperintensity are seen on T2-weighted images. The corpus callosum is often thinned or atrophic. In addition, irregularity of the lateral ventricular contour and asymmetric ventricular enlargement may be noted.

Neonatal Encephalopathy in Term Infants



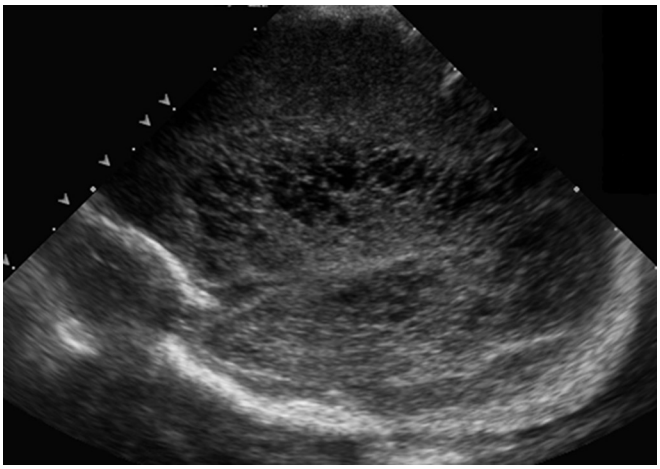
Neonatal encephalopathy is a condition that may result in severe neurologic deficit. Cranial ultrasound may appear normal or show diffuse cerebral edema (Fig. 38.49*A*). MR with special techniques like diffusion weighted imaging (DWI) play a central role in early diagnosis and prompt intervention.[8] DWI may show cytotoxic edema of hypoxic injury during the acute phase before signal intensity changes are evident on conventional T1 or T2-weighted images. Cytotoxic edema appears as high signal restricted diffusion on DWI and low signal on corresponding diffusion coefficient mapping (Fig. 38.49*B*). Diffusion restriction on DWI predicts a poor outcome.

Lenticulostriate Vasculopathy

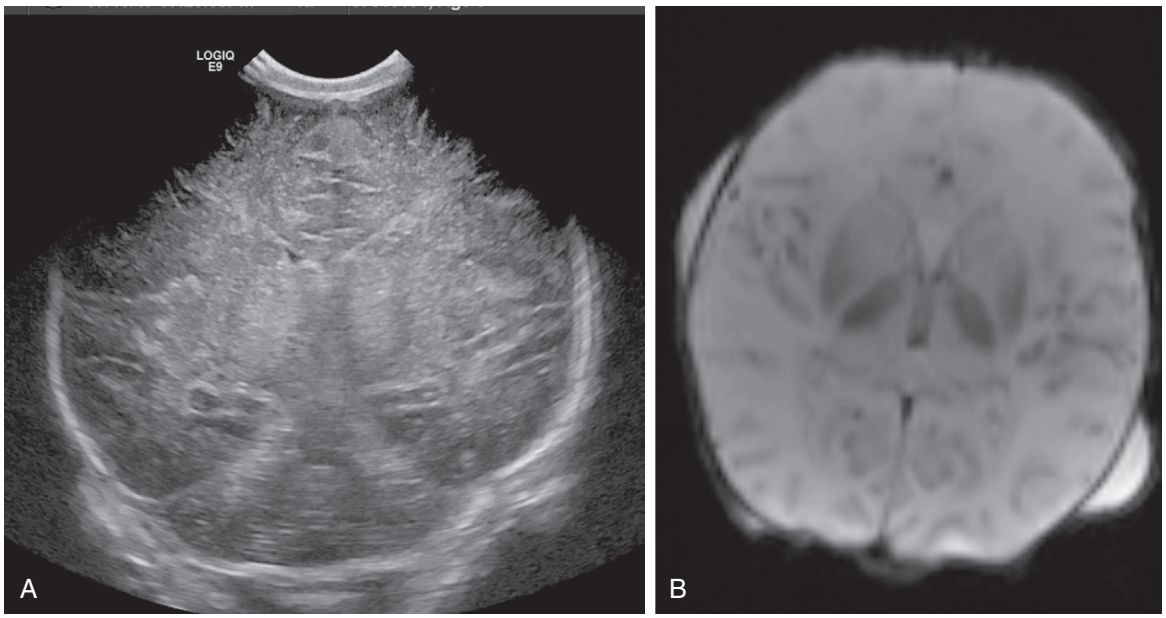
Lenticulostriate vasculopathy (LSV) describes the sonographic appearance of echogenic vessels in region of the basal ganglia and thalamus. Since it was first described in 1988, LSV has been reported in 0.3%-32% of populations

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

studied.[15] A common finding on neonatal cranial ultrasound, most infants with mild LSV show normal neurodevelopment, and no further imaging is needed. LSV may be a nonspecific marker of previous insult to the developing brain and has been associated with various congenital infections, including syphilis, rubella, toxoplasmosis, and cytomegalovirus. It also has been described in chromosomal abnormalities, fetal alcohol syndrome, bacterial meningitis, and perinatal asphyxia. Cranial ultrasound shows linear or branching areas of echogenicity in the thalami and basal ganglia that may be seen from the first week of life to several weeks of age (Fig. 38.50).[67]



• **Fig. 38.47** Early periventricular leukomalacia. Sagittal view through the parietal region demonstrates increased echogenicity.



Spine

Tethered Cord

A tethered cord is defined as a low position of the conus medullaris and thickening of the filum terminale. It is seen in association with various syndromes, spina bifida, meningocele, terminal lipoma, diastematomyelia, and sacral dimple. For those infants suspected of occult spinal dysraphism, sonographic examination using a high-frequency linear transducer is the primary screening tool. Terminal positioning of the conus medullaris at or below the L2-L3 disc space vertebrae confirms a tethered cord (Fig. 38.51*A*). Magnetic resonance imaging is typically performed in all abnormal cases to better evaluate for associated abnormalities (Fig. 38.51*B*).

• **Fig. 38.48** Late periventricular leukomalacia. Sagittal view through the parietal region demonstrates extensive cystic changes.

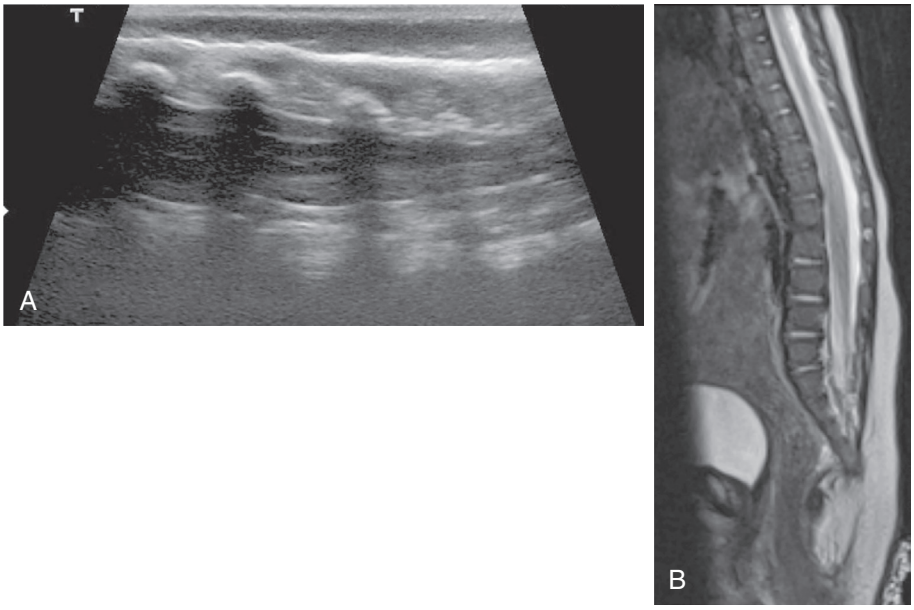
Skeletal

Intrauterine Infection

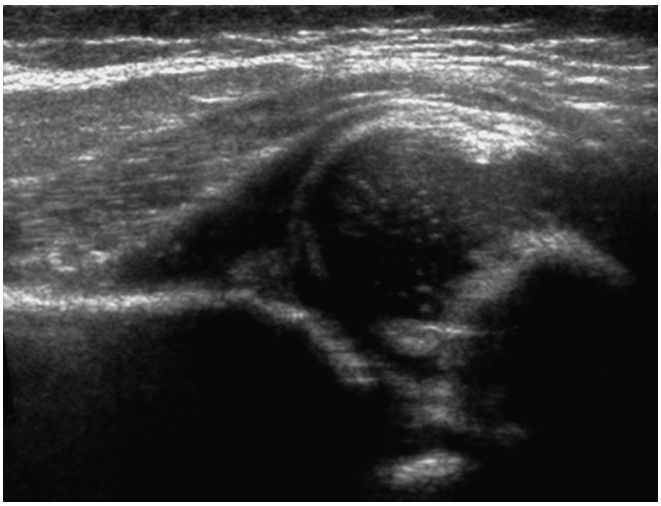
Intrauterine infection may involve the skeletal system. Congenital rubella and cytomegalovirus infection result in metaphyseal lesions with vertical striations that resemble a celery stalk. Congenital syphilis may cause both periostitis as well as single or multifocal metaphyseal lesions, which vary from radiolucent transverse metaphyseal bands to focal destruction and fragmentation of bone.



• **Fig. 38.50** Lenticulostriate vasculopathy. Longitudinal view through the right thalamus demonstrates branching linear areas of echogenicity.

Postnatal Infection

Neonatal osteomyelitis is typically caused by staphylococci, streptococci, or *Candida*. There is an increased risk of osteomyelitis in preterm infants. In infants, osteomyelitis is often seen in conjunction with septic arthritis, because the metaphysis and epiphysis have contiguous blood supplies. Skeletal radiography remains the initial mode of assessing suspected osteomyelitis. The earliest radiographic finding is soft tissue swelling that results in displacement or obliteration of fat planes. Bony changes include poorly defined metaphyseal lucency with progressively increasing bony destruction. However, these changes may not be present in the first 7-10 days. Magnetic resonance imaging is useful in the early detection of soft tissue and osseous abnormalities of osteomyelitis (see Chapter 98).



Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) may be seen in infants with breech presentation in the third trimester, family history of dysplasia, or other orthopedic problems like clubfoot and metatarsus adductus. DDH is more common in girls than boys. Sonography is the examination of choice for screening evaluation after 6 weeks of age; prior to this, there is overlap in findings with transient postnatal physiologic ligamentous laxity. Ultrasound for DDH can be performed up to 4-5 months of age, after which plain films are the preferred imaging modality. Sonography directly visualizes the cartilaginous components of the hip, including acetabular morphology and coverage of the femoral head (Fig. 38.52). Hip instability is assessed through dynamic imaging using stress maneuvers.

• **Fig. 38.51** Tethered cord. **A,** Prone sagittal sonogram shows the cord terminating at the L4-5 level. **B,** T2-weighted sagittal MR confirms tethered cord at L4-5 as well as fusion anomaly at L1-2.

Congenital and Developmental Anomalies

Skeletal radiography plays a primary role in the evaluation of congenital and developmental abnormalities of the axial skeleton and extremities. Imaging of a specific site is performed when there is a localized concern, such as craniosynostosis, congenital spinal deformity, radial ray abnormality, or scapular nondescent. When a skeletal dysplasia is suspected, a skeletal survey should be performed. This survey includes lateral views of the skull and spine as well as AP views of the upper and lower extremities, pelvis, chest, and abdomen.

Rickets

Inadequate mineral intake, chronic lung disease, parenteral nutrition, medications, and immobilization can contribute to metabolic bone disease of prematurity and rickets. The radiologic findings of rickets precede clinical manifestations and are most pronounced at the metaphyses of long bones with the greatest rate of growth. AP radiographs of the wrist or knee demonstrate loss of the zone of provisional calcification, with metaphyseal cupping, fraying, and irregularity. There is also diffuse demineralization or osteopenia (see Chapter 97).

Future Directions

The use of diagnostic imaging in neonates continues to evolve with advances in imaging technology and options for clinical management of these patients. The increasing use of fetal MRI will lead to earlier diagnosis and treatment of infants with conditions affecting the brain, spine, heart, chest, and abdomen. MRI evaluation of the newborn continues to progress with the design of faster sequences and increased use of functional imaging. In the near future, smaller MR scanners will allow imaging of critically ill patients to be performed within the neonatology intensive care unit. New post-processing techniques like iterative reconstruction will continue to decrease doses of ionizing radiation for infants needing a CT scan. The availability of higher frequency transducers and advancements in duplex and color Doppler technology are improving anatomic imaging and the ability to visualize lower velocities of blood flow in smaller vessels. The use of hand-held ultrasound technology will grow, providing point-of-care providers diagnostic information in minutes. These collective advances not only improve image quality, but also improve delivery of safe and timely diagnostic imaging for neonates.

Acknowledgments

The author would like to acknowledge the contributions of Dr. Carlos Sivit, Dr. Claudia Martinez-Rios, and Dr. Dayna Weinert, authors of this chapter in the previous editions.

Key Points

- Radiography remains the most widely used imaging modality in the newborn; cumulative radiation doses from serial neonatal radiographs are considered low dose radiation.
- The risk of a future cancer from low dose radiation used in neonatal imaging is considered too low to be detectable and may be nonexistent.
- Fluoroscopy remains the imaging modality of choice for diagnosis of intestinal malrotation, bowel obstructions, and gastrointestinal and urinary tract fistulae.
- Ultrasound, the second most widely used imaging modality in newborns, offers quick, portable and dynamic cine imaging of the neonatal brain, urinary tract, abdominal solid organs and vasculature.
- Magnetic resonance (MR) imaging is increasingly performed prenatally for congenital neurologic, thoracic, and abdominal malformations; postnatal MR is most widely used for follow-up of these malformations, early detection of hypoxic ischemic change, and cardiac disease.
- Computed tomography (CT), usually performed without sedation, is indicated for newborns with lesions not fully characterized with radiography and ultrasound. CT also offers diagnostic imaging for infants with congenital heart disease involving the aortic arch, pulmonary vascularity, or coronary arteries.

Anesthesia in the Neonate

JOHN E. STORK AND SHELLEY OHLIGER

Developmental Challenges of Neonatal Anesthesia

The administration of anesthesia to the neonatal patient requires knowledge and understanding of neonatal anatomy and pathophysiology in addition to the ability to understand how the pharmacology of standard anesthetic drugs is altered in preterm and term neonates. Anesthetic care of these oftentimes critical patients is best performed by specialty trained pediatric anesthesiologists. The creation of a surgical environment that is tailored to the neonatal patient with appropriate monitors, equipment, and personnel allows for both general and regional anesthetics to be safely and successfully carried out. The safety of modern anesthetics in this vulnerable population continues to be an area of concern, as animal studies have shown neuronal apoptosis and neurocognitive deficits as a result of exposure to most modern anesthetics. While recent human data suggests that brief anesthesia exposure early in life appears to be safe, it continues to be an area of intense focus and research.

Surgery in neonates is accompanied by a humoral stress response that leads to increased complications and mortality, as shown in the landmark study by Anand and colleagues in 1987.[4] This response is diminished by adequate anesthesia (Fig. 39.1; Table 39.1), resulting in improved surgical outcomes. Consequently, over the subsequent decades, anesthesia for all surgical procedures in neonates has been accepted as both a clinical and an ethical imperative.

It is also now generally accepted that neonates are capable of sensing pain and discomfort. We have no recallable memories before 3-4 years of age (termed *infantile amnesia*), but neonates do possess consciousness and a sense of self and can form implicit memories, that is, changes in behavior based on prior experience that do not require intentional recall. Plasticity is an inherent characteristic of the developing nervous system, and early pain experiences can lead to exaggerated responses to later painful stimuli or stress, as well as impaired neurodevelopmental outcome.[56,57] Activation of brain regions in response to graded moderate pain stimuli is significantly different in school-age children and adolescents with neonatal intensive care (NICU) experience compared with controls, as measured by functional magnetic resonance imaging (MRI).[29] Based on such evidence, the goals of anesthesia in neonates are not restricted to prevention of the stress response to surgery but also effective management of pain and discomfort.[1,2]

Coincident with a new understanding of the importance of anesthesia and pain management in neonates, numerous animal studies, including some in nonhuman primates, have demonstrated abnormal neuroapoptosis and, in some, long-term cognitive deficits including delayed learning, impaired memory formation and retention, altered motor development, and altered behavioral development. These studies have shown effect after early exposure to virtually all commonly used anesthetic and analgesic agents.[7,53] Development of the nervous system is complex, involving neuronal proliferation, migration, differentiation, and "pruning" accomplished by apoptosis. This development is in part dependent on the balance of excitatory and inhibitory stimuli and neurotransmitters. Given the complexity of the process, as well as the obvious physiologic and developmental differences inherent in application of animal studies to humans, the overall impact of these studies remains uncertain. Concerns have been raised with respect to the animal data regarding dosing and the time course of exposure. A clinically appropriate dose is the minimum necessary to induce anesthesia in the species. In some species, and with some agents, this dose also results in significant mortality, increasing the difficulty of interpreting the significance. Synaptogenesis in rats occurs postnatally over the first 2 weeks of life. An analogous period in humans would range from the third trimester of pregnancy through the first 3 years of life. Whether the child might be susceptible to anesthetic toxicity during this entire period is unknown. Elucidation of the critical period is of prime importance in anesthetic management. Studies in nonhuman primates are assumed to be more translatable to humans. Infant macaques exposed to multiple sevoflurane or isoflurane anesthetics exhibited increased anxiety behaviors and motor reflex deficits.[10,48] Finally, most of the animal studies of apoptosis involve anesthesia without surgery. Because neurodevelopment is related to the balance of stimulatory and inhibitory neurotransmitters, there is some indication that the absence of surgical stress may alter the neurodevelopmental response to anesthetics.

Abstract

The administration of anesthesia to the neonatal patient requires knowledge and understanding of neonatal anatomy and pathophysiology in addition to the ability to understand how the pharmacology of standard anesthetic drugs is altered in preterm and term neonates. Anesthetic care of these oftentimes critical patients is best performed by specialty-trained pediatric anesthesiologists. This chapter reviews how to create a surgical environment that is tailored to the neonatal patient with appropriate monitoring, equipment, and personnel. The preoperative evaluation and anesthetic plan take into account neonatal physiology and diseases of prematurity that may have an effect on the pharmacology of various anesthetic agents. Knowledge of these factors allows for both general and regional anesthetics to be safely and successfully carried out. Renewed interest in regional anesthesia has provided increasing data that neuraxial and regional blocks are safe to perform in the neonatal population. The safety of modern anesthetics in this vulnerable population continues to be an area of concern as numerous animal studies have shown neuronal apoptosis and neurocognitive deficits as a result of exposure to most modern anesthetics. Recent human studies are reviewed and suggest that brief anesthesia exposure early in life appears to be safe, but it continues to be an area of intense focus and research.

• **Fig. 39.1** Change (Δ) from baseline of epinephrine and norepinephrine in nanomoles per liter (nmol/L) before surgery to the end of the operation and for the first 24 hours thereafter. The two groups reflect nitrous oxide-fentanyl anesthesia (*red circles*) and nitrous oxide anesthesia (*blue circles*). In the patients given fentanyl, there was no increase in epinephrine or norepinephrine, not only during surgery but also for the first 24 hours after surgery, indicating a significantly blunted stress response.

Data from Anand KJ, et al. Randomised trial of fentanyl anaesthesia in preterm babies undergoing surgery: effects on the stress response. *Lancet.* 1987;1:62.

Confirmation of long-term and relatively subtle effects in humans is, of course, a daunting task. Prior to 2015, human studies of the long-term effects of anesthetic exposure on the developing brain were largely retrospective and observational, employed varying study designs, and used a wide range of tools to assess neurodevelopmental outcomes.[6,15,19,20,25,26,31,32,52,62] The results were inconsistent and at times conflicting. Exposure to multiple anesthetics during infancy and early childhood was often associated with poorer neurodevelopmental outcomes, whereas a single anesthetic exposure varied between no adverse outcomes to some degree of neurodevelopmental impairment.

Two recent prospective studies with more robust methodology reveal that a single brief anesthetic in early life may have no effect on long-term neurocognitive development. The GAS study, a prospective randomized controlled trial comparing sevoflurane general anesthesia to awake regional anesthesia (spinal or caudal) for herniorrhaphy in infancy, did not reveal any difference in neurodevelopmental outcome at 2-year follow-up.[13] The PANDA study, a prospective sibling-matched cohort study, compared neurocognitive outcomes in infants receiving a short inhaled general anesthetic for herniorrhaphy to a biological sibling with no anesthetic exposure. Follow-up neuropsychological assessment of sibling pairs at ages varying from 8-15 years old showed no difference in neurocognitive outcomes.[54]

In addition, three large retrospective matched cohorts with greater than 59,000 children combined did not find sufficient data to conclude that young age at initial exposure or multiple anesthetic exposures contributed to adverse neurodevelopmental outcomes.[23,24,44]

Despite these more recent studies pointing to the safety of brief anesthetic exposure, the US Food and Drug Administration (FDA), as a result of their ongoing initiative to study the risk of anesthetic exposure on brain development, has published a warning against repeated or lengthy use of general anesthetic and sedation drugs during surgeries and procedures in children younger than 3 years of age or in pregnant women.[17] Many questions still remain regarding anesthetic safety. What is the maximum duration or dose of safe anesthetic exposure? What are the long-term risks to those requiring multiple or longer anesthetic exposures? Do additional comorbid conditions predispose patients to a higher risk of neurocognitive impairment?

No one can question the overwhelming benefit of anesthesia in the setting in which a surgical procedure, or any

noxious procedure with significant stress, is required. The detrimental effects of surgical stress have been well shown. Similarly, the benefits of early repair of some surgical problems, such as tetralogy of Fallot or neonatal hernia with risk of incarceration, have been shown, although such repair may lead to anesthesia at a younger, and potentially more susceptible, age. Current human studies suggest that a short anesthetic during early development is safe.

When deciding to proceed with an anesthetic, the benefit versus the risk of delay in surgical procedures, particularly if performed in premature infants, should be carefully considered. Second, it seems reasonable to perform a "simple" anesthetic. There is virtually no extensive experience with many anesthetic agents in neonates. This lack of extensive experience is not unusual in neonates or pediatrics in general but may be of increased importance given the small therapeutic margin of most anesthetics. One preference is to use a predominantly narcotic technique in premature infants who may be most at risk, when appropriate. Fentanyl has little, if any, activity as either an *N*-methyl-D-aspartate (NMDA) antagonist or gamma-aminobutyric acid (GABA) agonist. It is well tolerated hemodynamically and effective at preventing the surgical stress reaction. This particular technique may prevent extubation at the conclusion of the procedure, but in this generally ill population, that is not always a consideration.

The goals of neonatal anesthesia are the same as in adults but require different skills, knowledge, and care. The differences between adults and children are most profound in neonates, particularly premature infants. Advances in neonatology and the almost routine survival of infants weighing greater than 1000 g have led to new challenges for pediatric anesthesiology. Successful anesthetic management in a neonate requires meticulous attention to detail and a thorough understanding of neonatal physiology and development, pharmacology, and pathophysiology. The neonatal period is characterized by immaturity of organ systems, homeostasis, and metabolic pathways. It is a time of major developmental changes, and the effects of anesthesia on that development are not well characterized.

Personnel, equipment, and the operating room environment need to be specifically adapted for neonates. Anesthesia-related morbidity is decreased in children anesthetized by pediatric anesthesiologists compared with children cared for by nonpediatric anesthesiologists.[30] Monitors, anesthesia delivery systems, mechanical ventilators, and environmental controls all need to be appropriate for use with neonates.

It is important to emphasize the perioperative nature of anesthetic management. Anesthesia care does not start and end at the door to the operative suite, and this is as critical in neonates as in older children and adults. Preoperative condition and management affect intraoperative care. Transport to the operating room can be one of the most critical aspects of an operation in a premature neonate. The postoperative period requires close monitoring and management of ventilation, fluid balance, and an environment tailored to the special needs of neonates. Assessment and control of postoperative pain require methods and tools specific to neonates.

Knowledge of the anatomic and physiologic differences among neonates, children, and adults is critical to careful anesthetic administration and management. Maturity of organ systems and metabolic processes varies significantly not only between adults and neonates but also between preterm and term neonates.

Anesthesia, Neonatal Physiology, and Specific Concerns

Transition Phase and Persistent Pulmonary Hypertension of the Neonate

In utero, the pulmonary circulation is a high-resistance circuit so that the lungs receive little blood flow, and oxygenation is a placental function. At birth, approximately 35 mL of amniotic fluid is expelled from the lungs, the lungs re-expand, and respiration begins. The lungs are initially very stiff (compliance very low), and the first breath may require negative forces of 70 cm H_2O or more. Pulmonary vascular resistance (PVR) decreases rapidly with lung distention, while oxygenation, pulmonary blood flow, and cardiac output increase. The increase in pulmonary blood flow coupled with decreased venous return from the inferior vena cava with clamping of the placenta causes left atrial pressure to exceed right atrial pressure, resulting in closure of the foramen ovale. The ductus arteriosus closes between 1 and 15 hours after birth.

Although PVR decreases, the pulmonary arterioles possess abundant smooth muscle, and the pulmonary vascular bed remains very reactive. In this setting, hypoxia, hypercarbia, or acidosis can cause a sudden increase in PVR and a return to a fetal circulatory pattern, a condition known as persistent fetal circulation or persistent pulmonary hypertension of the neonate (PPHN). Persistent pulmonary hypertension of the neonate is an acute, life-threatening condition, as shunt fraction increases to 70%-80%, and profound cyanosis results. Many factors during anesthesia can affect this transitional state. Anesthetic agents can markedly diminish systemic vascular resistance (SVR), resulting in a right-to-left shunt. Hypoxia or hypercarbia and acidosis from inadequate ventilation can increase PVR, as can increased sympathetic stimulation during surgical stress, with similar effects on right-to-left shunt.

Respiratory Physiology: Apnea, Central Control of Ventilation, and Respiratory Distress Syndrome

Anesthetic agents are respiratory depressants. Central regulation of breathing is obtunded under anesthesia, with a significant decrease in the ventilatory response to increased carbon dioxide (CO_2). Compared with older children and adults, in neonates, lung volume and functional residual capacity (FRC) as a percentage of body size are much less.

Alveolar ventilation per unit lung volume is very high, because the neonate's metabolic rate is about twice that of an adult. Most of this alveolar ventilation is provided by a rapid respiratory rate of 35-40 breaths/min, because tidal volume is limited, owing to the structure of the chest wall.

One consequence of the reduced FRC and high metabolic rate in a neonate is a diminished reserve. Changes in the fraction of inspired oxygen (FIO_2) are rapidly seen as changes in PO_2, and the neonate quickly desaturates if ventilation is interrupted. This situation limits time for intubation, and airway management can be difficult. The high alveolar ventilation also accounts for a very rapid uptake of inhalational anesthetic agents, especially in premature infants, making it easy to overdose with these agents. Closing volume, which is the lung volume at which smaller airways tend to collapse, is very close to FRC in neonates. It is well known that anesthesia causes decreases in FRC. In a neonate, this low closing volume can result in airway closure at end expiration, with resultant atelectasis, ventilation/perfusion mismatch, and increased intrapulmonary shunting.

An awake infant uses laryngeal braking, resulting in an auto-positive, end-expiratory pressure (auto-PEEP) to maintain FRC, but laryngeal braking is diminished by anesthesia. In a premature neonate, alveoli are immature and thick-walled and saccular. Surfactant production begins at 23-24 weeks' gestation, but it may remain inadequate until 36 weeks' gestational age; because of this, lung volumes and compliance are decreased further in very premature infants. Although the lung is less compliant in an infant than in an older child, the chest wall in an infant is very compliant. This combination results in increased work of breathing. Because resistance to airflow is inversely proportional to the fourth power of the radius of the airway, the work of breathing is increased further in neonates, particularly small premature infants.

Changes in airway resistance are also common during anesthesia, often resulting from small endotracheal tubes and equipment factors such as inspiratory and expiratory valves in the breathing circuit. Kinking of the endotracheal tube or the presence of secretions also can adversely affect resistance. Respiratory failure from fatigue can occur easily. Most neonates require controlled positive pressure ventilation during operative procedures because of the low FRC, increased closing volume, and increased work, along with changes induced by anesthetics. Infants already being ventilated require some increase in their ventilator settings after induction of anesthesia, and some infants require increased postoperative ventilatory support.

Tracheomalacia is common in premature infants, and if low in the airway, it may not be obviated by intubation. Bronchomalacia may result in airway collapse on expiration. Continuous positive airway pressure (CPAP) or PEEP increases FRC and decreases closing volume and helps to stent open the airway during anesthesia. Slower respiratory rates should be used with positive pressure ventilation to allow time for passive exhalation and prevent air trapping. The premature lung is very susceptible to barotrauma and oxygen toxicity. Pneumothorax and interstitial emphysema may develop if high peak inspiratory pressures are used.

Periodic breathing with intermittent apneic spells is common in neonates up to 3 months of age. Small premature infants have a biphasic ventilatory response to hypoxia, with an initial increase in ventilation, followed by a progressive decrease and eventual apnea. The ventilatory response to CO_2 is decreased in premature infants and, as noted, is decreased further by anesthesia. Postoperative apneic spells are common in premature infants, although incidence decreases with advancing postconceptional age. These episodes can be secondary to the immature respiratory control system (central), a floppy airway (obstructive), or both (mixed or combined). Cote and coworkers did a meta-analysis of data from eight separate studies and found wide variability among institutions. It was clear, however, that the risk of apnea was strongly inversely related to gestational age and postconceptional age. A full-term neonate is unlikely to experience significant postoperative apnea after 45 weeks' postconceptual age, while an infant born prematurely is at risk for postoperative apnea until 55-60 weeks' postconceptual age.[10a]

Airway Anatomy

Airway anatomy in infants differs from anatomy in older children. The infant's head is much larger compared to body size, with a more prominent occiput and shorter neck than that of older children. The infant's tongue is large, but the larynx is higher and anterior, with the cords located at C4 in the infant compared with C5 or C6 in an adult. The epiglottis of the infant is soft and folded. The neonate's larynx has historically been described as conical, with the narrowest point in the subglottic area at the cricoid ring. Studies have revisited this anatomy using magnetic resonance imaging (MRI)[37] and video-bronchoscopic imaging.[12] Based on these studies, the larynx is cylindrical, although not round in cross-section but rather elliptical, with the anteroposterior dimension slightly greater. A tight-fitting, round endotracheal tube might compress the lateral laryngeal mucosa; subglottic stenosis remains a common complication, especially with longer-term intubation. Although uncuffed endotracheal tubes previously were used in neonates and children, use of newer cuffed tubes, composed of very thin, low-pressure cuffs and thin walls, is feasible in many infants, although an uncuffed tube is still required in the smallest neonates. New tubes are available with very thin cuffs, and without the Murphy eye, which decreases the length of the tube below the cuff. This ensures that the entirety of the cuff is below the cords, avoiding pressure on the cords. A cuffed tube can be sized smaller, because the cuff prevents leakage and could decrease the incidence of subglottic stenosis rather than increase it as previously believed, especially when attention is paid to cuff pressures. Intraoperatively, a cuffed tube may be essential to minimize air leakage and allow for effective positive pressure

ventilation during surgical procedures that may significantly affect respiratory mechanics (laparoscopy, intrathoracic and intracardiac procedures with an open chest). Laryngeal and tracheal trauma is important because even modest airway edema can be serious. At the cricoid ring, 1 mm of edema results in a 60% reduction in the cross-sectional area of the airway, causing increased airway resistance and increased work of breathing. Laryngomalacia is also common in premature infants and can result in obstruction.

Cardiac Physiology

Transitional cardiac changes were discussed earlier. Immediately after birth, with an open ductus arteriosus, most of the cardiac output is from the left ventricle, and left ventricular end-diastolic volume is very high. Consequently, the neonatal heart functions at the high end of the Starling curve. As PVR decreases, output from the two ventricles becomes balanced at 150-200 mL/kg per minute. Heart rate is rapid at 130-160 beats/min. Because end-diastolic volumes are already high, the infant heart is unable to increase stroke volume to a significant degree, and increases in cardiac output depend entirely on increases in heart rate. Baseline blood pressure is lower in infants than in older children, particularly in preterm infants, because cardiac output is increased owing to a low SVR.

Almost all anesthetic agents have significant effects on the cardiovascular system. Inhalational agents tend to be cardiovascular depressants, and they can result in decreased myocardial contractility with bradycardia and subsequent decreased cardiac output. Most anesthetic agents cause decreased autonomic tone and peripheral vasodilation, decreasing afterload and preload. Because baroreceptor reflexes also are blunted by anesthesia, these decreases may make it impossible for the infant to compensate for pre-existing volume contraction or volume losses during anesthesia. Inotropic support may be necessary in a sick neonate, and almost all infants require some degree of volume loading during anesthesia. This belief may be at odds with contemporary thoughts on respiratory management, which emphasize diuresis; volume therapy needs to be carefully balanced to support tissue perfusion, urine output, and metabolic needs.

Patent ductus arteriosus is common in preterm neonates and can result in pulmonary overcirculation and congestive heart failure. The patent ductus arteriosus may close spontaneously. Medical therapy with nonsteroidal anti-inflammatory drugs is sometimes successful. A patent ductus arteriosus may require surgical ligation or, more recently, catheter-based occlusion. The potential adverse effects of anesthesia associated with ductal closure remain controversial.

Fetal Hemoglobin

The infant has approximately 80% fetal hemoglobin (hemoglobin F) at birth. Hemoglobin F has a P50 (partial pressure of oxygen at which hemoglobin is 50% saturated) of 20 mm Hg compared with a P50 of 27 mm Hg for hemoglobin A, which means that hemoglobin F has a higher affinity for oxygen and that the hemoglobin dissociation curve is shifted to the left. In utero, this hemoglobin dissociation curve favors transport of oxygen from the maternal to the fetal circulation. Put another way, for any given oxygen saturation, the infant has a lower Po_2. Unloading of oxygen at the tissue level also is diminished, although this is compensated for by an increased hemoglobin level of approximately 17.5 g/dL at birth. The decreased unloading can result in tissue hypoxia, however, if Po_2, hemoglobin, or cardiac output decreases during surgery, with secondary development of metabolic acidosis. The hemoglobin increases slightly just after birth, then decreases progressively to a level of 9.5-11 g/dL by 7-9 weeks of life, owing to decreased red blood cell life span, increasing blood volume, and immature hematopoiesis. Hemoglobin F synthesis begins to decrease after 35 weeks' gestation, and hemoglobin F is completely replaced by hemoglobin A by 8-12 weeks of life, paralleling the decrease in hemoglobin and helping to maintain tissue oxygenation.

Renal Physiology

Nephrogenesis is complete at 34 weeks' gestation, and the term neonate has as many nephrons as an adult, although they are immature, with a glomerular filtration rate (GFR) approximately 30% of the adult GFR. With increasing cardiac output and decreasing renal vascular resistance, renal blood flow and GFR increase rapidly over the first few weeks of life and reach adult levels by about 1 year of life. The diminished function over the first year is well balanced to the infant's needs, because much of the neonate's solute load is incorporated into body growth, and excretory load is smaller.

Several aspects of renal physiology are pertinent to anesthesia care. First, the neonatal kidney has only limited concentrating ability, apparently owing to a diminished osmotic gradient in the renal interstitium, whereas antidiuretic hormone secretion and activity are normal. Coupled with an increased insensible loss owing to a "thin" skin and increased ratio of surface area to volume, the limited concentrating ability of the kidney implies a tendency to become water depleted if intake or administration is inadequate. The neonatal kidney also is unable to excrete dilute urine efficiently and cannot handle a large free water load. In addition, primarily owing to a short, immature proximal tubule, infants are obligate sodium wasters. There is a tendency toward hyponatremia, especially if too much free water is administered during surgery, which can easily happen with continuous infusions from invasive pressure transducers, especially if adult transducers are used. Because of the lower GFR, the neonate also cannot handle a large sodium load and can easily develop volume overload and congestive heart failure. One final aspect concerns acid-base status: The neonatal kidney wastes small amounts of bicarbonate owing to an immature proximal tubule; infants are born with a mild proximal renal tubular acidosis, with

serum bicarbonate of approximately 20 mmol/L. All these changes are greater in preterm infants, particularly before nephrogenesis is complete at 34 weeks.

Temperature Regulation

Given a large surface area, small body volume, and minimal insulation, neonates are extremely prone to heat loss. Any degree of cold stress is detrimental and increases metabolic demands in the neonate. Infants are unable to shiver effectively, and cold stress causes catecholamine release, which stimulates nonshivering thermogenesis by brown fat. Premature infants have less brown fat, decreasing their capacity for nonshivering thermogenesis and increasing their risk for hypothermia. The increased catechols caused by cold stress can be detrimental, causing increased peripheral vascular resistance and SVR, increased cardiac stress, and increased oxygen consumption. Anesthesia blunts thermoregulatory sensitivity[5] and interferes with nonshivering thermogenesis and brown fat metabolism.[47] Anesthesia also increases heat loss by inducing cutaneous vasodilation. Surgical factors such as major operations with open body cavities and lower ambient temperatures requested in the operating room also contribute to increased risks of hypothermia in the neonate.[59] At all times, including during transport and in the operating room, the infant must be subjected to a neutral thermal environment. An environment that is too warm can be equally detrimental. Core temperature must be carefully monitored at all times in the operating room.

Carbohydrate Metabolism

Whole-body glucose demand corrected for body mass in neonates can be twice that in adults. Carbohydrate reserves, primarily hepatic glycogen, in a normal newborn are relatively low, and even lower in an infant with low birth weight. Hypoglycemia can readily occur if the infant is deprived of a glucose source. Even transient hypoglycemia may be associated with neurologic injury in neonates.[34] In contrast with adults, in whom hyperglycemia seems to potentiate brain damage during global and focal ischemia, hyperglycemia in neonates may provide some protection from ischemic damage.[11] Generally, intravenous glucose (10% dextrose) or intravenous hyperalimentation should be continued intraoperatively, especially in infants with low birth weight without adequate glycogen or fat stores. Nonetheless, hyperglycemia can also be a problem in the perioperative period. Insulin response is deficient in preterm infants, and high catecholamines owing to illness or intraoperative stress can result in hyperglycemia. Careful monitoring of serum glucose is indicated.

Oxygen Therapy and Retinopathy of Prematurity and Chronic Lung Disease

Hypoxia is a common pathologic condition in neonates because of the incidence of lung disease; congenital heart disease and disordered transition are other frequent causes. Tissue hypoxia, or oxygen delivery to the tissues inadequate to sustain oxidative metabolism, is harmful, with well-known pathologic sequelae. There is, at present, no good method for reliably detecting tissue hypoxia, particularly in a real-time manner. Due to the fear of hypoxia, oxygen therapy was widely used, particularly during anesthesia. However, there is increasing evidence that this resulting iatrogenic hyperoxia is causally associated with multiple pathologic conditions in neonates and should be strenuously avoided.[41,51]

Oxygen is a highly reactive molecule, and free radical formation by oxygen is well known. Reperfusion injury, which refers to damage resulting from free radical formation on reoxygenation after a period of hypoxia, is well established. Retinopathy of prematurity is the most widely known complication of hyperoxia, but there is increasing evidence that oxygen may play a role in chronic lung disease, neurologic impairment, and other pathologic conditions. There is also evidence that wide fluctuations in oxygenation, as often experienced during anesthesia, may be damaging.

Monitoring of oxygenation during operative procedures is problematic. Continuous pulse oximetry is the standard of care and has contributed to the safety of anesthesia by avoidance of hypoxia. The pulse oximeter is not as helpful for detection of hyperoxia. At hemoglobin saturations greater than 95%, most infants are hyperoxic; this is altered further by varying amounts of fetal hemoglobin. Maintenance of saturations greater than 95% is almost universal in most operating rooms but is probably not the best course for neonates. It has been suggested that for ongoing management of neonates in the NICU, oxygen saturation targets of 90%-95% should be used.[18,55] Similarly, it has become common practice to use blended oxygen levels of 30%-40% during initial resuscitation. Current anesthesia practice involves minimizing excessive oxygen administration in preterm neonates as long as oxygen saturation is 90% or greater. Many neonates can be managed intraoperatively on room air. Further consideration probably should be given to the universal practice of using 100% oxygen during induction and emergence from anesthesia, although this is more problematic, because hypoxia also should be avoided, and oxygen desaturation during induction and intubation is frequent. This possibility further underscores the need for experienced personnel during induction and intubation of neonates.

Conduct of an Anesthetic

Preoperative Evaluation and Preparation

The preoperative evaluation should encompass the infant's physical condition, including significant illness, the degree of transition from fetal to newborn physiology, maturity, and the presence of any congenital anomalies. Particular attention should be paid to cardiorespiratory status, required ventilatory or hemodynamic support, blood chemistries, and nutritional support. The course of pregnancy, labor, and delivery and a full maternal history are important details. As

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

is the case with older children, a family history of anesthetic difficulties may be important. Maternal diseases such as diabetes, systemic lupus erythematosus, and preeclampsia have implications for the neonate. Congenital infections, oligohydramnios, intrauterine growth restriction, and maternal drug and alcohol use are also important considerations.

Gestational age, birth weight, and postnatal age affect anesthetic care. Birth weight does not accurately reflect maturity unless the infant is appropriate for gestational age, which is defined as being within 2 standard deviations of the mean for gestational age. Infants who are small for gestational age are more mature than their birth weight would indicate. Infants who are large for gestational age are often children of diabetic mothers, and they are at increased risk of hypoglycemia in the first 48 hours after birth. Newborns are characterized by birth weight as low birth weight (≤2.5 kg), very low birth weight (≤1.5 kg), and extremely low birth weight (<1000 g). Term is gestational age of 37-42 weeks, preterm is younger than 37 weeks, and postterm is older than 42 weeks.

A history of birth asphyxia or neonatal resuscitation and Apgar scores are important. History should include complete details of the present illness and treatment. Medications and administration times, details of vascular access, and respiratory parameters including ventilator type and settings all are crucial details, especially in sicker infants. Infants on high-frequency oscillatory ventilation may need to be switched to conventional ventilation and observed for several hours to facilitate movement to an operating room. If the infant is on some other modality, such as inhaled nitric oxide or extracorporeal membrane oxygenation, arrangements may also need to be made, and transport to the operating room would require more resources and assistance.

The time of the last oral feed should be ascertained, especially in elective surgery in healthier infants. Attenuation of airway reflexes with induction of anesthesia places the infant at risk of aspiration of acidic gastric contents, which can lead to serious inflammatory pneumonitis. *Nil per os* (NPO; nothing by mouth) guidelines are summarized in Table 39.2[3]; these guidelines are more liberal for newborns than adults. This shorter length of time partially reflects more rapid gastric emptying, although in an infant, dehydration occurs much more quickly than in an adult, and this is a concern in an infant without an intravenous line. Attempts to minimize NPO time should be made to avoid interruptions in vital nutrition. As in adults, gastric emptying is delayed with stress, anxiety, and illness. Infants with diseases such as pyloric stenosis, duodenal atresia, malrotation, or other obstructive lesions are NPO before surgery, and they need an intravenous line to maintain appropriate hydration. Despite the NPO status, there usually are significant gastric contents, and rapid-sequence or awake intubation is required if there is any concern for obstruction. Emptying the stomach via nasogastric drainage is undependable and usually inadequate. Nasogastric feeds in intubated infants also should be discontinued at an appropriate time, because the infant may need to be reintubated during surgery, and a full stomach would increase the risk for aspiration.

TABLE 39.2 NPO Guidelines

Intake	Time (h)
Clear liquids	2
Breast milk	4
Formula	6

NPO, *Nil per os* (nothing by mouth).

Physical examination includes vital signs, including temperature. Volume status needs to be carefully assessed because major shifts can occur easily during surgery. Many infants requiring surgery are ill. Infants with congenital anomalies often have multiple defects, which may have an impact on anesthetic care. Often, a group of defects suggests a well-recognized and characterized syndrome. Common syndromes with their anesthetic implications are listed in Table 39.3. (This list is incomplete.)

Difficult intubation is a common problem in infants with congenital defects, and the airway needs to be carefully assessed. Because of the tendency for rapid oxygen desaturation in infants, difficulties with intubation can be extremely serious. In infants who are already intubated, tube size and position should be evaluated. The pressure at which a leak occurs around the tube should be documented. Nurses should be questioned about the quantity and consistency of secretions and need for frequent suctioning. The small tubes required in premature infants can easily be blocked by tenacious secretions and are easily dislodged. If there is any question about adequacy of intubation, the infant should be electively reintubated before surgery; emergently replacing an endotracheal tube under the drapes after beginning an operation is not a benign procedure.

A complete physical examination should be performed, with particular attention paid to cardiorespiratory status. Laboratory studies and x-ray films need to be reviewed, if applicable. Hemoglobin level usually should be greater than 10 g/dL to ensure adequate oxygen delivery to the tissues, given the decreased unloading at the tissue level by fetal hemoglobin. Metabolic acidosis should be corrected, preferably by reversal of the cause of the acidosis. Electrolyte levels help to guide fluid management; hypocalcemia should be corrected. For most operations, it is important to check that blood for transfusion is available; for major procedures, fresh frozen plasma and platelets for transfusion also may be required.

Several specific areas should be explored by the anesthesiologist. As previously discussed, the pulmonary circulation in a neonate is hyperreactive, and in a near-term infant, lung disease, asphyxia, and surgical stress can initiate episodes of pulmonary hypertension, resulting in decreased cardiac output and oxygen desaturation. Any history of such spells

TABLE 39.3 Anesthetic Implications of Neonatal Syndromes—cont'd

Syndrome	Clinical Manifestations	Anesthetic Implications
Osteogenesis imperfecta	Blue sclera, pathologic fractures, deafness Congenital heart defects Increased metabolism and hyperpyrexia	Difficult airway Careful positioning and padding Hyperpyrexia with anesthesia (not malignant hyperpyrexia)
Pierre Robin syndrome	Micrognathia Cleft palate Glossoptosis Congenital heart defects Cor pulmonale	Difficult airway, laryngeal mask airway may be useful Cardiac evaluation, prophylactic antibiotics
Potter syndrome	Renal agenesis Low-set ears Pulmonary hypoplasia	Spontaneous pneumothorax Renal failure Respiratory insufficiency
Sturge-Weber syndrome	Vascular malformations and hemangiomas (intracranial)	Possible blood loss
Treacher Collins syndrome	Facial and pharyngeal hypoplasia Micrognathia, choanal atresia Congenital heart defects	Extremely difficult airway Cardiac evaluation, prophylactic antibiotics
Trisomy 18	Congenital heart disease common Micrognathia	Difficult airway Cardiac evaluation, prophylactic antibiotics
Turner syndrome	Micrognathia Webbed neck, short stature Congenital heart defects Renal anomalies	Difficult airway Cardiac evaluation, prophylactic antibiotics Renal insufficiency
VACTERL association	Vertebral anomalies Imperforate anus Cardiac defects Tracheoesophageal fistula Radial dysplasia Renal anomalies	Cardiac evaluation, prophylactic antibiotics Tracheoesophageal fistula management
Williams syndrome	Elfin facies Infantile hypercalcemia Supravalvular aortic stenosis	Cardiac failure
Zellweger syndrome	Craniofacial dysmorphism Glaucoma Peroxisomal abnormalities in kidney and liver	Difficult airway Impaired renal drug excretion Electrolyte imbalance Abnormal coagulation

CNS, Central nervous system; ICP, intracranial pressure.

requires increased vigilance to avoid hypoxia, hypercarbia, and acidosis, which tend to increase pulmonary resistance. Bronchopulmonary dysplasia is a common chronic lung disease of premature infants. Infants with bronchopulmonary dysplasia are susceptible to excessive pulmonary vasoconstriction in response to hypoxia, hypothermia, or acidosis. Because of their chronic lung disease, these infants may have some degree of cor pulmonale, and decreases in myocardial function related to anesthetics may result in acute right heart failure. Other problems in bronchopulmonary dysplasia include airway hyperreactivity, increased airway secretions, electrolyte abnormalities because of diuretic therapy, and frequently tracheomalacia.[42]

Congenital anomalies of the heart also must be carefully evaluated. Right-to-left shunts affect the oxygenation of the infant, whereas left-to-right shunts typically result in volume overload. The infant should be carefully evaluated for signs of congestive heart failure, such as hepatic congestion, enlarged heart, and edema. The presence of single ventricle physiology is particularly important, because the anesthesiologist needs to take great care to maintain balance between the pulmonary and systemic circulations. High inspired oxygen concentration in these infants results in pulmonary vasodilation and pulmonary overcirculation at the expense of systemic circulation, with consequent acidosis. Particular attention should be paid to ventilation; in some cases,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

increased inspired CO_2 may be beneficial. Abnormal pulses on physical examination may indicate coarctation of the aorta. Antibiotic prophylaxis for endocarditis is also often important in neonates with congenital heart disease. Intrinsic arrhythmias are unusual in a neonate, although congenital heart block may occur in infants of mothers with systemic lupus erythematosus.

Neurologic function also should be carefully assessed. Hemodynamic changes during surgery may affect cerebral blood flow. A history of seizures should increase the anesthesiologist's level of suspicion for intraoperative seizure if there are unexplained tachycardias or blood pressure elevations. The presence of intraventricular hemorrhage requires increased care to maintain hemodynamic stability and is a contraindication to procedures requiring anticoagulation. A history of hydrocephalus mandates avoidance of factors that increase intracranial pressure.

Transport Within Hospital

Transport of a premature infant may be as great a risk as the surgery itself. Dedicated transport incubators, with a built-in ventilator, air and oxygen supplies, and a blender should be used if possible. If this equipment is unavailable, extra care must be taken. In addition to the inherent risks involved in the transport of a potentially unstable patient, premature neonates are particularly susceptible to cold stress. Heat loss during transport must be addressed, because the hospital corridors are rarely neutral thermal environments. If the infant is in an incubator, the incubator should be used for transport, because heat is retained even when it is unplugged. An infant on an open radiant warmer should be covered, including the head. In some institutions, plastic wrap is used to retain heat and reduce evaporative losses. Disposable chemical warmer packs are available and can be used under the infant either in an incubator or on the radiant warmer.

A need for assisted ventilation presents additional problems. During hand bagging with an anesthesia bag, CPAP or PEEP is generally lost; in most situations, a simple oxygen tank is also used, limiting ventilation to 100% FIO_2. The anesthesia bag always should include a manometer, because it is easy to reach pressures that can result in barotrauma complications such as pneumothorax. A self-inflating resuscitator can be used for room air ventilation, and a PEEP valve can be added to the device, but controlled oxygen delivery requires an additional air tank and a blender. In an intubated infant, CPAP or PEEP can be maintained using devices such as the Neopuff™. Particular care must be taken not to dislodge the endotracheal tube; small changes can result in either extubation or endobronchial intubation, particularly in a very premature infant. A laryngoscope, endotracheal tubes, and a face mask should be taken on transport in case the endotracheal tube is dislodged.

For all but the healthiest neonates, a physician experienced in neonatal resuscitation and who has the ability to manage critically ill neonates should accompany the transport. In most situations, this person should be the anesthesiologist. Monitoring during transport varies depending on the condition of the infant. As a minimum, a pulse oximeter provides pulse rate and arterial oxygen saturation. In most ill neonates, electrocardiogram (ECG) and blood pressure should also be monitored, especially if the infant has an indwelling arterial line. Any pumps providing infusions to the infant should have adequate battery power to operate throughout the transport, especially if vasoactive drips are running. Syringe pumps provide a very stable rate and have a long battery life, and the entire system is compact, minimizing the equipment needing transport. These pumps also run accurately at a low (0.5 mL/h) rate so that concentrated infusions can be used, minimizing fluid delivered to the neonate.

A complete round of resuscitative medications also should accompany any infant being transported to or from the NICU. Some transports require multiple personnel. With planning and adequate personnel, transport of infants on extracorporeal membrane oxygenation or infants receiving inhaled nitric oxide is possible.

In some situations, if the surgical procedure is appropriate, the surgeon is cooperative, and a suitable locale is available, it may be preferable to perform some procedures in the NICU. Basic requirements for a suitable locale include a clean area that can be closed off from traffic and adequate equipment, including overhead lights, surgical instruments and supplies, appropriate monitors, and anesthesia equipment. For premature neonates, an anesthesia machine is not usually needed, and a standard neonatal ventilator can be used. In many state-of-the-art NICUs, there is a dedicated operating room, with appropriate equipment, gases, and lights within the NICU, so that the most critically ill infants can be cared for with minimal transport.

Operating Room Equipment and Monitoring

The operating room should not merely replicate NICU capabilities; it should surpass them, because the neonate is subjected to the additional stress and destabilization of surgery. It is helpful if the room itself has adequate temperature control, because it may be necessary to increase room temperature to obtain a neutral thermal environment. Before draping, radiant heat lamps can be used, although care must be taken to not place the lamps too close to the infant because overheating can occur. The operating tables for neonates should use a heating pad. For longer cases, forced-air heaters with a "full access" disposable air blanket that is placed under the infant may be used. Care does have to be taken that the sheets and drapes around the infant are dry, however, as evaporative cooling can occur with the continuous air flow if the child is wet. Maintenance fluids, because they are given at a relatively slow rate, usually can be given at room temperature, but fluid warmers must be available for blood or faster fluid administration. Cooling is rarely necessary, but it is possible to overheat an infant if care is not taken. Temperature must be monitored. Core

• BOX 39.1 Routine Monitoring Requirements

Routine

- Precordial or esophageal stethoscope
- Pulse oximeter
- Electrocardiogram
- Blood pressure (noninvasive or arterial line-umbilical artery catheter or peripheral arterial catheter)
- Core temperature—rectal, esophageal, nasopharyngeal
- End-tidal CO_2
- Peak inspiratory pressure, tidal volume, positive end-expiratory pressure
- Fraction of inspired oxygen (FIO_2)

Optional

- Central venous pressure
- Blood gases—pH, PCO_2, PO_2
- Urine output
- Electrolytes

temperature is the best temperature to monitor. It can be measured with a rectal, nasopharyngeal, or esophageal probe. Bladder and tympanic membrane probes are rarely used in neonates because of size. Skin temperature is a poor choice for monitoring temperature, as it often better approximates the environmental temperature rather than the core temperature in a small infant.

Routine monitoring requirements for neonates are listed in Box 39.1. Continuous pulse oximetry has revolutionized anesthesia, and it is a standard of care in neonates as in adults. In some situations, particularly with congenital heart disease or PPHN, two pulse oximeters may be used to monitor preductal and postductal oxygen saturations. Heart rate is monitored from the pulse oximeter and the ECG. Disposable neonatal ECG pads are needed, from a size standard and because they may adhere better to the vernix caseosa-covered skin of the neonate. Noninvasive blood pressure can be measured, and most available machines have neonatal cuffs and a neonatal mode, which uses a smaller air volume for cuff inflation and is accurate in the neonate.

Invasive arterial blood pressure measurements from an indwelling line should be routine in most sicker or more premature infants. Common sites are the umbilical artery, either radial artery, and the femoral artery (as a last resort). Dorsalis pedis is rarely useful, but an axillary or posterior tibial line may be used occasionally. The arterial line site needs to be considered in relation to the clinical condition of the neonate; if coarctation of the aorta is present, a right radial line should be used. Similarly, if a right Blalock-Taussig shunt is planned, a left radial line is appropriate. Arterial lines in the neonate must be treated with the greatest delicacy. If blood is drawn from the line, a small syringe should be used, and suction should never be applied, because the artery easily can go into spasm. The line always should be flushed gently, again with a syringe and not with a pressure bag attached to the transducer. For smaller neonates, an intravenous infusion pump (not a pressure bag) should be used to keep a continuous flow through the transducer, to prevent inadvertent flushing and to limit the rate of fluid administration through the transducer (3 mL/h with the pressure bag vs. 0.5 mL/h with the pump).

End-tidal CO_2 measurements also have become a standard of care, and they can be very helpful, but obtaining accurate measurements in a small neonate can be difficult. With a typical capnograph, the accuracy depends on the actual site of sampling, the type of anesthesia circuit used, and the volume of fresh gas flow through the circuit. Patient factors such as right-to-left shunt also may alter the values. The most accurate measurements are obtained using a low dead space circuit, with the sampling site in the endotracheal tube, not on the circuit. This location is accomplished via an endotracheal tube connector with a side port molded into it, to which the capnograph sampling tubing can be attached. Blood glucose should be monitored intermittently during anesthesia; the importance of central venous pressure, urine output, and blood gases depends on the situation.

Previously, many anesthesia machines were equipped with a rudimentary, volume-limited, time-cycled ventilator, which even with a pediatric bellows was poorly suited for neonatal ventilation. Small tidal volumes were very difficult to set, and tidal volume and pressure varied tremendously depending on the fresh gas flow. In the best of hands, these ventilators are impossible to use with premature neonates. Newer anesthesia machines incorporate significantly more sophisticated ventilators, capable of either volume-limited or pressure-limited ventilation. These ventilators can be used in pressure-limited, time-cycled mode, and they incorporate a spirometer that can measure expired tidal volumes of 10 mL. Fresh gas flow is uncoupled from tidal volume, and changes in flows do not affect ventilation. Positive end-expiratory pressure can easily be added without the external valves used in older machines. These machines can be used routinely in infants weighing as little as 500 g.

An alternative method is to bring a NICU ventilator to the operating room. Critically ill neonates with high ventilator setting may be best served by the accuracy of a NICU ventilator. Pressure-limited, time-cycled, and volume-limited ventilators are widely used to ventilate the smallest neonates. A disadvantage of pressure-limited ventilation is that tidal volume varies with changes in compliance, and care must be taken during surgery to monitor tidal volume and blood gases and end-tidal CO_2 to ensure adequacy of ventilation. Using a neonatal ventilator usually prevents the use of inhalational anesthetic agents, and it requires an intravenous anesthetic technique.

The circle breathing system, with inspiratory and expiratory valves and incorporating a CO_2 absorber, has become standard in adult anesthesia. A major advantage is that a semiclosed technique with very low gas flows can be used, conserving anesthetic agent. Similar circle systems,

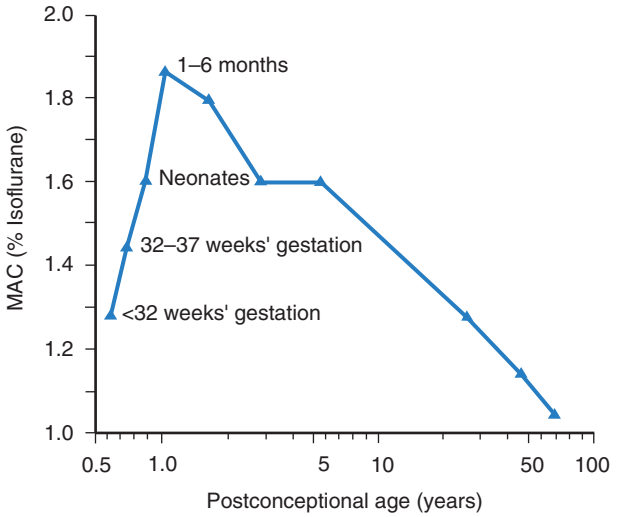
appropriately sized for infants, with lower compliance tubing and smaller bags, are commonly used in neonates.



The operating room must be equipped with appropriately sized airway equipment, including Miller No. 00, 0, and 1 blades; cuffed and uncuffed endotracheal tubes; and nasopharyngeal and oropharyngeal airways. An assortment of special blades should be available for difficult airway cases. The laryngeal mask airway (LMA) is a device that fits in the pharynx, covering the glottis and the esophageal opening. A cuff seals against the walls of the pharynx. Laryngeal mask airways do not occlude the esophagus and may notably increase the risk of aspiration during positive pressure ventilation. Laryngeal mask airways are available in small sizes but are not commonly used in neonates. Laryngeal mask airways can be very helpful in assisting with ventilation and intubation in some infants with congenital anomalies such as Pierre Robin syndrome, where securing the airway may be difficult. Essentially, the LMA is positioned, and a fiberoptic bronchoscope is passed through the LMA and into the trachea. An endotracheal tube can be passed through the LMA over the bronchoscope. The neonatal fiberoptic bronchoscope is essential for difficult airway cases. This bronchoscope is limited by extreme flexibility, and it does not have a suction channel, but it passes through a 2.5 endotracheal tube.

General Anesthesia

Most infants who require surgery receive a general anesthetic. There is increasing interest in regional techniques, but most often this is still combined with a general anesthetic. Successful delivery of general anesthesia in neonates requires knowledge of developmental pharmacology to predict and understand the responses of premature infants to anesthetic drugs. Size has an effect on response to anesthetics, and developmental age has a profound impact on the dose response, distribution, and metabolism of these drugs.

Inhalational Agents

Although common in older children, inhalational anesthesia has not been used as extensively in premature infants. Higher doses of volatile anesthetics required for an inhalation induction may be poorly tolerated, causing hypotension, bradycardia, and decreased cardiac output. Careful administration of inhaled anesthetics can allow for safe use of these drugs during the maintenance phase of anesthesia. The anesthetic effect of inhalational agents depends on the partial pressure of the anesthetic in the brain and the potency of the agent. For several reasons, very high partial pressures of the inhalational agents in the brain develop much more rapidly in neonates than in older children and adults. First, as already discussed, the ratio of alveolar ventilation (per minute) to FRC in neonates is 5:1 compared with 1.5:1 in adults, and consequently alveolar anesthetic concentration equilibrates with inspired concentration very quickly. Second, a greater fraction of the cardiac output in

• **Fig. 39.2** Minimum alveolar concentration (MAC) of isoflurane and postconceptional age on a semilogarithmic scale. (From LeDez KM. The minimum alveolar concentration [MAC] of isoflurane in preterm neonates. *Anesthesiology.* 1987;67:301.)

the neonate is distributed to the vessel-rich group and consequently the brain. Finally, the solubility of the inhaled anesthetics in blood is less in neonates than in adults.[36] Brain tissue equilibrates very quickly with the alveolar concentration of anesthetic and increases the risk of overdose in a neonate.

The potency of inhalational anesthetics is expressed using the minimum alveolar concentration (MAC). The MAC is the concentration at which 50% of patients exhibit no response to surgical stimulation such as skin incision. The MAC is related to postconceptional age and is lowest in very premature neonates, increasing to a peak at a postconceptional age of approximately 1 year and then decreasing progressively from childhood through adulthood. Fig. 39.2 shows this relationship for isoflurane.[36] As shown, isoflurane is more potent (lower MAC) in premature neonates than in older infants, but this MAC is not markedly different from that of adults, and difficulties using inhalational anesthetics are related more to the rapid uptake and equilibration.

Common inhalational anesthetics are the halogenated volatile anesthetics isoflurane and sevoflurane. Desflurane is rarely used in neonates. Inhalational anesthetics are complete anesthetics, with analgesic and amnesic properties. Isoflurane is very pungent and cannot be used for mask induction. Systemic vascular resistance is decreased by isoflurane and hypotension can result, especially if preload is diminished. Moderate volume loading helps to minimize any decrease in blood pressure. Isoflurane also causes cerebral vasodilation, and in the absence of hypotension, cerebral blood flow increases. In adults, isoflurane decreases cerebral metabolism and is cerebral protective.

Sevoflurane has become very popular in pediatric anesthesia for mask induction. It is not irritating to the airway, and it is almost insoluble in blood so that equilibration between brain and alveolus occurs rapidly. Onset of anesthesia during mask induction is very fast. Cardiovascular

effects are similar to effects with isoflurane. There is little published experience with sevoflurane in preterm infants, although it is used primarily for mask inductions in healthier neonates. Sevoflurane has been associated with prolongation of the Q-T interval of the ECG in adults and infants; this may be of concern because a long Q-T interval has been associated with sudden death. There have been no reports, however, of intraoperative or postoperative complications related to sevoflurane and cardiac repolarization abnormalities, and it is uncertain if this is of any clinical concern.[38]

Nitrous oxide is an inhalational anesthetic, but it is not in the same class as the halogenated agents. It is a weak anesthetic, with a MAC of 104% in adults, so that to reach MAC, nitrous oxide would have to be provided at hyperbaric pressures. The need for oxygen as part of inspired gases prevents achievement of these levels. Nitrous oxide also is almost insoluble, and onset of effect is fast. Insolubility and the high concentration that is necessary for any meaningful effect cause nitrous oxide to enter progressively and to expand any gas-filled space in contact with the circulation, which rapidly leads to bowel distention or expansion of pneumothorax. If ventilation is interrupted for any reason, nitrous oxide also rapidly fills the alveoli, leading to dilution of the alveolar oxygen, producing a hypoxic mixture and rapid desaturation. For these reasons, nitrous oxide is best limited to adjunct use during mask induction, with a switch to an air-oxygen mixture during maintenance anesthesia and has limited usefulness in the anesthetic management of the neonate. As previously discussed, all of the inhalational agents cause neuroapoptosis in animal studies.

Intravenous Agents

Intravenous agents for use in neonates include sodium thiopental, propofol, ketamine, various narcotics, and benzodiazepines. Sodium thiopental is an ultra–short-acting barbiturate used primarily as an induction agent. Thiopental is primarily a hypnotic, with little analgesic activity. Use is limited in smaller and sicker neonates, because it has negative inotropic activity and is a peripheral vasodilator. Hypotension is common, particularly in volume-depleted patients. At present, thiopental is not available for use in the United States.

Propofol is a phenol derivative supplied as an emulsion in lipid, which in older children and adults is used for induction and maintenance of anesthesia. Recovery from the drug is rapid in adults because of redistribution and metabolism by liver and tissues. Propofol has little analgesic effects, and for painful operations it should be used with narcotics. Propofol has been approved for children younger than 3 years, but there is little experience with the drug in premature infants. A slower recovery due to less fat and muscle for redistribution would be expected, as well as possibly slower hepatic metabolism owing to immaturity. It is a potent peripheral vasodilator, and hypotension is a common problem limiting its use in preterm neonates.[65]

Ketamine, a phencyclidine derivative, provides good hypnosis and amnesia and excellent analgesia. When used as a sole agent in adults and older children, it can cause a dissociative state with confusion, hallucinations, and other severe psychological side effects. Ketamine stimulates the sympathetic nervous system and causes minimal respiratory and cardiovascular depression, which may make it a useful adjunct in the anesthetic care of the infant. Blood pressure may increase, and increased intracranial pressure is a concern in infants with hydrocephalus or those at risk for intraventricular hemorrhage. Ketamine can be useful in breaking hypercyanotic spells in an infant with congenital heart disease and right-to-left shunt, because it anesthetizes and increases systemic vascular resistance.

Benzodiazepines are agents that produce sedation, anxiolysis, and amnesia, but little analgesia. They are incomplete anesthetic agents, although in adults they have been very useful in combination with an opioid. Midazolam is a very short-acting benzodiazepine, and it has been the most commonly used in anesthesia. Metabolism is almost entirely hepatic, and it should be expected that duration would be prolonged by immature hepatic function in a preterm neonate. Midazolam causes vasodilation, which can result in hypotension. In high doses, it can cause respiratory depression, although this is more common in conjunction with opioids. Midazolam and the longer-acting benzodiazepine lorazepam have been used for sedation in the NICU with mixed results. The Cochrane Neonatal Collaborative Review Group performed a meta-analysis of several studies on sedation in the NICU using midazolam. All three studies showed that midazolam was effective at providing sedation to the neonate. However, one study showed a higher risk of poor neurologic outcome or death in the midazolam-treated group as well as evidence of increased length of stay, which at least raises questions as to the safety of midazolam infusion in these infants.[43]

Fentanyl, a synthetic opioid, is widely used in neonatal anesthesia, and it is the most commonly used anesthetic for premature infants. It has a wide safety margin and beneficial effects on hemodynamic stability. Fentanyl can block pulmonary hypertensive crises, and it is useful in infants with pulmonary hypertension, such as infants with congenital diaphragmatic hernia, PPHN, and some cardiac defects. The pharmacokinetics of fentanyl in the early neonatal period is widely variable, depending on gestational and postnatal age and the type of surgery and medical problems of the infant.[49] Fentanyl is primarily metabolized in the liver, with only a small amount excreted unchanged by the kidneys. Clearance is lowest in the most premature infants, and it increases with gestational age and with age after birth, probably reflecting increasing hepatic maturation. Volume of distribution of fentanyl also seems to vary depending on gestational age and disease state. Neonates with increased intra-abdominal pressure seem to have slower clearance of fentanyl, likely due to the resulting decreased hepatic blood flow.

Given the highly variable pharmacodynamics, fentanyl dosing needs to be individualized and titrated to effect.

There is a fairly wide therapeutic range, and even with high doses, hemodynamic stability is maintained. All narcotics are respiratory depressants, however, and with higher doses of fentanyl, prolonged respiratory depression occurs, necessitating postoperative assisted ventilation.

Fentanyl in combination with a muscle relaxant has become the standard for anesthesia in premature neonates. This combination may also be used during elective (nonemergent) intubation in the NICU. Although fentanyl is a potent analgesic, it is not a complete anesthetic, and occasionally in adults, awareness has occurred with high-dose fentanyl alone. In the past, it was suggested that this was of minimal importance because neonates are not "aware," especially if pain was adequately treated. This belief is less well accepted today, and benzodiazepines or inhalational agents such as isoflurane are more commonly added to fentanyl anesthesia.

Other synthetic narcotics such as alfentanil and sufentanil rarely have been used in neonates. In adults, alfentanil is less potent than fentanyl, but it has a shorter half-life, whereas sufentanil is more potent than fentanyl. Pharmacokinetics in infants is probably similar to fentanyl, and there does not seem to be any significant advantage compared with fentanyl. Remifentanil is a newer opioid whose duration of action is terminated by hydrolysis by tissue esterases. Consequently, remifentanil does not accumulate or have prolonged duration of action. A half-life of 4.4 minutes and a clearance of 80 mL/kg per minute have been reported in neonates.[50] Duration of action is very short, and it may be of use for procedural analgesia with little persistent pain. Duration can be extended by using a continuous infusion, but this can be associated with opioid-induced tolerance and hyperalgesia.[45,50]

Morphine is the principal opium alkaloid, and it is the standard against which analgesics are measured. Morphine is less potent than fentanyl, but it has a longer duration of action and is more commonly used for postoperative pain. The duration of action of morphine is increased in premature infants. As with all narcotics, respiratory depression is a major side effect. In contrast to fentanyl, morphine causes histamine release, which limits its use as an anesthetic agent; although, it is well accepted for analgesia, postoperative pain, and overall sedation. Morphine distribution in neonates has been well studied and is very predictable, although required target concentrations in neonates are still uncertain.

Dexmedetomidine is a highly specific alpha$_2$-adrenergic agonist with hypnotic, analgesic, and anxiolytic properties. It is being used with increased frequency in the pediatric setting for sedation during nonpainful procedures such as MRI as an adjunct to other anesthetics during surgical procedures and for sedation of critically ill patients in the ICU setting. Despite the sedating properties of dexmedetomidine, there is little effect on respiratory function, thereby promoting earlier extubation and decreasing the need for analgesics that have respiratory depressant properties. Numerous studies have demonstrated the effectiveness and safety of dexmedetomidine as an analgesic and sedative in infants after cardiac surgery. Adverse effects of dexmedetomidine include bradycardia and hypotension as well as paradoxical hypertension, but it has been found to be well tolerated in neonates.[16] The drug undergoes hepatic metabolism and, therefore, has decreased plasma clearance and longer elimination half-life in preterm neonates with immature hepatocyte function.[9] Preliminary data in animals studies shows evidence that dexmedetomidine may actually protect against neuroapoptosis caused by other anesthetic agents.[46]

Neuromuscular Blocking Agents

Muscle relaxants are commonly used in anesthesia for neonates. They are often grouped according to mechanism of action (i.e., depolarizing versus nondepolarizing), but it is more important to consider rapidity of onset and duration of action.

Succinylcholine chloride is the only depolarizing agent used at present, and it remains the standard for rapid onset and rapid disappearance. The ED_{95} (effective dose in 95% of the population receiving the dose) in neonates for succinylcholine is twice that of adults at 1.5-2 mg/kg. Action is terminated by metabolism by plasma pseudocholinesterase. Succinylcholine is not routinely used in children because of several rare but serious adverse reactions. In patients with myopathies or neurologic diseases, succinylcholine can cause overwhelming hyperkalemia, muscle necrosis, and cardiac arrest that is refractory to resuscitation. Bradycardia also occasionally occurs during intubation in infants with succinylcholine. For this reason, some anesthesiologists routinely administer atropine with succinylcholine. In pediatric patients, succinylcholine is reserved primarily for rapid sequence induction when a full stomach is suspected.

Nondepolarizing relaxants competitively inhibit acetylcholine at the neuromuscular junction. Vecuronium bromide is an intermediate-acting relaxant occasionally used in neonates. It has little effect on the cardiac system, although it may cause bradycardia in combination with narcotics. Cisatracurium besylate undergoes spontaneous degradation by a chemical process (Hofmann elimination), and duration is not affected by liver or kidney function. Atracurium, its parent compound, is rarely used today because it causes histamine release. Rocuronium bromide is an agent with a rapid onset of action that can be used in place of succinylcholine for rapid sequence induction. Duration of action is dose dependent and significantly longer than succinylcholine.

Most relaxants probably have a prolonged duration of action in premature neonates, and frequency of dosing should be determined using a nerve stimulator to measure response to four spaced stimuli (train-of-four response). At the completion of surgery, muscle relaxation with nondepolarizing agents should be reversed with an anticholinesterase, typically neostigmine, and an anticholinergic, such as glycopyrrolate or atropine.

Induction of General Anesthesia

Most sick infants have intravenous access, and an intravenous induction can be performed. Premedication rarely is given to neonates, although some anesthesiologists recommend glycopyrrolate or atropine before laryngoscopy and intubation to mitigate any possible vagal response and bradycardia with intubation. Healthier infants without intravenous access can undergo mask induction, typically with 50% nitrous oxide and sevoflurane, after which intravenous access is rapidly obtained.

Infants with a full stomach, most commonly infants with intra-abdominal disease, must have an intravenous rapid-sequence induction. During rapid-sequence induction, the infant is first preoxygenated with 100% F_{IO_2} to maximize oxygenation during the apneic period of intubation. An IV induction agent such as propofol, along with a fast-acting paralytic, is administered in rapid succession. The use of cricoid pressure to prevent regurgitation of gastric contents is not routinely considered, as it can actually hinder successful intubation by obscuring the view of the glottic opening during laryngoscopy.[63] Positive pressure ventilation is avoided or provided very gently, and the infant is intubated expertly as soon as conditions are appropriate, usually after 45-90 seconds. There is little room for error with rapid sequence induction, and it should be performed only by individuals with significant expertise.

Awake intubation with continued spontaneous ventilation is an alternative, but it should be reserved for infants with concern for difficult airways, such as in Pierre Robin and Goldenhar syndromes, where maintenance of spontaneous ventilation is beneficial during situations where time to successful intubation may be prolonged. Minimal sedation can be given, but protective airway reflexes should not be obtunded. When the airway is secured, induction can continue by intravenous or inhalational route. Management of the difficult airway requires careful planning and the availability of additional "trained hands." A pediatric fiberoptic bronchoscope and a range of special-purpose laryngoscope blades may be useful. Pediatric ear, nose, and throat consultation may also be valuable. The LMA may assist with ventilation, but it does not protect the airway. The pediatric bronchoscope also can be used to intubate through the LMA. Awake intubations are known to cause higher rates of airway trauma and can have significant hemodynamic consequences in the neonate, such as arterial hypertension, pulmonary hypertensive crisis, and increased intracranial pressure due to pain and sympathetic stimulation.[35] This technique should be reserved for the most critical of circumstances.

Maintenance of Anesthesia

Maintenance of anesthesia requires monitoring as previously discussed. Temperature must be carefully controlled, and adjustments in heating or cooling must be appropriately made. Fluid and metabolic requirements also must be carefully assessed throughout the course of the surgery. Fluids should be administered with an infusion pump to prevent inadvertent overload. It is usually easiest to calculate and administer maintenance fluids separately from replacement. Maintenance fluids should include glucose unless the infant is known to be hyperglycemic. Intravenous hyperalimentation or a dextrose-electrolyte solution can be used, depending on the size, age, and clinical condition of the neonate. Third space losses should be initially replaced with a balanced crystalloid solution such as lactated Ringers. Blood loss also can be replaced with crystalloid initially.

Third space losses can be impressive, ranging from 2-15 mL/kg per hour, especially during procedures with large amounts of bowel exposed, such as for repair of gastroschisis and omphalocele. Many infants, especially if they are hypoalbuminemic, should receive some replacement as colloid, usually 5% albumin. In the sickest neonates, transfusion with packed red blood cells, fresh frozen plasma, and platelets may be required. Urine output should be followed as one sign of adequate fluid replacement.

Ventilation should be carefully controlled. Use of oxygen has been discussed; if controlled ventilation is employed, care should be taken to avoid hyperventilation and subsequent hypocapnia. Higher peak pressures can cause significant barotrauma. Accurate ventilation may be difficult to monitor because varying anesthesia circuits and adapters can result in widely varying dead space and a variable offset between end-tidal CO_2 and the actual blood P_{CO_2}. Cerebral oximetry employing near-infrared spectroscopy can provide information on changes in cerebral blood flow.

Recovery From Anesthesia

Emergence from anesthesia in the smallest and sickest premature infants is usually a prolonged event, because these neonates are not typical candidates for extubation at the conclusion of surgery; instead, they require continued intensive care in the NICU. Immaturity of drug clearance systems also prolongs recovery from the effects of most anesthetic agents in these infants. Transport from the operating room involves the same considerations of temperature maintenance and airway management that have previously been discussed. Older and healthier infants often can be extubated after surgery. Neuromuscular blockade should be reversed, as previously discussed. Hypothermia can prolong neuromuscular blockade, precluding extubation if temperature control has not been adequate, and infants with hypothermia may need to be actively warmed.

The infant should have resumed regular rhythmic respiration; to achieve this, ventilation may need to be decreased toward the end of the anesthetic to allow P_{CO_2} to increase to mildly hypercapnic levels. Volume status must be adequate, and plasma hemoglobin should be close to normal. Flexion of the hip and contraction of the rectus abdominis muscle have been used as signs of adequate motor strength, and the infant usually begins to gag on the tube. Laryngospasm can occur on extubation, and the anesthesia personnel need to be ready to treat and reintubate if necessary.

As previously discussed, premature infants often experience periodic breathing, and there is a risk of postoperative apnea in these patients that is inversely related to gestational age. Anemia may be a risk factor for apnea, although this is controversial. A conservative approach is to avoid elective surgery and anesthesia until the former preterm infant reaches 60 weeks' postconceptional age, at which time the risk of postoperative apnea seems small. If surgery cannot be delayed, the infant should be admitted and monitored for 12-24 hours after surgery or after the last apneic episode.

Local and Regional Anesthesia

Concerns about the neurotoxicity of general anesthetic agents have awakened new interest in regional anesthesia in children and neonates.[22,40] Widespread availability of ultrasound has made it both easier and safer to perform regional blocks in children.[60,61] Regional techniques are most commonly combined with general anesthesia, with the primary indication control of postoperative pain and decreasing postoperative analgesic requirements. There are inherent technical difficulties to performing regional anesthesia in neonates, including the need for appropriate-sized catheters and the need for specialized training to perform these blocks safely and successfully.

Local infiltration or nerve block is useful in certain specific procedures such as circumcision where a dorsal penile nerve block (DPNB) or penile ring block has been shown to be safe and effective. Other simple methods such as a sucrose-dipped pacifier, or a padded and physiologic restraint chair, further decrease objective signs of distress during circumcision performed with DPNB. Eutectic mixture of local anesthetic (EMLA) cream also has been used for neonatal circumcision. When used for circumcision, EMLA is more effective than no anesthesia, but it is not as effective as DPNB.[8] Other indications for use of EMLA include venous and arterial puncture, lumbar puncture, suprapubic puncture, and minor surgical procedures. Transversus abdominis plexus (TAP) blocks and rectus sheath blocks can be used to obtain anterior abdominal wall anesthesia and periumbilical anesthesia for abdominal surgeries such as umbilical hernia.[27]

Caudal anesthesia is often used with inguinal hernias, although an ilioinguinal nerve block can be done with ultrasound guidance and may provide a longer duration of analgesia. Intercostal nerve blocks can be used for thoracotomy and flank incisions; use of ultrasound-guided paravertebral blocks may be used in these cases. An indwelling catheter also can be placed in an intrapleural location by the surgeon and continuous infusion of bupivacaine given after thoracotomy.

Caudal anesthesia is a useful option for surgeries involving the lower abdomen, groin, and lower extremities. The epidural space can be entered by the caudal route through the sacrococcygeal membrane. Caudal anesthesia given as a single injection is commonly used in combination with a general anesthetic to allow for lower concentrations of inhalational agents as well as provide postoperative pain control. After a caudal anesthetic with bupivacaine or ropivacaine, most infants are free of pain immediately after surgery, with relief continuing for at least 3-4 hours. The single shot technique utilizes a 22-gauge, short-bevel needle or 22-gauge angiocath to enter the caudal space. Caudal anesthesia requires a higher dosage of anesthetic, so the possibility of an inadvertent intravascular injection is a concern. A catheter can also be threaded into the epidural space for continuous caudal anesthesia. With the continuous technique, the catheter can be threaded up into the epidural space, often high enough to give midthoracic anesthesia if needed. This technique seems to be well tolerated without significant hemodynamic effect. The use of neuraxial catheters, including thoracic, lumbar, and caudal epidural catheters, has the ability to provide an alternative strategy for pain control in the neonate. Epidural catheters allow for the continuous infusion of local anesthetic intra- and postoperatively, thereby minimizing the need for analgesics that may result in respiratory depression or may have altered pharmacokinetic properties in the immature neonate. Despite the ability to perform these procedures, there has long been concern over the safety of these techniques in the neonatal patient. An observational study utilizing the Pediatric Regional Anesthesia Network (PRAN) was able to evaluate the incidence of complications related to the use of neuraxial catheters in patients under one month of age. With over 300 neuraxial catheters placed, the most common complications were catheter malfunction, catheter contamination, and vascular aspiration, which were all managed by removal or adjustment of the catheter. There were no reports of more serious complications, such as persistent neurologic injury, deep infection, or epidural hematoma.[39]

Regional anesthesia in the pediatric patient is almost uniformly performed under general anesthesia with an exceedingly low complication rate.[58] A regional technique without general anesthesia can be used in some neonates considered to be at high risk, such as those with severe bronchopulmonary dysplasia in whom avoidance of intubation for a general anesthetic is preferred. Inguinal hernia repair is a common procedure performed on premature infants, and caudal or spinal anesthesia is considered a reasonable anesthetic technique for the procedure. One major problem seems to be a modest rate of failure of the technique, leading to the need for additional sedation or conversion to a general anesthetic.[21,33] Despite the avoidance of a general anesthetic the most robust study comparing general anesthesia to awake regional anesthesia did not reveal an overall reduction in postoperative apnea in those patients receiving a regional anesthetic, but the infants receiving spinal anesthesia had less clinically significant apneas.[14] Spinal anesthesia can be induced using a 25-gauge Quincke needle at the L4 or L5 level (below the cauda equina). Either tetracaine or bupivacaine can be used depending on the length of procedure. Due to the duration of the block, surgical procedures must be completed in less than 90 minutes in order for spinal anesthesia to be considered.

Caudal or spinal anesthesia can be used without additional sedation for appropriate procedures such as inguinal hernia repair. In this situation, simple nonpharmacologic comfort measures such as a pacifier are useful, and the technique seems to be well tolerated.

Given the concerns over the potential for anesthetic-related neurocognitive deficits, usage of regional and neuraxial anesthesia may well increase. However, it is important to remember there is also little experience with the increasing numbers of agents used for neuraxial and regional anesthesia, particularly in infants and neonates, and little is known concerning possible effects on the developing spinal cord. Further careful evaluation, including preclinical and animal studies, is also needed in this area.[64]

Key Points

- The goals of anesthesia care in the neonate include management of pain and discomfort associated with surgical procedures as well as prevention of the stress response.
- Animal studies have demonstrated abnormal apoptosis and long-term neurocognitive deficits in rats and primates exposed to most of the most commonly used anesthetic drugs.
- Recent prospective human studies suggest that a single brief anesthetic exposure during early development appears to be safe.
- Anesthetic management of neonates should be performed by pediatric anesthesiologists and care should occur in a setting specifically tailored to the pediatric patient.
- Preoperative evaluation and anesthetic management of the neonatal patient requires specific understanding of pathophysiology specific to these patients, including transitional circulation, PPHN, respiratory distress syndrome and bronchopulmonary dysplasia, apnea of the newborn, temperature regulation, carbohydrate metabolism, and retinopathy of prematurity.
- There are an extensive number of congenital syndromes that have anesthetic implications.
- Nearly all anesthetics, including inhalational agents, induction agents, opioids, and neuromuscular blockers, can be used in the neonatal patient, but an understanding of their pharmacokinetics and pharmacodynamics in the immature neonate is necessary for safe administration.
- The use of regional anesthesia techniques, both as part of a general anesthetic or as the sole anesthetic, can be performed safely and successfully in the neonatal patient.

The Late Preterm Infant

KIMBERLY V. PARSONS AND LUCKY JAIN

Births between 34 and 36 6/7 weeks' gestation (referred to herein as *late preterm births*) account for a significant proportion of preterm births in North America and elsewhere. These infants are larger than usual premature infants, and they are generally passed off as mature infants, but they often manifest signs of physiologic immaturity or delayed transition in the neonatal period. Several studies have documented the high incidence of neonatal complications leading to neonatal intensive care unit (NICU) admissions in these infants. They have a higher incidence of transient tachypnea of the newborn (TTN), respiratory distress syndrome (RDS),[29] persistent pulmonary hypertension of the newborn (PPHN),[60] respiratory failure,[16] jaundice, temperature regulation problems, hypoglycemia,[3] and feeding difficulties than term infants.[21]

Concern about higher morbidity in late preterm infants has led to numerous publications with largely the same conclusions: Late preterm infants are more prone to problems related to delayed transition and overall immaturity, and they should be treated differently from their more mature term counterparts.[17,34,43,63,71] These observations have led to greater attention being paid to tracking short-term morbidity, health care costs, hospital stays, and issues such as rehospitalization. Nearly three out of four preterm births occur at late preterm gestational ages, and while there has been a steady increase over the past couple of decades, we are now seeing a decline since 2007.[43] The significant contribution of late preterm births is a worldwide phenomenon, although reported rates seem to be quite variable. The late preterm birth rate was 4.8% in Canada in 2006–2014. Danish, Finnish, Norwegian, and Swedish late preterm birth rates were 3.6%, 3.3%, 3.8%, and 3.6% respectively.[59] In Brazil, a country known to have one of the highest preterm birth rates in the world, the first national birth survey estimated the late preterm birth rate to be 8.5% in 2011.[40]

Definition

Preterm infants have been aptly and clearly classified for many decades. The World Health Assembly in 1948 described preterm infants as those weighing less than 2500 g or being less than 37 weeks' gestation. In 1950, the World Health Organization revised this definition, identifying all infants born before 37 completed weeks' gestation (259th day), counting from the first day of the last menstrual period, as preterm infants.[55] The American Academy of Pediatrics and the American College of Obstetricians and Gynecologists (ACOG) agree with this definition.[4]

Although *preterm*, *term*, and *post-term* have been clearly defined according to the week and day of gestation by the World Health Organization, American Academy of Pediatrics, and American College of Obstetrics and Gynecology, not all subgroups within the preterm gestation are well defined. There is less ambiguity about infants less than 32 weeks' gestation in the literature, being defined as *very preterm* if less than 32 weeks' gestation and *extremely preterm* if less than 28 weeks' gestation, but historically no clear definition existed for infants of 32-37 weeks' gestation. These infants were known by several different names, including *moderately preterm*, *mildly preterm*, *minimally preterm*, *marginally preterm*, and *near-term*. These near-term infants have been inconsistently defined in the literature as 34-36 weeks' gestation, 35-37 weeks' gestation, and 35-36 6/7 weeks' gestation (Fig. 40.1).

To clarify, and to place a greater emphasis on the fact that these slightly premature infants have a greater risk of morbidity and mortality than term infants, an expert panel at a workshop convened by the National Institute of Child Health and Human Development of the National Institutes of Health in July 2005 recommended that births between 34 completed weeks (34 weeks or day 239) and less than 37 completed weeks (36 6/7 weeks or day 259) of gestation be referred to as *late preterm* infants (Fig. 40.2).[56] Several factors led to this definition; 34 weeks is considered a matu-rational milestone in obstetric practice, after which surfactant is usually present in the lungs and is often used as a cutoff for giving antenatal steroids. Because there is no such thing as a normal preterm infant, and the assumptions that these infants are as healthy as term infants, use of terms such as *near-term* was discontinued. Data have shown that term infants born at 37 and 38 weeks' gestation have higher morbidity and mortality than infants born at 39 weeks' gestation.[63] Now, infants between 37 completed weeks' gestation (37 weeks or day 260) and 38 completed weeks' gestation (38 6/7 weeks or day 274) are referred to as *early term* infants Engle and Kominiarek.[17]

Abstract

In this chapter we hope to highlight the physiology and pathology of late preterm infants that make them unique compared to their early term, full term, and early preterm counterparts. Late preterm infants (34-36 6/7 weeks' gestation) account for a significant proportion of all preterm births. Historically, they were regarded as just smaller in size than full-term infants. However, it has now been shown that there is a high incidence of morbidity in this population, leading to neonatal intensive care unit (NICU) admission. After a steady increase in the number of late preterm births over previous decades, there has now been a decline since 2007, largely as a result of obstetrical interventions and a push to deliver more infants at 39 weeks, recognizing the increased morbidity of being born even just a few weeks early. Due to physiologic immaturity, late preterm infants are at greater risk for transient tachypnea of the newborn (TTN), respiratory distress syndrome (RDS), persistent pulmonary hypertension of the newborn (PPHN), respiratory failure, jaundice, thermoregulation problems, hypoglycemia, and feeding difficulties than term infants. LPT infants are also at greater risk for neurodevelopmental impairment. Late preterm infants should be recognized as an at-risk population and treated differently than both their more mature and less mature counterparts. Greater understanding of the associated morbidities and the development of effective interventions will help improve the short- and long-term outcomes of late preterm infants.

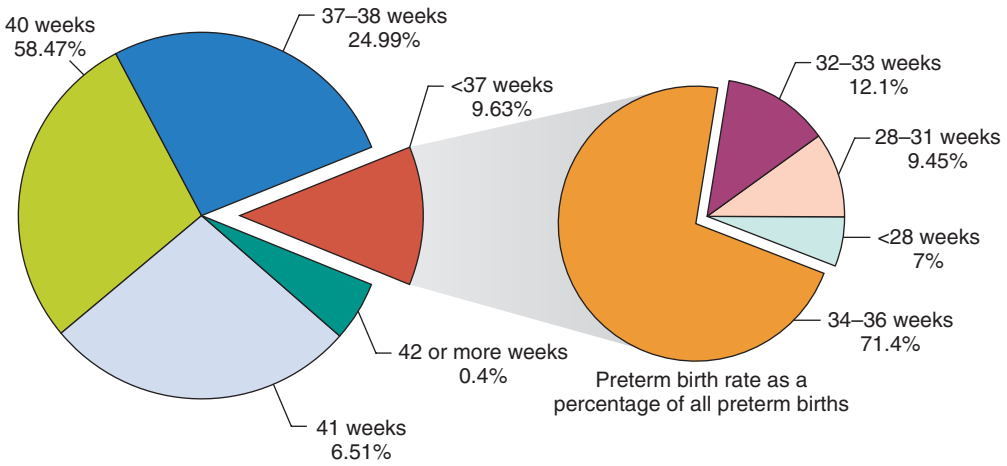
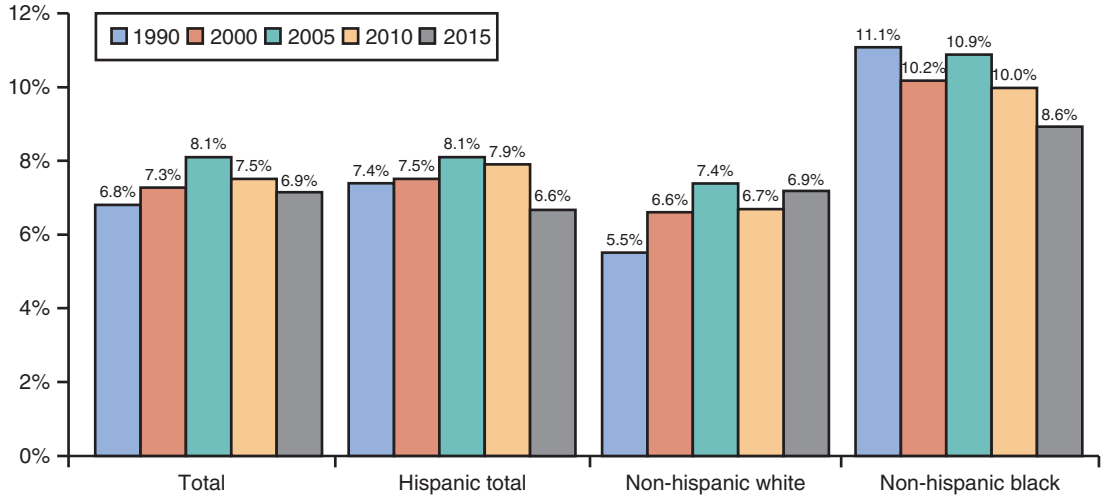
• **Fig. 40.1** Shifting distribution of gestational age among singleton live births, United States, 1990, 2000, 2006, 2010, and 2015. (Data from Martin JA, Hamilton BE, Ventura SJ, et al. National vital statistics reports. Vol. 61, no. 1. Hyattsville, MD: National Center for Health Statistics; 2015.)

• **Fig. 40.2** Definition of late preterm and early term. (Modified from Engle WA, Kominiarek MA. Late preterm infants, early term infants, and timing of elective deliveries. *Clin Perinatol.* 2008;35:325.)



Epidemiology and Trends

In the United States, there were 3,978,497 live births in 2015, of which 9.63%, or approximately 380,000, were preterm.[43] Late preterm infants at 6.87% constituted 71% of all preterm births (Fig. 40.3). Preterm births have steadily declined since a high of 10.44% in 2007. Increased awareness of the contribution of late preterm births to the total preterm birth rate and the increased risk to the infant lead to a significant reduction in such deliveries.[43] This decrease may be attributed to national efforts to decrease elective or nonmedically indicated deliveries before 39 weeks' gestation.[49]



Non-Hispanic black infants have nearly 1.5 times the late preterm birth rate than non-Hispanic white infants. The late preterm birth rate was 8.6% for singleton non-Hispanic black infants, 6.6% for Hispanic infants, and 6.5% for non-Hispanic white infants, showing a significant decline across all races over the past few years (Fig. 40.4).

Earlier studies indicated that late preterm infants have survival rates within 1% of term infants,[28] but there is mounting evidence to show that late preterm infants have

• **Fig. 40.4** Percentage of late preterm singleton births by race and Hispanic origin of mother in the United States, 1990, 2000, 2005, and 2010. (Data from Centers for Disease Control and Prevention, National Center for Health Statistics, National Vital Statistics System.)

significantly higher mortality compared with term infants. Mortality rates in the 2009 period linked birth and death certificate data showing that late preterm infants have three times the mortality rate (7.13/1000 live births) compared with term infants (1.98/1000 live births), and even early term infants had higher mortality (3.09/1000 live births) compared with full-term infants.

Etiology

The etiology of prematurity is complex and multifactorial, and although known clinical entities such as pre-eclampsia and premature rupture of membranes (PROM) are significant contributors to preterm births, several other causes have been implicated in the increase in the late preterm birth rate (Box 40.1).

Medical Interventions and Iatrogenic Causes

Cesarean section rates have dramatically increased in the United States and worldwide, increasing from a low of 5% in 1970 to a high of 32.9% in 2009, decreasing slightly to 32% in 2015.[43] Among the many reasons cited for this increase are increased fetal surveillance and interventions, increased age of women giving birth, increased number of multiple births resulting from fertility treatments, obesity, and heightened concerns of physicians and mothers about the risks of vaginal birth. Although spontaneous births and births from PROM declined during this period, births from medical interventions increased, with cesarean section accounting for most of the medical intervention group. In 2006, a national consensus conference coined a new term for cesarean deliveries for which no medical indication

• BOX 40.1 Etiology of Late Preterm Births

Medically Indicated

- Preterm labor
- PROM
- Preeclampsia

Medical Interventions and Iatrogenic

- Increased medical surveillance and interventions
- Cesarean or planned induction of labor. Medical indications:
  - Abnormal presentation, abnormal placentation, maternal or fetal conditions (e.g., PROM without labor, fetal hydrocephalus)
  - Repeat cesarean section
- Cesarean or planned induction of labor. No medical indication:
  - Induction of labor or cesarean section on maternal request
  - Fear of fetal and neonatal risks with vaginal delivery
  - Increased rate of stillbirths beginning at 39 weeks' gestation
  - Hypoxic-ischemic encephalopathy, brachial plexus, and other birth traumas
  - Fear of maternal risks with vaginal delivery
  - Risk for genital tract, anus, and perineal injury and sexual dysfunction
  - Perception that cesarean delivery is "easier" and "less stressful" than vaginal delivery
  - Fear of the second stage and having to "push the baby out"
  - Maternal willingness to accept risk on behalf of the infant
  - Convenience for mother and family

Gestational Age Assessment and Obstetric Practice Guidelines

- Inaccurate gestational age assessment during elective deliveries
- Maternal obesity
- Presumption of fetal maturity at 34 weeks' gestation
- Decreasing gestational age criteria for inductions and increased rate of stillbirths beginning at 39 weeks' gestation

Advanced Maternal Age, Assisted Reproductive Technologies, and Multiple Births

- Increase in multifetal pregnancies
- Delayed childbearing and increased risk for prematurity
- Use of assisted reproductive technologies (multifetal pregnancies) and increased risk for complications associated with premature delivery (e.g., preeclampsia, diabetes)

Physician Practice Patterns and Risk/Benefit Determination

- Concern for risk of adverse outcomes
- Convenience
- Liability

PROM, Premature rupture of membranes.
Modified from Engle WA, Kominiarek MA. Late preterm infants, early term infants, and timing of elective deliveries. *Clin Perinatol.* 2008;35:325.

could be found and where maternal choice was the leading factor—*cesarean delivery on maternal request*.[1] Although the exact number of such deliveries is hard to track, it is believed that 2.5% of cesarean sections may be performed at maternal request.[1,57]

Although elective cesarean sections are discouraged before 39 weeks' gestation, a study by Tita and associates found that nearly 36% of elective repeat cesarean sections were performed before 39 weeks' gestation.[70] Among these elective cesarean births, infants born at 37 and 38 weeks had greater than 1.5 times the odds of death or complications, including respiratory compromise, hypoglycemia, sepsis, and admission to the NICU (Table 40.1).[70] Induction rates have also increased with cesarean section rates, and there was a shift toward earlier gestations in both groups.[15] Historically, however, the induction rates for late preterm births have increased 130% since 1990. In 2012, 23.3% of all singleton live births were induced, with the rate of induction increasing 4% for late preterm births since 2006.[51] Although medically indicated interventions have led to a decrease in the number of stillbirths, we do not know how much this has contributed to the increase in the preterm birth rate or whether the gains realized in preventing stillbirths are offset by increased NICU admissions and complications associated with prematurity. More recently, many states have implemented quality improvement programs to decrease elective deliveries before 39 weeks' gestation. In one multistate collaborative undertaken over 12 months, elective scheduled early-term deliveries decreased from 27.8% in the first month to 4.8% in the 12th month; in addition, rates of elective scheduled singleton early-term inductions and cesarean deliveries decreased significantly.[50]

Some studies claim that the increasing cesarean section rates stem from the changing practice standards of medical professionals and their willingness to perform cesarean sections because of the perceived safety and protection from malpractice litigation.[44] Further prospective studies are required to quantify how much of the increase in late preterm births is owing to necessary medical interventions and how much can be attributed to cesarean section by physician or maternal request.

Gestational Age Assessment and Obstetric Practice Guidelines

Gestational age measurement is an inexact science; the methods currently used, such as the Naegele rule (which assesses gestational age from the first day of the last menstrual period) and ultrasound at 20 weeks' gestation, are accurate only to ±1-2 weeks' gestational age. Combined with the fact that developmental variability exists during fetal maturation, and conditions such as maternal obesity and PROM can cause an overestimation or underestimation

of gestational age, the task of accurate gestational age prediction is even more challenging. The ACOG more recently issued guidelines that cesarean delivery or induction on maternal request should not be performed before 39 weeks' gestation or without evidence of lung maturity.[2] This gradual shift toward lower gestational age along with the inaccuracies of gestational age measurement might have led to the increasing proportions of late preterm births.

Tocolysis and antenatal steroids are routinely recommended only for women at less than 34 weeks' gestation, because infants born at 34 weeks' gestation and beyond were believed to have mortality rates similar to that of term infants.[17] Studies have shown, however, that infants born at 34 weeks' gestation are at 50% increased risk for requiring intensive care,[18,33,47] and late preterm infants have increased morbidity such as RDS, intraventricular hemorrhage (IVH), and death,[68] and long-term morbidities such as behavioral and developmental delay.[45,79] The recent ALPS (Antenatal Late Preterm Steroids) study showed significant decreases in respiratory complications in late preterm infants born to mothers who received antenatal betamethasone at 34-37 weeks.[26] This will likely change obstetric clinical practice and outcomes for late preterm infants going forward.

Use of intrapartum fetal monitoring and prenatal ultrasound has been increasing over the years, from a rate of 68% and 48%, respectively, in 1989 to 85% and 67% in 2003.[17] Prenatal ultrasound can lead to an overestimation of gestational age in maternal conditions associated with fetal macrosomia, such as obesity and gestational diabetes, both of which have increased rapidly in the last decade. There is the possibility of earlier intervention (induction or elective cesarean section) when ultrasound estimates are used to guide the management plan.[55] Although fetal surveillance is designed to reduce adverse neonatal outcome, when coupled with antenatal tests with poor positive predictive value (biophysical profile, non-stress test), it may inadvertently increase medical interventions, with a resultant increase in late preterm and early term birth rates.[17]

Advanced Maternal Age, Assisted Reproductive Technologies, and Multiple Births

More women are now choosing to have children at a later age; it is well known that preterm birth is more prevalent among women with advanced maternal age. Women older than 35 years old also have nearly twice the rate of cesarean section compared with women 20-24 years old. Increasing numbers of women are also seeking assisted reproductive technologies (ART); 57,323 women delivered infants through ART in 2014, and more than 60% of these women were older than 35 years.[5] Of infants born by ART, 32% were of multiple gestations, with 57% of twins and 98.7% of triplets or more being born prematurely.[5] Singleton births from ART are also more likely to be preterm.[5]

Pathophysiology

It is surprising to some that late preterm infants, who are large and do not look anything like their tiny preterm counterparts, are at increased risk of medical complications related to prematurity. As their name implies, these infants are not term, however, and are prone to a host of clinical problems, including RDS, temperature instability, feeding difficulties, hypoglycemia, hyperbilirubinemia, apnea, late neonatal sepsis, prolonged hospital stay, and readmission.[18,29,56,68]

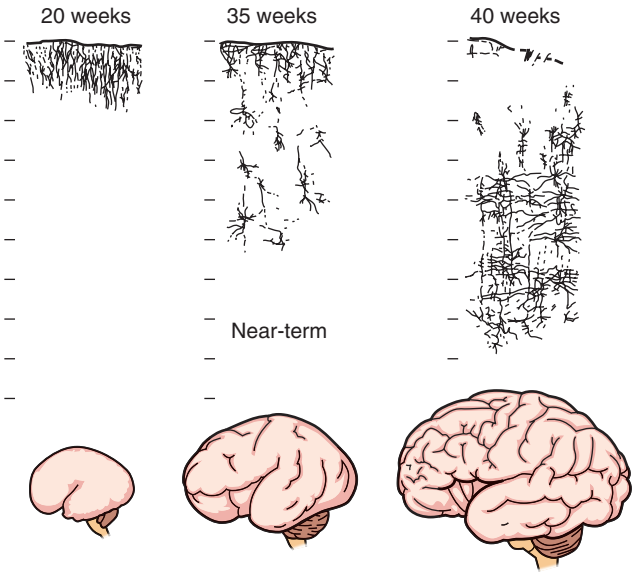
Thermoregulation



Thermoregulation in a newborn depends on the amount of brown adipose tissue, white adipose tissue, and body surface area (see Chapter 35). Nonshivering thermogenesis is controlled by the hypothalamic ventral medial nucleus through the sympathetic nervous system, which releases the neurotransmitter norepinephrine; this acts on the brown adipose tissue to liberate free fatty acids, which are eventually oxidized, producing heat. Late preterm infants have decreased stores of brown adipose tissue and the hormones responsible for brown fat metabolism such as prolactin, norepinephrine, triiodothyronine, and cortisol, which peak at term gestation. They are more likely to lose heat because of a decreased amount of white adipose tissue and less insulation. Also, their smaller size leads to an increased ratio of surface area to body weight, losing heat readily to the environment.[18,53]

Feeding

Late preterm infants have poor coordination of sucking and swallowing because of neuronal immaturity and have decreased oromotor tone, generating lower intraoral pressures during sucking.[18,37,53,56] Poor caloric intake and dehydration result in exacerbation of physiologic jaundice, leading to readmission to the hospital for dehydration and jaundice. These infants also have decreased activity of hepatic uridine diphosphate glucuronyl transferase enzyme and increased enterohepatic circulation because of immature gastrointestinal function and motility. This decreased ability for hepatic uptake and conjugation puts late preterm infants at increased risk of elevated serum bilirubin levels, and jaundice is more prolonged, prevalent, and severe in these infants.[9] One study showed that infants born at 36 weeks' gestation have an eight times greater risk of developing a total serum bilirubin concentration greater than 20 mg/dL (>343 mmol/L) compared with infants born at 41 weeks or later.[48a]

Glucose Homeostasis

The fetus gets a steady supply of glucose primarily by maternal transfer through the placenta. Immediately after birth, this constant supply of glucose is cut off, and the infant has to produce glucose primarily by hepatic glycogenolysis and gluconeogenesis.[27] The postnatal surge in catecholamines, glucagon, and corticosteroids plays an important role in maintaining euglycemic control. This increase in plasma concentrations of catecholamines causes a decline in circulating insulin concentrations and a subsequent surge in glucagon concentrations. Glucose-regulated insulin secretion by the pancreatic β cells is also immature, resulting in unregulated insulin production during hypoglycemia.[22] Late preterm infants are challenged to maintain euglycemia control secondary to developmentally immature hepatic enzyme systems for gluconeogenesis and glycogenolysis, hormonal dysregulation with inadequate adipose tissue lipolysis, and decreased hepatic glycogen stores that are depleted quickly after birth.[18,22,56]

• **Fig. 40.5** Development of the human cerebral cortex. The immaturity of the laminar position and dendritic arborization of neurons, as shown by Golgi drawings, in the cerebral cortex in a late preterm infant at 35 gestational weeks is striking compared with neurons at midgestation (20 weeks) and at term (40 weeks). (Modified from Kinney HC, et al. Perinatal neuropathology. In: Graham DI, Lantos PE, eds. *Greenfield's neuropathology.* 7th ed. London: Arnold; 2002:557-559.)

Neurologic Immaturity

At 34 weeks' gestation, brain weight is only 65% of a 40-week term infant, and cerebral volume is 53% of a 40-week infant (Fig. 40.5).[10,37] The brain of a late preterm infant is still immature and continues to grow until 2 years of age, when it reaches 80% of adult brain volume. The cerebral cortex is still smooth compared with that of a term infant, because the gyri and sulci are not fully formed on the cerebral cortex, and myelination and interneuronal connectivity are still incomplete in these infants. There is evidence that multiple insults during this critical phase of neuronal and glial maturation in these infants cause white and gray matter injury, particularly in the thalamic region and the periventricular white matter. All of this underscores the potential vulnerability of the late preterm infant to neuronal brain injury and poor developmental and long-term outcome.[37]

Respiratory

Several studies have consistently shown that late preterm and early term infants have higher respiratory morbidity and mortality, with increased risk of TTN, RDS, PPHN, and respiratory failure than term infants.[6,12,24,29,70] A review from the Extracorporeal Life Support Organization (ELSO) Neonatal Registry of nearly 14,500 infants between 1986

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

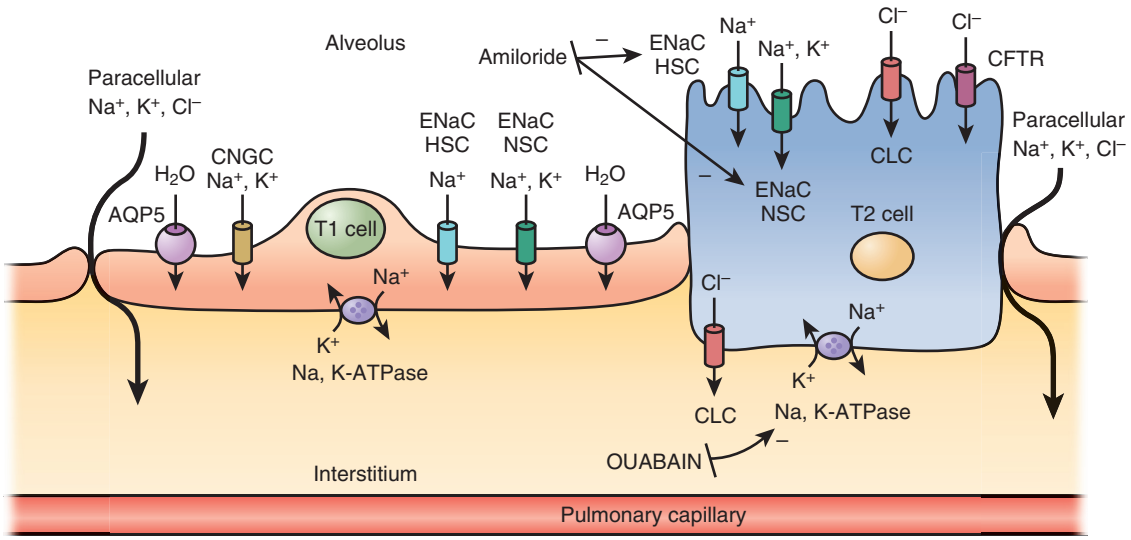
and 2006 with severe hypoxic respiratory failure requiring extracorporeal membrane oxygenation found that 14.7% were late preterm and 21.5% were early term infants. Although meconium aspiration was one of the primary reasons for the respiratory failure among term infants, late preterm and early term infants had a higher incidence of PPHN and RDS as the primary cause. They also had higher mortality (late preterm, OR 2.73; early term 1.63) and complications on ECMO when compared with term infants.[58] Late preterm infants and some early term infants born by cesarean section before the onset of labor have respiratory distress despite having mature surfactant profiles. To understand this vulnerability for respiratory problems, one needs to understand the pathophysiology of fetal lung fluid secretion and clearance, because it may play an important role in the development of RDS or PPHN along with surfactant maturation.

Role of Fetal Lung Fluid Clearance in Neonatal Transition

Throughout much of gestation, fetal lungs actively secrete fluid into alveolar spaces via a chloride secretory mechanism that can be blocked by inhibitors of Na-K-2Cl co-transport. This body of fluid plays a crucial role in lung development, providing a structural template that prevents collapse of the developing lung and promotes its growth. The fetus is presented with a challenge at birth. Often at short notice, and sometimes with no notice at all, the fetus is asked to clear the airspaces rapidly of the fluid that it has been secreting through much of the pregnancy. The lung epithelium is a key participant in this process, engineering the switch from placental to pulmonary gas exchange.[11,30]

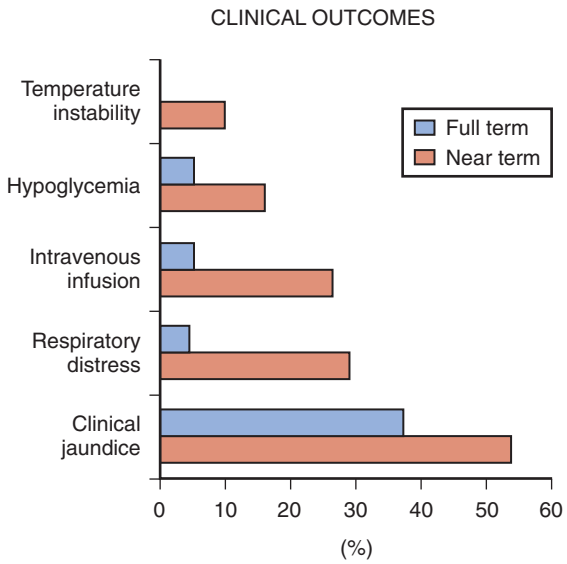
For effective gas exchange to occur, alveolar spaces must be cleared of excess fluid, and pulmonary blood flow must be increased to match *ventilation* with *perfusion*. Failure of either of these events can jeopardize neonatal transition and cause the infant to develop RDS. Clinicians are still far from completely understanding the mechanisms by which fetal lungs are able to clear excessive fluid at birth. It is clear, however, that traditional explanations that relied on "Starling forces" and "vaginal squeeze" can account for only a fraction of the fluid absorbed.[11,30] Amiloride-sensitive sodium transport by lung epithelia through epithelial sodium channels (ENaC) has emerged as a key event in the transepithelial movement of alveolar fluid.[11,31] Disruption of this process has been implicated in several disease states, including TTN and hyaline membrane disease. Using the fetal lamb model, several investigators have shown that much before the onset of spontaneous labor, the fetus begins preparation for extrauterine life by reducing the rate of lung fluid secretion and improving clearance.[30]

Developmental changes in transepithelial ion and fluid movement in the lung can be viewed as occurring in three distinct stages. In the first (fetal) stage, the lung epithelium remains in a secretory mode, relying on active chloride secretion via Cl^- channels and relatively low reabsorption activity of Na^+ channels. Why Na^+ channels remain inactive through much of fetal life is unclear. The second (transitional) stage involves a reversal in the direction of ion and water movement. A multitude of factors may be involved in this transition, including exposure of epithelial cells to an air interface and to high concentrations of steroids and cyclic nucleotides. This stage involves not only increased expression of Na^+ channels in the lung epithelia, but also possibly a switch from nonselective cation channels to highly selective Na^+ channels. The net increase in Na^+ movement into the cell can also cause a change in resting membrane potential leading to a slowing, and eventually a reversal, of the direction of Cl^- movement through Cl^- channels. The third and final (adult) stage represents lung epithelia with predominantly Na^+ reabsorption through Na^+ channels and possibly Cl^- reabsorption through Cl^- channels, with a fine balance between the activity of ion channels and tight junctions. Such an arrangement can help ensure adequate humidification of alveolar surface while preventing excessive buildup of fluid.



After birth, the remaining lung fluid is rapidly cleared by a two-step process (Fig. 40.6). The first step is passive movement of Na^+ from the lumen across the apical membrane into the cell through Na^+-permeable ion channels; the second step involves active extrusion of Na^+ from the cell across the basolateral membrane into the serosal space.[25] Epithelial Na^+ channels (ENaC), which regulate the first step, are rate-limiting in this process. Hummler and coworkers showed that inactivating the a-ENaC (a subunit of the epithelial Na^+ channel) leads to defective lung liquid clearance and premature death in mice.[24] Studies in human neonates have also shown that immaturity of Na^+ transport mechanisms contribute to the development of TTN and RDS.[32]

Epithelial Na^+ channel expression is developmentally regulated with peak expression in the alveolar epithelium achieved only at term gestation[65]; late preterm infants are born with lower expression of ENaC, which reduces their ability to clear fetal lung fluid after birth. High doses of glucocorticoids have been shown to stimulate transcription of ENaC in several sodium-transporting epithelia and the lung. In the alveolar epithelia, glucocorticoids were found to induce lung sodium reabsorption in the late gestation fetal lung. In addition to increasing transcription of sodium channel subunits, steroids increase the number of available channels by decreasing the rate at which membrane-associated channels are degraded, and they increase the activity of existing channels. Glucocorticoids have also been shown to enhance the responsiveness of lungs to beta-adrenergic agents and thyroid hormones.[55] The enhanced sodium reabsorption induced by glucocorticoids can be blocked by amiloride, suggesting a role for ENaC.[32]



Clinical Outcomes

Morbidity in late preterm infants increases with decreasing gestational age; it is estimated to be nearly 52%, 26%, and 12% in 34-, 35-, and 36-week gestation infants,

• **Fig. 40.6** Epithelial sodium (Na) absorption in the fetal lung near birth. Na enters the cell through the apical surface of alveolar type I and type II cells via amiloride-sensitive epithelial Na channels (ENaC), both highly selective channels (HSC) and nonselective channels (NSC), and via cyclic nucleotide gated channels (seen only in angiotensin I cells). Electroneutrality is conserved with chloride movement through cystic fibrosis transmembrane conductance regulator (CFTR) or chloride channels (CLC) in angiotensin I and II cells or paracellularly through tight junctions. The increase in cell Na stimulates Na, K-ATPase activity on the basolateral aspect of the cell membrane, which drives out three Na^+ ions in exchange for two K^+ ions, a process that can be blocked by the cardiac glycoside ouabain. If the net ion movement is from the apical surface to the interstitium, an osmotic gradient would be created, which would direct water transport in the same direction, either through aquaporins or by diffusion. • **Fig. 40.7** Graph of clinical outcomes in near-term (35-36 6/7weeks) and full-term infants as percentage of patients studied. (From Wang ML, et al. Clinical outcomes of near-term infants. *Pediatrics.* 2004;114:372.)

respectively. Infants born at 34 weeks' gestation had nearly a 20 times greater risk of morbidity compared with infants who were born at 40 weeks' term gestation.[63] Because of their physiologic immaturity, nearly every organ system is affected in late preterm infants (Fig. 40.7). Data from the British Columbia Perinatal Database Registry show that late preterm infants had 4.4 times the respiratory morbidity and 5.2 times the neonatal infection rate than term infants. They also had increased length of hospital stay compared with term infants (142 hours versus 57 hours).[36] A meta-analysis of 22 studies comparing late preterm and term infants showed higher risk of respiratory distress syndrome (relative risk [RR], 17.3), IVH (RR 4.9), death less than 28 days (RR 5.9), and cerebral palsy (RR 3.1).[68] In infants with critical congenital heart disease (CCHD), being born at 34-36 weeks was associated with a higher risk of death or morbidity than being born at 37-38 weeks (adjusted absolute risk reduction [ARD] 9.1%, 95% CI 5.5%-12.7%).[66] Mortality and morbidity are described in further detail in each physiologic system in this section.

Mortality

A systematic review of severe morbidity and mortality in late preterm infants was performed by Teune et al., compiling data from 2000-2010. Late preterm infants were four times more likely to die in the first year than term infants. Tomashek and colleagues, using US period-linked birth/infant death files for 1995-2002, found that despite significant declines since 1995 in mortality rates for late preterm and term infants, infant mortality rates in 2002 were three times higher in late preterm infants than term infants (7.9 vs. 2.4 deaths per 1000 live births); early (1-6 days), late

38	0.5	1.7	2.4†	2.0
39	0.2	0.8	1.2	1.2
40	0.3	Reference	1.4	Reference

*Mortality rates are per 1000 live births.
†Risk ratios are significantly different from 40 weeks.
Modified from Young PC, et al. Mortality of late-preterm (near-term) newborns in Utah. *Pediatrics*. 2007;119:e659.

(7-27 days), and postneonatal (28-365 days) mortality rates were six, three, and two times higher.[71] During infancy, late preterm infants were approximately four times more likely than term infants to die of congenital malformations (leading cause); newborn bacterial sepsis; and complications of placenta, cord, and membranes.

Young and associates, in a large cohort from Utah, showed increasing mortality and relative risk of death for every decreasing week in gestational age less than 40 weeks[80] (Table 40.2). Infants born only a few weeks before term gestation are at much greater risk of mortality; infant mortality rate in 2009 for late preterm infants was nearly three times the rate for term infants (7.13 vs. 2.36 per 1000 live births), and it was nearly 1.6 times higher for early term infants born at 37-38 weeks when compared with infants born at 39-41 weeks' gestation (3.09 vs. 1.98). The increased risk of morbidity and mortality is not limited to the immediate neonatal period. A study looking at nearly 675,000 singleton births in Sweden (between 1973 and 1979) found that infants born at late preterm gestation had increased risk of mortality at 18-36 years of age (adjusted hazard ratio 1.53 and 1.31 at early childhood and young adulthood).[14] This tells us that effects of late preterm birth are not limited to the neonatal period alone but also carry into adulthood.

Respiratory

Several studies have shown that late preterm infants have a higher incidence of RDS than term infants.[13,47,74] Wang and colleagues found that late preterm infants, despite their larger size and Apgar scores similar to term infants, had increased RDS (28.9% vs. 4.2%; odds ratio 9.14, $P < .00001$) and apnea (4.4% vs. 0%; $P = .05$) (see Fig. 40.7).[75] Estimates of incidence of RDS range from 7.4%-13.7% at 34 weeks, 4.5%-6.4% at 35 weeks, and 2.3%-3.6% at 36 weeks.[14,24,58,74,75] In a large study cohort of almost 47,000 newborns in California, the incidence of RDS was 22.1% at 33-34 weeks, 8.3% at 35-36 weeks, and 2.9% at 37-42 weeks of gestation.[19]

Data collected from 2002-2008 by the Consortium on Safe Labor reported that the odds of respiratory distress syndrome decreased with each advancing week until 38 weeks. The incidence of RDS was 10.5% at 34 weeks compared to 0.3% at 38 weeks.[29]

Along with increasing incidence of respiratory distress among late preterm infants, these infants have also been shown to require increased need for respiratory support. A study from St. Louis found the need for some kind of respiratory support at 30%, 33%, and 23% of the time at 34 weeks, 35 weeks, and 36 weeks.[73] Other studies have shown the need for mechanical ventilation at 3.3%-6.3% at 34 weeks, 1.7%-3.6% at 35 weeks, and 0.8%-2.3% at 36 weeks.[23,46] In a study of 1011 ventilated infants of 34 weeks' or greater gestation, Clark found that RDS (43%) was the most common cause of pulmonary illness, followed by meconium aspiration syndrome (9.7%), pneumonia/sepsis (8.3%), TTN (3.9%), idiopathic PPHN (3.2%), aspiration of blood or amniotic fluid (2.3%), and lung hypoplasia (1.4%).[12]

Prematurity, cesarean section, and absence of labor are independent risk factors for RDS, but together they pose a much greater risk to the infant. In a Swiss study, Roth-Kleiner and coworkers showed that term and near-term infants delivered by cesarean section before the onset of labor had much higher probability of having severe RDS.[60] Morrison and colleagues also showed that term infants have nearly seven times the odds risk for RDS when delivered by cesarean section without labor, and they showed an increasing incidence of RDS with decreasing gestational age from 41-37 weeks. Tita et al.[70] looked at nearly 24,000 elective cesarean sections and found the incidence of RDS or TTN at 8.2% for 37 weeks, 5.5% at 38 weeks and 3.4% at 39 weeks. Similarly, in a Dutch study looking at almost 34,000

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

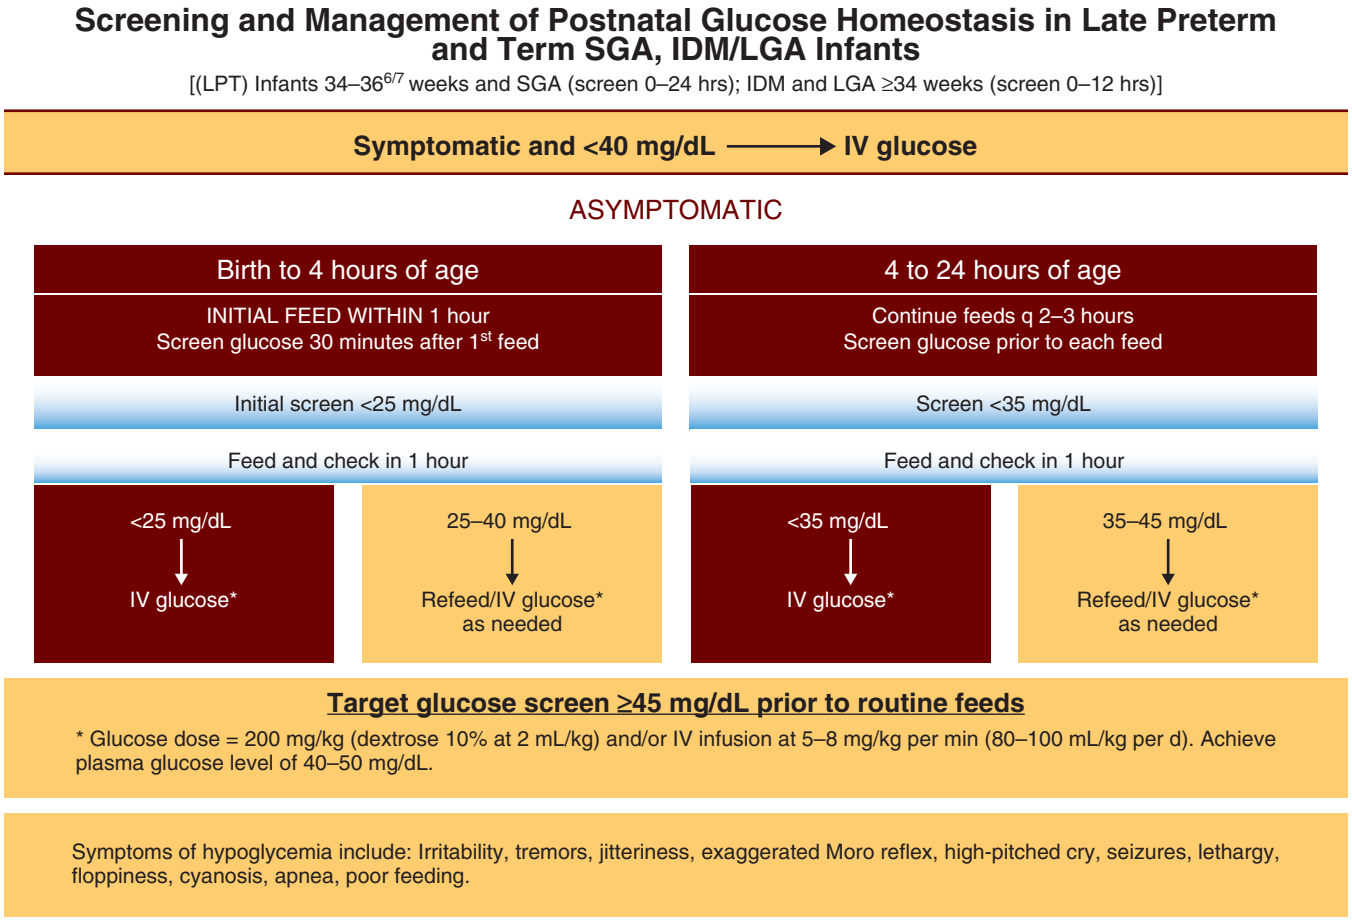
infants, Hansen and associates found that the relative risk of severe RDS increased with decreasing gestational age even among term infants, with nearly five times the odds at 37 weeks. Fetal lung maturity often is used as a criterion that late preterm and early term infants have mature lungs and are ready for postnatal life. However, several studies have demonstrated higher respiratory morbidity in neonates in spite of the mature surfactant profile. Kamath et al. showed that after adjustment for significant covariates, infants who were born at less than 39 weeks' gestation with documented fetal lung maturity had an increased risk of composite adverse outcome (odds ratio, 3.66; 95% confidence interval, 1.48-9.09; $P < .01$).[35]

Why is this slightly increased risk of RDS and TTN of concern? Most of these late preterm infants do well and are weaned off respiratory support quickly, but as shown from the mentioned studies, a few of them are at increased risk of PPHN, severe hypoxic respiratory failure, and need for extracorporeal membrane oxygenation, putting them at risk of severe morbidity and mortality. Clark showed that nearly 11% of late preterm infants developed chronic lung disease.[12] Data also show that they are prone to develop long-term respiratory complications such as asthma and decreased lung function later in life.[25,38]

Temperature Instability and Hypoglycemia

Cold stress manifests as tachypnea, poor color secondary to peripheral vasoconstriction, altered pulmonary vascular tone, and metabolic acidosis. In a late preterm infant, this condition can worsen respiratory transition and exacerbate hypoglycemia, and these signs can be misinterpreted as something more ominous, such as sepsis, prompting unnecessary interventions and work-ups. Very few studies have looked at temperature instability in late preterm infants, but from experience, preterm infants are more likely to have hypothermia and cold stress. A survey of rectal temperatures among 196 term infants in a Dallas hospital found that nearly 28% were less than 36.5°C.[39] Similarly, admission temperatures at a Rhode Island hospital NICU in infants weighing more than 2 kg and of greater than 32 weeks' gestation were reported to be between 34.5° and 36.5°C.[34] Wang and colleagues[75] found that late preterm infants were more likely to present with temperature instability (10% vs. 0%; $P < .0012$), and another study found that among late preterm infants admitted to the NICU, hypothermia was listed as the primary reason for admission in almost 5.2% of this group.[73]

Hypoglycemia is another component that can affect transition. The incidence of hypoglycemia in preterm infants is three times greater than in term newborns, and nearly two-thirds of these infants require intravenous dextrose infusions.[75] Severe hypoglycemia is a well-known risk factor for neuronal cell death and adverse neurodevelopmental outcomes, but the exact threshold for hypoglycemia is not well defined.[22,39] In 2011, the AAP Committee on Fetus and Newborn provided guidelines for screening and management of postnatal glucose homeostasis in late preterm infants, recognizing that they are an at-risk population along with term small-for-gestational-age (SGA) and infants of diabetic mothers (IDM)/large-for-gestational-age (LGA) infants (Fig. 40.8). These infants should receive their initial feed within the first hour of life and have a screening glucose 30 minutes after the first feed. The threshold for low blood glucose is <25 mg/dL in first 4 hours of life, <35 mg/dL from 4-24 hours of life, and <40 mg/dL when the infant is symptomatic (irritability, tremors, jitteriness, exaggerated Moro reflex, high-pitched cry, seizures, lethargy, floppiness, cyanosis, apnea, poor feeding). The algorithm then provides guidelines for treatment of hypoglycemia. The Pediatric Endocrine Society recommends that high-risk infants without a suspected congenital disorder (which would include late preterm infants) should maintain goal plasma glucose concentration >50 mg/dL <48 hours and >60 mg/dL >48 hours to minimize any long-term effects.[69] More studies are needed in late preterm infants to define the effects of hypoglycemia, identify at-risk infants, and determine long-term outcomes.



Gastrointestinal Tract

Late preterm infants adapt well to enteral feeds, but have poor oromotor tone and difficulty with sucking and swallowing coordination. Their deglutition, sphincter control, and peristaltic functions are less likely to be as mature as in term infants. One study found that approximately 27% of late preterm infants required intravenous fluids compared with only 5% of term infants (odds ratio 6.48, 95% CI 2.27-22.91, $P = .0007$), and among infants requiring prolonged hospital stay, poor feeding was cited as the primary reason in 76% of the late preterm infants.[75] Another study from St. Louis found that among late preterm infants admitted to the NICU, nearly 7.3% of infants of 35 weeks' gestation were admitted for feeding difficulties.[73] In a study of rehospitalizations after birth hospitalization, Escobar and associates found that 26% of the infants were readmitted for feeding difficulties, and late preterm infants were more likely to require rehospitalization (4.4% vs. 2% in term infants).[20] Dehydration also exacerbates physiologic jaundice in these infants, predisposing them to rehospitalization and other medical interventions. Whether the immature gut in late preterm infants predisposes them to increased risk of food allergies and diabetes in later life remains to be studied.[56]

Hyperbilirubinemia

Late preterm infants are 2.4 times more likely to develop significant hyperbilirubinemia than term infants.[61] Bhutani and associates, looking at the National Kernicterus Registry, showed that late preterm infants are at increased risk of kernicterus at bilirubin levels equal to or less than that of term infants.[9] They are also more likely to present with high total serum bilirubin levels (≥25 mg/dL) and are less likely

• **Fig. 40.8** Screening and management of postnatal glucose homeostasis during the immediate postnatal period in late preterm and term small-for-gestational-age (SGA) infants, infants of diabetic mothers (IDM)/large-for-gestational-age (LGA) infants. (Reproduced with permission from Adamkin DH. Postnatal glucose homeostasis in late-preterm and term infants clinical report—postnatal glucose homeostasis in late-preterm and term infants. *Pediatrics*. 2013;127(3):575–579. Copyright © 2013 by the AAP. https://doi.org/10.1542/peds.2010-3851.)

to recover without sequelae than term infants. Nearly all late preterm infants in this group were breastfeeding without adequate lactation support and with poor milk intake, and they were scheduled for follow-up appointments in 2 weeks.

Neonatal hyperbilirubinemia in late preterm newborns is more prevalent, more pronounced, and more protracted in nature than in their term counterparts. Jaundice was the most common cause of rehospitalization, and late preterm infants were more likely to be rehospitalized for jaundice than term infants (4.5% vs. 1.2% in term infants).[20] Hyperbilirubinemia is a significant problem in these infants, as shown by their overrepresentation in the kernicterus registry. The large size of late preterm infants may fool practitioners into complacency by treating them as term infants; however, close follow-up and monitoring for feeding difficulties should be mandated to prevent kernicterus in this vulnerable group.

Immunity and Infection

It has been shown that late preterm infants undergo work-ups for sepsis more often than term infants (36.7% vs. 12.6%; odds ratio 3.97, $P = .00015$) and receive antibiotics more often and for a longer duration (7-day course in 30% vs. 17% of term infants).[75] Another study found that the likelihood of having a work-up for sepsis increased with decreasing gestational age; 33% had work-ups for sepsis at 34 weeks compared with 12% at 39 weeks of gestational age ($P \leq .01$), of which only 0.4% of these infants had culture-proven sepsis.[46] Late preterm infants undergo work-ups more often for sepsis either as a part of a protocol after admission to the NICU or because of clinical manifestations of RDS, cold stress, and hypoglycemia, which may appear to be signs of sepsis to the physician.

Hospitalizations and Rehospitalizations After Discharge

Late preterm infants are more likely to require intensive care and are admitted to the NICU more often than term infants. Admission rates vary based on the policies of individual institutions and hospitals; some routinely admit all infants less than 35 weeks of gestation to the NICU, and

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

others do so only if there is a need. One large population-based study found that 88% of infants born at 34 weeks' gestation, 12% born at 37 weeks' gestation, and 2.6% born at 38-40 weeks' gestation were admitted to a NICU.[17] Another study found that 97%, 53%, and 32% of infants of 34, 35, and 36 weeks of gestation required NICU admissions.[73] Duration of hospital stay is also inversely proportional to gestational age, with late preterm infants requiring much longer hospital stays (6-11 days, 4-6 days, and 3-4 days in 34-, 35-, and 36-week infants, respectively).[36,73] The most common reasons for admission include jaundice, RDS, dehydration and poor feeding, hypoglycemia, and temperature instability.[73,75]

Aside from the greater need for specialized care and the prolonged initial hospital stay, late preterm infants are also at risk for rehospitalization after discharge from the hospital.[19,63,64] Looking at a large population-based cohort in a managed care organization, Escobar and colleagues found that late preterm infants (4.4%) had a higher rate of rehospitalization than term infants (2%), and the rate was higher than for infants less than 34 weeks' gestational age (3%).[19,20] They also found that infants between 34 and 36 weeks of gestation who were never admitted to the NICU, and infants with NICU stays less than 24 hours had nearly three times and 1.3 times the risk of readmission than term infants, which indicates that clinicians may be treating these immature infants based on their weight and failing to identify all of the risk factors.

The most common reasons cited for readmission include hyperbilirubinemia (63%-71%), feeding difficulties (16%), and suspected sepsis (6%-20%).[64,72] The infants requiring rehospitalization were more likely to be firstborn, be breastfed at discharge, have labor and delivery complications, be a recipient of a public insurance at delivery, or be of Asian/Pacific Islander descent.[64] Given that late preterm infants are at a much higher risk for rehospitalization, protocols need to be designed for closer monitoring of breastfed infants of new first-time mothers and infants at risk for jaundice, especially of Asian descent, avoiding early discharge until proper feeding has been established and ensuring early follow-up after hospital discharge.

Economic Impact

The Institute of Medicine estimated that every preterm birth costs $51,600, with a total impact of $26 billion in 2005.[7] Late preterm infants are responsible for a significant share of this burden, constituting two-thirds of all preterm births. It is estimated that a relative increase in direct costs for late preterm infants is 2.9 times that of a term infant, resulting in a cost increase of $2630 per infant.[75] A large population-based study over a 1-year period (1996) in California found that hospital costs for an infant of 34 weeks' gestation were $7200; of 35 weeks, $4200; and of 36 weeks, $2600, compared with $1100 for an infant of 38 weeks' gestation. Delaying delivery by just 1 week from 34-35 weeks reduced the cost by 42% and from 35-36 weeks by 38%.[23] A similar California cohort for 2000 showed hospital costs of $7081 for infants of 33-36 weeks' gestation.[62]

Another large cohort from a Dallas hospital over an 18-year study period found that the average hospitalization cost for late preterm infants was $3098, and for 39-week term infants was $1258 ($6094 for infants of 34 weeks; $3519 for 35 weeks; and $2019 for 36 weeks).[46] Similarly, Phibbs and associates looked at all births between 24 weeks and 37 weeks of gestation from 1998-2000 in California and found that the cost reduction for delaying preterm delivery by 1 week from 34-35 weeks was $4528 and by 3-37 weeks was $8508.[52] In a study by Gilbert and associates, the average cost for each infant of 25 and 35 weeks' gestation was approximately $200,000 and $4200, but when the total cost for all infants in each gestation group was calculated, the cost for 35-week infants was $41.1 million, and the cost for 25-week infants was $38.9 million.[23] Although extremely preterm infants are very expensive to treat, the overall cost of treating the cohort of late preterm infants is similar because of the large number of infants treated. They also estimated that the excess cost of medical care for the late preterm infants for that year in this cohort compared with the cost of treating the term infants was nearly $50 million, but it is very hard to separate preventable late preterm births from unpreventable births—hence the difficulty in estimating the excess cost attributable to iatrogenic and preventable preterm birth.

The costs are not just higher in the immediate neonatal period but also higher in early childhood. A Canadian study comparing late preterm to term infants found that late preterm infants are at greater risk for morbidities such as bronchiolitis and pneumonia during the first 3 years of life and that the hospitalization costs were nearly twice that of term infants in the first 2 years and nearly 46% greater in the third year.[8]

Long-Term Outcomes and Societal Costs

Although it is well known that very preterm infants are at a higher risk of psychomotor, behavioral, cognitive, and other developmental disabilities, late preterm infants also have more subtle findings of language delay, attention deficits, lower intelligence, behavioral problems, and academic achievement. There are few studies of long-term outcomes in late preterm infants. A large Swedish population-based study, including 903,402 children (32,945 late preterm infants) who were born alive without any congenital anomalies from 1967-1983 and followed through adulthood, found a higher incidence of cerebral palsy (relative risk 2.7, 95% CI 2.2–3.3, $P < .001$), mental retardation (relative risk 1.6, 95% CI 1.4–1.8, $P < .001$), disorders of psychological development, behavior and emotional disturbances, other major disabilities (blindness, low vision, hearing loss, and epilepsy), and medical disability affecting working capacity.[48] Woythaler and colleagues, using the Early Childhood Longitudinal Study-Birth Cohort (ECLS-B), found that late preterm infants had increased odds of lower mental

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

index scores (MDI <70; OR 1.51 [95% CI:1.26–1.82]) and lower psychomotor index scores (PDI <70; OR 1.56 [95% CI:1.29–1.88]) at 24 months of age.[79] Using the same cohort, they followed these late preterm infants to kindergarten and found that they are still delayed compared to their full-term counterparts based on having worse Total School Readiness Score (TSRS).[78]

Chyi and colleagues, using the Early Childhood Longitudinal Study-Kindergarten Cohort (ECLS-K), compared learning difficulties among moderately preterm (32-33 weeks of gestation), late preterm (34-36 weeks of gestation), and full-term infants using direct child assessment tests and teacher academic rating scale scores. They found that late preterm infants scored lower on direct child assessment tests than full-term infants for reading but not math in kindergarten and first grade. For teacher academic rating scale scores, late preterm infants scored lower in reading in kindergarten, first grade, and fifth grade, and scored lower in math assessments in kindergarten and first grade. Late preterm infants also showed an increased need for individualized educational programs and special education in kindergarten and first grade. In regression analysis, late preterm infants had a 24% increased adjusted odds ratio for below-average reading in the first grade and were 1.3 times more likely than full-term infants to have below-average reading across all grade levels in the teacher assessment scores. The reason for not seeing a difference in the later grades for mathematics scores was probably because of a high number of infants lost to follow-up toward the later grades (34% at fifth grade) and the higher number of disabilities seen in the lost-to-follow-up group. Talge and colleagues compared 336 pairs of late preterm and term infants and found the late preterm infants at 6 years of age had increased risk of lower IQ scores and higher incidence of teacher-reported behavioral problems.[67] These results were present after adjusting for other confounding variables such as maternal education, maternal IQ, residential setting, marital status, and child sex. A study of approximately 215,000 children from New York City in the Longitudinal Study of Early Development, data including nearly 13,200 late preterm infants, found that they had lower adjusted match and English language test scores when compared with term infants.[42] The Millennium Cohort Study, a longitudinal study of approximately 18,800 infants from the United Kingdom, found an association between late preterm birth and poor educational achievement at 5 years of age, including lower overall achievement, personal/social/emotional development, communication/language, and literacy and mathematical development.[54] Another study by Williams et al. evaluated the role of prematurity and maternal factors in first-grade academic failure; after adjusting for maternal and child characteristics, there were increased odds of failure of each component of the first-grade Criterion-Referenced Competency Test (CRCT) for children born late preterm versus term.[77]

These studies show us that late preterm birth has a significant impact on the immature preterm brain. These retrospective reports in no way confirm causality. It is unclear if the neurologic injury resulted from or predated the event that caused the late preterm birth. Societal costs are hard to estimate. A Swedish study by Lindstrom and colleagues estimated that among a cohort of approximately 500,000 adults in their twenties, moderately preterm infants of 33-36 weeks' gestation and early term infants received increased disability assistance/allowance and were less likely to attain university or postsecondary education.[41] Of neurologically disabled individuals in this cohort, 74% were born between 33 and 38 weeks of gestation.

Management

Late preterm infants are a special population that needs closer monitoring and care. A comprehensive guide for management of late preterm infants was published and is summarized in Box 40.2.[18]

Admission

It is recommended that infants of less than 35 weeks of gestation or weighing less than 2300 g should be admitted to an area where they can be monitored closely for stability. Transfer to the mother's room or regular "term" nursery environment should be considered only when they show stability of temperature, vital signs, blood glucose, and oral feeding. These infants should have a physical examination on admission and discharge, with determination of accurate gestational age on admission examination.

The obstetric estimate of gestational age is recommended if it is based on a first-trimester ultrasound. If there is a discrepancy (e.g., >2 weeks) between the gestational ages based on the obstetric estimate and the newborn examination, the use of gestational age based on the newborn examination is preferred. Vital signs and oxygen saturation should be performed on admission and monitored with appropriate frequency thereafter. Transfer to a NICU or tertiary care center should be considered if fraction of inspired oxygen (FIO_2) exceeds 0.4. A feeding plan should be developed, and formal evaluation of breastfeeding should be done at least twice daily after birth with documentation in the record by caregivers trained in breastfeeding. Serum glucose screening should be performed per existing protocols for infants at high risk of hypoglycemia—infants who are small for gestational age, large for gestational age, and infants of diabetic mothers.[76]

Discharge Criteria

Discharge should not be considered before 48 hours after birth. Vital signs should be normal for 12 hours preceding discharge: respiratory rate, less than 60 breaths/min; heart rate, 100-160 beats/min; and axillary temperature, 36.5°C-37.4°C in an open crib with appropriate clothing. There should be documentation of passage of at least one stool spontaneously, with adequate urine output, and 24

• BOX 40.2 Admission and Discharge Criteria Management of Late Preterm Infants

Admission Criteria

- Admit infants less than 35 weeks' gestational age or less than 2300 g birth weight
- If well late preterm infants are in their mothers' rooms in the first 24 hours, close monitoring is needed

Hospital Management

- Physical examination on admission and discharge
- Determination of accurate gestational age on admission examination
- Vital signs and pulse oximeter check on admission, followed by vital signs every 3-4 hours in the first 24 hours and every shift thereafter
- Caution against use of oxyhoods with high F_{IO_2}; consider transfer to NICU if F_{IO_2} exceeds 0.4
- Feeding plan should be developed; formal evaluation of breastfeeding and documentation in the record by caregivers trained in breastfeeding at least twice daily after birth
- Serum glucose screening per existing protocols for infants at high risk of hypoglycemia

Discharge Criteria

- Vital signs normal for 12 hours before discharge
- Passage of one stool spontaneously
- Adequate urine output
- Successful feeding for 24 hours: ability to coordinate sucking, swallowing, and breathing while feeding
- If weight loss greater than 7% in 48 hours, consider further assessment before discharge
- Risk assessment plan for jaundice for infants discharged within 72 hours of birth
- No evidence of active bleeding at circumcision site for at least 2 hours
- Initial hepatitis B vaccine has been given or an appointment scheduled for its administration
- Metabolic and genetic screening tests performed in accordance with local or hospital requirements
- Passed CCHD screen
- Passed car-seat safety test
- Hearing assessment has been performed and results documented in the medical record; follow-up if necessary has been arranged
- Family, environmental, and social risk factors have been assessed; when risk factors are present, discharge should be delayed until a plan for future care has been generated
- Identification of a physician with a follow-up visit arranged for 24-48 hours
- Mother and caregivers demonstrate competency in care of the infant

CCHD, Critical congenital heart disease; NICU, neonatal intensive care unit.
Modified from Engle WA, Tomashek KM, Wallman C. Late-preterm infants: a population at risk. *Pediatrics.* 2007;120:1390-1401.

hours of successful feeding; adequate oral feeding should be present with confirmation of coordination of sucking, swallowing, and breathing while feeding. If weight loss is greater than 7% in 48 hours, further assessment should be considered before discharge.

There should be a risk assessment plan for jaundice in infants discharged within 72 hours of birth; predischarge bilirubin check (serum or transcutaneous) should be done before discharge. A transcutaneous bilirubin of greater than 12 mg should be confirmed with a serum bilirubin, and bilirubin nomograms should be used to determine the risk and need for follow-up or treatment. There should be no evidence of active bleeding at the circumcision site for at least 2 hours. The initial hepatitis B vaccine should have been given or an appointment scheduled for its administration, and the metabolic and genetic screening tests should have been performed in accordance with local or hospital requirements. A critical congenital heart disease screening should be performed. A car seat safety test and a hearing assessment should be performed, and results should be documented in the medical record.

When social risk factors are present, discharge should be delayed until a plan for future care has been generated. A follow-up visit with a physician should be arranged for 24-48 hours after discharge. The mother and caregivers should have received training and demonstrated competency in the following activities: knowledge of urine/stool frequency, umbilical cord and skin care, identification of common signs and symptoms of illness, specific instructions concerning jaundice, specific instructions regarding sleeping patterns and positions, instructions on thermometer use, and instruction regarding responses to an emergency.

Key Points

- Nearly three out of four preterm births occur at late preterm gestational ages (34-37 weeks' gestation).
- Late preterm infants are at risk for complications associated with prematurity. Due to their more mature appearance, there has historically been a lapse in early recognition and management of these issues.
- Late preterm infants have higher morbidity and mortality compared to full-term infants.
- Antenatal steroids, previously only given before 34 weeks' gestation, have now been shown to reduce respiratory complications in infants when given at 34-37 weeks' gestation.
- Late preterm infants require close monitoring for feeding issues, hypoglycemia, hyperbilirubinemia, infection, and thermoregulation in the postnatal period, both during and after their hospital stay.

Nutrient Requirements/Nutritional Support in Premature Neonate

BRENDA B. POINDEXTER AND CAMILIA R. MARTIN

Current recommendations for the provision of parenteral and enteral nutrition to the infant born prematurely are based on the goal of approximating the rate and composition of weight gain of a normal fetus at the same postmenstrual age. For a number of reasons this goal is seldom achieved, and postnatal growth failure still remains a significant complication of extreme prematurity. Infants who experience one or more major morbidities, such as bronchopulmonary dysplasia, necrotizing enterocolitis (NEC), or late-onset sepsis in the neonatal period, demonstrate slower growth than their counterparts who do not experience these conditions. Of particular concern is the significant association between suboptimal postnatal growth and short-term morbidities as well as adverse long-term neurodevelopmental outcomes. This relationship persists even after adjustments for severity of illness, including the perception of illness, which may alter nutritional delivery in high-risk infants.[30] These findings reinforce the principle that nutritional delivery is critical in modifying disease risk in preterm infants. To emphasize the importance of a combined approach to optimize outcomes in the premature neonate, this chapter will first describe overall nutrient requirements and then provision of intense nutritional support with both early parenteral and enteral nutrition.

Growth in the Neonatal Intensive Care Unit

In the neonatal intensive care unit, birth-weight-derived intrauterine growth curves (such as the Fenton or Olsen) are typically employed to monitor postnatal growth. It is important to recognize the inherent limitation of such curves, namely that these curves were generated by measuring infants following premature birth, which is likely not the same physiologic state for the mother and/or fetus as if the infant had remained in utero until term. The revised Fenton growth curves include an international cohort of approximately 4 million infants from six population-based studies and are available online (http://www.biomedcentral.com/1471-2431/13/59) and have been incorporated into many electronic medical record platforms.[35] The Olsen curves include more than 250,000 infants born in the United States between 22 and 41 weeks' gestation and when combined with the WHO-CDC growth charts (http://www.pediatrix.com/workfiles/NICUGrowthCurves7.30.pdf) can be used to monitor postnatal growth through 50 weeks' corrected age. The number of infants born at 22-24 weeks' gestation is very low (less than 1% of the total cohort) in both of these growth charts, limiting their generalizability as the number of infants in this gestational age range increases in neonatal intensive care units. The Vermont Oxford Network (VON) database recently published growth curves derived from birth measurements in a cohort of 156,000 infants from 852 centers in the United States. The VON curves do include more infants born in the periviable period than previously published growth curves (2000 infants born at 22 weeks' gestation and 9000 infants born at 23 weeks' gestation).[12] Growth curves based on serial intrauterine measurements such as those generated by the INTERGROWTH-21st Project[68] may change the standard for the assessment of postnatal growth and may provide a more appropriate means to examine the relationship between growth and outcomes of infants born prematurely.

Growth and Neurodevelopmental Outcomes

Postnatal growth failure has commonly been defined as weight less than the 10th percentile for gestational age. At the time of birth, approximately 20% of very low birth weight (VLBW) infants are small for gestational age (defined as weight less than the 10th percentile). After a stay in the neonatal intensive care unit, however, many of these infants will have experienced poor growth and weigh less than the 10th percentile at 36 weeks' postmenstrual age. The incidence of postnatal growth failure at 36 weeks' postmenstrual age was 79% in a large cohort of VLBW infants

Abstract

The provision of nutrition to support optimal growth and outcomes of premature neonates includes a combined approach of both early parenteral and enteral nutrition. Growth (including weight, length, and head circumference) must be carefully monitored in the neonatal intensive care unit and strategies to avoid growth faltering employed. A thorough understanding of nutrient requirements, particularly for extremely premature infants, is necessary to avoid deficits that can compromise normal growth and development. Early initiation of parenteral nutrition, supplying 3.0-3.5 grams per kg and up to 3.0 grams per kg of lipids is recommended. Human milk is the preferred diet for premature infants, with multicomponent fortification to reduce the incidence of growth failure and to achieve appropriate bone mineralization. Future research is needed to develop better methods to monitor growth, particularly representative growth curves that are based on intrauterine growth of healthy fetuses and those that allow clinicians to not only assess anthropometric measurements but also to achieve proportional growth and body composition to support long-term outcomes. New products to specifically support the extremely premature infant and to avoid complications of nutritional support (such as cholestasis) are urgently needed. Finally, strategies that allow for a personalized approach to delivery of optimal nutrition are needed, particularly for those infants who suffer common morbidities of prematurity such as bronchopulmonary dysplasia or necrotizing enterocolitis and are at risk for growth failure during their stay in the NICU and beyond.

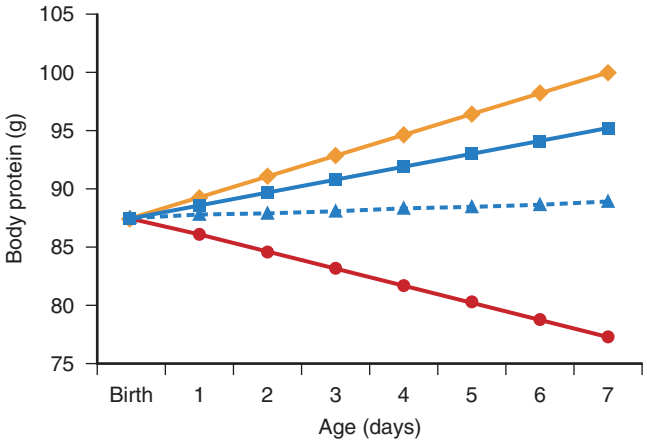
born between 2003 and 2007 at centers participating in the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD) Neonatal Research Network.[91] Improved growth outcomes in the past decade may reflect widespread use of early parenteral nutrition with protein and lipid delivery[37] at most neonatal intensive care units as well as a decline in the use of postnatal corticosteroids.[92]



The association between weight gain in the neonatal intensive care unit and neurodevelopmental outcomes was firmly established in a cohort of 600 extremely low birth weight (ELBW) infants reported by Ehrenkranz and colleagues.[31] Infants were divided into quartiles based on in-hospital growth velocity; infants in the highest quartile gained an average of 21 g/kg per day, and those in the lowest quartile gained 12 g/kg per day. Compared with infants in the highest quartile of in-hospital weight gain, the odds of cerebral palsy, Bayley Scales of Infant Development (BSID) II mental developmental index (MDI) less than 70, and neurodevelopmental impairment were significantly higher in infants in the lowest quartile of in-hospital weight gain. Similar findings were also observed with in-hospital head growth. Since this time, multiple studies continue to demonstrate these relationships with recent evaluations using a more contemporary population, and the new edition of the Bayley (BSID III) has reported findings consistent with the earlier work by Ehrenkranz.[18,29] Other investigators have described the association between poor linear growth and neurodevelopmental outcomes.[76] As evidence continues to accumulate that early nutritional inadequacies have long-term consequences, optimizing provision of both parenteral and enteral nutrition to high-risk neonates is crucial to ensure the best possible outcomes.

Among potential causes of postnatal growth failure are significant protein and energy deficits that occur in the early neonatal period and are difficult to recoup in extremely premature infants. The cumulative nutritional deficits described in the sentinel work by Embleton and colleagues underscore the urgency in avoiding early deficits in both energy and protein intake as a means of achieving optimal growth outcomes.[33]

Nutrient Requirements

Protein and Amino Acid Requirements

Duplicating rates of in utero protein accretion remains a difficult clinical challenge. Failure to provide adequate protein, either in quantity or in quality, can significantly impact the long-term outcome of extremely premature infants. A variety of methods have been used to quantitate protein requirements in human infants: fetal accretion rates, nitrogen balance studies, plasma amino acid concentrations, and stable isotope studies investigating the kinetics of labeled essential amino acids. Clearly, the gold standard needs to be that which safely optimizes growth and neurodevelopment.

• **Fig. 41.1** Change in body protein over the first week of postnatal life for a theoretical 1000-gram birth weight, 26 weeks' gestation infant provided with 1 g/kg/day (*blue line with dashes*) and 3 g/kg/day (*solid blue line*) of intravenous amino acids.[95,104] Rate of in utero protein gain for the reference fetus (*yellow line*) and extrapolated rates of protein loss for glucose alone[24] (*red line*) are shown for comparison.

Normal human fetal development is characterized by rapid rates of growth and accretion of protein. In fact, the greatest rate of relative protein gain throughout life occurs prior to birth. At 26 weeks' gestation, the human fetus gains approximately 1.8-2.2 g of body protein per day, with the placenta supplying about 3.5 g/kg per day of amino acids to the developing fetus. The placental supply of amino acids to the fetus is in excess of that needed for accretion of protein. The extra amino acids are oxidized by the fetus and contribute significantly to fetal energy production. In contrast to the high rate of protein gain in utero, protein losses in extremely premature infants are approximately twofold higher than in term infants. In the absence of intravenous amino acids, extremely premature infants lose approximately 1.2 g/kg of protein each day, which corresponds to a daily loss of 1%-2% of total endogenous body protein stores (Fig. 41.1).

Protein requirements and recommendations for protein intake in premature infants have been made based on several different approaches. Ziegler has quantified protein and energy requirements in relation to body weight using the factorial approach.[111] In the factorial approach, nutrient requirements are determined as the sum of the needs for growth plus needs for replacement of losses. The disadvantage of this approach is that it does not account for nutrient requirements for catch-up growth. It is important to note that protein requirements are inversely related to body weight. Based on the factorial method, protein requirements for infants who weigh less than 1200 grams are estimated at 4.0 g/kg per day. Other investigators have utilized empirical approaches to estimate the amount of protein intake required to duplicate fetal growth. The European Society for Paediatric Gastroenterology Hepatology and Nutrition (ESPGHAN) recommendation for protein intake in infants weighing up to 1000 g is 4.0-4.5 g/kg per day and 3.5-4.0 g/kg per day for infants weighing

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

1000-1800 g.[2] This recommendation takes into account the need to make up for accumulated protein deficits observed in nearly all extremely premature infants. The ESPGHAN committee further commented that protein intake can be reduced toward discharge if the infant's growth pattern allows. An international consensus panel has also recommended 3.5-4.5 g of protein per kg per day for very low birth weight infants receiving full enteral feedings.[51]

Protein Composition of Human Milk and Formula

The protein content and composition of human milk changes throughout lactation; the concentration diminishes from about 2 g/dL at birth to about 1 g/dL for mature milk. Qualitative changes also occur during lactation, resulting in a whey-casein ratio of 80:20 at the beginning of lactation, changing to 55:45 in mature milk. Although the levels of casein, α-lactalbumin, albumin, and lysozyme remain constant, the levels of secretory immunoglobulin A and lactoferrin decrease. Because these different protein fractions have different amino acid profiles, the content of the individual amino acids is also affected.

Casein-predominant cow milk formulas have the same whey-casein ratio as cow milk—that is, 18:82. Adding bovine whey makes whey-predominant formulas, such that the whey-casein ratio becomes similar to that of human milk (60:40). Nevertheless, the protein and amino acid profile remains very different from that of human milk. Compared with human milk, whey-predominant formulas have higher levels of methionine, threonine, lysine, and branched amino acids. These differences in amino acids have not resulted in any apparent clinical consequences in either term or preterm infants. Currently, most commercially available preterm formulas are whey predominant.

Energy and Carbohydrate Requirements

Fetal Glucose Metabolism

Because the supply of glucose to the fetus depends solely on maternal glucose, cord clamping at the time of birth requires that a number of events occur to maintain glucose homeostasis in the newborn. Fetal glucose use in utero matches umbilical glucose uptake, implying that glycogenolysis and gluconeogenesis are minimal in the fetus. Several factors promote glycogen deposition in utero: blunted pancreatic β-cell regulation of insulin secretion, high insulin receptor density, and relative glucagon resistance. In late gestation, the fetus begins to prepare for the transition to postnatal life by increasing hepatic glycogen stores and brown fat deposits. Hepatic glycogen synthesis increases in response to increases in adrenal corticosteroid production, also characteristic of late gestation. At the time of delivery, glucagon levels rise and insulin levels fall. Higher levels of plasma catecholamines, both epinephrine and norepinephrine, directly stimulate increases in hepatic glucose output. The increased levels of epinephrine and glucagon stimulate lipolysis and the activity of phosphorylase, a key enzyme in glycolysis. The increased level of glucagon also results in increased activity of phosphoenolpyruvate carboxykinase, a rate-limiting enzyme in gluconeogenesis. The newborn must be able to initiate gluconeogenesis, because glycogen stores can sustain glucose production only for several hours after birth. All of these changes act together to preserve glucose homeostasis after the infant's maternal source of glucose is removed with cord clamping.

Neonatal Glucose Homeostasis

Because neural tissue makes up a greater proportion of body weight, newborns have higher rates of glucose oxidation than adults, with glucose being the primary energy substrate for the brain. The rate of glucose production in term newborns is approximately 3-5 mg/kg per minute,[23] whereas extremely premature infants have an even higher rate of glucose production of approximately 8-9 mg/kg per minute.[44] Historically, glucose intolerance in infants with extremely low birth weights was attributed to persistent endogenous hepatic glucose production in the face of increased exogenous supply, insufficient insulin production, or tissue insensitivity to insulin. However, ELBW infants are able to suppress endogenous glucose production when given parenteral glucose.

Energy Expenditure

Preterm infants have very low energy reserves, owing to limited body fat and glycogen stores in the liver. Maintaining these limited energy stores requires an energy intake that approximates energy expenditure. Energy expenditure in premature infants is thought to be in the 50-60 kcal/kg per day range, but it must be noted that data for ventilated infants and infants with extremely low birth weights are limited. Thermal stress can substantially increase energy expenditure. Conversely, activity contributes relatively little to energy expenditure in premature infants. The energy cost of growth in these infants has been estimated at about 5 kcal/g. To achieve the equivalent of the estimated third-trimester in utero weight gain of 14-18 g/kg per day, theoretically, an additional energy intake of about 70 kcal/kg per day is necessary.

Energy balance is a delicate equilibrium between energy intake and energy loss plus storage. Positive energy balance is achieved when exogenous metabolizable energy intake is greater than energy expenditure. Growth is then possible, with the excess energy stored as new tissue, usually fat. If exogenous energy intake is less than expenditure, energy balance is negative, and body energy stores must be mobilized to meet ongoing needs. During the acute phase of disease, the primary goal is avoidance of catabolism. This is difficult for infants with very low birth weights, owing to their higher maintenance energy requirements, lower energy stores, and often reduced intake.

Energy is lost either by excretion or by expenditure. Energy excreted is lost primarily as fecal fat. In preterm infants receiving full enteral feeding, approximately 90% of energy intake is absorbed. Usual measurements of total energy expenditure include the energy used to maintain

basal metabolic rate (BMR), as well as the postprandial increase in energy expenditure (diet-induced thermogenesis), physical activity, and energy for the synthesis of new tissue. The BMR is the largest component of energy expenditure and includes energy requirements for basic cellular and tissue processes. In a critically ill patient, it also includes a "disease factor." Little is known about this component in neonates, but it may contribute significantly in neonates with fever, sepsis, and chronic hypoxia. Because the BMR can be measured only after overnight fasting, the resting metabolic rate (RMR) has been accepted as an alternative. The RMR of preterm infants on a per kilogram basis is higher than that of term infants, and the nutritional requirements on a per kilogram basis are correspondingly greater. The energy required for thermoregulation can be minimized by keeping the infant in a thermoneutral environment and limiting stimulation. For example, energy requirements for thermoregulation are negligible under thermoneutral conditions, but routine nursing procedures can increase oxygen consumption or energy expenditure by as much as 10% in stable preterm infants. Both of these components may be of considerable magnitude in a critically ill infant.

The level of energy intake and diet composition determine the magnitude of diet-induced thermogenesis, which represents the energy required for transport, metabolism, and conversion of nutrients into stored energy. Estimates of diet-induced thermogenesis in enterally fed preterm infants vary considerably, but this component of expenditure is probably small.

Total energy expenditure is affected by several factors, assuming a thermoneutral environment and minimal interference from nursing procedures. Increases in metabolic rate with postnatal age are influenced primarily by energy intake and weight gain. Energy expenditure increases with increases in metabolizable energy intake, indicating increased substrate oxidation or tissue synthesis. If the preterm infant is growing at the same rate as the fetus during the third trimester—that is, gaining approximately 15 g/kg per day—then about 15% of the total energy intake is used for synthesis of new tissue.

Energy storage is a linear function of metabolizable intake, and the accretion rate for energy is related more to the level of metabolizable energy intake than to diet composition. Energy requirements for energy storage are difficult to predict. The increase in tissue mass during growth includes the energy stored as protein, carbohydrate (usually less than 1% of body weight), and fat. Therefore, the energy stored can be assumed to equal the sum of the cost of protein plus fat gain. The energy storage component of the energy balance equation is a function of the composition of weight gain, which in turn is a function of protein and energy intake and is likely to be quite variable. Therefore, the energy intake required to produce a specific rate of weight gain cannot be predicted without specifying the composition of that weight gain. From the point of view of energy storage, protein is a poor material, because a small quantity of energy is stored per gram of weight gain. Approximately the same amount of energy is deposited in 1 g of fat tissue as in about 8 g of lean tissue.

Carbohydrates

Lactose is the predominant carbohydrate in human milk (6.2-7.2 g/dL) and supplies 40%-50% of the caloric content. Lactose is hydrolyzed to glucose and galactose in the small intestine by β-galactosidase (lactase). Despite low lactase activities in premature infants, lactose is well tolerated by premature infants, and stable isotope data suggest efficient lactose digestion. However, most premature infant formulas include glucose polymers as a significant source of carbohydrate; these glucose polymers are digested by α-glucosidases, which achieve 70% of adult activity between 26 and 34 weeks' gestation. In addition, salivary and mammary amylases may contribute to glucose polymer digestion. Glucose polymers have the advantage of increased caloric density without a rise in osmolality, and they may also enhance gastric emptying.

Recommended Energy Intake

Overall, the current recommendation for energy intake for an enterally fed VLBW infant is 110–130 kcal per kg/day.[51] It is important to recognize that this recommendation assumes that the infant is also receiving adequate protein intake. Infants who are small for gestational age or infants with diseases that increase energy requirements may need higher intakes to achieve the same growth rates. Infants with growth restriction often require an increased caloric intake for growth because of both higher maintenance energy needs and higher energy costs of new tissue synthesis.

Lipid Requirements

In humans, linoleic and linolenic acids cannot be endogenously synthesized and are, therefore, essential fatty acids. Biochemical evidence of essential fatty acid deficiency can develop in preterm infants within 72 hours. To meet energy requirements, additional intravenous lipid is required in early postnatal life.

Fat provides the major source of energy for growing preterm infants. At birth, the digestive function of premature infants is not fully developed; preterm infants have decreased gut absorption of lipids because of low levels of pancreatic lipase, bile acids, and lingual lipase. The fact that term and preterm infants absorb fat reasonably well is due to the development of alternative mechanisms for the digestion of dietary fat. One important mechanism is intragastric lipolysis, in which lingual and gastric lipases compensate for the low pancreatic lipase concentration. By 25 weeks' gestation, lingual lipase is secreted by the serous glands of the tongue, and gastric lipase is secreted from gastric glands. The fatty acids and monoglycerides resulting from intragastric lipolysis compensate for low bile acid concentration by emulsifying lipid mixtures. Lingual lipase can also penetrate the core of the human milk lipid globule and hydrolyze the triglyceride core without disrupting the globule membrane.

Human milk provides lipoprotein lipase, bile salt stimulated esterase, and nonactivated lipase to further aid lipolysis.

Lipid digestion and absorption are also affected by dietary fat composition. Fatty acid absorption increases with decreasing chain length[58] and with the degree of unsaturation, meaning that medium chain triglycerides (MCT) with chain lengths of 6-12 carbons are hydrolyzed more readily than long chain triglycerides (LCT), and that fatty acids with more double bonds are absorbed more efficiently. In an attempt to increase the fat absorption of premature infants, the fat in commercial formulas contains relatively high levels of MCTs that can be absorbed without the need for lipase or bile salts. Standard commercial formulas for healthy term infants do not contain MCTs, and human milk typically contains 8%-12% of fat as MCTs. Unlike LCTs, MCTs are readily hydrolyzed in the gut, and the released fatty acids are transported across the gut barrier without the need for bile acids. Then MCTs are transported directly to the liver via the portal vein as nonesterified fatty acids. In addition, MCTs can enter mitochondria and be oxidized without the need for carnitine-mediated transport through mitochondrial membranes. However, inclusion of MCTs in infant formula remains controversial, because the available data do not support the assertion of improved fat absorption or improved growth in preterm infants.

In human milk, fat is transported in globules consisting of a membrane composed of a polar mixture of proteins, phospholipids, triglycerides, cholesterol, glycoproteins, and enzymes surrounding a triglyceride core containing 98% of the fat in milk. The milk fat globules are among the largest structural components of milk, having a diameter of 4 mm in mature milk. The size of the globules increases with both length of lactation and length of gestation, with colostrum having smaller globules (especially in milk of women who deliver prematurely) than mature milk. After birth, as the total fat content of human milk increases, the percentage of cholesterol and phospholipids, both of which reside primarily in the milk fat globule membrane, decreases; in addition, the total phospholipid content decreases as lactation progresses. During the first weeks of lactation, preterm milk is also richer in membranous material compared with term or mature milk, resulting in a higher content of cholesterol, phospholipids, and very-long-chain polyunsaturated fatty acids (PUFA) with chain lengths of 20-22 carbons (C20-C22). Because these membranes act as emulsifiers that allow fat dispersion in an aqueous phase and limit lipolysis and oxidation, heat treatment or addition of fortifiers and supplements might disrupt this emulsion.

The milk fat content and nutritional value of human milk vary with time, and it does not always provide a complete source of nutrients for infants with very low birth weights. Its composition and energy content may vary in a pumping session and during subsequent changes throughout lactation. The total fat content of human milk at 3 days' lactation is approximately 2 g/dL; the fat content of mature milk is approximately 4-5 g/dL, with large individual variation possible. The triglyceride content of human milk is its most variable component, changing with gestational and postnatal age, time of day, duration of individual feeds, and maternal diet. Shifts in the dietary practices of a population result in changes in the fatty acid composition of human milk, because the type and amount of fat in the maternal diet affect the composition of milk fat. Maternal diets low in fat and high in carbohydrate lead to de novo synthesis of fatty acids within the mammary gland, which results in high concentrations of fatty acids of less than 16 carbons. Therefore, although the total amount of fat present in the milk remains in the normal range, the fat is more saturated.

Fatty acids represent about 85% of the triglycerides and, therefore, are the principal component of human milk lipids. Fatty acids in human milk are derived from the maternal diet, de novo synthesis by the mammary gland, and mobilization from fat stores. The fatty acid composition of human milk fat reflects the fatty acid composition of the maternal diet. The long-chain polyunsaturated fatty acid (LCPUFA) composition of the milk of women in the United States, Europe, and Africa is quite similar, with the exception of higher amounts of n-3 LCPUFA in the milk of women whose diets contain a large quantity of fish. Medium-chain fatty acids (C8-C10) do not normally account for more than 2% of the fats, even in milk from women who have delivered preterm. Arachidonic acid (C20:4n-6) is the main LCPUFA, and eicosapentaenoic acid (C20:5n-3) is found in small quantities in human milk. Docosahexaenoic acid (C22:6n-3) is the main LCPUFA of the n-3 series.

Fatty acid composition changes with progressing lactation and with gestational age. Most striking is the higher content of C8-C14 fatty acids and of LCPUFAs in preterm milk as compared with term milk; the content of LCPUFA decreases with increasing postnatal age. This may be an advantage for preterm infants because shorter fatty acids are easier to digest, and LCPUFAs are essential for brain and retinal development.

The LCPUFAs play an important role in the development of the infant's brain during the last trimester of pregnancy and also during the first months of life. The precursor C18 fatty acids for the n-6 and n-3 LCPUFA series are linoleic acid (C18:2n-6) and α-linolenic acid (C18:3n-3). These are further elongated and desaturated to form other fatty acids, of which arachidonic acid (AA) and docosahexaenoic acid (DHA) are essential for normal growth and development. Although the capacity for endogenous synthesis of LCPUFA from precursor fatty acids exists in both preterm and term infants, it remains unclear whether DHA and AA can be biosynthesized in quantities sufficient to meet the needs of these infants.

In utero, LCPUFAs are supplied to the fetus across the placenta. After birth and within the first postnatal week, preterm infants developed a deficit of DHA and AA compared to their starting point at birth, while almost tripling their linoleic acid (LA) levels.[59] These acute changes are likely due to the lack of adipose reserves as well as the lack

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

of early nutritional strategies that effectively meet the fatty acid requirements in the preterm infant. Although Smoflipid® contains DHA and AA, the use of Smoflipid® fails to correct these postnatal fatty acid deficits inducing a minimal change in DHA and a further decline in AA, and introduces a substantial increase in eicosapentaenoic acid (EPA) due to its fish oil component. Although the importance of DHA in brain and eye development has been established, accruing evidence suggests that a decline in AA is also of concern with increasing risks of late onset sepsis and retinopathy of prematurity with lower AA levels.[54,98]

Although naturally contained in human milk, DHA and AA have been added to most infant formulas for term and preterm infants. Multiple randomized controlled trials evaluating the addition of DHA and AA to preterm formulas have been conducted. Added DHA and AA have generally resulted in positive or neutral changes in growth, although there are some reports of a negative effect. Findings of improved visual acuity have been inconsistent. Formula supplemented with DHA and AA has produced positive changes in neurodevelopment measured in infancy in some, but not all, studies. A meta-analysis demonstrated no improvement in visual acuity or neurodevelopment.[85] The current recommendation is that VLBW infants receive 55-60 mg per/day of DHA and 35-45 mg per kg/day of AA.[51]

Cholesterol is a major component of cell membranes and a precursor in the synthesis of bile acids and some hormones. It is present in human milk in concentrations ranging from 10-15 mg/dL, although commercial formulas contain only trace amounts of cholesterol (approximately 1-2 mg/dL). The high cholesterol content of breast milk relative to formula is maintained at this level regardless of maternal diet. The groups that assessed the nutrient requirements for term and preterm infant formulas did not recommend addition of cholesterol to infant formulas, because there was no convincing evidence of a beneficial short- or long-term effect of such an addition. Furthermore, there is no evidence that added cholesterol would be equivalent to the cholesterol in a human milk globule.

Carnitine mediates the transport of long-chain fatty acids into mitochondria for oxidation and the removal of short-chain fatty acids that accumulate in mitochondria. Preterm infants may be at risk for carnitine deficiency, because they are heavily dependent on lipids as an energy source and because the plasma carnitine concentration of preterm infants is low, owing to limited endogenous synthetic ability. In preterm infants not receiving supplemental carnitine, plasma and tissue carnitine levels fall even in the presence of adequate precursor amino acid concentrations. Carnitine is found in human milk and is currently added to standard term and preterm formulas in amounts somewhat higher than in human milk.

Provision of Nutritional Support

The extremely premature neonate is born with glucose stores of only 200 kcal and loses 1% of body protein per day when provided with intravenous glucose alone. Consequently, extreme prematurity should be viewed as a nutritional emergency. A number of observational studies have described the influence of nutritional practices on growth and have found that differences in caloric and protein intake in the first weeks account for the largest difference in growth among premature infants.[66] In addition, there is a growing body of data that shows the association between early nutrient intake and growth and neurodevelopmental outcomes. This section reviews the basis of recommendations for nutritional support of premature infants. Practice decisions related to provision of early nutritional support provided to ELBW infants seem to be related to the perceived severity of illness of the infant by clinicians.[30] The use of standardized protocols for feeding (both parenteral and enteral) extremely premature infants can lessen variation in practice and improve outcomes.

Goals of Early Intense Nutritional Support

The goals of early nutritional support for the extremely premature infant include the following: to promote growth and nutrient accretion comparable to that of the fetus at the same gestational age, to avoid postnatal growth failure, to minimize the risk of necrotizing enterocolitis, and to optimize neurodevelopment and long-term health outcomes. Achieving full and consistent enteral nutrition in infants with extremely low birth weights is particularly challenging, given the inherent problems of immature gut motility and function, as well as the fear of necrotizing enterocolitis. Clearly, the relative risks must be carefully weighed against benefit. When sufficient data are not available to address the relative risk versus the benefit, clinical judgment must be used.

Intravenous amino acids should be given immediately after birth to provide 3.5 g/kg per day of amino acids. Many institutions utilize a neonatal "stock" or "starter" amino acid solution to ensure rapid availability. This solution, made in advance by the pharmacy, is typically comprised of a neonatal amino acid solution mixed in dextrose. To minimize deficits in energy intake, intravenous lipids should be started at 3 g/kg per day with the first day of full parenteral nutrition. In addition, trophic or minimal enteral feedings (10-20 mL/kg per day) should be initiated with expressed human milk as soon as possible after birth. Strategies related to the advancement of enteral feeds and weaning of parenteral nutrition will be discussed subsequently.

Initiation and Advancement of Enteral Feeds

The diversity of approaches to feeding preterm infants underlines the need for studies to dispel myths and find reasonable solutions to define the optimal feeding route. When neonatal amino acid solutions became available, many physicians chose to use parenteral nutrition exclusively in sick preterm infants because of concerns about necrotizing enterocolitis. Parenteral nutrition was thought

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

to be a logical continuation of the transplacental nutrition the infants would have received in utero. However, this view discounts any role that swallowed amniotic fluid may play in nutrition and in the development of the gastrointestinal tract. In fact, by the end of the third trimester, amniotic fluid provides the fetus with the same enteral volume intake and approximately 25% of the enteral protein intake of a term breastfed infant.

Minimal Enteral Feeding

Trophic or minimal enteral feedings involve hypocaloric, low-volume (typically ≤24 mL/kg per day) feeds to promote intestinal maturation and do not contain sufficient calories to sustain somatic growth. Proposed benefits include maturation of the preterm intestine (both structurally and functionally), reduced liver dysfunction, and improved feeding tolerance.

Animal studies have demonstrated a decrease in gut weight, mucosal weight, mucosal protein, DNA, disaccharide activity, and mucosal height when enteral nutrition is withheld. In a neonatal piglet model, at least 40% of total nutrient intake supplied enterally is needed to sustain normal gastrointestinal growth.[15] In preterm infants, the lack of any enteral feeding leads to villous atrophy.[64]

A systematic review evaluated the effects of early (introduced before 96 hours of age) trophic feeding versus a comparable period of enteral fasting in VLBW infants and found no difference in feeding tolerance, growth, or necrotizing enterocolitis.[13] The authors concluded that the available data cannot exclude important beneficial or harmful effects and that large randomized controlled trials are needed to evaluate the effect of early trophic feeds on important clinical outcomes in VLBW infants. A multicenter randomized trial is currently underway in the United Kingdom to evaluate the speed of increasing milk feedings (SIFT; ISRCTN76463425) in VLBW infants.[1] The primary outcome of the SIFT trial will be the effect on survival without moderate or severe neurodevelopmental disability at 24 months' corrected age.

Initiation of enteral nutrition is often delayed in premature infants with intrauterine growth restriction because of the concern that these infants are at an increased risk of necrotizing enterocolitis. However, a randomized trial that evaluated early versus delayed initiation of enteral feeding for preterm growth-restricted infants found no evidence of a difference in the incidence of necrotizing enterocolitis between groups. Consequently, the authors concluded that there was no evidence of benefit in delaying the introduction of minimal enteral feeds in preterm infants with intrauterine growth restriction beyond 24-48 hours of age.[53]

In summary, the data from these studies support physiologic and clinical benefit from early minimal enteral feeding, without an increased risk of necrotizing enterocolitis. Although a large multicenter trial that more clearly evaluates early feeding may be desirable, such a trial appears unlikely.

Rate of Advancement of Enteral Feeds

The rate at which enteral feedings should be advanced in preterm infants has also been the subject of much debate. Retrospective studies have reported an association between rapid advancement of enteral feeds and NEC. However, a systematic review evaluated the effect of slow (<24 mL/kg per day) rates of enteral feed advancement on the incidence of NEC, mortality, and other morbidities in VLBW infants and found no evidence that slow advancement of enteral feeds reduces the incidence of NEC.[62] Infants who had slow rates of feeding volume advancement took longer to regain birth weight and to reach full enteral feeds.

Based on the available evidence, a reasonable approach is to advance enteral feeds by 20-30 mL/kg per day in VLBW infants and by 15-25 mL/kg per day in ELBW infants. Future studies are needed to further define the optimal rate of advancement, especially in ELBW infants.

Gastric Residuals

Measurement of gastric residuals is a common practice in many neonatal intensive care units to evaluate tolerance of enteral feeds despite a paucity of evidence to support the utility of gastric residuals in the diagnosis of feeding intolerance or NEC.[69] In the absence of other symptoms, there is no evidence to support the discontinuation of enteral feeds based only on gastric residuals.[83,97]

Standardized Feeding Guidelines

Enteral feeding practices vary considerably among different centers.[50] The use of evidence-based standardized feeding guidelines has been shown to improve nutritional outcomes (such as time to reach full enteral feeds), reduce number of days on parenteral nutrition, and encourage growth. In addition, standardized feeding guidelines, regardless of the content of the guideline, have been shown to reduce the incidence of necrotizing enterocolitis in premature infants.[38,71]

Evidence Supporting Early Parenteral Amino Acids

Numerous randomized clinical trials of amino acid dose and advancement strategy to evaluate short-term tolerance, protein balance, and safety have been conducted in premature infants. Despite differences in study populations and composition of amino acid solutions, all studies demonstrated positive nitrogen balance in response to parenteral amino acids and improved protein balance with higher amino acid intake.[46,49,78,100,103] It is also important to point out that positive nitrogen balance was found despite low total caloric intake (approximately 50 kcal/kg per day). Consequently, the initial goal of limiting catabolism and preserving endogenous protein stores in premature infants can be accomplished with provision of as little as 1.0-1.5 g/kg per day of intravenous amino acids, whereas delivery of 3 g/kg per day of amino acids will result in net protein gain that approximates that of the reference fetus (see Fig. 41.1).

Stable isotope techniques have also been used to evaluate the effect of amino acids on protein metabolism in premature infants. In these studies, stable isotope tracers of one or more essential amino acids are used to reflect whole body protein kinetics. Rivera and colleagues found that administration of 1.5 g/kg per day of amino acids (Aminosyn-PF with cysteine added) beginning on the first day of life improved protein balance as a result of increased protein synthesis (as reflected by leucine kinetics).[78] Using similar techniques, van den Akker and colleagues demonstrated that protein anabolism produced by administration of early amino acids is accomplished through an increase in protein synthesis and not from a decrease in proteolysis (protein breakdown).[101]

Other investigators have assessed the safety and efficacy of different doses of amino acids. Thureen and colleagues conducted a randomized trial of low (1 g/kg per day) versus high (3 g/kg per day) amino acid intake in infants with extremely low birth weights immediately after birth.[95] The higher amino acid intake produced significantly greater protein accretion. In an open-label trial, te Braake and colleagues randomized VLBW infants to two different parenteral amino acid regimens.[94] Infants in the intervention group received 2.4 g/kg per day of amino acids starting immediately after birth. Infants in the control group received glucose alone on the first day of life, with a stepwise increase in amino acid intake thereafter (1.2 g/kg on day 2 and 2.4 g/kg on days 3 and 4). Infants who received amino acids on the first day of life were found to have positive nitrogen balance without any major adverse effects, whereas infants in the control group were in negative nitrogen balance on day 2. Ibrahim and colleagues evaluated an even higher initial dose of intravenous amino acids, randomizing VLBW premature infants to either 2 g/kg or 3.5 g/kg per day of intravenous amino acids on the first day of life. Similar to the studies discussed previously, the higher amino acid dose resulted in greater improvement in nitrogen balance without evidence of adverse effects.[46]

The safety of administration of early intravenous amino acids, particularly for premature infants, has been established in a variety of studies. Normal plasma amino acid concentrations have been reported using TrophAmine.[43] Rivera and colleagues studied infants with very low birth weights who were given amino acids in the first days of life and found no abnormal elevations of plasma amino acids, BUN, or ammonia.[79] Thureen and colleagues found that 3 g/kg per day of early amino acids appears to be as safe as 1 g/kg per day, based on BUN and plasma aminograms as indicators of acute amino acid toxicity.[67,95] Although most studies have not demonstrated any relationship between amino acid intake and BUN in the first days of life, two studies reported increased BUN levels in infants receiving higher amino acid intakes at 7 days of age.[11,19] As mentioned earlier, a significant proportion of the amino acids supplied to the developing fetus are oxidized and serve as a significant energy source for the fetus. Urea production is a byproduct of amino acid oxidation. In premature infants, rates of urea production are higher than in term neonates and adults, consistent with high rates of protein turnover and oxidation. Some investigators have even suggested that azotemia might be evidence of the effective utilization of amino acids as an energy supply rather than of protein intolerance, but this contention remains unproven. There are no data to support the need to advance amino acid intake slowly.

Although the initial goal of providing intravenous amino acids to premature infants to limit catabolism and preserve endogenous protein stores can be accomplished even if total caloric intake is low, ultimately both protein and energy must be supplied in quantities sufficient to support optimal growth. Protein quantity is the primary determinant of protein accretion. This is true regardless of whether parenteral nutrition is used exclusively or as a bridge to full enteral feedings. In a series of studies, Zlotkin and colleagues evaluated the effect of intravenous energy and nitrogen intake on nitrogen retention.[112] At constant nitrogen intake, increasing nonprotein energy intake from 50-80 kcal/kg per day resulted in increased nitrogen retention and weight gain. However, at low energy intake (~50 kcal/kg per day), increasing nitrogen intake from 494-655 mg/kg per day (3-4 g/kg of amino acids per day) had no effect on nitrogen retention or weight gain. However, at higher energy intakes (~80 kcal/kg per day), the same increase in nitrogen intake resulted in a significant increase in the rate of both nitrogen retention and weight gain.

Many conditions and interventions commonly encountered in extremely premature infants are known to increase protein requirements. Underlying disease states such as sepsis or surgical stress increase catabolism and can negatively impact protein accretion. In addition medications such as systemic steroids, fentanyl, and insulin can also impact protein accretion. Dexamethasone has been shown to increase protein catabolism by increasing protein oxidation and proteolysis, resulting in decreased accretion of protein.[104]

Intravenous Amino Acid Mixtures

The first parenteral amino acid solutions used in neonates were hydrolysates of fibrin or casein. Concerns about these first-generation solutions included high concentrations of glycine, glutamate, and aspartate; the presence of unwanted peptides; and high acidity. Reports of hyperammonemia and acidosis in the early 1970s were associated with the use of these first-generation solutions in neonates. Although amino acid solutions have been significantly modified, the perceived risks associated with the protein hydrolysates linger, contributing to the hesitancy by some clinicians to administer early parenteral amino acids.

The second generation of amino acid solutions consisted of crystalline amino acid mixtures (FreAmine III, Travasol, Aminosyn). The amino acid pattern of these mixtures reflects that of high-quality dietary proteins with large amounts of glycine and alanine, absence of glutamate and aspartate, and absence or poor solubility of tyrosine and cysteine.

Glutamic acid	820	500	1000
Aspartic acid	527	320	600

*Amino acid concentration in mg/dL; all amino acid mixtures shown are 10% solutions.
†Mixture of L-tyrosine and N-acetyltyrosine.

The newest solutions include modifications of crystalline amino acids for use in pediatric patients. The currently available solutions include modifications of crystalline amino acids for use in pediatric and neonatal patients (Table 41.1). TrophAmine was originally formulated to match plasma amino acid concentrations of healthy term, breastfed infants; Premasol is identical in composition to TrophAmine. The composition of Primene, available outside the United States, was derived from fetal and neonatal cord blood concentrations. Both TrophAmine and Premasol supply a mixture of L-tyrosine and N-acetyltyrosine. The bioavailability of N-acetyltyrosine, however, has been questioned. Neither Aminosyn-PF nor Primene supplies a substantial amount of tyrosine. Cysteine is not supplied by most amino acid solutions, because it is not stable for long periods of time in solution. However, cysteine hydrochloride can be added during the compounding process just prior to delivery of the solution.

It is no surprise that the ideal composition of intravenous amino acid mixtures is unknown. Although these solutions are widely used in the neonatal intensive care unit, normative data on plasma amino acid concentrations, particularly in ELBW infants, has not been established. Whether the goal should be to match amino acid concentrations of term, breastfed infants or some other standard is not known. Clearly, the ultimate goal is to achieve plasma amino acid concentrations in response to provision of parenteral nutrition that optimize both growth and neurodevelopment without toxicity. To optimize nutrition and growth, particularly in a premature infant, the requirements for specific amino acids need to be more precisely defined.

Several amino acids may be "conditionally essential" in premature infants. That is, the infant's ability to synthesize these amino acids de novo may be less than needed for functional metabolic demands. Cysteine, tyrosine, and arginine are often considered conditionally essential amino acids for premature infants.

Tyrosine is not present in appreciable amounts in currently available amino acid solutions because of its low solubility. Snyderman found lower rates of weight gain, nitrogen retention, and plasma concentrations of tyrosine in premature infants given a tyrosine-deficient diet.[86] Tyrosine is synthesized endogenously from phenylalanine by phenylalanine hydroxylase. The activity of this enzyme in premature infants was thought to be inadequate for growth and nitrogen retention without tyrosine supplements. However, stable isotope studies have demonstrated active phenylalanine hydroxylation in very premature (26 weeks) and premature (32 weeks) infants.[20,24] Therefore, in the strictest sense, tyrosine is not an essential amino acid. However, it remains unclear whether enough tyrosine can be endogenously produced from phenylalanine in premature infants to support normal rates of protein accretion. *N*-acetyl tyrosine, although currently added to TrophAmine, is not highly bioavailable. Nonetheless, several studies provide indirect evidence that *N*-acetyl tyrosine improves protein accretion in preterm infants.[41,42] In addition, it is unclear whether premature infants can adequately catabolize tyrosine via oxidation by the enzymes tyrosine aminotransferase and 4-hydroxyphenylpyruvate dioxygenase. Inability to catabolize tyrosine can lead to transient neonatal tyrosinemia. Further studies are needed to better define premature infants' ability to catabolize tyrosine and to determine whether an alternative source of tyrosine is needed in parenteral amino acid solutions.

Cysteine may be a conditionally essential amino acid for premature infants but is not contained in currently available amino acid solutions. Some studies have shown that the fetal liver lacks the enzyme system to convert methionine into cysteine and that infants on a cysteine-free diet demonstrate impaired growth and low plasma cysteine levels. Other studies have demonstrated that there is enough cystathionase in extrahepatic tissues of the fetus and premature infant to synthesize cysteine when an adequate amount of methionine is provided. Studies using stable isotope techniques have demonstrated active endogenous cysteine synthesis in low birth weight infants.[82] Nevertheless, there is

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

evidence to support that when cysteine hydrochloride supplements are added to parenteral nutrition, nitrogen retention is improved in premature infants.[87] Further, the addition of cysteine hydrochloride improves the solubility of calcium and phosphorus in parenteral nutrition solutions. However, it is important to note that cysteine hydrochloride supplements can produce metabolic acidosis unless appropriately buffered with acetate.

Glutamine is one of the most abundant amino acids in both plasma and human milk, yet it is not supplied by currently available amino acid solutions because glutamine is unstable in aqueous solution. Glutamine is a major energy substrate for small intestinal mucosa, as proved by a high glutamine uptake from the lumen and from arterial blood during the newborn period in rats. Adding glutamine to the parenteral nutrition (PN) solutions of animals prevents atrophy of small intestinal mucosa and smooth muscle, improves the gut immune function, and reduces the incidence of fatty infiltration of the liver. Several studies suggest that parenteral glutamine supplementation is of benefit in selected populations of critically ill adults. However, a large, multicenter, randomized clinical trial of parenteral glutamine supplementation found that parenteral glutamine supplementation did not decrease mortality or the incidence of late-onset sepsis in ELBW infants.[72]

Finally, taurine is synthesized endogenously from cysteine and is not part of structural protein. It is present in large concentrations in the retina and brain of the fetus, reaching a peak concentration at birth. When newborn nonhuman primates are fed taurine-deficient formula, growth is depressed, but this does not occur in human preterm infants, despite declining plasma and urine taurine levels. Nevertheless, there is some limited evidence that taurine supplementation might influence auditory brainstem-evoked responses. Several pediatric IV amino acid solutions (TrophAmine, Primene, Aminosyn-PF) contain one to three times the amount of taurine found in breast milk.

It is important to note that currently available amino acid solutions have not been modified for more than 20 years and that none were designed specifically to meet the needs of extremely premature infants. Future research efforts should be directed at designing a fourth generation of amino acid solutions to optimize amino acid nutrition provided to the most vulnerable infants.

Glucose

Glucose should be provided in the parenteral nutrition solution to maintain normal plasma glucose concentrations and to meet the demand for glucose use. From a practical standpoint, understanding rates of endogenous glucose production is important to avoid iatrogenic hyperglycemia. As discussed earlier in this chapter, rates of glucose production and utilization in term infants are approximately 3-5 mg/kg per minute, whereas an extremely premature infant has a much greater need, 8-9 mg/kg per minute. Infants who weigh 1000 g or more usually tolerate a 10% glucose solution initially, whereas infants weighing less than 1000 g probably need to be started on a 5% glucose solution, given their higher total fluid requirements and predisposition toward hyperglycemia. In ELBW infants, a reasonable approach is to start the glucose infusion rate at 6 mg/kg per minute, gradually advancing to 10-12 mg/kg per minute as long as hyperglycemia does not develop.

The definition of hyperglycemia also varies but is generally set at a plasma level above 150 mg/dL (8.3 mmol/L). Hyperglycemia is detected early through frequent glucose monitoring. Plasma glucose levels below 200 mg/dL usually do not require intervention. Reducing the fluid needs and insensible water loss can reduce the glucose intake. Alternatively, a lower concentration of dextrose solution can be used, although solutions less than 2.5% should be avoided.

Although some have advocated the use of insulin to "promote growth," using insulin to facilitate tolerance of added parenteral calories, other investigators found no net effect on protein anabolism in response to euglycemic hyperinsulinemia in ELBW infants.[73] In addition, increasing glucose infusion beyond the capacity for glucose oxidation can result in lactic acidosis. An international, randomized clinical trial was conducted to determine whether early insulin therapy would reduce hyperglycemia and affect outcomes in VLBW infants.[9] The study was terminated early because of futility concerns and concluded there is little clinical benefit of early insulin administration; although insulin may decrease the incidence of hyperglycemia, there was no difference in important outcomes such as mortality, and early insulin may also increase the number of episodes of hypoglycemia. Consequently, the routine use of exogenous insulin cannot be recommended. Administration of 0.05-0.1 U/kg per hour may be occasionally needed to treat hyperglycemia not responsive to decreases in the glucose infusion rate.

The appropriate balance of glucose and lipid in parenteral nutrition is critical for achieving maximal nutritional benefit. In fact, nutrient and protein retention is maximal if the nonprotein caloric balance between carbohydrate and lipid is approximately 60:40. This more closely mimics the fat content of breast milk and minimizes excess energy expenditure, which can occur if a disproportionate amount of nonprotein calories is given as glucose. Even at higher protein intakes, a parenterally fed infant with extremely low birth weight may need 80-90 kcal/kg per day for nonprotein energy supplies. The caloric requirements of a parenterally fed neonate are much lower than those fed enterally. It is important to realize that providing excessive calories via parenteral nutrition does not correlate with higher rates of growth. In addition, it should be emphasized that it is not difficult to provide adequate nonprotein energy, and it can be done without using highly concentrated glucose solutions. Therefore, glucose concentrations above 12.5% should be required only on rare occasions. In addition, glucose concentrations above 10%-12.5% should be reserved for use with central venous access.

TABLE 41.2 Composition of Available Intravenous Fat Emulsions (% of Lipid)

	Intralipid	Lipofundin	Lipoplus	Smoflipid	Clinoleic	Omegaven
Soybean oil	100	50	40	30	20	—
Olive oil	—	—	—	25	80	—
Medium chain triglycerides	—	50	50	30	—	—
Fish oil	—	—	10	15	—	100

Intravenous Fat Emulsions

Intravenous fat emulsions are important not only to prevent essential fatty acid deficiency, but also as a significant source of nonprotein energy. They are made up of neutral triglycerides, egg yolk phospholipids to emulsify, and glycerol to adjust the tonicity. The types of currently available lipid emulsions are shown in Table 41.2.[25] Until recently, Intralipid® was the primary lipid available for use in the NICU. Intralipid®, comprised solely of soybean oil, was developed in the early 1960s and received FDA approval in 1972. In 2016, Smoflipid® received FDA approval for use in adults, although there has been some adoption in use in the NICU. Smoflipid® is composed of a blend of soybean oil, MCTs, olive oil, and fish oil (15%). Despite the difference in oil sources, recent meta-analyses have not demonstrated improved neonatal outcomes with its use, including studies aimed at reducing the incidence of parenteral nutrition–associated liver disease (PNALD).[45,48] A large clinical trial comparing Intralipid® to Smoflipid® for the prevention of PNALD in high-risk preterm infants is still ongoing (ClinicalTrials.gov Identifier: NCT02579265). Early initiation of lipid emulsions is considered safe, and it is recommended to achieve a level of 3 gm/k/day within the first few days of life. Omegaven, a solely fish oil–based emulsion, was approved by the FDA in 2018 for the treatment of parenteral nutrition–associated liver disease (PNALD).[99a]

Lipids can be started at 3 g/kg per day[96,105] without the need to slowly increase the dose in a stepwise fashion. The early administration of intravenous lipids to preterm infants has been the subject of discussion and debate primarily centered on the acute metabolic effects of early intravenous lipids and potentially adverse effects, such as chronic lung disease and bilirubin toxicity as a result of free fatty acids displacing bilirubin from albumin-binding sites. A meta-analysis found no increase in chronic lung disease resulting from early lipid administration to premature infants.[84]

The rate of intravenous lipid infusion is important, and plasma lipid clearance is improved when intravenous lipid is given as a continuous infusion over 24 hours. Lipid infusion rates in excess of 0.25 g/kg per hour can be associated with decreases in oxygenation. Lipid infusion rates well under this value can be easily achieved in clinical practice if lipids are provided over 24 hours in an amount not exceeding 3-4 g/kg/day. This level of lipid intake is usually sufficient to supply the caloric needs of preterm infants (in combination with glucose) and is usually tolerated by premature infants. Triglyceride concentrations are most often used as an indication of lipid tolerance, and maintaining triglyceride concentrations below 200 mg/dL seems prudent.

Intravenous lipid emulsions may undergo lipid peroxidation, which may form organic free radicals and potentially initiate tissue injury. Light, especially phototherapy, may play some role in increasing lipid peroxidation in intravenous lipid emulsions. However, multivitamin preparations included in the intravenous solutions are a major contributor to a generation of peroxides, and lipid emulsions may have only a minor additive effect. Based on these studies, some clinicians protect intravenous lipid solutions from light, although the importance or efficacy of this practice is unclear.

Lipid particles supplied by intravenous lipid solutions are similar in size to endogenously produced chylomicrons. Like chylomicrons, clearance of these lipid particles also depends on the activity of lipoprotein lipase. In premature infants less than 28 weeks' gestation, lipoprotein lipase activity and triglyceride clearance are reduced. Heparin theoretically releases lipoprotein lipase from the endothelium into the circulation, but there is no evidence that this increases lipid utilization in preterm infants. In addition, increased lipoprotein lipase activity may produce high levels of free fatty acids and be in excess of the clearance capacity of the premature infant. Consequently, the routine addition of heparin to lipid emulsions for this purpose (to stimulate lipolysis) is not recommended on the basis of currently available evidence.

Carnitine facilitates transport of long chain fatty acids through the mitochondrial membrane, and as such plays an important role in the oxidation of these long chain fatty acids. Premature infants receiving parenteral nutrition have low carnitine levels, but the clinical significance of this remains uncertain.

Human Milk

There is general consensus that human milk is also the optimal primary nutritional source for premature infants.[2,32] The strongest evidence of the benefit of human milk for premature infants is a reduced incidence of necrotizing enterocolitis.[60,80] Maternal milk also improves neurodevelopmental outcomes in ELBW infants. Vohr and colleagues found that infants who received maternal human milk had

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

superior Bayley II scores at 24 months' corrected age compared with those who did not receive human milk. These investigators noted a dose-response effect; for each 10 mL/kg per day of maternal milk ingested, the MDI increased by 0.59 points, the psychomotor developmental index (PDI) increased by 0.56 points, and the rate of rehospitalization between discharge and 30 months decreased by 5%. It should also be noted that the beneficial effect of exposure to mother's own milk persisted at 30 months' corrected age.[106,107]

Donor Human Milk

The use of pasteurized donor human milk has been recommended for preterm infants if the mother's own milk is unavailable, in a statement by the American Academy of Pediatrics (AAP) Section on Breastfeeding and by ESPGHAN,[6,32] primarily based on evidence suggesting that avoidance of formula may reduce the risk of NEC. The impact of donor human milk on neurodevelopmental outcome has been assessed in several multicenter clinical trials. The Canadian DoMINO trial randomized 363 VLBW infants to donor human milk or preterm formula as supplemental diet to maternal milk. There was not a statistically significant difference in the primary outcome of the mean cognitive score on the Bayley Scales of Infant Development-III, although infants randomized to receive donor milk were more likely to score less than 85 on the BSID-III.[65,99] The NICHD Neonatal Research Network also has an ongoing trial to evaluate this question (NCT01534481).

Human Milk Fortifiers

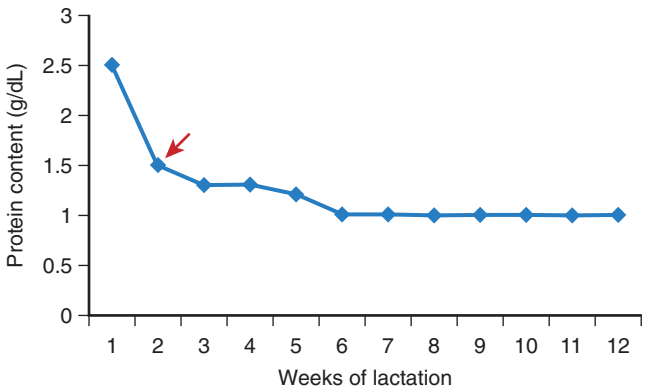
Human milk does not completely meet the nutritional needs of premature infants; insufficient protein, calcium, phosphorus, sodium, zinc, vitamins, and possibly energy are provided by human milk to optimally support most premature infants. Human milk fortifiers have been developed to address many of these inadequacies. Evaluation of the available evidence has shown that multicomponent fortification of human milk improves postnatal weight gain, linear growth, and head circumference growth.[52] One randomized trial found that a higher protein intake results in less growth-faltering in human milk–fed preterm infants.[61]

Current options for human milk fortification include bovine products and human milk–based fortifier. The use of powdered products is to be avoided, given potential risk of infectious complications.[88]

Only one of the new bovine liquid human milk fortifiers has been evaluated in a randomized clinical trial. Benefits found in preterm infants with weight less than 1250 g included improvements in weight and linear growth at 28 days compared with infants randomized to a control powdered human milk fortifier.[63] There were no differences in feeding tolerance, sepsis, or NEC between the groups in this small study.

A small, multicenter, randomized clinical trial evaluated the use of an exclusive human milk diet compared with maternal milk fortified with bovine human milk fortifier and preterm formula. In this study, the incidence of NEC or death was higher in the bovine fortifier group than in the exclusive human milk group.[93] It is important to note that this study found no difference between groups for the primary outcome of the trial, which was duration of parenteral nutrition.

As discussed earlier in this chapter, although the protein content of preterm human milk is greater than term human milk, the protein content declines over the first few weeks of lactation from approximately 1.7 g/dL at 7 days to 1.2 g/dL by 42 days. The protein content of donor human milk is markedly lower, with some investigators reporting protein content of less than 1 g/dL in samples of pooled donor milk. Manufacturers of human milk fortifiers, however, assume an average protein content of human milk of 1.4-1.6 g/dL. Consequently, assumptions about the final protein content of fortified preterm human milk after the second week of lactation must be challenged, given the steady decline in the protein content as lactation progresses (Fig. 41.2).



Fortification of human milk does not need to be delayed until full enteral feeds are achieved. Some have advocated for introduction of human milk fortifier as early as when enteral intake is greater than 50 mL/kg per day, in an effort to optimize growth.[81] Others have suggested a strategy of adjustable fortification with incremental increases in protein guided by measurement of blood urea nitrogen.[7] Individualized approaches to fortification have been proposed.[75]

Limited data do not provide evidence that use of multinutrient-fortified breast milk after hospital discharge has any impact on growth outcomes in infancy, and there are no data available on long-term growth outcomes.[110]

Formula

Preterm Formulas

Formulas for premature infants have been developed to meet the nutritional needs of growing preterm infants and have been in use for more than 30 years. It must be noted that the design and testing of these formulas did not

• **Fig. 41.2** Protein content of preterm human milk. Manufacturers of human milk fortifiers typically assume protein content of 1.4-1.6 g/dL (indicated by *red arrow*) and do not account for the decrease in protein over time.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

specifically include extremely premature (less than 1000 g) infants. Premature formulas contain a reduced amount of lactose (40%-50%), because intestinal lactase activity is low in premature infants. The remainder of the carbohydrate content is in the form of glucose polymers, which maintain low osmolality of the formula (300 mOsm or less with a caloric density of 80 kcal/dL). The fat blends of preterm formulas are 20%-50% MCTs, which are designed to compensate for low intestinal lipase and bile salts. It is not clear that MCTs are necessary in premature infant formulas. Recommendations for lipid intake in enterally fed VLBW infants are for 4.4-6 g per 100 kcal.[51]

Preterm formulas contain more protein than term formulas. Standard preterm formulas supply 3 g/100 kcal and "high protein" preterm formulas 3.3-3.6 g/100 kcal. A comparison of protein intake for various enteral feeds provided at 150 mL/kg per day is shown in Table 41.3. Even with use of "high protein" products, meeting the recommended protein intake of 4.0-4.5 g/kg per day of protein for infants less than 1 kg is a challenge. For infants weighing less than 1 kg, the so-called "high protein" formulas are barely adequate. Although most clinicians tend to think about daily enteral intake in terms of volume or calories per kg, quantifying protein intake on a daily basis is arguably even more important, given the crucial role of protein in overall growth and development.

Premature formulas are whey predominant, which reduces the risk of lactobezoar formation and may provide a more optimal amino acid intake. Calcium and phosphorus content are also higher in preterm formulas, which results in improved mineral retention and bone mineral content.

Specialized Formulas

Occasionally, infants do not tolerate feedings and require formulas specifically designed for conditions of malabsorption or other types of formula intolerance. These formulas are free of lactose and cow milk protein and provide alternative sources of protein (soy, casein hydrolysates, free amino acids) and carbohydrate (sucrose, corn syrup solids, tapioca starch, cornstarch). Some provide a significant percentage of the fat as MCTs. Specialized formulas are somewhat higher in protein and mineral content but similar in vitamin composition compared with formulas designed for term babies. The vitamin and mineral contents are, therefore, lower compared with formulas and human milk supplements designed for preterm infants. Multivitamin and mineral supplementation of specialized formulas is generally necessary to provide the recommended intakes for premature infants. Specialized formulas have not been tested in premature infants and, therefore, are used only temporarily, when necessary. Routine feedings for preterm infants are reinstituted as tolerated.

TABLE 41.3 Comparison of Protein Intake for Enteral Feeds at 150 mL/kg per Day

Feeding	Protein (g/kg per day)
Unfortified preterm human milk (assume 1.2-1.4 g/dL)	1.8-2.1
Unfortified donor human milk (assume 1 g/dL)	1.5
"High protein" preterm formula (24 kcal/oz)	4.0
Preterm formula	3.6
Transition/postdischarge formula	3.1
Term formula	2.1

Electrolytes

During the first week of life, sodium needs are low because of the expected free water diuresis. For ELBW infants, addition of sodium to parenteral nutrition may not be necessary for the first several days. It is, however, necessary to frequently measure sodium concentrations and assess water balance. After the initial diuresis, 2-4 mEq/kg/day is usually sufficient to maintain serum sodium in the normal range, but ELBW infants sometimes require higher sodium intakes to compensate for larger renal sodium losses. Chloride requirements follow the same time course as sodium requirements and are approximately 2-4 mEq/kg/day. When electrolytes are added to the parenteral nutrition solution, chloride intake should not be less than 1 mEq/kg/day, and all chloride should not be omitted when sodium bicarbonate or acetate is given to correct metabolic acidosis. Potassium requirements are also low in the first few days of life, and potassium should be omitted from parenteral solutions in ELBW infants until renal function is clearly established. Potassium intakes of 2-3 mEq/kg per day are usually adequate to maintain normal serum potassium concentrations.

Parenteral nutrition solutions usually require the addition of anions, either as acetate or chloride. In general, excess anions should be provided as acetate to prevent hyperchloremic metabolic acidosis. Acetate can help to avoid the metabolic acidosis associated with the addition of cysteine hydrochloride to parenteral nutrition solutions.

Sodium is essential for growth, and serum sodium concentration may not be a good measure of total body sodium stores. The sodium content of unfortified human milk is low, and premature formulas and fortified human milk provide only 2-3 mEq/kg per day at full enteral intake. Randomized controlled trials of sodium supplementation in premature infants have demonstrated improved weight gain and long-term neurodevelopmental outcome.[3,47] Provision of 3-5 mEq/kg sodium intake daily to premature infants may be necessary to match rate of intrauterine growth once full enteral feeds are established.

Minerals

The peak of fetal accretion of minerals occurs during the third trimester, placing the infant born prematurely at risk for osteopenia of prematurity. In addition to having low stores at birth, it is difficult to provide an adequate amount of minerals in parenteral solutions or to rapidly achieve sufficient supply by the enteral route. In addition, medications such as diuretics and corticosteroids can further negatively impact bone mineralization.

Supplying adequate calcium and phosphorus in parenteral nutrition remains a significant clinical challenge because of limited solubility. It is not possible to supply enough calcium and phosphorus to support optimal bone mineralization in premature infants using currently available solutions. The solubility of calcium and phosphorus in parenteral nutrition solutions depends on temperature, amino acid concentration, glucose concentration, pH, type of calcium salt, sequence of addition of calcium and phosphorus to the solution, the calcium and phosphorus ratio, and the presence of lipid. Adding cysteine to parenteral nutrition lowers the pH, which improves calcium and phosphorus solubility.

Mineral concentrations have been increased in preterm formulas and human milk supplements designed for feeding premature infants in an attempt to meet requirements. Significant increases in calcium and phosphorus content may affect magnesium retention. Several studies have shown improvement of mineral retention or bone mineralization in preterm infants who receive higher calcium and phosphorus intakes compared with their unsupplemented peers.[77]

Consumption of unfortified human milk by infants with very low birth weights after hospital discharge resulted in bone mineral deficits that persisted through 52 weeks postnatally, indicating the need for additional minerals after discharge. Fortification of human milk with minerals has been shown to increase linear growth during hospitalization.[52]

Based on rates of fetal accretion and an estimate of 50%-70% absorption, the recommended daily requirement for calcium is 120-200 mg/kg and for phosphorus is 60-140 mg/kg.[8] The Ca:P ratio should be approximately 2:1, which is similar to the ratio in human milk. Daily requirements for magnesium are 8-12 mg/kg, assuming 40% absorption.[2]

Zinc and Other Trace Elements

The fetus accumulates stores of trace elements primarily during the last trimester of pregnancy. Therefore, the premature infant has low stores at birth and is at risk for trace mineral deficiencies if intakes are not adequate to support requirements for growth. Trace elements contribute less than 0.01% of total body weight. They function as constituents of metalloenzymes; cofactors for metal ion activated enzymes; or components of vitamins, hormones, and proteins. Immature homeostatic control of trace element metabolism also increases the risk of deficiency. Trace minerals that have established physiologic importance in humans include zinc, copper, selenium, manganese, chromium, molybdenum, fluoride, and iodine. The trace minerals that are potentially toxic in pediatric patients are lead and aluminum. Requirements for trace elements for premature infants are not well defined, owing to a lack of clinical studies that assess safety and efficacy. There is reasonable consensus that zinc should be included early in parenteral nutrition solutions (400 μg/kg per day for premature infants). Other trace elements probably are not needed until after the first 2 weeks of life. Zinc and copper are available in the sulfate form and can be added separately to parenteral solutions. Several pediatric trace metal solutions are available that contain zinc, copper, magnesium, and chromium and are usually provided at 0.2 mL/kg per day. When trace metal solutions are used, additional zinc is usually needed to provide the recommended intake for preterm infants. Supplementation with selenium is suggested after 2 weeks of age, because premature infants can become selenium deficient after 2 weeks of exclusive parenteral nutrition. In infants with cholestasis, copper and manganese should be discontinued, and chromium and selenium should be used with caution and in smaller amounts with renal dysfunction. Infants who experience abnormal gastrointestinal losses (persistent diarrhea or excessive ileostomy drainage) often require supplementation with zinc and electrolytes.

Iron

Preterm infants are at increased risk for the development of iron deficiency, which can have adverse effects on brain development. Factors such as timing of umbilical cord clamping, need for frequent blood sampling, and treatment with erythropoietin can all affect iron requirements in preterm infants. Given the inability to excrete iron from the body, careful attention is needed to avoid excess iron supplementation, which contributes to an increased risk of sepsis and poor growth.[27]

Parenteral iron is not routinely recommended. The recommended iron intake in enterally fed premature infants is 2-3 mg/kg per day.[2] In general, enteral iron supplementation may be started between 2-4 weeks of age. However, given the iron content in many preterm formulas and human milk fortifiers, an additional source of iron may not be necessary. Infants receiving an erythrocyte-stimulating agent such as erythropoietin may need a higher dose of iron. Infants who have received a recent blood transfusion may have elevated serum ferritin concentrations; if these concentrations are found to be elevated, iron supplementation should not be given until the ferritin normalizes.

Vitamins

Vitamins are organic compounds that are essential for metabolic reactions but are not synthesized by the body. They are, therefore, needed in trace amounts from enteral or

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

parenteral sources. Higher amounts of select vitamins are required by preterm infants, who may have greater needs for growth or because of immature metabolic or excretory function. In addition, the vitamin content of human milk may be decreased by freezing or pasteurization.

Vitamins are classified as water soluble or fat soluble based on the biochemical structure and function of the compound. Water-soluble vitamins include the B complex vitamins and vitamin C. They serve as prosthetic groups for enzymes involved in amino acid metabolism, energy production, and nucleic acid synthesis. Needs are considered relative to dietary intake of calories and protein, as well as the rate of energy use. Water-soluble vitamins cannot be formed by precursors (with the exception of niacin from tryptophan) and do not accumulate in the body (with the exception of vitamin B_{12}). Therefore, daily intake is required to prevent deficiency. Excretion occurs in the urine and bile. Most water-soluble vitamins cross the placenta by active transport; vitamin C crosses by facilitated diffusion. Levels of water-soluble vitamins generally are higher in fetal than in maternal blood and are relatively independent of concentrations in the circulation of a nourished mother. Preterm infants and infants of undernourished mothers have lower blood levels of water-soluble vitamins at birth.

Altered urinary losses owing to renal immaturity during the first week of life predispose a preterm infant to vitamin deficiency or excess. The need for vitamin C may be greater in a preterm infant who experiences increased urinary losses and lacks *p*-hydroxyphenylpyruvic acid oxidase, an enzyme that catabolizes tyrosine and is stimulated by vitamin C. Transient neonatal tyrosinemia, however, has not been shown to be detrimental to infants.

Fat-soluble vitamins include vitamins A, D, E, and K. These vitamins function physiologically on the conformation and function of complex molecules and membranes and are important for the development and function of highly specialized tissues. They can be built from precursors, are excreted with difficulty, and accumulate in the body; therefore, they can produce toxicity. They are not required daily, and deficiency states develop slowly. Fat-soluble vitamins require carrier systems, usually lipoproteins, for solubility in blood, and intestinal absorption depends on fat absorption. They cross the placenta by simple or facilitated diffusion. Accumulation takes place throughout pregnancy and depends on maternal blood levels. Therefore, blood concentrations and body stores at birth are lower than normal in preterm infants and in infants of poorly nourished mothers.

Recommendations for vitamin D intake in premature infants are the same as for term infants. The current AAP recommendation of 400 IU/day of vitamin D is probably sufficient to prevent vitamin D deficiency rickets in preterm infants.[108]

Vitamin E in formula, required as 0.6 mg/g of PUFAs, provides adequate amounts to prevent hemolysis of red blood cell membranes when iron intake is not excessive. The recommended total intake is 3-4 IU/day for term infants. Recommendations are somewhat higher for preterm infants; however, pharmacologic supplementation of 100 mg/kg per day of vitamin E is not recommended to reduce the incidence or severity of retinopathy of prematurity, bronchopulmonary dysplasia, and intraventricular hemorrhage.

An adequate intake of vitamin K to prevent bleeding in the first week of life when enteral intakes are low is recommended as a 1-mg IM injection at birth in both term and preterm neonates over 1000 g birth weight. For premature infants less than 1000 g, 0.3 mg is recommended. Term infants can be given 2 mg orally as an alternative. Thereafter, 2-3 mg/kg per day or 5-10 mg daily is recommended in all babies.

Daily multivitamin or mineral preparations may be necessary for preterm infants once enteral feedings have been established. Preterm formulas and human milk fortifiers differ in the amounts of vitamins and minerals they contain; therefore, the need for supplementation varies for infants with very low birth weights.

Preterm infants who require specialized formulas or receive standard infant formulas designed to meet the vitamin and mineral needs of term infants must be able to consume 1000 mL/day and require supplementation with vitamins and minerals to provide the recommended intakes. Liquid multivitamin drops do not contain folic acid because of its lack of stability, but it can be added or given separately.

Breastfed infants who weigh less than 3.5 kg do not consume enough human milk to acquire the recommended intakes of some vitamins and minerals. Therefore, supplementation with a multivitamin, folic acid, calcium, phosphorus, zinc, and iron may be necessary, unless one of the commercially available milk fortifiers is used.

Complications of Parenteral Nutrition

Although a myriad of complications of older parenteral nutrition solutions have been reported, with the use of current parenteral formulations most of these are now rare. Some of the complications (electrolyte imbalance, hypoglycemia, hyperglycemia, hypocalcemia, hypercalcemia, hypophosphatemia) can be prevented or corrected by manipulating the constituents of the infusate. The primary complications of parenteral nutrition as currently used are cholestasis and complications related to central lines.

Hepatic dysfunction has long been recognized as an important complication of parenteral nutrition, manifested primarily as cholestatic jaundice. The initial lesion seen histologically is both intracellular and intracanalicular cholestasis, followed by portal inflammation and progressing to bile duct proliferation after several weeks of parenteral nutrition. With prolonged administration, portal fibrosis and ultimately cirrhosis may develop.

The etiology of Parenteral Nutrition Associated Liver Disease (PNALD) is unknown and most likely multifactorial. The patients at greatest risk are critically ill premature infants who are susceptible to multiple insults, such as hypoxia, hemodynamic instability, and sepsis. The most

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

frequently identified risk factors in parenteral nutrition–associated cholestasis are duration of parenteral nutrition, degree of immaturity, and delayed enteral feeding.[89] There is expanding evidence that even small-volume enteral feedings can reduce the incidence of cholestasis. Early studies of parenteral nutrition suggested a possible relationship between the quantity of amino acids and hepatic dysfunction. The specific role of the quantity and composition of parenteral amino acids in the cause of cholestatic jaundice in premature infants remains unclear. Some investigators have hypothesized that fish-oil lipid emulsions prevent steatosis, potentially through improved triglyceride clearance and anti-inflammatory properties.[4]

There have been several case reports in infants of improvement in PNALD with Omegaven.[16,26] Using historical controls as a comparison group, Gura and colleagues reported the safety and efficacy of fish oil–based lipid emulsions in 18 infants with short bowel syndrome who developed cholestasis while receiving soybean emulsions.[39] At the present time, this therapy is available in the United States only through compassionate-use protocols. Data from randomized clinical trials are needed before recommending a change in clinical practice to include Omegaven for the treatment of PNALD.

Indwelling venous catheters used to deliver PN also may be the source of complications. Both peripheral and central venous routes have been used to deliver PN, but central delivery allows use of more concentrated formulations. Quality initiatives have dramatically reduced the incidence of central line–associated bloodstream infections. In addition, intense nutrition initiatives have reduced the need for prolonged central lines.

Infection is probably the most frequent serious complication associated with peripheral and central catheters. Reducing line sepsis is another benefit of a combined approach of parenteral and enteral nutrition. The most commonly implicated bacterial agents are *Staphylococcus epidermidis* and *Staphylococcus aureus*, whereas *Candida albicans* and *Malassezia furfur* are the fungal agents most often implicated. The incidence of sepsis as a complication of PN increases as gestational age decreases and the duration of PN increases. The predisposition to develop sepsis in these infants probably is multifactorial. As noted earlier, the incidence of sepsis increases in infants who have developed cholestasis. Similarly, there are numerous reports of *M. furfur* fungemia in infants receiving intravenous lipid. In both cases, the incidence increases when lipid is added to the infusate, suggesting that the lipid may provide a rich growth medium for skin flora that have colonized indwelling catheters.

Postdischarge Nutrition

Most premature infants are discharged at far below term weight and may have ongoing and catch-up requirements that may not be met by term formulas. Three large, randomized, controlled trials have compared standard infant formula with a preterm infant discharge formula.[17,55,56] Preterm infant discharge formulas have a nutrient content between preterm and standard-term formulas. Improvements in weight and length have been measured in preterm infants receiving the discharge formulas. One study also demonstrated increases in head circumference in preterm infants with birth weights less than 1250 g who received the discharge formulas.[17] Premature infants with chronic lung disease may also benefit from enriched nutrient intakes, especially additional protein, calcium, phosphorus, and zinc.[14] The ESPGHAN has recommended use of special postdischarge formula with higher protein, mineral, trace element, and LCPUFA content for preterm infants discharged on formula,[34] and the AAP has endorsed use of these formulas as well.[5] However, a Cochrane review concluded that current recommendations to prescribe postdischarge formula for preterm infants are not supported by the available evidence, because there was not a consistent effect on growth at 12-18 months' corrected age in the trials included in the meta-analysis.[110] Further research on the impact of these formulas on later growth and neurodevelopmental outcomes is needed.

Long-Term Effects of Early Nutritional Support

Few studies have evaluated the longer-term effects of early parenteral nutrition. In a single center observational study, Stephens and colleagues found an association between increased protein and energy intake in the first week of life and higher Bayley Mental Development Index scores and lower likelihood of length growth restriction at 18 months' corrected age.[90] Other observational studies have also found that a prospective strategy of initiating amino acids in the first 24 hours of life in infants weighing less than 1500 grams at birth is associated with improved weight gain at 36 weeks.[102] Wilson and colleagues demonstrated in infants with very low birth weights that early, aggressive parenteral nutrition combined with early enteral feeding reduced growth failure without an increased incidence of adverse clinical consequences or metabolic derangement.[109] The effect of early parenteral amino acids on growth at 36 weeks' postmenstrual age and growth and neurodevelopment at 18 months' corrected age was assessed from a cohort of ELBW infants enrolled in the NICHD Neonatal Research Network multicenter randomized clinical trial of parenteral glutamine supplementation.[74] Infants who received a minimum of 3 g/kg per day of intravenous amino acids in the first 5 days of life were found to have improved growth outcomes (weight, length, and head circumference) at 36 weeks' postmenstrual age. The odds of having weight less than the 10th percentile for age at 36 weeks' postmenstrual age was approximately fourfold higher for infants who did not receive early amino acids. At 18 months' corrected age, no differences in neurodevelopment were observed between the groups, but male infants who did not receive early amino acids were twice as likely to have head circumference less than the 10th percentile.[74] Other investigators

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

have also reported gender-specific differences in the effects of suboptimal nutrition.[21,57]

Controversies in Neonatal Nutrition and Areas of Further Study

The Barker Hypothesis of rapid catch-up growth and later increased risk of metabolic disease has raised questions of how aggressively nutritional delivery and growth attainment should be pursued. The literature remains mixed in the balance of growth and later metabolic health, but also varies in degree of maturity and duration of long-term follow-up with some cohorts decades away from current nutritional practices.[10] Additionally, improved assessments of body composition are now being standardized, which may offer better insights in free versus fat mass and how specific types of growth correlate with long-term outcomes.[22,28,70] The risks and benefits of early rapid growth remain unclear and require further study.

Small cohort studies have suggested an increase in necrotizing enterocolitis (NEC) giving rise to the entity of transfusion-associated NEC (TANEC). TANEC has been variably defined as NEC occurring within 48 hours to any time after a blood transfusion. The mixed definitions of TANEC, the absence of effect with multiple meta-analyses, and the lack of association in large clinical trials studying restrictive versus liberal transfusion policies have raised questions about transfusion being a direct cause of NEC but rather being a proxy for other elements of acute illness such as degree of anemia.[36,40] It is not uncommon for feedings to be held for nongastrointestinal concerns; further work is needed to assess gut health and tolerance to nutritional delivery in the context of multiple exposures in the NICU to avoid unnecessary delay or interruption in critical nutrition.

Acknowledgment

The authors would like to acknowledge the significant contribution of the late Richard Ehrenkranz, MD. Dr. Ehrenkranz was not only one of the authors of this chapter in the previous edition, but also a legend in the field of neonatal nutrition, tireless advocate for research, a mentor's mentor, colleague, and friend.

Key Points

- Growth attainment in the NICU is directly linked to short-term and long-term neonatal health outcomes.
- Initiation of parenteral nutrition including 3.0-3.5 gm/k/d of protein and up to 3.0 gm/k/d of lipids is well tolerated and recommended.
- While human milk is the preferred diet, fortification and regular tracking of growth outcomes are necessary to minimize the risk of extrauterine growth restriction.
- Ongoing research is needed to further refine our nutritional strategies with the goal of moving toward better monitoring tools for growth and nutritional efficacy that allow for personalized medicine and optimal nutritional delivery for each infant.

Support for the Family

SUSAN HATTERS FRIEDMAN, FRANCES THOMSON-SALO, AND A. REBECCA BALLARD

Normal Mother–Infant Attachment

The birth of an infant initiates a series of interactions with parents (particularly the mother) designed to initiate attachment and ensure survival. Attachment is a bidirectional emotional and enduring bond that is reciprocated between infant and the caregiver, a process of synchronous coregulation that influences each other's internal state.[19] Human development is sufficiently resilient to withstand some disturbance of the normal postpartum sequence of events that initiate attachment; however, significant problems of either the infant (prematurity; congenital anomalies; transitional problems such as asphyxia, trauma, or peripartum infection) or the mother (complications of pregnancy, depression) have more substantial capacity to disrupt normal processes. These complications carry a risk for disorganized attachment[59] and adverse effects on long-term neurodevelopment in addition to the risks related to prematurity or underlying anomalies.[17]

Formation of Mother–Infant Attachment

Attachment in Pregnancy

Emotional and psychological groundwork for secure attachment begins in pregnancy. Increased levels of oxytocin throughout pregnancy facilitate the formation of an emotional bond between mother and infant in humans by acting to reduce anxiety and to ameliorate responses to external stresses. Mothers who have a less anxious state of mind are more able to increase their focus on infant care and recognize and respond effectively to nonverbal infant cues.[29] Unexpected hospitalization during pregnancy, feelings of anxiety and depression, and lack of social support interfere with the development of maternal antenatal attachment.[62] Hospital care practices that reduce anxiety, such as avoiding unnecessary separation of an infant from parents, can contribute greatly to early attachment.

Fig. 42.1 is a schematic diagram of the major influences on parental behavior and the resulting disturbances that may arise from them. Experiences during labor, parent-infant separation, and hospital practices during the first hours and days of life are the most easily manipulated variables in this scheme.

Attachment During Labor

When childbirth moved from the home to the hospital, continuous support of the mother during labor became the exception rather than the routine. Although husbands/partners and female relatives routinely accompany the mother to the delivery room, they usually have little experience in providing labor support and may need support themselves. The clinical value of continuous emotional and physical care during childbirth by a trained doula is supported by the results of the 22 randomized clinical trials conducted over more than two decades.[35] Women allocated to continuous support were more likely to have a shorter labor and a spontaneous vaginal birth. In addition, they were less likely to have intrapartum analgesia or a baby with a low 5-minute Apgar score. Beneficial findings are consistent across the studies despite different cultural, medical, and social practices.

Attachment in the First Hours After Birth

Nearly 90% of newborns require no special intervention at birth. Suctioning is not typically required with clear amniotic fluid, and clearing of the upper airway can be accomplished by simply wiping the infant's mouth and nose. Even nonvigorous infants with meconium-stained amniotic fluid do not need routine intubation and endotracheal suctioning.[3] It should not be necessary to separate the newborn from the mother to administer the initial steps in stabilization. The newborn should be placed on the mother's skin immediately after birth, covered by a blanket. Early skin-to-skin care results in more rapid thermal control and decreased incidence of hypothermia in term and late preterm infants.[56]

The sensory stimuli of touch, warmth, and odor between the mother and infant are powerful vagal stimulants resulting in release of maternal oxytocin, which aids in breastfeeding and mother–infant attachment.[51] Oxytocin production in mothers is maintained postnatally by lactation and also

Abstract

This chapter focuses on various aspects of support for the family, including an understanding of normal mother–infant attachment, progressing to understanding the challenges of attachment with the NICU infant, understanding parental mental health issues, and finally care of the long-stay infant and their parents. This chapter reviews the complex subject of supporting infants and their families during a particularly vulnerable time of human development. Having an infant in the NICU is a significant stressor for parents and families. Avoiding unnecessary separation of the infant from the parents contributes positively to early attachment. Parental role disruption in the NICU should be minimized, and parents should be supported to bond with their infants. Interventions in the NICU to promote the parental role and increase understanding of their premature infant may help reduce stress and prepare for discharge. Parental mental health is critical for attachment, bonding, and parent participation in care in the NICU. Mental health issues with which parents may present include postpartum depression, anxiety, grief, posttraumatic stress disorder (PTSD), psychosis, and personality issues. A cohesive, multidisciplinary team is important to providing the best care for families with complex needs. Appropriate boundaries and clear communication styles are critical as well.

• **Fig. 42.1** Major influences on parent–infant attachment and outcomes.

in response to innate infant behaviors such as suckling, clinging, facial expressions, and vocal calls.[29] Oxytocin levels in early pregnancy and the postpartum period are significantly correlated with the frequency of maternal bonding behaviors, including gaze, vocalizations, positive affect, and affectionate touch, as well as the degree of its coordination with the newborn's alert state, attachment-related thoughts, and frequent checking of the infant.[19]

In a concerted effort to promote breastfeeding, the American Academy of Pediatrics, endorsing the WHO/UNICEF publication *Ten Steps to Successful Breastfeeding*, recommends in a policy statement on breastfeeding that for healthy infants, "breastfeeding should begin within the first hour after birth (even for Cesarean deliveries) and that infants must be continuously accessible to the mother by rooming-in."[40] Routine procedures including weighing, measuring, bathing, blood tests, vaccines, and eye prophylaxis should be delayed until after the first feeding is completed. These recommendations stem from a global program launched in 1991 by WHO/UNICEF as the Baby-Friendly Hospital Initiative. A recent nationwide American quality improvement initiative of maternity care hospitals showed a rise in hospitals receiving the Baby-Friendly designation, along with an increase in breastfeeding and exclusive breastfeeding rates in those hospitals compared to hospital applicants not in the program.[20]

Attachment in the First Days of Life

Immediately after birth, parents enter a unique period in which their attachment to their infant usually begins to blossom and in which events may have many effects on the family.

The first feelings of love for the infant are often instantaneous with the initial contact. However, mothers may express distress and disappointment when they do not experience feelings of love for their infant in the first minutes or hours after birth. In a study of 100 primiparous mothers interviewed within 72 hours of delivery, 39% developed positive feelings prenatally, 42% on the first day, and 19% on the second or third day.[58] Most mothers develop affection for their infants within the first week.[64] Delay in positive feelings until after the first day was associated with labor longer than 8 hours, a feeling of disappointment with the "bonding" experience or breastfeeding, and high depressive symptoms, whereas mothers who fell in love on the first day were likely to cite privacy and the ability to hold their newborn as contributing factors.[58] Providers of health care to the maternal–infant dyad should be aware of the many factors that shape mothers' affective responses to their infants.

Sensitive Period

The period of labor, birth, and the following several days has been called a sensitive period, when the mother, and likely the father, are strongly influenced by the quality of care they themselves receive. Perceived stress, social support, and coping strategies are crucial variables in mothers' adaptation mechanisms at the time of childbirth. Social support during the antenatal or postnatal period appears to be a major factor related to mothers' psychological health.[63]

This beginning of parent–infant interactions has foundation in autonomic, neurologic, and endocrinologic systems in the mother and infant, and each become sensitized to the temporal patterns of the other, leading to the formation of a unique bond.[19] Rhythmic patterns of neonatal activity such as crying, nursing, or sucking serve as the earliest means of communication. Maternal cues of her voice, touch, and body rhythms in response create a synchronized "dance" between the mother and infant. The high level of positive arousal that infants co-construct with their parents during their face-to-face interactions accelerates the maturation of the infant's relational skills and provides essential environmental inputs for the development of self-regulation and the process of attachment.

These early interactions are not limited to infants and mothers. When fathers are given the opportunity to be alone with their newborns, they not only spend almost exactly the same amount of time with the infants as mothers do, but also respond to infant cues as effectively. Additionally, when fathers had more extended postpartum hospital contact with their infants, they were more involved in infant caretaking responsibilities.

These early affectional ties can be easily disturbed and may be permanently altered during the immediate postpartum period if a newborn requires separation from the mother for care.[41] A mother's anxieties about relatively mild conditions in the newborn (e.g., jaundice requiring phototherapy, slow feeding, mild respiratory distress) may affect her relationship with the child long afterward. Hospital routines should minimize unnecessary separation of newborns from their parents.

Feeding

Feeding, as part of the mother–infant relationship, should be an enjoyable experience in which the infant feels that his or her cues are being recognized. Supporting breastfeeding promotes attachment, pleasure, and autonomy for mother

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

and infant as they learn together the intricacies of feeding. Mothers may need support to establish breastfeeding using an electric pump. A mother may feel too self-conscious to express milk in public, be anxious about whether she has enough milk, or feel valued more for her expressed milk than for herself. She may delay breastfeeding out of ambivalence, may experience anxiety, or consider herself a failure if the infant is slow to suck, or she may feel confused between the use of breasts for nutrition and sexual intimacy. Mothers who do not wish to or cannot breastfeed also need support, whether or not they express milk. Continuing to express milk for months throughout the night is exhausting even for the most committed mother.

Infants who become exhausted while feeding, who experience painful oral interventions, or who have been forcibly fed may develop an oral aversion. Feeding difficulties may contribute to insecure parent–infant attachment, and infants may become distressed during sucking because they do not feel securely attached emotionally.

Attachment Challenges With Sick or Premature Infants

Preterm children, particularly those with neurologic impairment, have been reported to be at risk for dysfunctional attachment relationships.[59] Early separation between infant and mother is associated with disorganized attachment and linked to increased parental stress.[59]

Parents who live a distance from perinatal care centers may experience additional separation because of the necessity of transporting their child to a regional NICU. If the infant must be transferred to another hospital, it is important that parents be given a chance to see and touch the infant and take a picture before transfer occurs, receive contact information for the other hospital, and accompany the infant whenever possible.[13] Transporting the mother afterward for postpartum care is beneficial; however, financial barriers and lack of insurance provider coverage are problems in some areas. Parents of transported infants often describe the separation in terms of loss and may experience a grief response even when the condition of the infant is not serious. After the initial transport, parents living far away have continued difficulty visiting their infant and may be helped with access to overnight accommodations.

The design of the NICU impacts patients and families (see also Chapter 36). Emphasis on family-centered care has promoted design of single-patient rooms rather than the traditional open-bay NICUs. The single-patient room design can decrease stressful stimuli and allow a private space for parents and infants to have their first interactions. Randomized controlled trials have shown single-patient rooms allow for increased hours of parental visitation[61] and decreased length of stay.[57] However, after controlling for social support, mothers in single-patient rooms reported more NICU stress than mothers in an open-bay NICU design.[61] NICU design benefits from parent feedback in balancing privacy concerns and providing social support to families.

The NICU environment itself is an impediment to parent bonding with their child. The incubator is a physical barrier to the parent's comforting touch; the tubes and patches obscure the infant's cues.[42] In addition, the parents may be hesitant to interact with preterm infants due to their immaturity and medical severity. Preterm infants have less "babyish" physical features and are less active, alert, and responsive than full-term infants. Their cry is perceived more aversive and distressing to parents. Parental bonding may be delayed until the infant's physical condition appears to be improved and parents are assured of the infant's survival.[36]

Neonates experience a variety of stressors while in the NICU, including painful procedures, mechanical ventilation, decreased maternal care, and auditory and light stimulation. Exposure to painful stimuli causes activation of the hypothalamic-pituitary-adrenal (HPA) axis and subsequent release of glucocorticoids. Cumulative stress, such as a higher number of skin-breaking procedures, can result in altered programming of the HPA axis and decrease in cortisol release in response to stress. Such alterations to neurodevelopment following early-life pain exposure may account for adverse behavioral outcomes later in life, including poorer cognitive outcomes and increased internalizing behavior. Maternal care, especially kangaroo care (see below), can negate consequences related to neonatal pain and promote beneficial outcomes.[50]

Difficulty in Bonding

Staff need to be aware that if parents continue to approach their infants reluctantly, this may indicate a prolonged complicated reaction, different from a mother's reaction after birth when being close may stir mixed emotions, such as feelings of failure about the preterm birth. Parents may resist engaging with the infant because of a traumatic birth, shock at the infant's appearance, or a poor prognosis about survival and disability. When parents cannot hold their infant, they may find it hard to believe that the infant is their child, particularly with an in vitro fertilization (IVF)-conceived infant. Mothers with a very low birth weight infant may feel less effective because of the need for the nurses' care; when a parent finds it hard to attach to a very low birth weight infant, staff can talk with him or her about the infant's personality traits. It can be pointed out to parents who feel that they have to ask permission to hold their infant, that they do not have to ask permission to be loving parents. If parents become phobic about entering the unit because of its associations or their fear of bad news, this should be explored and additional support offered.

Interventions for Premature or Sick Infants and Their Parents

With advances in medical and neurodevelopmental care, preterm or seriously medically ill infants may be hospitalized

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

for many months. There is increased understanding that the quality of social interactions between parents and infants in the neonatal intensive care unit (NICU) can ameliorate the adverse effects of preterm birth, increase awareness of the psychosocial effects on the family, and guide professional interventions. An integrated multidisciplinary team, composed of doctors and nurses, as well as optimally also a social worker, neurodevelopmental therapist, lactation consultant, psychiatrist, infant mental health clinician, and pastoral worker, works in partnership with families to understand the complexity of the needs of the infant and family to promote attachment and autonomy, decrease parental stress, increase sensitivity, and prepare for discharge and eventual independence. Social work support is essential for parents' needs for accommodation, transportation, and child care. All staff should be aware of parents' individual mental and physical health, and provide care that is culturally sensitive and safe. A unified needs-based care plan takes parents' changing anxieties into account and empowers them as members of the caregiving team. This approach leads to improved family satisfaction and greater staff retention. The infant mental health clinician liaison should assist the staff by contributing the infant's perspective, clarifying the parents' experiences, and engaging in therapeutic work with parents and infants to improve the parent–infant relationship.[54]

Parental Stress

Parental anxiety may remain high for months because of concerns about health and parenting challenges. The experience of in vitro fertilization (IVF) is likely to accentuate the stress, which may be increased by caring for multiples. Anxiety often lies behind forgetting information, avoidance, and aggressive behavior. If the staff make time for parents to verbalize their worries, they may be able to suggest appropriate ways to manage the peaks of anxiety.

Parents bond in different ways and need to be supported in this. Staff can encourage parents of very preterm infants to smile and sensitively share eye contact and the same emotional state to promote optimal outcomes for their infant, pointing out that the infant prefers parents to nurses, which predisposes them to bond with their parents. Care is usually not only skin-on-skin, which lowers autonomic nervous system activity,[52] but also skilled care, such as tube feeding and intensive developmental care programs. Preterm infants show faster cognitive growth when parents are consistently responsive. Parents who are prevented from holding or touching their infant for long periods face greater difficulties in feeling connected and maintaining hope.

Although families need different kinds of support and information giving, support needs to be consistent, and parents find it helpful for staff to recognize their frustration and stress responses as normal. Information on care procedures may need to be repeated regularly because parents may not retain this information during the stress of concentrating on their infant. They may feel encouraged when the staff point out how the infant's record demonstrates an improvement in his or her responses when the parents visit. Information helps parents correct the perception that their infant is in pain. Parents should be reassured that they can positively influence their infant's development through early childhood.[71]

Parents may need encouragement to connect with, support, and to nurture themselves as they become exhausted. As the staff becomes familiar with communication patterns between parents and/or support persons, they can encourage parents to reconnect with their extended families, particularly if a mother's partner cannot support her or there is no partner available. Staff should work with the parents' support network and be nonprescriptive about how parents share information with the outside world. Parents often feel lonely in the NICU when contact from friends and family declines over time and may find even a brief contact with a clinician supportive. If parents find it difficult to limit intrusive family involvement, the staff can help to manage this sensitively. Siblings may experience adjustment reactions of jealousy and anger and feel neglected; reading relevant story books may help them process these feelings.

Interventions to Support Parents and Infant

Parents of preterm infants experience high levels of stress and often lack knowledge of how to parent and interact with their infants during their hospital stay. Interventions in the NICU to aid parents' understanding about their preterm infants and to promote their role as parents may help them participate in their infant's care in a developmentally sensitive manner, thereby reducing stress and preparing them for when the infant is discharged home. Different approaches are indicated at different times to support parents, the infant, and the relationship, in what has been described as a paradigm shift from healing the infant's medical problems to a focus requiring effective partnership with families[33] and including supportive and psychoeducational interventions and perinatal psychotherapy.[8]

A successful educational–behavioral intervention program for parents of premature infants 26-34 weeks' gestation (Creating Opportunities for Parent Empowerment or COPE) found that mothers in the intervention group exhibited significantly less stress while their infant was in the NICU and less depression and anxiety at 2 months' corrected age compared with mothers in the control group.[48] In addition, infants in the intervention group had a 4-day shorter length of stay (mean 35 vs. 39 days) compared with control infants.

Weekly support groups for parents that offer information and emotional support are helpful. Linking parents with others who have had a preterm infant could help them work through some of their grief relatively quickly. Early individualized family-based interventions reduce parental stress and depression.[54] Brecht and colleagues[9] carried out a

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

comprehensive review of psychoeducational programs, such as the COPE program. Such programs have been found to be effective in preventing post-traumatic stress reactions by helping parents to partner in providing care to the infant, by enhancing parental feelings of self-efficacy, and by reducing distress around the infant's birth and hospitalization. Brecht reports a trend toward early brief interventions that target parent trauma and utilize cognitive behavioral techniques with positive effects on maternal and infant outcomes.

A meta-analysis of interventions for parents to improve developmental outcomes for preterm infants found significant reduction in pooled effects for maternal anxiety and depressive symptoms and positive pooled effects on parental self-efficacy.[5] Interventions included psychosocial support, parent education, and/or therapeutic developmental interventions targeting the infant; the positive effects seen in the psychosocial aspects implicate mental health services for families in the NICU as an important adjunct to routine care.

Interventions to reduce maternal symptoms may not necessarily overlap with parental education and developmental care. A recent meta-analysis of NICU-based interventions to reduce maternal depression and anxiety symptoms found 5 out of 7 interventions for depression and 6 out of 8 interventions for anxiety reduced symptoms compared to the control group.[49] For maternal depressive symptoms, cognitive behavioral therapy was associated with significant improvement in maternal symptoms, whereas educational approaches and interventions focused on improving maternal–infant responsiveness were not.

Interventions to minimize the infant's distress center primarily on the Neonatal Individualized Developmental Care Assessment Program (NIDCAP) established by Heidelise Als,[2] which aims to reduce stress linked to the environment, increase awareness of the baby's behavior, and integrate the parents in their daily routine. The neurodevelopmental therapy team works with parents to develop individualized flexible developmental care plans based on an infant's developmental stage and behavioral cues. These continue to be important in a long hospitalization, because when reaching new developmental stages, an infant risks being overwhelmed or bored, and a care plan can offer the family greater consistency.

Infants find it both exciting and soothing to be gazed at by someone who delights in them. They respond best when parents are with them as much as possible and are willing to play with them with positive reciprocity and contingency without overwhelming them. This has positive results for cognitive and psychomotor development, and parents feel supported, knowing that their sensitivity optimizes brain development.[67] Parents, particularly fathers, report increased intimacy when they read books to their infants.[44] Infants also respond positively to a mutually supportive relationship between parents. Parents who need help to think about the infant's mind as intentional can be encouraged to carefully observe their infant and become curious about the meaning of behavior, such as playing with the pacifier, responding to imitation, fighting sleep, and being alert to their parent's feelings. This helps empower parents to respond in a holistic way.

The clinician, as well as thinking with parents about the infant's happiness, can underscore the importance of recognizing the infant as having agency and learning that negative affect expresses intention. When parents view this as being active and can share in a social exchange, infant competence increases. When parents are very anxious, encouraging neonatal behavioral observation has been found to be effective in enhancing engagement. Parents who are less sensitive and more controlling may need additional support.

Kangaroo Care (See Also Chapter 36)

Kangaroo care, now commonly referred to as *skin-to-skin contact*, originated in South America as a means of keeping at-risk infants warm with limited resources. Subsequent studies in high-income countries have indicated potential benefits in promoting breastfeeding, establishing parent–child attachment, and promoting neurodevelopment.

During kangaroo care, the diaper-clad infant is placed in flexed position directly onto the parent's chest, with maximal skin-to-skin contact, and covered with a shirt or blanket. Skin-to-skin care is useful in helping parents develop a closer tie to their infants and may be the first time that parents feel that the infant is truly theirs.[14] Specific maternal benefits to kangaroo care have been demonstrated, including reduced maternal anxiety, report of less maternal depression, and improved maternal attachment behavior in the postpartum period.[7,18]

The benefits of kangaroo care extend beyond promoting attachment. Kangaroo care promotes physiologic stability and maturation of the autonomic and circadian systems in premature infants, including more quiet sleep, longer sleep cycles, and increased respiratory regularity.[50] Kangaroo care decreases premature infant pain profiles prior to a heel stick and may be a viable analgesic for premature infants as young as 28 weeks' gestational age.[50] A meta-analysis of 21 studies involving low birth weight infants showed kangaroo care was associated with a reduced risk of mortality, nosocomial infection/sepsis, hypothermia, and length of hospital stay.[14] In addition, compared with conventional care, kangaroo care was associated with an increased weight, length, and head circumference, as well as an increase in the likelihood of exclusive breastfeeding at discharge or 40-41 weeks' postmenstrual age.

Benefits of kangaroo care are long-lasting. In follow-up at 10 years of age, premature infants who received skin-to-skin contact as neonates showed attenuated stress response, more mature autonomic functioning, organized sleep, better cognitive control, and a more reciprocal mother-child relationship.[18] A 20-year follow-up to the original Bogota study on kangaroo care found long-term social and behavioral benefits for infants who received kangaroo care, including increased brain volume, less aggression, and less antisocial behavior.[12]

Kangaroo care should be considered for all stabilized premature infants, although there is currently no standard definition of infant stabilization or consensus of infant age for its initiation. Additional research is needed to evaluate risks and benefits to more immature infants and those requiring highly technical care, such as conventional or high-frequency mechanical ventilation.

Family Engagement

Paternal Issues

There is increased recognition of the importance of the father's presence in the NICU, both to support the infant and develop the father–infant bond. Infants move differently in response to a father's voice.[37,55] This is also relevant with same-sex parenting. Fathers want to be viewed as important to their infant while different from the mother. The stress of keeping the family financially viable and making childcare arrangements for siblings has led to paternal stress being described as invisible; fathers often cope by delegating care.

Many fathers, although initially reluctant to be close to their infant, find the contact more positive than expected; a father's early involvement may positively influence the attachment process and support the mother. When fathers are helped to care for their infants, they relax more at the bedside in opportunities for "meaningful fathering moments," which in turn contributes to increased paternal nurturing. Involving fathers in developmental care reduces neonatal stress and its neurobiological sequelae and is likely to promote better infant and family outcomes.[65]

It is important to ask each father how he can best be supported; for example, by detailed information or an overview of his infant's status. Fathers should be offered appointments that fit in with their work schedules; they often make the necessary arrangements for these appointments. They tend to prefer support to come from professionals and to be empowered through sharing information in an accessible and two-way process and with written material and Internet resources.

A dedicated fathers' group in recognition of the stress fathers feel helps them feel more secure and connected with their baby.[70] A father's behavior toward and attachment to the baby is related to many factors including genetics, personal relationships, culture, his own experiences with parenting, his ability to tolerate stress, and the baby's responses to him. Fathers commonly experience a feeling of lack of control when their infant is in the NICU. Maintaining relationships with family, friends, and staff, and consistent information given orally and written, are ways of supporting fathers. Although mothers may be allowed maternity leave, fathers may need to return to work sooner. Work may lead to some sense of control and normalcy but can also lead to feelings of guilt.

Having an infant in the NICU stresses the couple's relationship. Partnerships already in difficulty often do not survive this stress, which is a further reason for providing support to the couple.

Staff–Parent Communication

Staff–parent communication is a critical part of the NICU experience. NICU parent studies indicate a need for improved communication. It has been recommended that staff discuss the baby's diagnosis and course using "simple straightforward language void of medical jargon and presented in a warm, sympathetic manner."[32] As well, it is suggested that staff interact with parents as an "expert coach and facilitator" to enable parents to become comfortable in their baby's care.[32]

Knowledgeable and understanding team members may be more effective in communication with parents suffering from mental health issues. A study of NICU staff found that challenging interactions were more common among parents with psychotic symptoms, parents who hover (likely related to anxiety levels), or parents who have addictions, among others.[21] Psychiatric referrals are needed in some cases, and appropriate boundaries should be set with families. Recommendations have been made that all NICU parents should interact with mental health professionals for support, education, screening, and psychotherapy when needed. As well, mental health professionals should provide support for NICU staff.[39]

Family-Centered Care in the Neonatal Intensive Care Unit

Family-centered care is based on the understanding that the family is the most consistent and influential force in the growth and development of the child, that patients and family are integral partners with the health care team, and that the perspectives and information provided by families are essential components of high-quality decision making.[13,33] Parents of infants admitted to the NICU are confronted with many challenges, including physical separation from their infant, a bewildering number of care providers, inability to protect their infant from painful procedures, and, frequently, financial concerns. Family-centered neonatal intensive care endeavors to support families during this stressful time by making the NICU a welcoming environment for families, encouraging parents to participate in care, and educating parents on the NICU environment and their infant's condition.

Family-centered care has roots in advocacy by NICU parents. In 1992, a group of parents met in a conference with neonatologists to address problems identified by the NICU parents and to explore possible solutions. The components laid out in the original document published after the conference, The Principles for Family-Centered Neonatal Care, have become incorporated in national statements recommending family-centered care and remain relevant today.[30]

The NICU should be family friendly, and care should be taken to reduce stressful noises and sights. Facilities for

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

parents' comfort and privacy such as rooms where they can relax should be provided, as well as a space in which fathers can work while their infant sleeps. The NICU should not be overly feminine; a father's name could be on his infant's crib. Prearranged discussion times that are scheduled to take place away from the infant's crib usually assist in communication. What the environment communicates to the family needs to be studied so that hidden barriers to communication and rigid policies can be tackled; however, parents should not feel that their actions are overly scrutinized. Nurses must be aware that witnessing distress in their infant generates feelings of anger in parents, which may compromise the parent-nurse relationship.[15] Increased support and involvement in the infant's care help allay complaints that stem from anxiety.

Some practices to be considered for implementing family-centered care include the following:

- Parents are not visitors but instead are essential components of the care team. "Visiting Policies" should address nonparent family members and friends, whereas policies related to parents should be more appropriately addressed as "participation in care."
- Parents are integral to care and are encouraged to participate in patient care rounds, communication with personnel at the change of shifts, and in the bedside care of their infant. Parents should have access to information in their infant's medical record. Many units have initiated parent documentation into the record.
- The physical environment should provide for the needs of parents, including needs for accessing information, rest, nutrition, privacy, childcare for siblings, and support for their infants by breast milk pumping. Standards for support of families are available.[74]
- Families should be incorporated at various levels as advisors. The perspective of experienced families should be integral to the unit administrative activities. These could include parents as teachers during orientation and continuing education of staff, parent advisory committees to collaborate in planning of new policies or ongoing quality improvement activities, and involvement in NICU parent support groups.

Parental Mental Health Issues

Parental mental health in the NICU is critical for attachment and bonding, participation in care, and infant development.[28] Psychiatric support in the NICU can be invaluable. Most referrals to psychiatrists during this time are for depression, anxiety, coping issues, and personality traits.[24,25,60]

Postpartum Depression

Postpartum depression (PPD) is a common complication of childbirth. It occurs in 10%-20% of postpartum women, with studies showing increased rates of 28%-70% in the NICU.[1,4,26,53] A systematic literature review showed higher depression scores of mothers of preterm LBW infants for at least 12 weeks postpartum and that higher levels of depressive symptoms can persist through the first postpartum year.[72] Risk factors include a personal or family history of depression, relationship issues, low socioeconomic status, and stressful life events. Obstetric- and NICU-specific risk factors include multiple birth, very low birth weight, recent stillbirth, less effective coping strategies, maternal role disruption, and lower perception of nursing support.[53] Symptoms may include depressed mood, decreased enjoyment (including of spending time with baby), decreased sleep (difficulty sleeping even when the baby sleeps), decreased energy, feelings of guilt/worthlessness, changes in appetite, and potentially suicidal or violent thoughts.

Differential diagnosis includes: "baby blues" (seen in the majority of women—with transient symptoms of irritability, tearfulness, and fatigue resolving within 2 weeks of delivery), postpartum psychosis, bipolar disorder, and medical illness (e.g., thyroid disease or anemia).[27] Depressed mothers are more likely to be disengaged, withdrawn, or hostile, with disrupted mother–infant bonding; thus, recognition and treatment are important. Of note, lower maternal NICU visitation rates predicted greater maternal depression at 4 months corrected age.[31]

Because of its prevalence, PPD screening and prevention measures should be integrated into NICU care. A widely used validated screening tool is the Edinburgh Postnatal Depression Scale (EPDS). A positive screen indicates that further evaluation is warranted. The EPDS is readily accessible online (e.g., through the American Academy of Pediatrics website). Mothers may be referred to psychiatry, family medicine, or obstetrics. If they are actively suicidal or homicidal, they should be evaluated emergently. Antidepressant medications and psychotherapy are treatments of choice. With mild symptoms, psychotherapy alone may be sufficient. In risk–benefit analysis regarding medications in lactation, just as in pregnancy, the well-established risks of untreated maternal depression on development should be considered.[22,23]

A recent study considered maternal stress in the NICU and child outcomes of very preterm infants. Predictors of NICU stress included maternal lower education level, stressful life events, postpartum depression, and unsettled/irregular infant behavior. They found NICU-related stress to be associated with child anxiety and poorer language skills at 4 years corrected age.[75] Another study that included nine home visits during the first year of life (to those who had been very preterm infants) by a physiotherapist and psychologist focusing on the parent–infant relationship, infant development, and parental mental health found that at 2 years of age, those in the intervention group demonstrated less dysregulation and externalizing behaviors, and parents had less anxiety and depression.[68]

Postpartum Anxiety

Anxiety is often comorbid with PPD. Risk factors include past traumas, prior high-risk pregnancy or postpartum course, prior fetal/infant loss, low socioeconomic status, poor social support, and past history. Anxiety can become excessive, interfering with daily life and bonding with the infant.

Mothers with generalized anxiety disorder (GAD) may demonstrate excessive worry, restlessness despite appearing tired, imaginings that the situation is worse than it is, and feelings of being unable to leave the infant's bedside because of an overwhelming fear of a bad outcome.[28]

Alternatively, in obsessive-compulsive disorder (OCD), intrusive thoughts and behaviors may occur and cause maternal distress. She may, for example, avoid holding the infant for fear that she will cause harm because of distressing obsessive thoughts. Anxious mothers experience higher investment in infant health concerns and intrusive thoughts—leading to more repetitive questions and phone calls and the repetitive need for reassurance.

Rates of anxiety are elevated among mothers with infants in the NICU.[4] Maternal role disruption should be minimized. Staff should encourage mothers to look beyond the machines and alarms, to touch and talk to their babies, and to participate in feeding and diapering. The new parenting role can be stressful for anyone, but attempting to take on a much-anticipated role with severely ill infants—infants with tubes and who may not be able to be held or snuggled—can be a significant stressor. Other NICU-specific stressors include feelings of loss of control and the daily uncertainties of life and death. Mothers' perceptions of their infants' illnesses are not correlated with the actual illness severity. The mother's stress level may be related to illness perception rather than to illness severity.[10]

Anxiety can become a significant issue during any high-risk pregnancy, because the mother may have worries about the baby's health, delivery, and how well she will fill her new role. Because it can decrease the number of "unknowns" in advance, a visit to the labor and delivery unit and to the neonatal intensive care unit (NICU) can be helpful. Empowering the pregnant mother (e.g., with Lamaze) may also be useful. Because high anxiety can decrease attachment, it is important to consider. Similar to PPD, treatment for anxiety disorders includes psychotherapy and medication.

Post-Traumatic Stress Disorder

Both mothers and fathers are at risk for acute stress disorder, identified in 35% of mothers and 24% of fathers within 3-5 days of infant's admission to the NICU.[45] A smaller percentage had persisting symptoms—15% of mothers and 8% of fathers met diagnostic criteria for post-traumatic stress disorder (PTSD) 30 days later. These symptoms can persist long after the birth. Symptoms of PTSD include hyperarousal, numbing, avoidance of triggers, and re-experiencing of traumas. The mother with PTSD may actually avoid the infant or the NICU if these experiences are her anxiety triggers. She may appear irritable, be easily startled, and have difficulty with bonding. Early PTSD symptoms predict less sensitive and more controlling maternal behaviors. Mothers of VLBW infants who experienced more symptoms of PTSD were less sensitive and effective at structuring the interaction when playing with their infant.[16] Mothers with PTSD are also noted to be more controlling in their interactions with baby.

A recent study seeking to prevent PTSD among mothers of preterm infants found that a brief six-session intervention using trauma-focused cognitive behavioral therapy was effective in reducing symptoms of anxiety and depression, with benefits noted at 6-month follow-up as well.[66]

Grief

Parents should have opportunities to grieve for the healthy infant they were expecting. Shock, anger, sadness, disbelief, and denial may occur. But the parents need to make their peace and bond with their infant. Sensitive care for these families positively impacts their coping. Pediatricians Kennell and Klaus were pioneers, recognizing the strong attachment occurring between mother and baby prior to delivery.

In the event of neonatal death, the significant loss should be acknowledged and culturally appropriate rituals used, conveying compassion. Parents should be able to see and hold their deceased infant. Mementos and photographs should be offered, with the option of a funeral or memorial service also discussed.[34]

Maternal grief may begin with a period of shock, confusion, numbness, irritability, or anxiety, followed by intense sadness, longing, guilt, and somatic complaints. A follow-up visit a month later can help ensure understanding of information and give an opportunity to address concerns and questions.[28] Parents may either avoid reminders of their loss (such as contact with mothers of healthy infants) or may seek opportunities to talk about the baby. Often, a year or two passes before a mother feels back to "normal" in her ability to enjoy life and invest in other relationships. Risk factors for pathologic grief include a history of psychiatric illness, childlessness, and poor social support.[38] Those exhibiting maladaptive or destructive behaviors, dominant somatic symptoms, or lack of improvement over the course of months should be referred for evaluation.

Persisting Trauma Reactions and Complex Grief

Many parents find the ongoing NICU experience traumatic, despite the initial support they receive over the preterm birth, and this may complicate the bonding process. A parent's own trauma history may affect his or her responses. For example, the multidisciplinary team needs to be aware

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

of a parent who is so anxious that he or she cannot participate in discussions about the infant's care, while still respecting the parent's dignity. Parents may face extreme distress or guilt or feel rejection toward the baby if the infant is visibly different or if they feel responsible for the fact that the infant is not as they wished. Deaths of other infants in the NICU may retraumatize parents. It is important that additional support is offered, because infants whose parents experience post-traumatic stress symptoms are more vulnerable to develop eating and sleeping difficulties in the first year of life.

Part of the experience of complex grief may include feeling guilty, for example, about reproductive loss, earlier fetal death, or having an infant with visible differences, or mourning the unavailability of the mother. Parents may feel that they face unbearable choices, whether or not their infant survives. Getting to know the infant as a person who is psychologically alive creates a memory of being the parents of their infant, supports them when they fear death, and aids decision making and grieving. Supporting parents while they face the reality that their child is dying requires a delicate balance. Staff need to be culturally sensitive, recognizing each person as a unique individual, whatever his or her ethnocultural group.[43] If parents are involved with staff in end-of-life decision making, this is usually associated with lessened grief. Mutual confidence and communication encourage freedom and creativity around the infant at this time.[11] Attention to the infant's and parents' pain is important.

Medical and parental views about prolonging life may diverge, particularly when a parent's spiritual and cultural values make it unacceptable to shorten life. The staff need to adopt an ethical embracing of difference and recognition when they cannot advise but need to maintain a dialogue to help the family work through the decision-making process.[73] Parents need to feel supported through the pain of end-of-life issues and know that their decisions were made out of parental love. They may need the staff to help access trusted supports. When a decision is made to forgo life-sustaining treatments, parents may appreciate being asked whether the staff should indicate to other parents what is happening in case they wish to avoid being there. Parents may need support in explaining to a young child why his or her infant sibling died.

Postpartum Psychosis

Postpartum psychosis (PPP) is much rarer, occurring in 1-3 per 1000 mothers. Delusions (fixed false beliefs out of line with one's cultural background), disorganized thoughts, hallucinations, rapid mood swings, insomnia, and confusion may occur, often within the first postpartum weeks. Risk is elevated in those with bipolar disorder, personal or family history, sleep deprivation, and psychosocial stressors.[27] Medical causes of mental status changes, including anoxia, electrolyte disturbances, thyroiditis, neurologic pathology, or drug-induced causes must be ruled out.

Because of its rapid onset, fluctuating course, and morbidity and mortality risks, psychiatric hospitalization for PPP is usually necessitated. Suspected cases should be referred emergently; untreated PPP carries elevated risks of infanticide and suicide. Mother-infant bonding need be less important than infant safety in cases of postpartum psychosis. Mainstays of treatment of PPP include antipsychotic and mood-stabilizing medications. Medication side effects such as sedation should be considered and, in some cases, breastfeeding may not be recommended owing to medication effects and the impact of sleep disruption on maternal symptoms. Mother–infant visits should be planned when safe and initially occur under supervision. Engagement and follow-up are critical, and child protective services usually need to be involved.

Personality Disorders

In contrast, people with personality disorders evidence chronic, inflexible patterns of behavior and perception. These patterns create dysfunction at work, in the family, and socially. Approximately 15% of adults experience personality disorders.[47] Personality disorders fit into general categories of odd/eccentric (e.g., paranoid), dramatic/erratic/emotional (e.g., borderline, narcissistic, histrionic), or anxious/fearful (e.g., dependent, avoidant). Short of a personality disorder, problematic personality traits tend to come out under periods of stress—such as during a NICU admission with an unwell infant.

Dysfunctional personality traits are an important predictor of parental problems coping with the NICU. A parent with narcissistic personality disorder may disrupt the NICU by excessive demands for special care, self-preoccupation, and lack of empathy, whereas another parent with borderline personality disorder and affective instability may cause difficulties in the team working together. Mothers with borderline personality disorder were significantly more likely to have negative birth outcomes in an Australian sample. They also had frequent comorbid substance abuse and other impairment.[6]

Addressing personality disorders in parents can help to diminish parental distress and improve physician–parent relationships and parent–infant relationships, in addition to reducing staff stress and unit chaos. To decrease NICU problems from personality disorders, the goals should be to support the parent, minimize disruption, and maintain safety. Consistent boundaries across members of staff are critical, allowing for a more predictable environment so that the focus can be on the needs of the sick infant.

Boundary Issues and Families With Multiple Risk Factors

In a long-stay admission, some families seek special treatment for their infant and themselves that tends to breach professional boundaries. Nurses on 12-hour shifts in high-technology, life-and-death situations may become

like family and find themselves under pressure as parents unconsciously seek concessions for their infant. Parents may also seem intimidating. When staff come to feel that some parents are "special," this is a sign of difficulties to be negotiated. Caring for such families may lead to splits in the team. Multidisciplinary team meetings are important in maintaining professional boundaries and minimizing mixed messages.

A cohesive multidisciplinary team provides the best care for families with complex needs, such as parents with anger management difficulties, serious mental illness, substance use, intellectual or physical disability, disadvantaged life circumstances, extreme youth, or a history of abuse or neglect of other infants. Parents whose behavior the staff find challenging may inwardly feel despairing or ashamed; terms such as "manipulative" should be avoided in considering needed support. Significant numbers of parents with a psychotic illness have contact with infants in the perinatal period, with symptoms and medication side effects impacting on interactions as well as the parent–child relationship; however, a parent's right to be treated as a parent should be recognized whenever possible. Staff may find the care of a parent who uses drugs and alcohol challenging if the parent is substance-affected at times or does not visit. Plans enabling parents to access ongoing supports after discharge should be in place. When a parent has anger management problems, the staff needs to set boundaries and address in a nonshaming way that anger is unacceptable, because infants should not be frightened. They should also inquire whether the parent needs further support. For the infant's safety, a referral to child protective services should be considered when there is considerable ambivalence (including self-harm), although it is not always clear when a parent is unable to be a caregiver. Parents may take hospital policy personally and blame the hospital for exacerbating mental health issues. If they are dedicated parents, they may feel offended if they are offered parenting skills advice. When violence is disclosed by a parent, the staff needs to be mindful of a power imbalance between the couple, and one partner may use the hospital as an escape. A nonjudgmental approach to referral for counseling or child protective services is needed, with the inclusion in care planning, if appropriate, of the violent partner. When an infant is to transition from a parent's care to other caregivers, the infant's interests must remain primary, and ruptures of attachment should be minimized. Some parents respond to the possibility of their infant's being removed from their care by becoming aggressive and may attempt to take flight with the infant.

Perinatal Psychotherapy

Although parents of a long-stay infant receive more structured interventions and become skilled at knowing their infant, they may increasingly value a confidential space to process feelings about the NICU experience. When they have difficulty relating to their infant, a flexible psychotherapeutic intervention to consolidate internal and external supports is indicated, usually consisting of less structured therapeutic sessions and coping strategies. The clinician needs to respond promptly to the request for help with a crisis or for supportive psychotherapy. Parents may be initially offered weekly appointments together, then flexibly as needed. Ideally, professional help is provided in the NICU environment because families may be reluctant to keep off-site appointments. Parents use this time to process the grief and anger about having a preterm infant, or anxiety about the effects on the couple's sexual relationship, while also focusing on finding joy in their infant.

Insight-oriented psychotherapy aims to help parents become aware of how the reactivation of past painful experiences contributes to difficulties in relationships with their infant or staff. Some parents decline the offer of medication and try to process their difficulties by talking. For example, a mother's sadness about her own mother's unavailability may be evident without being too distressing for her infant.

Parents' inconsistent messages negatively affect the attachment process, and the clinician should aim to reframe this. A parent's negative attributions from the first month onward, or suggestions of malevolence, need to be challenged so that they do not continue, and the pathologic link with the past must be lessened so as not to contribute to insecure attachment.[46] Guided observation of the infant can also modify the traumatic representation of the infant. When a parent rejects a tiny or ill infant, that infant urgently needs support to reduce the extreme ambivalence and negativity and to lessen the likelihood of infant withdrawal.

As parents explore feelings about loss or abuse and process recurrent traumatic memories, they usually feel relieved that traumatic feelings around their infant's birth can be lessened and value this time for themselves. It may be that the integrated care given to long-term NICU families prevents the neglect and abuse that might otherwise stem from unrelieved parental stress at this time.

Parents who feel sensitively cared for by staff are likely to be more sensitively caring of their infant, who in turn is less likely to become a vulnerable child. Above all, parent-inclusive assistance that will support these infants and their parents needs to be determined.[69]

A follow-up telephone call after discharge consolidates the support. Parents who may not be able to accept support during the hospital stay often renew contact with the staff much later and engage for a considerable time.

Discharge Planning

Even though parents wish for a long-stay infant to be discharged or transferred to a hospital nearer home, they may also be reluctant for this and feel abandoned by the staff. They may be anxious about managing the care of an infant on oxygen with a nasogastric tube even with outreach care, as well as resuming care of siblings, who may have adjustment reactions. Sustained discharge planning is supportive, including any necessary skills training. If single-room care

is not available, the opportunity for parents to room-in with their infant for at least a night in the hospital before discharge should relieve many of their fears about managing at home.

In summary, because the newborn completely depends on the parents for survival and optimal development, it is essential to understand the process of bonding as it develops from the first moments after birth. Although we have only begun to understand this complex phenomenon, individuals responsible for the care of mothers and infants should evaluate hospital procedures and ensure early, sustained mother–infant contact. Care practices should be developed that promote contact of the mother and father with their infant and help them learn and explore the wide range of sensory and motor responses of their newborn infant, whether healthy or requiring intensive care. Parental mental health should be optimized in the NICU to aid in bonding and caregiving.

Acknowledgments

Marshall Klaus and John Kennell, the original authors of this chapter, were pioneers in identifying the importance of this subject, and much of their work remains relevant, constituting a core of this knowledge.

Key Points

- Having an infant in the NICU is a significant stressor for parents and families.
- Avoiding unnecessary separation of the infant from the parents contributes positively to early attachment.
- Maternal oxytocin levels in pregnancy and postpartum are correlated with maternal bonding behaviors.
- NICU parents should be supported to bond with their infants.
- Parental role disruption in the NICU should be minimized.
- Parental mental health is critical for attachment, bonding, and parent participation in care in the NICU.
- A cohesive, multidisciplinary team with appropriate boundaries is important to provide the best care for families with complex needs.
- Interventions in the NICU to promote the parental role and increase understanding of their premature infant may help reduce stress and prepare for discharge.

Principles of Drug Use in the Fetus and Neonate

JACQUELYN D. MCCLARY

Fetal Drug Disposition

The use of medications during pregnancy, prescription and over-the-counter, is a common and increasing occurrence. Multiple studies have demonstrated that approximately 90% of pregnant women take at least one medication during the pregnancy.[10] The average number of medications used during pregnancy has increased by 68%, from 2.5-4.2, over the past 30 years, and the use of four or more medications has increased from 23%-50% of pregnant women.[10] When interviewed, patients, physicians, and pharmacists all cite safety of the mother and fetus as a top priority when making decisions about medication use.[13] Unfortunately, safety data for the vast majority of medications is limited.

Most of the drugs administered to the mother reach the fetus; the extent of fetal exposure depends on maternal drug disposition and placental drug transfer. The result of maternal drug disposition is the steady-state concentration of the drug in the maternal circulation, which ultimately determines the amount of the drug available for distribution to the fetal compartment. The steady-state concentration is impacted in varying degrees by maternal absorption, distribution, metabolism, and excretion of drug, all of which are altered during pregnancy.

Maternal Pharmacokinetics

Drug absorption is affected by a number of factors, including gastric emptying time and intestinal motility, which significantly change during pregnancy. Gastric emptying time is increased and intestinal motility is decreased during pregnancy. The result is a reduced rate of absorption of many medications with a potential increase in the extent of absorption due to the prolonged transit time through the intestinal tract. Intestinal metabolizing enzymes are also altered during pregnancy, which can result in either an increase or decrease in drug absorption. Together, these factors impact the oral bioavailability of a drug and ultimately the maternal steady-state concentration.

Steady-state concentration may also be altered by physiologic changes that occur during pregnancy and that influence drug distribution (Tables 43.1 and 43.2). Maternal total body water, extracellular fluid, and plasma volume all increase gradually during pregnancy by about 32%, 36%, and 52%, respectively (see Table 43.2). Maternal cardiac output also increases by about 40%-50% as a result of increases in both heart rate and stroke volume. The increase in body water is the primary reason for the observed decreases in peak drug concentrations with standard dosing of water-soluble drugs. When the drug dose is kept constant in the presence of increasing body water, the drug's apparent volume of distribution (Vd) increases, and steady-state drug concentrations decrease. Such a decrease in steady-state concentrations may alter the therapeutic effect of the drug in the mother and influence the amount of drug available for diffusion across the placenta. Similarly, the increase in cardiac output affects drug transfer by limiting the time a drug resides in the villous space of the placenta and is available for transfer to the fetus.

Coincident with the changes in body water distribution and cardiac output, the amount of maternal fat increases at a relatively constant proportion to the increase in body weight (see Table 43.2). The result is an increase in Vd for lipophilic drugs and the potential for accumulation within the adipose tissue. Minimal changes in drug efficacy are expected under these circumstances; however, the adipose tissue can act as a reservoir and slowly release the drug into systemic circulation. An increased half-life and prolonged drug effects may be observed.

Complicating the picture even further is the fluctuation in serum proteins during gestation. Both albumin and α_1-acid glycoprotein are decreased during pregnancy, resulting in an increase in the free (active) fraction of various highly protein-bound drugs. For example, the free fraction of tacrolimus may increase as much as 91% during mid and late pregnancy.[8] This unbound drug is not only the active moiety but is also the form that is available for metabolism and elimination by the mother and transfer to the fetus.

Abstract

The exposure of a fetus or neonate to medications is a common occurrence. Fetal drug disposition depends on maternal pharmacokinetics, which are altered throughout pregnancy and influenced by the placental handling of a drug together with fetal pharmacokinetics. Most pharmacologic agents detectable in the maternal circulation cross the placenta and enter fetal circulation. The impact these medications have on the fetus is often unknown, so that currently fewer than 30 drugs have been positively identified as human teratogens. After birth, sick or premature neonates may be exposed to a number of medications that could have long-lasting consequences.

TABLE 43.1 Influence of Pregnancy on the Physiologic Aspects of Drug Disposition

Pharmacokinetic Parameter	Physiologic Change	Pharmacokinetic Impact
Absorption	↑ Gastric emptying time ↓ Intestinal motility ↑ or ↓ Intestinal enzyme activity	↓ Rate of absorption ↑ or ↓ or Unchanged extent of absorption
Distribution	↑ Plasma volume ↑ Total body water ↑ Cardiac output ↑ Body fat ↓ Plasma proteins	↑ Volume of distribution ↑ Free (active) drug fraction
Metabolism	↑ or ↓ Hepatic enzyme activity (see Table 43.3)	↑ or ↓ Hepatic clearance
Excretion	↑ Renal blood flow ↑ Glomerular filtration rate ↑ Active renal transport	↑ Renal clearance

TABLE 43.2 Changes in Maternal Body Composition That Can Influence the Characteristics of Maternal Drug Distribution

Time of Gestation (wk)	Body Weight (kg)	Body Fat (%)	Plasma Volume (L)	Extracellular Fluid Volume (L)
0	50.0	16.5	2.50	11
10	50.6	16.8	2.75	12
20	54.0	18.6	3.00	13
30	58.5	20.0	3.60	14
40	62.5	19.8	3.75	15

Data from Mattison DR, et al. Physiologic adaptations to pregnancy: impact on pharmacokinetics. In: Yaffe SJ, et al, eds. *Pediatric pharmacology: therapeutic principles in practice*. Philadelphia: Saunders; 1992:81.

Changes in hepatic metabolism during pregnancy affect the normal rate and extent of drug transformation and ultimately renal elimination. During pregnancy, hepatic blood flow may increase, leading to increased drug metabolism in the liver; however, this is controversial. Less debated is the alteration in the activity of hepatic enzymes during pregnancy. Enzymes from the cytochrome P450 (CYP) family and those responsible for glucuronidation reactions (UGT) exhibit changes in activity as a result of pregnancy, which can potentially affect maternal and fetal drug exposure (Table 43.3). For example, labetalol is a commonly used antihypertensive agent in pregnant women, and it is extensively metabolized by UGT enzymes that have increased activity during pregnancy. Therefore, as expected, the clearance of labetalol after oral administration is increased during the second and third trimester by as much as 30%, and the half-life is significantly shorter in the pregnant compared with nonpregnant patient.[2] The consequence for the mother is an increase in total daily dose to maintain the same steady-state concentration and well-controlled blood pressure, which is critical for both mother and fetus.

Alterations in renal elimination during pregnancy also impact mother and fetus. These changes result from the increase in renal blood flow by 10%-40% and the increase in glomerular filtration rate by about 40%.[19] As a result, there is enhanced elimination of drugs typically excreted unchanged in the urine (e.g., penicillin, digoxin). Active renal transporters (OCT2, P-gp, OAT1) also exhibit increased activity during pregnancy, further enhancing elimination of some medications (metformin, digoxin).[26] The net result is a lower steady-state concentration that may or may not be clinically significant for the mother but will likely result in less drug exposure to the fetus.

Placental Handling of Drug

In addition to maternal pharmacokinetics, the placenta also plays a major role in determining fetal drug exposure. From the fourth week of gestation until term, the surface area of the placenta increases dramatically to accommodate the increasing needs of the maturing fetus. The surface area of the villi, which represents the real area for exchange, is about 3.4 m^2 at 28 weeks' gestation, compared with about 12.6 m^2 at term. In contrast, the thickness of the placental membrane decreases with advancing gestation. During late gestation (about 32 weeks), the tissue barrier separating the maternal and fetal circulations may be less than 2 mm, and the areas become specialized in the transport functions

• BOX 43.1 Mechanisms of Drug Transfer across the Human Placenta

Simple Diffusion

- Facilitated transport
- Active transport
- Pinocytosis (phagocytosis)

of the placenta (i.e., rapid diffusion of substances) rather than the metabolic ones. By term, the placenta has only a single cell layer of fetal chorionic tissue separating the fetal capillary endothelium from the maternal blood. This separation, with its loose intercellular connections, presents little hindrance to small molecule transfer. Both the decreasing membrane thickness and increasing surface area with advancing gestation favor the greater transfer of drugs as gestation progresses.

Very little specific information defines the mechanisms of the processes and extent of drug transfer across the placenta. A number of interdependent variables influence the rate and extent of drug transfer across the placenta from the maternal to the fetal compartment. Most investigators and clinicians believe that the vast majority of compounds found in the maternal circulation will cross the placenta and enter the fetal compartment. Therefore, the fundamental questions are about the rate and extent of this activity. Unfortunately, even today this information is only partially available for just a few chemical entities. Similarly, the mechanisms by which drugs are transferred across the placenta are not always clear, and more than one type of transfer may be involved.

The possible modes of drug transfer across the placenta are listed in order of importance in Box 43.1. For most drugs and other compounds, it is presumed that the primary mode of transfer is by simple, passive, nonionic diffusion, which requires no energy. Pinocytosis and phagocytosis require energy and likely occur much too slowly to have any significant impact on drug transfer, whereas facilitated and active transport play a role for some drugs.

Corticosteroids are an example of a drug class that undergoes facilitated diffusion. No energy is required to transfer steroids across the placenta, but the steroid must form a complex with a specific carrier on the placenta to be transferred from maternal to fetal circulation. Active transport occurs in a similar way, but energy is required for active transport to take place. Metformin is thought to undergo active transport via the placental OCT3 transporter, resulting in fetal concentrations that are 70% to greater than 100% of maternal concentrations.[26] Another important aspect of active transport involves the efflux of drugs back to maternal circulation subsequent to binding with a carrier on the placenta. Digoxin is one such drug that binds to the carrier protein P-gp.[26] P-gp is expressed on the maternal side of the placental-trophoblastic layer, where it mediates active efflux from the fetal compartment. This efflux is unidirectional from the fetal to maternal circulation and is probably responsible for the removal of a number of highly lipid-soluble compounds and drugs from the fetal compartment.[29] As stated, most drugs are transported across the placenta by simple diffusion, and the factors that influence this process have been more extensively evaluated than those affecting the other transport mechanisms discussed. Simple diffusion is described by the Fick equation as follows:

$$\text{Rate of diffusion} = K\,A\,(C_m - C_f)/d$$

where *K* is the diffusion constant of the drug, which is dependent on the drug's physicochemical characteristics; *A* is the surface area of the membrane to be traversed; *Cm* and *Cf* are the concentrations of the drug in maternal and fetal blood, respectively; and *d* is the thickness of the membrane to be traversed. Thus, $C_m - C_f$ represents the concentration gradient across the placenta, which is primarily regulated by the surface area (A) and thickness (d) of the placenta. As previously mentioned, changes in these characteristics as pregnancy progresses allow for easier transfer of drugs from maternal to fetal circulation.

The important physicochemical characteristics that influence passive drug transfer across membranes (i.e., placenta), as represented by K in the Fick equation, are

• BOX 43.2 Physicochemical Factors That Influence the Transfer of Compounds across the Human Placenta

Degree of Lipid Solubility

- Lipid soluble favored over water soluble.

Molecular Weight (MW)

- MW <100 daltons readily crosses the placenta.
- MW 100-500 daltons slower diffusion.
- MW 600-1000 daltons variable placental transfer.
- MW >1000 daltons impermeable.

pH

- Un-ionized form under physiologic or pathologic conditions favors transfer.

Protein Binding

- Low protein binding favors transfer across the placenta.

outlined in Box 43.2. The characteristics that facilitate placental transfer include high lipid solubility, the un-ionized form under physiologic and pathophysiologic conditions, low molecular weight (<500 daltons), and low protein binding. Very few clinically important drugs meet all these "ideal" characteristics, which explains the high degree of variability reported in various studies of placental transfer.

Other factors important to drug transfer across the placenta include differences between the maternal and fetal osmotic pressures and pH, as well as changes in uterine or placental blood flow. Under normal circumstances, the maternal osmotic pressure is higher than that in the fetal compartment, and a pH difference of 0.1-0.15 unit exists between the fetal and maternal blood (i.e., fetal umbilical blood is −0.1 unit of pH lower than maternal blood). If alterations in either the osmotic pressures or pH occur, drug transfer will be affected. With regard to changes in blood flow, the placental flow increases from 50 mL per minute at 10 weeks to 600 mL per minute at term, whereas uterine blood flow approaches 150 mL/kg per minute of newborn body weight at term.[25] Depending on the physicochemical characteristics of the drug, blood flow may have an important influence on the rate and amount of drug transfer.

The degree to which the placenta metabolizes a drug, if at all, also influences the amount that is estimated to cross the placenta and the amount of active drug that reaches the fetus. Many cytochrome P450 (CYP) mixed-function oxidase enzymes have been isolated from the human placenta.[29] The placenta also possesses some capacity to catalyze phase II conjugation reactions, which enhance water solubility of the affected drugs and ultimately drug transfer.

The number of different substrates biotransformed by enzymes located in the placenta is large, but the actual content of CYP enzymes in placental tissue is low, and the activity appears to be much lower than that determined in the fetal or adult liver. Thus the actual contribution of placental enzyme activity to the biotransformation of administered drugs is believed to be inconsequential and of limited clinical significance for most drugs administered maternally. Nevertheless, the differential placental metabolism of certain corticosteroids (e.g., prednisolone, in contrast to betamethasone)[5] and the resulting poor clinical outcomes with prednisolone compared with betamethasone in enhancing fetal lung maturation suggest a significant effect of placental metabolism in certain clinical scenarios.

Fetal Pharmacokinetics

Contrary to the popular belief that the fetus resides in a privileged and protected environment, it is clear that it is exposed to virtually every chemical entity to which the mother is exposed. Thus, the absorption of most drugs into the fetal circulation is both rapid and complete. Most of this absorption is believed to occur through passive nonionic diffusion down the concentration gradients between maternal and fetal blood (which oppose each other in the placental villi), where they are separated by only a single layer of cells. However, as described earlier, a number of energy-dependent placental transporters have been characterized and are responsible for drug influx and efflux.[29] In addition, the fetus may undergo continued drug exposure after its elimination because of the recirculation of amniotic fluid through the fetal gastrointestinal tract.

Once a drug is within the fetal circulation, we have little knowledge of its fate or potential activity. It will likely be distributed to the fetal organs in a manner similar to that observed after birth. However, it is not known whether there are any unusual fetal barriers to drug distribution analogous to those of the blood–brain barrier or the anterior chamber of the eye. In fact, it is not even known whether these barriers actually exist during fetal life. Additionally, a drug may have an increased affinity for a specific fetal tissue that is not the typical target tissue. For example, tetracycline has a high affinity for fetal teeth and warfarin for fetal bones.[4] Protein binding will also affect drug distribution. The fetus has lower levels of serum proteins, and the proteins that are present have a lower affinity for binding drugs. The serum protein levels increase with gestational age, but free drug levels remain high secondary to the binding affinity of fetal proteins.

Once a drug has reached various organs, it is often not known whether it has any effect at all. It is clear that both receptor number and receptor affinity change during development. Likewise, receptor–effector coupling undergoes a programmed maturation. Thus, even though a drug may interact with specific receptors, there may be no discernible pharmacologic effect, because the effector mechanisms have not yet developed.

There is no question that the mean residence time for drugs in the fetus is longer than that observed in older children and adults because of the immaturity of drug clearance mechanisms. For drugs undergoing significant hepatic metabolism, there are many unknown factors. Although

TABLE 43.4 Expression of Cytochrome P450 Forms in the Fetal Liver and the Adrenal Gland

Organ/Gland*	CYP Form
Liver†	1A, 2D6, 3A, 3A5, 3A7†
Adrenal†	1A1, 2A5, 3A,† 3A7, B1, 17
Questionable expression	2C, E1

*Primary form/isoform expressed at specific site.
†Primary site for CYP expression in the human fetus (fetal adrenal > liver containing CYP protein).

most hepatic metabolic pathways are less active in the fetus than in the adult, this is not universally true. Moreover, in the fetus, the adrenal gland has a significant complement of drug-metabolizing enzymes that, although active during fetal and neonatal life, disappear by 6 months of postnatal age. Thus the true ability of the fetus to metabolize drugs is largely unknown, but it at least partially depends on the particular drug under consideration, the gestational age of the fetus, and its drug metabolism phenotype.

As noted, multiple enzyme systems are involved in xenobiotic metabolism within the body. Of the phase I or oxidative enzymes, cytochrome P450 predominates. The human fetal liver contains many different CYP forms (Table 43.4), although they are present in fewer numbers and with less density than in the adult liver. The liver of the human fetus does exhibit some CYP450 activity, but the overall functional capacity of fetal CYP activity is very low, and its metabolic capacity is qualitatively and quantitatively very different from the activity observed in the adult liver. For example, nevirapine is metabolized by the adult liver via CYP 3A4, 2B6, and 2D6, but in the fetus only negligible metabolism of the drug occurs and it does not impact overall fetal drug exposure.[6]

The enzyme activity observed in the fetus is primarily caused by CYP3A7 expression, which is minimally expressed in the adult liver. CYP3A7 may serve as a detoxifying enzyme and protect the fetus from steroids and retinoic acid derivatives. Other enzymes expressed also serve protective roles for the fetus, such as CYP2E1, which is involved in fetal alcohol metabolism.[4] Although our understanding of the expression of CYP forms by the fetus is growing exponentially, unfortunately the extent of our understanding of their function remains limited. Nevertheless, the available data clearly indicate that the overall functional capacity of the fetus to effectively metabolize xenobiotics is limited.

Even more limited is the ability of the fetus to clear drugs that are entirely eliminated by renal excretion. The ontogeny of glomerular filtration and tubular secretion has been well studied, and renal elimination is not a significant mechanism of drug excretion for the fetus. Furthermore, any drug that is renally excreted by the fetus is eliminated into the amniotic fluid, which the fetus may swallow, leading to redistribution of the drug and the need for elimination again.

Exposure of the Fetus to Drugs

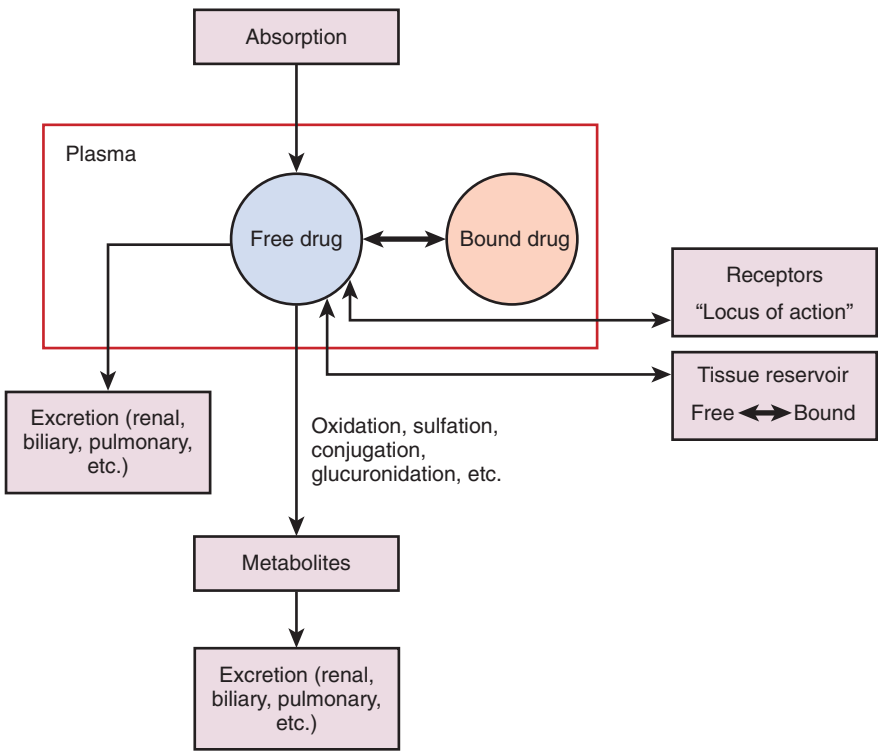
As discussed, most of the pharmacologic agents present in the maternal circulation cross the placenta and enter the fetal circulation and are, therefore, potentially harmful to the fetus. The adverse effects of in utero exposure to drugs can vary from reversible effects such as altered thyroid or renal function to irreversible effects such as fetal death, intrauterine growth restriction, structural malformations, and mental retardation.[16,18] Unfortunately, the details of drug interaction with the maternal-placental-fetal unit for most drugs are extremely complex and not well studied. In a review of 172 medications approved by the Food and Drug Administration (FDA) from 2000–2010, the teratogenic risk was undetermined for 97.7% of the medications.[1] This lack of knowledge not only places the fetus at risk but may also cause prescribers to inadequately treat pregnant women for fear of a drug's teratogenic potential.[10]

A number of drugs are possible teratogens in humans; however, at present only a few (<30) have been positively identified as such.[4] Preclinical testing during drug development is typically performed using a rodent model; however, not all human teratogens are teratogens in different animal species, and further postmarketing phase IV epidemiologic evaluations for teratogenic effects are vitally important. It has been estimated that to establish that a given drug changes the naturally occurring frequency of a congenital deformity by 1%, a sequential trial involving about 35,000 patients would be required. In the case of abnormalities that occur quite often in the population, physicians may not be alerted to the direct causal relationship between exposure of the fetus to the drug and the resulting adverse effect. Therefore, for most medications, it remains virtually impossible to prove teratogenicity, and prescribers must often rely on international pregnancy drug registries, the experience and reports of others, or animal studies to guide drug therapy during pregnancy.

The teratogenic effects of thalidomide, discovered in the 1960s, illustrate the totally unpredictable nature of drug toxicity in the fetus during the first trimester. Thalidomide doses that induced analgesia with no demonstrable undesirable side effects in the mother produced major structural defects in the fetus.[11] The discovery that thalidomide caused congenital malformations was made possible because this drug was widely used, induced dramatic and rare congenital defects, and had a high probability (estimated at 20%-35%) of producing a teratogenic effect after exposure from the third to the eighth week after conception. Unfortunately, these three criteria are rarely met when one is attempting to assess the teratogenicity of other drugs.

In the absence of any clear data for a particular drug's teratogenic potential, other factors can be taken into consideration to help predict the risk of drug exposure to the fetus. The timing of drug exposure is frequently a critical determinant of the effect of a drug on the fetus. During the first week of gestation, the most common adverse effect of drugs is the termination of pregnancy, which may occur

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.



before the woman even knows that she is pregnant. Exposure of the preimplantation embryo to embryotoxic drugs may retard development, perhaps by decreasing cell numbers in the blastocyst, or it may even produce malformations. In the second to the eighth week of gestation, drugs may produce dramatic and catastrophic structural malformations, such as the neural tube defects associated with valproic acid and carbamazepine. Other adverse effects during this period of organogenesis may include fetal waste, transplacental carcinogenesis (diethylstilbestrol), and intrauterine growth restriction. From the third to the ninth month of gestation, the effects of drugs on a fetus are widely varied and relatively specific to the drug administered. For example, angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) may cause oligohydramnios, tetracycline is associated with staining of the teeth and bones, and paroxetine may slightly increase the risk for cardiac malformations.[16]

In addition to the drug itself and timing of administration, the drug dose, maternal disease state, and number of medications administered are also important factors impacting teratogenicity. Epilepsy is one disease state in which these factors must be considered. Many antiepileptic drugs (AEDs) are associated with an increased risk of congenital malformations as well as adverse cognitive outcomes of the child. However, uncontrolled epilepsy also can be harmful to the fetus. Prolonged seizures have been associated with fetal loss, and frequent tonic-clonic seizures are associated with poorer cognitive development of the child.[28] It has been suggested that the teratogenic effects of AEDs are more common in women on multiple anticonvulsant medications and those on higher doses.[28] For these reasons, it is ideal to optimize an epileptic woman's drug regimen before conception with the fewest drugs possible at the lowest effective doses. Frequent monitoring throughout pregnancy is also required, as the state of pregnancy can significantly impact the pharmacokinetics of AEDs, possibly impacting both seizure control and fetal well-being.

The decision of whether to give a drug during pregnancy is difficult. If a mother is not healthy, the baby may not be healthy. If drug therapy can improve the mother's health, it seems it should also benefit the fetus. However, limited or incomplete knowledge of fetal outcomes for most drugs complicates the picture. Available information on the potential adverse effects for some of the commonly prescribed known or suspected teratogens is listed in Table 43.5.[15,16]

Neonatal Drug Disposition

At birth, a term infant in North America typically receives three medications: an ophthalmic antimicrobial agent, vitamin K, and the hepatitis B vaccine. Sick and premature infants receive an increasing number of drugs, with the constant introduction of new drugs or old drugs with new indications into the neonatal therapeutic armamentarium. The appropriate and safe use of these drugs requires a thorough understanding of the various pharmacologic profiles. Fig. 43.1 illustrates many of the interrelationships of the absorption, distribution, binding, biotransformation, and excretion of a drug and its concentration at the locus of action.[9] To produce its characteristic effect, a drug must be

• **Fig. 43.1** Interrelationships of absorption, distribution, biotransformation, and excretion of a drug and its concentration at the receptor site.

TABLE 43.5 Selected Therapeutic Agents With Known or Suspected Teratogenic Potential

Drug	Potential Defect(s) and Adverse Effects	Additional Information
Angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs)	Skull ossification defects, oligohydramnios, fetal lung hypoplasia, renal failure	Critical time period is ≥14 weeks' gestation
Carbamazepine	Neural tube defects, craniofacial defects, developmental delay	Critical time period is first trimester
Fluconazole	Abnormal facies, limb defects, cleft palate, congenital heart defects	Greatest impact at doses >400 mg/day for multiple weeks
Isotretinoin	Hydrocephalus, central nervous system defects, small/absent ears, hearing or eyesight problems, small or missing thymus, micrognathia, spontaneous abortion, stillbirth, developmental delay, congenital heart defects	Risk of defects is high with any dose or duration
Lithium	Ebstein anomaly, altered thyroid function, cardiac arrhythmias, hypoglycemia, polyhydramnios	Critical time period is ≤8 weeks' gestation for Ebstein anomaly; other adverse events are rare and associated with use later in pregnancy and higher doses
Methimazole	Esophageal atresia, choanal atresia, hypothyroidism, goiter, aplasia cutis	
Methotrexate	Craniofacial/skull abnormalities, limb defects, developmental delay	Critical time period is 8-10 weeks' gestation; greatest impact at doses >10 mg/week
Misoprostol	Skull defects, cranial nerve palsies, facial malformations, limb defects, spontaneous abortion	
Mycophenolate mofetil	Ear abnormalities; cleft lip and palate; anomalies of the distal limbs, heart, esophagus, and kidney; spontaneous abortion	Critical time period is first trimester
Paroxetine	Cardiac malformations, respiratory distress, persistent pulmonary hypertension of the newborn	Other selective serotonin reuptake inhibitors associated with respiratory distress and pulmonary hypertension, but less risk of cardiac defects
Phenytoin	Fetal hydantoin syndrome with mild to moderate growth and mental deficiencies, limb anomalies, and dysmorphic facies (low nasal bridge, short nose, eyelid ptosis), vitamin K deficiency with resultant hemorrhage	Critical time period is 3-12 weeks' gestation for hydantoin syndrome; critical time period for hemorrhagic disease is ≥13 weeks' gestation
Propylthiouracil	Face/neck defects, goiter, hypothyroidism, hydronephrosis	
Streptomycin	Hearing loss	
Tetracyclines (doxycycline, minocycline, tetracycline)	Discoloration of fetal teeth, inhibition of bone elongation/growth	Critical time period is ≥12 weeks' gestation
Thalidomide	Limb reduction defects, limb hypoplasia, ear and eye abnormalities, cardiac defects, developmental delay	Critical time period is 3-8 weeks' gestation
Valproic acid	Neural tube defects, cardiac defects, developmental delay, autism	
Warfarin	Nasal hypoplasia, stippled epiphyses, developmental delay, spontaneous abortion, fetal hemorrhage, fetal death	Critical time period is first trimester for nasal hypoplasia and stippled epiphyses; other adverse effects may occur from exposure at any time during pregnancy

present in sufficient concentrations at its sites of action or receptor sites. The concentration of the drug at the receptor site depends not only on the amount of drug administered but also on the interrelationships listed in the preceding and shown in Fig. 43.1. Those factors that have been evaluated in the newborn infant differ substantially from those in the adult and even in the young infant beyond the neonatal period.[9]

Absorption of Drugs in the Neonate

Drug absorption is the passage of a drug from its site of administration into the circulation. In neonates who can tolerate gastric feedings, the oral route of drug administration is the most common because of its convenience and safety. The absorption of a drug or substance through the gastrointestinal system may be defined as the net movement of a drug from the gastrointestinal lumen into the systemic circulation draining this organ. This process entails the movement of drugs across the gastrointestinal epithelium, which behaves like a semipermeable lipid membrane and constitutes the main barrier to absorption. The various processes operating to induce the transepithelial membrane movement of drug molecules include simple diffusion through lipid membranes or aqueous pores of the membrane; filtration through aqueous channels or membrane pores; carrier-mediated transport, such as active transport or facilitated diffusion; and vesicular transport, such as pinocytosis. Of these, the most important is the process of simple diffusion, because most drugs administered orally are absorbed through this process.

The rate and extent of gastrointestinal drug absorption are partly determined by the physical and chemical characteristics of the drug. Polarity, nonlipid solubility, and a large molecular size tend to decrease absorption. In contrast, nonpolarity, lipid solubility, and a small molecular size increase absorption. The degree of ionization, determined by the pK_a of the drug and the pH of the solution in which it exists, is an important determinant in drug absorption. The gastrointestinal epithelium is more permeable to the nonionized form, because this portion is usually lipid soluble and favors absorption. The degree of drug ionization changes as the pH increases from the stomach through the distal portion of the gut.

Ionization also changes with the substantial changes in gastric pH observed during the neonatal period. Gastric acid production is generally low at birth, and the gastric pH is usually 6-8. In the first few hours of life, a burst of acid secretion occurs, decreasing the pH to values of 1-3. Acid secretion then returns to a low level, and the gastric pH remains near neutral for the first 10 days of life.[27] The gastric pH then tends to fall and approaches adult values by 2 years of age. These initial fluctuations in gastric acid secretion do not appear to occur in premature neonates, because their gastric pH remains near 6-8 for the first 14 days of life.[3] Clinically, the result of any decrease in pH is the increased absorption of weak acids (e.g., furosemide, phenobarbital), because they are more likely to be in the un-ionized, lipid-soluble state. Conversely, an increase in pH enhances the absorption of weak bases (e.g., morphine, erythromycin) and limits the absorption of weak acids.

The slow gastric emptying time and intestinal motility in the newborn may also affect drug absorption. The primary site for drug absorption is the proximal bowel, which has the greatest absorptive surface area. With slower motility and emptying, it takes longer for a drug to reach this site of absorption, and the rate at which absorption can occur may be limited. Conversely, a slow transit time or slow intestinal motility may facilitate the absorption of some drugs, such as iron, which is primarily absorbed in the duodenum.

The colonization of the gastrointestinal tract by bacteria is another process that influences intestinal drug absorption. Intestinal flora are involved in the metabolism of bile salts and selected drugs, as well as intestinal motility. The gut flora vary with age, type of drug delivery, and type of feeding. Concurrent drug therapy also plays a role, particularly because antibiotics, which decrease intestinal flora, are some of the most commonly administered medications to neonates. Although the actual characterization of the colonization of intestinal flora relative to age is limited, data suggest that all full-term, formula-fed, vaginally delivered infants are colonized with anaerobic bacteria by 4-6 days of postnatal life. By 5-12 months of age, an adult pattern of microbial reduction products appears to be established.

Additional factors such as pancreatic and biliary function and the activity of intestinal drug-metabolizing enzymes and efflux transports can also alter absorption. As expected, this function and activity is not fully developed in the neonate, further contributing to the differences in absorption observed between neonates and older children or adults.[27]

Overall, the differences in the neonatal gastrointestinal tract likely impact the rate of drug absorption but not the extent. The gastrointestinal absorption of drugs is relatively slow in the neonate, which can prolong the time to reach the steady-state concentration but not the actual concentration achieved. Thus the clinical significance of altered absorption in the neonate is likely minor for the majority of medications.

Drug Distribution in the Neonate

Distribution of a drug into the extravascular tissues is largely influenced by body composition, which is much different in a neonate compared with an older infant or adult. Total body water is about 70%-75% of body weight in a term infant and is an even greater percentage of body weight in preterm neonates. In comparison, an adult has a total body water percentage of 55%-60%.[14] The extracellular water compartment of a neonate is also larger, whereas the fat content is lower. At 28 weeks' gestation, body fat is only 1%-3% of body weight, and at term, it is 15%-28%.[4] In addition, the fat that is found in neonates is about 50%

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

water, compared with 25% water in an adult. The end result of these differences is a larger Vd for hydrophilic drugs, whereas lipophilic drugs may not distribute as extensively as expected. In the case of water-soluble medications, a lower peak serum concentration, higher milligram-per-kilogram doses, and delayed excretion are often observed. For example, the Vd for micafungin in neonates has been reported as 0.44–0.62 L/kg, compared to 0.26 L/kg in adults. To achieve therapeutic plasma concentrations of micafungin in neonates, a dose of 15 mg/kg is required, compared to 5 mg/kg in adults.[24]

Protein binding also plays an important role in neonatal drug distribution. The unbound or free concentration of a drug in plasma is considered to be the pharmacologically active fraction of the drug. For some drugs, the binding to plasma proteins is decreased in the newborn compared with that in the adult (Table 43.6).[27] Reasons for this deficiency include decreased albumin concentrations in the neonate as well as qualitative differences in neonatal albumin. Albumin is the primary drug-binding protein in both neonates and adults, but the albumin found in neonates has less affinity for drugs compared with adult albumin. Competitive binding to albumin by many endogenous substrates such as hormones may also decrease protein binding. Hyperbilirubinemia may accentuate this competition, because bilirubin is able to displace some drugs, such as phenytoin, from the albumin-binding site. This activity contrasts with the well-known drug–protein binding interaction with bilirubin, in which drugs such as sulfonamides or their excipients may displace bilirubin from its binding site. Regardless of cause, the decrease in protein binding observed in neonates leads to an increase in free or active drug. This outcome suggests that a more intense pharmacologic response may be obtained in the newborn infant than the adult for the same total drug concentration. Clinically, decreased protein binding in the neonate does not typically affect initial dosing, but it is important to consider this factor in the application of adult therapeutic plasma concentrations to the neonatal patient.

TABLE 43.6 Comparative Protein Binding of Medications Used in Neonates

Drug	Percent Protein Bound	
	Neonate	Adult
Ampicillin	10%	18%
Digoxin	20%	32%
Morphine	20%	42%
Nafcillin	69%	89%
Phenobarbital	32%	47%

Drug Metabolism in the Neonate

Many drugs are lipophilic and require conversion to more water-soluble metabolites for efficient elimination from the body. These metabolic processes most often occur via drug uptake into the liver and are traditionally categorized as either phase I or II reactions. In a phase I reaction, a more polar compound is formed through oxidation, reduction, or hydrolysis of the parent molecule. Phase II metabolism involves conjugation with endogenous substrates such as sulfate, acetate, and glucuronic acid. Drugs may be conjugated directly or made more amenable to conjugation after the introduction of a functional group by phase I metabolism (e.g., hydroxylation). Typically, the metabolites formed by either type of reaction are inactive; however, some drugs can be transformed into active metabolites (e.g., theophylline to caffeine). It is well recognized that the neonate may have limited uptake of drug into the liver and is deficient in many of the enzymes responsible for phases I and II drug metabolism.[9,27]

Phase I metabolism is mediated primarily by the cytochrome P450 enzymes. These enzymes are present in several tissues throughout the body, including the intestine, lung, kidney, and adrenal glands, but are the most highly concentrated in the liver. Numerous isoforms have been identified; the primary enzymes involved in drug metabolism are listed in Table 43.7. Considerable individuality is evident with respect to substrate specificity, polymorphic expression, and susceptibility to induction and inhibition.

The general pattern of development of cytochrome P450 enzymes is illustrated in Fig. 43.2. In the fetal liver, studies have shown that CYP3A7 is by far the most significant cytochrome P450 enzyme in terms of protein expression and activity. CYP3A7 concentrations decline during the neonatal period as CYP3A4 concentrations increase.[27] CYP3A4 is the most abundant cytochrome P450 enzyme in adults, accounting for 30%-40% of hepatic cytochrome P450 and as much as 70% of the content of cytochrome P450 in the intestine. Most other cytochrome P450 enzymes develop rapidly in the neonatal period. Whether they are triggered

TABLE 43.7 Characteristics of the Primary Cytochrome P450 Enzymes Involved in Human Drug Metabolism

Enzyme	Total Cytochrome P450 in Adult Liver (%)	Selected Substrates	Inhibitors	Inducers
CYP1A2	15-20	Caffeine, theophylline, R-warfarin	Ciprofloxacin, cimetidine, erythromycin, amiodarone,	Omeprazole, tobacco smoke
CYP2C8/9	20-30 (includes CYP2C19)	Ibuprofen, phenytoin, S-warfarin	Fluconazole, amiodarone, trimethoprim	Rifampin
CYP2C19		Omeprazole, diazepam, phenobarbital, indomethacin, lansoprazole		Carbamazepine, prednisone, rifampin
CYP2D6	1-5	Dextromethorphan, codeine, propranolol	Amiodarone, cimetidine	Dexamethasone, rifampin
CYP3A4/5	30-40	Carbamazepine, erythromycin, ritonavir, midazolam	Erythromycin, cimetidine, grapefruit juice, fluconazole, amiodarone, ritonavir	Barbiturates, carbamazepine, glucocorticoids, phenytoin, rifampin, rifabutin

by the loss of a maternal repressing factor or stimulated by transcription factors intrinsic to newborns, concentrations of CYP2D6 and CYP2E1 increase within hours of birth, followed closely by the CYP2C and CYP3A4 enzymes.[9] By 1 month of age, hepatic concentrations are about 25%-30% of those in adults. The notable exception is CYP1A2, which develops more slowly, reaching less than 5% of adult concentrations in the first month.[9] It is generally assumed that premature babies exhibit greater impairment in drug metabolism than full-term infants; this response has been documented in several studies involving drugs metabolized by a wide range of cytochrome P450 enzymes.[12,22] It may result from the greater degree of immaturity of these enzymes at birth, a delay of the postnatal surge in cytochrome P450 concentration observed in full-term babies, or a combination of these two factors.

The pharmacokinetics of many drugs in neonates is consistent with the pattern of development of the cytochrome P450 enzymes shown in Fig. 43.2. Caffeine, which is administered for the treatment of neonatal apnea, exhibits an extremely prolonged half-life of several days in neonates compared with 4-6 hours in adults.[12] This result is caused by the delayed development of the CYP1A2 enzyme, which is responsible for the demethylation of caffeine, the primary metabolic pathway. The structurally related bronchodilator theophylline also exhibits reduced clearance and a prolonged half-life in neonates. However, the effect is not as dramatic as that observed with caffeine, because theophylline is partially oxidized by other cytochrome P450 enzymes, such as CYP2E1 in addition to CYP1A2. For drugs metabolized primarily by CYP2D6 or CYP2C, it seems reasonable to expect drug clearance to be low at birth but to increase rapidly during the first month of life. Data on tolbutamide and phenytoin, which are substrates for CYP2C9, support this view. The half-life of tolbutamide was found to decrease from 46 hours to 6 hours within the first 2 days after birth in a neonate exposed to the drug by placental transfer from the mother.

The clearance of drugs metabolized by CYP3A4 may be reduced less in neonates than substrates for other cytochrome P450 enzymes if CYP3A7 is capable of contributing to the metabolic process. CYP3A4 and CYP3A7 show more than 85% amino acid sequence homology and have partially overlapping affinities for both endogenous and exogenous substrates.[20] The catalytic activity of CYP3A4 toward drugs such as midazolam, carbamazepine, and nifedipine is greater than that of CYP3A7, whereas the latter appears relatively active in metabolizing erythromycin.[20] However, even if catalytic activity is low, CYP3A7 may contribute to the overall clearance of a drug at birth, owing to the high concentrations present. This activity may account for the observation that the elimination of CYP3A substrates such as carbamazepine[23] and the reverse transcriptase inhibitor nevirapine[17] during the first week of life is relatively similar to that observed in adults.

The metabolism of phase II drugs is mediated by a number of different enzymes, the most important of which are *N*-acetyltransferase (acetylation), sulfotransferase (sulfation), and uridine 5′-diphosphate glucuronosyltransferase (UGT) (glucuronidation). Acetylation and glucuronidation are not completely developed at birth, whereas sulfation appears to be reasonably well developed relative to other pathways of drug metabolism. Glucuronidation is an important route of metabolism for many drugs (acetaminophen, morphine, zidovudine) as well as endogenous compounds such as bilirubin.[27] Although UGT activity is generally presumed to be immature at birth, establishing a clear pattern for its development is complicated by the existence of numerous isoforms of the enzyme with broad and overlapping substrate specificity. UGT1A1, which is

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

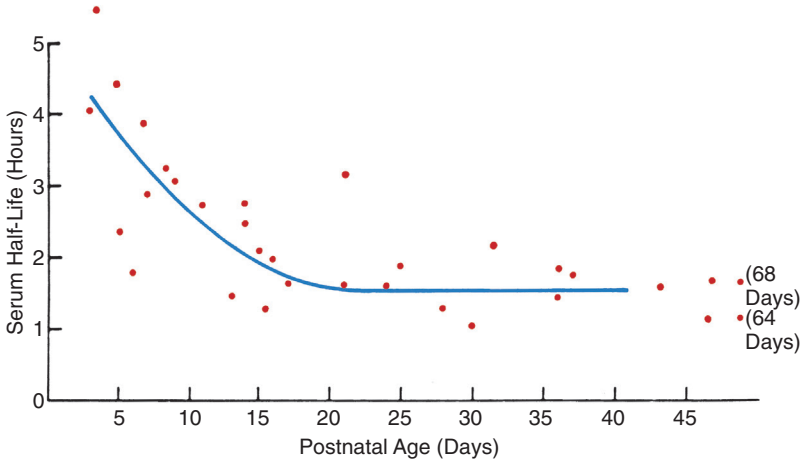
involved in the glucuronidation of bilirubin, is virtually absent in the fetus, and develops slowly over several months after birth. A somewhat similar pattern of development exists for UGT1A6, which is responsible for the glucuronidation of acetaminophen. UGT2B7 catalyzes the formation of morphine-3-glucuronide and morphine-6-glucuronide. Its activity is decreased in newborns and increases to adult levels by 2-6 months of age, thus morphine clearance in neonates remains well below that of older children.[27] For some medications such as acetaminophen, increased sulfation partially compensates for the reduced glucuronidation in neonates. The proportion of a dose of acetaminophen excreted as a sulfate conjugate is higher in neonates than older children or adults. Similar to observations with drugs metabolized by cytochrome P450, glucuronidation in premature infants is impaired to a greater extent than it is in full-term infants.[21]

Conclusions based on studies of drug metabolism in the term and preterm neonate must be interpreted with caution because of the small numbers of subjects in many investigations and the potentially confounding effects of genetics and disease states on metabolism. Nevertheless, the available data suggest the following tentative conclusions:

1. The rate of drug metabolism is generally low at birth in full-term babies and even lower in premature infants regardless of the specific route of metabolism. Decreased clearance and a prolonged drug half-life require drug administration with longer dosing intervals.
2. Many of the enzymes responsible for metabolism exhibit significant development during the first month of life. Dosing regimens appropriate during the first few days of postnatal life may not be appropriate 3-4 weeks after birth, because dose requirements may increase and dosing intervals decrease.
3. The development of individual drug-metabolizing enzymes varies widely among neonates and may be delayed in premature infants. Predicting clearance is difficult, and dosing regimens must be individualized for patients based on the careful observation of the patient's response and tolerance; monitoring of plasma drug concentrations may be useful for selected drugs.

Renal Excretion of Drugs



The kidneys are the most important organs for drug elimination for most agents. In the newborn, the most frequently used drugs, such as antimicrobial agents and caffeine in the premature neonate, are excreted by way of the kidney. Renal elimination of these drugs reflects and depends on neonatal renal function, which is characterized by a low glomerular filtration rate (GFR), low effective renal blood flow, and low tubular function (secretion and reabsorption) compared with that in the adult. The neonatal glomerular filtration rate is about 50% of the adult value and is greatly influenced by gestational age at birth. A term neonate has a glomerular filtration rate of 2-4 mL per minute per 1.73 m^2, whereas the glomerular filtration rate at less than 34 weeks of gestation is about 0.7-0.8 mL per minute per 1.73 m^2. The most rapid changes in renal function occur during the first week of life, but adult values are not reached until 6-12 months after birth in term neonates.[14,27] As expected, it takes even longer for the GFR to reach adult values in preterm infants secondary to the smaller number of glomeruli present.[14] Medications administered to the neonate can also cause a decrease in GFR and ultimately reduced elimination of concurrent drugs. For example, indomethacin inhibits prostaglandin synthesis, which leads to an increase in renal vascular resistance and thus a reduction in renal blood flow. The consequence of this is a decreased clearance of other medications such as gentamicin that are dependent on glomerular filtration for elimination.

Effective renal blood flow may influence the rate at which drugs are presented to and eliminated by the kidneys. Available data suggest that there is low effective renal blood flow during the first 2 days of life (34-99 mL per minute per 1.73 m^2), which increases to 54-166 mL per minute per 1.73 m^2 by 14-21 days and further increases to adult values of about 600 mL per minute per 1.73 m^2 by age 1-2 years. These data are probably not applicable to premature infants with very low birth weight, particularly those who weigh less than 750 g at birth. It is assumed, pending definitive data, that the glomerular filtration rate and renal blood flow in these micronates are substantially lower than those in bigger premature infants, such as those who weigh more than 1000 g at birth. Nevertheless, renal function in these patients is highly variable and reflected in the highly variable body clearance of a number of commonly administered drugs.

Tubular secretion and reabsorption are also variable and immature in neonates. Tubular secretion approaches adult values by 7-12 months of age in term neonates, while reabsorption maturation is more gradual and continues through adolescence.[27] In premature neonates, tubular function is even more limited. Drugs that require tubular secretion for elimination (e.g., furosemide, morphine) typically exhibit decreased clearance during the neonatal period.

The pharmacokinetic behavior of drugs eliminated through the neonatal kidneys exhibits characteristics similar to those underlying hepatic biotransformation. For instance, the half-lives of many antimicrobials, such as ampicillin (Fig. 43.3), show marked interindividual variability at birth, which narrows somewhat with advancing age. The plasma half-life also shortens progressively after birth, achieving adult rates of elimination within 1 month. Studies of the pharmacokinetics of ceftazidime and famotidine have shown direct correlations between plasma drug clearance and the maturational changes in renal function.[15] The drug-dependent variability in the elimination process partially reflects the major renal mechanisms of drug excretion. Those drugs that undergo substantial elimination by glomerular filtration (e.g., aminoglycosides) may be excreted more rapidly than those requiring substantial tubular excretion (e.g., penicillins).

As with hepatic metabolism, the renal excretion of certain drugs may be as efficient as that in adults. However, usually drug excretion by way of the neonatal kidneys is deficient relative to that in an adult. Pathophysiologic insults further compromise the inherent deficiency in drug elimination, complicating individual drug dosage regimens. Hypoxemia decreases the already slow glomerular and tubular functions in neonates, leading to the slower renal excretion of drugs, as shown with amikacin. Intrauterine growth restriction leads to a decrease in the number of nephrons and renal mass, leading to a prolonged half-life of drugs such as vancomycin.[7] Moreover, very small infants, who receive the most drugs in the neonatal population, exhibit the worst functional deficiency in drug elimination.

Age-related (gestational and postnatal) changes have been considered in the dosage regimen recommendations for antibiotics and other drugs used in the treatment of infants. Drug doses, particularly for those agents excreted by the kidneys, are dynamically changing as functions of gestational and postnatal ages. In general, the total daily dose of a drug is directly related to the postconceptional age, and the fetal maturity is inversely related to dose interval. Thus, as an infant matures, the total daily dose increases and the dose interval decreases. However, the neonate is often unpredictable, and rigorous monitoring of drug efficacy and patient tolerability are required regardless of gestational and postnatal age.[15]

Key Points

- Most drugs administered to the mother reach the fetus; the extent of fetal exposure depends on maternal drug disposition and placental drug transfer.
- Drug absorption, distribution, metabolism, and elimination all fluctuate throughout pregnancy, impacting maternal serum concentrations of medications and ultimately fetal exposure.
- The primary mode of drug transfer across the placenta is by simple, passive diffusion which occurs most readily for a drug with high lipid solubility, low protein binding, low molecular weight and in its un-ionized form.
- Fewer than 30 drugs are positively identified as human teratogens, while the vast majority of medications approved by the FDA are categorized as undetermined teratogenic risk.
- The pharmacokinetic processes of absorption, distribution, metabolism, and elimination are immature in a neonate and develop at varying rates after birth. The immaturity is more pronounced and the development slower in preterm neonates.
- Neonates often have a larger volume of distribution but delayed excretion compared to older children or adults, resulting in the need for higher mg/kg doses of medications with potentially longer dosing intervals.
- Dosing regimens for neonates over the first 3–4 weeks of life are dynamic and require adjustment based on maturational changes in hepatic metabolism and renal elimination.

Principles of Drug Use During Lactation

JACQUELYN D. MCCLARY

It is not disputed that breastfeeding has many benefits for both mother and baby and is the optimal nutrition for infants. With an increase in education and support of breastfeeding mothers throughout the United States, the rate of breastfeeding is on the rise. The Centers for Disease Control and Prevention report an increase of breastfeeding initiation from 79% in 2011 to 81.1% in 2013, with a steady annual increase since 2008.[5] As the incidence rises, there are more situations in which lactating women are exposed to various medications and more questions regarding the safety of these medications to the infant. Almost all medications enter the breast milk, but the amount in breast milk, and more importantly the amount absorbed by the infant, is rarely well defined. Despite this lack of information, most drugs are considered safe while breastfeeding. In the absence of specific details for a particular drug's passage into breast milk, the clinician can evaluate the physicochemical characteristics of the drug as well as the patient characteristics to determine the appropriateness of breastfeeding while the mother is taking the medication.

Passage of Exogenous Compounds From Maternal Blood to Milk

In general, drugs enter breast milk by passive diffusion. The presence and concentration of compounds in breast milk depend on a number of important factors, including the drug's molecular weight, degree of ionization, protein binding in blood, lipid solubility, and specific uptake by mammary tissue, as well as the amount and composition of the milk. The constituents of breast milk vary relative to the postpartum period and could influence drug distribution and accumulation within breast milk, depending on the drug's physiochemical characteristics. Drug characteristics that minimize the risk of transfer into breast milk are shown in Box 44.1.

Small compounds with molecular weights of less than about 200 daltons appear freely in breast milk and are presumed to have passed through pores in the mammary alveolar cell. Large compounds such as insulin or heparin, or those that are protein bound, do not enter the milk. Intermediate-sized compounds must penetrate the lipoprotein cell membrane by diffusion or active transport. Drugs or other chemicals that are very lipid soluble readily cross the alveolar cell, and because breast milk contains a considerable amount of lipid, these compounds are trapped in the milk. In general, drugs that are not ionized at blood pH traverse the alveolar cell membrane with greater ease than highly ionized compounds. Therefore, weak acids, which are more likely to be ionized at the plasma pH of 7.4, are less likely to enter breast milk, whereas weak bases pass into breast milk more readily. Because breast milk pH is 7 or slightly less, once a weak base crosses into breast milk, it may become more ionized and trapped.

A number of important variables specific for the type of drug, age, and time after delivery or disease influence a drug's ability to penetrate into breast milk. The interrelationships between these and other variables yet to be identified are complex, making it very difficult to predict the actual amount of drug distribution into the milk. Although many investigators and clinicians have attempted to collapse the many important characteristics into one simple surrogate marker of drug penetration into breast milk—the ratio of milk to plasma protein (M/P ratio)—this parameter is overly simplistic and often misrepresents the true nature of drug distribution into breast milk. The M/P ratio is defined as the ratio of the drug concentration in breast milk to the drug concentration in maternal plasma at a simultaneous point in time after maternal drug administration. A low M/P ratio (<1) is supposed to indicate no accumulation of drug in the mother's milk.[3] However, the M/P ratio is based on the assumption that the drug concentrations in maternal blood and milk are constant and in equilibrium at the time of sampling, which is most often not true. Based on its limitations, the M/P ratio should be used with caution, if at all, as a means of quantitating drug distribution in breast milk and infant exposure.

Alternatively, the relative infant dose (RID) can be used as a more accurate tool to estimate infant exposure to a drug if there are data available on the concentration of drug in the breast milk and volume of milk ingested by the infant

Abstract

Almost all medications enter breast milk, but the amount that an infant is exposed to through breastfeeding is rarely well defined. Physicochemical characteristics of the drug can be used to determine the appropriateness of breastfeeding while a mother is taking a medication. With few exceptions, each therapeutic class of medications includes at least one option that can be safely taken while breastfeeding. Commonly prescribed medications such as antibiotics and antidepressants are almost all considered compatible with breastfeeding. For antihypertensive and pain medications, there are some drugs that should be avoided; however, there are multiple alternative options that are considered safe within each category. Regardless of the medication being taken, the lowest effective dose should always be prescribed, monotherapy should be used when possible, and the nursing infant should be monitored for any side effects associated with the medication.

• BOX 44.1 Drug Characteristics That Minimize Transfer into Breast Milk

- Molecular weight >200 daltons
- Weakly acidic
- High degree of protein binding
- Water soluble

(often estimated at 150 mL/kg/day). The RID can then be calculated by dividing the infant dose measured in the breast milk (mg/kg per day) by the maternal dose (mg/kg per day) and expressing it as a percentage. It has been suggested that a RID greater than 10% may be of concern; however, every drug is different and depending on the specific patient and drug characteristics, a RID greater than 10% may be acceptable.[15]

Delivery of Compounds to and Disposition by the Infant

After ingestion of a drug via breast milk, the drug must either act locally in the infant's gut or be absorbed by the infant into systemic circulation to produce an effect. Generally, if a drug is not orally bioavailable (e.g., vancomycin), the infant will not absorb the medication, even if it is present in breast milk. However, it is possible that the bowel of a very young infant may permit the absorption of large molecules that are normally excluded. Another potential barrier to absorption is found in milk proteins that bind certain drugs and impede absorption. Unfortunately, for most drugs, the extent of oral absorption by the breastfed infant is unknown. If absorption does occur, the infant's handling of the medication is often unclear and changes with postnatal age. Ultimately, close monitoring of the infant for adverse effects associated with the maternal drug therapy is required.

Compounds in Breast Milk

Antibiotics

Fortunately, most antimicrobial agents in breast milk appear to be safe for nursing infants. Some antibiotics, particularly those with broad antimicrobial spectra, may change the infant's intestinal flora and cause diarrhea or thrush, but this quickly resolves upon discontinuation of the antibiotic and is not considered a contraindication to breastfeeding. Two antibiotic classes that are sometimes considered contraindicated in breastfeeding include sulfonamides and tetracyclines.

Sulfonamide derivatives are sometimes avoided during lactation, because they have the potential to displace bilirubin from albumin. The amounts present in breast milk, combined with the actual bioavailable dose to the infant, suggest that maternal sulfonamide administration is acceptable during breastfeeding except in neonates at high risk for hyperbilirubinemia, including extremely premature neonates or those with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Tetracyclines in breast milk purportedly have the potential to cause dental staining, and many sources have suggested that women taking tetracyclines avoid breastfeeding. Closer examination of these suggestions against breastfeeding during tetracycline therapy appear to be based on theoretical grounds rather than any supporting evidence. Moreover, the bioavailability of tetracyclines under the conditions of breastfeeding suggests that the maternal administration of tetracycline and its analogues is safe and without complications in infants.[6]

Overall, maternally administered antibiotics are considered safe for the breastfed infant, and only in rare instances should mothers requiring antibiotic therapy be recommended to discontinue breastfeeding their infant.

Anticoagulants

The use of anticoagulants may be critical to health of a mother with a history of pulmonary embolism, venous thrombosis, or other clotting disorder. Both parenteral and oral anticoagulant options are available that are compatible with breastfeeding. Heparin has a molecular weight of about 20,000 daltons and does not enter breast milk. Newer synthetic heparin has a much lower molecular weight (3000 daltons) but is still too large for passage into breast milk. Additionally, heparins are unstable in gastric contents, so any small amount that might pass into breast milk would be quickly degraded. Oral anticoagulants of the indanedione group, as well as bishydroxycoumarin and ethyl biscoumacetate, are found in milk and have been associated with infant coagulopathies. It is unknown if newer agents, including the direct thrombin inhibitor dabigatran and the factor Xa inhibitors rivaroxaban and apixaban, transfer into breast milk, but each of these agents has at least one physicochemical property that favors transfer.[1,7,14] Therefore, warfarin is considered the oral drug of choice, as it is a weak acid with a high degree of protein binding and it is undetectable in breast milk.

Anticonvulsants

Anticonvulsants are a common concern for breastfeeding mothers, whether being used for treatment of a seizure disorder or as a mood stabilizer. Valproic acid, lamotrigine, and topiramate are a few of the commonly used anticonvulsants. Valproic acid is known to have teratogenic potential when taken during pregnancy but is thought to be compatible with breastfeeding because of the low levels of drug transferred to milk (RID = 1.4%-1.7%).[15] Lamotrigine and topiramate, on the other hand, are more readily transferred into breast milk, with a RID of 9.2%-18.3% and 3%-23%, respectively.[15] Despite the fact that these drugs can be detected at significant levels in the plasma of breastfeeding infants, there are minimal reports of adverse effects in the infants. Breastfeeding while taking any of the above anticonvulsants should be encouraged, with appropriate

monitoring of the infant for any signs of toxicity (e.g., apnea, sedation).

Other anticonvulsants that are less commonly used include phenytoin, phenobarbital, and lithium. Phenytoin is found in small amounts in breast milk and is considered compatible with breastfeeding. Barbiturates, including phenobarbital, appear to be safe. However, phenobarbital is metabolized much more slowly in neonates than adults; it is possible that the drug may accumulate in the breastfed infants of phenobarbital-treated mothers. These infants should be monitored for lethargy and poor weight gain.

Lithium has been contraindicated during lactation because of a few case reports that described significant cardiovascular and central nervous system signs in two infants. It would appear from a closer evaluation of these cases that transplacental exposure cannot be ruled out, and maternal drug interaction may have predisposed these infants to a level of lithium toxicity beyond what would have occurred from breastfeeding alone. As a result, breastfeeding mothers who require lithium therapy should be permitted to continue to breastfeed, with close infant monitoring that could include the measurement of blood lithium concentrations in the infant 1-2 weeks after initiating breastfeeding, renal function tests, and thyroid function tests. Consideration should be given to an alternative anticonvulsant if an adjustment in the mother's therapy is not likely to compromise her health.

Antidepressants and Antipsychotics

Postpartum depression affects up to 20% of women and left untreated can be detrimental to both mother and baby.[13] Unfortunately, breastfeeding mothers often discontinue therapy to avoid perceived harm to the infant, despite the fact that there are many antidepressants that are considered safe while breastfeeding. Selective serotonin reuptake inhibitors (SSRIs) and selective norepinephrine reuptake inhibitors (SNRIs) are the most common antidepressants used in breastfeeding mothers. Sertraline is the most well-studied SSRI; it produces very low or undetectable milk and infant plasma levels.[15] Fluoxetine, which has a long half-life and active metabolite, is also well studied. There are reports of significant fluoxetine plasma levels in infants but no adverse effects have been identified.[15] In general, SSRIs and SNRIs are considered compatible with breastfeeding, and few if any adverse effects in the infant have been reported. Sertraline is often the drug of choice for nursing mothers; however, if another SSRI/SNRI is more effective or better tolerated by both mother and baby, it is an acceptable alternative.

The exacerbation of psychotic disorders is also very common in the postpartum period and is often treated with a newer class of drugs, the atypical antipsychotics. Quetiapine, risperidone, and olanzapine are three drugs within this class that have some data available from breastfeeding mothers/infants. For each of these medications, there are few reported adverse effects in the breastfeeding infant, and the RID is low for olanzapine (1.2%) and quetiapine (0.07%-0.1%).[10] For risperidone, the RID is widely variable (2.8%-9.1%) and dependent on maternal dose, so it is recommended that the lowest effective dose be used and that the infant be monitored closely for signs of toxicity such as somnolence or lethargy.[10]

Antihypertensives

There are multiple drug classes available to treat hypertension in breastfeeding women. Within each class, some drugs have more information about compatibility with breastfeeding than others, but there are multiple safe options for the treatment of hypertension in a breastfeeding mother. β-blockers are often one of the first drug classes used in treating hypertension, and most are compatible with breastfeeding. Metoprolol, propranolol, and labetalol have been used in breastfeeding mothers with no adverse effects experienced in the exposed infants. Other β-blockers (atenolol, acebutolol) have been associated with cyanosis, hypotension, and bradycardia and should not be used in breastfeeding mothers.[15]

Angiotensin-converting enzyme inhibitors (ACEIs) are also a mainstay in the treatment of hypertension. Two drugs in this class have data to support their use while breastfeeding. Captopril and enalapril have a RID of 0.002% and 0.175%, respectively, and neither has been associated with adverse effects in exposed infants.[15] A related class of drugs, angiotensin receptor blockers (ARBs), is often substituted for ACEIs if a patient experiences side effects from the ACEI. In the case of the breastfeeding mother, there are far more data and experience with ACEIs, so ARBs should be avoided if possible.

Calcium channel blockers may also be used to treat hypertension, typically as adjunct therapy, and have been used successfully in breastfeeding mothers without causing harm to the infant. There are studies evaluating the use of nifedipine, verapamil, and diltiazem, and all are considered compatible with breastfeeding.

Finally, diuretics are often part of a multidrug regimen to treat hypertension, and these are also likely to be compatible with breastfeeding. Theoretically, if a nursing woman became dehydrated because of diuretic use, milk production could be impacted, but this is controversial, and there is no contraindication to diuretic use and breastfeeding.

Oral Contraceptives

A common problem confronting health care providers is the maternal concern over the use of oral contraceptives during lactation. Contraceptives with a high concentration of estrogen and progestin may depress lactation, especially if they are begun soon after parturition. It is best to start treatment about 4 weeks after delivery, ensuring that lactation is already well established, and to use the lowest dosage possible. Previously, it was believed that progesterone-only contraception would decrease the risk of lactation suppression, but more recent data suggest no difference between progesterone-only or combined oral contraceptives with regard to successful breastfeeding and milk production.[9] Thus, any of the contemporary oral contraceptives, which

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

contain low maternal hormone doses, are considered compatible with breastfeeding.

Pain Medications

Pain medications are frequently needed while breastfeeding, especially after cesarean section. Depending on the severity of pain, the medications used range from acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) to opioids. Nonsteroidal anti-inflammatory drugs, such as ibuprofen, are acidic drugs with low lipid solubility and high protein binding; thus, transfer into breast milk is not favored.[4] In a case report of ibuprofen use while breastfeeding, the RID was 0.0008%, reflective of the physicochemical properties of the drug.[17] For acetaminophen, the RID is higher (8.81%) but still likely to be safe, considering it is commonly used in infants for the treatment of pain and fever.

Opioids are reserved for more severe pain but are often necessary after surgery (e.g., cesarean section) or injury. The concern for the breastfed infant with any maternal opioid use is most often sedation or lethargy. The choice of opioid, use of the lowest effective dose, and a limited duration of therapy can decrease this risk. Morphine and hydrocodone are preferred agents over codeine, oxycodone, and tramadol. Morphine has poor oral bioavailability in infants, along with a RID of 9.1%. Hydrocodone efficacy is largely a result of its active metabolite, hydromorphone, which also has a relatively low RID (0.2%-9%).[15] Codeine and oxycodone are not as predictable as morphine or hydrocodone and are associated with higher rates of infant sedation (16.7% and 20.1%, respectively).[15] Codeine, oxycodone, and tramadol are metabolized by CYP2D6 in an unpredictable manner to active metabolites. This is thought to be the underlying cause of the death of a breastfed infant associated with maternal codeine use. An increased rate of maternal metabolism of codeine to morphine likely played an important role in this scenario.[11] To avoid recurrence of this event, the Food and Drug Administration (FDA) has issued a warning against breastfeeding while taking tramadol or codeine and has required changes to the labeling of these medications.[16]

Reflux Medications

Medications for gastroesophageal reflux are readily available as over-the-counter products and, therefore, are likely to be commonly used during lactation. There are two drug classes, histamine-2 (H2) blockers and proton pump inhibitors (PPIs), that should be evaluated for safety while breastfeeding. The H2 blockers include famotidine, ranitidine, and cimetidine. Famotidine and ranitidine have relatively low RIDs (1.9% and 1.3%-4.6%, respectively) and are considered compatible with breastfeeding.[15] Cimetidine may be actively transported into breast milk, resulting in a much higher RID (up to 32.6%).[15] Therefore, cimetidine should be avoided during lactation given the safer alternatives. Proton pump inhibitors (e.g., omeprazole, lansoprazole) are also a safer alternative to cimetidine, as there is minimal drug transfer into breast milk and any drug that is present is not well absorbed by the infant.

Nontherapeutic Agents in Breast Milk

Caffeine

One hour after the ingestion of an average cup of coffee, a peak breast milk caffeine level of about 1.5 mg/mL is reached. Caffeine levels in breast milk are about half the corresponding maternal blood level. Although the daily amount of caffeine consumed by a nursing infant might be small, the long half-life of caffeine could cause symptoms such as wakefulness or jitteriness and might be considered in the evaluation of infants whose mothers consistently consume large quantities of caffeine-containing products (e.g., cola, diet aids, coffee, tea).

Nicotine

Nicotine from smoking or replacement therapy (e.g., patch) is transferred into breast milk along with its active metabolites. If the mother is smoking, the toxic additives that are part of the cigarette and the secondhand smoke are also transferred to the infant. In a study of smoking cessation using nicotine patches in breastfeeding women, the dose of nicotine transferred to the infant steadily decreased as the nicotine patch dose was reduced.[15] Breastfeeding women should be encouraged to use nicotine replacement therapy to limit infant exposure to nicotine as well as other toxins in cigarettes.

Marijuana

Tetrahydrocannabinol (THC), the active ingredient in marijuana, is transferred into breast milk, but the amount varies depending on the frequency of the mother's use. Similar to nicotine, the toxic additives and secondhand smoke are significant concerns, as marijuana smoke contains an additional 150 compounds.[8] If absorbed by the infant, THC would be expected to rapidly distribute into the brain and theoretically impact the infant's brain development, but this has not been well studied. For these reasons, nursing mothers should be counseled to avoid THC.

Ethanol

Ethanol, a small molecule, is freely diffused into breast milk and achieves levels equivalent to those in blood. Infrequent and moderate amounts of alcohol ingestion are not a contraindication to breastfeeding, but care should be taken to avoid breastfeeding at times when the concentration of alcohol in the breast milk will likely be high. For every drink consumed, the mother should avoid breastfeeding for at least 2 hours.

Narcotics

Breastfeeding while abusing narcotics, such as heroin, oxycodone, or codeine, should not be promoted. Heroin readily transfers into breast milk; however, the extent of exposure to the infant can vary widely depending on the frequency and amount the mother uses. Drug purity can also impact infant exposure, not only to heroin but to other compounds that may be mixed with the heroin. Similar rationale is applied to the abuse of prescription narcotics

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

(e.g., oxycodone, codeine); the varying dose and frequency of maternal use put the infant at risk for side effects from these drugs (see Pain Medications). In the setting of illicit drug use, the risks of unpredictable drug exposure outweigh the benefits of breastfeeding.

Conversely, methadone and buprenorphine, an opioid and partial opioid agonist respectively, are frequently used in breastfeeding mothers as part of an addiction program, and the infant has most likely been exposed to the drug in utero as well. These medications do transfer into breast milk, with a RID of about 2%-3% for methadone and <1% for buprenorphine.[2,12] The use of these medications while breastfeeding may actually alleviate some of the withdrawal symptoms that these infants often exhibit, and breastfeeding while on methadone or buprenorphine as part of a treatment program should be encouraged.

Conclusions Concerning Breastfeeding and Maternal Drug Therapy

As with the fetus in utero, the nursing infant is exposed to nearly everything entering the body of its mother. Clinicians are often faced with difficult decisions when counseling a mother regarding the safety of a medication while breastfeeding. There are rarely clear data that define a drug as safe or harmful to a breastfed infant. In those gray situations, the following simple guidelines may be helpful:

1. Therapy should be with single agents if possible. In the case of long-term therapy, consideration should be given to monitoring the infant's activity and growth.
2. The physiochemical characteristics of multiple drugs within a given therapeutic class should be evaluated. Based on these properties, the drug least likely to pass into breast milk or be absorbed by the infant should be prescribed.
3. Attempt to minimize the dosage to the infant. Use the lowest effective dose, and counsel mothers to avoid nursing at maternal peak plasma levels.
4. Signs and symptoms in a nursing child should be correlated with maternal drug ingestion.

Key Points

- Most drugs are considered safe while breastfeeding.
- The relative infant dose (RID) derived from drug concentration in breast milk and volume of milk ingested can be used to estimate infant exposure to a drug.
- The physicochemical characteristics of different medications within a drug class should be used to guide drug selection.
- Illicit drug use is a contraindication to breastfeeding; however, mothers who demonstrate compliance with a treatment program should be encouraged to breastfeed.

Pharmacokinetics in Neonatal Medicine

KELLY C. WADE

The safe and effective use of medications in the newborn intensive care unit (NICU) requires an understanding of the principles of pharmacokinetics (PK) and pharmacodynamics (PD) that guide individual dosing and aim to provide drug exposures designed for the best clinical outcomes and lowest risk of toxicity. The PK of drugs in neonates is unique and cannot be extrapolated from older children or adults (for excellent comprehensive reviews see references 1, 6, 14, 20). Biological variation among infants in the NICU is extensive: infant's weight varies at least 10-fold (0.5-5 kg), gestational age at birth varies between 22-42 weeks, and postnatal age ranges from 1-150 days. Infants are undergoing dramatic changes in body size, body composition, cardiac output and perfusion, renal and hepatic function, and ontogeny (age-related maturation) of drug metabolizing enzymes. This means that infants in the NICU will exhibit wide variations in drug exposures, and care providers often need to consider dose adjustments for these differences. Basic knowledge of PK and PD drives rational dosing across a broad spectrum of prematurity, clinical conditions, and drug classes. The interplay of PK and PD relationships allows clinicians to target specific drug concentrations that have been associated with therapeutic efficacy (Fig. 45.1).

Anti-infective drugs are the most common class of drugs used in the NICU and provide a useful context to understand basic principles of PK and PD (see Fig. 45.1). The goals of antimicrobial therapy are simple: eradicate the pathogen, minimize toxicity, and prevent emergence of resistant organisms.[3,8] The PK of a drug explains the dose-concentration relationship, whereas the PD of a drug explains the relationship between the concentration of the drug in the body and the therapeutic or toxic response. With basic PK knowledge, clinicians can predict the concentration of drug in the plasma at a given time after a given dose. If a specific drug plasma concentration is known, then dose modification can be determined to provide the desired drug concentration in that infant.

This chapter reviews basic PK and PD principles and the mathematical formulas that enable clinicians to predict an infant's dose-exposure relationship.[1,14,19,20] Both drug- and infant-specific factors can be used to explain the large variation in drug exposures that are expected among infants in the NICU. Optimal dosing in neonates requires that care providers understand the basic principles of the PK and the developmental and physiologic basis for the variation in drug exposures among term and preterm infants. Examples illustrate the use of simple PK calculations to predict differences in drug exposures among very preterm and term neonates.

Drug Disposition Explains Drug Exposure Over Time: Absorption, Distribution, Metabolism, and Excretion

Drug disposition describes how drugs enter and exit the body and explains how concentrations in the body change over time (Figs. 45.2 and 45.3). Four basic processes explain the disposition of drugs through the body: absorption, distribution, metabolism, and excretion. These processes are affected by chemical properties of the drug, patient-specific physiology, body composition, developmental maturation, and pathophysiology relating to disease state. Applying PK principles in neonates requires an understanding of drug disposition and the impact of both developmental pharmacology and patient-specific physiology.[1,6,14,20]

Drug Absorption and Route of Drug Administration

Absorption specifically refers to the process of drug transfer from its site of administration to the bloodstream (see Fig. 45.2). Drugs typically enter the body via intravenous (IV), enteral (per oral, PO), intramuscular, intrapulmonary, subcutaneous, or percutaneous routes and are then absorbed into the circulation as free drug. The route of administration affects the concentration of the drug over time (see Fig. 45.3). Bioavailability of a drug refers to the fraction of the administered dose that reaches the circulation but does not

Abstract

The safe and effective use of medications in the newborn intensive care unit (NICU) requires an understanding of the principles of pharmacokinetics (PK) and pharmacodynamics (PD) that guide individual dosing and aim to provide drug exposures designed for the best clinical outcomes and lowest risk of toxicity. The PK of drugs in neonates is unique and cannot be extrapolated from older children or adults. In the NICU, infants are undergoing dramatic changes in body size, body composition, cardiac output and perfusion, renal and hepatic function, and ontogeny (age-related maturation) of drug metabolizing enzymes. This means that infants in the NICU will exhibit wide variations in drug exposures, and care providers often need to consider dose adjustments for these differences. Basic knowledge of PK and PD drives rational dosing across a broad spectrum of prematurity, clinical conditions, and drug classes. This chapter reviews basic PK and PD principles that explain rational dosing across a broad spectrum of prematurity, clinical conditions, and drug classes. Clinicians will understand the drug- and infant-specific factors that explain the variation in PK and drug exposures that are expected among infants in the NICU. Clinicians will be able to apply basic mathematical formulas to derive infant-specific PK parameters, predict an infant's drug exposure after a given dose, and modify the dose as needed to achieve the desired therapeutic exposure.

consider the rate of drug absorption. Bioavailability is determined by comparing the respective area under the plasma concentration curves (AUC) after a non-IV form of administration with the AUC after an IV administration. IV administration of a drug provides the most consistent, reliable absorption into the circulation and, therefore, defines a bioavailability of 100%.

For enteral medications, the bioavailability depends on biochemical properties of the drug, the formulation, and patient-specific factors such as gastric acidity, gastric emptying time, and intestinal absorption and transit time. Bioavailability is reduced by incomplete absorption and

• **Fig. 45.3** Plot of drug concentration over time after a single dose comparing different routes of administration. Drug concentrations represent the disposition of drug through the body. Route of administration changes the shape of the drug concentration. IV, Intravenous; IM, intramuscular; PO, per oral.

by first-pass metabolism as the drug enters the portal circulation where it can be metabolized in the liver before reaching the systemic circulation. Drugs administered enterally enter the circulation more slowly than IV bolus-administered drugs and therefore achieve a lower maximum drug concentration (C_{max}) later after administration (see Fig. 45.3). Drug-specific dose adjustment is needed when converting IV to enteral formulations to achieve consistent exposure.

Neonates have unique absorption properties that impact drug concentrations after enteral administration.[1,6,14,20] Reduced gastric acidity can increase absorption of acid-labile molecules (penicillin) and decrease absorption of weak organic acids (phenytoin, phenobarbital). Slower gastric emptying time and intestinal motility can change the time to absorb the drug and amount of drug absorbed. Enteral absorption often improves as infants become older. Absorption of enteral medications is often decreased in infants with GI pathology or changes in perfusion to the GI system. Anticipating differences in bioavailability helps guide dose adjustment when converting between IV and PO route of administration.

Bioavailability after intramuscular (IM) and percutaneous (topical) administration can be affected by tissue mass, perfusion, drug permeability, and surface area. In neonates, reduced muscle perfusion and contractility can limit absorption after IM administration.[1,14] When drugs are applied topically, the percutaneous absorption of the drug is directly related to the degree of skin hydration and relative surface area and inversely related to the thickness of the stratum corneum. Percutaneous application of medications in premature infants can lead to large systemic drug exposures given their larger surface area and thin stratum corneum.

Drug Distribution and Volume of Distribution

Distribution refers to the process by which drugs move from the central circulations through various compartments and

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

peripheral tissues in the body according to physiochemical properties such as the molecular size, ionization constant, and relative hydrophilic/lipophilic properties (see Fig. 45.2). The central compartment typically refers to the vascular space with rapid distribution to the heart, kidney, and liver. From the central compartment, drugs distribute at a slower rate to the peripheral compartment(s) that can include brain, fat, and muscle. From the peripheral tissues, drugs traverse back into the central compartment to be eliminated. Drug distribution depends on drug-specific factors (molecular size, ionization constant, relative hydrophilic/lipophilic properties, protein binding) and infant-specific factors (body composition, membrane/tissue permeability, cardiac output). Distribution is an important concept to understanding PK, because it relates to the maximum drug concentration after a given dose and the volume of distribution (Vd). The kinetics of drug transfer to and from the peripheral and central compartments also affects the kinetics of drug excretion and the shape of the drug concentration curve over time.

The apparent volume of distribution (Vd) for a drug is defined as the hypothetical fluid volume through which the drug is dispersed. It is calculated by dividing the total amount of drug given by the concentration of drug in plasma (Table 45.1, Eq. [3]). Vd does not refer to any physiologic compartment nor the blood volume. Instead, Vd relates to the hypothetical volume of the total compartment that explains the concentration of the drug achieved after administering a given amount.

Understanding the factors that contribute to variation in Vd is helpful in determining the optimal dose of a medication to achieve a desired peak concentration (C_{max}) in a specific patient. An infant with a higher Vd will have a lower peak concentration of drug in circulation. High Vd can

indicate that the infant has an increase in total body water and extracellular fluid or that the drug has a wide distribution to peripheral tissues where it also might be sequestered. Gentamicin is a highly polar, hydrophilic molecule that distributes readily in extracellular fluid. Preterm infants have a high body water content and, therefore, require a higher dose of gentamicin to achieve the same peak concentration as a term infant.

Plasma protein binding can have significant effects on distribution. Drugs that exhibit high protein-binding capacity often have smaller Vd, because they bind to plasma proteins and are maintained in the circulation. Protein binding is also affected by availability of binding proteins, differences of binding capacity among different proteins, and increases in bilirubin or free fatty acids that can reduce drug protein binding. Protein binding also influences drug activity and elimination. Drugs that remain unbound to proteins ("free" drugs) are not only pharmacologically active but also more available for metabolism and/or elimination. Neonates typically have a higher proportion of "free drug" compared to total drug due to difference in binding proteins. Increased concentrations of bilirubin and free fatty acids can also compete with drugs for protein binding.

Drug Metabolism

Biotransformation is the process that typically converts lipophilic drug molecules into more polar, hydrophilic derivatives (see Fig. 45.2).[1,2,5,14] Polar metabolites are less likely to diffuse across cell membranes, less likely to distribute into peripheral tissues, and more likely to be eliminated from the body. These polar metabolites are typically inactive, although some metabolites exhibit partial activity. Drugs undergo metabolism or biotransformation to polar metabolites by endogenous enzymatic pathways in the liver or less often in the kidneys, intestinal mucosa, or lungs. Biotransformation can also produce active metabolites from prodrugs, as with theophylline or valganciclovir, or toxic metabolites, as in the case of acetaminophen metabolite *N*-acetyl-p-benzoquinone imine.

The metabolism of drugs is typically classified into two phases, nonsynthetic phase 1 and synthetic or conjugation phase 2.[1,2,5] Enzymes responsible for phase 1 metabolism convert a parent drug to a polar metabolite by introducing or unmasking a more polar site typically from oxidation, reduction, hydrolysis, or demethylation. The cytochrome P450 enzymes found in the liver and other tissues are primarily responsible for phase 1 oxidative metabolism. The most common cytochrome P450 drug-metabolizing enzymes are the CYP3A4 and CYP3A5 isoforms that together are responsible for metabolism of about 50% of medications. CYP isoforms are differentially expressed across human development; notably, CYP3A4 and 3A5 are only expressed after birth, whereas CYP3A7 is expressed in the fetus but expression declines after birth.[1,2,5]

Enzymes responsible for phase 2 metabolisms typically add an endogenous substance to the drug to form a highly polar metabolite using UDP-glucuronosyltransferase, glutathione S-transferase, N-acetyltransferase, or sulfotransferase.[2,5] Expression of phase 2 enzymes varies with both postnatal and postmenstrual age. At birth, sulfation is relatively developed; however, acetylation and glucuronidation are not well developed.[1,2,4,5,7] Glucuronidation is an important pathway for metabolism of morphine and acetaminophen. Morphine clearance is low in neonates, and different morphine-glucuronide metabolites predominate as glucuronidation pathways are underdeveloped at birth.[7] In neonates receiving acetaminophen, sulfation compensates for some of the glucuronidation deficiencies at birth such that sulfate-conjugated metabolites become the predominant excreted form.[4] Phase 2 drug metabolism varies greatly among preterm and term infants in the NICU. While glucuronidation capacity is low after birth, it subsequently increases with weight and postnatal age, resulting in changes in the metabolism of drugs among infants in the NICU.[1,4,5,7]

In general, neonates exhibit reduced hepatic metabolism that leads to increased drug concentrations, delay clearance, and longer half-life of medications that require biotransformation prior to excretion.[1,6,14] This delay in hepatic metabolism is due to decreases in production in many drug-metabolizing enzymes and limited uptake of drugs into hepatocytes. Metabolism may also be enhanced or impaired by environmental, genetic, and physiologic factors. Environmental influences include concomitant medications that may induce or inhibit drug-metabolizing enzymes; fluconazole inhibits CYP2C9 and CYP3A4, whereas phenobarbital induces CYP2B and CYP3A. The cytochrome P450 genes also exhibit wide genetic variation explained by single nucleotide polymorphisms that can diminish or enhance enzyme activity and significantly affect drug metabolism. For example, codeine is metabolized to morphine by CYP2D6; children whose CYP2D6 genotype leads to ultra-rapid metabolism of codeine can experience morphine toxicity.[15] Other factors affecting hepatic metabolism include uptake of drugs into hepatocytes, hepatic blood flow, body temperature, and disease states affecting perfusion.

Hepatic processes change rapidly over the first month so dose adjustment is often necessary with advancing postnatal age and maturation. Fentanyl is metabolized by hepatic CYP3A4 mediated N-de-alkalation to norfentanyl. Fentanyl elimination depends on liver blood flow, hepatic uptake, and CYP3A4 activity. Not surprisingly, fentanyl PK is highly variable in neonates, half-life ranges from 317-1266 minutes, and clearance increases threefold in the first 2 weeks of life.[12] In the first 48 hours after birth, fentanyl clearance increases 40% between infants born at 29 weeks' gestation compared to 41 weeks' gestation.[13] Understanding the differences in drug metabolism is important to understanding drug exposures in neonates; if neonates cannot effectively metabolize a drug, then higher concentration of active drug can potentiate effects of the drug or lead to toxicity. In the absence of specific drug-metabolizing enzymes,

neonates may use alternative pathways and produce different metabolites with different activity or toxicity profiles. As drug-metabolizing capacity improves with age, higher doses are necessary to achieve desired concentration and response.

Drug Excretion

The excretion of active drugs or their metabolites is the process by which drugs are removed from the body. Drug excretion primarily occurs through the kidney and liver (see Fig. 45.2).[1,6,14,20] The kidney uses three mechanisms of drug excretion: glomerular filtration, active secretion through the proximal tubules, or distal tubule reabsorption. Glomerular filtration is very low in the first few days after birth and increases with hemodynamic changes and improved renal perfusion. Glomerular filtration also increases with gestational age; preterm infants typically have delayed renal clearance and longer half-life compared to term infants.[1,6,14,20] Disease states common in critically ill newborns such as neonatal encephalopathy, sepsis, acute kidney injury, and congenital heart disease all have been associated with reduced glomerular filtration and reduced drug excretion.

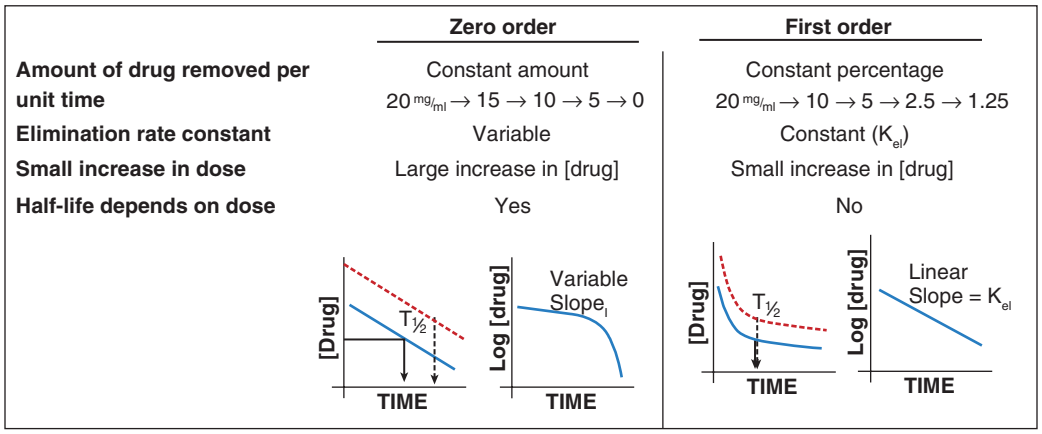
Tubular processes related to drug secretion and reabsorption are also important to renal elimination yet incompletely understood particularly in neonates. Drug secretion in the proximal tubules uses transport systems that typically eliminate organic anions. Secretion transporter proteins secrete drugs that are conjugated with glucuronic acid, glycine, and sulfate, such as penicillin or furosemide. Tubular secretion is less developed in newborns, thereby partially explaining the prolonged half-life of penicillin and furosemide.[1,14,20] Membrane transporters in the distal tubule can actively reabsorb drugs from the tubular lumen back into the systemic circulation. Tubular reabsorption is also delayed in neonates. Glomerular filtration rate typically improves with maturation faster than tubular mechanisms.

The liver uses four mechanisms of drug excretion: drug metabolism, excretion into bile, fecal elimination, and enterohepatic recirculation. Hepatic drug elimination can be dependent on hepatic blood flow and the metabolic capacity of liver. Patients with hepatic insufficiency have decreased elimination of drugs because of alterations in protein levels and protein binding, decreased liver blood flow, decreased uptake into hepatocytes, and altered hepatic enzymatic reaction. Patients with hepatic insufficiency, however, exhibit marked variability in drug metabolism and elimination. Infants with hepatic insufficiency typically benefit from lower doses of drugs that are eliminated by hepatic biotransformation and therapeutic drug monitoring when possible.

Regardless of excretion mechanism, the rate at which drugs are eliminated from the circulation is essential to the PK properties of drug clearance (CL), elimination rate constant (K_{el}), and half-life ($T_{½}$) (see formulas in Table 45.1, Eq. [4.6]). Drug CL is defined as the volume of blood from which all drug is removed per unit time; K_{el} represents the elimination rate constant, in other words, the slope of the drug concentration time curve on a semi-logarithmic plot; and $T_{½}$ is defined as the time it takes to clear half of the drug from plasma. Clearance can be affected by body weight, body surface area, cardiac output, hepatic function, renal function, plasma protein binding, concomitant medications, and variation in expression of drug metabolizing enzymes. At steady state, drug input is equal to drug elimination and, therefore, the dose given (dose/interval) is equal to the amount of drug removed (CL x drug concentration at steady state).

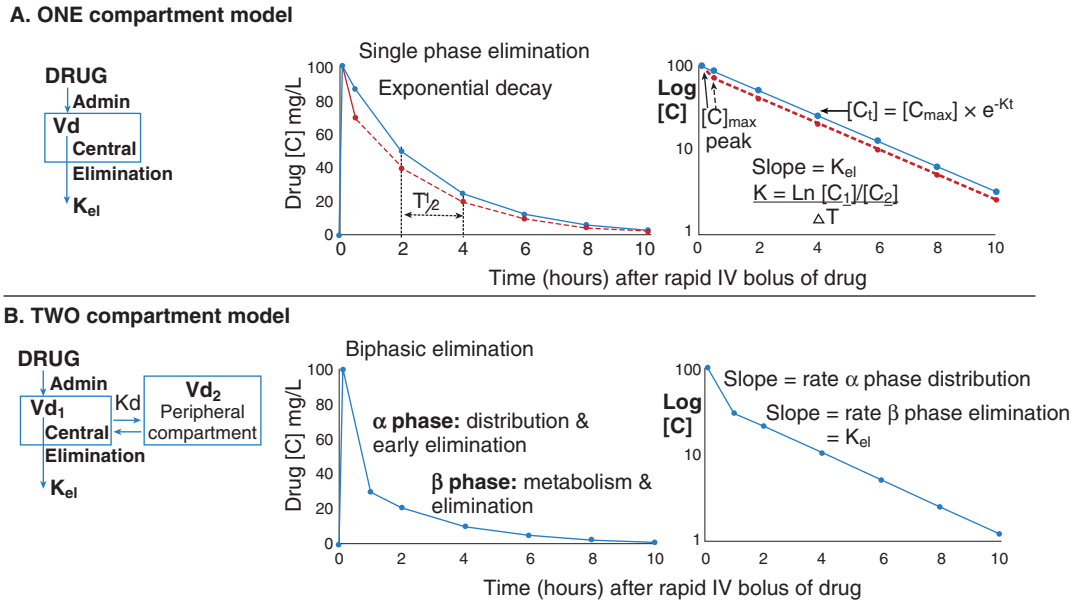
Drug Disposition Impacts PK Characteristics of Drugs in Neonates

Drug disposition (absorption, distribution, metabolism, and excretion) exhibits marked complexity and interpatient variability in neonates given the infant specific differences in body size and composition, maturation, postnatal age, organ function, and clinical disease (pathophysiology).[1,14,20] In neonates, the Vd is often higher for hydrophilic drugs leading to lower maximum drug concentration. Elimination (K_{el}) and CL are often slower due to reduced rates of biotransformation and renal elimination. The expected changes in drug metabolism with maturation can be highly variable and depend on both the drug, the metabolic pathways, and clinical disease. The PK characteristics of drugs, specifically Vd and CL, need to be studied across a broad range of prematurity, body compositions, postnatal ages, and disease states.



Pharmacokinetic Models Describe Concentration of Drug Over Time

Pharmacokinetic models describe the mathematical relationship between the dose of a medication administered to a patient and the drug concentration over time after a given dose (Figs. 45.4 and 45.5). These drug concentration-versus-time curves describe the disposition of drug through the body and are the basis for the mathematical models (kinetics of decay) that predict individual drug concentrations over time in specific patients. Drug concentrations are typically only available from the blood and serve as a surrogate for drug concentration at sites of action to correlate with pharmacologic response.



First-Order or Zero-Order Kinetics

The drug-concentration-over-time graphs in Fig. 45.4 depict the rate of elimination of a drug from the body on a linear and semi-logarithmic plot. Most drugs follow first-order kinetics, and mathematical equations in Table 45.1 are appropriate for drugs that are eliminated using properties of first-order kinetics.[19,20] For drugs that follow first-order kinetics, a constant percentage of drug is metabolized

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• **Fig. 45.4** Kinetic properties of drug elimination. Drugs that follow zero order kinetics have a constant decrease in concentration over time. Drugs that follow first-order kinetics have a constant percentage of decrease in concentration over time. This affects the shape of the concentration curve over time on both a linear and semi-logarithmic plot. K_{el}, Elimination rate constant; $T_{½}$, half-life.

• **Fig. 45.5** Drug concentration over time profile after single IV bolus of a drug that follows first-order kinetics. One (A) and two (B) compartment models are shown with associated graphs of drug concentrations plotted over time on a linear (*left*) and semi-logarithmic (*right*) scale. A one-compartment model is a simplified, hypothetical example of a drug with instantaneous distribution. In reality (dashed line in A with peak measured 30 minutes after end of infusion), drugs that have a rapid distribution phase and longer elimination phase can approximate one compartment model, allowing the use of simplified formulas to calculate PK parameters. [C_{max}] allows calculation of the Vd. The drug concentration at any time t ([C_t]) can be calculated using C_{max} and exponential decay factor (e^{-Kt}). C, Drug concentration; IV, intravenous; K_{el}, elimination rate constant; $T_{½}$, half-life; Vd, volume of distribution.

over time. Since the rate of elimination (K_{el}) is proportional to the amount of drug in the body, then a large amount of drug is removed per unit time initially with a small amount drug when concentrations are low. When drugs follow first-order kinetics, the concentration time curve shows an exponential decrease in the plasma drug concentration over time, and a linear decrease in drug concentration on logarithmic scale (see Fig. 45.5). The half-life of drug elimination is independent of drug dosage. Most drugs used in neonates follow first-order kinetic properties, including ampicillin, gentamicin, and phenobarbital.

Rarely, drugs may follow what is called zero-order kinetics or nonlinear, saturable kinetics. In drugs that follow zero-order kinetics, a constant amount of drug is metabolized or eliminated per unit of time regardless of concentration. The drug concentration follows a linear decrease of serum concentration over time (see Fig. 45.4). The elimination rate constant (K_{el}) is highly variable, with a

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

smaller percentage of the drug eliminated at the beginning and a higher percentage of the residual drug eliminated toward the end, as demonstrated on log-transformed scale. The half-life of drugs whose elimination follows zero-order kinetics is dependent on drug dosage; larger doses yield a longer half-life. One example is ethanol. After ingesting alcohol, the liver's alcohol dehydrogenase quickly becomes saturated such that only a fixed amount can be metabolized over a given amount of time. There is a maximum yet constant amount that the body can eliminate at any given time. Small increases in dose can yield large increases in levels, because the amount of drug removed is constant and not proportional to the dose. Phenytoin is another zero-order kinetic drug, owing to saturable kinetics of the metabolizing enzymes.[9] Some drugs that typically follow first-order kinetics can follow zero-order kinetics when given at a very high dosage if enzymatic metabolism becomes saturated until the drug concentrations decrease to the point that enzymatic reactions are no longer saturated and then first-order kinetics can resume.

One- Versus Two-Compartment PK Models

The mathematical principles that describe the first-order kinetics of the dose-to-concentration relationship over time often use a compartmental approach to represent how a drug distributes through the body and the different rates of concentration changes in the body over time (see Fig. 45.5). In one-compartment models, a drug hypothetically distributes instantaneously in a homogeneous fashion into one compartment representing the entire body, and then the concentration declines linearly on logarithmic scale with one rate constant (K_{el}) as the drug is eliminated. This simplified, one-compartment hypothetical model is most appropriate for drugs that are administered by fast infusion, rapidly distribute throughout the central compartment (short alpha phase), and have a relatively long beta phase of elimination that is the primary determinant of drug concentration over time (shown in dashed curve in one compartment example in Fig. 45.5).

The two-compartment model is used to describe a drug with first-order kinetics that moves through the body in two distinct phases (see two-compartment model of Fig. 45.5). The alpha phase typically describes the drug's initial distribution throughout the circulation with a relatively rapid rate of concentration decline, followed by the slower beta phase that describes the drug elimination from the body, in which drug concentrations decline more slowly. Two different exponential rates of decay are demonstrated by the change of slope in the semi-logarithmic plot of a concentration-versus-time. The distribution and elimination properties of widely distributed drugs that enter and exit numerous compartments often require multicompartment models. The mathematical principles underlying multicompartment models are beyond the scope of this chapter.

Body Composition and Organ Function Affect Pharmacokinetics

In neonates, developmental changes in body composition, renal, and hepatic function, as well as pathophysiology with clinical disease, can affect PK characteristics of drugs, specifically Vd and CL.[1,14,20] Much of the variation in Vd across varying gestational ages and postnatal ages can be explained by differences in body composition. Neonates have higher proportions of extracellular and total body water compared to older infants and children. Premature infants have the highest amount of total body water. Therefore, hydrophilic drugs that distribute in water have larger Vd in newborns and even larger Vd in premature newborns. Infants with larger Vd will have lower peak drug concentrations unless they receive a higher dose. Infants with excess extracellular fluid, such as those with ascites or hydrops, can also have large Vd for hydrophilic drugs.

For lipophilic drugs, the body composition of fat can affect drug distribution into adipose tissue. If more drug is sequestered in fat, then plasma drug concentrations will be lower, Vd higher, and even the drug elimination characteristics (CL) can be affected since drug sequestered in fat is less available for elimination. Very preterm infants with minimal body fat will have smaller Vd and less storage of lipophilic drugs (e.g., benzodiazepines, fentanyl) in peripheral fat; whereas large-for-gestational-age infants born to diabetic mothers can sequester lipophilic drug in their peripheral tissue and, therefore, exhibit larger Vd and lower plasma drug concentration.

Infants with low protein stores will have greater proportion of free drug for a given total plasma drug concentration. The free drug component is the pharmacologically active moiety and may be more likely to distribute into peripheral tissues (larger Vd). The increased proportion of free or unbound drug can also contribute to faster elimination and shorter half-life since free unbound drug is more available for drug excretion mechanisms. However, the higher proportion of active, unbound drug relative to total drug concentration may explain toxicity at a similar total drug concentration. Neonates can also have a higher proportion of free drug compared to older infants due to endogenous competitors of protein binding, such as bilirubin or free fatty acids.

Age-dependent differences in drug binding in tissues can also affect distribution. Drugs can have extraordinarily large Vd if they are bound to proteins in the peripheral tissues. The disposition of these drugs through the body typically requires a two- or three-compartment model to account for the transfer of drug in and out of peripheral tissues (see Fig. 45.5). For example, digoxin has low plasma concentration and very large Vd; the drug is bound to proteins in skeletal and cardiac muscle and thus sequestered in the peripheral tissue.[11] Infants and children have increased myocardial uptake of digoxin partially explaining the higher Vd in infants.

At birth, elimination of drugs through the kidney is inefficient leading to delayed drug clearance and prolonged half-life of many drugs. Renal elimination is limited by renal blood flow and functional immaturity of the kidney, specifically glomerular filtration and tubular capacity for secretion and reabsorption. Glomerular filtration of drugs is dependent on renal blood flow and protein binding of the drug in plasma. Drugs bound to proteins are typically too large to pass through glomeruli. Tubular secretion and reabsorption of drugs involve transport processes that are impacted by prematurity yet remain incompletely understood.[1,14]

Hemodynamic changes after birth lead to increased renal blood flow and rapid changes in glomerular filtration rate (GFR) over the first week after birth. Glomerular filtration is decreased in premature infants, and although the GFR increases after birth, its increase does not match the increased GFR seen in term infants. In 3-day-old neonates, mean GFR increased significantly with advancing gestational age from 24 through 37 weeks.[17] After birth, GFR increases significantly over the first 10 days after birth although less dramatically in very preterm infants.[16] Delayed renal clearance in the youngest, most immature infants can lead to high plasma drug concentration. Dose adjustment for prematurity at birth and again for advancing postnatal and postmenstrual age is often warranted for drugs with renal elimination.

Infants with significant renal disease have changes in drug disposition as reflected in differences in Vd and CL. In addition to the expected reduction in GFR, infants with significant renal disease often have electrolyte abnormalities that can affect the serum pH, which in turn affects the ionization state of drug molecules. Infants with significant renal disease also can accumulate organic acids in the plasma that compete with protein-bound drugs for albumin binding, thereby altering the Vd and availability of free drug for renal clearance. Alteration in pH of tubular fluid also affects the ionization state of a drug molecule, which in turn can affect tubular reabsorption.

Patients with liver disease or hepatic congestion often accumulate active drugs owing to their diminished metabolic capabilities and decreased first-pass metabolism. Patients with liver disease typically have low albumin or altered glycoprotein levels that may affect fractional protein binding of drugs, thereby altering availability of free drug and volume of distribution. Slow gut motility or bowel wall edema can impair enteral absorption.

Patients with cardiac dysfunction can exhibit altered perfusion, edema, hepatic congestion, and/or decreased renal perfusion. All phases of drug disposition (absorption, distribution, metabolism, and excretion) can be affected, and change in PK properties of Vd and CL would be expected. Altered tissue perfusion and increased total body water, as is seen in cardiac, renal, or hepatic dysfunction, can unpredictably alter Vd and CL based on patient physiology and drug-specific properties.

Basic Pharmacokinetic Calculations for Clinicians

Basic PK principles can guide clinicians in how to use drug concentrations derived from therapeutic drug monitoring to determine appropriate dosing for an individual infant. This bedside PK approach, albeit simplified, is appropriate for many drugs used in newborns. Drug concentrations at different time points are used to derive infant-specific Vd, CL, K_{el}, and $T_{1/2}$. These infant-specific PK parameters can then be used to determine what dose modifications are needed to achieve the desired drug concentrations over time for that specific infant (see Table 45.1). (For a more thorough explanation, see references 19, 20).

This approach is most appropriate when the PK properties of the drug can be approximated by a one-compartment model. In reality, these simplified formulas can provide good estimates if the drug has a rapid distribution phase followed by a long beta phase of elimination, when therapeutic drug monitoring occurs during the elimination phase, and when the drug is administered by short infusion time and long dosing intervals (see Fig. 45.5). In these scenarios, the drug concentrations at a given time after infusion are primarily impacted by the prolonged elimination beta phase.

This simplified approach of a one-compartment model is appropriate for gentamicin. Gentamicin PK properties (Vd, K_{el}, $T_{1/2}$, and CL) can be estimated using a peak level obtained 30 minutes after the end of drug infusion when equilibrium is expected to be established in circulation and a trough level obtained before the next dose. The peak level will be somewhat lower than if measured at the end of the infusion. However, by obtaining the peak concentration 30 minutes after the end of infusion, there can be two drug concentrations within the beta phase of elimination to allow calculation of K_{el}.

Peak concentration achieved from the dose of gentamicin is used to estimate Vd. In simplest terms, the volume of distribution is the amount of drug infused divided by the amount of drug measured in the plasma. If 4 mg/kg is given and 10 mg/L is measured in the blood, then the Vd is 0.4 L/kg (see Table 45.1, Eq. [3a]). This Vd is slightly larger than would be predicted if peak was obtained at the end of infusion. This small difference is likely insignificant in the effort to target a therapeutic peak concentration. For precise calculation of Vd, one would use calculations that incorporate time of infusion and time after end of infusion (see Table 45.1, Eqs. [7.10]).

In the gentamicin example, two drug concentrations obtained during the beta phase of elimination are needed to calculate K_{el}. Since the peak level was obtained after short alpha phase, then the peak and trough concentrations represent two concentrations during the beta elimination phase. The elimination rate constant (K_{el}) represents the slope of the line (change in concentration per change in time) on log plot as shown in Table 45.1, Eq. [4a].

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

The half-life ($T_{1/2}$) is the time it takes to reduce the drug concentration (C) in half as shown in Eq. [5a], Table 45.1, and relates to the slope (elimination rate constant K_{el}) of concentration time curve on a semi-logarithmic plot. Half-life can be estimated from the drug concentration time curve (see Fig. 45.5) or from the elimination rate constant ($0.693/K_{el}$) or Vd and CL (see Table 45.1, Eq. [5]).

Clearance (CL) is a measure of the rate of drug elimination from the body. Clearance is formally defined as the volume of blood from which all drug is removed per unit of time. Clearance can be calculated using Vd and K_{el} (see Table 45.1, Eq. [6]). At steady state, drug input is equal to drug elimination; therefore, the dose given (dose/interval) is equal to amount of drug removed (CL x drug concentration at steady state) (see Table 45.1, Eq. [6c]).

Pharmacokinetic Calculations Accounting for Infusion Time

In special circumstances when drugs are infused over long time periods, then the maximal concentration of drug measured at the end of infusion may be lower than expected and may overestimate the Vd. The lower C_{max} is because drug is being eliminated during the same time drug is being infused. In this case, more complicated exponential equations would be necessary to estimate the Vd while taking drug elimination into account (see Table 45.1, Eqs. [7, 8, 9, 10]). The concentration of drug at end of infusion (C_{max}) is derived using the rate of the infusion (R_0 defined as dose mg/kg divided by the time of infusion t_{inf}), the CL, and the fraction of drug removed during the infusion time (see Table 45.1, Eq. [7]). If the peak concentration is obtained 30 minutes after the end of the infusion to allow for equilibrium after rapid distribution phase, then multiply C_{max} by the decay factor (e^{-kt} where t = 0.5 hour) to predict this peak level at the time used in therapeutic drug monitoring (see Table 45.1, Eq. [8]). Clinicians can predict the concentration at any time relative to C_{max} at the end of infusion by adjusting the time parameter "t" in the decay factor (e^{-kt}) (see Table 45.1, Eq. [8]). Because CL is derived from the ratio of Vd and K_{el}, this equation can be rearranged to calculate Vd while considering drug loss owing to elimination during infusion time (see Table 45.1, Eq. [9]). For calculations during continuous infusions it is wise to consult a pharmacist.

Fortunately, most drugs in the NICU are administered IV over short (≤60 minutes) infusion times. These infusion times are short compared with the slow drug elimination rate and longer dosing intervals. Therefore, only a very small quantity of drug is eliminated during the actual infusion, allowing the use of simplified calculations.

Pharmacokinetic Calculations After Multiple Doses

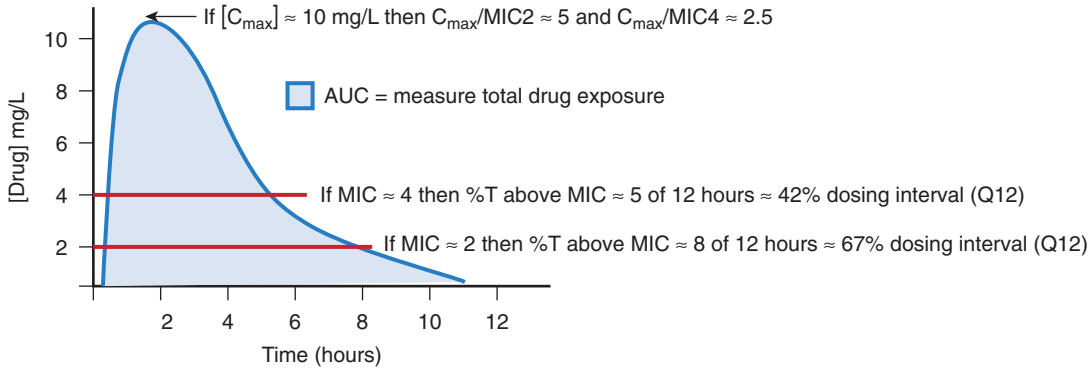
Therapeutic drug monitoring often takes place after multiple doses have been administered. Different formulas can be used that incorporate both the dosing interval referred to as tau (τ) and the number of doses (*n*). If multiple doses have been administered, but it is not known if steady-state has been reached, then formulas allow for calculation of C_{max} after *n* doses. Once C_{max} is determined, then the decay factor ($e^{-kt'}$) allows for calculation of drug concentration at time t after the *n*th dose (see Table 45.1, Eqs. [11, 12, 13]). Once at steady-state, CL can be determined from the dose, interval, and average steady-state drug concentration (see Table 45.1, Eq. [6c]).

Pharmacodynamics

The pharmacodynamics (PD) of a drug explain the relationship between the concentration of a drug in the blood and the biochemical and physiologic effect of that drug on the body.[1,3,8] The effect of a drug can relate to either its efficacy or toxicity. The PD properties are drug specific, because they reflect their mechanism of action, potency, desired effect, and/or toxicity profile. Many drugs, such as dopamine, bind to physiologic receptors; agonists mimic the effects of endogenous ligands, whereas antagonists block the effects of endogenous ligands. The pharmacodynamics of receptor-binding drugs is altered during development because of changes in receptor binding, receptor density, and downstream signal transduction. Disease states, maturity, and concomitant medications can also alter drug pharmacodynamics.

When clinical trials do not show desired efficacy, then one needs to reconsider the dose-exposure-response paradigm presented in Fig. 45.1. Lack of efficacy may be caused by the dose being too small and thus yielding subtherapeutic concentrations. Alternatively, the dose may have achieved the desired concentration, but in the young infant that plasma concentration did not correlate with the desired response.

PD principles are well established for the treatment of infections.[3,8] Antimicrobial drugs target the pathogen; therefore, the exposure targets for bacterial or fungal eradication are likely to be appropriate across diverse age groups. Most infants in a NICU receive an antimicrobial drug; therefore, it is worth reviewing the PK/PD paradigms that guide drug dosing for the effective treatment of infections.



The goals of antimicrobial therapy are simple: Eradicate the pathogen, minimize toxicity, and prevent emergence of resistant organisms (see Fig. 45.1). Once a drug has been chosen, the hard part is choosing the right dosing strategy to accomplish these goals. The PK properties of a drug, specifically the CL, K_{el}, $T_{1/2}$, and Vd, explain the relationship between dose and concentration. PD tell us what concentration is necessary to kill the organism and reduce the risk of emerging resistance based upon human, animal, and in vitro studies. Optimal treatment of infections requires clinicians to incorporate both PK/PD principles (see Fig. 45.1) and use doses of antimicrobial drugs designed to meet PK/PD exposure targets.[3,8] The concentration of the drug in the plasma is just one important aspect of treatment. Infant factors such as immunocompetence, bacterial load, and drug concentration at the site of infection are also important, but they are difficult to modify.

Two important determinants of effective antimicrobial therapy are the drug exposure profile and the minimal

inhibitory concentration (MIC) of a given bacteria or organism (Fig. 45.6).[3,8] The drug concentration curve demonstrates three important measures of exposure: (1) the maximal concentration referred to as C_{max} or Peak, (2) the area under the concentration curve (AUC) that refers to a measure of total drug exposure, and (3) the time or percent of dosing interval that the drug concentration is maintained above the MIC of the organism (% time). Effective therapy means optimizing this concentration curve relative to the MIC as illustrated by the three PK/PD exposure targets: C_{max}/MIC, AUC/MIC, and % T > MIC.[3,8]

These three PK/PD exposure targets guide effective treatment.[3,8] Antimicrobial drugs can be classified into three major categories: concentration-dependent killing, time-dependent killing, and time-dependent killing with some moderate persistent effects (Table 45.2). Gentamicin is concentration dependent; therefore, the higher the dose, the higher the C_{max}, the more killing is achieved. Gentamicin also has a significant postantibacterial effect, meaning that the higher the C_{max}, the more bacterial growth is subsequently suppressed after levels decrease. Beta-lactam antibiotics, such as ampicillin, are not concentration dependent; efficacy is associated with the percent of time that the concentration is maintained above the MIC. For ampicillin, effective bacterial killing starts to occur when levels are twofold greater than MIC. Increasing ampicillin concentration to more than fourfold MIC does not decrease the bacterial burden. Ampicillin has no postexposure antibacterial activity, so bacterial growth can occur when concentrations are below the MIC. Beta-lactam antibiotics require more frequent dosing or prolonged infusion time to sustain drug levels above the MIC for at least 50% of the dosing interval. Finally, bacterial killing with vancomycin is independent of concentration; however, there is a modest postantibacterial effect such that higher levels are associated with prolonged killing even as levels decrease. Vancomycin efficacy is associated with the AUC/MIC exposure target. Antimicrobial

• **Fig. 45.6** PK–PD exposure targets guide optimal treatment of infections. This graph shows how a drug concentration changes over time after dose. The drug exposure is shown relative to potential minimal inhibitory concentrations (MIC) of an offending organism. Effective therapy meets one of three potential PK/PD exposure targets: C_{max}/MIC, AUC/MIC, and the %T > MIC (%T > MIC refers to the percent of time the concentration of drug is above the MIC during dosing interval). As the MIC increases, the PK/PD exposure target becomes more difficult to obtain. AUC, area under concentration curve.

TABLE 45.2 Pharmacokinetics (PK)—Pharmacodynamics (PD) Relationships and Exposure Targets for Optimal Antimicrobial Treatment

Antimicrobial Activity	PK–PD Exposure Target	Definition	Drug Class	Dosing Goal
Concentration-dependent killing with postantibiotic effect	C_{max} / MIC	Bacterial killing is proportional to maximal concentration achieved relative to MIC of offending organism	Aminoglycosides Fluoroquinolones Daptomycin	Enhance peak concentration
Time-dependent killing	Time [drug] > MIC	Bacterial killing is proportional to the amount of time the drug concentration is maintained above the MIC of offending organism	Beta-lactams Penicillins Cephalosporins Carbapenems	Enhance duration of exposure by short dosing intervals
Time-dependent killing with postantibiotic effect	AUC / MIC	Bacterial killing is proportional to the amount of total drug exposure relative to MIC of offending organism	Vancomycin Clindamycin Linezolid Azoles	Enhance amount of drug using both dose and interval

drug dosing guidelines are designed to optimize these PK/PD exposure targets. However, because the exposure targets are all relative to the MIC, the higher the MIC, the harder it is to achieve the exposure target, even if the MIC is within the sensitive range for that drug.

When approaching drug choice and dosage, it is necessary to consider factors that affect PK/PD target attainment and potential outcomes. Patient-specific factors such as maturity, organ function, and fluid status affect attainment of PK/PD targets. Pathogen-specific factors determine susceptibility to drugs. Drug-specific factors such as tissue penetration, formulation, and the availability of PK information in neonates are also important. Finally, the site of the infection and ability to achieve adequate drug concentration at the site of infection can affect outcomes. Neonates are notorious for their susceptibility to meningitis and severe abdominal infections associated with ascites and large fluid shifts. Clinical disease states affect the disposition and PK of drugs in patients.

Example of Simple Pharmacokinetic Calculations to Derive Dose Adjustments

Clinicians can use the formulas in Table 45.1 to perform simple calculations to estimate an individual infant's Vd, CL, K_{el} and $T_{½}$ and then to determine dose modification for that individual infant.[19,20] To demonstrate the use of these formulas, the extended-interval dosing of gentamicin in three newborns of varied gestational age is reviewed (Box 45.1). Gentamicin serves as one of the best examples of PK/PD-derived dosing

• BOX 45.1 Examples of Pharmacokinetic Calculations

A. Mary is a 40-week-gestation term infant who received a 4 mg/kg IV dose of gentamicin every 24 hours. The dose is infused over 30 minutes (t_{inf} = 0.5 h), and she has a peak concentration of 10 mg/L measured 30 minutes after end of infusion (t′ = 0.5 hr from end of infusion), and a trough concentration of 0.3 mg/L drawn 1 hour before the next dose. The time between the peak and the trough is 22 hours. Standard pharmacokinetic (PK) formulas yield the following individual PK characteristics, including K_{el}, $T_{½}$, Vd, and CL.

STEP 1: CALCULATE ELIMINATION RATE CONSTANT AND HALF-LIFE

Eq. [4a] $K_{el} = \ln([C_1]/[C_2])\ \text{mg/L}/\Delta t\ \text{hr}$ or
$= \ln(10/0.3)/22$
$= \ln 33.33/22$
$= 0.159\ \text{hr}^{-1}$

Eq. [5a] $T_{½}\ \text{hr} = 0.693/K_{el}$
$= 0.693/0.159$
$= 4.3$ hr (q 24 hr = 5–6 half-lives)

STEP 2: CALCULATE VD AND CL

Eq. [3a] $\text{Vd L/kg} = [\text{Dose}]\ \text{mg/kg}/[\text{Gent}]\ \text{mg/L}$
$= 4\ \text{mg/kg}/10\ \text{mg/L}$
$= 0.4\ \text{L/kg}$

Eq. [6a] $\text{CL} = K_{el}\ \text{hr}^{-1} \times \text{Vd L/kg}$
$= 0.159 \times 0.4$
$= 0.0636\ \text{L/(kg} * \text{hr)}$

EXTRA CREDIT:

The delay in measuring the gentamicin trough 30 minutes after infusion ends ensures that both the gentamicin peak and trough are in the drug elimination phase.

What are the Vd and CL if corrected for 30-minute delay in drawing gentamicin peak and 30-minute infusion time?

t_{inf} = 0.5 hr, t = 0.5 hr, and R_0 = dose/t_{inf} mg/kg * hr, K = K_{el} = hr^{-1}

Eq. [9] $\text{Vd} = (R_0/[C_t \times K]) \times (1 - e^{-K\text{tinf}}) \times e^{-Kt}$
$\text{Vd} = ([4/0.5]/[10 \times 0.159]) \times (1 - e^{-((0.159)(0.5))}) \times e^{-((0.159)(0.5))}$
$\text{Vd} = 5.03 \times 0.076 \times 0.8953 = 0.326\ \text{L/kg}$

Eq. [6a] $\text{CL} = K_{el}\ \text{hr}^{-1} \times \text{Vd L/kg}$
$= 0.159 \times 0.326$
$= 0.052\ \text{L/(kg} * \text{hr)}$

Note: These are estimates that assume a constant K_{el} during infusion and time before gentamicin peak as would be seen in a one-compartment model. It does not account for a faster K_{el} in the alpha distribution phase.

B. Jack was born at 30 weeks' gestation and weighed 1500 g. He should not receive the same dose as Mary. Using knowledge of prematurity, organ maturation, and fluid status, one could predict that he would have a larger Vd, delayed CL, and longer $T_{½}$. It could be predicted that Jack would need a larger dose and longer interval.

If infants born at 30 weeks' gestation have a Vd of 0.52 L/kg and $T_{½}$ of 11 hours, then can you estimate Jack's peak (30 minutes post end of infusion) and trough levels (1 hour before the next dose) if he received a 4 mg/kg dose every 24 hours or a 4.5 mg/kg dose every 36 hours? In this example, the 4.5 mg/kg dose every 36 hours leads to more optimal gentamicin exposure.

Dose 4 mg/kg q 24 hr
STEP 1: ESTIMATE PEAK GIVEN VD

From Eq. [3a] Vd L/kg = [Dose] mg/kg/[Gent] mg/L
Rearrange to

$\text{Peak [Gent] mg/L} = [\text{Dose}]\ \text{mg/kg}/\text{Vd L/kg}$
$= 4\ \text{mg/kg}/0.52\ \text{L/kg}$

Peak [Gent] mg/L = 7.7 mg/L

Dose 4.5 mg/kg q 36 hr
STEP 1: ESTIMATE PEAK GIVEN VD

From Eq. [3a] Vd L/kg = [Dose] mg/kg/[Gent] mg/L
Rearrange to

$\text{Peak [Gent] mg/L} = [\text{Dose}]\ \text{mg/kg}/\text{Vd L/kg}$
$= 4.5\ \text{mg/kg}/0.52\ \text{L/kg}$

Peak [Gent] mg/L = 8.7 mg/L

• BOX 45.1 Examples of Pharmacokinetic Calculations—cont'd

STEP 2: CALCULATE K_{EL} USING EQ. [5A]

$K_{el} = 0.693 / T_{1/2}$ hr $= 0.693/11 = 0.063\ hr^{-1}$

STEP 3: ESTIMATE C_2[TROUGH] 22 hr AFTER PEAK

Eq. [4a] $K_{el}\ hr^{-1} = Ln\,[C_1]\ mg/L - Ln\,[C_2]\ mg/L/\Delta t\ hr$

$0.063\ hr^{-1} = Ln\,[7.7] - Ln\,[trough]\ mg/L/22\ hr$

Rearrange to solve for [trough]

$Ln\,[trough] = Ln\,[7.7] - (22\,(0.063)) = 0.655\ mg/L$

gent [trough] $= e^{0.655} = 1.92\ mg/L$

STEP 2: CALCULATE K_{EL} USING EQ. [5A]

$K_{el} = 0.693 / T_{1/2}$ hr $= 0.693/11 = 0.063\ hr^{-1}$

STEP 3: ESTIMATE C_2[TROUGH] 34 hr AFTER PEAK

Eq. [4a] $K_{el}\ hr^{-1} = (Ln\,[C_1] - Ln\,[C_2])\ mg/L/\Delta t\ hr$

$0.063 = (Ln\,[8.7] - Ln[trough])\ mg/L/34\ hr$

Rearrange to solve for [trough] mg/L

$Ln\,[trough] = Ln\,[8.7] - (34\,(0.063)) = 0.021\ mg/L$

Gent [trough] $= e^{0.021} = 1.02\ mg/L$

C. Ava was born at 25 weeks' gestation and weighed only 500 g. With more prematurity comes larger volume of distribution and slower clearance. By measuring a few gentamicin levels, we could derive her individual Vd, CL, K_{el}, and $T_{1/2}$. Ava had a gentamicin peak of 6.8 mg/L after a 4 mg/kg dose and a trough of 3 mg/L at 22 hours after the peak dose. Use equations in Table 45.1 to estimate what dose and interval she would need to have a desired peak of 8-10 mg/L and the desired trough concentration of less than 2 mg/L. Predict her gentamicin peak and trough levels after three doses.

To Estimate Optimal Dose

STEP 1: ESTIMATE VD GIVEN PEAK [GENT] mg/L

Eq. [3a] $VdL/kg = [Dose]\ mg/kg/[Gent]\ mg/L$

$= 4/6.8$

$= 0.59\ L/kg$

STEP 2: WHAT DOSE WOULD ACHIEVE PEAK 8.5 mg/L

Eq. [1] $[Dose]\ mg/kg = Vd\,L/kg \times [Gent]\ mg/L$

$= 0.59 \times 8.5$

$= 5\ mg/kg$

To Estimate Optimal Dosing Interval

STEP 3: CALCULATE K_{EL}, $T_{1/2}$, CL

EQ. [4A, 5A, 6A]

$K_{el} = (Ln\,[C_{t1}] - Ln\,[C_{t2}])\ mg/L/\Delta t\ hr$

$= (Ln\,[6.8] - Ln\,[2.8])\ mg/L/22\ hr = 0.04\ hr^{-1}$

$T_{1/2} = 0.693/K_{el}\ hr^{-1} = 17.3\ hr$

$CL = K_{el} hr^{-1} \times Vd\,L/kg = 0.04 \times 0.59 = 0.024\ L/(hr * kg)$

STEP 5: ESTIMATE TROUGH 1 HOUR BEFORE 48 HOURS DOSING (46 HOURS AFTER PEAK)

Eq. [4a] $K_{el}\ hr^{-1} = (Ln\,[C_1] - Ln\,[C_2])\ mg/L/\Delta t\ hr$

$0.04 = (Ln\,[8.5] - Ln\,[trough])\ mg/L/46\ hr$

Rearrange to solve for [trough]

$Ln\,[trough] = Ln\,[8.5] - (46\,(0.04)) = 0.3\ mg/L$

Gent [trough] $= e^{0.3} = 1.3\ mg/L$

STEP 4: AFTER A 5 mg/kg DOSE, PEAK 8.5 mg/L, HOW MANY HOURS NEED TO ELAPSE BEFORE TROUGH WOULD APPROXIMATE 1 mg/L?

Eq. [4a] $K_{el} hr^{-1} = ln\,[C_1] - Ln\,[C_2]\ mg/L/\Delta t\ hr$

$\Delta t\ hr = Ln\,[peak] - Ln\,[trough]\ mg/L/K_{el}$

$\Delta t\ hr = Ln\,[8.5] - Ln\,[1]/0.04 = 53\ hr$

In 53 hr (three half-lives), levels will be ≈ 1 mg/L, thus q48 hr is reasonable. Gentamicin levels are expected to decline from 8.5 to 4.25 to 2.12, and finally, to 1.06 mg/L

STEP 6: WHAT IS BEST DOSE FOR AVA AT 25 WEEKS?

Gentamicin 5 mg/kg q 48 hr yields

Gentamicin peak 8.5 mg/L and trough 1.3 mg/L

Estimate Peak and Trough after *n* = three doses, dose interval τ = q 48 hr

Eq [14]

$C_{max}\,(n) = (Dose/Vd) \times [(1 - e^{-nK\tau})/(1 - e^{-K\tau})]$

$C_{max} = 5\ mg/kg/0.59\ L/kg) \times [(1 - e^{-(3)(0.04)(48)})/(1 - e^{-(0.04)(48)})]$

$= 8.47 \times [(1 - 0.00315)/(1 - 0.1466)]$

$= 8.47 \times (0.00685/0.8533)$

$= 9.9\ mg/L$

Eq [15]

$C_t\,(n) = (Dose/Vd) \times [(1 - e^{-nK\tau})/(1 - e^{-K\tau})]$

$\times e^{-Kt}$ (conc at time t = 46 hr after peak, after three doses)

$C_{t'} = 5\ mg/kg/0.59\ L/kg) \times [(1 - e^{-(3)(0.04)(48)})/(1 - e^{-(0.04)(48)})]$

$\times e^{-(0.04)(46)}$

Or $C_t = C_{max} \times e^{-Kt}$

$= 9.9\ mg/L \times e^{-(0.04)(46.)} = 9.9 \times 0.158$

$= 1.56\ mg/L$

Gent, Gentamicin.

guidelines for neonates across the gestational age spectrum. Gentamicin has concentration-dependent killing.[3,8] In adults, first dose peak levels of 8 to 10 mg/L are associated with survival in gram-negative bacteremia.[10] In adults, once-daily high-dose regimens have shown enhanced efficacy with less toxicity. Decreased renal toxicity is attributed to the reduction in renal drug accumulation because the uptake of drug into the kidney becomes saturated, limiting the amount of update at high concentrations (saturable drug uptake).[18] The extended interval allows for appropriate washout. In the examples found in Box 45.1, *A-C*, Mary, Jack, and Ava are three newborns who all receive gentamicin as empiric coverage for early onset sepsis.

This example demonstrates how PK properties of drugs in newborns are affected by gestational age. As predicted, prematurity was associated with larger Vd, delayed CL, and longer $T_{1/2}$. In this example, Ava, a 25-week gestation infant, had a threefold reduction in gentamicin CL and a 1.5-fold increase in Vd when compared with Mary, a term infant. Ava has the lowest renal clearance such that after three doses, gentamicin accumulates to higher peak and trough concentrations. Repeat peak and trough levels may be warranted if treatment is continued beyond two doses. With a few gentamicin levels, individual PK properties could be predicted and optimal dosing determined for Jack and Ava that target the PD properties of gentamicin.

Key Points

- The success of drug therapy is determined by complex interactions between the administered drug and its drug exposure profile, the host, and the disease process or the pathogen.
- Wide variation of drug exposures among infants in the NICU can be partially explained by specific drug properties and differences in body composition, organ function, and disease states.
- Optimizing antimicrobial therapy needs to consider both the pharmacokinetic (PK) drug exposure profile and the pharmacodynamics (PD) of drug–organism interactions.
- When therapeutic drug monitoring is available, clinicians can use plasma drug concentrations to estimate individual PK parameters. Once patient-specific PK parameters are known, dosing can be individualized to achieve desired exposure.
- PK studies are needed in premature and term neonates over wide ranges of postnatal ages to determine the effective dosing regimens that target PD exposures.

Infants of Substance-Using Mothers

MARK L. HUDAK

Misuse or abuse of certain illicit and prescription drugs in the United States adversely affects public health in diverse ways and substantially increases overall health care expenditures. Some antenatal drug exposures can produce significant short-term consequences or serious permanent long-term injuries in the child (Table 46.1). The US Department of Health and Human Services, through its annual National Survey on Drug Use and Health (NSDUH), extrapolates the annual use of illegal drugs (including marijuana, cocaine, hallucinogens, methamphetamine, inhalants, and heroin) and the nonmedical use of prescription drugs (pain relievers, tranquillizers, sedatives, and stimulants). The 2016 NSDUH found that 20.1 million Americans age 12 or older, or 7.5% of this population, admitted to misusing or abusing one of more of these types of drugs within the past month of being surveyed. Heavy or binge drinking and smoking in the past month, which also negatively impact public health but are not necessarily illegal activities, occurred at significantly greater rates of 24.2% and 23.5%, respectively.[106]

For many years, marijuana has been the most commonly used recreational drug among the US population age 12 or greater. Recently, a number of states have legalized its use. In 2016, the NSDUH estimated that 4.0 million people (1.5% of the population age 12 or greater) had a marijuana use disorder. The survey estimated the prevalence of substance use disorders for cocaine (867,000), methamphetamine (684,000), heroin (626,000), and inhalants (600,000). In comparison, 1.8 million people had a prescription opioid use disorder. In past surveys, the NSDUH has reported lower, but still unacceptably high, rates of substance use in pregnant women compared to the general population. However, the rate of misuse of prescription opioids during pregnancy has increased by an alarming degree.

Antenatal drug exposure can have a host of effects on the developing fetus. Drugs act as teratogens (from the Greek, meaning "monster producing") when time-dependent fetal exposures cause major morphologic abnormalities of the developing organ systems during the embryonic period (roughly the first 8 weeks of development) or when continued exposure during later fetal life results in minor morphologic abnormalities or physiologic defects. Thalidomide, a medication that became available in Europe in 1959 as an aid for sleeping and "morning sickness" in pregnant women, was distributed for use by physicians in the United States without formal federal approval and serves as the archetypal example of a teratogen. Use of this drug was linked to an epidemic of phocomelia in newborn infants, half of whom died in the first year of life. This tragedy shattered the illusion that the uterine environment sequestered the fetus from adverse effects due to drugs. As a result, in 1962, Congress passed the Kefauver-Harris amendments to the Federal Food, Drug, and Cosmetic Act of 1938 that gave the Food and Drug Administration (FDA) additional authority to regulate drug use in pregnant women.

Drugs can also have other direct and indirect effects on the fetus. Drugs can directly affect fetal growth and maturation; can alter levels of brain neurotransmitters or expression of neural receptors; and can disrupt normal brain morphogenesis throughout the continuum of neurogenesis, proliferation, migration, organization, and synaptogenesis. Examples of indirect effects include uteroplacental insufficiency caused by vasoconstriction of uterine or placental vessels and drug-induced alterations of maternal behavior that secondarily compromise maternal, and hence fetal, well-being. Poor nutrition, diseases transmitted through sexual contact or by needle stick, exposure to violence, and inadequate access to health care can all result in maternal and fetal harm.

Near the time of birth, maternal drugs can produce signs of acute toxicity in the newborn infant, cause persistent abnormal neurobehavior, or result in signs of withdrawal. For some fetal drug exposures, long-term outcome studies suggest a quantifiable impact on internalizing and externalizing behaviors as well as on cognition, especially with respect to higher-level executive functioning.

The distinction between an acute or chronic drug effect and the signs of drug withdrawal is important but on occasion difficult to determine for certain. Signs of acute neonatal drug toxicity abate as the drug is eliminated from the infant. Signs of chronic drug effect on neurobehavior may remain static for a prolonged time independent of fluctuations in total body storage and blood or cerebral spinal fluid concentrations of drug. Alcohol can cause both acute toxic effects (depressed sensorium) and chronic effects (fetal

Abstract

Antenatal drug exposure can affect fetuses in many ways. Teratogens can cause a spectrum of abnormalities from major congenital anomalies to minor malformations. Drugs may also adversely impact somatic growth and maturation of organ systems; alter brain development and long-term cognitive and behavioral functions; cause short-term toxicity due to drug effect; or result in transient neurobehavioral abnormalities consistent with drug withdrawal. Fertile women should minimize smoking; exposure to alcohol, marijuana, and illicit drugs; and misuse of prescription drugs such as opioids, and benzodiazepines to optimize fetal health. Cigarette smoking and marijuana use in pregnancy should be discouraged. Obstetricians should identify pregnant women with alcohol and substance use disorders through screening and refer these women for appropriate treatment. Women with opioid use disorders and their fetuses have improved outcomes with medication-assisted treatment. New opioid prescription during pregnancy should be avoided if possible, and if necessary, short-acting preparations should be prescribed at the minimum effective dose for the minimum duration needed. Most infants exposed close to birth to long-acting opioids will exhibit signs of withdrawal before 5 days of age. Infants at risk for withdrawal should be monitored carefully and treated with intensive nonpharmacologic methods as first-line therapy. Physiologic stabilization using oral opioids may be necessary, and rigorous adherence to a standardized treatment protocol will minimize duration of hospital stay and postnatal drug exposure. Infants exposed antenatally to opioids may be at increased risk for attention deficit disorder and for internalizing and externalizing behavior abnormalities.

TABLE 46.1 Summary of Effects of Prenatal Drug Exposure

	Marijuana	Opioids	Cocaine	Methamphetamines
Short-Term Effects				
Fetal growth	None	Moderate	Moderate	Moderate
Birth defects	None	Possible	None certain	None
Neonatal withdrawal	None	Severe	None	None
Neurobehavior	Mild, transient	Dominated by withdrawal	Mild, transient	Mild, transient
Long-Term Effects				
Growth	None	None	None	Too few data
Behavior	Mild	Mild	Mild–moderate	Too few data
Intelligence	Mild	No consensus	Mild	Too few data
Language	None	Too few data	Mild	Too few data
Achievement	Mild	Too few data	No consensus	Too few data

Adapted with permission from Behnke M, Smith VS. Committee on Substance Abuse and Committee on Fetus and Newborn. Prenatal substance abuse: short- and long-term effects on the exposed fetus. *Pediatrics*. 2013;131:e1009-e1024.

alcohol syndrome) depending on whether the exposure occurred just prior to birth or for a sustained period of time including early gestation. Signs of neonatal withdrawal worsen as levels of the active drug moiety decrease due to its metabolism and excretion. Many intrauterine drug exposures have been associated with signs of neonatal withdrawal.[59] The overwhelming majority of cases of neonatal withdrawal result from intrauterine opioid exposure. Antenatal fetal exposure to benzodiazepines and barbiturates is a less common cause of neonatal withdrawal.

Prenatal and Perinatal Considerations

Prevention of drug effects on the fetus and newborn must begin with preconceptional education of women of childbearing age, their families, and their physicians. Because teenage females who become pregnant are more likely to have engaged in risky behaviors such as illicit drug use, alcohol, and smoking than their nonpregnant peers, early education about drug effects on a fetus and newborn that begins at home and is reinforced in elementary and middle school curricula is important. The pediatrician also has an important role in screening adolescent females for high-risk behaviors and providing factual information in a nonjudgmental manner about the consequences of unhealthy lifestyle choices.

Women of childbearing age and their sexual partners should be counseled to discontinue use of illegal nonopioid drugs before conception. Women with an illicit or prescription opioid use disorder should be encouraged to enroll in a supervised opioid maintenance treatment program. Women who are pregnant should be counseled to seek prenatal care as soon as possible and to abstain completely from use of any illegal drugs and from use of other prescription drugs that are not medically indicated. If a pregnant woman requires new or continued treatment for a medical or mental health condition, her physician should choose the drug class or the specific medication within the drug class that might be expected to confer the highest fetomaternal benefit-to-risk ratio. Often, however, limited data are available to guide decisions. Nonetheless, the pregnant woman should be given the most current evidence-based information about possible short- and long-term consequences to the fetus of any drugs that she uses or that might be recommended for use. Consistent with guidelines from the Centers of Disease Control and Prevention, new opioid prescriptions for pain should be considered only when other medications such as ibuprofen are inadequate. If opioids are required, only immediate-release, short-acting opioids should be prescribed, at the lowest dose and with shortest duration necessary. Concomitant use of opioids and benzodiazepines is contraindicated. These recommendations are particularly critical in women of childbearing age where both a woman and her fetus could be affected by injudicious prescription of opioids.[39] The obstetric provider should conduct periodic SBIRT (screening by interview; brief intervention; referral to treatment) procedures for each pregnant woman under care.[6] A short screening interview can help to determine whether a pregnant woman is likely to be engaged in surreptitious drug use. Several short questionnaires, including CAGE questions adapted to include drugs (CAGE-AID),[21] 4P,[26] and CRAFFT,[71] have been validated. The four CAGE-AID questions are listed in Box 46.1. If two or more yes responses are obtained, this screen has a 70% sensitivity to identify use of illegal drugs or misuse of prescription drugs. A brief intervention consisting of short, focused education and referral to appropriate treatment can be performed for those women who admit to a problem.

• BOX 46.1 CAGE Questions Adapted to Include Drugs (CAGE-AID)

1. Have you ever felt you ought to cut down on your drinking or drug use?
2. Have people annoyed you by criticizing your drinking or drug use?
3. Have you felt bad or guilty about your drinking or drug use?
4. Have you ever had a drink or used drugs first thing in the morning to steady your nerves or to get rid of a hangover (eye-opener)?

If a pregnant woman admits to or is suspected to be engaged in such drug use, she should be asked to provide informed consent for biologic testing. Urine testing is preferred, and positive tests should be confirmed with mass spectrometry/gas chromatography. The clinician should be aware of limitations of testing. Tests vary widely with respect to which specific drugs are assayed. Threshold detection levels are set to avoid false positives, but levels that fall below the threshold owing to low dose exposure or a long interval between the most recent exposure and testing will provide a false negative result. Positive results may result from legitimate use of prescription drugs or in some cases from intense secondhand exposure.

A flexible and nonjudgmental approach to the care of women who abuse illicit drugs or misuse prescription drugs should be adopted, and appropriate community resources for education (e.g., community support groups) and treatment (e.g., rehabilitation centers) should be incorporated into the care plan. The goals of the provider are to establish a trusting relationship with each woman so that she continues regular prenatal care to reduce harm to the woman and her fetus without necessarily counseling cessation of the drug (e.g., in the case of a pregnant mother in an opioid maintenance program), to recognize and treat potential comorbidities, and to counsel about the possible maternal and fetal effects of the use of other drugs. In particular, because catastrophic obstetric complications can accompany the use of certain drugs, the pregnant woman should be educated about the signs of antepartum hemorrhage, premature rupture of membranes, premature onset of labor, and meconium-stained amniotic fluid so that prompt diagnosis and treatment can ensue.

Owing to guilt or to fear of legal action (incarceration, initiation of child welfare proceedings), a pregnant woman with illicit drug use may not have sought prenatal care before presenting with an obstetric complication, the onset of labor, or a medical comorbidity. The legal consequences to a woman abusing illicit drugs or misusing prescription opioids varies among states. Some states have passed punitive legislation whereas others have worked to encourage prenatal access to comprehensive care and treatment without legal repercussions. Emergency room visits and hospital admissions may afford the only windows of opportunity to evaluate such a patient and then to refer her for appropriate multidisciplinary treatment. During obstetric-related hospitalizations, providers can counsel a woman about the prevention of future drug-exposed pregnancies, sexually transmitted diseases, and HIV infection.

Neonatal Considerations

Providers who care for infants during the initial birth hospitalization should understand that maternal self-reporting, restricted implementation of screening procedures, and maternal drug tests do not identify all infants with significant antenatal exposure to drugs. Newborn caregivers should be knowledgeable about patterns of illicit drug abuse or the misuse of prescription drugs in their community. Guidelines for neonatal biologic testing at birth for exposure to illicit drugs are commonly based on associated conditions, such as maternal self-reporting of alcohol or drug use, inadequate or no prenatal care, presence of certain sexually transmitted maternal diseases, premature onset of labor, abruptio placentae, intrauterine growth restriction, congenital malformations, and overt signs of neonatal withdrawal. However, restricting testing of mothers and infants based on these or similar criteria will fail to detect all exposed infants. For these reasons, some have advocated for universal drug testing of all pregnant women or newborns. In 2013, most hospitals in the Cincinnati, Ohio, area implemented a policy of universal maternal testing but allowed the mother to opt out.[95] A study at one Cincinnati hospital showed that this approach did identify substance-exposed infants that conventional screening procedures would have missed.[116]

Marijuana (Cannabinoids)

Whereas the principal active cannabinoid in marijuana (δ-9-tetrahydrocannabinol) readily crosses the placenta, a major metabolite (11-nor-9-carboxytetrahydrocannabinol) remains sequestered in the maternal circulation.[9] However, marijuana remains in the body tissues of chronic users for as long as 30 days and so can result in prolonged fetal exposure.

Marijuana does not independently affect somatic fetal growth and results in no known congenital anomalies. If marijuana affects newborn neurobehavior, the effects are subtle. Newborns have not demonstrated signs of withdrawal secondary to marijuana exposure. No study has discerned an independent effect of prenatal marijuana exposure on childhood growth through adolescence. Multiple studies have suggested that prenatal marijuana exposure exerts long-term effects on behavior (inattention and impulsivity), problem-solving skills, and underachievement in reading and spelling, but not on IQ or language.[13] However, some preparations of marijuana (and synthetic cannabinoids) available today are much more potent than in the past, so that the results of existing studies that evaluated long-term outcomes of fetal exposure to lower potency marijuana may not accurately reflect current risk.[41]

The American Academy of Pediatrics considers maternal marijuana use to be a relative contraindication to breastfeeding. The American College of Obstetrics and Gynecology also discourages marijuana use by lactating mothers.[33]

Opioids

Opioids are a class of chemical compounds that activate μ-opioid (but also κ- and δ-opioid) receptors primarily in the central nervous system (CNS) to produce supraspinal analgesia. The term opiate refers to a subclass of alkaloid opioids. Naturally occurring opioids are present in the opium poppy (e.g., morphine) and occur endogenously (e.g., enkephalins, endorphins, endomorphins). Opioids can be synthetic (e.g., methadone and fentanyl are synthesized from nonopioid precursors) or semisynthetic (e.g., heroin and buprenorphine, which represent modifications of natural opioid compounds) in origin. Other acute effects of opioids include sedation, euphoria, miosis, respiratory depression, and decreased gastrointestinal motility. Prolonged use results in physical and psychologic dependence. As a class of drugs, opioids demonstrate a narrow therapeutic index within a given patient. However, the observed range in dose that achieves a similar therapeutic effect in a large population is fairly wide because of genetic differences in pharmacokinetics and pharmacodynamics.[103] Opioids acutely inhibit the release of noradrenaline at synaptic terminals. The synthetic opioid methadone exerts secondary effects by acting as an N-methyl-d-aspartate receptor antagonist to block the actions of glutamate, the primary excitatory neurotransmitter in the CNS. In patients who are chronically exposed to some opioids, tolerance can develop, because over time the rate of noradrenaline release increases toward normal. The molecular mechanisms that result in substance abuse disorder and produce signs and symptoms of withdrawal are complex and incompletely understood.

Opioids are variably lipophilic compounds of low molecular weight that cross both blood–brain and placental barriers. Because heroin is more lipophilic than morphine, it crosses the blood–brain barrier more rapidly and causes a greater euphoric "high." Methadone is well-absorbed orally; it has a mean half-life of approximately 1 day so that it produces a sustained effect compared to heroin that has a much shorter half-life of 15-30 minutes.

Opioid use in pregnant women carries risks for the mother, fetus, and newborn. Intravenous injection of heroin exposes the mother and her fetus to potential drug overdose, to a greater risk of acute bacterial endocarditis, and, owing to contaminated needles, to serious viral infections (e.g., hepatitis B and C, HIV/AIDS). Other direct and indirect prenatal complications of heroin use include extrauterine pregnancies owing to salpingo-oophoritis, premature labor, premature rupture of membranes, antepartum hemorrhage, fetal demise, and low birth weight. Mothers who use heroin experience rapid fluctuations in opioid concentration because of its short half-life so that the fetus may also suffer intermittent withdrawal effects. Therapeutic opioid maintenance therapy employs an opioid with a long half-life to minimize fluctuations between peak and trough fetal drug levels. A more stable maternal opioid level reduces overall fetal stress.

Maternal opioid detoxification is generally not recommended because of concerns about a possible increased risk of fetal distress and fetal loss during withdrawal[93] as well as a high rate of maternal recidivism. In situations where a mother does not have access to a supervised opioid maintenance program, the American College of Obstetricians and Gynecologists has stated that medically supervised detoxification may be considered.[32] Opioid maintenance therapy with daily methadone (a full μ-opioid agonist and a Food and Drug Administration [FDA] Schedule II controlled drug) for pregnant women can sustain opioid concentrations in the mother and fetus in ranges that minimize opioid craving, suppress abstinence symptomatology, block heroin-induced euphoria, and minimize fetal stress. Other benefits from this once-controversial treatment are optimization of prenatal care and general maternal physical and mental health as well as preparation for potential signs of withdrawal in the newborn infant. Disadvantages of methadone include greater difficulty in achieving successful detoxification after delivery and a more severe and prolonged course of neonatal abstinence syndrome (NAS) compared, for instance, with heroin exposure. These issues have encouraged the development of other opioids as alternative treatments to methadone.

Buprenorphine is a semisynthetic opioid with partial μ-opioid agonist and kappa-opioid antagonist properties that was first introduced in France in 1996 as an alternative to methadone. This drug demonstrates high receptor affinity and low intrinsic activity compared with other opioids. In adults, buprenorphine evokes fewer autonomic signs and symptoms of opioid withdrawal following abrupt discontinuation. In contrast to methadone, which is typically dispensed on a daily basis by methadone clinics, obstetricians who receive special training can dispense buprenorphine for a week or more. In late 2017, the Food and Drug Administration approved an intramuscular preparation of buprenorphine (RBP-6000) that can be dosed once a month. Benefits of this preparation include convenient monthly dosing and the elimination of any possibility of drug diversion.

Subsequent to the Drug Addiction Treatment Act of 2000 that allowed office-based treatment of addiction using FDA Schedule III-V drugs, buprenorphine was approved by the FDA in 2002 as a Schedule III controlled drug for the treatment of opioid dependence. Neither methadone nor buprenorphine is approved for use in pregnant women, and both were categorized by the FDA as class C pregnancy drugs (i.e., animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks). Nonetheless, buprenorphine, either alone

(Subutex) or in combination with naloxone (Suboxone), has been used both as a first-line treatment for heroin addiction and as a replacement drug for methadone. Results from the MOTHER (Maternal Opioid Treatment: Human Experimental Research) study suggest that newborns experience some benefits when mothers are maintained on buprenorphine rather than on methadone. Buprenorphine-exposed infants demonstrated shorter hospital stays (10 vs. 17.5 days) and treatment durations for NAS (4.1 vs. 9.9 days) and required a lower cumulative dose of morphine (1.1 vs. 10.4 mg) compared with infants born to mothers on methadone maintenance.[64] Nonetheless, it is not currently recommended that mothers already on a successful methadone maintenance regimen switch to buprenorphine until it can be shown that this transition does not result in a higher than expected rate of nonadherence to treatment.

Birth Defects

Surprisingly, it is still uncertain whether opioids are teratogenic. A number of studies have suggested an increased risk of fetal anomalies. As an example, one study reported that fetal exposure to opioids resulted in a slight increase in the risk of certain types of congenital heart disease (conotruncal defects, atrioventricular canal, hypoplastic left heart syndrome), neural tube defects (anencephaly, spina bifida), and gastroschisis. The effect was important as evidenced by odds ratios for these anomalies that ranged from 1.8-2.7.[18,79] However, a recent systematic review found that 10 of 12 methodologically adequate case–control studies and 7 of 18 cohort studies found statistically significant associations between maternal opioid use and congenital malformations. In the case–control studies, the most frequent associations occurred with oral clefts and ventricular septal/atrial septal defects, whereas the cohort studies found clubfoot to be the most frequent association.[79]

Growth

The preponderance of evidence suggests that opioids have a mild independent effect on fetal growth, but many confounders exist. Birth weight percentiles of babies born to mothers who adhere to methadone maintenance therapy are greater than those of babies born to heroin addicts.[66] Some studies suggest that buprenorphine-exposed fetuses demonstrate better growth than fetuses exposed to methadone. Analysis of data in the NIH-sponsored Maternal Lifestyles Study revealed that opioid-exposed infants born at or after 33 weeks' gestation had lower birth weight after controlling for other potential confounders.[8] However, prenatal exposure to opioids does not affect long-term growth.[101]

Neonatal Neurobehavior/Withdrawal

Prevalence

Neonatal abstinence syndrome (NAS) is the term that encompasses the constellation of clinical signs associated with opioid withdrawal. Signs of withdrawal develop in 55%-94% of neonates exposed to opioids in utero. The incidence of NAS has increased dramatically in the past decade. Reviews of national hospital discharge records from 2000-2012 found that the incidence of NAS among newborns discharged after birth increased from 1.20-5.8 per 1000 hospital births per year. Rates of NAS varied with geography from a high of 16.2 per 1000 births in the East South Central United States (Kentucky, Tennessee, Mississippi, and Alabama) to a low of 2.6 per 1000 births in West South Central United States (Oklahoma, Texas, Arkansas, Louisiana).[90] Rates of NAS are high in northern New England and in some areas of the Pacific Northwest.

Epidemiology

The distribution of specific opioids that cause NAS likely varies substantially from region to region. In Appalachia and northern New England, the use or misuse (nonmedical use) of prescription opioids (especially of extended-release and long-acting opioid preparations such as OxyContin®) has been a key driver of the growth of the epidemic. Beginning in January 2013, the state of Tennessee implemented mandatory reporting of infants with NAS. Data from January to November 2017, as detailed in Table 46.2, support this supposition and demonstrate that pregnant women commonly access multiple sources of opioids.[109]

How do pregnant women access these potent drugs? The 2016 NSDUH reported that 53% of the population that is dependent or addicted to pain relievers acquired drugs at no cost or purchased drugs from relatives or friends, 38% used drugs remaining from prior physician prescriptions or

TABLE 46.2 Sources of Antenatal Opioid Exposure in Tennessee Infants with Neonatal Abstinence Syndrome (January-November 2017)

Source of Maternal Drug	Cases (%)*
Medication-assisted treatment	69.2
Legal prescription of an opioid pain reliever	5.2
Legal prescription of a nonopioid	8.6
Prescription opioid obtained without a prescription	28.5
Nonopioid prescription substance obtained without a prescription	15.2
Heroin	5.1
Other nonprescription substance	20.3
No known exposure	0.3
Other	3.1

*The sum of cases exceeds 100%, because an infant may have had antenatal exposure from more than one source.

stole drugs from a physician office, and the remaining 9% obtained them by purchase from a dealer or some other way.[106]

Risk Factors

The clinical presentation of NAS varies with the opioid, maternal drug history (including timing of the most recent use of drug prior to delivery), maternal metabolism, net transfer of drug across the placenta, placental metabolism, infant metabolism and excretion, genetics, environmental care, and other factors. Maternal use of other drugs such as cocaine, selective serotonin reuptake inhibitors, barbiturates, hypnotics-sedatives, and cigarettes[29,89] may influence the severity and duration of NAS.

Studies have found either a correlation[34,36,37,54,83,86,96,105] or no correlation[15,19,31,73,82,100] between maternal methadone dose and the incidence and severity of NAS. However, there were substantial variations in the mean and range of daily methadone dose among the populations. Studies that found no correlation tended to include infants born to mothers who had been prescribed higher doses of methadone (50-200 mg/day), whereas those who did note a relationship between maternal dose and NAS sequelae reported lower maternal doses (e.g., less than 50 mg/day) or included women undergoing partial detoxification.[34] So there may be a threshold dose above which nearly all infants will exhibit signs of withdrawal. There is also significant interindividual variability in maternal methadone metabolism[40] that can result in different cumulative fetal exposure in mothers on equivalent methadone regimens.

Some evidence suggests that the presence of certain single-nucleotide polymorphisms of the opioid receptor (OPRM1) and the catechol-O-methyltransferase (*COMT*) genes in babies with NAS correlates with shorter lengths of hospital stay and less severe signs of withdrawal as measured by the need for pharmacologic treatment.[114] These findings are consistent with other studies that have linked these same single-nucleotide polymorphisms to the risk of opioid addiction in adults.

Clinical Presentation

Because opioid receptors are concentrated in the CNS and the gastrointestinal tract, the predominant signs and symptoms of pure opioid withdrawal reflect CNS irritability, excessive autonomic activity, and gastrointestinal tract dysfunction (Table 46.3). Excess environmental stimuli and hunger will exacerbate the perceived severity of NAS. Methadone and buprenorphine may produce slightly different patterns of signs of withdrawal. Abnormal motor findings (tremors, hyperactive Moro reflex) are more common in methadone-exposed infants, whereas buprenorphine-exposed infants are more likely to demonstrate autonomic and gastrointestinal signs (nasal stuffiness, sneezing, loose stools).[48]

Because of differences in drug half-lives, the onset of signs attributable to neonatal withdrawal from heroin may be present at birth or begin within 24 hours of birth, whereas withdrawal of an infant of a mother on a daily methadone maintenance program typically commences around 24-72 hours of age.[119] For both opioids, evidence of withdrawal is occasionally delayed beyond 7 days of age.[65] A consensus has developed that buprenorphine-exposed infants experience a slightly later onset and less severe signs of NAS compared to infants withdrawing from heroin or methadone,[77] but outliers do exist, and some buprenorphine-exposed infants undergo severe withdrawal.[67,74,99] If more than 1 week has elapsed between the last maternal opioid use and delivery of the infant, the incidence of neonatal withdrawal is relatively low.[104] In the acute phase, seizures of unknown etiology and long-term significance have been reported in 2%-11% of infants withdrawing from opioids[55,65,119]; however, abnormal electroencephalograms (EEGs) without overt seizure activity have been reported in greater than 30% of neonates.[91,112] Hence, it is not completely certain that opioid withdrawal in fact causes seizures rather than precipitates marked hypertonicity, hyperactivity, hyperreflexivity, and increased clonus. Subacute signs of opioid withdrawal may last up to 6 months.[35]

Preterm infants have been described as being at lower risk of drug withdrawal with less severe and/or prolonged courses. Infants born at less than 35 weeks' gestation whose mothers received methadone maintenance had significantly lower total and CNS abstinence scores than did term infants of mothers receiving similar methadone dosages.[37] Lower gestational age has correlated with a lower risk of neonatal withdrawal.[81] The apparent decreased severity of signs in preterm infants may relate to developmental immaturity of the CNS that minimizes expression of motor signs, differences in total drug exposure, or lower fat depots of drug. Alternatively, the clinical evaluation of the severity of abstinence may be more difficult in preterm infants, because scoring tools to describe withdrawal were largely developed in term or late preterm infants.[46,80]

TABLE 46.3 Clinical Features of Neonatal Narcotic Abstinence Syndrome

Neurologic Excitability	Gastrointestinal Dysfunction
Tremors	Poor feeding
Irritability	Uncoordinated and constant sucking
Increased wakefulness	Vomiting
High-pitched crying	Diarrhea
Increased muscle tone	Dehydration
Hyperactive deep tendon reflexes	Poor weight gain
Exaggerated Moro reflex	Autonomic signs
Seizures	Increased sweating
Frequent yawning and sneezing	Nasal stuffiness
	Fever
	Mottling
	Temperature instability

Diagnosis

A diagnosis of NAS is established by admitted or suspected maternal use of opioids, supportive findings on maternal or infant biological testing, and some subset of the constellation of clinical signs in Table 46.3. The legal implications of testing and the state or hospital requirement for maternal consent for infant testing vary from state to state and from hospital to hospital.[58] Each hospital should adopt a policy for maternal and newborn testing to avoid discriminatory practices and to comply with local laws.

Biologic testing is most commonly accomplished using neonatal urine specimens. A urine sample must be collected as soon as possible after birth, because many drugs are rapidly metabolized and eliminated.[12,23,24] A negative urine test may not identify remote use of opioids because opioids as well as amphetamines, benzodiazepines, and cocaine metabolites are usually cleared within 1-3 days after birth. Marijuana and cocaine metabolites may be detectable for weeks, depending on maternal usage.[92]

Drugs that are excreted in the hepatobiliary system as well as drugs excreted by the fetal kidneys into the amniotic fluid are concentrated in meconium, which forms in the second and third trimesters. Hence, meconium analysis is most useful when the history and clinical presentation strongly suggest neonatal withdrawal but maternal and neonatal urine screening results are negative. Drawbacks of testing for drugs in meconium are that it is not typically performed by hospitals and that reporting of results may be delayed beyond initial hospital discharge. Meconium must be collected before transitional, human milk or formula stools are passed—otherwise, the assay may not be valid or the reference laboratory may reject the sample. Assay of meconium, although not conclusive if results are negative, is more likely to identify infants of drug-abusing mothers than is testing of infant or maternal urine.[87,97] Other specimens that have been tested in research laboratories are maternal and neonatal hair.[88,113] Testing of umbilical cord tissue using drug class–specific immunoassays has been shown to be in concordance with testing of paired meconium specimens at rates of 97%, 95%, 99%, and 91% for the detection of amphetamines, opiates, cocaine, and cannabinoids, respectively.[84] The availability of this tissue from the moment of birth (in contrast to the inherent delay in collecting urine or meconium) has made this an attractive method of testing in situations in which urine testing is negative.

Withdrawal signs in the newborn may mimic other conditions, such as infection, hypoglycemia, hypocalcemia, hyperthyroidism, intracranial hemorrhage, hypoxic-ischemic encephalopathy, and polycythemia/hyperviscosity.[24,27] If none of these diagnoses are present, a diagnosis of NAS should be entertained. Corroboration may require interviewing the mother about illegal drug use by her partner, friends, and parents as well as her prescription and nonprescription drug use.[24,27]

Neonatal testing should be performed, but by the time signs develop results may not be confirmatory. It is important that the clinical signs are not attributed solely to drug withdrawal on the basis of a positive maternal history without considering and excluding other causes.

Assessment

Infants at risk for NAS should be carefully monitored in the hospital for the development of signs consistent with withdrawal. The appropriate duration of hospital observation is variable and will depend on a careful assessment of the maternal drug history. An infant born to a mother on a low-dose prescription opioid with a short half-life (e.g., hydrocodone; average half-life 4 hours) may be safely discharged if there are no signs of withdrawal by 2-3 days of age, whereas an infant born to a mother on an opioid with a prolonged half-life (e.g., methadone or buprenorphine) should be observed for a minimum of 5-7 days. Maternal or infant screening for comorbidities, such as polydrug abuse and infection with HIV or hepatitis C virus, should be performed. In some populations, more than 25% of mothers of infants with NAS have concomitant hepatitis C.

Discrete and serial clinical scoring of signs of NAS can assist with therapeutic decisions. The Lipsitz tool, also known as the Neonatal Drug Withdrawal Scoring System,[80] is a relatively simple metric with good sensitivity for identifying clinically important withdrawal. However, the Finnegan Neonatal Abstinence Scoring System (Fig. 46.1)[45] is now the predominant tool used in the United States.[98] This more comprehensive instrument assigns a cumulative score based on the interval observation of 21 items relating to signs of neonatal withdrawal.[50] It is important that scoring is done after a baby has received optimal comfort care (i.e., after feeding, diaper changing, and quieting) and that scoring is performed per standardized recommendations. The Finnegan tool has been normalized in opioid-naïve infants. Median scores remained at 2 during each of the first 3 days of life, with 95th percentile scores of 5.5 and 7 on days 1 and 2, respectively.[120]

Recently, a number of centers have adopted use of frequent evaluation of an infant's functional performance as an alternative to quantitative instrument-based assessments. One center has reported a novel comprehensive paradigm for care and assessment that markedly improved neonatal outcomes. Infants were provided hospital care outside of the NICU in rooms that facilitated family rooming-in and environmental control and optimized provision of nonpharmacologic care. Each infant was assessed with respect to feeding (e.g., does the baby take at least one ounce per feeding?), sleeping (e.g., does the baby have uninterrupted sleep for at least one hour?), and consolability (e.g., can a caregiver quiet a baby in 5-10 minutes?)—an evaluation abbreviated as ESC (eat, sleep, console). Vital signs and weight were also monitored. This center witnessed a dramatic fall, compared to historical controls, in hospital length of stay and the use of pharmacologic treatment in babies exposed prenatally to methadone.[51]

	Initials of Scorer			

• **Fig. 46.1** Neonatal abstinence score used for the assessment of infants undergoing neonatal abstinence. Evaluator should check sign or symptom observed at various time intervals. Add scores for total at each evaluation. (Adapted from Finnegan LP, Kaltenbach K. The assessment and management of neonatal abstinence syndrome. In: Hoekelman RA, et al, eds. *Primary pediatric care*. 3rd ed. St Louis: Mosby; 1992:1367.)

Nonpharmacologic Treatment

A plan to institute early supportive care is critical in infants who are at risk for withdrawal. Effective measures include minimizing environmental stimuli (both light and sound) by placing the infant in a dark, quiet environment; avoiding autostimulation by careful swaddling; responding early to an infant's distress signals; adopting appropriate infant positioning and comforting techniques (vertical rocking while the baby is held in the C-position); and providing frequent small volumes of hypercaloric formula or human milk to minimize hunger. In an infant with severe signs of withdrawal, necessary caloric intake to achieve growth has been reported to be as high as 150-250 cal/kg per day because of increased energy expenditure and loss of calories from regurgitation, vomiting, and/or loose stools.[56,117] The infant should be observed carefully to recognize fever, dehydration, or weight loss promptly. The major goals of therapy are to ensure that the infant achieves adequate nutrition and sleep, establishes a consistent pattern of weight gain, and begins social integration. Additional supportive care in the form of intravenous fluids, replacement electrolytes, and gavage feedings are rarely necessary to stabilize the infant's condition in the acute phase.

When possible and if not contraindicated for other reasons, mothers who adhere to a supervised drug treatment program (and who have tested negative for other drugs) should be encouraged to breastfeed so long as the infant continues to gain weight. Breastfeeding or the feeding of human milk has been associated with less severe NAS that has a later onset and less frequently requires pharmacologic intervention.[1,60] Methadone is present in very low concentrations in the human milk of mothers on methadone

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

maintenance therapy. Cumulative daily intake of methadone in fully breastfed infants has been estimated to range from 0.01-0.15 mg/day during the first 30 days of life[62] and 0.15-0.30 mg/day between 30 and 180 days of life.[63] Similarly, the amount of buprenorphine excreted in human milk is small. Although more information is needed to evaluate long-term neurodevelopmental outcome of infants exposed to small quantities of buprenorphine, there is no clear reason to discourage breastfeeding in mothers who adhere to methadone or buprenorphine maintenance treatment.[2] Given the relatively small amounts of opioid ingested via breast milk, it is likely that the process of breastfeeding has potent therapeutic benefit for both mother and baby. Each nursery should adopt a protocol for the evaluation and management of neonatal withdrawal, and staff tasked to care for and assess NAS infants should be trained to use an abstinence-scoring instrument in a consistent manner to minimize interobserver variability.

Pharmacologic Treatment

For the infant who does not respond to optimized nonpharmacologic management, drug therapy may be appropriate to reduce the severity of signs of NAS to mild to moderate but tolerable levels and to prevent complications such as fever, feeding intolerance or weight loss, sleeplessness, and seizures. Since the introduction of the abstinence scales in the 1970s, single or serial withdrawal scores have typically guided the decision to initiate pharmacologic treatment. Infants should be scored at the initial appearance of NAS symptoms and then every 3-4 hours based on feeding times. A typical protocol has been to initiate pharmacotherapy when scores average 8 or higher over three scoring intervals or 12 or higher over two scoring intervals. However, no studies to date have compared the use of different withdrawal score thresholds for initiating drug therapy on short-term outcomes (e.g., severity and duration of withdrawal signs, weight gain, duration of hospitalization, need for pharmacologic treatment, or cumulative drug exposure). Although severe withdrawal may be life-threatening, withdrawal of mild to moderate severity is a self-limiting process. Initiation of drug therapy with the intent to achieve drug levels that result in near resolution of signs of withdrawal guarantees prolongation of drug exposure and of hospitalization, which can disrupt maternal–infant bonding. The only certain benefit of drug treatment is a short-term reduction in clinical signs. No study has addressed whether long-term morbidity related to NAS is decreased by drug treatment, nor whether continued postnatal drug exposure increases the likelihood or extent of long-term neurobehavioral and cognitive problems.

Over the past four decades, a variety of drug preparations have been used to treat NAS, including opioids (tincture of opium, neonatal morphine solution, methadone, and paregoric), barbiturates (phenobarbital), benzodiazepines (diazepam, lorazepam), clonidine, and phenothiazines (chlorpromazine). Most US clinicians now use an opioid (oral morphine or methadone) as their drug of first choice. The AAP recommended against using paregoric, because paregoric contains variable concentrations of other opioids as well as toxic ingredients such as camphor, anise oil, alcohol, and benzoic acid.[5]

If the goal of treatment is to achieve substantial diminution of signs of withdrawal, initiation of drug therapy should begin with an intermediate dose that can be increased as necessary to achieve adequate relief but not completely eliminate the signs of NAS. Recommended initial and maximum doses of opioids and secondary drug treatments are detailed in Table 46.4. When the infant is on a stable and effective dose, a process of steady committed weaning should commence. In practice, weaning regimens vary and have not been systematically studied. Some providers tie weaning strictly to Finnegan scores; one or two abnormal or incorrect scores will then prolong the weaning process or lead to an increase in opioid dose. Other providers will wean by 10%-20% of the initial total dose every 12-48 hours if most of the time the infant exhibits only mild signs of withdrawal, feeds acceptably, demonstrates reasonable weight gain, and sleeps adequately. Failure to achieve acceptable control of signs of NAS despite doses of opioids in the higher ranges of usual practice (see Table 46.3) may indicate prenatal exposures to other nonopioid drugs and suggests the need to consider adding a second medication (phenobarbital; clonidine) in another drug class.[85,98] Phenobarbital, a sedative–hypnotic, is sometimes used as the primary treatment of NAS, but it is also the most commonly used medication to supplement opioid therapy. Adjuvant phenobarbital therapy may be helpful in relieving signs of NAS in severely affected infants and allows tapering of opioid therapy, but prolonged outpatient phenobarbital therapy has been reported.[107] Clonidine is an α_2-adrenergic receptor agonist that has been used successfully in combination with an opioid or other drug in older children and adults to treat the signs of withdrawal.[49,118] There are only limited case series in newborns. Via a negative feedback mechanism, clonidine reduces central nervous system sympathetic outflow and palliates symptoms of excess autonomic activity such as tachycardia, hypertension, diaphoresis, restlessness, and diarrhea. In a small case series, six of seven infants with NAS showed significant resolution of signs when treated with oral clonidine.[57] In a randomized, double-masked, controlled trial, Agthe and co-investigators compared the efficacy and safety of treating NAS with diluted tincture of opium (DTO) plus oral clonidine (1 mcg/kg every 3 hours) versus DTO plus placebo in 80 infants with prenatal exposure to methadone and/or heroin.[3] The combination therapy significantly reduced the median length of treatment for all infants and for infants exposed to methadone, but more infants in the DTO/clonidine group required resumption of DTO after initial discontinuation. Additional pharmacokinetic and safety information is needed before clonidine can be recommended for routine use. Recently investigators have reported success using a sublingual preparation of buprenorphine, achieving shorter duration of treatment and hospital stay compared to a regimen of oral morphine.[72]

TABLE 46.4 Drugs Used in the Treatment of Neonatal Narcotic Withdrawal

Drug	Initial Dose	Increment	Maximum Dose	Comments
Primary Therapy				
Oral morphine[3,61,69,76]	Maintenance dose 0.2-0.3 mg/kg/d Divided every 3-4 hours	0.08-0.16 mg/kg/d	1.2 mg/kg/d	With moderate signs of NAS, start at 0.24 mg/kg/d (0.03 mg/kg every 3 hours or 0.04 mg/kg every 4 hours) If signs of NAS are not sufficiently relieved after initial dose, may give additional dose of 0.03-0.04 mg/kg to achieve adequate level
Oral methadone[75,114a]	Maintenance dose 0.2-0.3 mg/kg/d Divided every 6-12 hours	0.1-0.2 mg/kg/day	0.5-0.6 mg/kg/d	Because of prolonged time for methadone to reach steady-state level, consider loading with 0.2 mg/kg followed by institution of maintenance dose in 6-12 hours
Adjunctive Therapy				
Oral clonidine[3,57]	0.5-1 micrograms every 6 hours		1 microgram every 4 hours	If signs of NAS are controlled with opioid plus clonidine, wean opioid first and then wean clonidine
Oral phenobarbital[5]	Loading dose 10-20 mg/kg Maintenance dose 5 mg/kg/d Divided every 12 hours			Caution that effect of phenobarbital is heightened by systemic opioids

NAS, Neonatal abstinence syndrome.
From Kilpatrick SJ, Papile L, Macones GA. *Guidelines for perinatal care*. 8th ed. Elk Grove Village, IL: American Academy of Pediatrics and American College of Obstetricians and Gynecologists; 2017.

The extant literature does not identify the optimal initial drug or the drug regimen for the treatment of NAS. Published studies are few and generally report small sample sizes. Older studies are often marred by methodological flaws such as quasi-random patient allocation; substantial and often unexplained differences in allocation of patients to treatment groups; imbalances in group characteristics after randomization; failure to mask study treatments; and failure to mask outcome measurements. One recent single-center study showed that methadone compared to morphine treatment significantly reduced hospital length of stay.[20] Results of a larger multicenter study are pending (www.clinicaltrials.gov NCT01958476). With further study, it is possible that an accurate quantification of all prenatal drug exposures will allow specification of optimal pharmacologic treatment. In the future, genetic and epigenetic analyses may more clearly indicate the likelihood and severity of NAS in an exposed infant. In any case, standardization of a comprehensive treatment protocol within a center has been shown to reduce length of stay and length of drug treatment.[53]

Early discharge and subsequent outpatient management of infants with NAS occur in some areas of the country. Existing literature reports experience mainly from abroad and has documented successful but in some cases very prolonged outpatient treatment with both opioids and phenobarbital. Typically, families are carefully screened for eligibility for an outpatient management program. A recent retrospective study reported that 46 of 121 infants with NAS qualified for outpatient management with methadone. The infants with continuing outpatient care had shorter hospital stays and lower hospital costs than the inpatient group. The total duration of medication was higher in the outpatient group, but the total dose of medication was the same between the groups. Readmission rates were similar in the two groups.[115] The prolonged duration of drug exposure with outpatient management raises concerns. Certainly, to safely accomplish home management in these high-risk patients, a multidisciplinary team with frequent assessment of home safety is imperative.

Prevention of NAS

As with most diseases, prevention of NAS is preferable to treatment. Levels of prevention are shown in Box 46.2. The principal means of primary prevention, reducing the number of fetuses exposed to opioids, will require significant

• BOX 46.2 Overview: Levels of Prevention of Neonatal Abstinence Syndrome

Primary Prevention

- Reduce the number of fetuses exposed to opioids
- Alter the nature, dose, and timing of opioid exposure

Secondary Prevention

- Improve the identification of mother–fetal dyads at risk for NAS
- Modify co-exposures that amplify signs of NAS

Tertiary Prevention

- Minimize postnatal drug exposure
- Promote family resiliency and successful home transition

progress toward reducing the national opioid epidemic; this will result in a parallel decrease in the number of women of reproductive age with opioid dependence. Use of implantable long-acting reversible contraceptives in women on opioids who wish to avoid pregnancy is very effective, but implementation has been stymied in many states by unfavorable Medicaid policies on payment. Finally, there is growing experience with medically supervised maternal opioid withdrawal treatment.[14] It appears promising that appropriate management and provision of intensive outpatient support can achieve detoxification that is safe for both the mother and the fetus and that minimizes maternal recidivism. Further careful research is needed about selection criteria, withdrawal regimen, and intensive supportive outpatient care to verify safety and efficacy.

Long-Term Outcomes

Relatively few studies that control adequately for confounding variables have followed drug-exposed children beyond the first few years of life. Nonetheless, there is emerging evidence for an increased risk of hyperactivity and attention-deficit problems in toddlers and school-age children and of abnormalities in memory and perception in older children. Data do not yet exist or are inconclusive with respect to the independent effect of opioids on intelligence, executive functioning, language, or academic achievement[13] (see Table 46.1). An Australian study has documented that children with a history of NAS are at increased risk for abuse, physical injury, and death during a subsequent hospitalization compared to control children.[111]

Benzodiazepines and Barbiturates

Infants with antenatal exposure to benzodiazepines or barbiturates (nonopioid hypnosedatives) may develop signs of drug withdrawal as late as 7-21 days of age. Usually, the mother has been on high doses of the drug for a long duration before birth. Rarely, infants develop signs of withdrawal when a mother has been exposed to therapeutic doses for a short time. As with the opioids, benzodiazepines with longer half-lives (e.g., diazepam) are associated with more severe signs and duration of withdrawal. Common signs include hypertonia or hypotonia; excessive or poor suck; and vomiting. If an infant has severe signs, these infants have typically been treated with phenobarbital. In such cases, outpatient weaning of phenobarbital has been reported to require weeks to months.

Cocaine

Cocaine (benzoylmethyl-ecgonine) is an alkaloid stimulant drug that is derived from *Erythroxylon coca* shrub leaves. Its derivative, cocaine hydrochloride, can be snorted as a powder as well as ingested orally or administered intravenously. In adults, cocaine can cause convulsions, myocardial infarction, and death. Smoking of "crack" cocaine, an alkaloid free-base form of nearly pure cocaine, became widespread in the 1980s and affected large numbers of women of childbearing age. Inner-city hospitals that provided obstetric and newborn care witnessed rising numbers of cocaine-exposed infants. Initially confined to the high-intensity, drug-trafficking areas, this epidemic subsequently spread to remote rural areas. Media attention focused on the fate of so-called "crack" babies and unfortunately resulted in dissemination of much information that was later proved to be untrue or misleading.

Cocaine alters the norepinephrine, dopamine, and serotonin neurotransmitter pathways. Cocaine inhibits norepinephrine reuptake so that norepinephrine concentration increases in the synaptic cleft and produces tachycardia, arrhythmias, hypertension, vasoconstriction, diaphoresis, and mild tremors through persistent stimulation of the postsynaptic norepinephrine receptors. Similarly, its ability to block dopamine reuptake stimulates dopamine neurotransmission and initially results in neurochemical amplification of the pleasure response, increased alertness, enhanced sense of well-being and self-esteem, and heightened energy and sexual excitement. However, compulsive users soon experience anxiety, depression, and exhaustion, and addicts may exhibit mood disorders, paranoid ideation, and sexual dysfunction. Acute tolerance, rebound mood swings, and cravings are explained by regulatory changes in presynaptic and postsynaptic dopaminergic receptors secondary to persistent use. Cocaine blocks the uptake of tryptophan, hence decreasing endogenous synthesis of serotonin and reducing the perceived need for sleep.

Cocaine readily crosses the placenta and is also excreted in breast milk. Metabolism of cocaine occurs primarily by plasma and hepatic cholinesterases that produce inactive compounds that are eliminated by the kidneys. In pregnant women, fetuses, and infants, plasma cholinesterase activity is diminished, increasing the half-life of cocaine. The degree to which an individual is susceptible to the effects of cocaine may be related to genetic polymorphisms of the cholinesterase enzyme. The term placenta may also provide a degree of protection for individual fetuses by converting cocaine

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

into less active metabolites, presumably via cholinesterase activity.

Cocaine use during pregnancy impacts fetal oxygenation by reducing uterine and placental blood flow and impairing fetal oxygen transfer. Pregnant women who use cocaine are at increased risk for spontaneous abortions, abruptio placentae, premature rupture of the membranes, and death. Transient neonatal ventricular tachycardia has been associated with maternal cocaine use shortly before delivery. Higher arterial blood pressure and diminished cardiac output and stroke volume, presumably affected by increased norepinephrine levels, have also been reported in full-term, cocaine-exposed infants compared with drug-free infants on the first postnatal day.

Birth Defects

Animal studies of cocaine exposure show a wide variety of congenital anomalies, including exencephaly, anophthalmia, malformed or missing lenses, cryptorchidism, hydronephrosis, grossly distended bladder, limb reduction defects, ileal atresia, and cardiovascular anomalies. Nonetheless, no consistent teratogenic effect has been found in cocaine-exposed newborns. In the Sprague-Dawley rat model, cocaine causes structural anomalies in a dose-dependent manner during late organogenesis or during the post-organogenic period. Reduction deformities of the limbs and tail and genital tubercle defects occur as a result of hemorrhagic necrosis, disruption, and amputation of existing and developing structures.[7] The etiology of these structural defects may be related to alterations of fetal, placental, and uterine blood flow that cause fetal vascular disruption. Cocaine-induced ischemia may play a role in the development of intestinal atresia and necrotizing enterocolitis, which has been reported in a small series of term and preterm infants prenatally exposed to cocaine.

Growth

Cocaine independently reduces fetal growth.[4,11,30,43,94,121,122] A large single-site cohort study that controlled for potential confounders revealed an independent effect of antenatal cocaine exposure in term infants on birth weight, length, and head circumference.[10] Data from the NIH Maternal Lifestyles Study suggested that the impact of prenatal cocaine exposure on fetal growth may be more pronounced later in gestation, with a cocaine-associated deceleration in growth occurring after 32 weeks' gestation.[8,10] Catch-up growth in early childhood has been observed in some studies and may be a risk factor for later obesity.

Neurobehavior/Withdrawal

Neurobehavioral abnormalities[11,44] frequently occur in neonates with intrauterine cocaine exposure, most frequently on the second or third postnatal days.[25] These abnormalities may include irritability, hyperactivity, tremors, high-pitched cry, excessive sucking, and poor alertness and orientation.[42] Because cocaine or its metabolites may be detected in neonatal urine for as long as 7 days after delivery,[25] observed abnormalities in exposed infants may reflect drug effect rather than withdrawal. In an unmasked study, 6%, 14%, and 35% of infants exposed to cocaine only, heroin only, or cocaine plus heroin, respectively, qualified for treatment on the basis of scoring.[47] Several studies that used masked evaluators found that cocaine-exposed infants had either no[28,52] or minimal[70] withdrawal signs compared with cocaine-naïve infants (i.e., those never exposed). Eyler and colleagues conducted a prospective controlled study of three groups of infants: One group had no documented exposure to cocaine by history or by maternal and infant urine testing; a second group was cocaine exposed but had negative urine screening at birth; and a third group had cocaine metabolites detected in neonatal urine.[44] Observers masked to infant status performed assessments using the Brazelton Neonatal Behavioral Assessment Scale.[17] Infants who were positive for cocaine metabolites did not differ significantly from metabolite-negative infants with a history of exposure or from cocaine-naïve infants. These findings supported neither a withdrawal nor a drug toxicity syndrome. Cocaine-exposed infants have been described as having a higher incidence of abnormal auditory brainstem responses and EEGs compared with unexposed infants.[38,108] In another study, infants with heavy exposure to cocaine had similar Brazelton findings at 2-3 days of age, as did infants with light or no exposure; however, by 17 days of age, heavily exposed infants were more excitable and demonstrated poorer state regulation.[110]

An abstinence syndrome after intrauterine exposure to CNS stimulants such as cocaine and amphetamine has not been clearly defined. Many studies that have assessed behavior and neurologic signs in cocaine-exposed infants have used scoring systems that were designed to evaluate opioid withdrawal.

Long-Term Outcomes

Large prospective studies have begun to show converging evidence for significant, albeit relatively subtle, cocaine-associated deficits in a number of domains of neurobehavioral and neuropsychologic functioning, such as sustained attention, language functioning, and external behaviors. In many of the studies, the observed deficits appear to be statistically robust indicators of cocaine exposure, because they persist even after controlling for numerous environmental confounding variables. Furthermore, in some studies, the effects have been shown to be dose dependent, which lends credence to a teratogenic effect. The importance of cocaine-associated subtle deficits should not be overlooked, because they may be costly in terms of increased numbers of children qualifying for special services in the school system.[78]

Significant deficits in executive function may not become apparent until the child reaches late adolescence or young adulthood as complex frontal lobe neurons complete their

developmental trajectory of maturation into adulthood. Thus "sleeper effects" of prenatal cocaine exposure may emerge later to affect real-life functionality as these children face increasing demands related to academics, social situations, and acceptance of responsibility for the well-being of themselves and others. Cocaine may have a subtle effect on language. Studies are inconsistent with respect to an effect of cocaine exposure on school achievement.

Mothers who use cocaine often use other drugs that independently or via drug–drug interactions can affect long-term outcomes of interest. Environmental risk factors (e.g., poverty and exposure to domestic violence or community violence) and caregiver attributes also modulate long-term outcomes. The presence of factors that can confer resiliency to the child may countermand any adverse effects of antenatal exposure.

Amphetamines

Methamphetamine abuse has been reported among pregnant women,[102] although overall rates are low compared with cocaine and appear to have decreased in the general population.[106] Methamphetamine is an extremely potent sympathomimetic agent that induces euphoria and increases alertness and self-confidence, because it produces a massive efflux of dopamine in the central nervous system. Pregnant women who abuse methamphetamine are at increased risk of preterm birth, placental abruption, fetal distress, and intrauterine growth restriction at rates similar to those for pregnant women who use cocaine. In one study, only 4% of infants exposed to methamphetamine were treated for drug withdrawal, but it was not possible to exclude concomitant abuse of other drugs as contributory in all cases.[102] There are reports of long-term adverse neurotoxic effects of antenatal methamphetamine exposure on behavior, cognitive skills, and physical dexterity.[16,22]

Key Points

- Antenatal substance exposure may act on a developing fetus as teratogens, inhibitors of somatic growth and organ maturation, and disruptors of central nervous system development; in addition, at or shortly after birth, infants may demonstrate signs of toxicity or withdrawal.
- Prenatal exposure to alcohol causes the greatest single drug-induced cumulative preventable intellectual deficit in children.
- Infants with prenatal exposure to opioids are at risk to develop a constellation of signs of withdrawal, known as neonatal abstinence syndrome (NAS), involving primarily the central and autonomic nervous systems and the gastrointestinal system; infants at highest risk at birth are those most recently exposed to long-acting opioids with co-exposures due to maternal smoking or use of selective serotonin reuptake inhibitors.
- All mothers should be interviewed during prenatal care for the use of drugs and substances so that appropriate treatment can be provided to minimize risks to mother and fetus.
- The primary treatment of NAS is intensive nonpharmacologic support and monitoring; infants with severe signs of NAS that significantly compromise feeding and growth, sleeping, and socialization respond to pharmacologic therapy.
- While significant prenatal exposure to alcohol may have devastating long-term effects, the long-term impact of marijuana, opioids, and cocaine on growth, behavior, intelligence, language, and achievement appear to range from no effect to mild effects and may be modifiable by subsequent environmental exposure and intrinsic resiliency.

Developmental Immunology

JOHN T. BENJAMIN AND AKHIL MAHESHWARI

Birth represents a functional watershed in the developing immune system. In utero, the fetus is exposed to a constant barrage of "foreign" antigens that are derived mainly from the mother and must downregulate its immune responses to survive. However, after birth, the neonatal immune system is exposed to a new, more varied set of antigens and must evolve dichotomous responses to simultaneously "contain" microbial populations on various cutaneous and mucosal surfaces and also develop tolerance to commensal microbes and dietary macromolecules. While some components of the neonatal immune system perform adequately and on par with adults, immaturity of several major arms of immunity results in a developmentally regulated, transient state of immunodeficiency during early infancy. This chapter highlights major strengths and limitations of the neonatal immune system.

The immunologic system is broadly comprised of two major host defense mechanisms: innate, or nonspecific, immune mechanisms, and the acquired, or specific, immune mechanisms. By definition, *innate immunity* includes host defense mechanisms that operate effectively without prior exposure to a microorganism or its antigens. Some of these mechanisms include physical barriers, such as intact skin and mucous membranes, and chemical barriers, such as gastric acid and digestive enzymes. Beneath these important protective layers lie phagocytic cells, which constitute the first line of host defense against any microbes that breach the cutaneous and mucosal barriers. Soluble plasma and tissue proteins serve to amplify the function of the phagocytic cells as innate immune effectors. *Acquired,* or specific, *immunity* comprises primarily the cell-mediated (T lymphocyte) and the humoral (B lymphocyte and immunoglobulin) systems.

Both innate and acquired immune mechanisms are necessary for an individual to be fully immunocompetent. These systems are intimately interrelated and interdependent. Phagocytes such as neutrophils and the cells of the monocytes–macrophage lineage are important effectors of innate immunity, because these cells function to ingest and clear microbial pathogens from normal tissues. Monocytes and macrophages also process microbial antigenic material for presentation to T lymphocytes, a pivotal step in the initiation of the adaptive immune response.

Overview of Hematopoiesis

During fetal development, hematopoiesis first begins in the extra-embryonic mesoderm of the yolk sac and later shifts to the liver and then to the marrow. Yolk sac hematopoiesis continues from the 3rd through the 8th-10th week. Hepatic hematopoiesis begins in the 5th week and continues through 20-24 weeks and is mainly erythropoietic; although myeloid progenitors are abundant in the liver, mature neutrophils are not identifiable. Hematopoiesis is observed in the marrow by the 11th week, when committed granulocytic progenitors are first seen in the clavicular marrow. As gestation proceeds to the 20th week, the bone marrow becomes the major site of hematopoiesis and thereafter remains the primary reservoir for replenishing circulating populations of immune cells.

All the cellular components of the immunologic system have limited life spans, and the cells must be constantly replenished from a pool of undifferentiated precursor cells derived from a pluripotent stem cell.[50] Through mechanisms that are not well understood, pluripotent stem cells are stimulated to divide and differentiate into committed progenitor cells that mature into circulating blood cells. Progenitor expansion and differentiation is normally driven and regulated by a variety of growth factors supplied by fibroblasts, endothelial cells, and macrophages present in the microenvironment of the hematopoietic stem cells. Emerging evidence also indicates a role for the local extracellular matrix; specific matrix-associated glycoproteins may favor one cellular lineage over another.

Pluznick and Sachs[39] and Bradley and Metcalf[9] first cultured hematopoietic progenitor cells in semisolid media and named these progenitors *colony-forming units* (CFUs). CFUs producing a mixture of granulocytes, macrophages, and erythrocytes were called *CFU-MIX*, whereas the CFUs producing granulocytes, macrophages, erythrocytes, and megakaryocytes were called *CFU-GEMM*. Other CFUs gave rise to only 1-2 cell lineages: *CFU-G* produced only

Abstract

The transition from fetal to neonatal life marks a critical watershed period in the developing immune system. In utero, the fetus is primarily exposed to maternal antigens and must downregulate its immune responses to survive. In contrast, after birth, the developing newborn is exposed to a greater diversity of antigens, including pathogenic and commensal microbes, dietary macromolecules, and self-antigens. The neonate must thus evolve dichotomous immune responses to simultaneously fight various pathogenic microorganisms while also developing immune-tolerance to self-antigens. Although some components of the neonatal immune system are functionally similar to adults, others are immature, leading to a developmentally regulated state of relative immunodeficiency in the neonate. This chapter highlights the major quantitative and qualitative changes occurring in the innate and adaptive arms of the immune system in the developing fetus and the neonate.

neutrophils, *CFU-M* produced monocytes, *CFU-GM* gave rise to both neutrophils and monocytes, and *CFU-Meg* produced only megakaryocytes. More recently, development of monoclonal antibodies that recognize cell surface molecules expressed on hematopoietic stem cells has permitted the isolation and characterization of these cells.

Innate Immunity

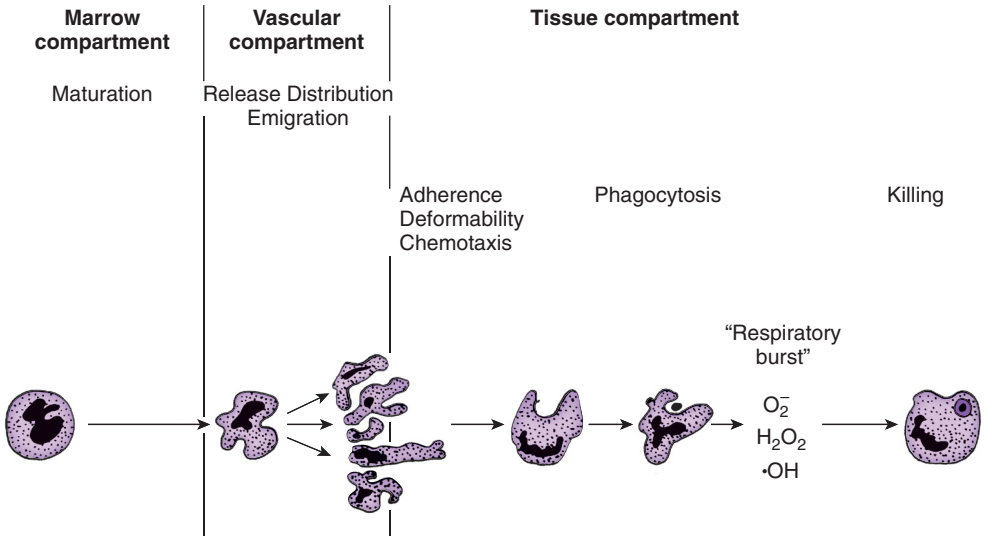
Cellular Components

The most primitive host defense mechanism involves the ingestion and killing of bacteria and other microorganisms by phagocytic cells. Polymorphonuclear neutrophils (PMNs), monocytes, and macrophages are the major cell types that accomplish this aspect of host defense. Natural killer (NK) cells are also important components of the innate immune system, but these cells kill invading pathogens by non-phagocytic mechanisms. All these cell types can eliminate pathogens from the host, but do so more efficiently when the pathogens are opsonized, or coated, by complement components and other soluble proteins of the innate immune system. Similarly, non-phagocytic methods such as lysis of infected cells by PMNs and macrophages are also augmented in the presence of specific antibody to the target organism. This section provides an overview of neutrophils and monocyte/macrophages, important phagocytic cells mediating the innate immune response.

Polymorphonuclear Neutrophil System

Kinetics of Production and Circulation

In the human fetus, granulocytopoiesis takes place almost exclusively in the bone marrow. The PMN system arises from two major hematopoietic progenitors, the CFU-mix and the CFU-GEMM. In the bone marrow, the neutrophil cell lineage includes early precursors, which have a capacity for 4-5 cell divisions (the neutrophil proliferating pool or the NPP), and the later, postmitotic stages that are in the process of differentiation (neutrophil storage pool or NSP). In adults, the NPP contains about 2×10^9 cells/kg body weight, and the NSP contains about 6×10^9 cells/kg body weight.[28] The NPP and NSP together contain nearly 90% of all neutrophils in the body. The NSP constitutes a reserve pool of mature cells, including metamyelocytes, band neutrophils, and segmented neutrophils that may be rapidly mobilized into the circulation in response to inflammation.[28]



Positive and negative regulators of PMN production have been identified. Positive regulatory factors are interleukin (IL)-3, granulocyte-colony stimulating factor (G-CSF), and the granulocyte-macrophage colony-stimulating factor (GM-CSF). Several negative regulators of PMN production have also been identified, including the interferons (IFNs), transforming growth factor-α, macrophage inflammatory protein-1α (CC motif-ligand 3), prostaglandins, and lactoferrin and other iron-binding proteins. Although the mechanisms by which PMNs are released from the marrow under physiologic conditions are unclear, increasing evidence indicates an important role for the chemokine receptor CXCR4. During inflammation, IL-1, tumor necrosis factor (TNF), epinephrine, and complement fragments can stimulate PMN release from the bone marrow. Once released from the marrow, mature PMNs circulate for approximately 6-8 hours before migrating into tissues, where these cells survive for about an additional 24 hours. While in the bloodstream, half of the PMNs are attached to the microvascular endothelium, mainly in the lungs, and the other half are free in circulation. After PMNs emigrate from the blood vessels and enter a tissue, they do not reenter blood vessels but age and die in the tissue. Although the actual site of PMN clearance is unknown, macrophages may play an important role in ingestion and degradation of senescent apoptotic PMNs.

Mature PMNs are first identified in the fetal bone marrow at approximately 14 weeks of gestation.[28] By 22-23 weeks of gestation, the circulating PMN count increases but remains lower than in term newborns. The fetal blood contains 10- to 50-fold higher concentration of CFU-GM than adult blood, yet the fetus has a much smaller total pool of neutrophil progenitors. One explanation for the high concentration of circulating progenitors is that these stem cells may have left one hematopoietic environment (the liver) for another (the bone marrow).

In the mid-gestation fetus and preterm infant, the NSP is very small in size and can be readily exhausted during sepsis.[28] The NPP is also smaller, about one-tenth the size (per kg body weight) of adults. Interventions such as administration of recombinant granulocyte-colony stimulating factor (G-CSF), granulocyte macrophage-colony stimulating factor (GM-CSF), and corticosteroids can release neutrophils from the NSP. Epinephrine can also rapidly release marginated neutrophils into circulation, and a mild demarginating response may also be observed in preterm infants after red cell transfusions.

Normal PMN Concentrations and Neutropenia. Circulating concentrations of PMNs increase dramatically at birth, peak at 12-24 hours, and then decline slowly by 72 hours to remain stable during the rest of the neonatal period. Blood PMN concentrations can be interpreted using one of several available reference ranges.[30,34,43] The absolute neutrophil count can be calculated from a routine complete blood count (CBC) by multiplying the white cell count with the sum of segmented and band neutrophil percentages on the differential count. Manroe et al. were the first to compile reference ranges for blood neutrophil concentrations in neonates using data from a cohort of 434 neonates born at 38.9 ± 2.4 weeks' gestation.[31] They showed that the neutrophil counts peaked at 12-24 hours with 95% confidence limits of 7,800-14,500/μL and then stabilized at a lower value of 1,750 by 72 hours of life. A stable upper limit was achieved at 6.6 days of age. Although these ranges were useful for term and late preterm neonates, these did not include many preterm infants. To address this deficiency, Mouzinho et al. compiled ANC values from 1,788 CBCs drawn from 63

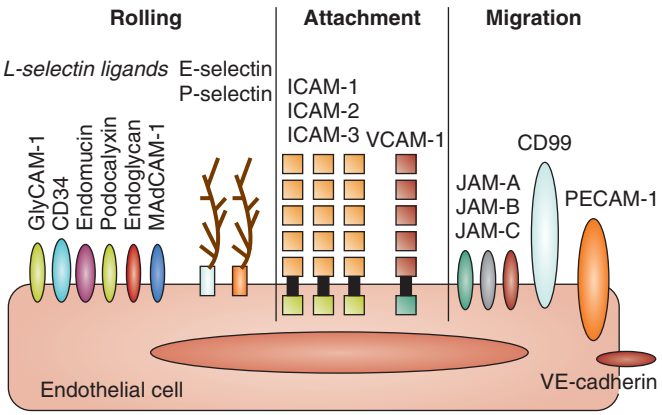
• **Fig. 47.1** Overview of polymorphonuclear neutrophil (PMN) functions. PMNs are produced and mature in the bone marrow over a 2-week period. On release from the marrow, PMNs circulate for 6-8 hours before emigrating into tissues. At sites of infection, chemotactic factors enhance PMN adhesion to and emigration through vascular endothelium, and PMNs migrate in a directed fashion (chemotaxis) toward the pathogens. Phagocytosis of the offending organisms stimulates an increase in production of oxygen metabolites (respiratory burst), which facilitates PMN killing of the ingested microbes.

neonates born at 29.9 ± 2.3 weeks' gestation.[34] Their revised charts were comparable to those from Manroe et al. near the upper limits of blood neutrophil concentrations but showed greater variation at the lower limit. In a more recent study, Schmutz et al. compiled a new set of reference ranges for ANCs using data from 30,354 CBCs from neonates born at 23-42 weeks' gestation.[43] Besides the large sample size, a major strength of this study was the use of automated blood counting instrumentation, which allowed greater consistency in identification of neutrophils. In the interval between 72 and 240 hours after birth, the ANC ranged between 2700-13,000/μL (5th-95th percentile) for infants >36 weeks' gestation, between 1000-12,500/μL at 28-36 weeks, and 1300-15,300/μL at <28 weeks' gestation. The upper limits of ANC in this data set were higher than ranges reported by both Manroe and Mouzinho, which may have been due to the high altitude at which the participating centers were located.



When searching for the cause of neutropenia (<1500 PMNs/mm^9) in infants, a strong suspicion of infection is warranted, although maternal preeclampsia, premature birth, birth depression, intraventricular hemorrhage, and hemolytic disease may result in low peripheral PMN counts. Persistent neutropenia is one feature that is frequently seen in patients who succumb to overwhelming sepsis. Neutropenia in these infants may be due to increased margination of activated circulating cells or to rapid depletion of circulating and bone marrow storage pool PMNs. Failure to provide adequate numbers of PMNs to the sites of microbial invasion may contribute to the risk of overwhelming sepsis in neonates.

Overview of Polymorphonuclear Neutrophil Function

The PMN is qualitatively and quantitatively the most effective killing phagocyte of host defense. Numerous coordinated steps are required to attract a large number of PMNs from the circulating blood into a tissue at the site of microbial invasion (Fig. 47.1). During acute inflammation, first mature neutrophils, and then progressively immature cells, are released from the bone marrow storage pool into the circulation. The circulating PMNs exit the intravascular compartment to enter tissue sites of inflammation in three steps: margination and rolling on vascular endothelium, attachment to the endothelial cells, and transendothelial migration. In the face of microbial translocation across cutaneous or mucosal barriers, a variety of chemoattractants recruit circulating PMNs, including microbial products such as *N*-formyl-methionyl-leucyl-phenylalanine (f-MLP), and host factors such as CXC chemokines (particularly those expressing the tripeptide sequence glutamic acid-leucine-arginine, such as IL-8), products of the complement system (C5a), lipids such as leukotrienes (LTB4) and hepoxilin-A3, collagen fragments containing the tripeptide sequence proline-glycine-proline, and nuclear matrix proteins (such as high-mobility group box-1) that are released during cell death.

Rolling and Adhesion. PMN adhesion to endothelial cells is a crucial step in the recruitment of these leukocytes to inflammatory sites. Although PMNs can adhere to normal or activated vascular endothelium, inflammation is associated with hemodynamic and biochemical changes in blood vessels that facilitate leukocyte adhesion to the vessel endothelial lining. PMNs flowing through an

• **Fig. 47.2** Adhesion of white blood cells to endothelial cells is mediated by several receptor–ligand pair interactions. A distinct set of endothelial molecules are involved in each stage of leukocyte recruitment (rolling, attachment, and transendothelial migration). In the rolling phase, L-selectin receptors on neutrophils bind to one of several ligands on the endothelial cells. Similarly, in the attachment phase, neutrophil β-integrins bind to the ICAM 1-3 or VCAM-1 receptors.

inflamed venule may transiently adhere to the endothelium to "brake" their flow, causing the neutrophils to "tumble" or "roll" on the vascular surface. Leukocyte rolling is mediated via the interaction of L-selectin molecules on neutrophils with endothelial glycoproteins called addressins (Fig. 47.2): glycosylation-dependent cell adhesion molecule-1 (GlyCAM-1), CD34/sgp90, endomucin, podocalyxin, endoglycan, and the mucosal vascular addressin cell adhesion molecule-1 (MAdCAM-1). Endothelial cells also express two selectin molecules, P-selectin/CD62P and E-selectin/CD62E, which interact with the P-selectin glycoprotein ligand-1 (PSGL-1) and L-selectin on leukocytes. Engagement of these selectins activates signaling pathways in neutrophils that initiate neutrophil rolling and activation.[1,29]

Circulating neutrophils usually roll along vascular endothelial cells with transient interactions between neutrophil selectins on the cell surface and counter-receptors on the endothelium. When endothelial cells are activated during inflammation, more selectin counter-receptors are expressed, and additional proteins (intercellular adhesion molecule [ICAM]-1 and ICAM-2) of the immunoglobulin supergene family, which serve as ligands for the neutrophil integrin family, are activated. Specific receptor-ligand interactions at the cell surface membrane facilitating neutrophil adhesion to vascular endothelium are shown in Fig. 47.2.

After a few rolling events, leukocytes slow down and rest on the endothelium. During this phase, the interaction of leukocyte integrins with endothelial receptors initiates signaling events in the endothelium leading to transendothelial migration of leukocytes. Integrins involved in neutrophil trafficking include three heterodimeric proteins, each of which consists of one immunologically distinct "α" subunit (leukocyte functional antigen-1; CD11a, Mac-1; CD11b, p150, 95; CD11c), along with a common "β" subunit (CD18). Monoclonal antibodies directed against CD11b/CD18 inhibit PMN aggregation, spread, chemotaxis, and adhesion to endothelial cells. CD11b/CD18 and CD11c/CD18 serve as complement receptors and mediate complement-coated (fragment iC3b) particle ingestion by PMNs. CD11a/CD18 has been shown to be important in PMN killing of target cells through antibody-dependent mechanisms. Patients with a heritable deficiency of these leukocyte cell surface glycoproteins have recurrent infections characterized by failure to accumulate granulocytes at sites of infection.

Increased interactions of neutrophil cell surface integrins with endothelial ICAM-1 and ICAM-2 results in firm neutrophil-endothelial adhesive interactions. After tight adhesion, the PMN begins a process of diapedesis through adjacent endothelial cells and the intact underlying basement membrane. Once the PMN has penetrated the basement membrane, the cell migrates from the blood vessel into the area of inflammation. In the tissues, initial random migration (chemokinesis) becomes progressively directed (chemotaxis) toward the nidus of microorganisms along concentration gradients of bacterial products or chemotactic factors.

Adhesion of PMNs to artificial surfaces in vitro is comparable for unstimulated PMNs isolated from neonatal or adult blood. When PMNs from term neonates are stimulated with chemotactic factors, adhesion is greatly diminished, however, compared with cells isolated from adults. More profound deficits are displayed by PMNs from preterm infants. Neonatal PMNs show lower selectin expression, defective shedding of L-selectin, and less stimulated mobilization and overall expression of CD11b/CD18 glycoproteins on the plasma membrane. Other causes of diminished stimulated adherence include impaired capacity to upregulate cell surface chemotactic receptors, lower granular content of lactoferrin, less fibronectin binding to the cell surface, and less shape change (failure to increase significantly overall cell surface area on chemotactic factor stimulation). Downregulation of L-selectin expression on term newborn cord blood granulocytes and monocytes during acute inflammation has been shown, although the pattern and level of shedding vary from neutrophils isolated from adult subjects.

Compared to neutrophils from adults, neutrophils from both term and preterm neonates adhere poorly to endothelium. Neonatal neutrophils have lower selectin and β-integrin expression. In neonates, L-selectin expression is lower at birth than in adults and decreases further during the first 24-72 hours. Neonatal "stress," as in perinatal asphyxia, may further reduce L-selectin expression on neutrophils. In addition, neonatal neutrophils display defective shedding of L-selectin. The combination of lower expression and impaired shedding of L-selectin reduces the frequency of neutrophil rolling events, which are a rate-limiting step in the tissue recruitment of neutrophils. Characteristics of preterm vascular endothelium such as lower *P*-selectin expression further contribute to these defects in neutrophil recruitment.

Neonatal neutrophils have lower expression of Mac-1(CD11b/CD18), which correlates with lower neutrophil–endothelial adherence and transmigration. In addition, neutrophils from both preterm and term infants are unable to upregulate Mac-1 expression following stimulation by bacterial products.

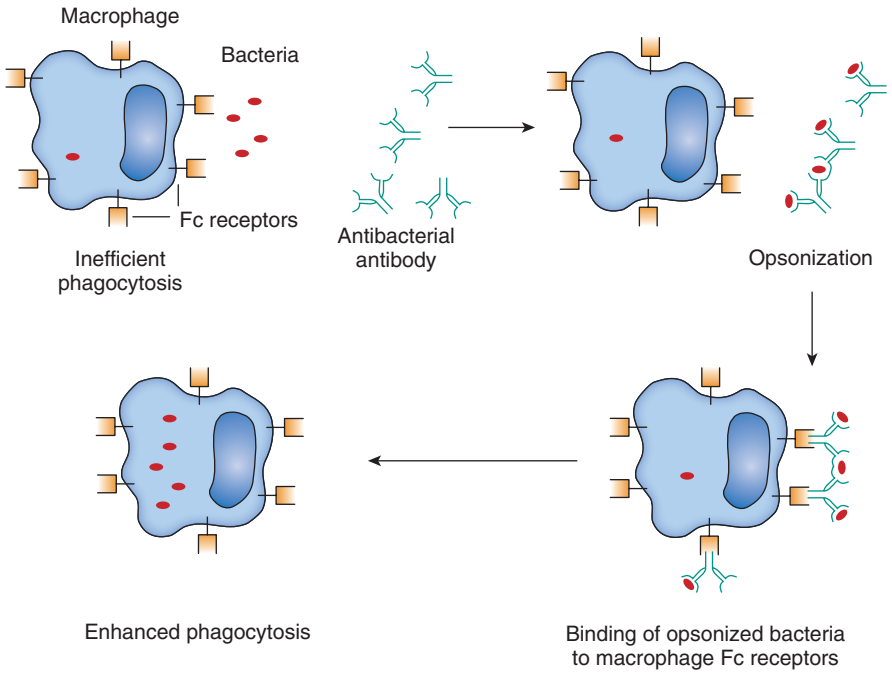
Transendothelial migration of neutrophils is affected to some degree by deformability of neutrophils. Although initial studies reported conflicting data, deformability of mature resting neutrophils appears to be similar in healthy preterm neonates to their full-term counterparts and adults. However, the release of immature neutrophils from the NSP during sepsis is associated with an overall reduction in neutrophil deformability.

Interventions such as administration of recombinant G-CSF increase the expression of β_2-integrins but lower L-selectin expression on neonatal neutrophils (both term and preterm). In contrast, early dexamethasone administration decreases β_2 integrin expression on neutrophils.

Chemotaxis. Chemotaxis is defined as the directed cellular migration along the concentration gradient of a chemoattracting substance. This movement involves a series of orchestrated events, including the binding of the chemoattractant to cell surface receptors, generation of an intracellular second messenger that is coupled to the receptor-ligand binding, and remodeling of the plasma membrane and cytoskeleton to produce shape changes and proper orientation of the cellular contents toward the highest concentration of the chemoattractant. Morphologically, the PMN orients toward the chemoattractant with the formation of a lamellipodium along the leading edge. Most of the intracellular organelles remain at the posterior pole of the cell (uropod). As the cell moves, the leading edge adheres to available surfaces, and contraction of cytoskeletal microfilaments (actin and myosin) pulls along the rest of the cell. Many aspects of this process are poorly developed in PMNs isolated from neonatal blood. Some of the chemotactic defects of PMNs present during the neonatal period persist throughout early childhood.

Neutrophils from both term and preterm neonates have an impaired chemotactic response and migrate slowly compared to adult cells. Although neutrophils from term infants achieve normal chemotactic function by 2 weeks after birth, such postnatal neutrophil maturation begins 2-3 weeks after birth in immature preterm infants and proceeds very slowly. Neutrophils from preterm infants born at 34-36 weeks' gestation achieve normal chemotaxis by 40-42 weeks' postconceptional age (PCA). In more immature preterm infants (<34 weeks), neutrophil chemotaxis improves with time but remains impaired in comparison to adults, even at 42 weeks' PCA. The presence of various clinical confounders makes it difficult to separate the effects of clinical stress from the effects of prematurity on neutrophil function. Gram-negative sepsis may depress neutrophil chemotaxis whereas superficial infections are associated with enhanced chemotaxis.

Neonatal neutrophils bind various chemoattractants normally. However, chemoattractant-induced membrane depolarization, calcium transport, and sugar uptake are relatively less efficient. Neonatal neutrophils show an incremental chemotactic response to increasing chemokine concentrations, but these responses remain lower than adult neutrophils. The chemotactic defect in neonatal neutrophils may be multifactorial, affected by factors such as a larger, poorly motile neutrophil subpopulation; impaired calcium mobilization; and aberrations in intracellular signaling pathways such as NF-B activation. Lower Mac-1 expression can also impede chemotaxis due to impaired neutrophil interaction with the extracellular matrix.



In preterm infants, intrapartum exposure to magnesium sulfate reduces both neutrophil chemotaxis and random motility. Theophylline concentrations in the high therapeutic range (84 μmol/L or 15 μg/mL) cause dose-dependent reductions in neutrophil chemotaxis. Cells from preterm infants are particularly sensitive to this effect. In contrast, theophylline concentrations in the low therapeutic range (28 μmol/L or 5 μg/mL) increase neutrophil activity. Indomethacin, too, has an adverse effect on neutrophil chemotaxis, which is more pronounced in preterm infants. Both G-CSF and GM-CSF increase neutrophil chemotactic responsiveness to other chemoattractants.

Phagocytosis. Phagocytosis is a process of particle ingestion. Most particulate matter must be opsonized (coated) with IgG, complement fragments C3b or iC3b, fibronectin, or other proteins before being recognized and engulfed by PMNs (Fig. 47.3). Neutrophils express IgG receptors such as Fcγ receptors I-III (or CD16, CD32, CD64), C3b (CR1), and iC3b (CR3). After binding of the opsonized microbe by an appropriate cell surface receptor, the PMN extends pseudopods to surround the particle and form a phagocytic vacuole. Microbes may also be ingested without opsonization through several interactions like lectin-carbohydrates on bacterial fimbriae that interact with neutrophil glycoproteins, protein–protein (such as filamentous hemagglutinin that express the argly-asp), and hydrophobic-protein (bacterial glycolipids and neutrophil integrins) interactions.

Neutrophils from preterm neonates show impaired phagocytosis, which corrects by late third trimester or term gestation to become comparable to adults. Preterm neutrophils ingest particles more slowly and ingest fewer bacteria. The lack of opsonic activity is an important consideration, as preterm infants often have lower concentrations of specific antibodies. Adult neutrophils lose their phagocytic efficiency if suspended in serum of preterm infants. Similarly, neutrophils of preterm neonates can increase their phagocytic function following exposure to adult serum or therapeutic immunoglobulin preparations.

Compared to term neonates and adults, preterm neutrophils have a lower expression of CD16 ($F_c\gamma$RIII) and CD32 ($F_c\gamma$RII), the two most abundant neutrophil IgG receptors. In "stressed" preterm neonates with severe RDS or sepsis, CD16 expression may be even lower. Whereas CD16

• **Fig. 47.3** Antibody-dependent opsonization and phagocytosis of bacteria. Antibody binding to particles such as bacteria can markedly enhance the efficiency of phagocytosis. Enhancement of phagocytosis in macrophages involves increased attachment of the coated particle to the cell surface membrane and commensurate activation of the phagocyte, both of which are mediated through occupancy of Fc receptors. (From Abbas AK et al., eds. *Cellular and molecular immunology*. 2nd ed. Philadelphia: Saunders; 1994, with permission.)

expression normally increases to adult levels over the first 3 weeks of life, CD32 deficiency does not correct with time. CD32 is the high-affinity receptor for IgG_2 (important against encapsulated bacteria), and hence CD32 deficiency may represent an important immune defect in preterm neonates. Unlike CD16 and CD32, CD64 expression on neonatal neutrophils (both preterm and term) may be higher than neutrophils from adult subjects. CD64 is not affected by neonatal "stress" as in respiratory distress and/or prolonged rupture of membranes, and emerging data suggest that CD64 might be a useful early marker for bacterial infections.

Recombinant G-CSF and GM-CSF both activate neutrophil phagocytosis. The benefits of intravenous immunoglobulin (IVIG) as a source of opsonic activity remain uncertain. A major limitation may be in the formulation of current IVIG preparations, which may not have adequate concentrations of antibodies against neonatal pathogens.

Microbicidal Activity. The phagolysosome provides an enclosed space in which an ingested microbe is exposed to high concentrations of toxic substances while limiting the exposure of the phagocyte and other cells to these potentially injurious agents. The major killing mechanism in neutrophils involves the generation of highly reactive free oxygen radicals in a "respiratory burst." An NADPH-dependent respiratory burst oxidase localized on the cell membrane (and therefore, the phagosome membrane) reduces molecular oxygen (O_2) to superoxide anion ($O\bullet_2^-$). Subsequent generation of hydrogen peroxide (H_2O_2) and the hydroxyl radical (OH•, formed in the presence of iron) also contributes to the microbicidal capacity of neutrophils.[1]

These oxygen-dependent bactericidal mechanisms can be broadly divided into myeloperoxidase (MPO)-independent (such as hydrogen peroxide) and MPO-dependent (MPO catalyzes reactions between H_2O_2 and halides to form highly reactive products). H_2O_2 is a weak bactericidal agent per se, but the MPO-H_2O_2-halide system increases its efficacy by nearly 50-fold. The bactericidal effects of free oxygen radicals are due to oxidizing effects on various components of the bacterial cell wall.

Although preterm neutrophils have a higher oxygen consumption and normal/elevated release of superoxide and H_2O_2, the respiratory burst is, overall, depressed. This deficiency may be more marked in preterm infants with a high severity of sickness. Neutrophil oxidative burst remains impaired in preterm infants despite opsonization with IgG and complement.

Perinatal events can influence the respiratory burst in neonatal neutrophils. Labor and vaginal delivery activates the generation of free oxygen radicals in neonatal neutrophils. In contrast, perinatal distress can suppress the neutrophil respiratory burst. Both LPS and cytokines such as interferons and TNF can prime neutrophils for an accelerated respiratory burst in vitro, but prolonged exposure to these agents (during sepsis) can dampen their effect. Reduced respiratory burst activity in preterm infants

correlates with impaired intracellular killing of *S. aureus* or *E. coli.* Whereas bacterial killing by neutrophils from term neonates has consistently been found to be normal, killing of staphylococci was impaired in preterm neonates.

The postnatal maturation of respiratory burst response varies according to gestational age. During the first week, infants born at 24–28 weeks have a lower respiratory burst than those born at 29-35 weeks. The differences between preterm infants born at different gestational ages disappear in about 2 months, but overall, neutrophils from preterm infants continue to have a weaker oxidative burst than adults. The postnatal maturation of the respiratory burst may not be seen at all in sick preterm infants receiving intensive care.

In "stressed" preterm infants receiving intensive care, recombinant GM-CSF can boost the neutrophil respiratory burst to levels seen in term neonates. Similarly, G-CSF can enhance neutrophil respiratory burst response in septic preterm infants. In adults, hypertonic saline may enhance host response to bacterial challenge by augmenting superoxide formation in neutrophils. Intracellular killing may also be augmented by fluoroquinolones such as ciprofloxacin, which have a potent intraphagosomal bactericidal activity against both gram-positive and gram-negative bacteria.

Neutrophils also contain additional elaborate nonoxidative killing mechanisms, including cationic proteins like defensins, bactericidal/permeability-increasing protein (BPI), and LL-37; proteolytic enzymes such as lysozyme, proteinase 3, and neutrophil elastase; and metal chelator proteins such as lactoferrin.[1] Defensins are broad-spectrum antimicrobial peptides with activity against gram-positive and gram-negative bacteria, fungi, and enveloped viruses. BPI binds lipopolysaccharide (LPS) and blocks its effects, can damage the outer membrane of gram-negative bacteria, and has some opsonic activity. Lactoferrin, an iron chelator, is bacteriostatic as it deprives bacteria of the iron required for growth. Lactoferrin is also involved in neutrophil degranulation, in oxygen radical production, and in granulocytopoiesis. Lysozyme hydrolyzes a glycoside bond in the bacterial cell wall peptidoglycan. Primary granules also contain other cationic antibacterial proteins such as azuricidin, indolicin, and cathelicidins.

Another elegant antimicrobial defense system demonstrated by neutrophils is their ability to form neutrophil extracellular traps (NETs). Upon activation, neutrophils can undergo a type of cell death in which chromatin is released from the cell in the form of NETs. These NETs also contain histones and other antimicrobial proteins that function to trap and kill microbes in the extracellular space. However, neonatal neutrophils are deficient in their ability to form NETs.[4] The mechanisms leading to NET formation and its ability to fight infectious agents is still not well understood and is an active area of investigation.[1]

Degranulation. Neutrophils contain three major types of granules: (1) the "azurophilic" granules (stain positive with the azure A dye), (2) "specific" granules (do not stain with azure A), and (3) "gelatinase" granules. Azurophilic granules contain myeloperoxidase (MPO); proteolytic enzymes such as cathepsin G, proteinase-3, and neutrophil elastase; and antimicrobial proteins such as defensins and the bactericidal permeability-increasing protein (BPI). These granules release their contents into the phagolysosomes and are involved in intracellular killing. The specific granules contain antibacterial agents such as lactoferrin and lysozyme, receptors for complement components, and bacterial products such as f-MLP. Specific granules fuse with the cell membrane to release their contents by exocytosis and also bring functionally important membrane proteins such as integrins, cytochrome-b_{558}, and receptors for chemotactic agents and opsonins to the cell surface. Specific granules play an important role in extracellular killing. Gelatinase granules contain fewer antimicrobial cargo but are storage sites for gelatinases and other metalloproteases.[1]

Neutrophils from term neonates have granule content and degranulation responses similar to adults. However, neutrophils from preterm infants have a lower capacity to release BPI, elastase, and lactoferrin than in adults and term infants. G-CSF activates mature neutrophils without degranulation of primary granules, whereas GM-CSF induces degranulation and exocytosis of granule contents. However, anti-inflammatory agents such as corticosteroids and indomethacin inhibit the degranulation of secondary granules.

Summary

PMNs of term and preterm infants are limited in chemotactic, phagocytic, and microbicidal activities. The physiologic rationale for the use of hematopoietic growth factors to improve neutrophil function qualitatively and quantitatively has been well established. The use of G-CSF and GM-CSF has been shown to increase the neutrophil storage pool, induce neutrophilia, and improve many neutrophil functions. In meta-analysis, G-CSF administration was shown to reduce mortality in neonates with sepsis.[5] However, when the nonrandomized studies were excluded, the analysis did not remain statistically adequate. G-CSF therapy is generally well tolerated in neonates, and many centers now use recombinant G-CSF in infants with severe neutropenia (absolute neutrophil counts <500 for 48 hours or between 500-1000 for more than 5-7 days).[16] However, based on current literature, a clear recommendation for the use of these growth factors to decrease the incidence of morbidity and mortality associated with sepsis in newborns cannot yet be made. Further studies are needed in high-risk neonatal subgroups with sepsis, as preliminary evidence suggests that such an approach may be more effective. The newer, longer-acting polyethylene glycol-conjugated or glycosylated forms of G-CSF also hold promise as viable therapeutic alternatives.

Mononuclear Phagocyte System

Production and Differentiation

The mononuclear phagocyte system comprises bone marrow monocyte precursors, circulating monocytes, and mature

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

macrophages. As with the granulocyte lineage, mononuclear phagocytes are derived from CFU-GM progenitor cells. Several hematopoietic growth factors influence mononuclear phagocyte production. CSF-1 or macrophage CSF is the major hematopoietic growth factor influencing maturation and production of mononuclear phagocytes. Cells of this lineage seem to be unique in expressing cell surface receptors for CSF-1. On leaving the bone marrow, monocytes circulate for nearly 72 hours and then migrate into tissues, where the local extracellular milieu strongly influences monocyte-to-macrophage differentiation. Although the ultimate fate of macrophages is unclear, these cells have been observed to live for several months in many human tissues.

Embryonic macrophages are first seen in the yolk sac at 3-4 weeks of gestation. Unlike macrophages in the fetus and the adult that are derived from circulating monocytes, these large-sized histiocytic cells develop in the early embryonic period from yolk sac progenitors prior to the first appearance of monocytes. At 5 weeks of gestation, two distinct cell lineages with a dendritic/macrophage structure can be identified in the yolk sac, mesenchyme, and the fetal liver. The larger subgroup is MHC II–negative, and there is only a minor population that expresses these antigens. MHC II–negative cells also appear in the thymic cortex, in the marginal zones of lymph nodes, in the splenic red pulp, and in the bone marrow. A few MHC II–positive cells are seen in the liver at 7-8 weeks of gestation, the lymph nodes at 11-13 weeks of gestation, and the T-cell areas of the developing thymic medulla by 16 weeks of gestation. Subsequently, the numbers increase gradually, and MHC class II–positive cells are also seen in the skin and gastrointestinal tract.

During the second month of gestation, as hematopoiesis becomes established in the fetal liver, monocytes are seen in high proportions and constitute nearly 70% of all hematopoietic cells. Over the next 6 weeks, as the erythroid cells predominate, this proportion falls to 1%-2%. The first monocytes in circulation are not seen until about the fifth month of gestation and remain uncommon until the bone marrow becomes the predominant site of hematopoiesis. At 30 weeks, monocytes comprise 3%-7% of hematopoietic cells. Term cord blood studies show a relative monocytosis, which persists during the neonatal period. Although there is some disagreement between various reports on normal blood monocyte counts in neonates, recently normal ranges of absolute monocyte counts using data from more than 62,000 blood counts have been described, where it was shown that blood monocyte concentrations increase almost linearly between 22-42 weeks' gestation. Monocyte concentrations also increased during the first 2 postnatal weeks.[12] These data are consistent with previous kinetic studies in human fetuses, which show a similar maturational increase in monocyte precursors. In neonates, monocytosis has been associated with lower birth weight and gestational age, multiple transfusions, albumin infusions, and theophylline therapy. Monocytosis has also been described in infants with congenital infections, such as candidiasis and syphilis, and immune-mediated neutropenia.

Monocyte-to-macrophage differentiation has been well characterized, but the control mechanisms involved remain elusive. As monocytes develop into macrophages, certain morphologic changes occur. The cells increase in diameter more than threefold and acquire more cytoplasmic granules and vacuoles. Differentiation is also associated with increased expression of cell surface receptors, biosynthesis of numerous biologically active molecules, and improved phagocytic activity. Similar to PMNs, all mononuclear phagocytes have a well-developed cytoskeletal apparatus that is important in determining cell mobility and participation in many adhesion-related functions.

Information on tissue macrophage kinetics in the neonatal period is mainly from autopsy studies. The size of the macrophage pool varies in different organ systems. In the gastrointestinal tract, macrophages appear in the *lamina propria* as early as 10 weeks of gestation, and a sizable macrophage population can be seen during midgestation. In contrast, the alveolar macrophage population remains small in the fetus and expands during the early neonatal period.[6] This increase may result both from an influx of monocytes from the circulation as well as from clonal expansion in situ.

A lower proportion of cord blood macrophages stains for esterase, although there are no discernible differences in peroxidase activity. Neonatal monocytes have lower expression levels of the aforementioned surface markers, except for CD14. During infections, macrophages show an "activated" phenotype with enhanced phagocytic function, enhanced capacity to kill facultative intracellular microorganisms. These cells can be identified by unique morphologic features like larger diameter and greater number of pseudopods and pinocytotic vesicles.

Mononuclear Phagocyte Functions

Unlike neutrophils, the major host defense functions of monocytes in cord blood of term infants are intact. Cord blood monocytes show adherence, random migration, bactericidal activity, phagocytosis-associated chemiluminescence, production of superoxide anion ($O\bullet_2^-$), and generation of hydrogen peroxide at levels comparable to those of cells from healthy adult volunteers. One exception may be in the ability of cord monocytes to ingest group B streptococci (GBS). However, phagocytosis of GBS improved when neonatal monocytes were incubated with organisms preopsonized with fibronectin and IgG. The ability of fetal and neonatal monocytes to kill a variety of pathogens including *S. aureus*, *S. epidermidis*, *E. coli*, and *C. albicans* appears to be equivalent to that of adults.

Chemotaxis of cord blood monocytes is nearly normal, but monocytes isolated from the peripheral blood of newborns do not migrate normally. The chemotactic activity of these cells sequentially declines over the first week of life before slowly improving and achieving (by age 6 years) the chemotactic activity of monocytes isolated from the blood of adults. Impaired migration in response to

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

chemoattractants may be a primary factor in the delayed influx of monocytes at inflammatory sites during the neonatal period.

Cytokine Production. Resident macrophages are often the first phagocytic cells of the innate immune system to encounter invading pathogens. These cells serve important host defense functions through phagocytosis and also as sentinel cells that regulate local inflammatory responses by producing various cytokines and chemokines. Most studies on monocyte/macrophage cell function have been done on cord blood, and fetal cells have not been studied to the same extent so far. Term cord-blood monocytes produce IL-1, IFN-α, and TNF in concentrations that are comparable to adults, but the levels of IFN-γ, IL-8, IL-10, and GM-CSF are lower. These cells also produce lower concentrations of extracellular proteins like fibronectin and bioreactive lipids like leukotriene B_4. Impaired monocyte function in neonates may be partially responsible for poorer cytokine responses of neonatal T cells.

Generally, mononuclear phagocyte recruitment and accumulation lag behind the brisk PMN influx by 6-12 hours, but the former process persists for several days. In addition to the host defense functions, mononuclear phagocytes also help regulate the process of tissue debridement and initiation of wound repair. During resolution of inflammation, the macrophage populations switch from a pro-inflammatory to an anti-inflammatory phenotype.[44] Emerging evidence indicates that macrophages are dynamic and heterogeneous cells, which are polarized into the classically activated M1 macrophages that express various inflammatory signals and the M2 macrophages that display an anti-inflammatory profile.[51] The effect of development on macrophage polarization is unclear.

Summary

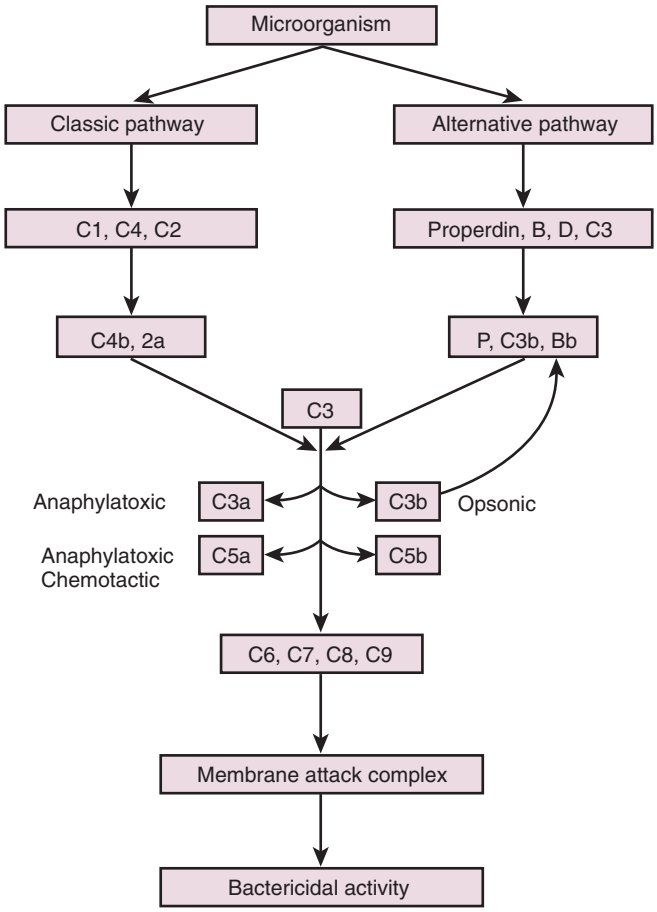
The influx of mononuclear phagocytes to sites of inflammation is delayed and attenuated in newborns. This defect is most likely related to the impaired chemotactic activity displayed by the peripheral blood monocytes of these infants. Phagocytosis and microbicidal activity seem equivalent to the level displayed by mononuclear phagocytes of adults. In vivo studies of macrophage function at birth and during the neonatal period are limited, but pulmonary alveolar macrophages seem to function normally in the infants examined to date.

Humoral Components

Overview of Serum Opsonins

The role of humoral factors in the enhancement of leukocyte phagocytosis of bacterial pathogens has been known since the turn of the 20th century. These heat-labile and heat-stable plasma proteins, called opsonins, consist mainly of serum antibodies and components of the complement system, although several other proteins seem to play important roles (see later). The opsonic activity of plasma or serum from newborn term infants is equivalent to activity measured in sera from adults until the test concentrations of plasma or serum are reduced to less than 10%. At low serum concentrations, opsonic activity against various bacteria and fungi is diminished during the neonatal period. Opsonic activity is reduced even more in premature infants and persists at test concentrations of plasma or serum greater than 10%. These deficiencies in opsonic activity may be related partly to lower complement and IgG and IgM concentrations in newborns. The complement system is described in the following section. The opsonic role and other functions of immunoglobulins are reviewed later, when antibodies are discussed as humoral components of specific immunity.

Complement System



Activation Pathways and Overview of Functional Products

The complement system plays an important role as one of the principal humoral effector pathways of immunity. Its major function is to facilitate the neutralization of foreign substances either in the circulation or on mucous membranes. This function is accomplished by a series of plasma proteins that are involved in specific and nonspecific host defense mechanisms.

The classic pathway of complement activation requires the presence of specific antibodies against a particular antigen and the formation of immune complexes (Fig. 47.4). Two antibody molecules of the immune complex are bridged by the first component of complement, C1, which initiates a chain reaction in which one activated component serves as the enzyme that cleaves the next component in line. The order of component activation in the classic pathway is C1, C4, C2, and C3. Peptides with different biologic activities are created and either remain attached to the site of activation or diffuse into the milieu. C1 is itself a multimeric complex consisting of C1q, C1r, and C1s. When C1q binds the Fc portion of IgG or IgM immune complexes, C1 is activated. This cleaves C4, generating the C4a and C4b fragments. C4b then cleaves C2 into C2a and C2b. The C4b2a complex binds to microbial surfaces and acts as the C3 convertase, a protease that cleaves the third component of complement, C3, into membrane-bound C3b and the fluid-phase C3a. With the generation of C3b, the classic pathway merges with the other mode of complement activation, the alternative pathway.[11]

In contrast to the classic pathway, the alternative pathway may be activated by bacterial or mammalian cell surfaces in the absence of specific antibodies. This activation is possible because small amounts of C3 in the circulation are constantly being converted to C3b. This complement component can bind to cell surfaces, interact with the next alternative pathway components in sequence (factors B and D), and form a potent enzyme for further C3 activation (C3bBb). C3b originally generated by the classic pathway may involve this amplification loop of the alternative pathway and significantly enhance local C3 activation. The lectin pathway provides yet another mode of complement

• **Fig. 47.4** Complement system activation cascade. Activation of the classic pathway (*left*) and the alternative pathway (*right*) causes generation of soluble factors that amplify phagocyte functions and produce a membrane-bound attack complex that damages cell membranes. (From McLean RH, et al: Genetically determined variation in the complement system: relationship to disease. *J Pediatr.* 1984;105:180, with permission.)

activation. This pathway is activated by binding of Mannose-binding lectins and ficolins with carbohydrate moieties on the surface of pathogens. These lectins are normally bound in complexes with MBL-associated serine proteases (MASP). Activation of MASP-2 results in cleavage of C4, forming C4a and C4b, which, as in the classical complement pathway, then cleaves C2 into C2a and C2b. The C4b2a complex that is then formed acts as the C3 convertase enzyme, resulting in C3 cleavage and activation.[11]

The central location of C3 in the complement pathway is important not only because the classic and alternative pathways converge at this point, but also because many biologic effects are determined by the interaction of this important molecule with various regulatory systems. The direction in which the complement pathway proceeds depends on the surface to which the C3b molecule is bound. Certain bacteria and other membranes offer a "protective surface" that favors the binding of C3b to factors B and D and the assembly of the enzyme that converts the next component in line, C5, into two biologically active fragments. The smaller product, C5a, acts as an anaphylatoxin to promote many aspects of acute inflammation, including chemoattraction of leukocytes and increasing vascular permeability. The larger fragment, C5b, remains attached to the C5 convertase on the membrane and assembles the components of the membrane attack complex: C5b, C6, C7, C8, and C9. Insertion of this complex into the cell membrane results in loss of membrane functions and cellular integrity.

In the absence of a protected site, C3b is exposed to factors I and H, which facilitate cleavage of C3b into iC3b and C3d. All these fragments of C3 can function as ligands for cellular receptors, which are located on erythrocytes and almost all immunocompetent cells. The C3b receptor (CR1) is known to mediate adherence of complement-coated complexes to erythrocytes, neutrophils, and mononuclear phagocytes and plays an important role in the clearance of immune complexes, bacteria, and cellular debris from the circulation. Other receptors also have been identified, such as the C3b binding protein, CR2, which is found on B lymphocytes and eosinophils. Its function awaits clarification, but there is evidence that adherence of the Epstein-Barr virus is mediated by this receptor. Finally, the iC3b receptor (CR3, CD11b/CD18) seems to be important for the ability of the host to overcome bacterial invasion. As previously mentioned, patients with a genetic deficiency of leukocyte cell surface CR3 experience severe recurrent bacterial infections. In addition to their roles in innate immunity, complement receptors may play important roles in adaptive immunity. Both CR1 and CR2 receptors are present on B-lymphocytes and play roles in B-cell differentiation and responses when presented with antigens. Similarly, T cells express receptors for the anaphylotoxins C3a and C5a, which maintain T-cell proliferation, viability, and differentiation.[41]

Ontogeny and Analysis of the Complement System in the Neonatal Period

Complement proteins are synthesized early in gestation. Synthesis of C2, C3, C4, and C5 can be confirmed between 8 and 14 weeks of gestation. Most evidence, derived through several methods, confirms that there is no transplacental passage of complement components. The components of the classic and alternate complement system and their functional activity (measured by total hemolytic complement assay) in full-term neonates are generally lower than normal adults (Table 47.1). Most serum alternative complement component values reach adult levels by 6-18 months of age. Proteins in the lectin pathway are also lower in neonates compared to adults and are decreased in preterm compared to term infants.[33]

Summary

Whether deficiencies in the complement system predispose a neonate to infection has not as yet been established. Defects in the complement system and in the alternative pathway, in particular, are likely to play a role in susceptibility to infection, especially in preterm infants. Newborns

TABLE 47.1 Summary of Published Complement Levels in Neonates

Complement Component	Mean Percentage of Adult Levels	
	Term Neonate	Preterm Neonate
CH_{50}	52-81	32-78
AP_{50}	49-65	49-54
C1q	53-73	27-37
C4	54-80	42-59
C2	62-77	69
C3	50-97	39-60
C5	67-79	60-71
C6	44-58	35-39
C7	67-120	73-75
C8	36-38	29
C9	14-55	33-56
B	36-73	36-53
D	120-129	—
P	27-71	13-65
H	56-73	60
I	39-58	45

Adapted from McGreal EP, et al. Off to a slow start: under-development of the complement system in term newborns is more substantial following preterm births. *Immunobiology*. 2012;217:176-186.

have a limited spectrum of antibody transmitted across the placenta; they receive IgG, no IgM, and little antibody to the entire range of gram-negative bacteria. The classic pathway has relatively little value at and shortly after birth. It follows that, in the absence of specific antibody, activation of the biologically active fragments and complexes of the complement system through the alternative or lectin pathways becomes an extremely important defense mechanism for neonates during the first encounter with many bacteria. In most neonates, functional deficiencies in these pathways, in conjunction with impaired functioning of PMNs, is likely to be clinically relevant as suggested by lower levels of MBL and ficolin lectins in neonates with culture-proven sepsis.[42]

Fibronectin

Fibronectins are a class of multifunctional, high–molecular weight glycoproteins that serve to facilitate cell-to-cell and cell-to-substratum adhesion. Fibronectins play a key role in organogenesis and for hemostasis, hematopoiesis, inflammation, and wound healing. In many pathophysiologic conditions (e.g., sepsis, thrombosis, cancer, organ fibrosis), the normal structure, physiology, and function of fibronectins are altered in a way that contributes to the underlying tissue or organ dysfunction.

Structure and Function

Fibronectins exist as soluble and insoluble dimeric molecules. Soluble fibronectins have been identified in nearly every body fluid tested (synovial, ocular, pleural, amniotic, cerebrospinal, and others). Insoluble fibronectins are present in many connective tissues and extracellular matrices throughout the body. It is apparent that structural variants (isoforms) of fibronectin exist and that expression of these isoforms is highly regulated in a cell-specific and tissue-specific fashion.

All fibronectins are capable of binding to multiple ligands simultaneously. The modular design of these glycoproteins translates into a linear array of active globular functional domains. Fibronectins display individual binding sites for some molecules and multiple sites for others. Fibronectins bind certain bacteria, heparin, fibrin, IgG, and DNA in several separate domains, but other bacteria, matrix molecules, actin, complement component C1q, and gangliosides are bound at unique sites in individual domains. In this way, fibronectin facilitates the interaction of cells with other cells, bacteria, tissues, particles, and soluble proteins.

Circulating plasma fibronectin concentrations are reduced in fetal cord blood (120 fg/mL) and in term infants (220 fg/mL). Premature infants of 30-31 weeks' gestation have significantly lower plasma concentrations (152 fg/mL) than term infants. Lower plasma concentrations in neonates are correlated with decreased synthetic rates, but plasma clearance of fibronectin also is measurably slower. Plasma fibronectin concentrations are reduced further in infants with respiratory distress syndrome, birth depression, sepsis, and intrauterine growth restriction.

Role in Immune Responses

Fibronectin improves leukocyte function in vitro. Plasma fibronectin and proteolytic fragments of fibronectins promote human adult peripheral blood neutrophil and monocyte chemotaxis, adhesion, and random migration. In addition, fibronectin enhances phagocyte ingestion, reactive oxygen intermediate production, and killing of opsonized (complement or IgG) yeast and bacterial organisms. Fibronectin seems to play an important role as an enhancer of phagocyte function.

Summary

Circulating concentrations of fibronectin are decreased in the neonatal period and are correlated with gestational age. Even lower plasma concentrations are measured in infants who are ill. Plasma fibronectin increases phagocyte function in vitro. The role of fibronectin in host immune defense in neonates remains uncertain, but in vitro data suggest a potential role as an enhancer of phagocyte function.

Other Humoral Factors

Pentraxins

Pentraxins are a superfamily of proteins characterized by a 200–amino acid pentraxin domain at their C-terminal end.[8]

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

They are broadly classified as short or long pentraxins depending on their primary structure. The classical short pentraxin, C-reactive protein (CRP), is an acute-phase reactant originally identified by its ability to bind to a pneumococcal polysaccharide antigen. It is primarily synthesized in the liver in response to inflammatory signaling, particularly IL-6. This protein has strong functional similarity to the complement component C1q-binding domain of IgG, and similar to IgG is able to activate the classic complement pathway by binding C1q. The polysaccharide antigen recognized by CRP is expressed by many bacteria and some fungi. When CRP binds to the antigen, and the complement system is activated, the organism is effectively opsonized, and rapid clearance occurs through neutrophil, monocyte, or macrophage phagocytosis.

CRP is synthesized by the fetus and the newborn. Serum concentrations seem equivalent in uninfected neonates and adults. CRP is one of the most rapidly responsive acute-phase proteins, with increases of 100-fold to 1000-fold (in adults) in the serum concentration detectable during an infection. In surveys of infants with proven infections, an elevation of CRP serum concentration has been observed in 50%-100% of patients. Normal values of CRP are less than 1.6 mg/dL on postnatal days 1-2 and less than 1 mg/dL thereafter. Diminished or absent increases in the CRP concentration have been observed during the first 12-24 hours of life in infected newborns, particularly in newborns infected with group B streptococci. CRP levels decrease rapidly in infants who clinically respond to antimicrobial therapy and return to normal in 5-6 days.

The long pentraxin, PTX3 (Pentraxin 3), is primarily produced by mononuclear phagocytes, dendritic cells, and neutrophils. Like CRP, surface-bound PTX3 can also activate the classical complement pathway by fixing complement component C1q on the surface of pathogens. In contrast, fluid-phase PTX3 can bind and sequester free C1q, thus inhibiting complement activation. Thus PTX 3 may play a dual role in regulation of the complement pathway. Normative levels of PTX 3 in term and preterm infants and its role in preserving innate immune defenses in the newborn remains to be determined.

Lactoferrin

Lactoferrin is a member of the transferrin family of iron-binding glycoproteins that is normally secreted at epithelial-lining mucosal surfaces and plays important roles in innate immune mechanisms in humans. High concentrations of lactoferrin are found in colostrum and breast milk.[17] Lactoferrin is also present in specific granules of neutrophils. It is released into the phagosome after particle ingestion and is deposited on the cell surface membrane during stimulated degranulation. By chelating iron, lactoferrin removes an important nutrient required for pathogen growth. It also destabilizes microbial membranes and prevents microbial adherence to host cells. Thus, it has potent antimicrobial actions. Lactoferrin also enhances neutrophil–endothelial adhesion interactions and neutrophil aggregation, reactive oxygen intermediate production, and chemotaxis.[26] Deficient neutrophil adherence and directed migration have been reported in studies of patients with a heritable deficiency of lactoferrin-containing, neutrophil-specific granules.

Neonatal cord blood neutrophils contain less lactoferrin when compared to adult neutrophils. Oral prophylaxis with bovine lactoferrin has been shown to reduce the incidence of late-onset sepsis in very low birth weight preterm infants, suggesting that quantitative deficiencies in lactoferrin may predispose to infections in the neonatal period.

Collectins

Collectins are soluble proteins that play a role in innate immunity. These molecules include mannose-binding lectin and surfactant proteins A (SP-A) and D (SP-D) in humans and the bovine molecules conglutinin, CL-43, and CL-1. Collectins share several structural features, including a collagen domain, a neck region, and a globular carboxyl-terminal C-type (calcium-dependent) lectin-binding domain. Collectins specifically recognize the patterns of carbohydrates on the outer walls of microorganisms. In essence, collectins function by binding to microorganisms and enhancing uptake and clearance by phagocytes. MBL can also function to activate the classic complement pathway in much the same fashion as the complement component C1q. MBL, SP-A, and SP-D bind to one or more receptors on phagocytes and stimulate chemotaxis, the respiratory burst, and the phagocytosis of a wide variety of microorganisms, including group B streptococci.

SP-A and SP-D are synthesized by type II alveolar epithelial cells and by nonciliated bronchiolar epithelial (club) cells. As with other components of surfactant, the biosynthesis and secretion of these collectins increases dramatically during the third trimester of pregnancy. Acute injury or inflammation results in rapid increases in SP-A and SP-D biosynthesis. While predominantly present in the lung, SP-A and SP-D are also found in other sites in the body. SP-A is present in small intestinal cells, and SP-D protein is also found in gastric mucosal cells. The important role for SP-A and SP-D in innate immunity is suggested by the increased susceptibility to bacterial and viral infections in mice deficient in either of these pulmonary collectins. In humans, genetic variations in SP-A and SP-D are associated with increased neonatal susceptibility to RSV-bronchiolitis.

Mannose-binding lectin (MBL) is synthesized in the liver and secreted into the circulation. MBL serum concentrations vary widely (1000-fold) in adult human subjects primarily related to inherited polymorphisms in the promoter region of the gene. Neonatal serum MBL concentrations generally are lower than the levels measured in adult serum. In addition, MBL levels are lower in the first week of life and lower in preterm compared to term infants. Polymorphisms in the MBL gene and low MBL serum levels are both associated with increased risk of neonatal sepsis, suggesting its possible role as an essential innate immune defense component in the newborn infant.

Cytokines and Chemokines

Overview

Newborn infants have an increased susceptibility to infection because of various host defense impairments that exist during the neonatal period. The generation and maintenance of acquired immune responses are controlled by a network of regulatory glycoproteins and phospholipids that mediate the interactions between cells. These cytokines and chemokines are responsible for the generation of the immune response and differentiation of a wide variety of immune and nonimmune cells. The infant's ability to generate the right balance of proinflammatory and anti-inflammatory cytokines when challenged with an infectious agent allows recovery from the encounter with minimal residua. When the balance is not perfectly controlled, morbidity and mortality are increased. Unregulated production of cytokines in neonates may contribute to the development of necrotizing enterocolitis, bronchopulmonary dysplasia, and hypoxic-ischemic brain injury. The number of newly discovered cytokines is increasing on a yearly basis. This section focuses on the major cytokines involved in the immune responses to infectious agents and noninfectious stimuli, their developmental patterns in fetuses and newborns, and their coordinated role in neonatal sepsis.

Cytokine and Chemokine Biology

Interleukin-1 Superfamily. IL-1 family is a group of 11 immunoregulatory cytokines with complex pro- and anti-inflammatory effects[20] (Table 47.2). The three best-known members of this family are IL-1α, IL-1β, and IL-1 receptor antagonist [IL-1ra]). IL-1α and IL-1β are translated as precursor peptides. Pro-IL-1α is fully active and resides in the cytoplasm but can be transported to the cell surface where it has a role in cell–cell communication. IL-1α appears in the circulation only during severe disease. IL-1α and IL-1β share little sequence homology but bind to the same receptor and have the same tertiary structure. Pro-IL-1β (the main circulating member of this family) is inactive and must be cleaved by a cysteine protease (IL-1β-converting enzyme or caspase I) before it is secreted. IL-1ra is a competitive inhibitor of the other members of the family that has no agonist activity. There are two varieties of IL receptors: The type I receptor binds all members of the family; the type II receptor binds only IL-1β. Both receptors are members of the IL-1 receptor/TLR superfamily.

IL-1 is synthesized by a wide variety of immune and nonimmune cells, including monocytes, macrophages, neutrophils, endothelial cells, and epithelial cells. Synthesis of these ILs is triggered by microbial products of inflammation, and many of the features of the inflammatory response syndrome can be directly attributed to members of this family. IL-1 production by monocytes and macrophages from term and premature newborns is equivalent to that of adults. In preterm infants with sepsis, monocyte secretion may be diminished, however, during the acute phase of the disease.

Interleukin-6. IL-6 is secreted in a variety of different molecular forms as a result of post-translational modification. IL-6 synthesis is initiated by cytokines (including IL-1 and IL-6), platelet-derived growth factor, epidermal growth factor, viral and bacterial infections, double-stranded RNA, endotoxin, and cyclic adenosine monophosphate. The receptor for IL-6 consists of two subcomponents: (1) a ligand-binding molecule that is not responsible for signal transduction (IL-6R) and (2) a non-ligand-binding signal

TABLE 47.2 Members of the Interleukin-1 Family

Traditional Name	Family Name	Receptor	Coreceptor	Characteristics
IL-1α	IL1F1	IL-1RI	Interleukin-1 receptor accessory protein (IL-1RacP)	Proinflammatory
IL-1β	IL1F2	IL-1RI	IL-1RacP	Proinflammatory
IL-1Ra	IL1F3	IL-1RI	NA	Antagonist for IL-1α, IL-1β
IL-18	IL1F4	IL-18Rα	IL-18Rβ	Proinflammatory
IL-36Ra	IL1F5	IL-1 receptor related protein 2 (IL-1Rrp2)	NA	Antagonist for IL-36α, IL-36β, IL-36γ
IL-36α	IL1F6	IL-1Rrp2	IL-1RAcP	Proinflammatory
IL-37	IL1F7	Unknown	Unknown	Anti-inflammatory
IL-36β	IL1F8	IL-1Rrp2	IL-1RAcP	Proinflammatory
IL-36γ	IL1F9	IL-1Rrp2	IL-1RAcP	Proinflammatory
IL-38	IL1F10	Unknown	Unknown	Unknown
IL-33	IL1F11	ST2 (suppression of tumorigenicity 2)	IL-1RAcP	Th2 responses, proinflammatory

TABLE 47.3 Members of the IL-10 Superfamily

Member	Receptor	Function
IL-10	IL10-R1/IL10-R2	Immune suppression, anti-inflammatory
IL-19	IL20-R1/IL20-R2	Skin development, immunoregulatory
IL-20	IL20-R1/IL20-R2, IL22-R1/ IL20-R2	Skin development and inflammation, hematopoiesis
IL-22	IL22-R1/IL10-R2	Acute-phase response, innate immunity
IL-24	IL20-R1/IL20-R2, IL22-R1/ IL20-R2 (skin only)	Pro-apoptosis, epidermal functions, inflammatory cascade
IL-26	IL20-R1/IL10-R2	Mucosal and cutaneous immunity
IL-28, IL-29	IFNLR1/IL10-R2	Antiviral immunity

transducer (gp130). A soluble form of the IL-6 receptor (sIL6Ra) also exists. sIL6Ra can bind to IL-6 and then interact with gp130 on cells that do not express the IL-6 receptor. IL-6 injected intravenously into human patients is less toxic than IL-1β and TNF but does result in chills and fever. IL-6 is known to activate T and B cells, stimulate maturation of megakaryocytes, increase the production of acute-phase response proteins, and enhance NK cell activities. Monocytes from term infants produce adequate amounts of IL-6 after stimulation with lipopolysaccharide (LPS) but not IL-1. Cells derived from preterm infants exhibit decreased production no matter what the stimuli. Circulating levels of IL-6 in newborns are lower than corresponding maternal values; however, the percentage of IL-6-positive monocytes (after stimulation with LPS) is higher in preterm and term neonates.

Interleukin-10 Superfamily. The IL-10 gene superfamily includes IL-10 and several other immunoregulatory cytokines, including IL-19, IL-20, IL-22, IL-24, IL-26, IL-28, and IL-29.[37] These cytokines, their cognate receptors, and the principal biological effects are summarized in Table 47.3. IL-10 is a potent anti-inflammatory/immunosuppressive polypeptide synthesized by monocytes, macrophages, T cells, and B cells in response to bacteria, bacterial products, viruses, fungi, and parasites. IL-10 decreases the synthesis of a wide variety of proinflammatory cytokines and increases the production of naturally occurring proinflammatory cytokine inhibitors (e.g., IL-1ra). The synthesis of IL-10 is enhanced by various other cytokines, including TNF, IL-1, IL-6, and IL-12. In contrast, IL-10 enhances B-cell function and promotes development of cytotoxic T cells. IL-10 receptors are members of the class II cytokine receptor family and consist of two subunits. IL-10 production in neonates is diminished.

Interleukin-12 and Interferon-γ. IL-12 is a heterodimer consisting of two subunits (p35 and p40) encoded by different genes.[47] The p40 subunit mediates binding to the IL-12 receptor, whereas the p35 subunit is needed for signal transduction. The p40 subunit can also form homodimers with itself that bind to the IL-12 receptor with equal affinity but without eliciting a cellular effect. The homodimers may help modulate the effects of IL-12. The synthesis of the p35 and p40 subunits is regulated independently. In response to a given stimulus, cells secrete 10-100 times more of the homodimer than the heterodimer. IL-12 is produced by phagocytic cells (e.g., monocytes and macrophages) in response to bacteria and bacterial products, intracellular pathogens, and viruses. The IL-12 receptor is a member of the gp130 cytokine receptor superfamily. The IL-12 receptor consists of two subunits, and both must be activated for signal transduction. The principal cellular targets of IL-12 are T cells and NK cells. IL-12 induces the production of interferon (IFN-γ), stimulates proliferation, and enhances cytotoxicity. The production of IL-12 by cord blood–derived mononuclear cells (in response to endotoxin) is diminished; however, normal IL-12 synthesis has been observed with heat-killed *S. aureus* as the stimulus.

IFN-γ is produced by NK cells, type 1 T-helper (Th) cells, and cytotoxic T cells in response to IL-12, TNF, IL-1, IL-15, and IL-18. The receptor for IFN-γ has two subunits; one is responsible for binding, and the other is responsible for signaling. IFN-γ induces class II histocompatibility antigens and activates macrophages and is important for host defenses against intracellular pathogens, among other functions (Box 47.1). Synthesis of IFN-γ is greatly diminished in neonates.

Tumor Necrosis Factor Superfamily. The TNF family has 18 members, which serve in a variety of developmental, inflammatory, and cytotoxic roles (Table 47.4).[15] The two best known members of this family are TNF (previously TNF-α, cachectin) and lympotoxin-α (LT-α, previously TNF-β). TNF exists as a transmembrane form (prohormone) and a smaller secreted form consisting of three monomers. The soluble form of TNF is formed by the cleavage of the prohormone by a matrix metalloproteinase disintegrin. The transmembrane and the secreted forms of TNF can be biologically active. Similar to IL-1, synthesis of TNF is triggered by microbial products of inflammation (and by IL-1 and TNF themselves). A wide variety of cells are capable of producing TNF; however, monocytes and macrophages represent the major sources of this circulating cytokine.

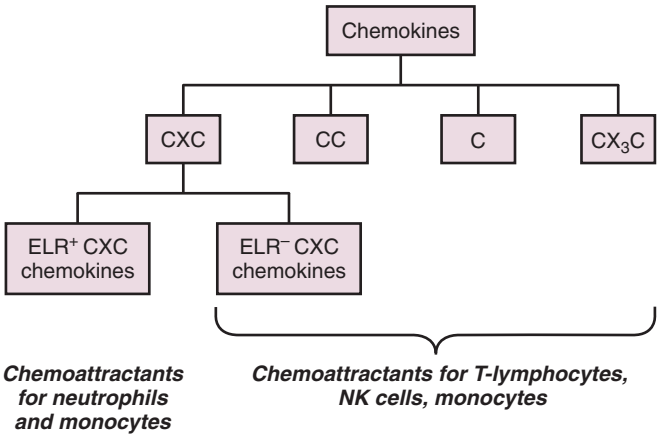
TNF-α and LT-α bind to two cognate receptors—TNF-RI and TNF-RII. Stimulation of TNF-RI reproduces many TNF functions, including cytotoxicity and upregulation of adhesion molecules. TNF-RI contains a cytoplasmic sequence of 80 amino acids that regulates programmed cell death. TNF-RII may facilitate binding of TNF to TNF-RI.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

The production of TNF by neonatal monocytes and macrophages is less than that in adults. Endotoxin-stimulated cord blood cells from preterm infants secrete significantly less TNF than cells derived from term infants or adults. The expression of TNF receptors may also be diminished.

• BOX 47.1 Functions of Interferon-γ

- Enhances macrophage microbicidal activity
- Promotes secretion of inflammatory mediators
- Enhances host cell resistance to nonviral intracellular pathogens
- Upregulates surface Fc receptors and class II major histocompatibility complex antigens on phagocytes
- Inhibits macrophage migration
- Promotes formation of giant cells
- Induces myelosuppression
- Augments functioning of mature neutrophils
- Enhances differentiation of cytolytic T cells, natural killer cells, and lymphocyte-activated killer cells
- Activates endothelial cells
- Suppresses host protein synthesis



Platelet-Activating Factor. Platelet-activating factor (PAF) is a potent phospholipid inflammatory mediator that is rapidly degraded by acetylhydrolase. PAF is produced by many cell types; however, only macrophages and eosinophils exhibit regulated release. PAF primarily resides on the cell surface, where it acts as an intercellular messenger. Intravenous administration of PAF results in systemic hypotension, capillary leakage, pulmonary hypertension, neutropenia, thrombocytopenia, and ischemic intestinal necrosis in animals. At a cellular level, PAF is a potent activator of neutrophils. PAF production is increased by cellular exposure to lipopolysaccharide (LPS), hypoxia, hematopoietic growth factors, TNF, IL-1, thrombin, bradykinin, and leukotriene C4. PAF stimulates the production of other mediators, including TNF, complement, oxygen radicals, prostaglandins, thromboxane, and leukotrienes. There is a strong association (but not a proven etiologic relationship) between neonatal necrotizing enterocolitis and increased concentrations of PAF.

Chemokines. Chemokines are the largest cytokine family, comprised of approximately 50 chemokine ligands and 20 different signaling receptors involved in the

TABLE 47.4 Members of the Tumor Necrosis Factor Family of Cytokines

Traditional Name	Family Name	Receptor
Lymphotoxin-α	TNFSF1	TNF-RI/TNFRSF1A, TNF-RII/TNFRSF1B
Tumor necrosis factor	TNFSF2	TNF-RI/TNFRSF1A, TNF-RII/TNFRSF1B
Lymphotoxin-β	TNFSF3	TNFRSF3
Ox40 ligand	TNFSF4	Ox40LR/TNFRSF4
CD40 ligand	TNFSF5	TNFRSF5
Fas ligand	TNFSF6	Fas/CD95/TNFRSF6
CD27 ligand	TNFSF7	TNFRSF7
CD30 ligand	TNFSF8	TNFRSF8
4-1 BB ligand	TNFSF9	TNFRSF9
TRAIL (TNF-related apoptosis-inducing ligand)	TNFSF10	TRAIL-R1/TNFRSF10A, TRAIL-R2/TNFRSF10B, TRAIL-R3/TNFRSF10C, TRAIL-R4/TNFRSF10C
RANK ligand (receptor activator of nuclear factor kappa-B ligand)	TNFSF11	TNFRSF11A, TNFRSF11B
TWEAK (TNF-related weak inducer of apoptosis)	TNFSF12	TNFRSF12, TNFRSF12A
APRIL (a proliferation-inducing ligand)	TNFSF13	
BAFF (B-cell activating factor)	TNFSF13b	TNFRSF13B, TNFRSF13C
LIGHT (lymphotoxin-like, exhibits inducible expression and competes with HSV glycoprotein D for herpesvirus entry mediator, a receptor expressed by T lymphocytes)/CD258	TNFSF14	TNFRSF14, TNFRSF6B
TL1 (TNF-like cytokine 1)/TL1A	TNFSF15	TNFRSF12, TNFRSF6B
GITRL (glucocorticoid-induced TNFR-related protein ligand)	TNFSF18	
Nerve growth factor	-	NGFR/TNFRSF16

• **Fig. 47.5** Chemokines are classified according to the position of conserved cysteine residues near the *N*-terminus. In CXC chemokines, two conserved cysteine (C) residues are separated by a variable amino acid (X). CC and C-chemokines have conserved cysteines, whereas the CX3C chemokine, fractalkine, has two cysteines separated by three variable amino acids.

activation and recruitment of a wide variety of cell types.[21] Chemokines are 8- to 12-kDa heparin-binding proteins ranging from 70-100 amino acids in length. All chemokines contain four cysteine motifs (forming double bonds) and are classified according to the arrangement of the cysteines at the amino-terminal end. Of the four subgroups (CXC, CC, C, and CX3C; Fig. 47.5), the CC and CXC are the largest (Table 47.5). Chemokine receptors belong to the seven transmembrane-spanning family of G-protein-coupled receptors. Chemokines are constitutively produced in organs where cell attraction is required for maintenance of local homeostasis. Most chemokines are inducible by inflammatory cytokines and endotoxin. In inflammatory states, chemokines are responsible for navigation and homing of effector leukocytes. In addition, chemokines induce a wide variety of leukocyte responses, including enzyme release from intracellular stores, oxygen radical formation, shape change through cytoskeletal rearrangement, generation of lipid mediators, and induction of adhesion to endothelium and extracellular matrix proteins. Chemokines are quite diverse in their target cell selectivity. CXC chemokines generally are more selective for neutrophils and T cells, whereas CC chemokines mainly attract monocytes and T lymphocytes. Considerable data suggest that chemotactic factor generation is deficient in newborn infants.

Coordinated Inflammatory Response in Neonatal Sepsis

In human bacterial sepsis, cytokines are released in a sequential manner, resulting in a cytokine cascade. After a challenge with a low dose of endotoxin, TNF peaks within 90 minutes. Other pro-inflammatory cytokines are released shortly afterward, and anti-inflammatory mediators follow in close sequence. The peak in IL-10 production may not occur for hours, however. In general, cytokines are not stored in intracellular compartments; they are synthesized and released in response to an inflammatory stimulus. Regulation of cytokine production occurs at the level of gene transcription. Specific transcription factors (e.g., NF-κB) bind to DNA response elements that either inhibit or promote gene transcription. Pro-inflammatory and anti-inflammatory cytokines or molecules are produced in response to an inflammatory stimulus. The anti-inflammatory molecules include soluble cytokine receptors (resulting from proteolytic cleavage of the extracellular binding domain), anti-inflammatory cytokines (e.g., IL-10), and cytokine receptor antagonists (e.g., IL-1ra).
