Fanaroff and Martin's Neonatal-Perinatal Medicine

Diseases of the Fetus and Infant

11th Edition

Richard J. Martin, MBBS, FRACP

Professor, Pediatrics, Reproductive Biology, and Physiology and Biophysics
Case Western Reserve University School of Medicine
Drusinsky/Fanaroff Chair in Neonatology
Rainbow Babies and Children's Hospital
Cleveland, Ohio

Avroy A. Fanaroff, MD, FRCPE, FRCPCH

Emeritus Professor, Pediatrics and Reproductive Biology
Case Western Reserve University School of Medicine
Emeritus Eliza Henry Barnes Chair in Neonatology
Rainbow Babies and Children's Hospital
Cleveland, Ohio

Michele C. Walsh, MD, MSE

Professor, Pediatrics
Case Western Reserve University School of Medicine
William and Lois Briggs Chair in Neonatology
Chief, Division of Neonatology
Rainbow Babies and Children's Hospital
Cleveland, Ohio

To our spouses

Patricia Martin and Roslyn Fanaroff

to the Martin children and grandchildren

Scott, Molly, William, and Adelaide Martin;
Sonya Martin; and Peter, Mateo, and Soren Graif

to the Fanaroff children and grandchildren

Jonathan, Kristy, Mason, Cole, and Brooke Fanaroff;
Jodi, Peter, Austin, and Morgan Tucker;
and Amanda, Jason, Jackson, and Raya Hirsh

to the Walsh children

Sean and Tiffany Sukys
and Ryan Sukys

with love, admiration, and deep appreciation
for their continued support and inspiration

Dedication

Contributors

Preface

1. Growth of Neonatal Perinatal Medicine—A Historical Perspective
2. Epidemiology for Neonatologists
3. Medical Ethics in Neonatal Care
4. Legal Issues in Neonatal-Perinatal Medicine
5. Evaluating and Improving the Quality and Safety of Neonatal Intensive Care
6. Simulation and Debriefing in Neonatal-Perinatal Medicine
7. Practicing Evidence-Based Neonatal-Perinatal Medicine
8. Perinatal and Neonatal Care in Developing Countries
9. Social and Economic Contributors to Neonatal Outcome in the United States
10. Genetic Aspects of Perinatal Disease and Prenatal Diagnosis
11. Perinatal Ultrasound
12. Estimation of Fetal Well-Being
13. Surgical Treatment of the Fetus
14. Adverse Exposures to the Fetus and Neonate
15. Intrauterine Growth Restriction
16. Developmental Origins of Adult Health and Disease
17. Hypertensive Disorders of Pregnancy
18. Pregnancy Complicated by Diabetes Mellitus
19. Obstetric Management of Prematurity
20. Fetal Effects of Autoimmune Disease
21. Obstetric Management of Multiple Gestation and Birth
22. Post-Term Pregnancy
23. Immune and Nonimmune Hydrops Fetalis
24. Amniotic Fluid Volume
25. Perinatal Infections and Chorioamnionitis
26. Placental Pathology
27. Anesthesia for Labor and Delivery
28. Physical Examination of the Newborn
29. Birth Injuries
30. Congenital Anomalies
31. Overview and Initial Management of Delivery Room Resuscitation
32. Role of Positive Pressure Ventilation in Neonatal Resuscitation
33. Oxygen Therapy in Neonatal Resuscitation
34. Chest Compression, Medications, and Special Problems in Neonatal Resuscitation
35. Thermal Environment of the Intensive Care Nursery
36. Optimization of the NICU Environment
37. Biomedical Engineering Aspects of Neonatal Cardiorespiratory Monitoring
38. Diagnostic Imaging of the Neonate
39. Anesthesia in the Neonate
40. The Late Preterm Infant
41. Nutrient Requirements/Nutritional Support in Premature Neonate
42. Support for the Family
43. Principles of Drug Use in the Fetus and Neonate
44. Principles of Drug Use During Lactation
45. Pharmacokinetics in Neonatal Medicine
46. Infants of Substance-Using Mothers
47. Developmental Immunology
48. Postnatal Bacterial Infections
49. Fungal and Protozoal Infections of the Neonate
50. Viral Infections in the Neonate
51. Normal and Abnormal Brain Development
52. White Matter Damage and Encephalopathy of Prematurity
53. Intracranial Hemorrhage and Vascular Lesions in the Neonate
54. Hypoxic–Ischemic Encephalopathy
55. Seizures in Neonates
56. Hypotonia and Neuromuscular Disease in the Neonate
57. Intracranial and Calvarial Disorders
58. Spinal Dysraphisms
59. Hearing Loss in the Newborn Infant
60. Early Childhood Neurodevelopmental Outcomes of High-Risk Neonates
61. The Role of Neonatal Neuroimaging in Predicting Neurodevelopmental Outcomes of Preterm Neonates
62. Lung Development and Maturation
63. Assessment of Neonatal Pulmonary Function
64. Respiratory Distress Syndrome in the Neonate
65. Assisted Ventilation of the Neonate and Its Complications
66. Neonatal Respiratory Disorders
67. Neonatal Apnea and the Foundation of Respiratory Control
68. Upper Airway Lesions in the Neonate
69. Bronchopulmonary Dysplasia in the Neonate
70. Therapy for Cardiorespiratory Failure in the Neonate
71. Cardiac Embryology
72. Pulmonary Vascular Development
73. Prenatal Diagnosis of Congenital Heart Disease
74. Patent Ductus Arteriosus
75. Congenital Defects of the Cardiovascular System
76. Cardiovascular Problems of the Neonate
77. Disorders of Cardiac Rhythm and Conduction in Newborns
78. Neonatal Management of Congenital Heart Disease
79. Hematologic and Oncologic Problems in the Fetus and Neonate
80. Blood Component Therapy for the Neonate
81. Development of the Neonatal Gastrointestinal Tract
82. Gastrointestinal Reflux and Motility in the Neonate
83. Disorders of Digestion in the Neonate
84. Selected Gastrointestinal Anomalies in the Neonate
85. Neonatal Necrotizing Enterocolitis
86. Disorders of Carbohydrate Metabolism in the Neonate
87. Disorders of Calcium, Phosphorus, and Magnesium Metabolism in the Neonate
88. Thyroid Disorders in the Neonate
89. Disorders of Sex Development
90. Inborn Errors of Metabolism
91. Neonatal Jaundice and Liver Diseases
92. Fluid, Electrolytes, and Acid-Base Homeostasis
93. The Kidney and Urinary Tract of the Neonate
94. The Skin of the Neonate
95. Examination and Common Problems in the Neonatal Eye
96. Retinopathy of Prematurity
97. Musculoskeletal Disorders in Neonates
98. Bone and Joint Infections in Neonates
99. Congenital Abnormalities of the Upper and Lower Extremities and Spine

Therapeutic Agents

Tables of Normal Values

Schedule for Immunization of Preterm Infants

Contributors

Steven A. Abrams, MD
Professor
Pediatrics
Dell Medical School at the University of Texas at Austin
Austin, Texas
Disorders of Calcium, Phosphorus, and Magnesium Metabolism in the Neonate

Johan Ågren, MD, PhD
Associate Professor
Department of Women's and Children's Health
Uppsala University
Uppsala, Sweden
Thermal Environment of the Intensive Care Nursery

Sanjay Ahuja, MD, MSc
Associate Professor
Pediatrics
Case Western Reserve University
Rainbow Babies and Children's Hospital
Cleveland, Ohio
Hematologic and Oncologic Problems in the Fetus and Neonate

Mohammad A. Attar, MD
Professor of Pediatrics
Division of Neonatal-Perinatal Medicine
C.S. Mott Children's Hospital
Michigan Medicine, University of Michigan
Ann Arbor, Michigan
Assisted Ventilation of the Neonate and Its Complications

Jill E. Baley, MD
Associate Medical Director, Transitional Care Unit
Rainbow Babies and Children's Hospital
Professor of Pediatrics
Case Western Reserve University School of Medicine
Cleveland, Ohio
Viral Infections in the Neonate
Schedule for Immunization of Preterm Infants

A. Rebecca Ballard, MD
Neonatologist
Pediatrix Medical Group
Woodlands, Texas
Support for the Family

Eduardo H. Bancalari, MD
Professor
Pediatrics
University of Miami
Miami, Florida
Bronchopulmonary Dysplasia in the Neonate

Nancy Bass, MD
Associate Professor
Pediatrics and Neurology
Case Western Reserve University
Rainbow Babies and Children's Hospital
Cleveland, Ohio
Hypotonia and Neuromuscular Disease in the Neonate

Sanmit K. Basu
Director, Pediatric Cardiac CT-MR Imaging
Assistant Professor of Pediatrics
University of Chicago Medicine–Comer Children's Hospital
Chicago, Illinois
Congenital Defects of the Cardiovascular System

Cynthia F. Bearer, MD, PhD
Mary Gray Cobey Professor of Neonatology
Chief, Division of Neonatology
Pediatrics
University of Maryland School of Medicine
Baltimore, Maryland
Adverse Exposures to the Fetus and Neonate

William E. Benitz, MD
Professor of Neonatology
Division of Neonatal and Developmental Medicine
Stanford University School of Medicine
Palo Alto, California
Patent Ductus Arteriosus

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

John T. Benjamin, MD, MPH
Assistant Professor of Pediatrics
Division of Neonatology
Vanderbilt University Medical Center
Nashville, Tennessee
Developmental Immunology

Sheila C. Berlin, MD
Associate Professor and Vice Chair
Department of Radiology
University Hospitals of Cleveland
Cleveland, Ohio
Diagnostic Imaging of the Neonate

Shazia Bhombal, MD
Clinical Assistant Professor of Pediatrics
Division of Neonatal and Developmental Medicine
Stanford University School of Medicine
Palo Alto, California
Patent Ductus Arteriosus

Isaac Blickstein, MD
Professor
Department of Obstetrics and Gynecology
Kaplan Medical Center
Rehovot, Israel
Pregnancy Complicated by Diabetes Mellitus
Fetal Effects of Autoimmune Disease
Obstetric Management of Multiple Gestation and Birth
Post-Term Pregnancy

Martin L. Bocks, MD
Director of Pediatric Interventional Cardiology
The Congenital Heart Collaborative
Rainbow Babies and Children's Hospital
Cleveland, Ohio
Neonatal Management of Congenital Heart Disease

Brian A. Boe, MD
Assistant Professor of Pediatrics
The Heart Center
Nationwide Children's Hospital
Columbus, Ohio
Neonatal Management of Congenital Heart Disease

Jennifer C. Burgis, BS, MD
Clinical Associate Professor
Pediatrics-Gastroenterology
Stanford University
Stanford, California
Neonatal Jaundice and Liver Diseases

Bryan Cannon, MD, FAAP, FACC, FHRS
Vice Chair for Education
Department of Pediatrics
Mayo Clinic
Rochester, Minnesota
Disorders of Cardiac Rhythm and Conduction in Newborns

Waldemar A. Carlo, MD
Edwin M. Dixon Professor of Pediatrics
Pediatrics
University of Alabama at Birmingham
Birmingham, Alabama
Perinatal and Neonatal Care in Developing Countries
Assessment of Neonatal Pulmonary Function

Gisela Chelimsky, MD
Professor of Pediatrics
Pediatrics-Gastroenterology
Medical College of Wisconsin
Milwaukee, Wisconsin
Disorders of Digestion in the Neonate

Alison Chu, MD
Assistant Professor-in-Residence
Pediatrics
University of California Los Angeles
Los Angeles, California
Intrauterine Growth Restriction

Janet Chuang, MD
Assistant Professor
Pediatric Endocrinology
Cincinnati Children's Hospital Medical Center
Cincinnati, Ohio
Thyroid Disorders in the Neonate

Maged M. Costantine, MD
Associate Professor, Maternal Fetal Medicine
Department of Obstetrics and Gynecology
The University of Texas Medical Branch
Galveston, Texas
Obstetric Management of Prematurity

Moira A. Crowley, MD
Associate Professor of Pediatrics
Case Western Reserve University School of Medicine
Cleveland, Ohio
Neonatal Respiratory Disorders

Pe'er Dar, MD, FACOG, FACMG
Professor, Obstetrics and Gynecology and Women's Health
Director, Division of Fetal Medicine and OBGYN Ultrasound
Albert Einstein College of Medicine/Montefiore Medical Center
Bronx, New York
Perinatal Ultrasound

Peter Davis, MBBS, MD
Professor
Neonatology
The Royal Women's Hospital
Melbourne, Victoria, Australia
Role of Positive Pressure Ventilation in Neonatal Resuscitation

Linda S. de Vries, MD, PhD
Neonatology
Wilhelmina Children's Hospital
University Medical Center Utrecht
Utrecht University
Utrecht, Netherlands
Intracranial Hemorrhage and Vascular Lesions in the Neonate
Hypoxic–Ischemic Encephalopathy

Katherine MacRae Dell, MD
Professor of Pediatrics
Case Western Reserve University School of Medicine
Cleveland, Ohio
Fluid, Electrolytes, and Acid-Base Homeostasis

Eric J. Devaney, MD
Department of Pediatrics
Case Western Reserve University School of Medicine
Division of Pediatric Cardiology
Rainbow Babies and Children's Hospital
Cleveland, Ohio
Cardiac Embryology

Sherin U. Devaskar, MD
Distinguished Professor of Pediatrics
Pediatrics, Neonatology and Developmental Biology
David Geffen School of Medicine at UCLA
Los Angeles, California
Intrauterine Growth Restriction
Developmental Origins of Adult Health and Disease
Disorders of Carbohydrate Metabolism in the Neonate

Juliann M. Di Fiore, BSEE
Research Engineer III
Department of Pediatrics
Case Western Reserve University
Cleveland, Ohio
Biomedical Engineering Aspects of Neonatal Cardiorespiratory Monitoring
Assessment of Neonatal Pulmonary Function

Michael Dingeldein, MD, FACS
Assistant Professor of Surgery
Division of General and Thoracic Pediatric Surgery
Rainbow Babies and Children's Hospital
Case Western Reserve University
Cleveland, Ohio
Development of the Neonatal Gastrointestinal Tract
Selected Gastrointestinal Anomalies in the Neonate

Nancy C. Dobrolet, MD
Director, Cardiac Stepdown Unit
Cardiology
Rainbow Babies and Children's Hospital
Cleveland, Ohio
Congenital Defects of the Cardiovascular System

Steven M. Donn, MD
Professor of Pediatrics
Division of Neonatal-Perinatal Medicine
C.S. Mott Children's Hospital
Michigan Medicine, University of Michigan
Ann Arbor, Michigan
Assisted Ventilation of the Neonate and Its Complications

Josephine M. Enciso, MD
Associate Clinical Professor
Pediatrics, Division of Neonatology and Developmental Biology
David Geffen School of Medicine at UCLA
Los Angeles, California
Developmental Origins of Adult Health and Disease

Frank Esper
Staff
Center for Pediatric Infectious Diseases
Cleveland Clinic Children's Hospital;
Assistant Professor
Department of Pediatrics
Cleveland Clinic Lerner College of Medicine of Case Western Reserve University
Cleveland, Ohio
Postnatal Bacterial Infections

Alison J. Falck, MD
Pediatrics, Division of Neonatology
University of Maryland School of Medicine
Baltimore, Maryland
Adverse Exposures to the Fetus and Neonate

Mobolaji Famuyide, MD, MA
Associate Professor
Pediatrics/Newborn Medicine
University of Mississippi Medical Center
Jackson, Mississippi
Social and Economic Contributors to Neonatal Outcome in the United States

Jonathan M. Fanaroff, MD, JD
Professor of Pediatrics
Case Western Reserve University School of Medicine;
Director, Rainbow Center for Pediatric Ethics
Rainbow Babies & Children's Hospital
Cleveland, Ohio
Medical Ethics in Neonatal Care
Legal Issues in Neonatal-Perinatal Medicine

Stephanie M. Ford, MD
Department of Pediatrics
Case Western Reserve University School of Medicine
Divisions of Neonatology and Pediatric Cardiology
Rainbow Babies and Children's Hospital
Cleveland, Ohio
Cardiac Embryology

Susan Hatters Friedman, MD
The Phillip Resnick Professor of Psychiatry;
Associate Professor of Pediatrics
Case Western Reserve University School of Medicine
Cleveland, Ohio;
Associate Professor of Psychological Medicine
University of Auckland
Auckland, New Zealand
Support for the Family

Mark E. Galantowicz, MD
Chief, Department of Cardiothoracic Surgery
Co-Director, The Heart Center
Nationwide Children's Hospital
Columbus, Ohio
Neonatal Management of Congenital Heart Disease

Meena Garg, MD
Professor of Pediatrics
Pediatrics, Neonatology and Developmental Biology
David Geffen School of Medicine at UCLA
Los Angeles, California
Disorders of Carbohydrate Metabolism in the Neonate

Ciprian P. Gheorghe, MD, PhD
Assistant Professor of Gynecology and Obstetrics and Basic Sciences
Lawrence D. Longo MD Center for Perinatal Biology
Loma Linda University School of Medicine
Loma Linda, California
Genetic Aspects of Perinatal Disease and Prenatal Diagnosis

Allison Gilmore, MD
Associate Professor
Department of Pediatric Orthopaedic Surgery
Rainbow Babies and Children's Hospital
Cleveland, Ohio
Bone and Joint Infections in Neonates

Jay P. Goldsmith, MD
Clinical Professor
Pediatrics
Tulane University,
New Orleans, Louisiana
Overview and Initial Management of Delivery Room Resuscitation

Blanca E. Gonzalez, MD
Assistant Professor
Pediatrics Infectious Diseases
The Children's Hospital
Cleveland Clinic Foundation
Cleveland, Ohio
Viral Infections in the Neonate

Jeffrey B. Gould, MD, MPH
Robert L. Hess Professor of Pediatrics
Stanford University School of Medicine and Lucile Packard Children's Hospital
Palo Alto, California
Evaluating and Improving the Quality and Safety of Neonatal Intensive Care

Pierre Gressens, MD, PhD
Inserm-Paris Diderot University
Paris, France
Normal and Abnormal Brain Development
White Matter Damage and Encephalopathy of Prematurity

Floris Groenendaal, MD, PhD
Doctor
Department of Neonatology
Wilhelmina Children's Hospital
University Medical Center Utrecht
Utrecht University
Utrecht, Netherlands
Hypoxic–Ischemic Encephalopathy

Preface

Together with my colleague Avroy A. Fanaroff (and more recently, Michele C. Walsh), we have been privileged to transform the third edition (1983) of this text into its 11th edition over a span of 35 years. This has been a great honor and an enormous learning experience. Over this time, although neonatal survival rates may give reason to rejoice, the persistent respiratory and neurodevelopmental problems observed in former preterm infants remain cause for concern. Fortunately, we have made great strides in our ability to control nosocomial infections in preterm infants, and both target and achieve the intrauterine rate of growth through improved nutritional support. Meanwhile, the complex, ever-expanding genetic disorders and birth defects now loom as major problems in the neonatal intensive care unit and as leading causes of neonatal mortality.

The field of Neonatal-Perinatal Medicine has transitioned from anecdotal medicine to evidence-based medicine. The problem is that evidence-based medicine predicts outcomes for groups but not individuals. The next frontier, individualized or personalized medicine, requires application of the human genome project to the individual patient. That frontier may be rapidly approaching with the acquisition and application of new knowledge and technology. Over the last decades, translation of bench research to bedside innovation has proceeded remarkably as has understanding of the underlying mechanisms of many complex disorders. Advances in genetics have provided insight into the etiology of many disorders, and many previously mysterious diseases can now be attributed to single gene defects or mitochondrial disorders accompanied by cellular energy failure. We have attempted to address and incorporate these advances into the body of the text.

For this 11th edition, we have added several new sections and multiple new authors, notably expanding our international contributors, hence providing a truly global perspective. Many sections have been completely reorganized, and a large number of chapters have been rewritten or updated. We remain exceedingly grateful to our accomplished authors who have responded enthusiastically and maintained our need for a rapid timeline in this electronic era. As with prior editions, the 11th edition is available both in print and as an e-book on the Expert Consult platform, in a fully searchable and portable format.

This book would not exist without the remarkable clinical and intellectual environment that constitutes Rainbow Babies & Children's Hospital in Cleveland. On a daily basis, we gain knowledge from our faculty colleagues and fellows, and wisdom from our nursing staff who are so committed to their young patients. Once again, we have been blessed with an in-house editor, Bonnie Siner, to whom we cannot adequately express our thanks. She is the glue behind the binding in the book, and she has worked tirelessly with Elsevier staff members to bring this project to fruition. Elsevier has, once again, provided the resources to accomplish this mammoth task.

1

Growth of Neonatal Perinatal Medicine—A Historical Perspective

TONSE N. K. RAJU

We trust we have been forgiven for coining the words, "neonatology" and "neonatologist." We do not recall ever having seen them in print. The one designates the art and science of diagnosis and treatment of disorders of the newborn infant, the other the physician whose primary concern lies in the specialty. … We are not advocating now that a new subspecialty be lopped from pediatrics … yet such a subdivision … [has] as much merit as does pediatric hematology.

—A. J. Schaffer, 1960[75]

The terms *neonatology* and *neonatologist* were not in general use until the mid-1960s. In the preface to the first edition of his monograph *Diseases of the Newborn*, Dr. Alexander Schaffer christened the new specialty and its practitioners, asking our "forgiveness" for doing so.[75] An apology was not needed, because time has proven him to be immensely prophetic. In 1975, the first neonatal-perinatal medicine subspecialty examination was offered by the American Board of Pediatrics, and 355 were certified as the country's first neonatologists. After the 2012 certifying examination, 5552 individuals have been certified by the Board as neonatologists, and several hundred more since then. This phenomenal growth has been matched by an increasing fund of knowledge. Today a cursory search using the subject heading "newborn" in the National Library of Medicine's PubMed database yields nearly 60,000 citations.[59] Thus at the beginning of the twenty-first century, neonatology stands tall and strong as a specialty, carving a unique niche, bridging obstetrics with pediatrics and intensive care with primary care.

Although the formal naming of our specialty appears to be recent, its roots extend into the nineteenth century, when systematic and organized care for premature infants began in earnest. This chapter traces the origins and growth of modern perinatal and neonatal medicine, with a brief perspective on its promises and failures. The reader may consult scholarly monographs and review articles on specific topics for in-depth analyses.[6,7,24,31,79,80]

Perinatal Pioneers

Many scientists played strategic roles in developing the basic concepts in neonatal-perinatal medicine that helped to formalize the scientific basis for neonatal clinical care. Their work and teachings inspired generations of further researchers advancing the field. For brevity's sake, only a few are shown in Fig. 1.1.

Medicinal chemistry (later called biochemistry) and classic physiology gained popularity and acceptance toward the end of the nineteenth century, inaugurating studies on biochemical and physiologic problems in the fetus and newborn. Some leading scientists in the early twentieth century, making fundamental contributions and training scores of scientists from around world, included Barcroft[8,34] and his mentee Dawes in England (gas exchange and nutritional transfer across the placenta and oxygen carrying in fetal and adult hemoglobin); Ylppö in Finland (neonatal nutrition, jaundice, and thermoregulation); Lind in Sweden (circulatory physiology); Smith in Boston[81] (fetal and neonatal respiratory physiology); DeLee in Chicago[26,27] (leading researcher on incubators and in high-risk obstetric topics, he also founded the first US "incubator station" at the Chicago Lying-in Hospital); Day in New York (temperature regulation, retinopathy of prematurity, and jaundice); and Gordon[38] in Denver (nutrition). Although no formal curriculum existed, all these centers offered rigorous training in perinatal physiology and clinical medicine. Smith once said, "If you were interested in babies and liked Boston, I was the only wheel in town!"[60] Table 1.1 highlights some milestones in perinatal medicine.

The High-Risk Fetus and Perinatal Obstetrics

Because so many deaths occurred in early infancy in times past, many cultures adopted remarkably innovative methods to deal with such tragedies. According to a Jewish tradition, full, year-long mourning is not required for infants who die

Abstract

Emerging from centuries of humble origins, the field of maternal and newborn care has matured into a robust medical specialty. This growth, however, has not been smooth. Along with spectacular advances in physiology, clinical sciences, and technological innovations over the decades, humbling setbacks have led to course corrections in our collective historic march. This chapter attempts to provide a historical perspective, highlighting important milestones, on the growth of neonatal perinatal medicine.

before 30 days of age.[40] In some Asian ethnic groups, infant-naming ceremonies are held only after several months, until which time the infant is simply called "it." In India, an odd or coarse-sounding name is given to the first surviving infant after the death of a previous sibling; this is aimed at deflecting evil spirits. In her book on the history of the Middle Ages, Tuchman notes that infants were seldom depicted in medieval artworks.[89] When they were drawn (e.g., the infant Jesus), women in the pictures looked away from the infant, ostensibly conveying respect but perhaps because of fearful aloofness.

Since antiquity, the care of pregnant women has been the purview of midwives, grandmothers, and experienced female elders in the community. Wet nurses helped when mothers were unavailable or unwilling to nurse their infants. Little or no assistance was needed for normal or uncomplicated labor and delivery. For complicated deliveries, male physicians had to be summoned, but they could do little because many of them lacked expertise or interest in treating women. Disasters during labor and delivery were common, rendering this phase in their lives the most dreaded for women.[43] In the early 1900s unexpected intrapartum complications accounted for 50% to 70% of all maternal deaths in England and Wales.[17,56] Because the immediate concern during most high-risk deliveries was to save the mother, sick newborns were not given substantial attention; their death rates remained very high.

Occasionally, happy outcomes of high-risk deliveries did occur. In one of the oldest works of art depicting labor and delivery (Fig. 1.2*A*), a bearded man and his assistant are standing behind a woman in labor, holding devices remarkably similar to the modern obstetric forceps. The midwife has delivered an evidently live infant. In Fig. 1.2*B*, three infants from a set of quadruplets, nicely swaddled, have been placed on the mother, as the unwrapped fourth infant is being handed to her for nursing. A divine figure in the background is blessing the newcomers.

Cesarean sections were seldom performed on living women before the thirteenth century. Even subsequently, the procedure was performed only as a final act of desperation. Contrary to popular belief, Julius Caesar's birth was not likely by cesarean section. Because Caesar's mother was alive during his reign, historians believe that she probably delivered him vaginally. The term *cesarean* probably originated from *lex caesarea*, in turn from *lex regia*, the "royal law" prohibiting burial of corpses of pregnant women without removal of their fetuses.[11,94] The procedure allowed for baptism (or a similar blessing) if the child was alive or burial otherwise. Infants surviving the ordeal of cesarean birth were assumed to possess special powers, as supposedly

TABLE 1.1 Selected Milestones in Perinatal Medicine

Category	Year(s)	Description
Antenatal aspects	1752	Queen Charlotte's Hospital, the world's first maternity hospital, is founded in London.[57]
	1915-1924	Campbell introduces outlines of regular prenatal visits, which become a standard.
	1923-1925	Estrogen and progesterone are discovered.
	1928	First pregnancy test is described, in which women's urine is shown to cause changes in mouse ovaries.
Fetal assessment	1543	Vesalius observes fetal breathing movements in pigs.
	1634	Paré teaches that absence of movement suggests a dead fetus.
	1819, 1821	Laënnec introduces the stethoscope in 1819, and his friend Kergaradec shows that fetal heart sounds can be heard using it.
	1866	Forceps are recommended when there is "weakening of the fetal heart rate."
	1903	Einthoven publishes his work on the ECG.
	1906	The first recording of fetal heart ECG is made.
	1908	The term *fetal distress* is introduced.
	1948-1953	There are developments in the external tocodynamometer.
	1953	Apgar describes her scoring system.[3]
	1957-1963	Systematic studies are conducted on fetal heart rate monitoring.
	1970	Dawes reports studies on breathing movement in fetal lambs.
	1980	Fetal Doppler studies begin.
	1981	Nelson and Ellenberg report that Apgar scores are poor predictors of neurologic outcome.
Labor and delivery	ca. 1000–500 BC	In Ayurveda, the ancient Hindu medical system, physicians describe obstetric instruments.
	98-138	Soranus develops the birthing stool and other instruments.
	1500s	There are isolated reports of cesarean sections on living women.
	1610	The first intentional cesarean section is documented.
	1700s	The Chamberlen forceps are kept as a family secret for three generations.
	1921	Lower uterine segment cesarean section is reported.
	1953	The modern vacuum extractor is introduced.
Fetal physiology	1900-1950	Barcroft, Dawes, Lind, Liley, and others study physiologic principles of placental gas exchange and fetal circulation.

ECG, Electrocardiogram.
See references 41, 43, 60-62, 70-72, 82, 83.

did Shakespeare's Macduff—"not of a woman born," but of a corpse, and able to slay Macbeth.[54]

Soranus of Ephesus (circa 38-138 AD) influenced obstetric practice for 1400 years. His *Gynecology* can be regarded as the first formal "textbook" of perinatal medicine. Initially extant, it was rediscovered in 1870 and translated into English for the first time in 1956.[88] Soranus wrote superbly about podalic version, obstructed labor, multiple gestations, fetal malformations, and numerous other maternal and fetal disorders. In an age of belief in magic and the occult, he insisted that midwives should be educated and free from superstitions. He forbade wet nurses from drinking alcohol lest it render the infant "excessively sleepy." His chapter, "How to Recognize the Newborn That Is Worth Rearing," remains one of the earliest accounts on assessing viability of sick newborns—a topic of great concern even today.

Midwives and Perinatal Care

Although occasionally caricatured (Fig. 1.3), midwives were responsible for delivering obstetric care for thousands of years. Men disliked obstetrics, and women were too shy to let male physicians handle them. Good midwives were always in great demand, and many of them held important social and political positions in European courts.[43,61,91]

The emergence of man-midwives (Fig. 1.4) in England had a major effect on high-risk obstetric practice. Chamberlen the Elder (1575-1628) is usually credited for inventing the modern obstetric forceps.[43,61,63] For 150 years, through three generations of Chamberlens, the instrument remained a trade secret. By then, others had developed similar devices, and patients began associating good obstetric outcomes with male physicians—a strategic factor in transforming midwifery to a male-dominated craft.[43] The shift from women-midwifery to men-midwifery might also have been caused by changing social values and gender relationships in which women voluntarily began making choices about their bodies.[91] Today's increasing roles for female midwives and the higher proportion of women choosing specific birth practices (e.g., home versus hospital delivery, "underwater births," cesarean delivery on request) offer interesting contrasts and perspectives to eighteenth century obstetrics.

Neonatal Resuscitation: Tales of Heroism and Desperation

Popular artworks and ancient medical writings provide accounts of miraculous revivals of apparently dead adults and children.[66] These are tales of successes only, for the failures were buried and rarely reported. Attempts to "stimulate" and revive apparently dead newborns included beating, shaking, yelling, fumigating, dipping in ice-cold water, and dilating and blowing smoke into the rectum and other techniques.[25,30,66,93] Oxygen administration through an orogastric tube to revive asphyxiated infants persisted well into the mid-1950s, when James and Apgar showed conclusively that the therapy was useless.[1,52]

Apgar and the Language of Asphyxia

Few scientists in the twentieth century influenced the practice of neonatal resuscitation as profoundly as Apgar (1909-1974). A surgeon, she chose obstetric anesthesia for her career. Her simple scoring system inaugurated the modern era of assessing infants at birth on the basis of simple clinical examination.[3] Right or wrong, the Apgar score became the language of asphyxia. It is often said that the first words heard by a newborn infant are "What's the Apgar score?" Although "giving an Apgar" has become a ritual, its profound effect has been on formalizing the process of observing, assessing, and communicating the infant status at birth in a consistent and uniform manner. This process eventually led to the formal steps of resuscitation at birth using the score. Few people know that it was also Apgar who was the first to catheterize the umbilical artery in a newborn.[16] A woman of enormous energy, talent, and compassion, Apgar was honored with her depiction on a 1994 US postage stamp (Fig. 1.5).

Foundling Asylums and Infant Care

In its early days, the Roman Empire experienced decreasing population growth. The emperors taxed bachelors and rewarded married couples to encourage procreation.[82] In 315 AD, Emperor Constantine, hoping to curb infanticide and encourage the adoption of orphans, decreed that all "foundlings" would become slaves of those who adopted them. Similar humanitarian efforts by kings and the Council of the Roman Church led to the institutionalization of infant care by establishing foundling asylums for abandoned infants,[82] also called "Hospitals for the Innocent"—the first children's hospitals. Parents of unwanted infants "dropped off" their infants in a revolving receptacle at the door of such asylums, rang the doorbells, and disappeared into the night (Fig. 1.6). Sadly, such incidences occur even in modern times.[73]

Foundling asylums adopted pragmatic techniques for fundraising. In eighteenth century France, lotteries were held, and souvenirs were sold. In May 1749, Handel gave a concert to support London's "Hospital for the Maintenance and Education of Exposed and Deserted Young Children." The final item of the program was the playing of "The Foundling Hymn."[82]

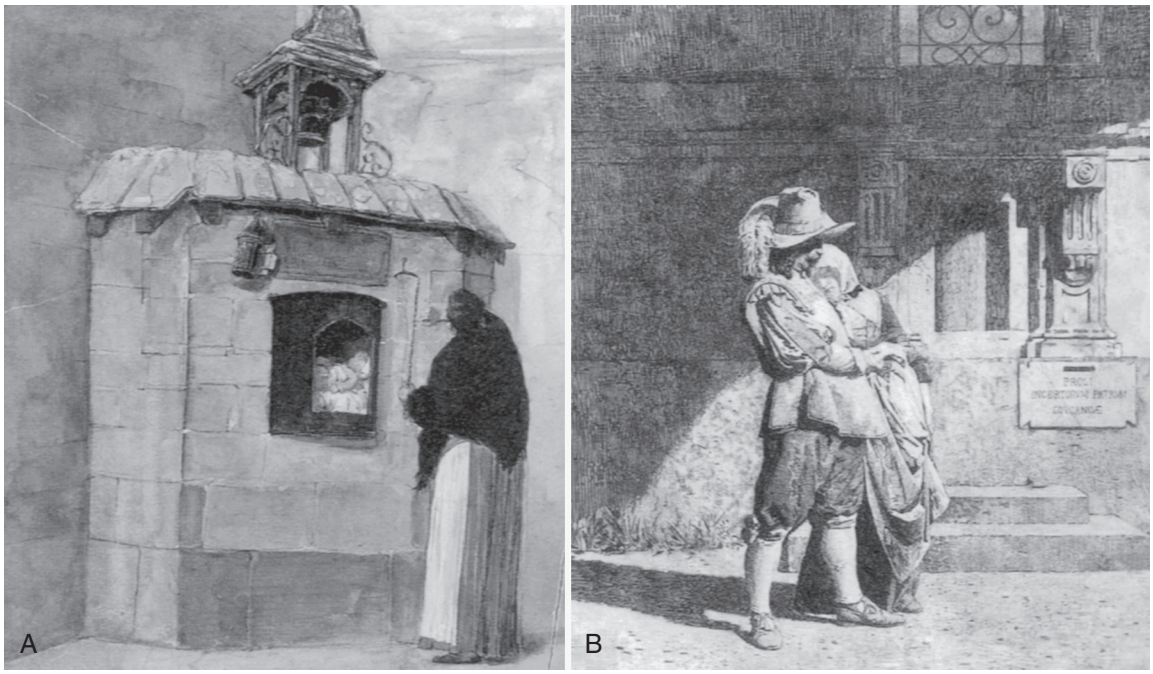
Saving Infants to Man the Army



During the French Revolution, France faced appalling rates of infant mortality. With rates greater than 50%, the Revolutionary Council in 1789 enacted a decree proclaiming that working-class parents "have a right to the nation's succors at all times."[82] The post-revolutionary euphoria about equality and fraternity among men stimulated reforms, heralding an idealistic welfare state, leading to collecting and maintaining valid statistics about children. The world's first national databases began in France in the late eighteenth century.[82]

Over the next century, France faced a population problem similar to that of ancient Rome—a negative population growth. The birth rate had declined, and infant mortality remained high. Fearing future shortages of troops, the military leaders, deeply engaged in battles with Prussia, were naturally alarmed. Commissions were set up to study the depopulation problem and develop remedial actions. A series of measures began to improve maternal and neonatal care.[6,7,22,24,82,83] Young parents were encouraged to uphold their patriotism and bear more children to "man the future armies." It is the irony of our times that such noble intentions as saving infants were motivated by brutal needs for enhancing military might.

An Ingenious Contrivance, the *Couveuse*, and Premature Baby Stations

A popular story of the origin of modern incubator technology is that upon seeing the poultry section during a casual visit to the Paris Zoo in 1878, Tarnier (1828-1897), a

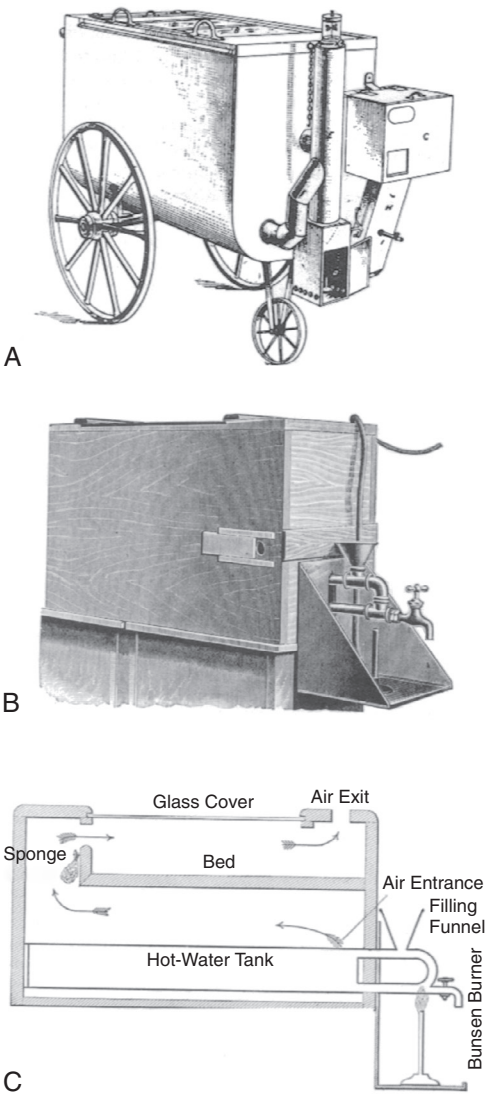
(**A** and **B,** Courtesy of the Museum of the History of Medicine, Academy of Medicine, Toronto, Ontario, Canada; from Spaulding M, Welch P. *Nurturing Yesterday's Child: A Portrayal of the Drake Collection of Pediatric History.* Philadelphia: Decker; 1991, p 110 [**A**] and p 119 [**B**].)

renowned obstetrician, conceived the idea of "incubators" similar to the "brooding hen" or *couveuse*.[6,7,22,24] He asked an instrument maker, Martin, to construct similar equipment for infants. With a "thermo-syphon" method to heat the outside with an alcohol lamp, Martin devised a sufficiently ventilated, 1 m^3 double-walled metal cage, spacious enough to hold two premature infants. The first *couveuses* were installed at the Paris Maternity Hospital in 1880. Tarnier's efforts led to dramatic improvements in survival rates for preterm infants.

Although a few others had developed incubators before Tarnier,[7] it was he and his students, Budin (1846-1907) and Auvard (1855-1941), who are largely responsible for institutionalizing preterm infant care. They placed several incubators side by side, promoting the concept of caring for groups of sick preterm infants in geographically separate regions within their hospital.[6,7,69,86] Budin and Auvard improved the original *couveuse* by replacing its walls with glass and using simpler methods for heating. Their efforts greatly influenced incubator technology during the first half of the twentieth century in Europe and the United States (Fig. 1.7 and Table 1.2).



In 1884, Tarnier made another important contribution; he invented a small, flexible rubber tube for introduction through the mouth into the stomach of preterm infants. With this tube, he could drip milk directly into the stomach. This method of nutritional support he called "gavage feeding." Gavage feeding plus keeping infants in relatively constant and warm temperatures had a dramatic impact on improving survival rates.[15,21] Tarnier also recommended that the legal definition of viability should be 180 days of gestation, which was opposed by contemporary obstetricians, who thought that the concept was "therapeutic nihilism."[7] Defining *viability* remains a highly emotional and contentious issue in contemporary neonatal-perinatal practice.

Incubators, Baby Shows, and Origins of Neonatal Intensive Care Units

Almost two decades after its debut in France, incubator technology appeared in the United States, heralding organized newborn intensive care. As in France, it was an obstetrician who spearheaded the movement. In 1898, DeLee established the first "Premature Baby Incubator Station" at the Sara Morris Hospital in Chicago. During the early 1900s, as academic obstetricians and pediatricians were organizing specialized care for premature infants, an interesting, if bizarre, set of events led to the era of "premature baby shows," which began in Europe and continued in the United States, lasting well into the 1940s.[6,7,78]

Couney, a Budin associate of doubtful medical credentials, wished to popularize the French technology abroad and show the value of "conserving" premature infants. (This account has been doubted.[7]) Couney obtained six incubators, probably from the French innovator Lion. Initially, Couney wanted to exhibit only the incubators as a technology of hope for saving infants. To add drama, however, he brought six preterm infants from Virchow's maternity unit in Berlin and exhibited them inside the incubators at the

1896 Berlin Exposition. He coined a catchy phrase for the show—*kinderbrutanstalt* or "child hatchery"—igniting the imagination of a public thirsty for sensational scientific breakthroughs.

Couney's Berlin exhibit was an astounding success. One such show was at Great Britain's Victorian Era Exhibition in 1897. The show was praised by *Lancet* in an editorial that recommended that large "incubator stations" be established similar to fire stations, where parents could borrow incubators.[36] This was the origin of the phrase "premature baby incubator stations," which became part of the medical lexicon. In a later editorial, *Lancet* also criticized the "danger of making a public show of incubator for babies."[37] Couney sailed to the United States and, beginning in 1898, started premature infant exhibitions at many state fairs, traveling circuses, and science expositions, and finally settled in New York City to organize annual incubator baby shows in Coney Island. The last infant show was held during the 1939 to 1940 season in Atlantic City.[78]

In 1914, Hess of Chicago started a Premature Infant Station at the Sarah Morris Children's Hospital (of the Michael Reese Medical Center). With great attention to environmental control and aseptic practices and a regimental approach to feeding, Hess and his head nurse, Evelyn Lundeen (Fig. 1.8), achieved spectacular survival rates.[47,68] Hess also developed an incubator built on the concept of a double-walled metallic "cage" with warm water circulating between the walls. He used electric current for heating and devised a system to administer free-flow oxygen (Fig. 1.9). Only a few Hess incubators are known to have survived to this day. Hess's premature unit outlasted the DeLee Premature Station. In December 2008, the Michael Reese Medical Center closed, however, declaring bankruptcy.

The story of development of incubators and their impact on pediatrics is a tale of the success of technology and that of the perils technology might beget (see later section on the relationship of improved incubator care and the retinopathy of prematurity [ROP] epidemic). In the heroic age of the mechanical revolution, the notion that machines could solve all human problems was all too appealing. The incubator stands as the most enduring symbol of the spectacular success of modern intensive care and (paradoxically) some of its failures.[79,80]

Supportive Care and Oxygen Therapy

In a single-page note in 1891, Bonnaire referred to Tarnier's use of oxygen in treating "debilitated" premature infants 2 years earlier[14]; this was the first published reference to the administration of supplemental oxygen in premature infants for a purpose other than resuscitation. The use of oxygen in premature infants did not become routine, however, until the 1920s. Initially, a mixture of oxygen and carbon dioxide—instead of oxygen alone—was employed to treat asphyxia-induced narcosis. It was argued that oxygen relieved hypoxia, whereas carbon dioxide stimulated the respiratory center.[85] Oxygen alone was reserved for "pure asphyxia" (whatever that meant). The advent of mobile oxygen tanks and their easy availability in the mid-1940s enabled the use of oxygen for resuscitation.[51,53,79]

The success of incubator care brought new and unexpected challenges.[68,69] Innovative methods had to be developed to feed the increasing number of premature infants who were surviving for longer periods than ever before. Their growth needed to be monitored, and illnesses related to prematurity, such as sepsis, apnea, anemia, jaundice, and respiratory distress, had to be studied and treated. Another completely unexpected peril from "improved" incubator technology was the epidemic of blindness from ROP (then called retrolental fibroplasia), documented in vivid detail elsewhere.[79,80] The apparent culprit in cases of ROP was the "leakproof" incubator that led to a great increase in the inspired oxygen concentrations (piped in free-flow manner),

TABLE 1.2 Evolution of Incubators

Year(s)	Developer/Product	Comments
1835, ca. 1850	von Ruehl (1769-1846)	A physician to Czarina Feodorovna, wife of Czar Paul I, von Ruehl develops the first known incubator for the Imperial Foundling Hospital in St. Petersburg. About 40 of these "warming tubs" are installed in the Moscow Foundling Hospital in 1850.
1857	Denucé (1824-1889)	The first published account of introducing an incubator is a 400-word report by Denucé. This is a "double-walled" cradle.
1880-1883	Tarnier (1828-1897)	Tarnier incubator is developed by Martin and installed in 1880 at the Port-Royal Maternité.
1884	Credé (1819-1892)	Credé reports the results of 647 infants treated over 20 years using an incubator similar to that of Denucé.
1887	Bartlett	Bartlett reads a paper on a "warming crib" based on Tarnier's concept but uses a "thermo-syphon."
1893	Budin (1846-1907)	Budin popularizes the Tarnier incubator and establishes the world's first "special care unit for premature infants" at Maternité and Clinique Tarnier in Paris.
1893	Rotch (1849-1914)	The first American incubator with a built-in scale, wheels, and fresh-air delivery system is developed; the equipment is very expensive and elaborate.
1897	Holt incubator	A simplified version of the Rotch incubator is developed. In this double-walled wooden box, hot water circulates between the walls.
1897-1920s	Brown, Lyons, DeLee, Allin	Many modifications are made to the early American and European incubators by physicians. These are called baby-tents, baby boxes, warming beds, and other names.
1922	Hess	Hess introduces his famous incubator with an electric heating system. For transportation, he develops special boxes that can be plugged into the cigarette lighters in Chicago's taxi cabs.
1930-1950s	Large-scale commercial incubators	There is worldwide distribution of Air-Shields and other commercial ventilators.
1970-1980	Modern incubators	Transport incubators with built-in ventilators and monitoring equipment are developed—mobile intensive care units.

coupled with the belief that oxygen was innocuous and that if a little bit could save lives, a lot could save even more lives. Because more and more sick and small preterm infants began to survive with incubator care, providing ventilatory assistance became an urgent necessity.

Ventilatory Care: "Extended Resuscitation"

The first mechanical instrument used for intermittent positive pressure ventilation in newborns was the *aerophore pulmonaire*, a simple device developed by the French obstetrician Gairal.[65,66] It was a rubber bulb attached to a J-shaped tube. By placing the bent end of the tube into the infant's upper airway, one could pump air into the lungs. Holt recommended its use for resuscitation in his influential 1897 book.[48]

Before starting mechanical ventilation, one needed to cannulate the airway, a task nearly impossible without a laryngoscope and an endotracheal tube. Blundell (1790-1878), a Scottish obstetrician, was the first to use a mechanical device for tracheal intubation in living newborns.[13,32] Introducing two fingers of his left hand over the infant's tongue, he would feel the epiglottis and then guide a silver pipe into the trachea with his right hand. His tracheal pipe had a blunt distal end and two side holes. By blowing air into the tube about 30 times a minute until the heartbeat began, Blundell saved hundreds of infants with birth asphyxia and infants with laryngeal diphtheria. His method of tracheal intubation is practiced in many countries today.[90] In the

• **Fig. 1.10** The Man-Can, circa 1873 to 1875. A handheld, negative-pressure ventilatory device for which a patent was applied in 1876.[19,20] (From DeBono E. *Eureka! How and When the Greatest Inventions Were Made: An Illustrated History of Inventions from the Wheel to the Computer*. New York: Holt, Rinehart & Winston; 1974, p 159.)

late nineteenth century, a wide array of instruments evolved to provide longer periods of augmented or extended ventilation for infants who had been resuscitated in the labor room. Most of the early instruments were designed for use in adults, however, and were used later in newborns and infants, particularly to treat paralytic polio and laryngeal diphtheria.[39,45,81,85]

The iron lung (or "man-can") was one of the earliest mechanical ventilatory devices (Fig. 1.10), and a US patent was issued for it in 1876.[19,20,42] In other ventilatory equipment, varying methods for rhythmic inflation and deflation of the lungs were used for prolonged ventilation. Among those, the Fell-O'Dwyer apparatus used a unique foot-operated bellows system connected to an implement similar to the aerophore bulb.[25,65,66]

Between 1930 and 1950, there were sporadic but important reports of prolonged assisted ventilation provided to newborns.[12,62,84,85] Beginning in the late 1950s and through the 1960s, more neonatal intensive care units (NICUs) began providing ventilatory assistance regularly (Table 1.3). Ventilatory care did not become predictably successful, however, until the early 1970s, when continuous positive pressure was incorporated into ventilatory devices.[44,58,62,84]

Supportive Care: Intravenous Fluid and Blood Transfusions

When it comes to intravenous therapy, our legacy is one of bloodletting, not of transfusing. Blundell (of intubation fame) also made a major contribution to transfusion science. Believing that "only human blood should be employed for humans," he developed instruments, syringes, and funnels for this purpose. In 1818, Blundell carried out the first direct transfusion from a healthy donor into a recipient; 5 of his first 10 patients survived.

Human-to-human transfusions gradually became accepted, but physicians in the nineteenth century were puzzled about unexpected disasters among blood transfusion recipients. It took 15 years after Landsteiner's discovery of blood groups in 1901 for the general acceptance

TABLE 1.3 Ventilatory Care, Respiratory Disorders, and Intensive Care

Category	Approximate Time Span	Procedures and Techniques
Resuscitation and oxygen	From antiquity to early 1970s	Mouth-to-mouth breathing (although it fell from favor in the late eighteenth century because many influential physicians declared it a "vulgar method" of revival)
	1878	Tarnier uses oxygen in debilitated premature infants.
	1900-1930s	Schultz, Sylvester, and Laborde methods of resuscitation involve various forms of swinging infants (Schultz), traction of the tongue (Sylvester), and compression of the chest (Laborde).
	1930-1960s	Oxygen administration to the oral cavity through a rubber catheter
	1930s-1940s	Tight-fitting tracheal tube and direct tracheal oxygen administration
	1913-1920s	Byrd-Dew method: immersion in warm water, with alternate flexing and extending of the pelvis to help the "lungs open"
	1850-1930s	Dilation of the rectum
	1930-1950s	Inhalation of oxygen and 7% CO_2 mixture (for morphine-induced narcosis)
	1940-1950s	Positive-pressure air-lock (Bloxsom method)
	1940 to late 1950s	Concept that "air in the digestive tract is good for survival" is promoted—administration of oxygen to the stomach
	1950 to late 1960s	Hyperbaric oxygen in Vickers pressure chamber
	1950-1960s	Mouth-to-mouth or mouth-to-endotracheal tube breathing
Assisted ventilation	1930s-1980s	Bell develops a negative-pressure jacket
	1930-1950	Negative-pressure ventilators and iron lungs, used rarely in infants
	1960s	Positive-pressure respirators used for prolonged ventilatory support
	1971	Continuous positive airway pressure introduced for use in newborns
	1973	Intermittent mandatory ventilator
	1970-1980s	High-frequency ventilators; continuous monitoring of pulmonary function
Surfactant	1903	Hochheim reports "hyaline membranes" noted in the lungs of infants with RDS
	1940-1950s	Clinical descriptions and pathology studied
	1955–1956	Pattle discovers surfactant in pulmonary edema foam and lung extracts.
	1959	Avery and Mead show absence of surfactant in infants with hyaline membrane disease.[4]
	1971	Gluck introduces lecithin/sphingomyelin ratio.
	1973	Liggins suggests that antenatal steroids help mature the pulmonary surfactant system.
	1980	First effective clinical trial of postnatal surfactant therapy (bovine, Fujiwara)
	1989-1991	Commercial surfactants become available.
	1995	Widespread antenatal steroid use leads to declines in rates for RDS and improves survival rates for infants with birth weight <1000 g, heralding a new era of epidemics of bronchopulmonary dysplasia and retinopathy of prematurity.
Education research and patient care	1950 and beyond	Era of controlled clinical trials in neonatal medicine begins
	1970s	Regionalization of neonatal-perinatal care
	1990s	Evidence-based medicine, systematic reviews
		Large perinatal networks for research (self-funded and federally funded)
	2005	Hypothermia for perinatal hypoxic-ischemic encephalopathy
Border of viability debates	2005	Improved survival rates for infants between 22 and 26 weeks' gestation raise questions about the definition of border of viability and the ethics of intensive care for such infants. Debates and dilemma continue.
Adults born preterm	2008–2017	Large population-based national cohorts and longitudinal studies are beginning to report health and social well-being of adults born at preterm gestation.[67]

RDS, Respiratory distress syndrome.
See references 2, 4, 5, 18, 25, 46, 49, 58, 61, 92.

and understanding of the scientific basis for blood group incompatibility.[92]

Adult transfusions were rare, but newborn transfusions were rarer still. On March 8, 1908, a 4-day-old term infant who had hemorrhagic disease of the newborn made history. "As the child's skin became waxen white and mucous membranes without color, it was decided to attempt transfusion of blood obtained from the infant's father," wrote Lambert from New York.[55] Carrel, a surgeon from Rockefeller University Hospital, performed an end-to-end anastomosis of

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

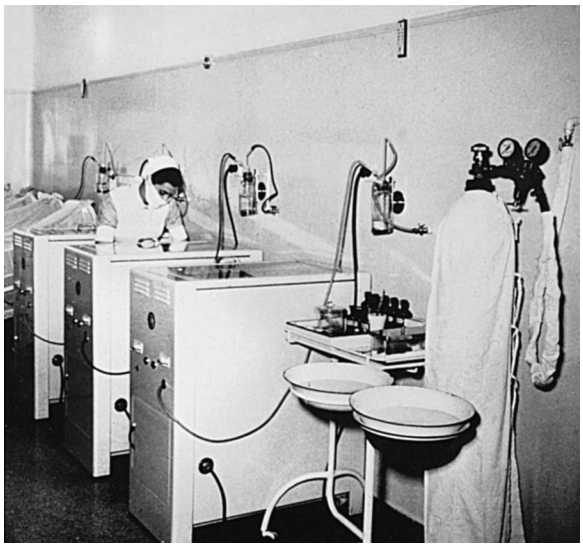
the right popliteal vein of the infant with the left radial artery of the father. No anesthetic was given to either patient. "The amount of blood transfused could not be measured, but enough blood was allowed to flow into the baby to change her color from pale transparent whiteness to brilliant red…[and] as soon as the wound was sutured, the infant fed ravenously and immediately went to sleep," according to Lambert. Incidentally, Carrel was the first surgeon to develop innovative methods of suturing blood vessels—a contribution for which he received the 1912 Nobel Prize.



Despite Lambert's dramatic report, direct father-to-infant transfusion did not become routine. Because of unexpected reactions among the recipients, blood transfusions continued to be risky, despite proper matching of the donors' blood for major blood types. The mystery was understood only after the discovery of Rh subtypes by Landsteiner and Wiener in 1940.[92,95]

The discovery of the Rh blood types, leading to the conquest of erythroblastosis fetalis, remains an unparalleled triumph in pediatric medicine. This is an example of an orderly progression of accumulating knowledge leading to the near-eradication of a disease. First, there were the clinical descriptions of the disease (erythroblastosis); then there was a revolutionary, if symptomatic, therapy for it (exchange transfusion); then in utero transfusions; and finally, successful efforts to prevent it (RhoGAM). The enthralling story of the conquest of erythroblastosis has been described superbly in many monographs and comprehensive review articles.[28,29,92,95]

Tools and Supplies for Neonatal Intensive Care Units

It may be impossible for us to realize the hardship of performing such simple and mundane chores as the collection of blood from or insertion of catheters into the veins of preterm infants before the advent of ultrasmall needles, pumps, and tubing. These were not available until the 1930s. In 1912, Blackfan (1883-1941) developed an ingenious suction device for blood collection.[9] Obtaining blood was done by puncturing the sagittal sinus or femoral or carotid veins; the latter sometimes led to accidental puncture of the nearby arteries. Well into the early 1970s, only a handful of laboratories could perform arterial blood gas analyses with less than 5 mL of blood.

Using the intraperitoneal route for treating dehydration or hypovolemic shock was common. Electrolyte solutions and blood were being administered directly into the peritoneal cavity with the expectation that its large absorptive surface allowed for rapid absorption.[10,95] In 1923, Sidbury introduced umbilical venous catheterization for neonatal blood transfusions,[77] and in the 1950s, Diamond and colleagues began using this route for exchange transfusions.[28,29] Indwelling polyethylene tubes were not introduced for gastric feeding until 1951.[74,95,96]

• **Fig. 1.11** The first preterm infant unit in Athens, Greece, using incubators with oxygen flowing into them (circa 1947). (Courtesy of John Sofatzis, MD, Athens, Greece.)

Pediatric Surgery: Not for Rabbits Anymore

As the trend of specialization among surgical subspecialties became popular, generalist surgeons resisted the change. Churchill, a famous surgeon, once remarked that his surgical residents at Massachusetts General Hospital "were quite proficient at operating on rabbits," and there was no need for a subspecialty in pediatric surgery.[35] Despite those objections, Harvard Medical School founded the first department of pediatric surgery in 1941 and named Ladd as its chair.

Global Neonatal Care

By the middle of the twentieth century, scores of neonatal units based on the Hess model were built in many European countries (Fig. 1.11) and the United Kingdom.[33,61] During the final decades of the twentieth century, in many Asian countries, indigenous instruments and devices were being developed to improve neonatal resuscitation and intensive care for sick newborns.

Medical Errors and "Patient Safety" as a New Discipline

It appears that the flip side of the well-known adage *to err is human* is the saying that *truth is a corrected error*. . . . In a series of papers, Robertson provides a breakdown of errors in neonatal medical practice in the twentieth century.[70-72] He defined years 1920 to 1950 as the *hands-off years*, 1950 to 1970 as the *heroic years*, and 1970 to 2000 as the *experienced years*. An astounding range of errors has affected our

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

field: from iatrogenic hypothermia of preterm infants to aniline dye–contaminated diapers leading to epidemics of methemoglobinemia; chloramphenicol causing shocklike syndromes; sulfisoxazole causing kernicterus; and infant formulas causing metabolic alkalosis and lactobezoars.

As technological advances bring new modes of diagnostic methods and treatments, there are risks for also bringing new types of errors. We regret errors, and we learn a great deal by understanding the causes and consequences of errors and by developing effective means of preventing them. Toward this end it is gratifying to note that *patient safety* has evolved as a new discipline.[76]

Controlled Clinical Trials, Evidence-Based Medicine, and Research Networks

The modern era of controlled clinical trials evolved in the second half of the twentieth century. The first randomized controlled clinical trial (RCT) in the United States was on a neonatal topic.[79,80] In 1949, in their newly established "infant station" at the Babies Hospital, New York, Silverman and colleagues saw an infant with a severe stage of ROP. This 1200 g infant was the son of a biochemistry professor. Desperate to do "anything" to prevent the infant becoming totally blind, Silverman's group decided to administer adrenocorticotropic hormone (ACTH). The infant made a dramatic recovery. This gave them the inspiration to "try" to design a placebo-controlled randomized trial using ACTH for ROP.

The results were disappointing. In addition to causing steroid-related side effects, ACTH was no more effective than the placebo in reducing ROP severity. The experience of organizing this trial led Silverman to develop additional RCTs in neonatal medicine; the most famous of which is the multicenter trial of curtailed or liberal use of oxygen to prevent ROP.[79,80]

With RCT as the backbone, advances in statistical methods and computer sciences gave rise to the science of systematic analyses, culminating in the founding of the Cochrane Collaboration in 1993, named after the British epidemiologist Cochrane. The Collaboration produces and disseminates systematic reviews on therapies in all of medicine.

Another welcome trend of the 1980s was the development of cooperative clinical and research networks. Examples of these include the self-funded Vermont Oxford Network and the federally funded Maternal-Fetal Medicine Units and the Neonatal Research Networks. Such cooperative networks have also been organized in the United Kingdom and European countries. These networks have conducted many highly successful collaborative clinical trials. With common protocols and shared resources, they have managed to enroll and study large numbers of research subjects within short time spans. The generic database maintained in these networks has become an invaluable resource for observational research. From the perspective of a historian, however, the long-term impact of these developments on the neonatal practice at the community (or practitioner) level and their overall impact on neonatal outcomes need to be studied systematically.

Future of Neonatal Research, Education, and Databases in the Internet Era

Of all the advances in the twentieth century, none has made a greater impact on our lives than computers, the Internet, and information technology. The Internet and information technology opened new avenues for dissemination of research information and helped the development of clinical research databases. These resources need to give way for creative means pooling our collective experiences in patient care in a prospective manner.

Although today's NICU is a technological marvel, conceptually it remains a miniaturized version of the adult intensive care unit. Knowledge about the environmental influences on growth and development may change the shape of future NICUs. Although the immediate and long-term adverse effects of excessive noise, light, handling, and pain on infant growth are being studied, attempts are being made to transform the impersonal intensive care environment into an infant-friendly experience. Many ultramodern NICUs have now been built on the concepts of environmental care. Such "kind and gentle" NICUs may be what Tarnier, Budin, Hess, and others conceived of some 100 years ago.

Despite incredible advances in the care of premature infants, today's scientists are facing many unresolved issues, including limits of viability, cost of care, quality of life for intensive care "graduates" (into their adult lives), and an ever-increasing battle against opportunistic nosocomial microorganisms. A major concern is the definition of border of viability and the ethics of providing intensive or palliative care for infants born between 22 and 25 weeks' gestation. To the long list of new problems, one might add the growing realization that many adult-onset disorders may have developmental origins.

These and similar concerns also vexed the early pioneers of our subspecialty. Future historians may assess this century of neonatal medicine with the same sense of surprised wonder and awe that we now feel when remembering the days of infant hatcheries and baby incubator shows.

Some Famous High-Risk Infants

Shakespeare's King Henry VI offers one of the most poignant musings on the burdens of disability and the difficult birth (owing to footling presentation) of his brother, the Duke of Gloucester, who later became Richard III. Henry says to the Duke,[54] who was supposedly born premature (although not confirmed by other historians), "Thy mother felt more than a mother's pain, yet brought forth less than

TABLE 1.4 Ominous Beginnings for Some Famous Historical and Fictional Personalities

Category	Name	Description*
Religious	Moses	Jewish tradition holds that Moses was born "6 months and 1 day" after he was conceived; thus, he could be hidden for 3 months from Pharaoh's soldiers who were looking to find and kill the liberator of Jews.[50,60]
Historical personalities and characters	Duke of Gloucester (later Richard III) (1452-1485)	Footling presentation, possibly premature; might have had cerebral palsy (hemiplegia?)[54]
	Macduff (Scottish nobleman in Shakespeare's *Macbeth*)	Delivered by cesarean section after his mother's death—"not of a woman born" but of a corpse[54]
Artists and writers	Jonathan Swift (1667-1745)	Mentioned by Cone[24]
	Licetus Fortunio (1577-1657)	"A fetus no more than five and one-half inches" at birth[86]
	Pablo Picasso (1881-1973)	Left on the table as a stillbirth; his uncle, Don Salvador, a physician, resuscitated him
	Voltaire (1694-1778)	Premature and asphyxiated, the "puny little boy" was not expected to live and was hurriedly baptized; he was raised in the attic to keep him warm
	Samuel Johnson (1709-1784)	A huge baby, he was "strangely inert" at birth, requiring slapping and shaking. With persuasion, he made a few whimpers and lived.
	Johann Wolfgang von Goethe (1749-1823)	After 3 days of labor, his mother delivered him; he was "lifeless and miserable" and thought to be stillborn at birth.
	Anna Pavlova (1882-1931)	"A premature, so puny and weak," she was wrapped in cotton wool for 3 months.
	Thomas Hardy (1840-1928)	He was thrown aside as dead at birth. "A good slapping" from the midwife revived him.
	Sidney Poitier (born 1927)	Being 3 months premature, he was so small that his father "could place him in a shoebox." His grandmother said that despite prematurity, he would "walk with the kings." He did, when he became Bahamian ambassador to Japan in the 1990s.†
Scientists	Johannes Kepler (1571-1630)	A "seven-month" baby; estimated IQ, 161
	Christopher Wren (1632-1723)	Mentioned by Cone[24]
	Isaac Newton (1642-1727)	Thought to be "as good as dead" at birth. He was such a "tiny mite" that he could be placed in a quart mug.
Politicians	Franklin D. Roosevelt (1882-1945)	Weighed 10 lb at birth but was "blue and limp with a deathlike respiratory standstill" from too much chloroform given to his mother, Sara Roosevelt
	Winston Churchill (1874-1965)	His early birth "upset the ball." Later a duchess remarked that the baby had such a lusty "earth-shaking" cry as she had ever heard. Recent historians doubt his premature birth.

*The biographical notes are derived mostly from anecdotal statements of historians or family members or are from later recollection by the individuals themselves; we cannot be certain of the scientific validity of these stories.
†Quoted by Sidney Poitier in the television show *Biography,* CNN, Spring 2000.
See references 54, 64, 87.

a mother's hope." King Richard himself in a different Shakespearean play bemoans his misfortune[54]: "Deformed, unfinish'd, sent before my time/Into this breathing world, scarce half made up."

Did King Richard have hemiplegic cerebral palsy as a consequence of prematurity? We cannot be sure. The list of leaders, celebrities, and famous individuals supposed to have been regarded as being at high risk at birth (Table 1.4) is impressive,[64] although the authenticity of the stories is difficult to confirm because most of them were derived from anecdotal statements.

Acknowledgment

The author sincerely thanks Caroline Signore, MD, for helping during the preparation of the manuscript, and he thanks all of the copyright holders for permission to reproduce the illustrations used in this chapter.

Key Points

- The past: Neonatology has a rich history focused largely on basic supportive care until the 1970s.
- The present: The last 40 to 50 years have seen the advent of significant innovative interventions and changed from anecdotal to evidence-based care, with many randomized clinical trials enabled by the establishment of cooperative clinical and research networks.
- The future: Challenges include optimizing the NICU environment, data collection and its dissemination in the digital age, defining limits of viability, introducing precision medicine, and optimizing quality of life for NICU graduates.

Epidemiology for Neonatologists

ANDREA N. TREMBATH

Introduction

Epidemiology is the study of health and disease and the associated causes.[9,23] The role of epidemiology in neonatal-perinatal medicine is to define the prevalence and causes of illness in women and children by exploring risk factors and their associations. Specifically, maternal and infant mortality rates are used to assess the levels of health, access to needed health care, and quality of health care provided by a region or country.

Common Epidemiologic Concepts

In epidemiology, risk describes the probability of disease occurrence; however, it may represent a wide variety of statistical measures that include incidence, prevalence, rate, or odds. A risk factor often implies an increase in the outcome of interest with exposure, although risk measures may also represent protective effects. Risks are often compared using relative measures such as the risk ratio, odds ratio, and rate ratio (Table 2.1). Relative measures are helpful in the identification of risk factors but can be misleading if not accompanied by absolute measures such as the risk difference. For example, a relative risk of 2.0 indicates that the exposed group is twice as likely to develop the disease as the unexposed group. However, twice as likely may represent an absolute change in risk from 0.2 (20%) to 0.1 (10%; risk difference of 0.1 or 10%) or may represent an absolute change in risk from 0.002 (0.2%) to 0.001 (0.1%; risk difference of 0.001 or 0.1%). A small change in absolute risk, therefore, may have little to no clinical impact.

In neonatology, the impact of single risk factors on outcomes is generally small, and caution should be used when inferring causality. Most diseases such as intraventricular hemorrhage (IVH), necrotizing enterocolitis (NEC), and bronchopulmonary dysplasia (BPD) have many component causes, some of which remain either unknown or unmeasurable. These component causes can occur at different times, and the sequence of their occurrence may be important in the development of the disease.

Health Statistics and Data Sources

A clear understanding of the definitions used to calculate the epidemiologic data for health statistics is essential. In the United States, population-level health data is primarily derived from birth and death certificates submitted to the National Vital Statistics System (NVSS) by individual states and territories.[11] The standardized terminology and definitions allow direct comparison of important population-level health markers such as birth, death, and outcome rates[21] (Table 2.2). A standard set of reporting measures are reported to the NVSS; however, individual states may choose to collect additional data of importance to their specific population. In the United States, completion of a birth certificate form is required for all births regardless of length of gestation or weight and uses uniform definitions[4,11,21] (Table 2.3). Fetal death reporting requirements, however, vary by state and may be based on gestational age or birth weight criteria.

The ability to make inferences based on health statistics relies on the availability of large datasets such as those found through the NVSS. However, many of the important questions regarding survival and neurodevelopmental outcomes of the smallest and sickest infants in neonatology represent only a small total number nationwide. Single centers often do not have large enough populations of neonates to have the statistical power to determine clinically important differences in outcomes. To meet this need, several networks of neonatal and maternal centers have been established.

The National Institute of Child Health and Human Development (NICHD) Neonatal Research Network (NRN), established in 1986 to improve the medical care for newborns and their families, is a consortium of US neonatal intensive care units (NICUs) that conducts multicenter clinical trials and observational trials on infants.[8] Among the ongoing observational trials, the Generic Database Study (GDB) has been collecting information on very low birth rate (VLBW) infants since 1987, including data on hospital admission as well as follow-up data that includes standardized neurodevelopmental assessments. In addition, the NRN designs and executes high-quality clinical trials

Abstract

Perinatal epidemiology aims to define the prevalence and causes of health and disease in women and children. Health statistics derived from national databases including the National Vital Statistics System provide information on birth and death rates and include information on neonatal and maternal morbidities. Specifically, information on maternal and infant mortality rates are critical indicators of a population's health and wellness.

Keywords

epidemiology
infant mortality
pregnancy-related death
prematurity
health disparities

TABLE 2.1 Common Measures and Definitions

Risk ratio	Ratio of the incidence of risk in an exposed group to the incidence risk in the unexposed group
Odds ratio	Ratio of the odds of an event in the exposed group to the odds of an event in the unexposed group
Incidence	Proportion of individuals who are initially free of an outcome who subsequently develop the outcome over a specified period of time
Prevalence	Proportion of individuals who have a specific outcome at a given time

TABLE 2.2 Commonly Reported Rates

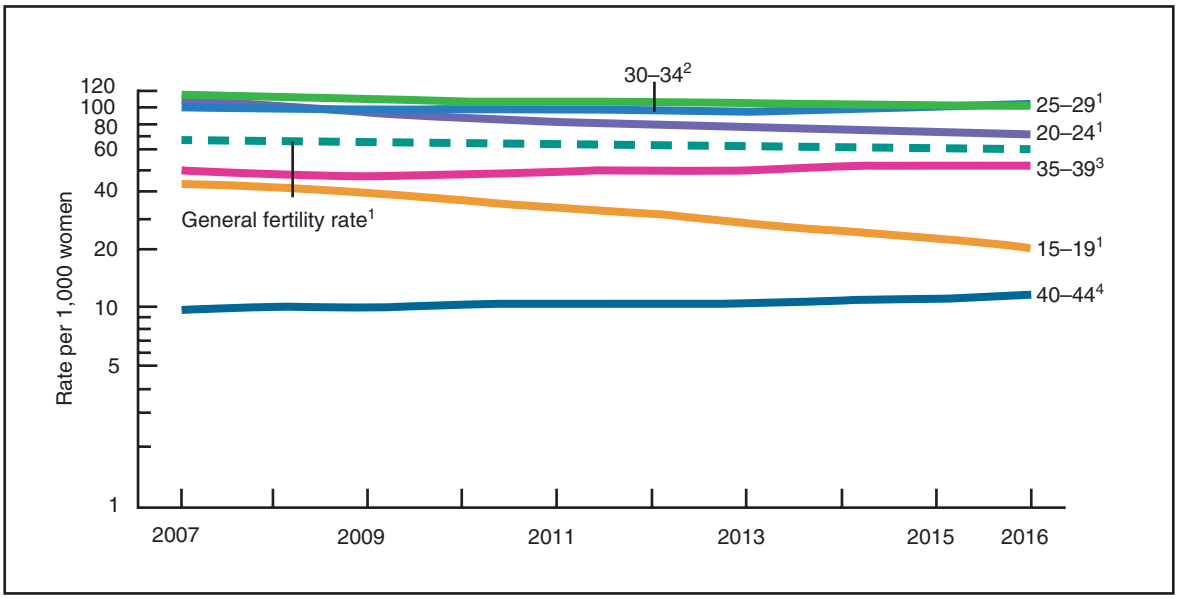
Perinatal mortality (PMR)*	Infant deaths under 7 days of age and fetal deaths ≥28 weeks' gestation per 1000 live births plus fetal deaths
Infant mortality rate (IMR)	Deaths prior to 1 year of life per 1000 live births
Neonatal mortality	Deaths prior to 28 days of life per 1000 live births
Post-neonatal mortality	Deaths from 28 days to <365 days per 1000 live births

*PMR definition I is used for international and state-specific comparisons because of differences among countries and states in the completeness of reporting of fetal deaths prior to 28 weeks' gestation.

TABLE 2.3 Vital Statistics Definitions

Live birth	The complete expulsion or extraction from the mother of a product of human conception, irrespective of the duration of the pregnancy, which, after such expulsion or extraction, breathes or shows any other evidence of life, such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles, regardless of whether the umbilical cord has been cut or the placenta is attached. Heartbeats are to be distinguished from transient cardiac contractions; respirations are to be distinguished from fleeting respiratory efforts or gasps.
Fetal death	Death before the complete expulsion or extraction from the mother of a product of human conception, irrespective of the duration of pregnancy that is not an induced termination of pregnancy. The death is indicated by the fact that, after such expulsion or extraction, the fetus does not breathe or show any other evidence of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles. Heartbeats are to be distinguished from transient cardiac contractions; respirations are to be distinguished from fleeting respiratory efforts or gasps.
Infant death	Live birth (as above) that results in death prior to 1 year of life (<365 days).
Neonatal death	Death before 28 days of life
Post-neonatal death	Death at 28 days to 364 days of life

that provide epidemiologic data on subset populations and specific neonatal diseases.



The Vermont Oxford Network (VON) is an international collaborative of more than 1000 NICU and medical centers established in 1988.[24] The mission of VON is "to improve the quality and safety of medical care for newborn infants and their families through a coordinated program of research, education, and quality improvement projects." VON maintains a database of inpatient hospital information on VLBW infants using standardized measures. In total, more than 2.2 million infants are represented in this database, providing a rich resource for information on the care and hospital outcomes of high-risk infants.

National and international quality collaboratives are filling an important role in neonatology by providing a platform to gather information on maternal child health as well as improving the care delivered to newborns. While the scope and direction of the quality initiatives vary, several perinatal state collaboratives, such as California Perinatal Quality Care Collaborative, the Ohio Perinatal Quality Collaborative, the Perinatal Quality Collaborative of North Carolina, and Tennessee Initiative for Perinatal Quality Care, have contributed valuable data on rates of late onset sepsis, nonindicated cesarean section, antenatal corticosteroid use, and narcotic abstinence syndrome.[10,15]

Birth Data

There were 3,978,497 births in the United States in 2015, a number that has remained fairly stable for nearly a decade.[12,19] The mean age of a mother at first birth has risen to 26.3 years in the United States and 28 in the United Kingdom.[20,22] The increase in maternal age at first birth is reflected in a steady rise in the birth rate for women in their thirties and forties, 101.5 per 1000 births for women age 30-44.[20] The teenage birth rate (ages 15-19), however, has

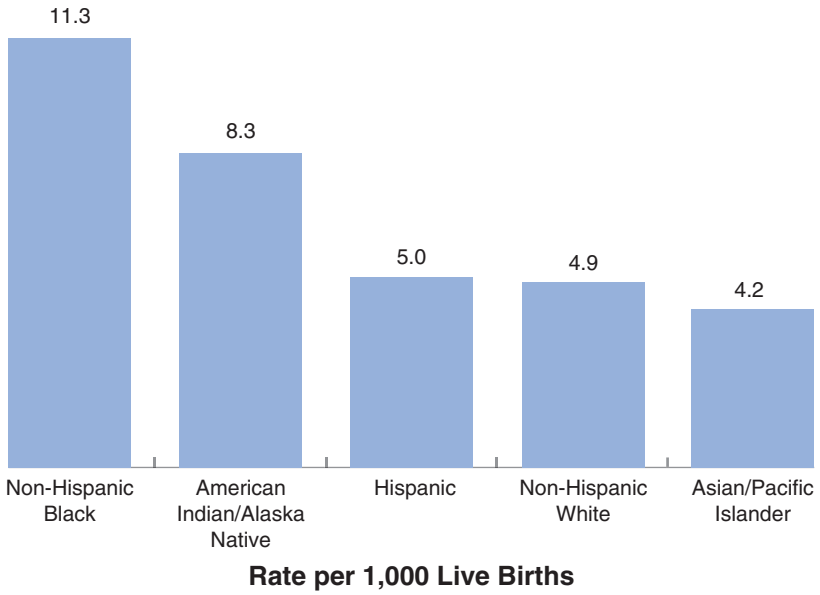
continued to decline to 22.3 per 1000 live births—an over 60% reduction from its peak in 1991[19] (Fig. 2.1).

In the United States, the overwhelming majority of births occur in a hospital (98.5%) and are attended by an allopathic doctor of medicine (84%). Nurse midwives attended 8% of deliveries in 2015.[19] Among out-of-hospital deliveries, 63% occurred at home and 30.9% occurred at a birthing center. The rate of delivery by cesarean section in the United States remains around 32% overall; however, rates among all age groups have continued to decrease since 2009. Among women younger than 25 years, the rate of cesarean section has had the most significant declines. However, the rate of cesarean section delivery is nearly double among women age 40 and over.[5,12,19]

In 2015, 133,155 infants were born as twins in the United States, a rate of 33.5 per 1000 births. The twin birth rate increased steadily by 76% between 1980 and 2009. The increase has slowed since the mid-2000s; however, the peak rate was in 2014 at 33.9 per 1000 births.[5,19] The increases in twinning rates have been associated with increased use of assistive reproductive therapies (ART) such as fertility-enhancing drugs and are reflected by the increasing mean maternal age. In contrast, the rate of higher-order multiples has decreased dramatically (103.6/100,000) since the 1998 peak of 193.5 per 100,000 births. The reduction in higher-order births has been associated with more conservative use of ART, such as limiting the numbers of implanted embryos during in vitro fertilization.

Fetal Deaths



Rates of fetal death are the most difficult-to-interpret statistic because of inconsistencies in reporting. For statistical purposes, the fetal period is defined as the in utero period from 8 weeks after conception until term. A fetal death is commonly referred to as a miscarriage if it occurs at less than 20 weeks' gestation and a stillbirth if it occurs after 20 weeks' gestation.

Infant Deaths

Infant mortality (IM) is a critical measure of the health and welfare of a population. In 2015, 26,000 infants died before reaching age 1, resulting in an infant mortality rate of 5.9 deaths per 1000 live births.[14] This rate achieved the Health People 2020 IM goal of 6 per 1000 live births, and overall, the rates of IM in the United States have been declining steadily for at least 40 years.[13] Despite reaching the Health People 2020 goal, the United States ranks 32nd in infant mortality when compared to other developed countries, well behind Sweden, Japan, Singapore, and Hong Kong. Six countries had an infant mortality rate less than half the US rate.

The leading causes of infant mortality in the United States include premature birth and low birth weight (which accounts for nearly half of infant mortality), congenital defects, sleep-related deaths, pregnancy-related

complications, and injuries.[18,19] While these are primarily medical diagnoses, they are highly influenced by the social determinants of health. Social determinants of health are defined as those "nonmedical factors that influence health, including health-related knowledge, attitudes, beliefs, or behaviors."[6] These include socioeconomic factors such as education, employment, and neighborhoods, as well as health behaviors such as tobacco use and diet/exercise. The impact of these social determinants of health can be seen in the marked health disparities that exist in IM rates by race. The rate of IM among black infants is more than 2 times the rate of that for non-Hispanic white infants[19] (Fig. 2.2).

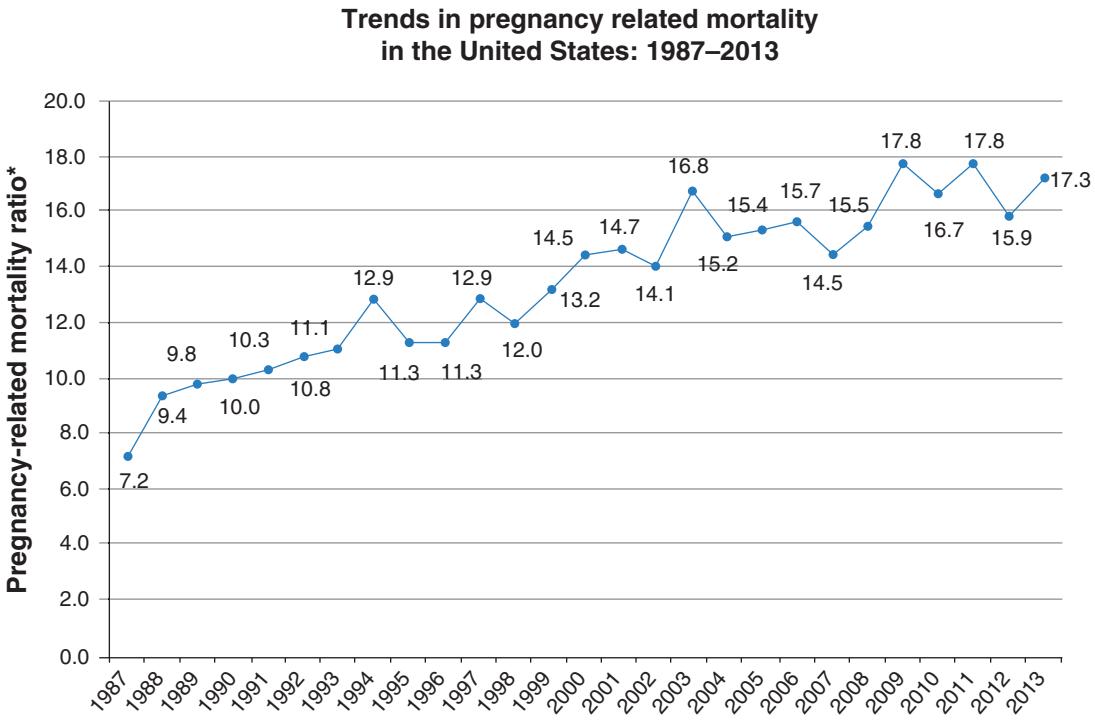
Pregnancy-Related Deaths

Pregnancy-related deaths, also known as maternal mortality, is defined as death of a woman either during pregnancy or in the 1 year following the end of pregnancy and is related to pregnancy or its management, excluding those caused by accidents or incidental causes. In 1983 the CDC began surveillance of pregnancy-related deaths using death certificates voluntarily submitted by the 50 states, New York City, and the District of Columbia.[7] From 1987 to 2013, the rate of pregnancy-related deaths has increased from 7.2 to 17.3 per 100,000 live births[5,7] (Fig. 2.3). The reasons for the increased rates of mortality are unclear, although may be due in part to increased reporting. However, it is well recognized that there has been an increase in the number of pregnant women with chronic health conditions such as obesity, hypertension, diabetes mellitus, and cardiovascular disease.[1,17] These conditions place a pregnant woman at a higher risk of adverse outcomes (Fig. 2.4).

In addition, significant disparities in rates of pregnancy-related deaths occur according to race and sociodemographic levels. Black women experience pregnancy-related mortality rates nearly 3.5 times higher than those of white women or other races (43.5 vs 12.7 and 14.4 per 100,000 live births).[7]

Maternal Morbidity

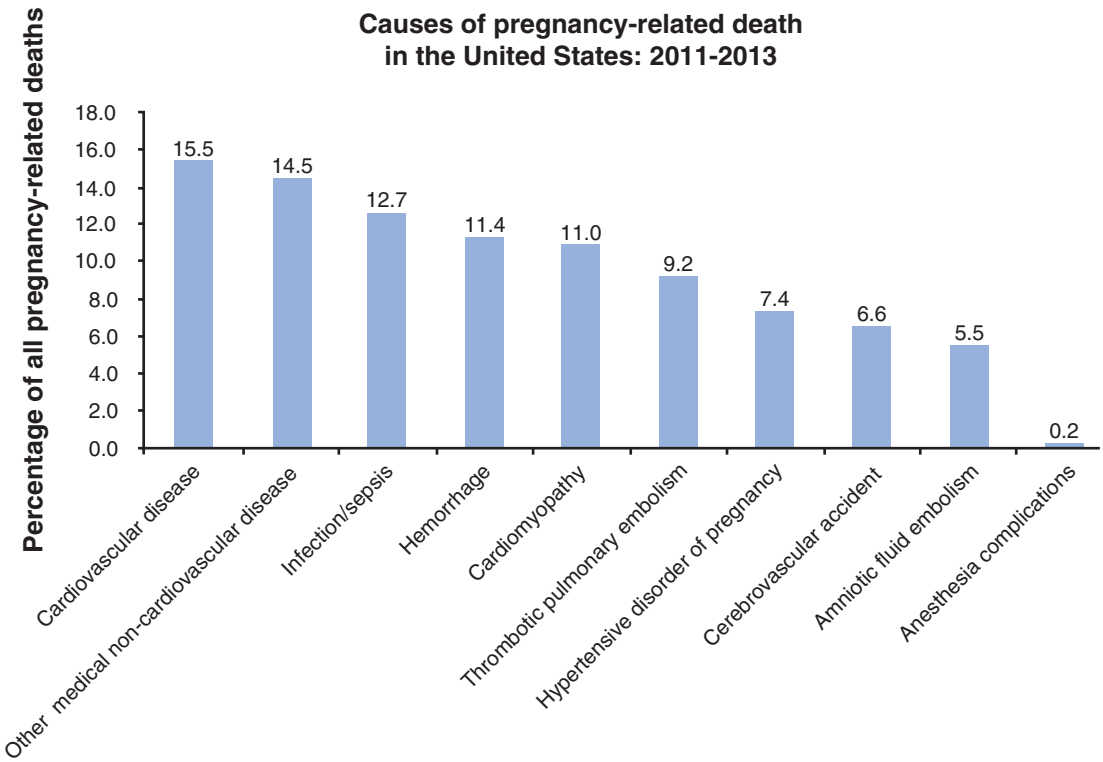
Severe maternal morbidity is any unexpected outcome of the pregnancy or labor and delivery process that results in short- and long-term impacts on a woman's health. The rate of severe maternal morbidity has increased in recent years, affecting approximately 50,000 women in 2013 and 2014.[5] The increase is likely due to an overall increase in the rates of maternal chronic conditions that predispose to higher rates of complications, such as the need for blood transfusions or hysterectomy (Fig. 2.5).



Neonatal Morbidity

Prematurity and Low Birth Weight

Prematurity and low birth weight are the leading causes of infant mortality and the primary driver of serious neonatal morbidity. In total, 382,786 preterm births occurred in the United States in 2015, and the rate of low birth weight (defined as <2500 g) infants was 8.16%—a number that has continued to rise nearly 2% from 2014.[18,19]



Traditionally, prematurity has been defined as birth prior to 37 weeks' gestation and is still the primary definition used in most national health statistics. However, in 2013, the American College of Obstetrics and Gynecology (ACOG) recognized the role that a few weeks makes in the risk for morbidity or mortality in the preterm infant by reclassifying full-term delivery as 39 0/7 weeks through 40 6/7 weeks' gestation[2] (Table 2.4). The change in terminology

TABLE 2.4 Definitions of Premature and Term Gestation

Extremely preterm	<28 weeks
Very preterm	28 0/7 to 31 6/7 weeks
Moderate preterm	32 0/7 to 33 6/7 weeks
Late preterm*	34 0/7 to 36 6/7 weeks
Early term*	37 0/7 to 38 6/7 weeks
Full term*	39 0/7 to 40 6/7 weeks
Late term*	41 0/7 to 41 6/7 weeks
Post term*	42 0/7 weeks or beyond

*Based on American College of Obstetrician Gynecologists definition of term pregnancy.

acknowledges that the morbidity and mortality due to prematurity does not abruptly cease after 37 weeks. Rather, infants born at 37-38 weeks' gestation have an infant mortality rate nearly double that of infants born at 38-39 weeks (3.01 vs 1.85).[19] Infants delivered by elective cesarean section at 37-38 weeks' gestation are twice as likely to have adverse respiratory outcomes and require intensive care unit admission compared with infants delivered at 39 completed weeks of gestation.[2] In addition to the medical morbidity and mortality, prematurity comes with a significant cost to the health care system as the average first year cost of caring for a preterm infant (<37 weeks) was nearly 10 times that of caring for a term infant (37 weeks and greater) and costs the US health care system approximately $26 billion dollars annually.[16]

Multiple perinatal quality collaborative organizations nationwide, the March of Dimes, and other national organizations including the American Academy of Pediatrics have campaigns to educate the public about these increased risks and to encourage delays in delivery until 39 completed weeks of gestation.[3] In 2010, the Joint Commission on Hospital Accreditation established a perinatal core measure requiring the reporting of rates of nonmedically indicated deliveries performed between 37 and 39 weeks' gestational age.

Because of these initiatives and many others, the rate of preterm birth in the United States declined to 12.3% in 2008 following three decades of increases, and by 2011, the rate dropped further to 11.72%.[19] In 2016 the percentage of preterm births was 9.84%, based on best obstetrical estimate of delivery prior to 37 weeks' gestation.[12] Infants in multiple gestation pregnancies are more likely to be born prematurely and are more likely to be low birth weight than those in singleton pregnancies. Thus they are at a greater risk of early death—with twins 5 times (and triplets 10 times) as likely to die in infancy. In addition, rates of preterm birth demonstrate marked health disparities with the highest rates of prematurity among non-Hispanic black births, as compared to non-Hispanic white births (13% vs 9%).[14]

Key Points

- Birth rates in the United States have remained stable for nearly a decade.
- Pregnancy-related deaths and maternal morbidity rates continue to rise.
- The US infant mortality rate was 5.9 deaths per 1000 live births.
- Prematurity and low birth weight are the leading causes of infant mortality and demonstrate significant health disparities.

Medical Ethics in Neonatal Care

NAOMI T. LAVENTHAL AND JONATHAN M. FANAROFF

This chapter explores the complexity of moral problem solving in neonatal medicine. First, principles of medical ethics and key terms and concepts are defined, followed by the application of these concepts in specific moral problems that arise (1) when a pregnant patient refuses treatment, (2) in the prenatal consultation at the limits of gestational viability, and (3) when withholding and withdrawing life-sustaining medical treatment in the neonatal intensive care unit (NICU) is undertaken. This list is not an exhaustive representation of ethical challenges facing NICU providers but rather highlights some that are frequently encountered, and the principles offered to address them are applicable to many other situations. A collaborative, procedural framework for consensual end-of-life decision making is described, and specific ethical issues that may arise in end-of-life care are discussed, including the use of analgesic agents, brain death and organ donation, palliative care, and the withdrawal or withholding of artificial nutrition and hydration. This chapter includes guidelines for ethical conflict resolution and an approach to the conduct of clinical research. Finally, a brief summary of ethical responsibilities of neonatal physicians is presented.

Three elements characterize the practice of medicine that are timeless, universal, and irrefutably true: (1) the *fact* of illness and the vulnerability it creates, (2) the *act* of the profession (the use of medical skills for the benefit of the patient), and (3) the *practice* of medicine itself—that which physicians and patients do together in the clinical encounter, characterized by mutual intentionality.[112] These three elements are well exemplified in the care of sick neonates, in which the vulnerability of anxious parents is manifest, the clinical competence and moral discretion of health professionals are used for the benefit of newborn patients and their parents, and the practice is carried out in a patient-parent-physician relationship characterized by mutual trust and pursuit of the neonatal patient's and parents' good.

Medical ethics involves the systematic, reasoned evaluation and justification of the "right" action in pursuit of human good or well-being in the context of medical practice. It involves a critical examination of the concepts and assumptions underlying medical and moral decision making, and it may include a critical examination of the kind of person a physician should be.[118] Medical ethics has become a central focus in the practice of neonatal intensive care, because it contains all the elements of moral discourse but without clear-cut "right" answers expected in routine clinical practice. Numerous ethical issues arise as physicians attempt to determine how best to use technology in pursuit of what is right and good for the patient, in consideration of the values parents place on different outcomes.

These issues are compounded by several limitations on NICU providers' ability to elicit and understand parents' values; these can be pragmatic, related to patient and professional time limitations, but may also result from limitations in the provider's knowledge and expertise of how best to have these difficult conversations.[10,14,75,80,132] Care is also complicated by the medical uncertainty surrounding accurate outcome prediction of potentially adverse findings and by the very nature of many decisions in which quality of life and life *itself* may be under consideration.[74,100] All these issues make the NICU a challenging, highly scrutinized environment in how ethical issues are examined, reasoned, and justified, and raise fundamental questions about what the responsibilities of neonatal health care providers should be.

Ethical issues may be experienced as moral dilemmas, moral uncertainty, or moral distress. A *moral dilemma* is present when the physician believes there is an obligation to pursue two (or more) conflicting courses of action. Because only one of these courses can be pursued, the physician has to make a value-based choice that compromises one of these obligations. Conflict between respect for parental authority and professional duty to provide recommended medical care is a frequently encountered example of a moral dilemma.

Moral uncertainty arises when the presenting issue is unclear. This is commonly manifest as ambivalence on the part of parents who might struggle with a concomitant desire to prolong the life of their infant and wish to avoid burdensome procedures or impaired survival. On the part of physicians, moral uncertainty might arise when treatments are readily available, but with a low likelihood of success.

Moral distress arises when the decision maker feels certain about the morally right thing to do, but this perceived "right" course of action is precluded for numerous reasons,

including the caregiver's lack of decision-making authority or institutional or financial constraints. This phenomenon has been most extensively described among nurses but is also experienced by other NICU providers, including physicians, and involves a sense of powerlessness, frustration, physical symptoms, and ultimately professional "burnout."[15,37,56,115,137] Although unprocessed moral distress can result in maladaptive "moral residue,"[37,123,133] contemporary explorations of this topic have focused on constructive approaches to building moral resilience[116,150] and directing moral distress toward positive actions to improve patient care.[115]

Principles in Medical Ethics

Ethical reasoning requires an understanding of the fundamental principles that define a domain (Box 3.1). Beauchamp and Childress have described four core bioethical principles: autonomy, beneficence, nonmaleficence, and justice. Consideration of a real time ethical conflict or dilemma in the context of these principles can be a useful starting point and can be particularly helpful in articulating the ethical questions, uniting a struggling team by use of commonly held, noninflammatory language. However, a principles-based approach is of limited value when the problem revolves around a conflict between the principles themselves, as is often the case in the NICU. In many cases, a "principalis" paradigm may not do justice to the nature or complexity of the moral problem. In addition, in a purely principle-based approach, the role of the neonatal health care provider as *moral agent* (i.e., someone with personal virtues and values and the opportunity to take action that comports with that judgment of morality) is de-emphasized. This chapter does not prescribe adherence to any particular ethical theory but aims to enhance appreciation of the language of ethical discourse to enable nuanced reflection, reasoning, and ethical decision making, and to underline the role of the health care provider in these situations.

Autonomy

The principle of autonomy supports the right of competent patients to make their own health care choices. An individual who makes an autonomous choice acts intentionally, with understanding and without external controlling influences.[12] An idealized expression of autonomy occurs when a competent adult chooses voluntarily and intelligently from among various options whose relative risks and benefits have been fully explained to him or her by the physicians (i.e., via a truly informed consent process).

The term *parental autonomy* is often used interchangeably with *parental authority*, although most argue that autonomy can strictly be used only when making decisions for oneself. *Parental authority* is the more correct term when referring to the role of parents in decision making for their newborn infants.

Neonatal health care professionals should show respect for parental authority/autonomy: (1) because of the presumption that parents will make decisions that are in their child's best interests (parents are often described as the "natural surrogate decision makers" for children)[41] and (2) as a means of promoting shared decision making with physicians. Parents are not uniform in their desire to direct or even participate in medical decision making for their children.[9,61,81,96,143] However, physicians must be conscious of the impact of *their* authority, the power that derives from expertise and confidence, as well as limitations in their own ability to determine how directive parents wish for them to be in preference-sensitive decisions.[10,50,51,120]

In the second half of the 20th century, there was a shift away from a paternalistic approach to information sharing and medical decision making toward empowerment of the patient to make autonomous choices.[35] This condemnation of paternalism has more recently been viewed as excessively burdening some patients with weighty decisions that they do not wish to make alone.[110] There is a body of evidence that the prevailing bioethics emphasis on autonomy and self-determination can be overwhelming to parents,[108,151] and numerous studies show that respect for parental authority does not require physician adherence to a strict informed consent interaction. A more nuanced application of this respect can be satisfactorily achieved by including parents in decision making within a trusting parent–physician relationship.[64,107] Parental insistence on their right and role as final decision maker should be addressed carefully and viewed as a warning signal that there has been a degradation of the quality of communication with the medical team, or a sense that their authority as parents has been denigrated.

Too rigid or simplistic an interpretation and application of respect for parental autonomy by physicians is also problematic, such as when agreeing to a parental statement that "we want everything done." Without exploring what underlies this declaration, physicians may neglect the complexity of the situation and the underlying parental fear of "abandonment."[43] Finding the right balance between respect for parental autonomy and the physician's role and responsibility in any decision-making process requires

• BOX 3.1 Key Concepts Underlying Ethical Care in the Neonatal Intensive Care Unit

- Respecting parental authority/autonomy
- Applying the best interests of the infant standard of judgment
- Minimizing harm to the newborn
- Developing sound parent-physician relationships
- Empowering and informing parents
- Applying family-centered care principles
- Respecting parents' values and cultural and religious beliefs
- Sharing decision making
- Developing respectful interprofessional (moral) teamwork

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

insight, empathy, and great analytical and communication skills.

Beneficence

Beneficence is the obligation to "do good," that is, to promote the best interests of their patients. In newborns, this obligation is embodied in the concept of the "best interests of the newborn." This is a moral and legal *standard of judgment* that helps to establish the primacy of duties to infants, ensuring they be regarded as fully human individuals with interests, even when clearly unable to express their own value system. Pursuing a course of action in the best interests of an infant implies determining what treatment course has a more favorable benefit-to-harm ratio than other possible options. Interpretation of the meaning of "benefit" can vary between infants and between stakeholders (parents, relatives, health care providers) for the same infant. Interpretations of what it means for a treatment to be beneficial include improvement in the infant's condition, stabilization of the infant's condition, or delaying the onset of clinical deterioration. Amelioration of clinical symptoms, or avoidance of complications of treatment, might also be construed as benefit. Benefit can also be achieved by identifying a less restrictive or intrusive treatment.

Determination of best interests requires an assessment of the child's potential *quality of life*. Quality-of-life considerations encompass the predicted cognitive and neurodevelopmental outcome, the potential for motor disability or other physical handicap (e.g., vision, hearing), and longer-term concerns such as behavioral and learning difficulties or school problems. It also considers the requirements for repeated or prolonged hospitalization, surgery, or medication; technology dependence; and the potential for pain and suffering to be endured. Quality-of-life considerations may also include less concrete medical states, such as the capacity for meaningful and potentially enjoyable interaction with other people and the environment. Some of the most ferocious disagreements between and within NICU teams relate to the inherently subjective nature of quality of life. Contemporary clinical ethicists have moved away from seemingly quantifiable assessments of quality of life, related to measurable outcomes, toward a more subjective interpretation, informed largely by the parents' expressed values.[75] Physicians and other care providers in the NICU must exercise caution not to misidentify expressions of hope, such as descriptions of future milestones and achievements, as manifestations of maladaptive denial of likely outcomes, particularly given that parents have been shown to identify with providers who express hope and compassion in their communication.[14,18,68,96] Although well-intentioned providers might seek to "correct" parents' interpretation of the quality of an anticipated outcome, recognition that some families might see more value in survival with neurodevelopmental disability or technology dependence than others is crucial to family-centered care and shared decision making.

The standard of best interests of the newborn acts as a threshold for judgment, yet the subjective nature of this assessment and the fact that the assessment is being done by surrogate decision makers must always be recognized. Additionally, it is imperative for clinicians to be aware of their limited powers of prognostication. Repeated studies by Meadow and colleagues have shown that when health care professionals predict that an infant will not survive to discharge, they are incorrect relatively frequently.[76,97,98] However, there are circumstances in which the best interest standard can be very helpful to medical teams, such as when urgent decisions must be made in the absence of parental input or when parents refuse clearly life-saving interventions. For the latter, best interest serves as a standard for overriding parental decisions.

Diekema has suggested that the more conservative "harm" principle be applied in overriding parental wishes. By this principle, rather than determine the "best interests," a harm threshold will be determined below which the parents' decision will be overruled.[29] Although invocation of the harm principle can be quite helpful, stakeholders for sick neonates must be careful to apply it in the context of illness severity, urgency, and maintenance of professional standards and integrity.[106,110]

Despite these definitional difficulties and suggested alternative standards such as the "harm" principle, "best interests of the newborn" is accepted as a guiding principle for decision makers because it unites different meanings under one standard and exhibits reasonableness, given the prevailing conditions.[73] Properly understood, the concept can serve as a powerful tool in settling disputes about how to make good decisions for individuals who cannot decide for themselves.

Nonmaleficence

The principle of *nonmaleficence* implies an obligation not to inflict *harm* on others. It has been closely associated with the maxim *primum non nocere* (first do no harm).[12] Although beneficence incorporates preventing and removing harm as part of promoting "the good" of a patient, the injunction not to *inflict* harm remains a distinct principle and requires intentionally refraining from actions that cause harm. Such harm is generally interpreted as *physical harm*, especially pain, disability, or death. Nonmaleficence requires that no initiation or continuation of treatment be considered without consideration of whether the treatment is overly burdensome or harmful. This is especially relevant given a historical context in which attention to pain in neonates has been sorely disregarded, to the degree in which surgeries were performed without anesthesia. However, as for benefit, defining events and interventions that are harmful to the event can be subjective. For some, harm is narrowly defined as pain or anxiety related to the condition or its treatment; assessment of this kind of harm can be aided by the use of bedside pain scores and other objective measures. For

others, any intervention that does not change the ultimate outcome for the infant imparts undue burden. Providers and parents may differ about whether hospitalization in an intensive care unit, without the promise of recovery or discharge home, is harmful to the infant.

Justice

Justice is the dominant principle relating to *social cooperation*. Justice is the framework by which we determine how social benefits, such as health care, and burdens, such as research risks, are distributed. Although justice is regarded as a guiding principle for any health care system, no single, simple, ideal implementation adequately addresses the priorities of all relevant stakeholders. Generally, concepts of justice range from the broader utilitarian calculus to promote the greatest good for the greatest number in underwriting the *distribution of resources* (*macroallocation*) to a more narrowly focused equality of opportunity for each individual (*microallocation*). Justice in the distribution of resources requires that (1) patients in similar situations have access to the same health care, and (2) the level of health care available for one set of patients takes into account the effect of such a use of resources on other patients. Contemporary interpretations of resource allocation have focused on disparities,[1] both on equality in access to care, upstream from provision of the medical intervention itself, and emphasized the principle of *equity* over *equality*. This distinction is important in emphasizing the equality of health *outcome* rather than equality in provision of any specific resource.

Reasoning in the context of allocation of resources for the individual patient allows that fairness is an important consideration but is not the fundamental standard in this interaction. Microallocation issues are very rarely appropriate at the bedside; individual providers caring for individual patients are poorly suited to make decisions about whether one patient, or another, is more deserving of a limited resource, or to make *ad hoc* institutional-level decisions about how limited resources will be distributed. First, there is an inherent conflict of interest, in which the provider might rightly prioritize the immediate needs of the patient she is caring for over larger, systems-level considerations. Second, rationing and allocation schemes depend on economic and public health expertise beyond that possessed by most providers. However, individual providers *do* have a moral obligation to judiciously use medical resources for individual patients and ought not use unnecessarily expensive treatments or treatments that will not effectively promote the patient's health. The conventional ethical prohibition of bedside rationing is also complicated by daily realities of medical care in which time, ICU beds, and limited-quantity equipment are tacitly managed as a matter of routine.[127]

In every system, the provision of neonatal services requires guidelines to be developed for determining appropriate use of these costly and often limited resources. Priorities must be set and justified by organizational leaders. Any changes in the way neonatal care is delivered also need to be fair and accessible, as well as open and challengeable. Disputes should be addressed based on the acceptance of objective measures and trust in the integrity and fairness of the process and the individuals responsible for management of the process. With greater attention being paid to escalating health care costs, there is little question that how resources for sick newborns are used and justified may become more critically and ethically questioned. However, neonatal intensive care has been shown via a number of approaches to be remarkably cost effective,[146] particularly relative to the care of other patient populations.[55,99]

Key Terms and Concepts

Communication With Parents

Parents require complete and truthful information about their infant—the diagnosis and prognosis, the available treatment options (including, where relevant, the option of no treatment), the benefits and harms associated with each option, and the limits of available technology. The manner in which this information is communicated influences parents' understanding of the situation,[65,89] their ability to discuss moral issues and values openly, and their ability to participate effectively in a decision-making process (Box 3.2). Information communicated in an honest and respectful manner is likely to foster trust; information that is confusing, incomplete, evasive, or conveyed in a hurried or dismissive way will engender mistrust. *Transparency* in communication is crucial: It emphasizes the physician's reasoning, builds an understanding of the illness, makes the connection between data and their implications, and tempers unrealistic parental expectations.[66]

As medicine advances, physicians and parents must sometimes struggle with information that is at the limits of medical knowledge and in which the implications of findings are uncertain. The manner in which *medical uncertainty*, specifically *prognostic uncertainty*, is (or is not) communicated is extremely important and influences subsequent decision making. Individual practitioners and neonatology groups may espouse different strategies to dealing with prognostic uncertainty. One is to examine outcome data and identify thresholds below which intensive care will not be offered because outcomes are unacceptably poor and thresholds above which intensive care is insisted upon because outcomes are reasonably good. In isolation, this strategy often fails (1) because one or more stakeholders cannot accept the possibility of foregoing a chance of survival for statistical outliers, (2) because of limitations to available outcome data, or (3) because statistical information is not viewed as helpful to decision making.[28,75] This approach has been increasingly subject to criticism.[33]

A more *wait-until-certainty approach* begins with treatment for almost every infant with any chance of survival. It establishes momentum in favor of continuing treatment

• BOX 3.2 Guidelines for Respectful Communication With Parents

- Create an environment for communication that encourages parents' participation and their becoming as fully informed as possible.
- Identify and remove barriers that limit parents' role in communication (e.g., language, physical distance).
- Communicate with parents: at the time of admission, at any crisis point in their child's NICU course, via periodic reviews of longer stay patients, and other unstructured opportunities.
- Encourage parents to seek clarification of information at any point by requesting an appointment with the child's responsible physician.
- Provide open, truthful communication at all times.
- Provide information as accurately as possible and with as much certainty of diagnosis and prognosis as is possible in each clinical situation.
- Identify areas of medical uncertainty.
- Use easily understandable language, and pay attention to health care "literacy" issues.
- Assess family communication preferences, and attempt to communicate within those parameters.
- Be pre-emptive in communication (i.e., foresee what problems or issues may arise in the child's course).
- Be proactive in communication in any clinical situation in which a poor outcome is predicted.
- Convene meetings with both parents when important decisions need to be made.
- Keep parents informed of any special investigations/tests that are planned in the course of management of their child.
- Recognize the need for time to process and absorb information.
- Promote consistency and continuity of communication in the face of medical staff changes and handovers.
- Practice open, honest, and timely disclosure regarding medical error.

NICU, Neonatal intensive care unit.

as long as the medical course remains relatively uneventful. The possibility of withdrawal or discontinuation of life-sustaining medical treatment is considered only when severe, adverse medical findings become unequivocally evident. A problem with this strategy is the often false promise that certainty will, at some point, exist, and potentially relegates parents and other members of the health care team to the role of bystanders as the medical course unfolds.

Contemporary approaches to decision making have focused on individualization within consistently and fairly applied institutional guidelines, in which available population-based epidemiology, individual factors not accounted for by large studies, and parental values are all considered, using the language of *trial of therapy*,[100] to emphasize the remaining prognostic uncertainty, even for families requesting that "everything be done." Ongoing moral responsibility of the decision makers is emphasized in an effort to involve parents and the health care team in navigating the ensuing prognostic uncertainty.

The *timing* of any communication with parents is crucial. Ideally parents' readiness to receive information and their coping resources should be ascertained so that appropriate information is shared with consideration of their adaptation to the medical setting. In acute situations, if an urgent decision is required, the physician needs to move the relationship rapidly, however, from one of "moral strangers" to one in which moral issues can be openly discussed.

Obtaining *parental consent* for each planned intervention for the infant is often the prompt for communicating with parents in the neonatal intensive care unit (NICU). Some authorities may regard that obtaining formal, informed consent from parents for virtually every neonatal test or procedure is a means of maintaining a high standard of ethical care. Ensuring that parents are kept up to date and advised of treatment plans is important; however, information gathered from an ethnographic study showed that parents did *not* want to be asked to consent to every procedure.[2] They often felt overwhelmed when asked to consent for routine and minor procedures and felt they were given the illusion that they could or should say stop when there was no real choice and no time to learn more about each procedure. It was also clear that the more the staff offered information and time to listen to parents when *not* driven by a consent process, the easier it was for parents to discuss questions and dilemmas on fairly equal terms. When consent was required, parents emphasized the need for a two-way informed agreement between fairly equal partners with established mutual trust and respect.

A sound *patient-physician relationship* is a *sine qua non* of good medicine, for it is within this relationship that physicians exercise their humanity, understanding, and respect for the values of others. Every communication interaction with parents is an opportunity for relationship building. The ideal model in *adult* patient-physician relationships is considered to be the *deliberative-interactive model*, wherein physicians not only help the patient with clarification of his or her values but also strive to make their own reasoning transparent for the patient to appreciate the many factors that inform their professional recommendation.[35] In neonatal medicine, the physician's communication relationship is with the parents (or legal guardians) of the newborn, and the optimal parent-physician relationship aims to mirror the deliberative-interactive model, wherein physicians provide parents with accurate and timely information (with as much medical certainty as possible) and encourage and empower them to identify their values and treatment preferences. This model of relationship respects parental authority, encourages the physician's expression of his or her own clinical judgment, and, in so doing, promotes the best interests of the newborn and the family. A family-centered approach to daily rounds, in which parents are invited to actively engage in the exchange of information and formulation of the daily plan, can be facilitative toward building relationships and obviate the need for extensive and granular medical updates to precede substantive exploration of the prognosis or the goals of care. However, providers must be cognizant of barriers to daytime parental presence at the bedside, such as responsibilities to other children and

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

family members, costs of transportation to and from the hospital, and the need for one or both parents to return to work. Physicians might also face barriers to spending time with parents at the bedside, such as competing patient care, as well as administrative and academic obligations. There may also be personal *physician-related factors* that need to be overcome, such as physicians' reluctance to express their views, a focus on short-term goals, an inherent avoidance of prognostication and discussion about outcomes, and a fear of damaging the relationship by being the bearer of bad news. Nevertheless, it is incumbent on physicians to attempt to develop a *therapeutic alliance* with parents and to engage in relationship building with them. The responsibility for a parent-physician relationship always rests with the physician.

Teams and Communication

Although it is important that the responsible physician attempt to integrate all of the important information and maintain a consistent relationship and pattern of communication with parents, neonatal intensive care is provided by many clinicians with expertise in different fields. This requires an understanding among the team members of the differences in responsibility in communication with parents, such as when conveying day-to-day quantifiable, objective information, or when communicating severe diagnoses or the more speculative, prognostic significance of specific findings. Although the responsibilities of each discipline are generally known, in certain situations communication boundaries may need to be defined to minimize fragmented and inconsistent information. Interdisciplinary meetings, in which all the practitioners involved with the patient share their findings and perspective, are crucial in ensuring that consistent patterns of communication are maintained. It is sometimes said that the ability to communicate is innate. This is not, however, borne out in the literature. For both family and team interactions, "relational competence" is a primary skill that can and should be improved and developed throughout one's career.[130]

Family-Centered Neonatal Intensive Care

Family-centered care is a philosophy that acknowledges the sick newborn infant's place within the social unit of the family. It also acknowledges that cultural, emotional, and social support by the family is an integral component of the infant's care. Family-centered care shapes policies, programs, facility design, and day-to-day interactions but should reflect values and attitudes just as equally as protocols. The potential benefits of a family-oriented approach include improved parental satisfaction with care and decision making, decreased parental stress, greater parental ability to cope with their infant's appearance and behavior, improved success with breastfeeding, and increased parental comfort and competence for post-discharge care.[31] The role of the parent perspective is increasingly highlighted in every step of NICU care, including unit design, development of rules and policies, and even in quality improvement initiatives.[32] In addition, many NICUs have begun to engage "resource" or "veteran" parents into their daily activities.[16]

Recognition of the child's place within the family highlights the cultural, religious, and spiritual dimensions of families' lives and may bring to light significant diversity within these domains. In a pluralistic society, parents and physicians are unlikely to share the same values, cultural systems, personal histories, and experiences, and at times of stress these differences may present health care providers with significant challenges.

The first challenge is to recognize, understand, and respect the cultural, religious, and spiritual views and values of parents and families. Misperceptions caused by a lack of sensitivity can lead to inappropriate care or poor clinical outcomes. *Cultural competence* is more than acknowledgement of cultural norms different from one's own. Rather, cultural competence is an ability to interact effectively with people of different cultures and comprises four components: (1) the individual's awareness of his or her own cultural worldview, (2) the individual's attitude toward cultural differences, (3) the individual's knowledge of different cultural practices and worldviews, and (4) the individual's cross-cultural skills.[91] Developing cultural competence results in an ability to understand, communicate with, and interact effectively with people across cultures.

The second challenge for neonatal health care providers involves the limits of tolerance—where to draw the line between accepting patterns of decision making between couples or within families that contrast markedly with the prevailing cultural norm of shared parental responsibility for decision making.

A third challenge arises because not only are parents and physicians products of their own respective cultures but also their interactions occur within a further "culture"—that of medicine and intensive care itself—with its own values, assumptions, and understanding of what should be done.

Although the health care team should recognize how families' interests are shaped by social, cultural, and other contexts, it is important *not to stereotype* the members of specific social, cultural, ethnic, or religious groups. Individuals' affiliations may not be predictive of their beliefs and values in the care of their infant, and the health care team should regard each patient and family as *unique* and attend carefully to their specific views and values.

When attentiveness to the views and values of families is difficult because of language barriers, professional interpreters should be used. Use of an interpreter is advisable for three reasons: (1) it ensures that parents' views are available to the health care team, (2) it removes the burden on family members or friends for the transfer of information, and (3) it limits the potential for miscommunication. In certain situations, a *cultural interpreter* not only can facilitate language comprehension but can also provide useful information about cultural norms and traditions that are unfamiliar to the health care team. Access to high-quality

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

interpretation services is an essential component of ethically and culturally sensitive care that also satisfies a regulatory requirement and decreases medicolegal risk.

Religion and the more general concept of *spirituality* as a major determinant of culture, tradition, and family values often needs to be addressed with parents, particularly when end-of-life decision making is undertaken. A qualitative questionnaire study completed by parents after their child's death revealed the emergence of four explicitly spiritual/religious themes: prayer, faith, access to and care from clergy, and belief in the transcendent quality of the parent-child relationship that endures beyond death.[121] Other significant themes with a religious/spiritual dynamic include finding meaning, hope, trust, and love. In another study focused on the delivery room consultation, mothers stated that religion, spirituality, and hope were the major factors that guided their decision making.[14] The implication of these studies is that health care teams need to consider whether they have or need to create an environment that is hospitable to, and supportive of, religious or spiritual practice; that clinical staff recognize parents' spiritual needs and provide access to hospital chaplains and community clergy; and, on a deeper level, appreciate parents' religious and spiritual perspectives in prenatal consultations and end-of-life discussions.

Consensual Decision Making

Consensual decision making implies that the parents and the physician/health care team are involved in the decision-making process—that they share relevant information with each other, they express their treatment preferences, and when a final decision is made, all parties are in agreement. The ideal consensual decision is one in which neither party feels individually responsible for that decision. Parents often feel *burdened* by what they perceive as their responsibility for the decision.[24] When the process of consensual decision making is handled well by the physician/health care team, the burden of the consequences of the decision is shared.

Team Consensus in Ethical Issues

How teams that normally function synergistically in terms of purely medical matters operate when dealing with ethical issues may be very challenging, not only because of the difficulty in defining roles and responsibilities in matters of ethical deliberation but also from a more fundamental aspect in that the two major professions, medicine and nursing, have differed over time in their preparation for this practice.[131] Medical professionals tend to view their role as one in which the patient's best interest is served by being given the medical care best supported by scientific evidence, with less attention to deeper questions such as the goals and limits of medicine and the moral core of the profession. The seemingly less objective goals, such as emotional support and values exploration, are relegated to other health professionals, such as nurses and social workers.[10] In interactions concerning the end of life of a neonate, physicians see the focus of their moral obligations on decision making with parents, whereas neonatal nurses see their moral obligations focused on the process and moment immediately surrounding death.[36] What is needed, according to Storch and Kenny,[131] is "shared moral work": Interprofessional practice implies that individual health care practitioners are aware of their own professional values and the need to work collaboratively, build understanding, and work toward resolution with other professionals, particularly when different perspectives threaten team function. The beneficial effects of multidisciplinary participation and perspectives have been well shown in teams developing guidelines for decision making, such as those at the limits of viability.[11,63]

Clinical Applications in Specific Moral Problems

Refusal of Treatment During Pregnancy

When a pregnant woman acts in such a way as potentially to create a serious risk of harm for her developing fetus, either by declining a recommended intervention or by actively engaging in a behavior that is harmful to the fetus, some authorities argue that state intervention is morally justified in an effort to promote fetal health and well-being. Other authorities maintain that such intervention not only violates the pregnant woman's autonomy, integrity, and privacy, but also undermines the principle of reproductive freedom.[40]

Authorities who advocate state intervention place some limits on the principle of reproductive freedom: Whatever rights a pregnant woman may have to direct the course of her pregnancy, they do not include an unlimited right to harm the fetus. In practice, which maternal behaviors lead to state intervention is generally determined by the legality rather than the inherent harmfulness of the intervention, leading, for example, to paradoxically harsher repercussions for occasional tetrahydrocannabinol use than for heavy alcohol consumption, even though the harms to the fetus from the former are not nearly as well described as those from the latter.

Arguments in favor of limiting the autonomy of the pregnant woman are based, at least in part, on the argument that, in choosing to continue her pregnancy, the woman has incurred an obligation to do what is necessary to ensure that the fetus is born healthy.[94] If she violates this obligation, the state has the authority, and perhaps even the obligation, to intervene to protect the fetus. However, this argument mischaracterizes the relationship between the pregnant woman and fetus as adversarial—the woman is cast in the role of aggressor with the fetus in the role of innocent victim, failing to account for numerous psychosocial and socioeconomic complexities that play a role in reproductive health decisions and outcomes, on substance use disorders and their treatment, and on priorities in law enforcement.

Significantly, professional bodies have commonly resolved the moral dilemma between the pregnant woman's

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

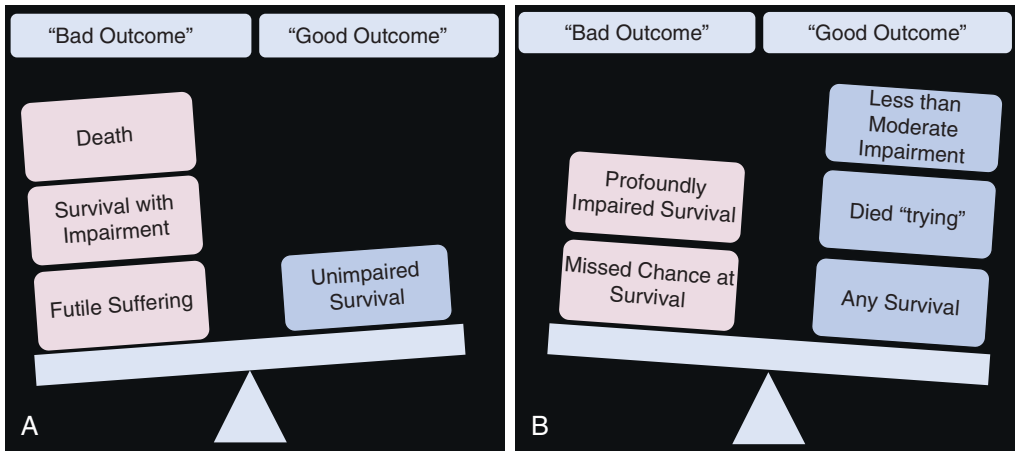
autonomy and the fetus's well-being in favor of respecting the *principle of autonomy*. The American College of Obstetricians and Gynecologists has stipulated, "Every reasonable effort should be made to protect the fetus, but the pregnant woman's autonomy should be respected. … The use of courts to resolve these conflicts is almost never warranted."[6] Similarly, the Society of Obstetricians and Gynecologists of Canada Ethics Committee "opposes involuntary intervention in the lives of pregnant women. … The primary objective of physicians who work with pregnant women should be to promote women's health and well-being while respecting their autonomy."[129]

This emphasis on the autonomous rights of the pregnant woman is informed not only by a principled commitment to individual autonomy but also by another set of other claims. First, punitive state intervention rarely provides direct fetal benefit (the injury has already occurred). Second, a policy of state intervention may discourage women whose fetuses are most at risk from seeking appropriate care, for fear of being prosecuted.[90] Third, state interventions disproportionately impact poor and minority women and more generally enforce societal gender biases and inequities, ignoring paternal actions that are hazardous to the fetus.[86] Fourth, state intervention in pregnancy is an intrusion into the lives of pregnant women in excess of anything that would be tolerated to protect nonfetal lives.[40] The moral obligations of health professionals caring for pregnant women who decline recommended interventions or engage in medically ill-advised behaviors are to offer information, resources, and support, with clear and direct recommendations. Anticipatory guidance about possible postnatal repercussions of maternal behaviors, such as investigation by child protection agencies or the need for additional medical observation or treatment for the infant, is essential. Coercive behaviors by physicians in pursuit of perceived good for the fetus are not ethically permissible.

Prenatal Consultation at the Limits of Viability

With advances in medical technology, neonatology teams have developed the capacity to maintain physiologic signs of life at extremely low gestational ages, with survival possible after a gestation of 22 weeks. Use of a physiologic definition of viability, such as the point at which life can be maintained outside of the uterus, might suggest that every neonate born at such gestational ages should be given an opportunity for extrauterine life and be actively supported. Other definitions of viability do not focus exclusively on the likelihood of survival but rather include quality-of-life considerations in which there is an explicit value judgment regarding the degree of morbidity that is acceptable if such a life were to be maintained.

In clinical practice, there is no universally accepted definition of a *viable* fetus; however, guidelines from professional societies in several countries have defined gestational age ranges at which the benefit-to-burden ratio of aggressive obstetric or neonatal care becomes questionable.[85,114,126] Recent exploration of the outcomes of infants born at 22 weeks' gestation identify some survivors, and some neurologically intact survivors, resulting in a recent shift to move the lower border of marginal gestational viability from 23 to 22 weeks.[28,124] Similarly, examination of the outcomes of infants born at or after 25 weeks suggests that the majority of these infants survive, and the majority of NICU graduates survive without moderate or severe neurodevelopmental impairment. Although some intensive care units continue to allow parents to forego resuscitation until 26 weeks, resuscitation of infants born at or after 25 weeks should be considered to be the default plan in the absence of major comorbidities, such as extreme intrauterine growth restriction or major congenital anomalies.



The challenge facing the life-defining "resuscitate or not" issue for parents and the neonatal team in the "gray zone" is compounded by the "moral strangeness" between the participants, the vulnerability and unfamiliar physical and emotional context for parents, constraints of time, and the great degree of medical uncertainty in prognosticating outcome for individual infants. Nevertheless, the urgent context exerts its own demands, and the opportunity for prenatal consultation must be optimized, because it is considered more conducive to an exploration of parental and physician/team views than if this conversation occurs in the delivery room or in the NICU in the first few hours of the infant's life. In all situations, descriptions of gestational viability in prenatal consultation should be sensitive to the parents' identification of personhood of the fetus. Reduction of a future child, whose sex might be known, whose name is picked out, and whose bedroom is already decorated, to the status of a "nonviable fetus" has the potential to be antagonizing to parents and present an obstacle to productive prenatal decision making.

A discussion with the pregnant patient about the limits of viability, even earlier in pregnancy, free of the threat of imminent delivery and with enough time for absorption of information and ability to participate objectively in such difficult decisions, has been proposed.[22,125] Generating an *advance directive* for managing early delivery would obviate much uncertainty for the medical team; this approach may gain momentum, despite the potential of producing anxiety in most pregnancies that would continue to term. A limitation to this approach is the question of whether a parent's response to *hypothetical* preterm delivery differs considerably from her response when faced with the *actual* circumstance.[78]

The prenatal consultation at the limits of gestational viability has two primary aims: (1) to provide information on which decisions can be based and (2) to support parental decision making about whether a trial of therapy will be undertaken in the delivery room. These activities should be viewed as inextricably linked rather than sequential components of the consultation encounter.

It is important to have the best data available[84]—data that are current, based on a number of pertinent factors rather than simply gestational age, and germane to the unit

• **Fig. 3.1** Values-based shared decision making in the antenatal period. **A,** A neonatologist may perceive a high likelihood of nonsurvival paired with a high chance of moderate-to-severe impairment among survivors as dismal, with a very low chance of the "desired" outcome of intact survival. Due to the statistical probabilities, the burdens of infant suffering and societal cost may appear to outweigh benefit of therapy, and comfort care may logically be recommended. **B,** A parent, however, may view these outcomes very differently. If any survival, even with significant impairment, is seen as a desirable outcome, the probability of a "good" outcome rises. If having a surviving, very impaired, child is considered the most undesirable outcome, the risk of this is quite low, as many of the sickest infants die. Finally, if dying following intensive care is perceived as more favorable than possibly missing an opportunity to have an intact survivor, the risk of the unfavorable outcome falls to zero if an attempt at resuscitation is made. (From Kukora SK, Boss RD. Values-based shared decision-making in the antenatal period. *Semin Fetal Neonatal Med*. 2017;23:17-24.)

in which the patient is being cared for (or the geographic region, where appropriate). The data should include survival statistics *and* information about the long-term outcomes—including quantitative and qualitative measures when available (functional abilities, learning, behavior, impact on family)—with recognition that parents may differ in their previous experiences with disability and chronic disease and the value they place on these outcomes; this emphasizes the importance of thorough medical record review and history taking as part of the counseling endeavor. Kukora and Boss have offered a conceptual model parental characterization of a "good" or "bad" outcome (Fig. 3.1), which offers explanation for why some parents pursue interventions in the face of a poor prognosis. Even in the setting of a value-exploration approach, a standardized form (Fig. 3.2) may provide a reminder to the clinician of topics that should be covered.[46] Access to reasonably up-to-date outcome data has been facilitated by the development of population-based outcome tools. Tyson and coworkers, for example, developed an "outcomes estimator" that takes into account five factors (gestational age, estimated birth weight, singleton status, antenatal steroids, and gender) and provides the likelihood of death or adverse neurodevelopmental outcome. The estimator is available without charge on the Internet (http://www.nichd.nih.gov/about/org/der/branches/ppb/programs/epbo/pages/epbo_case.aspx), and although not perfect, it does seem to "promote treatment decisions that are less arbitrary, more individualized, more transparent, and better justified than decisions based solely on gestational age thresholds."[136] Use of this predictive model, in particular, has been instrumental in highlighting the limitations of gestational age alone in decision making. However, although this instrument is widely used, not all neonatologists find that it and similar instruments are helpful to expectant parents.[104] This may be explained, at least in part, by the tendency for parents to "use hope and denial to interpret the limits imposed by statistics."[26] The counselor should be cognizant of important differences in the way seemingly objective information can be shared with expectant parents. An evolving body of science explores how best to support patients and parents in preference-sensitive decision making and have largely focused on use of decision support tools and enhanced information to improve this process.[47–49]

In one qualitative study of counseling at the margin of gestational viability, two models were used by neonatologists regarding resuscitation decisions at this threshold.[111] In a *neutral information model*, parents ultimately made their decision after comprehensive information, which they were to interpret independently, was given. In an *assent model*, the neonatologist's preferences were clearly expressed, and a decision was sought during the consultation. Prognostic statistics were used as information to justify and reflect on the suggested course of action.

Neither the neutral information model nor the assent model fully addressed parental expectations. In the neutral information model, parents expressed the need for a more individualized and humane relationship, which could not be addressed by a clinical focus on "objective/neutral facts." In the assent model, when decisions between parents and neonatologists were in accord, parents felt included, but when the neonatologist's recommendation did not fit with the parents' expectations, parents tended to feel abandoned and left on their own to confront the event. This study advocated that between the "liberal autonomous decision"

and a "paternalistic decision-making process,"[107] there is the need for an intermediate "shared relational space"—for a more caring relationship between the decision makers and more time to allow exploration of the facts, expectations, and values that are inherent in this interaction.

It is crucial to explore with prospective parents their preferences in relation to the data provided. Some parents may regard 20% as a fair chance of a "good enough" outcome, whereas others may regard 80% as not enough of a guarantee.[45] Elucidating parents' views raises the question of how much *moral weight* should be given to these views for delivery room decisions. Leuthner described different weightings ascribed to parental views in terms of models of best interests[82]: in a *medical expertise model*, outcome data are used in more directive counseling in pursuit of the physician's judgment of the best possible outcome, with less parental input. In the *negotiated model*, parental input is maximized and the decision attends to the moral values of the physician and the parents.

It is worth reflecting on the reasons for the lack of congruency in decisions between physicians and parents, where differences seem to arise from three sources:[111]

1. *Different starting points*. Physician's intent is to give the facts, whereas the family's reaction is to the premature interruption and fracture of the family narrative and a threat to their anticipated parenthood.
2. *How information is used*. Physicians attempt to be as objective as possible with facts and figures, whereas parents reformulate those chances.
3. *What constitutes the "right" decision*. For physicians, a good decision follows full parental comprehension of provided information. For parents, it is after they have had their own experience taken into account, and their decision is supported by a scientifically competent and humane medical team.

By focusing first on the *parents*, sharing two-way information, recognizing the importance of "relational space," and overcoming differences in starting points, physicians may achieve greater consensus and more acceptable decisions for all. The challenge in moving forward from a purely information-sharing interaction cannot be overemphasized; in a survey study, neonatologists viewed their primary role as providing factual information almost exclusively, with few considering their role as assisting in weighing risks and benefits and only 2% regarding their primary role as discussing potential differences in views between parents and the medical team.[10]

Numerous guidelines and frameworks for decision making at the limits of viability have been developed and are helpful in setting out parameters of practice.[13,63,114,126,145] They are generally not intended to be prescriptive, however, and decisions still need to be made specific for the individual patient, parent, physician, and team. Treatment considerations for extremely premature infants must be viewed in context against other areas of medicine in which difficult decisions must be made. There is evidence that, without clear justification, premature infants are considered "morally different" from older children and adults.[58,59,79] Despite repeated recommendations that "decisions should be made on a case-by-case basis,"[19,38,87] individualization requires that in each interaction, relevant information is methodically and thoroughly collected but applied consistently and fairly; all families are different, but decisions for that family should not depend on which doctor is on call. A model of "controlled improvisation" seeks to employ the benefits of scripted information gathering and sharing while recognizing the need for interpersonal connection and individualization.[52] In addition, the individuals undertaking these decisions need to make their reasoning behind their approach explicit. "Message framing," for example, whether the reported outcome is mortality or survival, and a priori "default options" have a major impact on decision making.[53]

Although populations of infants born with congenital anomalies and genetic disorders have not been as extensively studied, either in terms of short- and long-term outcomes or in terms of approaches to counseling and decision making, many of the principles that apply to antenatal consultation at the margin of gestational viability are also applicable to these other maternal and fetal complications. Particularly for rare diseases or constellations of congenital anomalies without a well-described natural history, recognizing and grappling with prognostic uncertainty remains a challenge for both providers and expectant parents. "Perinatal palliative care" has gained momentum as an approach to advance care planning for the delivery of infants born with life-limiting diseases.[92]

Withholding and Withdrawing Life-Sustaining Medical Treatment in the Neonatal Intensive Care Unit

Withholding life-sustaining medical treatment involves a choice not to provide a form of treatment that is not considered beneficial, whereas *withdrawal* involves a choice to remove treatment that has not achieved its beneficial intent.[140] From a moral perspective, there is no difference between these two acts: If it is morally right (or wrong) to withhold treatment deemed to be ineffective, it is equally right (or wrong) to withdraw this same treatment after it is started, should it later become clear that the treatment is ineffective. However, this concept is emotionally difficult to accept for many parents *and* for many health care providers. Supporting stakeholders struggling with the moral weight of withdrawing an ongoing therapy with reinforcement of the ethical equivalence of withdrawing and withholding is crucial to provision of end-of-life care, particularly as many neonates die with stable physiology after decisions to discontinue life-prolonging care rather than with unstable physiology after a code.[139] It is also important to avoid using phrases such as "withdraw support" or "withdraw care," as these may reinforce fears that families may have of being abandoned by their medical providers once a decision has been made to prioritize palliative goals, or that they

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

themselves have made a decision to abandon or "give up on" their baby. *Withdrawal of life-sustaining medical treatment* and *redirection of care* are more appropriate terms for these activities.

Criteria for decisions to withhold or withdraw life-sustaining medical treatment are usually based on one of three general criteria:

1. *Inevitability of death*. When infants are very likely to die in the NICU, regardless of whether life-sustaining treatment is continued, life-sustaining treatments that serve only to delay the moment of death need not be continued. However, clinicians must recognize the difficulty in predicting outcomes with certainty, as studies suggest that in many circumstances neither clinical intuition nor objective scoring systems are reliably able to predict mortality in critically ill neonates.[99] In addition, while additional hours or days of survival might not ultimately change the outcome for the infant, this time might be highly valued by the family, either as a good unto itself or as an opportunity to gather friends and loved ones in anticipation of the death of the infant.
2. *Ineffective treatment*. Treatment that has not or is not expected to meet the intended goals, particularly when the treatment that imparts pain and suffering to the infant without appreciable benefit is considered ineffective.
3. *Poor quality of life*. As described previously in this chapter, despite the difficulty in determining the quality of a life with limited cognitive or relational capacity, mobility, or self-awareness, or a life of continued pain and suffering, poor quality of life is a valid consideration and ethically permissible reason to withdraw or withhold life-sustaining interventions.

Some authors cite *futility* of medical treatment as a criterion for withholding or withdrawing medical treatment. It is difficult to know what follows from such claims, however, because there is considerable debate and diversity of opinion as to the meaning of futility.[57] True futility, in which death is inevitable or exceedingly likely, should not be conflated with risk of a poor neurologic outcome. In addition to the debate about the meaning of the term *futility*, arguments have emerged about the authority of the physician to determine when an intervention is futile. Some authors contend that futility is a medical decision to be made by the physician alone, whereas others believe that the decision is value-laden and that parents should be involved in this determination. When futility is determined solely on the basis of medical or physiologic factors (a rare occurrence unless death is imminent), unilateral decision making by the physician based on sound medical knowledge and expertise may be appropriate. When subjective elements form part of the determination, however, the physician has no unique claim to moral expertise. In consideration of these more value-laden and subjective determinations of futility, the term "potentially inappropriate" has been put forth as more encompassing of the complexities of these situations.[72] The Society for Critical Care Medicine has published a seven-step process for an organizational approach to conflict resolution in consideration of potentially inappropriate treatments.[71] These guidelines, which are not specific to neonates, do take into account the value of neurologic recovery to the point of being able to "perceive the benefits of treatment" and emphasize the role of individualization, time-limited trials of interventions, and careful attention to pain and suffering. The American Academy of Pediatrics offers specific guidance on forgoing life-sustaining medical treatment for children, which recognizes the role of parents in decision making, communication, iterative examination of the child's condition and prognosis, and reliance on other supportive hospital services, such as ethics committees, pastoral care, palliative care, and others.[142]

Collaborative, Procedural Framework for End-of-Life Decision Making

Following a structured decision-making process helps to ensure that appropriate views and preferences are made explicit. Harmonious decision making is promoted, as all of the participants in the process may come to understand the reasons and values underlying a particular choice. The following procedural framework is suggested.

1. Create an optimal environment for discussion. It is important to create a quiet and uninterrupted environment in which ethical issues and values can be thoroughly explored, despite the demands on the time and energy of parents and staff. In the setting of a teaching hospital, the value of educational opportunities for students and trainees should be balanced with parent-centered goals of creating a comfortable and nonintimidating environment.
2. Establish that the presenting issue is an ethical problem, one in which moral values conflict or moral uncertainty exists. Ethical deliberation is often complicated by communication problems and psychological issues. These need to be disentangled from the ethical issues. Consultation with hospital ethics committees, or in some cases palliative care or clinical mediation services, can be helpful in supporting constructive, nonconfrontational dialogue and use of a common, respectful vocabulary. In most hospitals, ethics committees will offer nonbinding recommendations or delineate whether the proposed course of action is ethically permissible. Generally, clinical ethics consultants will not interpret medical facts or supplant the responsible physician as the arbiter of medical decisions.
3. Identify the rightful decision makers. Many individuals may legitimately be involved in the decision-making process, including, at least, the parents, the physician with primary responsibility, and other members of the health care team directly involved in the care of the patient. More generally, individuals who bear the greatest burden of care and conscience; individuals with special knowledge; and nurses and other health care professionals with the most continuous, committed, and trusting relationship with

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

the patient or parents should be involved in decision making.[101] Thorough documentation of family meetings, medical decision making, and ethical rationale can be helpful to unify the team and minimize miscommunication, particularly when shift work and irregular schedules preclude participation of important medical provider stakeholders. Disagreements about the rightful surrogate decision makers for neonates are rare, as in most cases, parents assume this role by default. Rare scenarios, in which parents disagree with each other, are incapacitated and unable to participate in decision-making, or in which biological or legal parenthood is in dispute, may call for consultation with the hospital ethics committee, along with other ancillary hospital services.

4. Establish the relevant facts. "Good ethics begins with good facts." Medical facts include the diagnosis, the prognosis (and the estimated certainty of outcomes), past experience on the unit, relevant institutional policies, and relevant professional guidelines. Nonmedical facts include information about family relationships, language barriers, cultural and religious beliefs, and past experiences with the health care system. It is also important to explore parents' understanding of the medical facts, parents' expectations of the technology involved, the quality of communication between the parents themselves, and the degree of trust in physicians and the medical system. The willingness of the physician to discuss personal views and beliefs may enhance gathering of such information.
5. Explore the options. Explicit discussion of treatment options and their known potential short-term and long-term consequences should occur. The principle of informed consent requires parents to be presented with the risks, benefits, and alternatives of each option. How the information is presented can strongly influence parents, and clinicians must be careful to avoid coercion.[54]
6. Develop consensus. All decision makers should be in agreement with the plan of action proposed at the time, even though, occasionally, agreement may be a temporizing measure. Open, honest discussion of the goals and consequences of treatment allows parents, physicians, and other legitimate decision makers to consider carefully a range of professional and personal beliefs, values, and preferences, and to explore reasoned arguments for and against various options meaningfully. This process holds the promise of harmonious, consensual decision making. Although care must be taken to ensure that parents do not feel abandoned or overburdened by these high-stakes decisions, a decision to withdraw or withhold life-sustaining treatment unilaterally against parental wishes should occur only after all avenues of reconciliation, including transfer of care to another institution for a second opinion, have been exhausted.
7. Implement the decision. When a consensual decision has been reached, additional issues may need to be addressed with parents to ensure effective implementation. When the decision is made to withhold or withdraw life-sustaining treatment, there should be an open discussion about the manner of death, the option for parents to be present, the performance of religious rituals, the anticipated grieving process, and the supports available for bereaved parents.[147] Clinicians always have a duty to care for their patients, even when the goals have shifted from aggressive measures to comfort and palliation.

Specific Issues in End-of-Life Care

Brain Death, Donation After Cardiac Death, and Organ Donation

Brain Death

Brain death is well-defined for older age groups and has been accepted in most jurisdictions for decades as the threshold criterion for the removal of organs from heart-beating donors (without violating the dead donor rule). Guidelines for determining brain death in children were first published in 1987. Numerous clinical issues initially limited the usefulness of the concept in this patient population, including the difficulty of establishing the exact cause of the coma, the clinical assessment of brain death (particularly the determination and reliability of the absence of brainstem reflexes), and the uncertainty regarding the validity of adjunctive laboratory tests. Revised guidelines were published in 2011 and reaffirmed in 2015. These guidelines retain the definition of brain death as "irreversible cessation of all functions of the entire brain, including the brainstem."[105] The updated guidelines contain detailed algorithms, tables, and examination checklists to aid the clinician. Determination of brain death in a term neonate generally requires two examinations performed at least 24 hours apart. Because of insufficient data, there are no criteria to diagnose brain death in premature infants.

While brain death has been well accepted, it is not without controversy. As noted in a *New England Journal of Medicine* editorial from 2001, "one subject [that] can be said to be at once well settled and persistently unresolved…[is]…how to determine that death has occurred."[20] This was demonstrated in a recent highly publicized pediatric case. Thirteen-year-old Jahi McMath was declared brain dead following a postoperative hemorrhage after a tonsillectomy on December 9, 2013. The parents are "Christians with firm and sincerely held religious beliefs that as long as a person's heart is beating, that person is alive."[30] While a death certificate was issued for Jahi, a judge granted the McMath family's request to transfer Jahi to a Catholic hospital in New Jersey where a tracheostomy was performed. Nearly five years later, on June 22, 2018, Jahi was declared dead by cardiac criteria following complications of an intestinal surgery.[33a,93]

Donation After Cardiac Death

The traditional definition of death occurs when an individual has sustained "irreversible cessation of circulatory and

respiratory function."[105] This is generally known as cardiac death, and often under these circumstances the warm ischemia time renders many organs unsuitable for transplant. In an effort to improve the ability to obtain viable organs from non-heart-beating donors, there have been recent efforts to better control the circumstances of withdrawal of life support, thereby allowing "donation after cardiac death" (DCD). The DCD protocols are considerably different from traditional end-of-life situations. The patients are brought to the operating room before withdrawal of life support, and once there has been circulatory arrest for a period of time; organ recovery efforts are immediately begun.

Although the goal of DCD is laudable and there is a major shortage of organs for the neonatal and pediatric population, there are a number of ethical concerns that have yet to be satisfactorily addressed. First, there is no consensus on the length of time between the onset of circulatory arrest and pronunciation of death. Indeed, there is considerable variability, from less than 2 minutes to more than 5 minutes.[7] Second, there must be clear management of the potential conflict of interest between the donor's interests and the preparations that must be made before death that are meant to benefit the recipient rather than the donor. This can be accomplished with a clear separation of roles of the care team and the transplant team.[4]

Finally, there must be a unified approach that continues to focus on humane and compassionate care of the patient and family. Many NICUs have well-established bereavement and end-of-life care protocols that encourage families to gather, participate in religious and cultural traditions, and spend hours to days with their baby after death has occurred. Donation after cardiac death policies may disrupt the flow of this care and families need to be informed about the changes. It is also essential that DCD protocols provide families "a clear understanding of the DCD donation process and a realistic understanding of all possible outcomes of donation, including successful transplant or an inability to recover or transplant for medical reasons."[148]

Use of Analgesic Agents at the Time of Withdrawing Life-Sustaining Medical Treatment

Both physicians and nurses have an ethical obligation to relieve pain and suffering, and this applies to infants at the end of life.[102] Partridge and Wall showed that in most cases of withholding or withdrawing life support from critically ill infants, neonatologists provided opioid analgesia to these infants, despite the potential respiratory depression of these agents, the so-called double effect.[109] The *intent* of the action—to alleviate pain and promote comfort—distinguishes the use of analgesics from the use of other agents, such as paralyzing agents, whose intent is to *ensure* death. The introduction of neuromuscular blocking agents at the time of withdrawal of life-sustaining medical treatment is considered ethically inappropriate, as is any form of active euthanasia.[134]

Although the expressed intention of alleviating suffering and discomfort is usually cited as justification for the "double effect" of analgesics and sedatives, the distinction from hastening death is sometimes difficult. To some authors, such as April and Parker,[8] the ban on active euthanasia (i.e., the use of drugs with the specific intent to end life) exists largely because professional guidelines in most jurisdictions call for the distinction and as such is a reflection of current consensus. They contend that relief of symptoms and concern for a newborn's suffering should be the primary goal, and the ban on physicians' role in active euthanasia is in their view not a moral argument but an appeal to public opinion and the moral primacy of the status quo.

This issue has been stirred by the Groningen protocol in the Netherlands where, in rare cases, in a newborn with an extremely poor prognosis and intractable suffering, and after all measures to alleviate the suffering have been unsuccessful, the deliberate ending of life may be considered legal.[62,138] Many, but not all, authorities consider such active neonatal euthanasia to be unsupportable and believe that the Groningen protocol should be abandoned.[70,132] Most authorities believe, similar to Costeloe,[27] that despite the conceptual difficulty in defining the difference between drugs used to alleviate pain and drugs given with the intention of ending life, in practice, "experienced neonatologists and neonatal nurses feel comfortable with this distinction." They can discuss it openly with families and help them understand the acceptability of infusing opiates at a dose that controls pain and distress but the unacceptability of increasing the dose further with the primary intention of hastening death.[27]

Palliative Care in the Neonatal Intensive Care Unit

Until recently, withdrawal or withholding of life-sustaining treatment in the NICU tended to be considered only when life-prolonging treatments were determined to be ineffectual and burdensome and death seemed imminent. Many factors may account for the slow adoption of palliative care in the NICU, such as the uncertainty in determining an infant's terminal prognosis, the difficulty in moving away from an interventionist approach when therapeutic options still seem possible, the divergent caregiver perceptions of the "right" action, a degree of moral and legal ambiguity in pursuing such a course, the fear of a "lingering death,"[95] a tendency for the compartmentalization of medical care into specialist teams with differing agendas, and a lack of formal training and experience in this aspect of care.

The dilemma of continuing the intensive care of a critically ill newborn when it is likely to result in a prolonged dying process or survival with profoundly limited capabilities and long-term suffering for the infant and his or her family has highlighted the need for a change in this approach. This has led to the incorporation of palliative care practices into the NICU environment, where a cure-oriented approach is replaced by an entire spectrum of

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

management to prevent and relieve suffering and improve the transition to dying. This approach has been supported in three general clinical situations: (1) congenital anomalies incompatible with survival, (2) newborns born at the limits of gestational viability, and (3) infants who have overwhelming illness not responding to life-sustaining intervention.[103] This approach is also being increasingly considered when a diagnosis is made prenatally in conditions of certain lethality. Palliative care principles can be used to guide supportive conversations during the pregnancy and enable the preparation for a perinatal death in facilities supportive of such an approach.[92] Greater adoption of palliative care at the time of birth for antenatally diagnosed lethal anomalies has had an impact on decisions of pregnant women regarding termination during the pregnancy.[17]

Palliative care involves a team approach to the prevention and relief of physical, psychological, social, and spiritual suffering for the dying infant and the family.[23] Protocols aim to ensure continuity of care; symptom management and comfort care for the infant; family-centered decision making; practical, emotional, and spiritual support for the parents; and organizational, emotional, and spiritual support for the intensive care clinicians.[25] The ultimate goal is personalized decision making that empowers the parents in developing a care plan, which can also incorporate input from appropriate hospital and community resources, and occasionally the district coroner, in situations when there is the strong likelihood of the infant dying at home.[34a]

Within the spectrum of palliative care, after other, more obviously invasive forms of life-sustaining medical treatment have been withheld or withdrawn, the *withdrawal of artificial hydration and nutrition* may become a focus of consideration. Justification for this practice (after clearly showing the inability of an infant to tolerate oral feeds safely) revolves around the question of whether providing hydration and nutrition via other routes is a medical treatment or an obligatory part of basic humane care. All forms of maintaining artificial hydration and nutrition (the passage of nasogastric tubes, the insertion of intravenous needles, or more invasive interventions such as the surgical placement of a gastrostomy tube) are invasive to some extent and carry medical risks of dislodgment, migration, error, infiltration, and infection.[60] There has been general agreement, at least over the past two decades, that artificial nutrition and hydration is a *medical treatment*, on par with mechanical ventilation and other life-sustaining technologies,[60,135] and that it should not be held to a higher standard than other forms of life-sustaining treatment.[21]

In terms of the best interests standard of judgment in which the benefits and burdens of withdrawing or withholding hydration and nutrition are considered, studies in adult patients have shown that death is caused by dehydration, not starvation, and that dehydration leads to a decrease in nausea, vomiting, diarrhea, and urine output, with little, if any, discomfort, perhaps because of the release of endogenous opioids with fasting and ketosis.[149] In addition, patients experience little, if any, hunger or thirst if appropriate mouth care is provided.[34] One qualitative study that explored parents' experiences found that all of the parents were satisfied with their decisions to withdraw artificial nutrition and hydration and perceived their children's deaths as peaceful and comfortable.[118] Withdrawal of artificial hydration and nutrition in newborns is considered an ethically legitimate option by organizations such as the American Academy of Pediatrics when it is clear that cure is no longer possible and that an interventionist approach does not serve the child's (or family's) best interests.[5,83]

Despite the acceptance by many authors of withdrawal of hydration and nutrition as a moral way of responding to severe terminal suffering,[117] the literature has highlighted difficulties, particularly for nurses with "ethical proximity" to the patient, when this has been implemented.[113] These types of issues require significant attention if this practice is to become more clinically accepted. When withdrawal of medically provided fluids and nutrition occurs in the hospital setting, it is advisable to have a plan in place to support care providers who find this practice to be morally unacceptable, in some case by use of institutional conscience-based refusal policies.

Conflict Resolution When Consensus Cannot Be Reached

In most instances, participants in a decision-making process can arrive at a morally sound decision regarding the best course of action in a particular situation. Attempts at consensual decision making are sometimes unsuccessful, however, and may result in conflict and intractability. Occasionally, this conflict is between parents who disagree with each other regarding what is in the best interests of their newborn. More frequently, the conflict is between the parents of a newborn and the health care providers who have different perceptions of the child's best interests.[119]

The following guidelines are proposed to promote continuing negotiation and resolution of conflict in the NICU:

1. *Allow time for further clinical observation*. In the specific case of parental objections to forgoing treatment that the physician believes is not beneficial, it may be unrealistic to expect agreement from the parents the first time this option is raised. Prudence suggests moving as fast as the slowest member of the decision-making group, provided that the infant is not compromised further.
2. *Ensure full parental comprehension of the medical information*. Early expressions of treatment preference by parents, such as "do everything possible," need to be examined carefully. There is a tendency for busy medical teams to reduce parental expressions into simple one-line statements and not to explore their meaning. Such statements may be an expression of parental love or an expression of frustration with the medical team and not really an informed choice about what is in the best interests of the newborn. In addition, in view of parents' potential denial of the severity of their infant's condition, it is

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

important to check parents' understanding repeatedly. If it seems that inconsistent information has been provided by different individuals or teams, it may be advisable to convene a formal interdisciplinary case conference to explicate these differing viewpoints.

3. *Continue to discuss, explore, and challenge the underlying reasons for the differences in choice*. It is important for health care providers to try to understand the parents' views, beliefs, and preferences. Physicians must recognize that the parents' beliefs and values are informed by ethnic and cultural traditions, customs, and institutions, and that these influences may be significantly divergent from their own.
4. *Continue to negotiate toward consensus*. Parents may have great difficulty in making an unassisted decision. The burden and potential guilt of decision making experienced by parents is often immense and may be underappreciated by the medical team. The consensual nature of a joint decision-making process and the shared burden of the decision must be reinforced. In addition, there may be medically imposed obstacles to achieving consensus, such as frequent changes in the responsible physician from one neonatologist to the next, the failure of a physician to establish a therapeutic alliance with the parents, the persistence of communication barriers between the physician and the parents, or the development of a "contest of wills" between the physician and parents as to who will sway the other. All these factors need to be overcome when negotiating with parents toward consensus.
5. *Broaden the parents' moral community*. Identifying the locus of decision-making authority within each family's moral community may involve the inclusion of additional family members, grandparents, significant others, and religious or spiritual advisors in meetings with parents and the physician/team or in less structured communication opportunities.
6. *Share the attending physician's moral load by actively seeking opinions from colleagues*. Although the attending physician responsible for the infant bears the final responsibility for the approach taken with the parents, for personal and legal reasons, it is often helpful to obtain a second opinion from a colleague.
7. *Involve a bioethicist or ethics consultation team, as appropriate*. It may be beneficial to involve an institutional ethics committee with experience in case consultation and review, a clinical ethics consultation team, or a clinical ethicist, depending on available resources. Many hospital ethics committees are multidisciplinary in nature and include experts in medicine, nursing, philosophy, law, religion, and social services. The function of these committees varies widely. In some institutions, the ethics committee as a whole reviews cases; more commonly, a smaller subcommittee, an infant care review team, or an individual ethics consultant undertakes this responsibility. Ethics consultants can be very helpful in working to clarify values and build consensus (i.e., a process to ensure that facts are confirmed, relevant parties are involved, and decision makers are empowered, but not to be the decision-making group per se). In a multidisciplinary ethics committee, team members may disagree among themselves, some members may dominate others, the committee or consultation team may not be qualified to deal with the subject matter, or the team may be overly concerned with the institutional impact of a decision rather than with the specifics of the case. Experience suggests that consultation with individual bioethicists and smaller ethics consultation teams may be of greater benefit to decision makers than the practice of "ethics by committee."
8. *Consider transferring responsibility of care for the infant to another accepting service or institution*. In some situations, the therapeutic alliance between a particular physician and an infant's parents can be fractured beyond repair, and transfer to another unit or another hospital becomes a reasonable option. Although this can be procedurally difficult and require an adjustment for the parents as well as the infant, realities of NICU staffing schemes "firing" of specific neonatologists (or other care providers) is difficult to carry out and is not generally advisable, as it is potentially harmful to the functioning of the medical team. However, when differences of opinion remain and the degree of physician moral compromise is significant, it may be advisable to involve another staff member with whom the parents have formed a therapeutic alliance to help mediate the conflict.

Despite these efforts, the moral problem may not be amenable to consensual resolution. Rational people of good will may hold views that are irreconcilable. Individuals involved in a failed attempt at deriving consensus may experience what Webster and Baylis[141] term *moral residue*—"that which each of us carries with us from those times in our lives when in the face of moral distress we have seriously compromised ourselves or allowed ourselves to be compromised."

Until consensus can be achieved, withdrawal of life-sustaining medical treatment should generally not be undertaken. Rarely, physicians seek authority to make *unilateral decisions* via institutional or legal redress. When ethical conflict seems intractable, an institutional decision may be made to seek *legal recourse*. This course of action, although sometimes necessary, is generally unsatisfactory: It increases the anguish for patients and families, it destroys the parent-physician relationship, it creates (or increases) conflict between members of the health care team, and it invariably results in a significant drain on staff time and morale. It can also be extremely costly and time consuming for all parties involved. Ideally institutional policies developed by the hospital ethics committee and staff should be in place to minimize the need for judicial intervention.

Ethics of Research in the Neonatal Intensive Care Unit

Clinical research on sick newborn infants is required to advance clinical care; improvements in the practice of clinical

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

neonatology would not occur without such research. Research in children, let alone newborn infants, has historically been difficult to justify. Until more recently, a very protectionist view prevailed, such that studies in children were justified only if they were unsuitable in adults. This perspective has changed, reflecting the move from the dominance of beneficence or protectionism toward vulnerable groups, such as infants, to a stance based more on the principle of justice as the important consideration whereby individuals who are the subject of a treatment should have an equal opportunity to share the benefits of human research. This move is also a reflection of the fact that newborns have been harmed by the adaptation of results of treatment in other groups being applied to them without adequate research.

Despite the imperative for research, there are many challenges to neonatal research.[77] It is difficult to obtain "authentic," morally valid, informed consent from parents, because this requires surrogate decision making by anxious and stressed decision makers, often following an unanticipated, acute emergency. In addition, parents are often young, healthy members of society with little prior medical exposure and familiarity with the concept of medical research. Language and cultural and religious diversity add further complexity, and the act of soliciting consent itself often further exacerbates parental stress. Parents or guardians feel beholden to the caregivers of their vulnerable infants, and in cases in which the relationship between caregiver and researcher is unclear, there is the potential for "therapeutic misconception" (i.e., attributing therapeutic intent to research).

It may also be disturbing for parents to learn that there is much uncertainty about neonatal practice, such that their confidence in NICU caregivers may be diminished. Before discussing informed consent in neonatal research, other more general issues facing the ethical conduct of research need to be ensured, including the scientific value and validity of the study proposal, the existence of clinical equipoise in randomized trials, the distinction between therapeutic and nontherapeutic research (where the study would not lead to direct benefit for that infant), the existence of any potential conflicts of interest or financial incentives, and the overall risk/benefit analysis of the research proposal.

Informed consent is enshrined as a foundational cornerstone of the ethical practice of protecting human subjects from research risk.[69] The four domains within informed consent are (1) disclosure of information, (2) understanding, (3) competence or capacity, and (4) voluntariness or freedom to choose. Decisions that adults make on their own are morally robust, but decisions made for others cannot have the same degree of authenticity and are necessarily less valid in children.[69] Despite these challenges, it is widely accepted that neonatal research investigators have the obligation to obtain truly informed parental consent. Golec and colleagues described various models of consent in neonatal research[44]; this includes the standard model in which parents are solicited when their infant becomes eligible for a study, given written and verbal information, encouraged to ask questions, and required to sign a consent form. Other means of obtaining consent have included a steplike process of consent[3]; advanced consent, in which parents are approached in anticipation that their infant may meet inclusion criteria at a later date; emergency consent; and randomization without consent, in which randomization occurs before potential participants are approached, and only participants allocated to experimental therapies are informed of the trial and invited to give or withhold consent (Zelen randomization).[128] The individuals allocated to continue with standard therapies are not informed that they are trial participants at that stage.

Significant controversy involving consent and neonatal research issues surrounded the National Institute of Health–funded Surfactant, Positive Pressure, and Oxygenation Randomized Trial (SUPPORT). The study was designed to determine the appropriate range of oxygen saturation in extremely premature infants by using two target saturation ranges, one low and one high. Consumer advocacy group Public Citizen accused the investigators of deceiving parents with "egregious" deficiencies in the informed consent process.[39] While the consent documents varied by institution, they were approved by 23 institutional review boards, and while there were certainly ethicists criticizing the study, most leading pediatric ethicists vigorously defended the ethics of the study.[88,144] Ultimately, the most positive outcome of the controversy has been a renewed focus to optimize the consent process in neonatal research, including "deliberative democratic discussions with a broad array of societal representatives (parents, clinicians, researchers, and ethicists)."[67]

The optimal model for consent for neonatal research is one that protects and promotes parental authority, is sensitive to the vulnerability and stress of the parents, and is beneficent to the infants. Golec and colleagues[44] suggested that a "morally optimizing approach to research recruitment" is one in which:

1. Parents are approached one study at a time.
2. Studies have relevance to the current clinical status of the neonate.
3. Researchers minimize information overload.
4. Researchers promote respect for parental autonomy.
5. Researchers inform parents about research in a continuing process, not as an event.
6. Adequate time is allowed to make decisions.
7. There are limits on subsequent solicitation approaches.

No model of soliciting parental permission is perfect, and the concept of informed consent cannot be the sole safeguard protecting the welfare of the neonate in research studies. The integrity of the researcher, the role of the institutional review board, and safety and monitoring by all individuals involved help to ensure the safety and protection of neonates. Another important resource to ensure ethical conduct of neonatal research is the role of the NICU nurse. Not only are nurses in a strategic position to promote parental understanding and improve the likelihood that the conditions of informed consent are met, but nurses also can

• BOX 3.3 Ethical Responsibilities of Neonatal Physicians

- To neonatal patients—"right and good" action in their best interests
- To parents—constructive, respectful relationship
- To NICU team—leadership, direction with open, questioning culture
- To trainees—educational experience and model of professionalism
- To institution—in accord with mission, maintenance of data, review of practice
- To society—trust in profession, technical competence, and moral discretion in resource use
- To self—moral conscience

NICU, Neonatal intensive care unit.

help set priorities in neonatal research by playing an active role in the formulation of research policy and being "at the table" where priorities are set.[42]

Ethical Responsibilities of Neonatal Physicians

How neonatal medicine is practiced will certainly change, but the fundamental ethical obligations of neonatal physicians and health care practitioners will remain unchanged (Box 3.3). The physician's responsibility to the competent pregnant patient is defined and well established—to respect the patient's wishes regarding treatment even when this may be contrary to fetal best interests. So too, the physician's responsibility to the neonatal patient is well defined and established—right and good action within the best interests standard of judgment. In the broadest terms, these responsibilities are best discharged in the context of a constructive and mutually respectful parent-physician relationship that recognizes that patient and family values and beliefs are integral to the decision-making process. Physicians' responsibilities include the necessity of challenging parental views that they consider contrary to the patient's best interests.

In the context of team medicine, the attending physician is responsible for developing and maintaining positive relationships with all members of the health care team to promote better, open discussion of moral problems and to work toward consensus among the individuals directly involved in the patient's care. The physician also has an obligation to foster the ethical experience and education of the interdisciplinary team and that of junior staff and trainees. The perinatal high-risk unit or NICU team should be more than a group of physicians, nurses, and many other professionals working in an isolated area of the hospital trying to master new technology and break new ground. Ideally it should be an open, analytic, self-critical, and responsive group providing ethically responsible care to pregnant women, newborn infants, and their families.

By setting a standard of ethical responsibility for the care of newborns and families, physicians working in neonatal care send a message to society that promotes public confidence and trust in their professional practice and responsible use of expensive resources. Finally, all health care practitioners in neonatal care need to consider their own moral conscience and agency. Ethical deliberation is essentially a reflective task that requires participants to be explicit about what they believe and why, as well as what they value and on what grounds.

Acknowledgment

The authors and editors acknowledge the contribution of Jonathan Hellmann to previous editions of this chapter, portions of which remain unchanged.

Key Points

- Ethical issues in the NICU occur as physicians attempt to determine what is right and good for the patient, taking into consideration the values parents place on different outcomes.
- The standard of best interests of the newborn acts as a threshold for judgment, yet the subjective nature of this assessment and the fact that the assessment is being done by surrogate decision makers must always be recognized.
- Prenatal consultation at the limits of viability should provide parents with data on which decisions can be based and support parental decision making.

Legal Issues in Neonatal-Perinatal Medicine

JONATHAN M. FANAROFF AND ROBERT TURBOW

Clinicians, especially clinicians working in the intensive care unit environment, are accustomed to a modicum of predictability. Treatment plans are generally based on years of clinical experience coupled with robust dialogue with one's colleagues. How should physicians react to the $21 million "wrongful birth" verdict against a geneticist who missed the diagnosis of Smith-Lemli-Opitz syndrome? How does one prepare for the resuscitation of a 23-week-gestation infant knowing that some physicians have been sued for resuscitating such infants and others have been sued for failing to resuscitate them? Does the Born-Alive Infants Protection Act require that 22-week fetuses be given a trial of an endotracheal tube?

The medical profession tends to view the legal system with mistrust. The unfamiliar concepts and vocabulary coupled with the seemingly unpredictable nature of legal decision making can create an environment of confusion and apprehension. For various reasons, these concerns are particularly acute for neonatal-perinatal practitioners. Tremendous clinical and ethical uncertainty can surround the decision to resuscitate an extremely premature infant. Neonatologists are often asked to attend deliveries for premature infants at the limits of viability. Must the physician honor the parents' requests? What if the parents request that their extremely premature infant not be resuscitated? What are the roles and duties of the perinatologist, the neonatologist, and the hospital administration? These questions are not obscure or theoretical. A $60 million verdict by one jury, subsequently overturned, accentuates the importance of a clinician's familiarity with the laws that affect clinical practice. In these cases, the legal system can seem capricious and arbitrary. When the stakes are so high, and there is a lack of applicable case law, it is understandable that clinicians are left in a quandary.

During residency and fellowship training and after training is completed, clinicians interact with the legal system. This interaction may be in the form of a contract with a new employer, a lease for office space, or as a defendant in a medical malpractice suit. This chapter focuses on more recent legal developments in neonatal-perinatal medicine that can affect the daily professional lives of individuals who work in high-risk maternal units, delivery rooms, and neonatal intensive care units (NICUs). Several complex issues are addressed: What are the legal ramifications of a neonatologist disregarding a parent's request to forgo delivery room resuscitation? What are a physician's liabilities when providing phone supervision of an ambulance transfer of a critically ill patient? What are the elements of a medical malpractice case?

Practicing clinicians must understand their rights, duties, and liabilities as physicians. They must understand the legal relationship that they have with their employers, the hospital, referring physicians, consultants, and neonatal nurse practitioners (NNPs), and physician assistants (PAs) they supervise.

This chapter also assists the clinician in understanding basic terms and concepts of medical law. A certain baseline vocabulary is necessary to discuss the relevant issues adequately. Terms and definitions are introduced throughout the chapter. Additionally, certain landmark cases are discussed. This chapter provides legal background so that the clinician has a more complete understanding of the legal principles, cases, and statutes that affect the daily practice of neonatal-perinatal medicine.

Although the focus of this chapter is on the US legal system, the rate of medical malpractice litigation has been increasing internationally at a dramatic rate. Many European countries have seen double-digit (Great Britain >50%) and triple-digit (Germany and Italy >200%-500%) percentage increases in the number of cases presumed "malpractice or bad health care."[28] Clinicians across the globe must be aware of the legal environment particular to the country in which they practice.

educating clinicians. Nothing contained in this chapter should be viewed as substantive legal advice. This chapter does not create an attorney-client relationship between the authors and any readers.

Laws generally vary from state to state in the United States. Federal laws may represent a separate body of rules that can affect a given practitioner.

Legal cases often hinge on very specific facts. Courts and juries make determinations based on the facts of a given case. A slight variation in circumstances, or the same facts argued by a different lawyer or in front of a different jury, can result in a completely different legal outcome. A practitioner should never assume that his or her situation is identical to the parties in another situation. Seasoned practitioners recognize that not all 27-week-gestation infants with respiratory distress syndrome have identical courses. Likewise, each legal situation has its own nuances that can determine a distinct outcome. Courts expend considerable effort to distinguish the facts when comparing one case with another.

The authors neither advocate for nor reject the judicial decisions and legislative actions described in this chapter. Readers should become familiar with the current laws that affect practice in their states. If readers have specific questions, they should consult with a qualified attorney.

General Legal Principles

Legislative Law and Case Law

Individuals unfamiliar with the US legal system may have difficulty understanding the distinction between case law and statutes. Generally, a significant portion of US law is based on the common law. These laws have roots in English law from the last few hundred years. In many ways, the common law provides the foundation for the US perspective on contracts, property, torts, criminal law, evidence, and many other legal disciplines.

The common law was created by judges who were generally evaluating disputes between parties. More recently, well-known cases such as *Brown v Board of Education* or *Roe v Wade* are examples of judicial decisions that became US law. These were cases that involved defined parties. The US Supreme Court made a determination, and the law was established.

In addition, many laws are created by elected legislative bodies, such as the US Congress or a state legislature. Often court opinions state that it is not the role of the judiciary to redefine or change the definition of laws that were created by a legislative body; rather, the legislature is generally responsible for changing a law.

The case of *Vo v Superior Court* is illustrative.[83] This Arizona case involved a woman who was shot in the head during a drive-by shooting on the freeway. The woman and her 23-week fetus died as a result of the shooting. The prosecutor subsequently charged Nghia Hugh Vo with two counts of murder. The Arizona Court of Appeals considered the propriety and legality of charging Vo with two counts of murder. The court stated that when the legislature created the murder statutes, it did not intend to include a fetus in the definition of a person or human being. The court concluded that the unlawful killing of a fetus could not be murder. Then the court stated that if the legislature intended to include a fetus in the definition of a person, it was the responsibility of the legislature to change the homicide statute. Shortly after the *Vo* opinion, the Arizona legislature amended the manslaughter statute to include "knowingly or recklessly causing the death of an unborn child by any physical injury to the mother."[13]

The *Vo* case serves as an example of the dynamic balance between the two branches of government that create law. In this case, the judges stated that it was the responsibility of the legislature to change the definition of manslaughter. The legislature responded to this case by expanding the definition of manslaughter to include unlawful killing of a fetus. Although the *Vo* case has also been included in the acrimonious debate of fetal rights, it is presented here to elucidate the concept of legislative law as opposed to judicial law.

State Law and Federal Law

Another area of potential confusion is the differences between state laws and federal laws. Medicine is generally regulated at the state level, and consequently most clinicians find themselves in state court subjected to state laws. Significant restrictions exist that keep most cases out of federal court. A civil rights case, a dispute involving the Americans with Disabilities Act (ADA), or a malpractice case that occurred at a military hospital are three examples of cases that could be adjudicated in federal court. Unless a case meets narrow criteria to qualify for federal adjudication, most legal disputes involving perinatal or neonatal practitioners are tried in state court.

How do laws in one state affect clinical practice in another state? Practitioners may wonder how a Michigan court decision would affect a practitioner in Ohio or Nevada. Generally state court decisions are binding only in that state. If the Texas Supreme Court has ruled on an issue, the court's findings are viewed as state law in Texas, and the legislatures and courts of California, North Carolina, or Wyoming are not bound by the Texas court ruling. A state court's ruling could be persuasive in other states, but the conclusions of one state court are not generally viewed as binding on courts in other states.

This concept of one state's laws affecting another state also holds true for laws passed by state legislatures. If the California legislature passes a law concerning access to prenatal care, the law would have essentially no effect on citizens of Connecticut or Virginia. Issues such as the definition of "live birth" are treated differently by different state governments. Clinicians should be familiar with their applicable state laws before relying on case law or statutes cited in this chapter.

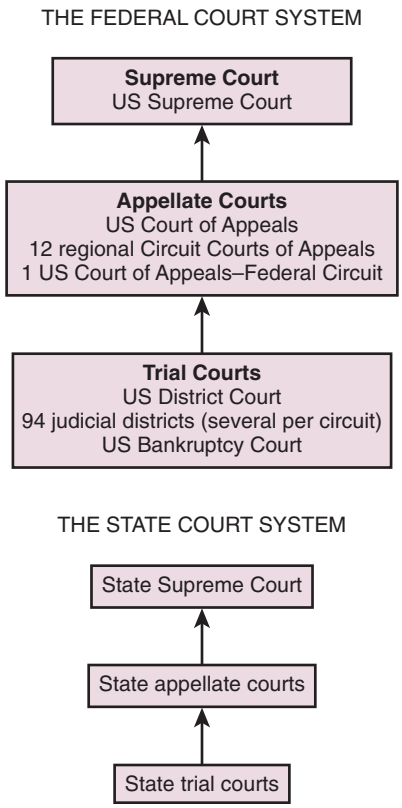
General Structure of the Federal and State Court Systems



Several of the cases cited in this chapter mention the holdings of various state and federal appellate courts, and several US Supreme Court decisions are also discussed. How does a case get to an appellate court or to the US Supreme Court? Various rules determine which court hears a dispute and which appellate court has the jurisdiction to review the decisions of the lower courts. Most of the cases discussed in this chapter would be adjudicated in the state court system. The general hierarchies of the federal and state court systems are depicted in Fig. 4.1.

Supervision of Others

Theories of Liability for Attending Physicians

Attending neonatologists carry substantial responsibility. Generally, they bear ultimate medical responsibility for the neonates under their care. Practically speaking, it is impossible for one physician to provide all of the care for a sick newborn. Depending on the clinical setting, nurses, NNPs, PAs, respiratory therapists, social workers, residents, fellows, consultants, and many others all contribute greatly to patient care. The exact demarcation of responsibility and liability borne by attending physicians for these alternate providers is often difficult to determine.

In holding attending physicians liable for the acts of others, courts tend to rely on three different theories of liability. An early theory of attending liability was known as the "captain of the ship doctrine." Physicians, particularly surgeons, were assumed to be similar to naval captains and to have complete control over the operating room (the "ship") and all the medical personnel (the "crew") within. With this control came responsibility for all negligent actions performed by anyone under the surgeon's "command."[63] Most courts now recognize the increasing complexity of health care provision and have rejected the captain of the ship doctrine as "an antiquated doctrine that fails to reflect the emergence of hospitals as modern health care facilities."[49]

• **Fig. 4.1** Hierarchy of the federal and state court systems in the United States.

Respondeat superior is a more accepted doctrine of physician liability for negligence of others under his or her control. *Respondeat superior* literally means "let the master answer." Because an attending physician has a right of control over an NNP or resident, the negligence of that provider is imputed to the attending physician in certain circumstances. Under *respondeat superior*, the attending physician would be responsible if a resident negligently places umbilical lines or an endotracheal tube. The attending physician would not be liable, however, under *respondeat superior* if a bedside nurse was negligent in the observation or reporting of a significant intravenous infiltrate. Under the earlier "captain of the ship" doctrine, the attending physician may have been deemed to be responsible for the intravenous infiltrate.

The attending physician can also be held liable for providing "negligent supervision." For supervisees under his or her charge, the attending physician is responsible for providing adequate training and supervision. The attending physician must be readily available and promptly respond to requests for assistance. This responsibility was underscored in a 2004 obstetric malpractice case in which the attending anesthesiologist was not immediately available for an emergency cesarean section, and the fetus allegedly suffered as a result. The case was settled for $35 million.[14]

Finally, in many cases, an attending physician becomes liable for the actions of supervisees by the creation of a physician-patient relationship that flows from the patient through the supervisee to the attending physician. In a case in New York, a patient was seen by a nurse practitioner in an emergency department, and the nurse practitioner misdiagnosed the condition. The attending physician discussed the patient with the nurse practitioner and signed the chart but did not personally examine or speak with the patient. The court, interpreting New York's law regarding nurse practitioners, held that "the ultimate responsibility for diagnosis and treatment rests with the physician."[66]

Residents and Fellows

During their postgraduate training, residents and fellows gain increasing experience and clinical skills under the supervision of attending physicians. Under the doctrine of *respondeat superior*, the educational institution and the attending physician are generally responsible for the medical care provided by residents and fellows.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Residents who have completed their first year of training are eligible to be licensed to practice medicine without supervision. Because of this fact and the expectation of appropriate supervision, most states treat residents as physicians rather than students and hold them to "the same standard of care as physicians who have completed their residency in the same field of medicine."[15] Nevertheless, because trainees are thought to be agents of the hospitals in which they work, often have limited financial resources from which to pay a judgment against them, and always have an attending physician assigned to the patients for which they are caring, the institution and the attending physician are almost always named in the lawsuit as well.

Neonatologists must be very careful about appropriately supervising residents and fellows. In some cases, inexperienced trainees are responsible for caring for some of the sicker patients in the NICU. From a legal standpoint, the supervising neonatologist must remain involved in the care of these patients and provide an appropriate level of oversight. The level of supervision would vary based on a variety of factors, including the condition of the patient, the likelihood of major changes in that condition, and the experience and skill of the resident providing the care. Failure to provide appropriate supervision can result in liability for negligent supervision.[45]

Physician Assistants

Many NICUs now employ physician assistants (PAs). A PA is a health care professional who may practice medicine only with physician supervision. A certified PA is a health care professional who has completed training and passed a national certification examination. The scope of practice of PAs is governed by state law and varies from state to state. In many states, PAs are authorized to prescribe medications. Physician assistants can contribute greatly to the care of neonates, and some centers that have found it difficult to recruit an adequate number of NNPs have found PAs to be an "untapped resource for the NICU."[67] It is important, however, for physicians to determine the scope of practice for PAs in their individual state for two reasons. First, there is increased potential malpractice liability for the supervising physician when PAs exceed their scope of practice. Second, physicians may risk loss of their licenses if they are "found to have condoned the unauthorized practice of medicine by a nurse or other health care professional for whose conduct [they are] responsible."[17]

Advanced Practice Neonatal Nurses

There has been a rapid increase in recent years in the number of advanced practice neonatal nurses (APNNs) in the United States. An APNN is a registered nurse who has completed a master's degree in advanced nursing practice and, in most cases, has passed a national certifying examination. Advanced practice nurses are regulated at the state level, and educational requirements can vary. Most states require a graduate degree, generally a master's, for authorization to practice at the advanced practice level, and 45 states require national certification.[56] Additionally, the National Association of Neonatal Nurses supports a "future goal" of having all APNNs be prepared through a Doctor of Nursing Practice.[57] APNNs have played an invaluable role in improving health care for neonates in various settings ranging from urban academic centers to small rural hospitals. Under certain circumstances, there can also be additional liability for the physician.

In neonatology, there are generally two recognized types of APNNs: clinical nurse specialist and neonatal nurse practitioners. The clinical nurse specialist is a registered nurse with a master's degree who has expertise in neonatal nursing. The NNP is a registered nurse with experience in neonatal nursing (many have completed a master's degree) and additional clinical training in the management of newborns. Neonatal nurse practitioners are allowed to assess, diagnose, and treat newborns independently or under the supervision of a physician.

The licensure and scope of practice of APNNs vary considerably from state to state. Each institution must have policies and procedures for granting privileges for APNNs. The American Academy of Pediatrics Policy Statement on Advanced Practice in Neonatal Nursing released in June 2003 recommends the following:

- A neonatologist should supervise an APNN in the NICU.
- The APNN should collaborate and consult with other health care professionals.
- The APNN should be certified by a nationally recognized organization and should maintain that certification.
- The APNN should participate in continuing education.
- The APNN should comply with hospital policy regarding credentialing and recredentialing.[10]

One critical issue concerning APNNs is the liability of the supervising physician. In some states, NNPs are licensed to practice independently and require no supervision under the law. If an NNP is hired by a hospital as an independent contractor with his or her own privileges, the physician does not employ the NNP. In these situations, when the NNP and physician are interacting in the management of an infant, the physician is acting the same as when consulting with any other provider, with similar liability.

In most instances, however, and in almost all NICU environments, APNNs are not hired as independent contractors but rather as employees of the physician or hospital. In these cases, the employer is vicariously liable for the acts of the employee. The NNP is often supervised by an attending neonatologist who bears ultimate responsibility for the patient, as discussed earlier.

Malpractice

Medical malpractice litigation can be contentious and acrimonious. It is a pervasive issue that appears with great regularity in the popular press. Many books have been dedicated to the subject of medical malpractice. In his 2011 State of the Union Address, President Obama voiced support for

• BOX 4.1 Common Malpractice Suits in Neonatology

Delivery Room Management or Resuscitation

- Poor neurologic outcome
- Cerebral palsy: neonatologist named as codefendant with obstetrician-perinatologist
- Neonatal encephalopathy: plaintiff alleges some component of injury occurred postnatally

Line Complications

- Vascular accidents related to central venous lines
- Loss of fingers or toes associated with central lines
- Thrombus and complications from thrombus

Delay in Diagnosis or Treatment

- Poor blood gases, prolonged hypotension
- Delay in antibiotic administration
- Congenital hip dislocation
- Congenital heart disease

Transport Team

- Medications or care provided by transport team (e.g., excessive heparin given)

Failure to Monitor Adequately

- Blood glucose
- Blood oxygen: either hypoxia (brain damage) or hyperoxia (retinopathy of prematurity)
- Seizure

"medical malpractice reform to rein in frivolous lawsuits."[77] This section is largely limited to a discussion of malpractice in neonatal-perinatal medicine (Box 4.1).

Malpractice is part of a broader area of law known as *torts*. Tort law largely deals with the duties and responsibilities that individuals have toward one another. Torts are generally divided into two groups: intentional torts and unintentional torts. Defamation, invasion of privacy, civil battery, and professional malpractice are all torts, but malpractice is a type of unintentional tort.

Negligence means that an individual's behavior has deviated from a standard of "due care." Malpractice is considered a specific type of negligence. By some interpretations, malpractice is also considered a type of breach of contract with the patient, so the defendant is technically being accused of committing a tort and violating contract law.

Lawyers, accountants, physicians, and other professionals are held to a certain level of conduct. If one's professional conduct is substandard and a client, customer, or patient is harmed by this substandard conduct, a plaintiff may attempt to show that the practitioner has committed malpractice. To win a malpractice case, the plaintiff must show four critical elements: duty, breach, causation, and damages.

Duty

"The duty of care owed to an individual, for purposes of a claim of medical malpractice, is based primarily on the existence of the physician-patient relationship."[73] To proceed with a negligence case, the plaintiff must show that the defendant had a duty to the plaintiff. This has been described as a "threshold issue." Does the defendant owe a duty to the injured party? If there is no duty, no claim of negligence can be sustained.

If a neonatologist has privileges only at hospital A, and the physician is called and refuses to attend a high-risk delivery at hospital B, the physician likely would have no professional relationship with the pregnant woman or her infant at hospital B. The neonatologist cannot breach his or her duty if no duty to the defendant exists. This concept of duty is separate from the moral or ethical obligation to provide care. A physician cannot be liable to a patient if there is no legal duty. Likewise, if NNP Smith is on call for the evening, and NNP Jones has left town with his family for a scheduled vacation, it would be difficult for an injured plaintiff to show that NNP Jones had a duty to attend a high-risk delivery while he was out of town.

Does a physician caring for a pregnant woman have a duty to the newborn even after the infant is born and being cared for by another physician? In *Nold v Binyon*,[59] a woman tested positive for hepatitis B. Her newborn did not receive hepatitis B immunoglobulin or the hepatitis B vaccine, and the infant subsequently became a chronic carrier for hepatitis B. The trial court ruled, and the Kansas Supreme Court agreed, that the delivering physician had a duty to inform the woman of her hepatitis B status. The Supreme Court stated, "A physician who has a doctor-patient relationship with a pregnant woman who intends to carry her fetus to term and deliver a healthy baby also has a doctor-patient relationship with the fetus."

Supervising Others

As discussed earlier, neonatologists are often asked to supervise the care provided by others. This supervisory role generally establishes a physician-patient relationship with any patient who is cared for by the supervised NNP or PA. In these cases, the physician has a duty to the patient even if the supervised NNP is providing all of the bedside care.

Telephone Advice

Is "duty" established when one physician consults with another over the phone? Telephone advice and transport present an interesting legal challenge. On many transports, the responsible physician at the receiving facility is not physically present with the transport team. The receiving physician often begins to offer clinical advice, however, when first contact is initiated by the referring facility. Generally, this can be a situation of shared duty. The referring physician and the receiving physician may have a duty to the patient. The receiving physician may have no duty to the patient, however, if the receiving physician is acting more in the role of a consultant.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

In *Sterling v Johns Hopkins*,[73] a woman was admitted at approximately 32 to 33 weeks' gestation to a hospital, and she developed severe preeclampsia and suspected HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome. The treating physician called the emergency transport service to arrange transport to Johns Hopkins, because the receiving hospital had a NICU that could potentially care for a premature infant. The receiving physician spoke with the referring physician on the telephone. The woman became unresponsive during the transport. She experienced an intracranial bleed and later died.

The husband sued the receiving hospital, alleging negligent advice given over the phone. The court determined that there was no physician-patient relationship between the receiving physician and the pregnant woman. Because the receiving physician was acting more in the role of a consultant and the referring physician was free to make his or her own management decisions, the court ruled that the receiving physician did not have a duty to the pregnant woman. "Where the treating physician exercises his or her own independent judgment in determining whether to accept or reject [a consultant's] advice, … the consultative physician should not be regarded as a joint provider of medical services with respect to the patient." In this case, the court determined that the treating physician maintained decision-making power and that the physician at the receiving facility was acting more as a consultant than co-managing the patient. The court determined that no duty existed between the receiving facility and the patient.

Telemedicine

With changes in technology, there has been a rapid increase in the use of telemedicine, which is defined by the American Telemedicine Association as "the remote delivery of health care services and clinical information using telecommunications technology. This includes a wide array of clinical services using internet, wireless, satellite, and telephone media."[12] A number of legal issues have arisen with respect to telemedicine, and the law has not been able to keep pace with the technology. Many of these issues have to do with licensure, credentialing, and reimbursement as well as liability. For example, a physician based in state A who cares for a patient via telemedicine located in state B may be found to be practicing without a license and subject to disciplinary action in state A as well as medically liable in state B. Some states have created special laws or offer limited telemedicine licenses. Other states have specific regulations about the care provided. Colorado, for example, requires that "Any health benefits provided through telemedicine shall meet the same standard of care as for in-person care."[23] Additionally, many malpractice insurance policies specifically exclude telemedicine coverage. There is little question that telemedicine has significant potential to improve quality and access to care for patients, especially in underserved areas. Given the legal risks, however, it is important to seek legal counsel and be aware of relevant laws and regulations.

Prenatal Consultation

Prenatal consultations might or might not give rise to a duty between the neonatologist and the pregnant woman and her child. Among the determining factors, courts seem to evaluate the formality of the consultation and the presence or absence of contact between the parties. In *Hill v Kokosky*,[37] an obstetrician informally consulted with a neonatologist. The plaintiff had been admitted to the hospital at 22 weeks' gestation with a diagnosis of incompetent cervix. The two physicians informally discussed the case over the telephone. The obstetrician discussed the case in the abstract, and the neonatologist tended to agree with the obstetrician's management. There was no referral or formal consultation. From the record, it seemed that the neonatologist did not review the chart, speak with the mother, or even know the mother's name. The infant was born 2 weeks later and developed severe cerebral palsy.

In her malpractice action against the neonatologist, the mother maintained that the neonatologist gave substandard advice concerning birthing options and that this substandard advice contributed to her infant's injuries. Given the facts, the court concluded that no physician-patient relationship existed between the neonatologist and the family. It is important to understand why the court ruled for the defendant in this case. Casual telephone advice was given to a colleague. The neonatologist did not know the name of the patient and never spoke with her. The court concluded that the neonatologist did not prescribe a course of treatment but rather gave recommendations that could be accepted or rejected by the obstetrician.

In contrast to this case, if a neonatologist is formally consulted and speaks with a family and makes recommendations concerning management, there may be a duty to the mother and her infant. Judicial decisions also seem to hinge on whether or not a consulting physician is recommending a specific course of therapy or merely making suggestions that the original physician either can follow or can ignore.

Generally, it is not difficult for a plaintiff to establish that a clinician had a duty to the patient. Usually, the physician has provided care to the patient, and the plaintiff easily establishes that the duty requirement has been met. Especially in the case of hospital-based physicians, such as neonatologists, the element of "duty" is generally established.

Breach

Standard of Care

What is the duty that is owed? The duty is to provide reasonable care under the circumstances. Although generalists are held to a standard of "same or similar community," specialists and subspecialists, such as neonatologists, NNPs, and perinatologists, are generally held to the higher national standard of care.[60] An expert witness from a different state can testify about the national standard of care for a neonatologist. In these cases, the neonatologist's care

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

is not being compared with the care provided in a similar community; the care is evaluated in light of national standards.

In many malpractice suits involving obstetricians, perinatologists, and neonatologists, considerable emphasis is placed on this element. Often the defense vigorously maintains that "the doctor did nothing wrong." The defense often takes the position that there has been an unfortunate outcome, but the defendant practiced within the standard of care. If the defense can prove that the physician acted within the standard of care, the plaintiff cannot successfully maintain a malpractice action.

A typical case is a brachial plexus injury after birth. In *Knapp v Northeastern Ohio Obstetricians*,[46] a mother alleged that her infant's brachial plexus injury was the result of excessive traction applied by the obstetrician. The trial court found, and the appellate court affirmed, that the evidence did not support the mother's allegations. The court concluded that the obstetrician had not breached the standard of care.

Retinopathy of prematurity (ROP) is another common source of negligence cases involving newborns. In *Brownsville Pediatric Associates v Reyes*,[20] a pediatrician was found liable for substandard ventilator management. The expert witness testified that the child's resulting brain damage and ROP were related to hyperventilation and hyperoxia. The plaintiff was awarded $8 million, and the defendant's appeal was denied.

Another ROP case dealt with the responsibility of the neonatologist, the pediatricians, the pediatric ophthalmologist, and the parents when 29-week-gestation twins missed their follow-up appointments for ROP evaluation.[34] The twins became legally blind. In this case, the neonatologist apparently provided all necessary referrals and documentation, and she was not named in the resulting suit.

Role of the Expert Witness

In tort proceedings other than medical malpractice, a person with common knowledge generally knows and understands "due care." If someone is walking down the street with closed eyes and bumps into someone else and injures the other person, a lay juror does not need an expert witness. The lay juror understands that one should not walk down the street with closed eyes, because someone else could be injured as a result. In medical malpractice cases, however, the lay juror generally does not have a grasp of "reasonable care under the circumstances." This is one of the roles of the expert witness. To serve as an expert witness, an individual must have specific knowledge and training that qualifies him or her to serve in this capacity. The Rhode Island statute,[68] for example, states "only those persons who by knowledge, skill, experience, training, or education qualify as experts in the field of the alleged malpractice."

If a fetal monitoring strip shows severe, repetitive, late decelerations, should the obstetrician perform a cesarean section? It is the role of the expert witnesses to educate the jury so that the jurors have a grasp of what is (and is not) reasonable care under the circumstances. Both sides (plaintiff and defendant) usually hire their own expert witnesses. The plaintiff's expert generally maintains that the physician practiced outside of the standard of care. The defense expert maintains just the opposite. After the expert witnesses are examined and cross-examined, it is up to the jury (or arbitrators) to decide whether the clinician committed a breach in the standard of care.

Expert witness testimony is often required in neonatal-perinatal malpractice cases. Expert witnesses were used in the 2000 Pennsylvania case *Sonlin v Abington Memorial Hospital*.[71] In this case, a premature infant girl who was born at approximately 34 weeks' gestation had an umbilical line. The infant developed vascular compromise in her left leg, which resulted in a thrombus that required amputation of the extremity. The plaintiff maintained that the neonatologist did not recognize the thrombus and that he did not institute corrective action in a timely fashion.

Expert witnesses would have to explain to a jury why umbilical lines are placed, how long they are left in place, and the potential complications from indwelling arterial catheters. In this case, an expert would have to explain the effect of prematurity on lung development and the subsequent necessity for monitoring blood oxygen levels. Basically, the expert must explain the standard of care, the indications for the procedures, and the potential complications.

In the Louisiana case *Hubbard v State*,[39] a full-term newborn was admitted with meconium aspiration and hypoglycemia. A peripheral intravenous infusion of 10% dextrose in water was ordered. After a change was made in the intravenous fluid, it was noted that the infant's hand became red and swollen, and the infant became lethargic. His blood glucose was 450 mg/dL. Because of an error, the infant had received 50% dextrose in water instead of the 10% dextrose in water that was ordered. The infant sustained third-degree burns that left permanent disfigurement of the hand, and a computed tomography scan showed a "possible venous thrombosis of the transverse and sagittal sinus." By the time this case reached the Louisiana Appellate Court, the child was almost 8 years old. In the interim, the child had been found to have Russell-Silver syndrome, a condition known to be associated with developmental impairment. The expert witnesses were extensively questioned about whether the dehydration and possible venous thrombosis contributed to the child's observed mental delays.

These cases represent a potential breach in the standard of care. Mistakes were made, infants were harmed, and the families attempted to hold the caregivers responsible for the damages that occurred. In both of these cases, expert witnesses were needed to assist in delineating the standard of care for the legal decision makers.

Unbiased and truthful expert witnesses are an important component of the American tort system. An American Academy of Pediatrics policy statement describes professional

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

expectations for expert witnesses, including "thorough, fair, objective, and impartial" testimony provided for reasonable compensation.[11] Additionally, the experts must base their opinions on "sound scientific principles."

Res Ipsa Loquitur

Res ipsa loquitur is a legal doctrine that means "the thing speaks for itself." Common medical examples of this doctrine include a retained surgical sponge, removal of the wrong kidney, or operation on the wrong patient. These three examples are factually simple. A juror's common knowledge would guide him or her to a reasonable conclusion. In practical terms, *res ipsa loquitur* generally means that the plaintiff does not need an expert to show that there was a deviation in the standard of care.

The doctrine means that certain things do not just happen. Historically, the *res ipsa loquitur* doctrine can be traced to an English case from 1863 in which a passerby was injured when a barrel fell from a window.[21] The doctrine was developed to explain that barrels do not fall out of windows unless someone has acted negligently.

A 2003 case from New York relied on the *res ipsa loquitur* doctrine. In *Rosales-Rosario v Brookdale,* a woman was hospitalized to give birth.[69] An epidural line was placed, and she was partially anesthetized. It was subsequently noted that she had sustained a burn to her leg. She had no idea how she sustained the injury. Her leg possibly was burned by an examination light, but because of her anesthetized state, she did not recall how the injury occurred. She relied on the doctrine of *res ipsa loquitur*. The trial court dismissed the case, but the appellate court reversed the lower court's decision. The appellate court stated the rule of *res ipsa loquitur*: "To rely on the doctrine of *res ipsa loquitur*, a plaintiff must submit sufficient proof that: (1) the injury is of a kind that does not occur in the absence of someone's negligence; (2) the injury is caused by an agency or instrumentality within the exclusive control of the defendants; and (3) the injury is not due to any voluntary action on the part of the injured plaintiff."[69]

In the *Rosales-Rosario* case, the court concluded that leg burns do not just occur, so the first element of *res ipsa loquitur* was satisfied. In addition, the physicians and hospital personnel were in exclusive control of all equipment in the delivery room, including the examination light. Finally, the patient did not engage in a voluntary act that resulted in her injuries.

Showing *res ipsa loquitur* means that the plaintiff has overcome the burden for breach. The plaintiff still has the burden of showing the other elements of the tort suit, but the deviation in standard of care has been proved if the court accepts the doctrine of *res ipsa loquitur*.

Causation

Of the four essential elements of a tort suit, causation is perhaps the most challenging to understand. Regardless of whether the dispute is malpractice or another civil complaint, causation is not always intuitive. In brief, the defendant's breach must be the cause of the plaintiff's injury; mere correlation is insufficient. The plaintiff must show a reasonable inference that the deviation in care resulted in the injury. Stated differently, assuming the plaintiff has suffered an injury, did the deviation in standard of care cause this injury? Expert testimony is often required to answer these questions. Did the obstetrician's decision to allow a vaginal birth in the face of severe decelerations result in the newborn's neurologic damage? Did the neonatologist's "delay" in the decision to perform a double-volume exchange transfusion result in kernicterus that would have otherwise been avoided?

In many malpractice cases, the issue of causation can be complex. Causation can be particularly perplexing, however, in the context of a neonatal-perinatal medical malpractice case. In the *Hubbard* case described earlier,[39] multiple expert witnesses disputed whether the severe dehydration contributed to the child's mental delay. What is the impact of the diagnosis of Russell-Silver syndrome? Was this the cause of the mental delay? The child had also had at least two documented falls during early development. Did the head injuries, which led to evaluation in an emergency department, cause the findings?

This case elucidates the particular challenge of causation. Board-certified neonatologists and pediatric neurologists could have well-substantiated, yet differing, opinions on the etiology of this child's mental deficits. How is a jury to rule on this complex issue? As in essentially all medical malpractice cases, expert witnesses must testify on the issue of causation. The concepts are usually too specialized for a nonexpert juror. Absent the testimony of an expert witness, a juror's common knowledge is often inadequate to decide the issue of causation.

Damages

The final element that a plaintiff must show is *damages*. For plaintiffs to recover any type of award, they must show that they were harmed. They experienced either pain and suffering or a loss of some kind, such as loss of wages or loss of consortium. In some cases, damages are presumed. If a surgeon leaves a surgical sponge in the patient, the patient requires an additional surgery to remove the sponge. In this case, the patient would be able to show that the second surgery led to discomfort, time away from home, time away from work, and lost wages.

To understand the concept of damages, one should be familiar with the common distinction between economic and noneconomic damages. Economic damages include medical expenses, costs of burial, lost earnings, and loss of employment. These damages are often less complicated to calculate. Alternatively, some plaintiffs claim noneconomic damages, which are more subjective. Among other claims, noneconomic damages can include pain and suffering, emotional distress, mental anguish, or destruction of parent-child relationship.

Many state legislatures have attempted to cap awards for pain and suffering or for wrongful death. The California legislature has placed a $250,000 cap on noneconomic damages.[22] This generally means that any litigation involving the death of a newborn has a maximum pain and suffering award of $250,000. If older patients die, their estate can seek damages for lost wages, lost consortium, or other losses. The award for wrongful death of a newborn is essentially capped in California, however. In addition, several state legislatures have placed caps on other noneconomic damages such as pain and suffering. In Louisiana, the Malpractice Liability for State Services Act has capped state hospitals' liability at $500,000 for "pain and suffering."[47]

A great deal of tort reform litigation deals with the issue of damages. There continues to be a national debate concerning caps on noneconomic damages as well as multiple legal challenges to state caps on noneconomic damages. These challenges have had mixed success, with state courts recently upholding limits in some states (Louisiana, California, Indiana), whereas other states have ruled the limits unconstitutional and thus invalid (Oklahoma, Georgia, Illinois).[30]

If a negligent act is committed and someone is harmed, damages are usually limited to compensatory awards. Punitive damages are awarded if the defendant is found to have committed a particularly egregious act. These damages are rarely awarded in medical malpractice cases. If a physician were to alter a chart or make another attempt to change the medical record, however, a jury may award punitive, or punishment, damages. "Spoliation of evidence" can lead to punitive damages.

Burden of Proof

How does a plaintiff win a case? Generally, each element must be proved by a preponderance of the data. This is also called the "51% test." The attorneys often frame their questions in terms of "is it more likely than not." Whether the attorneys are questioning expert witnesses or making statements to the jury, they often refer to the burden of proof. Generally, this burden is on the plaintiff. The plaintiff must show that the defendant had a duty, that the duty was breached, that the plaintiff sustained damages, and that the breach was the legal cause of the damages. The plaintiff must prove each of these elements by a preponderance of the data.

Burden of proof can be contrasted with the common criminal standard of proof known as "beyond a reasonable doubt." In criminal cases, the state must show the defendant's guilt beyond a reasonable doubt. Another standard that may be familiar to readers is the "clear and convincing" standard. This standard is sometimes used in cases involving the withdrawal of care when the patient cannot communicate his or her wishes.[41] In civil cases, and particularly in malpractice cases, the standard is generally a preponderance of the evidence.

Protected (Nondiscoverable) Proceedings

Many hospitals have committees that review the care provided at that institution. Although the precise operations of these committees might differ, committees generally review cases that have had an untoward or unexpected result. In some institutions, all deaths are reviewed. Many state legislatures have provided protection for the proceedings from these committee meetings. The Georgia statute specifically shields the specified proceedings from being used by a plaintiff in a medical malpractice case.[31] This is an issue of public policy. It is believed that care would be improved if caregivers could discuss challenging cases openly in a protected environment.

Clinicians must recognize that these proceedings do not limit the plaintiff's ability to bring suit against the physicians or the institution. A meritorious plaintiff can still subpoena hospital records and successfully bring suit against the caregiver. The protected proceedings would be unavailable as evidence in the case, however. From a legal standpoint, the proceedings are "nondiscoverable." Before a physician discusses a case with an untoward outcome at a medical staff proceeding, the physician might wish to confirm that the proceedings of that meeting are nondiscoverable.

Other Tort Actions

In the context of neonatal-perinatal medicine, there are two unique causes of action. These actions are *wrongful life* and *wrongful birth*. There are distinctions between the two, and these causes of actions are not allowed in some states.

Wrongful Birth

Wrongful birth cases are brought by parents who have given birth. The cause of action is maintained on behalf of the parents. The parents contend that the child should never have been born, and they seek recovery based on the birth. These cases are often seen after the failure of a sterilization procedure or after a physician has assured a patient that he or she is not fertile. The parents generally seek economic damages related to the cost incurred in raising the child.

In 2007, a Florida family was successful in suing a geneticist on a wrongful birth cause of action. The case involved the alleged misdiagnosis of a child with Smith-Lemli-Opitz syndrome.[24] The family had one child with multiple anomalies, including microcephaly, micrognathia, cleft palate, syndactyly, hypospadias, and cryptorchidism. This child also had severe developmental delays. The family alleged that they brought the child to a geneticist who failed to make the diagnosis. The family was allegedly told that their chances of having a normal child were the same as anyone else's. Based on this information, the family conceived and did not seek genetic diagnosis of the fetus. Within hours of birth, this child was diagnosed with Smith-Lemli-Opitz syndrome. Subsequently, the first child was also diagnosed with Smith-Lemli-Opitz syndrome.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

The family contended that they would have terminated the pregnancy if they had been aware of the diagnosis of the second fetus. Expert witnesses testified that failure to diagnose the older child with Smith-Lemli-Opitz syndrome was below the standard of care. A plaintiff's expert also testified that the conduct of the original geneticist was egregious. The plaintiff expert testified that the family should never have been told that they had no increased risk of having a child with birth defects. The family sued, and a jury awarded more than $21 million.[76]

Wrongful Life

Wrongful life cases are maintained on behalf of a newborn. The plaintiff usually maintains that there was negligence in the diagnosis or treatment of the mother and that the infant should not have been born. In essence, the parent is claiming that the infant would be better off if the infant had not been born. Historically, these cases tended to be brought on behalf of newborns with severe congenital anomalies. A family maintains that an obstetrician or ultrasonographer missed certain important findings. The family claims that they would have terminated the pregnancy if they had known the child's diagnosis.

Ethically and philosophically, this tort raises many more questions. What is the value of human life? Can a person actually sustain a cause of action simply because that life exists? Would any person actually be better off if he or she had not been born?[33] As ill-equipped as many clinicians are to deal with these questions, the courts are at an even greater disadvantage. Courts tend to rely on facts and evidence. How does one compare a damaged existence with no existence at all?

Courts have grappled with this issue. Some courts have stated that there is sanctity in an impaired existence but that this sanctity does not preclude a child's recovery for wrongful birth.[81] Courts have said that there is an almost insurmountable challenge in attempting to compare what judicial opinions characterize as the "utter void of nonexistence" with an impaired existence; however, some states do allow recovery.

The *Estrada* case addresses some of the issues associated with genetic testing.[32] If genetic testing is indicated and is not offered to a family, certain states allow a wrongful life cause of action. Most states do not allow this cause of action.

Wrongful Death

A wrongful death action is seen in other civil suits as well as in medical malpractice cases. If a person dies as the result of another's negligence, the estate may pursue a wrongful death claim. If a pregnant woman is involved in a car crash and she miscarries as a result, the woman may be able to sue for wrongful death of her fetus.

Although wrongful death claims can be part of other negligence suits, the claim is common in malpractice actions. Although some states allow for the wrongful death of a fetus, other states recognize this claim only after a live birth.[18] A case in Connecticut seems to allow for a wrongful death if the fetus is viable.[29] Other states, such as West Virginia, allow recovery for the wrongful death of a fetus of any gestation.[27]

Strategies for Avoiding Tort Litigation

Physicians maintain a vested interest in avoiding malpractice litigation. When untoward medical complications arise, physicians may experience deep empathy for the patient and personal feelings of doubt or inadequacy. The allegation of medical malpractice may lead the physician to experience numerous physical and emotional symptoms, collectively referred to as the *medical malpractice stress syndrome*.[70] Besides the mental anguish that one can experience as a result of being named as a defendant in a malpractice case, these proceedings are often time consuming and expensive. Physicians can adopt certain personal guidelines to minimize their chances of being named in a malpractice suit (Box 4.2).

Clinicians should make all necessary efforts to stay current in their discipline. Attending conferences and reading journals and textbooks assist physicians in their clinical practice. In the 1990s, dexamethasone was widely used to wean premature infants with chronic lung disease from ventilators. Because of long-term neurologic concerns, this therapy is now normally reserved for only the sickest infants. A neonatologist who does not keep up with current practices could be administering a medication or offering a form of therapy well after its use has been widely abandoned or curtailed.

Neonatal intensive care units are often part of a regional system of neonatal-perinatal services. Small and large community NICUs can maintain professional ties with one another and with larger medical centers. These ties allow professional interchange of ideas and recent developments. Clinicians would be wise to view their professional development as an ongoing process.

A clinician who is faced with a rare or particularly challenging case can consider calling a colleague. Attending physicians often maintain contact with their former trainees. These contacts with former mentors can provide great benefit for one's patients. Perhaps a former attending

• BOX 4.2 Strategies to Avoid Tort Litigation

- Stay current by reading journals and textbooks and by attending continuing medical education conferences.
- Maintain professional ties with a tertiary care medical center.
- When facing a difficult situation, consider consulting with a colleague.
- Maintain open communication with parents and families.
- Practice timely documentation of procedures, communication, complications, and persons present.
- Document telephone advice.
- Be aware of state laws that affect your practice.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

physician can shed some light on a difficult situation. At large academic centers, attending physicians generally make it a point to discuss regularly the most difficult clinical cases at fetal boards, morning report, grand rounds, or other venues. By phoning a colleague, a community-based neonatologist can maintain a similar professional network.

In addition to maintaining good communication with colleagues, few issues are more vital than optimal communication with parents. It is not always easy to maintain good communication with parents, but the implications of poor communication are generally unacceptable. If parents believe a clinician is hiding something from them, they often become frustrated and angry. Parents are already dealing with having a sick infant in the NICU. If they feel mistrust, the physician's relationship with a family can quickly deteriorate. A suboptimal relationship with the family of a sick newborn can be a harbinger of a pending malpractice suit.

Besides optimal communication, the clinician's other major defense to a tort suit is documentation. Entries in the chart should be punctual, legible, and accurate. If circumstances necessitate that a late entry be made, this should be clearly documented as such. If a particularly important event has occurred, whether a complication with the infant or a comprehensive family conference, it should be documented in the chart. With respect to family conferences, it is important to document who was present and what was discussed.

One area clinicians often fail to document is the advice that they give over the phone. Because this can be time consuming and logistically difficult, some physicians open themselves to liability by giving advice and failing to document that advice. Referring physicians or parents may ignore a physician's advice. In these situations, documentation of the phone discussion can save a tremendous amount of money, time, and frustration at a later date.

Many neonatologists are now using electronic medical records (EMR) to document patient care. The medicolegal impact of the EMR is unclear. With widespread access to the full patient record, no legibility issues, and the ability to provide support for decisions, there is hope to improve safety and quality and to decrease liability. Experience so far, however, has shown that in addition to benefits there are a number of drawbacks, including system failures (rendering the chart completely inaccessible), inefficiency (poorly designed, slow systems), and inappropriate shortcuts (use of cut-and-paste that transfers incorrect information into the patient note). As a result, liability may potentially increase with improper use of the EMR.[74]

Finally, clinicians should be aware of state laws that affect their practices. This chapter presents cases and statutes from several states. Which ones affect a particular physician's practice? Many issues, such as resuscitation of extremely premature infants or accreditation of NICUs, are largely controlled by state law.

Trends in Malpractice Legislation

For the last several decades, insurance companies, large corporations, and attorneys have actively participated in the tort reform debate. Tort reforms may include limits on noneconomic damages, limits on attorney fees, expert witness standards, and inadmissibility of apology statements by health care providers.[58] In the context of malpractice law, consumer advocates argue that meritorious plaintiffs are entitled to compensation when they are injured by medical negligence. Insurance companies and providers counterargue that juries should be restricted from awarding massive monetary verdicts, because the costs of these verdicts are reflected in increasing health care bills, physicians' unwillingness to practice in certain locales, and the increase of "defensive medicine."

California enacted the Medical Injury Compensation Reform Act of 1975 (MICRA) in an effort to address increasing malpractice premiums. The MICRA addressed various issues, including caps on noneconomic damages (e.g., pain and suffering, loss of consortium) and mandated that attorneys' contingency fees be based on a sliding scale. The American Medical Association has expressed its support for MICRA-type reforms.[51]

Tort reform is often considered by state legislatures to address a medical malpractice system that is considered "costly and inefficient." Estimates of the national overall medical liability system costs, including "defensive medicine," run from $55 billion annually to $200 billion.[58] Generally, state legislatures have evaluated the merits of the medical malpractice system and passed bills designed to curb certain monetary awards.

In a move that alarmed many physicians and hospitals, Florida voters passed a constitutional amendment that has come to be known as the "three strikes malpractice law."[78] Article X, Section 26 of the Florida Constitution automatically revokes the license of any physician with three malpractice judgments against him or her. To avoid a "strike" from losing a malpractice case, there is strong incentive for physicians to settle all malpractice claims.

In contrast, legislation placing limits on damages in Texas, authorized by a constitutional amendment, resulted in a 50% increase in physicians applying to practice in that state. An environment in Texas that provides some protection for physicians has helped to relieve specialty shortages in rural areas. Challenges to the Texas legislation are illustrative of national efforts to overturn tort reform. In 2008, a class action lawsuit was filed alleging that limits on damages violate constitutionally guaranteed rights, including equal protection and due process. The plaintiffs in this class action suit claimed that the state-mandated limits on medical malpractice awards do not provide adequate compensation for their injuries. Among the plaintiffs were at least two children who allege injuries they sustained as newborns. One plaintiff in this suit allegedly sustained permanent brain damage because fetal distress was not diagnosed quickly enough. Another infant plaintiff allegedly sustained injury

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

because of inappropriate respiratory management and because hypoglycemia was not promptly diagnosed and treated.[79] In 2012, a Texas court of appeals ruled that the cap on damages was in fact constitutional.[52]

Conclusions

Generally, a plaintiff must show that all four elements (duty, breach, causation, and damages) are present. Showing only that the physician made a decision outside an acceptable standard of care is insufficient. Likewise, a patient cannot sustain a cause of action simply because of a poor outcome. The physician may have no duty to the patient, or the damages sustained may have no relation to the alleged breach in the standard of care. Of the four elements, breach and causation are the main elements that are commonly disputed in a malpractice case. The plaintiffs argue that the physician's care deviated from an acceptable standard and that this deviation harmed the patient. The defendant maintains that the care was acceptable and that any damages were not the result of faulty care (or decision making) by the defendant.

Live Birth

As the fetus descends through the birth canal and emerges as a living infant, many critical transitions occur. Readers of this textbook are familiar with the physiologic adaptations that accompany a live birth. In a legal sense, the fetus generally acquires full personhood when there has been a declaration of a live birth. Before birth, the cases cited earlier determine the fetus's legal status. Although the rules differ from state to state, there is consistent interpretation that at the moment of live birth, the infant has all of the associated rights, privileges, and consequences of personhood in civil and criminal matters.[80]

It would seem intuitive how to define "live birth." Each state has a definition for "live birth," and there is considerable overlap in these definitions, but some states have placed additional clarification in the statutory language.

The Utah statute states that live birth "means the birth of a child who shows evidence of life after the child is entirely outside of the mother."[82] This statute can be contrasted with the Alabama statute, which states, "When used with regard to a human being, [live birth] means that the human being was completely expelled or extracted from his or her mother and after such separation, breathed or showed evidence of any of the following: beating of the heart, pulsation of the umbilical cord, definite movement of voluntary muscles, or any brain-wave activity."[8]

A common thread in the states' statutes is to include some physiologic sign of life, whether it is a beating heart, pulsation of the umbilical cord, spontaneous respiratory activity, or spontaneous movement. Beyond these findings, some states clarify further that an infant is considered to be alive whether or not the placenta is still attached and that an infant of any gestation can be a live birth.[53] Some statutes specifically differentiate between heartbeats and "transient cardiac contractions."[26] There is also an effort to distinguish breathing from "fleeting respiratory efforts or gasps."

The Alaska statute seems to contemplate all of these variables.[9] It states that "live birth means the complete expulsion or extraction from its mother of a product of human conception, irrespective of the duration of pregnancy, that, after the expulsion or extraction, breathes or shows any other evidence of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles, whether or not the umbilical cord has been cut or the placenta is attached." Additional language is added to the Maine statute, which specifically states that "[e]ach product of such a birth is considered live born and fully recognized as a human person under Maine law."[50]

In the context of criminal law, the *American Law Reporter* proposes a different test for "life." This is known as a showing of a "separate and independent existence."[6] For purposes of homicide, a newborn is considered to have been born alive if it ever showed a separate and independent existence from its mother.

Born-Alive Infants Protection Act

In 2002, Congress passed by an overwhelming majority the Born-Alive Infants Protection Act (BAIPA).[65] The act states that when the terms *individual*, *person*, *human being*, and *child* are used in any law, it should be interpreted to include every infant who is born alive at any stage of development. The law defines *born alive* to mean "the complete expulsion or extraction from his or her mother of that member, at any stage of development, who after such expulsion or extraction breathes or has a beating heart, pulsation of the umbilical cord, or definite movement of voluntary muscles, regardless of whether the umbilical cord has been cut, and regardless of whether the expulsion or extraction occurs as a result of natural or induced labor, cesarean section, or induced abortion."[65]

The BAIPA was passed with the notion that legal protections should be provided to infants born alive after failed abortions. According to the US Congress, it was not relevant if the parents intended to have a live infant. If the infant was born alive, the infant must receive a "medical screening," and appropriate care must be provided.

There has been some concern that the impact of the BAIPA would be to require neonatologists to resuscitate all extremely premature infants at every gestation.[16] The American Academy of Pediatrics Neonatal Resuscitation Program Steering Committee has maintained a different position, stating that the BAIPA "should not in any way affect the approach that physicians currently follow with respect to the extremely premature infant."[61]

In the first decade the Act has seemed to have little impact. At a minimum, however, the federal law requires that all live-born infants require the same level of medical screening regardless of the reasons for the birth.

Handicapped Newborns

Federal and state governments have created protections for the most vulnerable members of society. This section deals largely with federal issues, but the states have also adopted guidelines to protect handicapped individuals. Individuals with disabilities are protected by the Americans with Disabilities Act (ADA).[4] All children are protected by child abuse and child neglect statutes. The government generally places a high emphasis on protecting the lives of fragile children. Parents can lose custody of their children if they violate laws related to abuse or neglect, and they can be incarcerated for criminal endangerment if their behavior is particularly egregious.[54]

With the growing expertise in prenatal diagnosis, it is increasingly rare that the family and the health care team are surprised by the birth of an infant with congenital anomalies. Maternal serum markers, prenatal ultrasound, amniocentesis, prenatal percutaneous umbilical blood sampling, and other procedures provide the practitioner with a considerable armamentarium to diagnose anomalies. In the case of "lethal" anomalies, this advance notice gives the family time to consider how they wish to proceed. There is often ample opportunity for the practitioners and the family to discuss the diagnosis, the implications of the diagnosis, and the care options. In the case of lethal anomalies, care options selected by the parents may include comfort care only, aggressive resuscitation, or any level of care in between.

Federal law prohibits discrimination on the basis of handicap. Under this law, nourishment and medically beneficial treatment (as determined with respect for reasonable medical judgments) should not be withheld from handicapped infants solely on the basis of their present or anticipated mental or physical impairments.[4]

Baby Doe

Handicapped newborns and the care that they receive became a mainstream issue in the 1980s. The controversy created by the Baby Doe case still governs many decisions made by neonatologists. Baby Doe lived for less than 1 week, but his legacy remains more than a quarter century later.

Many neonatal-perinatal practitioners are familiar with the basic facts of Baby Doe.[42] The infant was born with Down syndrome in Bloomington, Indiana, on April 9, 1982. As is the case with many infants with this disorder, he had a gastrointestinal tract atresia. Practitioners recognize that gastrointestinal atresias are usually surgically correctable. Duodenal atresia is more common in Down syndrome, but Baby Doe had esophageal atresia. Because of the atresia, the infant could not be fed. Baby Doe's parents, on the advice of their obstetrician, elected to forgo surgery. After discussions with the family, food and water were not provided, and the infant died at 6 days of age.

Down syndrome is not considered a lethal anomaly. Had Baby Doe not had Down syndrome, deferring surgery would not have been considered an acceptable option. Because Baby Doe did not have lethal anomalies, it was assumed that medical and surgical care were withheld because of the mental deficits associated with Down syndrome. The hospital went to court trying to override the parents' decision and force surgery for Baby Doe. Because the obstetrician agreed surgery should not be done, the judge sided with the parents, stating that the parents should "have the right to choose a medically recommended course of treatment." Because Baby Doe had already died by the time of appeal, higher courts[72] refused to hear the case.[40]

The case received national attention, and the decision to forgo care was largely viewed as unacceptable. Advocates for the handicapped were particularly concerned about this case. They proposed that Baby Doe had been discriminated against on the basis of the infant's handicap and that there had been a violation of Section 504 of the Rehabilitation Act of 1973.[1]

For various reasons, the Baby Doe case was a landmark decision. In the 3 years following Baby Doe's death, the executive, legislative, and judicial branches of the federal government became involved. The American Medical Association, the American Academy of Pediatrics, the American College of Obstetrics and Gynecology, and other professional organizations also became involved. The Reagan administration's position was that all handicapped newborns must be treated aggressively unless the care is obviously futile. The Reagan administration believed that physicians should be liable for neglect and discrimination if they did not comply with these rules.

The Reagan administration attempted to force hospitals to treat all severely handicapped newborns, regardless of the parents' wishes. The Department of Health and Human Services (HHS) promulgated "Baby Doe regulations" that required federally funded hospitals to post certain rules in the hospital.[5] Notices were to be prominently posted in delivery wards, maternity wards, pediatric wards, and each nursery. These signs encouraged concerned parties to call the HHS toll-free number to report suspected cases of discriminatory withholding of care from handicapped newborns. The rules also encouraged the creation of infant care review committees to assist in decision making for difficult cases. Many of these regulations were ultimately disallowed by the courts. The current incarnation of the Baby Doe regulations is found in the Child Abuse Protection and Treatments Act (CAPTA), which prevents the "withholding of medically indicated treatment," which is defined as "failure to respond to the infant's life-threatening conditions by providing treatment … which, in the treating physician's … reasonable medical judgment, will be … effective in … correcting all such conditions."[2]

Although infant care review committees are encouraged, the courts have ruled that parents, in conjunction with their physicians, should have the right to make health care decisions for their handicapped children. When the US Supreme Court decided against hearing the Baby Doe case,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

the matter was deferred only for a few years, until the Baby Jane Doe case.

Baby Jane Doe

In 1983, the year after Baby Doe died, a child was born in New York with meningomyelocele, hydrocephalus, microcephaly, bilateral upper extremity spasticity, a prolapsed rectum, and a malformed brainstem. She has been immortalized in the neonatal literature as "Baby Jane Doe." Her parents were presented with two options to treat the meningomyelocele: primary skin healing or surgical repair. The parents refused consent for surgical repair of the defect and for the placement of a shunt for hydrocephalus. Instead, the parents requested that the infant be treated with antibiotics and nutritional support.

An attorney who was not related to the family thought that the parents' request was an inappropriate medical decision. This attorney requested that the trial court appoint an independent guardian for the infant so that consent could be given to perform the surgeries. The trial court granted the attorney's request, but the appellate court overturned that decision the following day. The appellate court found that the parents had chosen an acceptable medical option and had acted in the best interest of their child.

While this issue was being dealt with in the state court system, HHS received a complaint from a "private citizen." This complaint stated that Baby Jane Doe was being discriminated against because of her handicap. The Department of Health and Human Services referred the case to Child Protective Services, which concluded that there was no cause for state intervention. During this time, HHS also made repeated requests of the hospital to produce the infant's medical records. The hospital refused on the grounds that the parents had not consented to release the records. The federal government sought to compel access to the medical chart and filed a suit in federal district court under section 504 of the 1973 Rehabilitation Act.[3] The courts found that the hospital had not violated any of the pertinent statutes, because it was willing to perform the surgery if the parents would consent.

As the case proceeded through the federal court system, various judges asserted that the infant was not being discriminated against on the basis of her handicap. Ultimately, the case reached the US Supreme Court.[19] The US Supreme Court took the opportunity to review the Baby Doe case, the Baby Doe regulations, the care of handicapped newborns, the role of the federal and state government in these cases, the rights of parents, and the rights and duties of caregivers.

The court found that there was no violation of Section 504, because the withholding of treatment was secondary to lack of parental consent, not secondary to discriminatory withholding based on the infant's handicap. Among other conclusions, the US Supreme Court found that the parents had made reasonable decisions that were consistent with the best interests of their child. The court found no discrimination. The court also stated, "A hospital's withholding of treatment when no parental consent has been given cannot violate Section 504, for without the consent of the parents or a surrogate decision maker the infant is neither 'otherwise qualified' for treatment nor has he been denied care 'solely by reason of his handicap.' Indeed, it would almost certainly be a tort as a matter of state law to operate on an infant without parental consent." The final sentence of this quotation raises interesting questions in light of the Miller case, which is discussed later.

Baby K

Baby K was found prenatally to have anencephaly.[43] Her mother declined termination of the pregnancy, and the infant was delivered by cesarean section on October 13, 1992. The infant was initially placed on mechanical ventilation so that the diagnosis could be confirmed. After confirmation of the diagnosis, the caregivers approached the infant's mother to request permission to withdraw the ventilator. Based on the mother's religious beliefs that all life is sacred and must be protected, she insisted that the ventilator support be continued.

When the infant was 9 days old, the hospital ethics committee met with the physicians and concluded that the care was futile. Attempts to transfer the infant to another facility were not successful, and eventually Baby K no longer required the ventilator and was transferred to an extended care facility. Baby K required three subsequent hospitalizations secondary to respiratory distress. Each time, the mother insisted that the infant be reintubated. The caregivers and the infant's father believed that the treatment was futile and inappropriate.

The hospital sought a federal court ruling that would allow them to withhold the ventilator from Baby K in the future. The hospital sought a declaratory judgment that by withholding the ventilator that they would not violate the Emergency Medical Treatment and Active Labor Act (EMTALA), the state Child Abuse Amendments, the state Malpractice Act, or ADA. The court ruled (and the 4th Circuit of the US Court of Appeals[44] upheld) that the hospital was not entitled to such a declaration. The court reasoned that the infant's anencephaly qualified her as "handicapped" and "disabled" for the purposes of ADA. Because of procedural concerns and federal and state issues, the court did not rule on the topics of malpractice or child abuse.

In the court's interpretation of EMTALA, it reasoned that because "stabilization" included establishing and securing an airway, the refusal to intubate Baby K would be a violation of EMTALA. Because Baby K was handicapped and disabled, and the hospital received federal funds (e.g., Medicare payments), the hospital could not deny the requests of Baby K's mother.

The EMTALA legislation was initially intended to prevent hospitals from "dumping" nonpaying patients to

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

other facilities. In this case, the hospital was not contending that the issue was payment for the treatment. The court found that EMTALA applied, however, and Baby K must be intubated and ventilated as long as that was the mother's wish. The court stated that "absent finding of neglect or abuse, parents retain plenary authority to seek medical care for their children, even when the decision might impinge on a liberty interest of the child."

The 4th Circuit of the US Court of Appeals stated that it was beyond its judicial limits to address the moral and ethical implications of providing emergency care to anencephalic infants. It stated that Congress did not want a case-by-case analysis but rather desired that hospitals and physicians provide stabilizing care to all patients who present with an emergency condition.

Many ethicists and clinicians view anencephaly as "a paradigm case of medical futility."[48] For them, the Baby K decision was considered inappropriate, mandating treatment that would not be considered in the best interests of the patient. Four years after the original decision, the 4th Circuit placed some limits on the reach of the Baby K decision. In *Bryan v Rectors of the University of Virginia*,[7] the court limited the scope of EMTALA to emergency stabilizing treatment and declined to apply EMTALA to a hospital that entered a "do not resuscitate" order against the wishes of the family 12 days after the patient had been admitted.

Sun Hudson

Sun Hudson was born in Houston, Texas, in September 2004 to his mother, Wanda, and an unknown father. He was intubated shortly after birth and subsequently diagnosed with thanatophoric dysplasia, a typically fatal short-limbed skeletal dysplasia. The neonatologists and bioethicists at Texas Children's Hospital believed that "it would be unethical to continue with care that is futile and prolongs Sun's suffering."[38] His mother disputed the hospital's diagnosis, however, and fought to keep Sun on the ventilator. Under the Advance Directives Act,[75] signed into Texas state law by then-governor Bush, physicians and hospitals can unilaterally withdraw life support against the family's wishes as long as the hospital's ethics committee agrees with the decision. The hospital is also required to allow at least 10 days so that the family can find another facility to accept the patient. In Sun's case, Texas Children's contacted more than 40 hospitals but was unable to find another facility to accept him. In addition, although court approval is not required by the statute, the hospital offered to pay Ms. Hudson's attorney fees, and the case was heard in court.

After several months, a judge supported the position of the hospital. Sun was extubated and died in February 2005. The case is significant because it represents a rare case in which a judge has allowed withdrawal of life-sustaining treatment against a parent's wishes.

Conclusions

The preceding cases present the challenges faced when damaged newborns receive a level of care that is viewed to be inappropriate by some observers. If a child has "lethal" anomalies or a "terminal" condition, the courts generally find that parents are the primary decision makers concerning the level of care.

In the Baby Doe case, the infant did not have a lethal underlying condition. Treatment would not have been "futile," and, in retrospect, many observers believed that the decision to forgo surgery was not "reasonable." The resulting national outcry was a measure of people's dissatisfaction with the decision made by the physicians and the parents.

In contrast, Baby Jane Doe had a course of therapy that was selected by her parents. Although it was not the most aggressive course of treatment, some experts believed that allowing the skin to grow over the meningomyelocele was an acceptable option. Other experts take issue with this course of therapy. The court ruled, however, that the parents selected an acceptable treatment option for their daughter.

In the Baby K case, the child had what is largely viewed as a "lethal" anomaly. Despite the heartfelt objections of the physicians and staff, the courts ruled that care could not be withheld simply because the caregivers considered it to be morally and ethically inappropriate.

The case of Sun Hudson shows that parents' rights are not completely unlimited. In this case, however, the medical community and bioethicists agreed that Sun was suffering, and Texas had a law in place specifically allowing unilateral withdrawal of support.

Can these four cases be reconciled? In the Baby Doe case, the parents made decisions that could be viewed as neglect. Baby Doe did not receive life-saving surgery because he was handicapped. It would seem that such withholding of treatment would not be accepted if Baby Doe were born today. Baby Jane Doe's parents made a choice that the court ruled was a reasonable one. There was no discriminatory withholding of care. In Baby K's case, the courts supported a parental decision to ventilate a child with no cerebral cortex, a decision that many clinicians find untenable. Sun Hudson's condition, thanatophoric dysplasia, was believed to lead to his prolonged suffering, and this may have contributed to the judge's decision to override the mother's wishes. If conclusions can be drawn, they would seem to indicate that the courts support parents' interests as long as decisions are not being made solely on the basis of handicap and as long as the infant is not believed to be suffering. The personal morals and ethics of the caregivers are fundamentally irrelevant in the legal context of parental decision making. If the parents' decisions are reasonable and if there is no evidence of neglect or suffering, parents seem to have substantial decision-making power.

Providing Care Against Parents' Wishes

One of the most challenging aspects of neonatology is caring for extremely premature infants. A substantial portion of this textbook addresses the medical issues involved in caring for these infants. Although the care of extremely premature neonates largely defines the parameters of the specialty, it also creates many of the legal and ethical quandaries for caregivers and families. These tiny individuals existing on the cusp of viability have the same legal rights as all citizens. They are entitled to equal protection, due process, and all other constitutionally guaranteed rights and privileges of the citizens of the United States. By virtue of a heartbeat or spontaneous respiratory effort, an extremely premature infant is transformed into a "person." As mentioned in the earlier discussion of live birth, in many states, the gestational age and whether the placenta is attached are legally irrelevant.

The pending delivery of a 23-week-gestation fetus generally carries a wide variety of concerns. What are the family's wishes? Will the resuscitation go smoothly? Will all the equipment function properly? How will the infant respond to the resuscitation? Will stabilization be difficult? Will the infant require significant ventilator support, volume boluses, or an infusion of catecholamines?

More recently, the overriding concern is whether the infant must be resuscitated if considered to be previable. What if the parents request no resuscitation? Are the caregivers liable if they overrule the parents and proceed with resuscitation of a 23-week-gestation infant? What if the parents request no resuscitation for a 25-week or 26-week infant?

This extraordinarily difficult situation is exacerbated by a relative lack of statutory and case law. The existing case law seems to conflict with itself. This section addresses the unique challenge associated with the delivery of extremely premature infants. To gain insight into this convoluted area of law, the reader should review the material on perinatal issues (maternal-fetal conflict), live birth, informed consent, and limiting care. The reader should have a grasp of the *Cruzan* decision[25] and the associated liberty interest in keeping one's body free from unwanted medical intervention. Likewise, one must appreciate that courts have found that parents generally have the right to refuse certain unwanted medical interventions for their children as long as this refusal is not neglect or abuse. Without a familiarity with the rules governing informed consent, the reader lacks the necessary foundation to appreciate the following discussion.

Miller Case

In 1990, Karla Miller went into preterm labor at approximately 23 weeks' gestation. After the neonatologist explained the grim prognosis for infants born at this gestation, Mark and Karla Miller requested that the infant not receive heroic measures. Initially, the obstetrician and neonatologist agreed to honor the parents' wishes. A hospital administrator claimed, however, that the hospital had a policy requiring that the infant be resuscitated if she weighed more than 500 g. This policy was explained to the parents, who again requested that the infant not be resuscitated.

Sidney Miller was born later that night, several hours after Mrs. Miller was admitted to the hospital. The infant was resuscitated, and she survived with severe impairment. The parents sued the hospital, asserting claims in battery and negligence. They did not sue the physicians, although they were involved in the trial, because they believed that the physicians were following orders from the administration. The main allegation was that the hospital was liable for mandating Sidney's resuscitation without parental consent. The hospital maintained that the parents had no right to refuse lifesaving intervention.

The jury awarded the family approximately $60 million. The appellate court overturned this verdict.[35] In its analysis, the appellate court stated that this was a situation of the emergency exception to the informed consent rule. The court also relied on the Advance Directives Act. This act protects caregivers and hospitals who withhold care from terminally ill patients. The court reasoned that because Sidney Miller's condition did not fit the definition of terminal, the parents had no right to refuse lifesaving therapy. The court stated that although parents have a right to determine health care decisions for their children, this is not an absolute right, and the state also has an interest in the health of children. "Having recognized, as a general rule, that parents have no right to refuse urgently needed life-sustaining medical treatment to their non-terminally ill children, a compelling argument can be made to carve out an exception for infants born so prematurely and in such poor condition that sustaining their life, even if medically possible, cannot be justified." The appellate court concluded that perhaps the legislature should address the issue of defining "terminal" with respect to some premature infants who are born so small and so sick.

A dissenting judge on the appellate court believed that the parents' course of action was lawful. This judge supported his opinion by quoting the US Supreme Court's decision in the Baby Jane Doe case. This dissenting judge stated that no emergency existed. The emergency exception to the informed consent rule was not available to the caregivers. According to the dissent, it was the caregivers' delay and indecision that led to the urgency.

Thirteen years after Sidney Miller was born, the Texas Supreme Court ruled on the case.[36] This court found that the hospital was not liable for resuscitating the infant. Although the Texas Supreme Court analyzed the case differently than the appellate court had, the decision was the same: The hospital had no liability. The high court reasoned that because it was impossible to predict how sick the infant would be at birth, the emergency did not exist until after Sidney was born. The physician could not evaluate the situation until after the infant was born.

Messenger Case

Gregory Messenger and Traci Messenger were faced with a situation similar to that of the Miller family. Traci Messenger went into labor at 26 weeks. Gregory Messenger was a physician (dermatologist). After discussing their options with their caregivers, the Messengers requested that the infant not be resuscitated. The request was not honored. The infant was resuscitated and brought to the NICU. Dr. Messenger went into the NICU, extubated his son, and placed him in Traci Messenger's arms. The baby died shortly thereafter. The neonatologist listed the cause of death as "homicide." Approximately 1 year later, Dr. Messenger was acquitted of manslaughter.[62] Among other conclusions, the jury believed that Dr. Messenger was acting in the "best interest"[84] of his son.

The Messenger case was a criminal trial with a higher standard of proof. Dr. Messenger was acquitted of a crime. He removed his own extremely premature son from a ventilator, and he was found to be not guilty of intentional killing.

Montalvo Case

Baby Emanuel (Montalvo) Vila was born in Wisconsin in November 1996 at 23 weeks' gestation weighing approximately 679 g. His mother had presented earlier with preterm labor, and after attempts to delay his birth were unsuccessful, a cesarean section was performed after informed consent was obtained. Three years after his birth, the family sued the obstetrician, the neonatologist, and the hospital, alleging that they had resuscitated Emanuel without advising the parents of the risks or potential consequences of an extremely premature infant. The trial court found for the physicians and the hospital, and the family appealed.

The Wisconsin State Court of Appeals agreed with the trial court for two reasons. First, the court noted that under Wisconsin law, in the absence of a persistent vegetative state, a parent does not have the right to withhold life-sustaining medical treatment. Second, the court looked at the current incarnation of the Baby Doe regulations, known as CAPTA regulations (discussed earlier). The court believed that the parents did not have a choice to refuse resuscitation because "[t]he implied choice of withholding treatment … is exactly what CAPTA prohibits."[55] The trial court and the appellate court addressed the public policy issues associated with resuscitation of extremely premature infants, and both courts pointed out that the decision-making authority in these cases cannot be placed "wholly" in the hands of the parents. This portion of the opinion would seem to imply that parents and caregivers have decision-making responsibility in these cases.

The potential implications of the Montalvo case are considerable. Because neonates are rarely in a persistent vegetative state, the ruling does not seem to give the option to withhold or withdraw treatment for most critically ill neonates. The decision applies only in Milwaukee, which is the area covered by District 1. Also, the court stated that parents were not "wholly" responsible for these decisions. This language would imply some role for parental decision making in concert with the attending physicians. To date, the *Montalvo* decision has not been widely upheld in other courts.

Conclusions

The *Miller* case was one decision made in one state. The decision was made by the Texas Supreme Court, so the decision is the current law only in Texas. The court's decision in the *Miller* case may or may not have any effect in any other state. Currently, if one practices in Texas, *Miller v HCA* controls one's practice. Clinicians should be familiar with the facts and the judicial conclusions in this case. It seems that clinicians and hospitals in Texas would not be liable for resuscitating 23-week-gestation infants against the parents' wishes. Despite the parents' clear request to forgo resuscitation, a lapse of several hours between the time of the request and the time of birth, and no effort on the part of the clinicians or the hospital to transfer care to another provider, the court found no liability. It is also important to recognize that the physicians would not be liable for respecting and adhering to the parents' wishes under the *Miller* opinion.

In Wisconsin, the Montalvo case seems go a step further and suggests that neonatologists may be required to resuscitate all extremely premature infants. In stark contrast to the American Academy of Pediatrics' emphasis on shared decision making, the court claims that parents have no rights to decline treatment under the current Baby Doe regulations. Yet this interpretation is controversial. The Institute of Medicine report on preterm birth notes that the Baby Doe regulations "were not originally intended to apply to premature infants; rather, they were intended to apply to disabled full-term infants."[64] As a state appellate court ruling, however, this interpretation applies only in the Milwaukee area.

In the Baby Jane Doe case, the US Supreme Court did comment on decision making being taken away from parents. In defending the hospital's decision to honor the request of Baby Jane Doe's parents, the US Supreme Court stated, "It would almost certainly be a tort as a matter of state law to operate on an infant without parental consent."

What of the remainder of the United States? Perhaps some courts in other states would follow the trial court or the appellate court dissent in Miller. The trial court in Miller allowed a $60 million verdict. The dissent in the appellate court quoted the US Supreme Court decision in Baby Jane Doe, to question the propriety of imposing on parents the consequences of resuscitation of 23-week-gestation infants.

The Texas Supreme Court and the Wisconsin Appellate Court decided, using different rationales, that parents have no right to refuse resuscitation of their extremely premature infants. The Texas court relied heavily on its interpretation that the emergency did not exist until Sidney Miller was

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

born. The hospital and caregivers would basically always be protected by the emergency exception to the informed consent rule. The *Montalvo* court relied on a State (Wisconsin) Supreme Court ruling and the federal Baby Doe regulations. The court believes that CAPTA prohibits withholding of resuscitation no matter how small or immature the infant. This is a drastic change from the manner in which many clinicians currently practice and removes physician judgment and the parents' view of what is best for their child from the equation.

How does one reconcile Miller, Montalvo, and Messenger? It is intellectually dissatisfying to conclude that the major difference among these cases is that they were adjudicated in different states. The inherent conflict between the cases must have more substantial legal underpinnings than a simple difference in jurisdiction. The fact that the Messenger case was a criminal trial with a higher burden of proof on the prosecution has some effect on the legal comparisons, but the inherent inconsistencies exist.

In the Miller case, an extremely premature infant is resuscitated against the parent's wishes, and the hospital has no liability. In the Montalvo case, an extremely premature infant is resuscitated, and when the parents state that they were not adequately informed, the court states that informed consent is irrelevant because the Baby Doe regulations do not allow parents to refuse resuscitation for even the smallest and most immature patients. In the Messenger case, an extremely premature infant was resuscitated against the parents' wishes, and the father had no criminal liability for disconnecting the ventilator with the intent to hasten the infant's death. If the infant was lawfully being cared for, how could the father be acquitted of manslaughter? If caring for the infant against the parents' wishes was not lawful, why did the Miller and Montalvo courts find for the hospital?

These cases leave in question the exact legal status of extremely premature infants. The infant is "alive" by statute. In some jurisdictions, the infant can recover for wrongful life. In some jurisdictions, a wrongful life claim would be denied because the parents have no right to refuse the care. In some jurisdictions, there is no criminal liability for a parent who overrules the physicians and takes matters into his or her own hands.

So what should a clinician do when called to the birth of a previable or periviable newborn? One should understand the issues, understand the rights of the newborn, understand the rights and the duties of the parents, and understand one's own rights and duties. Box 4.3 provides some general lessons from existing case law concerning situations in which parents and caregivers disagree on the care of critically ill newborns.

What would happen if Sidney Miller had been born in a state other than Texas? Did state politics play a role in this case? Is it a coincidence that Gregory Messenger was acquitted in Michigan? These are not trivial questions, but they are unanswerable given the current case law on this issue. To the family of Sidney Miller, the Supreme Court of Texas determined that the child and the family should recover nothing.

• BOX 4.3 When Parents and Caregivers Disagree on the Care of Critically Ill Newborns: Lessons From Existing Case Law

Parents Request Full Supportive Care and Caregivers Disagree

- General rule: provide full supportive care.
- Anencephaly: Baby K case likely controls (federal case).

Parents Want No Resuscitation and Caregivers Disagree

- Miller (Texas): no liability for caregivers.
- Montalvo (opinion covers Milwaukee, Wisconsin): no liability for caregivers.
- Messenger (Michigan): no criminal liability for father who disconnects the ventilator.

Parents and Caregivers Agree to Forgo Aggressive Treatment

- Possibly covered by Baby Jane Doe case: parents have right to make reasonable choice.
- Baby Doe case: cannot make decision solely based on present or future handicap.
- Montalvo (opinion covers Milwaukee, Wisconsin): parents may not have right to make reasonable choice.

Summary

A physician facing a legal issue can experience various difficulties. Physicians are often unfamiliar with the legal process, and the new terminology can be daunting. Compared with science, legal results can seem to be unpredictable. In law, there are no double-blind, randomized, controlled trials. Additionally, legal events often elicit strong emotions. With respect to malpractice, families may have suffered tremendous losses, and juries in some states can award tens of millions of dollars.

Generally, practicing strong clinical medicine requires the clinician to stay current in the specialty, to maintain excellent communication with families and the hospital staff, to strive consistently to make ethical decisions, and never to violate the law knowingly. Veteran neonatologists know the value of good documentation and effective communication with colleagues, staff, and families. Many other nuances exist, however. Practitioners benefit from understanding the elements of a tort suit; recognizing the importance of informed consent; and knowing the law concerning the care of handicapped newborns, anencephalic infants, and extremely premature infants. With respect to extremely premature newborns, it is particularly difficult to discern clear legal principles from the various court decisions in this arena. This issue speaks to the importance of knowing the law in the state in which one practices. In Wisconsin,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

clinicians must know the appellate court district in which they are practicing.

Although the law may seem to be arbitrary, there are substantial underlying principles that courts and legislatures have honored for hundreds of years. Fundamentally, the legal system is not unpredictable. It can be daunting to a physician, but the process can be demystified. If one is experiencing a significant health problem, one seeks out medical advice. Likewise, the legal profession can provide meaningful insight to a physician who is in need of counsel.

Key Points

1. Physicians and other health care professionals should understand their rights, duties, and liabilities while practicing health care.
2. While both federal and state laws affect the practice of medicine, medicine is primarily regulated by the states.
3. Strategies to minimize the risk of a malpractice lawsuit include staying up to date, communicating well with parents as well as other members of the health care team, and documenting in a factual and professional manner.

Evaluating and Improving the Quality and Safety of Neonatal Intensive Care

JOCHEN PROFIT, HENRY C. LEE, JEFFREY B. GOULD, AND JEFFREY D. HORBAR

Making improvements happen also requires … unshakeable belief in the idea that everyone in healthcare really has two jobs when they come to work every day: to do their work and to improve it.[6]

More people die in a given year as a result of medical errors than from motor vehicle accidents, breast cancer, or AIDS.[152]

Systematic evaluation of the quality, safety, and efficiency of clinical care has become an integral part of medical practice. Physicians, hospitals, and large health care organizations are under increasing pressure to monitor, report on, and continuously improve their services. Public release of hospital performance data is becoming increasingly common. In this new era, health professionals in neonatology must learn how to evaluate themselves and learn how they will be evaluated by others, including policy makers, hospital administrators, regulators, payers, and the families and public they serve.

Evaluation is not an end in itself. Health professionals must learn how to use available information to improve the quality and safety of medical care continuously. This is not just an option. It is a responsibility. Since 2010, the American Board of Pediatrics' maintenance of certification requirement that neonatologists be actively engaged in quality improvement emphasizes this professional responsibility (www.ABP.org).

In this chapter, we review the ways data can be collected, evaluated, and applied to improve the quality and safety of medical care for newborn infants and their families. We discuss the available sources of such data for neonatology and describe how these data can be used to evaluate and improve the processes and outcomes of medical care for newborn infants, as well as the organizational context in which care is delivered.

The Case for Improvement

Public health and health care delivery systems in high-income nations have a great deal of which to be proud. Over the last century, they have combined to reduce infant and maternal mortality, as well as to prolong life expectancy to unsurpassed levels. During the twentieth century, infant mortality dropped from more than 100 per 1000 live births to about 5 per 1000 live births; maternal deaths dropped by 99% to about 10 per 100,000 live births.[45,52]

During the first half of the twentieth century, these improvements were driven largely by advances in public health, especially access to clean water, which dramatically reduced infection-related morbidity and mortality. However, although health care delivery conferred little benefit to population-based health during the first half of the century, there have since been demonstrable contributions to added life expectancy. Neonatal intensive care is a case in point. Although relatively few interventions (i.e., heated incubator care, intravenous nutrition, oxygen) were available to support sick newborns until the 1960s, technical and scientific advances in nutrition, physiologic monitoring, mechanical ventilation, and pharmaceuticals have made it possible for infants to survive previously fatal degrees of prematurity, genetic disease, or other (or acquired?) newborn disease.[49,51]

On the other hand, new medical treatments in combination with greater access and demand for care, a rise in the prevalence of chronic disease conditions, and inefficient market conditions have resulted in rising health expenditures, which have outpaced national incomes.[171] As a consequence, in the United States, health care consumes an ever-greater proportion of gross domestic product (GDP). In 2015, national health expenditures accounted for 17.8% of GDP, which severely strains the budgets of those paying for health care: consumers, through taxes, co-pays, deductibles, insurance, and reduced wage growth; companies,

Abstract

The concern for quality and safety in health care has increasingly become an integral aspect of medical practice, both for individual practitioners and health care systems. The continued presence of variations in care and health outcomes signifies that strategies to improve and provide equitable care are necessary for perinatal medicine. Health care has benefitted from pioneers in quality improvement science both within and outside of the medical profession, and innovators working today continue to advance the field. This chapter gives a broad overview of the history and current state of quality improvement science, issues concerning data for improvement, and sustainment of initiatives, and also provides an example of a local quality improvement project.

through insurance; and state and federal governments, through obligations under Medicaid and Medicare.

In light of these resource constraints, a commitment to population health requires optimization of the value of each dollar expended for health care. However, research summarized in the sentinel Institute of Medicine of the National Academy of Sciences report *To Err Is Human* has consistently highlighted that health care delivery, including neonatal intensive care, falls short of its potential.[152] This report as well as its successor, *Crossing the Quality Chasm: A New Health System for the 21st Century*, present a clear and compelling challenge to all health care professionals to improve the quality and safety of the medical care for the patients and families they serve.[53]

Despite overwhelming evidence that deficiencies in quality and safety are widespread throughout the American health care system, many health care professionals in neonatology may feel that these problems do not apply to our clinical specialty. This is not the case. In neonatology, as in other clinical fields, opportunities for improving the quality and safety of medical care are substantial.

First, there is a large body of literature documenting tremendous variation in how medical resources are distributed, care is delivered, and outcomes are achieved. One of the best-known examples is the work by Wennberg and Fisher, who developed the *Dartmouth Atlas of Healthcare*.[160,161] For more than 25 years they have documented large variations in the efficiency of local delivery systems that are not explained by patients' health or preferences for care or by malpractice pressure and that do not seem to be associated with systematically better quality of care, patient outcomes, or satisfaction. In fact, this kind of variation has been shown across many settings (states, regions, cities, hospitals), many different types of patients (newborn, elderly), and many different types of care (medical, surgical, hospital, outpatient). Differences in care delivery and cost are almost entirely explained by differences in the volume of health care services received by similar patients, that is, "supply-sensitive care."[27,28] Higher-spending regions have more hospital beds, doctors, and specialists. Neonatology is no exception. The presence of this variation means that the goal of lowering costs while preserving quality is attainable and already achieved by many providers.

In the neonatal intensive care unit (NICU) setting, in addition to supply-sensitive care, dramatic variation in the processes and outcomes of care has been documented that cannot be explained by differences in case mix, suggesting differences in the quality of care delivery.[46,74,126,156] In a study of over 400,000 infants with birth weights of 401 to 1500 grams born from 2005 to 2014 and cared for at 756 Vermont Oxford Network–member NICUs in the United States, the ratio of the risk-adjusted rates for mortality and major morbidities at hospitals with the highest 10% of the rates to the risk-adjusted rates for hospitals. The lowest 10% of rates in 2014 were 1.2 for mortality and severe intraventricular hemorrhage, 1.7 for chronic lung disease, 1.9 for late onset infection and necrotizing enterocolitis, and 2.0 for severe retinopathy of prematurity. This means that for several major morbidities of very low birth weight infants, NICUs in the worst decile have rates nearly twice as high as those in the best decile. For comparison, an analysis including 22 million all-payer inpatient adult admissions demonstrated a 2.1-fold difference in risk-adjusted mortality rates and an 18.3-fold difference in central venous catheter bloodstream infection rates between top and bottom decile hospitals.[123]

Despite the variation among NICUs, there has been dramatic improvement in mortality and morbidities for very low birth weight infants in the last decade.[46] Health care–associated infection rates provide a striking example.[145] At the 756 US NICUs in the study described above, the rate of late bacterial (including coagulase-negative staphylococcus) or fungal infection significantly decreased from 2005, when 21.9% of infants had infections, to 2014 when 10.1% of the infants had infections. Dramatically, by 2014, 98% of NICUs had achieved rates for late onset infection as low or lower than the rates achieved by the best 25% of units only a decade earlier, and 91% of NICUs had achieved rates as low or lower than the best 10% of units.[155] Over the last decade, reduction of health care–associated infections has been at the center of national health policy efforts to improve the value of health care delivery, including aligning hospital payments with quality-of-care delivery. Widespread efforts in the neonatal community have proved successful in facilitating broad-based and sustained reductions in health care–associated infection rates and represent an encouraging blueprint for improvements in care in other areas.[51] However, the continued wide variation indicates that opportunities for improvement in many NICUs still remain.

Another indicator for quality deficits in the neonatal intensive care setting is the widespread delivery of inappropriate care—defined as underuse, overuse, and misuse of interventions.[15] Examples include the underuse of hand hygiene by NICU personnel,[100] the overuse of antibiotics, and the misuse of medications because of medical errors.

We have provided an example of underuse above. A good example of an effort to address overuse and misuse is the Choosing Wisely (www.choosingwisely.org) effort.[44] Medical interventions are frequently overused or misused and contribute to health care waste. Choosing Wisely, an initiative of the American Board of Internal Medicine, has challenged national medical specialty societies to identify Top Five lists of tests or procedures commonly used in their field whose necessity should be questioned and discussed with patients. The American Academy of Pediatrics Section of Neonatal Perinatal Medicine (SONPM) developed a Top Five list for newborn medicine using a process that began with a survey of neonatologists in SONPM and physicians, nurses, other NICU health professionals, and families of NICU patients at the Vermont Oxford Network Annual Quality Congress. The survey asked participants to provide from one to ten examples of tests and treatments that, in their opinion, met one or more of the following criteria:

• BOX 5.1 Choosing Wisely Top Five List for Newborn Medicine

- Avoid routine use of antireflux medications for treatment of symptomatic gastroesophageal reflux disease or for treatment of apnea and desaturation in preterm infants.
- Avoid routine continuation of antibiotic therapy beyond 48 hours for initially asymptomatic infants without evidence of bacterial infection.
- Avoid routine use of pneumograms for predischarge assessment of ongoing and/or prolonged apnea of prematurity.
- Avoid routine daily chest radiographs without an indication for intubated infants.
- Avoid routine screening term-equivalent or discharge brain MRIs in preterm infants.

(1) evidence of lack of efficacy, (2) insufficient evidence of efficacy, or (3) unnecessary utilization of staffing or material resources. Next, a multidisciplinary expert panel of fifty-one individuals used a modified Delphi Process in which they scored each item. After the first two rounds, the items with the highest scores were subjected to a literature review and the strength and quality of the evidence were summarized using Grading of Recommendation, Assessment, Development, and Evaluation (GRADE) criteria.[40] The panel reviewed the GRADE summaries in the final round, and the five items with the highest total points in that round were included in the newborn medicine Top Five list. The final Top Five items are shown in Box 5.1.

Another important example of misuse are medical errors, which will be briefly discussed here. Current health care operations produce unacceptable rates of medical errors that result in patient injury or death. In *To Err Is Human,* the Institute of Medicine concluded that between 44,000 and 98,000 Americans die annually from hospital errors, killing more Americans than breast cancer, traffic accidents, or AIDS.[152]

Preterm infants in the NICU are particularly vulnerable to medical errors owing to their small size, physiologic immaturity, and limited compensatory abilities.[113,142] These circumstances make preterm infants particularly vulnerable to lapses in patient safety.[36,117] A study at two Boston hospitals has documented that errors in the process of ordering, dispensing, or monitoring medications occurred for more than 90% of the infants cared for in the NICU. Another study, using a trigger tool in the electronic health record, identified 0.74 adverse events per patient.[138] Fifty-six percent of these were deemed preventable. These estimates are likely only the tip of the iceberg.

Using a voluntary, anonymous, Internet-based error-reporting system established by the Vermont Oxford Network, Suresh and colleagues have documented a broad range of errors and near errors at 54 neonatal intensive care units.[147] Only about half of the reported events involved medications; the remainder involved a wide variety of errors in multiple domains of care. A study from eight Dutch NICUs found that incidents concerning mechanical ventilation, blood products, intravascular lines, parenteral nutrition, and medication dosing errors pose the highest risk to patients in the NICU.[143] Medication errors are a common problem in sick newborns owing to breakdowns in patient identification,[35] rapid changes in physiologic maturity, body weight, and volume of distribution requiring frequent dose adjustments. Although establishing the frequency of medication errors in the NICU is difficult, published studies indicate that medication errors in the NICU are common, ranging from 13 to 91 medication errors per 100 NICU admissions.[141] One study found that medication errors occurred in 57% of infants less than 27 weeks' gestation age, compared with 3% reported in the care of full-term infants.[63] In addition, NICU patients are more likely to experience a medication error than other hospital patients[138] and to experience more harm when a medication error occurs.

Finally, our health care delivery system has not reliably delivered many interventions that are deemed to be effective. McGlynn,[85] first in adults and later with Mangione-Smith in children,[82] demonstrated that Americans receive guideline-recommended care only about half the time. In the newborn setting, although antenatal steroids have been demonstrated to prevent respiratory distress syndrome and intraventricular hemorrhage after preterm birth, there remains wide variation in its administration to eligible mothers.[70,105,158]

The inability of the health care system to consistently deliver the highest quality of care results in enormous waste in human lives and valuable resources. Berwick and Hackbarth showed that "in just six categories of waste—overtreatment, failures of care coordination, failures in execution of care processes, administrative complexity, pricing failures, and fraud and abuse—the sum of the lowest available estimates exceeds 20% of total health care expenditures. The actual total may be far greater."[11]

In the United States, the care of preterm infants consumes about $35 billion annually (adjusted for inflation).[171] These health expenditures directly affect families and patients. About one half of the 1.45 million American families that filed for bankruptcy in 2001 cited medical causes, even though three-fourths of them had insurance at the onset of illness. About 10% of families cited childbirth-related and congenital disorders as the principal cause.[43]

With the recognition of the extent of the opportunities for improvement have come efforts by providers, provider networks, payers, nongovernmental organizations, and governmental agencies to improve the value of health care expenditures. At the provider network and health system level, efforts have focused on quality assurance and alignment of financial incentives. For example, quality assurance has been pursued through benchmarking of performance by provider networks such as the California Perinatal Quality Care Collaborative (CPQCC)[32] or the Vermont Oxford Network[48]; other statewide neonatal collaborative organizations, including those in Massachusetts, Ohio, Tennessee,

North Carolina, Florida, Wisconsin, and Michigan; or by Medicare through its Hospital Compare Program. (http://www.medicare.gov/hospitalcompare/search.html). Significant efforts have been made to develop, evaluate, and harmonize quality measures through organizations such as the National Quality Forum. Public reporting[41,77,89] of quality measures and realignment of financial incentives away from a fee-for-service system toward a pay-for-quality system are becoming more widespread. More detail on these issues is provided later in this chapter.

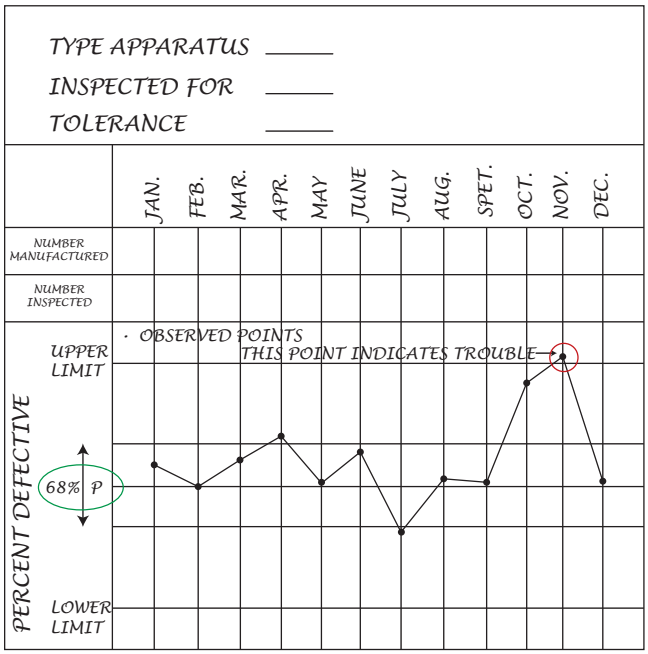
At the hospital level, providers have engaged in quality improvement efforts to meet the expectations of this changing marketplace. Several institutions have undergone fundamental re-engineering of their health care delivery systems. Intermountain Healthcare, under the leadership of Brent James, has been a pioneer in this transformation and an example for many other health care systems.[54]

Intermountain's transformation has been the consequence of a growing recognition that the current model of health care delivery is in many ways outmoded and has failed to incorporate many of the lessons that propelled other sectors of the economy to large gains in quality and productivity. Even today in many health care organizations, the norms for care delivery are founded on a cottage industry–based delivery model wherein the physician artisan, through training, personal competence, and professionalism, devises individualized diagnostic and treatment regimens.[148] Although this approach may offer ideal care for some, it has limited ability to promote continual learning and improvement, because each physician may have a differing approach to a similar patient while firmly considering his or her own approach to be optimal. However, even the expert mind is fallible: (1) there is often a lack of knowledge regarding best therapy, resulting in variability of approaches and outcomes that are often not systematically tracked; (2) expert opinion has been shown to yield widely disparate results,[21] undermining its validity and reliability; (3) humans have inherent biases that are hardwired into our brains and lead to biased judgments[56,165]; (4) the expert mind is limited to processing information on 7 ± 2 variables simultaneously, often less than what is required in complex critically ill newborns; and finally (5) the exponential expansion of medical knowledge, with a doubling time reduced to 8 years, makes it very difficult to stay up to date on the latest science.[15,*] For all these reasons, a continuation of a craft-based approach to health care delivery has become untenable, and a new approach based on standardization and systematic use of clinical data and evidence rather than opinion must be pursued. Other industries have grappled with similar transitions and have provided a blueprint for improvement that is now actively pursued by many high-performing health systems. We briefly examine some of the historical foundations of these developments.

*The line of reasoning presented here reflects teachings by Dr. Brent James at Intermountain Healthcare's Advanced Training Program.

Brief History of Industrial Quality Improvement

A thorough description of the history of quality improvement is beyond the scope of this chapter. Instead, we provide a brief overview of stages of progress that are particularly salient for medicine.



Before the late nineteenth and early twentieth centuries, quality was largely conceived of as quality assurance (oversight) and the result of personal excellence and training. For example, craftsmen organized in guilds chose their trainees selectively, often based on heritage, and provided formal apprenticeships. Mastery of the craft was achieved through training, supervision, and ongoing practice. The guilds secured a livelihood for their members through a combination of trade secrecy, price collusion, and monopolistic behaviors. The quality of labor and goods was the result of limited competition, quality controls by the authorities, and peer review. This approach is still prevalent in medicine today.

With the advent of industrialization and mass production of goods, a new field called scientific management emerged, a field that combined lessons from statistics, management, and economics. The goal of this movement was to increase productivity, reduce scrap, and reduce cost. Frederick Taylor (1856–1915) was one of the main innovators during this era. A mechanic and pattern maker by training, Taylor used time and motion studies and statistical production sheets to increase efficiency and workflow. Famous for his principles, Taylor held seminars on scientific management and worked as a consultant. One of his contractors was the Ford Motor Corporation, where Taylor played an important role in the success of the famous Model T. Gains in factory efficiency substantially lowered the overall cost of each car and enabled Ford to undercut the price of other cars on the market.

Taylor's methods transferred the control of production away from frontline workers to management and engineers, but his methods proved controversial. He was quoted as saying: "Hardly a workman can be found who doesn't devote his time to studying just how slowly he can work." This negative view of frontline workers and the drive to maximize their efficiency not infrequently resulted in social unrest. The large power differential between management and workers also tended to exclude those with the most detailed knowledge of production processes from participating in quality improvement.

The next leap in industrial management was achieved through the work of Walter Shewhart (1891–1967). An engineer, physicist, and statistician, Shewhart is known as the "father of statistical quality control." Before Shewhart, industrial quality mostly involved inspection and removal of defective products. Working at Bell Telephone Laboratories, he investigated variation in production systems and pointed out the importance of reducing variation in manufacturing processes, a concept that also offers an important lesson

• **Fig. 5.1** Control chart by Walter Shewhart. (From http://www.firstmetre.co.uk/methods/tutorials/412/; accessed October 31, 2017.)

for medicine. Shewhart highlighted that continual process adjustment in reaction to process nonconformance actually increases variation and degrades quality. This behavior is called "tampering" and is common in patient care. Shewhart framed the problem of process variation in terms of assignable and chance variation (Deming later called these special and common cause variation) and developed the "control chart" (Fig. 5.1) to operationalize these concepts. A control chart or the related run chart, described later in the chapter, allows for simple tracking of process variation. It allows one to estimate the extent to which a process varies over time; the idea being that excessive common cause variation indicates a poorly controlled process that is not being addressed in a standardized way. It also identifies special cause variation according to a variety of patterns, including, for example, performance outside of statistical control limits. Both excessive common cause and special cause variation are indications of opportunities for quality improvement and should be further investigated and remedied. Shewhart emphasized the importance of bringing and keeping a production process in statistical control so as to predict and manage future output.[166]

William Edwards Deming (1900–1993) is perhaps the most influential thinker on quality during the last century. Inspired by Shewhart's teachings on statistical process control, Deming realized that these principles could be applied not only to manufacturing processes but also to the management of companies.

Deming is most famous not for his work in the United States but for his contributions to Japan's economic revival after World War II. While working under General Douglas MacArthur as a census consultant to the Japanese government, he famously taught statistical process control methods to Japanese business leaders. Difficult to imagine today, Japan once had a reputation for poor-quality products. Quality control relied largely on inspection, rework, or scrapping of finished products (control of the output). This production system produced lots of waste and became a major impediment to postwar reconstruction. Japanese industrial leaders and the American Engineering Corps recognized the need to change the quality of industrial output through process control rather than output control to rebuild Japanese infrastructure and industry. In 1950, on invitation from the Japanese Union of Scientists and Engineers, Deming gave a legendary lecture series to engineers, managers, scientists, and leaders of Japanese industry. His teachings sparked an industrial revolution and are widely credited with jump-starting the Japanese postwar revival. In the United States, Deming's teachings remained largely unknown until American industry was rapidly losing market share to the Japanese competition. In 1980, he explained his ideas in an NBC broadcast "If Japan can … why can't we?"

Deming's philosophy taught that by adopting appropriate principles of management, organizations can increase quality and simultaneously reduce costs (by reducing waste, rework, staff attrition, and litigation while increasing customer loyalty). When organizations focus on quality by improving their work processes, costs will fall. Oppositely, when organizations focus on costs, then quality will fall and costs will rise. Deming developed the Plan-Do-Study-Act (PDSA) cycle, which he called the Shewhart cycle, a strategic staple in modern quality improvement. He also developed 14 Key Points in Management and 7 Deadly Diseases (Box 5.2).

Deming was a strong opponent of performance appraisals, incentives, short-term thinking, and punitive benchmarking, all strategies currently proposed as "solutions" to increase the value of health care delivery. For Deming, the key to success was to practice continual improvement in the quality of products, uniformity of processes, and qualification of employees. He taught that all processes yield three parallel outcomes that must be measured: a work product (medical outcome), cost outcome, and service outcome (patient satisfaction). All processes contain built-in variation (common cause), but they are also affected by external factors (special cause). Management, not frontline workers, controls common cause variation through systems design. In opposition to Taylor's view of frontline workers, Deming cherished their contributions and felt that involving them in improving care processes would instill meaning and pride in their work.

Kiichiro Toyota, the founder of Toyota Motor Company, was among Deming's audience in 1950. Based on his lectures, Toyota developed the Toyota Production System (TPS), an integrated sociotechnical system that comprises its management philosophy and practices. The system is a precursor of the more generic "Lean Manufacturing." At the core of TPS is elimination of waste (muda) and total focus on reliable high quality through continuous improvement

• BOX 5.2 Deming's Management Principles and Deadly Diseases

14 Management Principles

1. Create constancy of purpose toward improvement of product and service, with the aim to become competitive, stay in business, and provide jobs.
2. Adopt the new philosophy. We are in a new economic age. Western management must awaken to the challenge, learn their responsibilities, and take on leadership for change.
3. Cease dependence on inspection to achieve quality. Eliminate the need for massive inspection by building quality into the product in the first place.
4. End the practice of awarding business on the basis of a price tag. Instead, minimize total cost. Move toward a single supplier for any one item, on a long-term relationship of loyalty and trust.
5. Improve constantly and forever the system of production and service, to improve quality and productivity, and thus constantly decrease costs.
6. Institute training on the job.
7. Institute leadership. The aim of supervision should be to help people and machines and gadgets do a better job. Supervision of management is in need of overhaul, as well as supervision of production workers.
8. Drive out fear so that everyone may work effectively for the company.
9. Break down barriers between departments. People in research, design, sales, and production must work as a team, so as to foresee problems of production and usage that may be encountered with the product or service.
10. Eliminate slogans, exhortations, and targets for the work force, asking for zero defects and new levels of productivity. Such exhortations only create adversarial relationships, because the bulk of the causes of low quality and low productivity belong to the system and thus lie beyond the power of the work force.
11. a. Eliminate work standards (quotas) on the factory floor. Substitute with leadership.
    b. Eliminate management by objective. Eliminate management by numbers and numerical goals. Instead substitute with leadership.
12. a. Remove barriers that rob the hourly worker of his right to pride of workmanship. The responsibility of supervisors must be changed from sheer numbers to quality.
    b. Remove barriers that rob people in management and engineering of their right to pride of workmanship. This means, *inter alia*, abolishment of the annual or merit rating and management by objectives.
13. Institute a vigorous program of education and self-improvement.
14. Put everybody in the company to work to accomplish the transformation. The transformation is everybody's job.

7 Deadly Diseases

1. Lack of constancy of purpose
2. Emphasis on short-term profits
3. Evaluation by performance, merit rating, or annual review of performance
4. Mobility of management
5. Running a company on visible figures alone
6. Excessive medical costs
7. Excessive costs of warranty, fueled by lawyers who work for contingency fees

(kaizen). Lean production focuses on just-in-time use of materials and optimization of production flow (mura) in response to customer demand. Toyota's success derived from its innovative production engineering, which puts quality control in the hands of the frontline workers who can stop the production line and call for help when something goes wrong. However, production engineering is only part of Toyota's success. An equally important contributor to Toyota's success has been coined the Toyota Way, which embodies a relentless focus on the needs and desires of customers.

Another variant of statistical process control originally developed by Motorola in 1985 is called Six Sigma. Six Sigma comprises a set of tools and strategies for process improvement and seeks to improve quality by minimizing defects and variability. In Six Sigma, a defect is defined as any process output that does not meet customer specifications or that could lead to creating an output that does not meet customer specifications. The term "Six Sigma process" means that if one has six standard deviations between the process mean and the nearest specification limit, only 3.4 out of 1 million outputs will fail to meet specifications. To illustrate, if a hospital achieved Six Sigma in the administration of antenatal steroids, only about three in a million preterm infants would fail to receive them. Although technically this equates to only a 4.5 sigma process, the remainder is meant to account for the fact that over the long term, processes tend to become more error prone (entropy). A one sigma process produces 69%, a two sigma process produces 31%, and a Six Sigma process produces 0.00034% defective outputs. Current evidence suggests that much of health care operates at the one to two sigma level.[82,85] Six Sigma includes methodologies that lean on Deming's PDSA cycle, such as DMAIC for reengineering existing processes. DMAIC stands for define the problem; measure key aspects; analyze data for key relationships; improve the current process (using a set of specific techniques); and control the future process.

Industry has undergone fundamental changes over the last century. Scientific approaches to process improvement and management have resulted in dramatic increases in quality and productivity. Health care systems that have implemented change based on Deming's principles have seen similar benefits.

Industrial quality improvement methods have been applied to health care for more than 30 years. In *Curing Health Care: New Strategies for Quality Improvement*, Berwick and co-workers provided the initial evidence that the tools of modern quality improvement, with which other industries have achieved breakthroughs in performance, can help in health care as well.[10] Since then, the core ideas of quality improvement have been adapted to the particular

needs of health care and implemented by health care organizations around the world. In neonatology, multidisciplinary teams from NICUs across the United States have applied quality improvement tools and methods to address the quality and safety of medical care for newborn infants and their families.[25,32,58,97]

An additional challenge for effective QI is that many health care providers have not been actively engaged in quality improvement efforts or exposed to the lessons from industrial engineering. Successful adaptation of these methods to the NICU setting requires recognition that health care is a process and that quality improvement requires process management. Albeit, a focus on care delivery processes, although necessary, is not sufficient. Rather, similar to the way that Deming expanded Shewhart's focus on process control to include organizational management, medical process management needs to be accompanied by efforts to optimize the organizational environment in ways that promote continual learning, teamwork, and adherence to the mission of serving patients and families.

Several theoretical frameworks exist to further our understanding of the complex interplay between organizational environment, process, and outcomes.

Definition and Conceptual Frameworks for Quality

Definition

The Institute of Medicine defines quality of care delivery as the extent to which health services provided to individuals and patient populations improve desired health outcomes. In *Crossing the Quality Chasm*, it developed the following six domains of quality of delivery of care.

Safety: Avoiding preventable injuries, reducing medical errors
Effectiveness: Providing services based on scientific knowledge (clinical guidelines)
Patient-centeredness: Care that is respectful and responsive to individuals
Efficiency: Avoiding the wasting of time and other resources
Timeliness: Reducing wait times, improving the practice flow
Equity: Consistent care regardless of patient characteristics and demographics

These domains are useful guideposts for practitioners in developing comprehensive quality programs and measurement systems.[47]

Conceptual Framework for Quality

Various authors have developed conceptual or explanatory models that provide users with a systematic understanding of the components and facilitators of high-quality health care delivery. These frameworks are often adapted from other sciences, including manufacturing, engineering, organizational theory, and psychology. The key to these frameworks and their application is an understanding that high quality of care delivery is the result of efforts to create a work environment in which people work together to reliably execute processes that are known to work or thought to work and to avoid care that is known to be unhelpful.

Donabedian: Structure, Process, Outcomes

Maybe the best-known framework for quality improvement was developed by Avedis Donabedian, MD (1919–2000). Donabedian was the first to collate evidence on the quality of health care delivery; he derived a simple structure, process, and outcome model of quality that has been the mainstay of quality research.[20]

Structure traditionally has been interpreted as the physical facilities and the training and education of staff. This notion has been expanded to include executive leadership, organizational culture, organizational design, incentive structure, and information systems and technology.[30] Processes comprise the activities clinicians and support staff undertake as part of or in support of care delivery. Outcomes are the results of these activities.

Pawson and Tilley: Realistic Evaluation

Similar but distinct frameworks have been described by others. Social scientists Ray Pawson and Nick Tilley highlight the importance of local context in their book, *Realistic Evaluation*.[95b] Realistic evaluation goes beyond the traditional cause-and-effect paradigm and poses that program effectiveness also depends on many interrelated contextual variables. This is formalized by the following formula: Context + Mechanism = Outcome (C + M = O). A given intervention does not necessarily work for the group as a whole but may be quite useful to some individuals, depending of their specific circumstances.

Batalden: Five Knowledge Systems

Batalden applies a similar formula to quality improvement and describes how knowledge systems combine to produce improvement: Generalizable Scientific Evidence + Particular Context → Measured Performance Improvement.[6] Each of the five components in this formula is driven by knowledge. Knowledge of scientific evidence stabilizes context as a variable and reduces its effect on what is being studied. Knowledge of context is gathered through inquiry of local care processes and culture. Knowledge on the benefits and side effects of the intervention is developed through appropriate measurement over time. The plus symbol represents knowledge about the locally available modalities (forcing functions, academic detailing, standardization, etc.) for implementing the scientific evidence. The right arrow represents knowledge required for execution of the intervention. Acquiring all five kinds of knowledge requires both scientific and experiential learning and is critical to optimizing quality improvement.

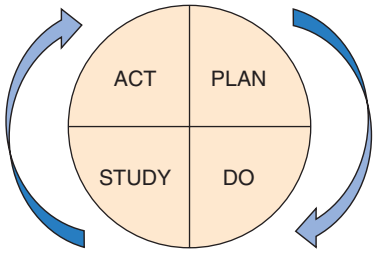
Complexity Theory

Complexity theory is another framework that has seen increasing prominence in health care. Complexity theory recognizes that health care delivery is nonstatic, fluid, and interconnected. This makes improving health care delivery quite different from improving a machine. Providers must give consideration to how changes in a care delivery process affect other actors in the system. Driving out variation through rigid care guidelines may not improve overall care delivery because perceived improvements in one area may have detrimental effects in others. In addition, even when evidence-based, guideline-driven care needs to account for individual patient complexity. Quality improvement according to principles of complexity uses global guideposts and promotes interdisciplinary, small-scale experimentation to test the effect of change on the health care delivery system.[101,102]

Translation of Frameworks into Action

Frontline application of quality improvement efforts draws from the various theoretical frameworks presented in the preceding section. In the following, a few approaches are highlighted that are commonly applied in neonatology. For practitioners, the practical application of quality improvement work may be more effective if supported by a formal approach, as provided by Dr. Deming (integration and standardization as practiced by Intermountain Healthcare), Lean, Six Sigma, or the Model for Improvement, advocated by the Institute for Healthcare Improvement. Each of these frameworks makes use of various management tools to assist with project planning and execution, including team organization, process mapping, problem identification, problem resolution, task prioritization, and execution. We briefly mention several of these in the section titled Quality and Safety Applied. However, a full description of these tools is beyond the scope of this chapter. For more detail on these, refer to the extant literature.



Model for Improvement

The Model for Improvement has been widely adopted as a strategy for collaborative quality improvement in the neonatal community.[150] It is based on *The Improvement Guide*, by Langley and Nolan, and identifies four strategic elements of successful process improvement[65]: (1) specific and measurable aims, (2) measures of improvement that are tracked over time, (3) strategic changes that will result in the desired improvement, and (4) a series of PDSA cycles during which teams learn how to apply crucial change ideas.[150] These principles correspond to three questions asked of collaborative teams (Fig. 5.2).

The first question, which refers to the aim(s) of the project, is "What are we trying to accomplish?"[150] In other words, what are the main outcomes that the team is trying to change or improve? There are several concerns when considering the aim of a prospective project. Are there historical and/or peer benchmark data to suggest that there is a problem in the local NICU? Is there a variation in the outcome among NICUs to suggest that variations in practices can lead to differences in outcomes? Are there evidence-based practices that have been shown to improve the outcome of interest? The aim should be well defined and realistic. It should also be quantifiable and encompass a defined time period.[22]

One helpful framework in crafting a well-designed aim statement is the "SMART Aim" approach (Box 5.3). An example of a suboptimal aim statement may be, "Reduce

- What are we trying to accomplish?
- How will we know that a change is an improvement?
- What change can we make that will result in improvement?

• **Fig. 5.2** The Model for Improvement.

• BOX 5.3 SMART Aim Statement

Specific
- *What exactly are we going to do for whom?*
  - Should specify target population, setting, and actions.
  - Uses verbs such as train, increase, decrease.

Measurable
- *Is it quantifiable and can we measure it?*
  - Source and mechanism for collecting data are identified, and collection of data is feasible.
  - Baseline data are available to document change.

Achievable
- *Can it be done (time frame and resources)?*
  - Project is feasible with available resources and appropriate in scope.
  - A more time-limited aim may make it easier to collect relevant clinical and cost data.

Relevant
- *Will this objective have an effect on the desired mission/broader goal?*
  - May be informed by literature review, best practices, or your theory of change.

Time Bound
- *What is the time frame for change? When will this be accomplished?*
  - Indicate a specified and reasonable time frame in the aim statement.
  - Take into consideration the environment, scope of change, and how it fits into the overall work plan.

infection rates in our NICU." Although a worthy goal, that statement is vague, and it will be difficult to assess if it has been accomplished. In contrast, the following aim statement is more specific and follows the SMART Aim approach: "Reduce by 50% the number of central line–associated bloodstream infections as defined by the Centers for Disease Control in infants born at 24 to 30 weeks' gestational age in the NICU by using an insertion and maintenance bundle over a 12-month time period."

The second question, corresponding to the measures of the project, is "How will we know that a change is an improvement?" As a team embarks on a quality improvement project, one can consider three main groups of measurements: outcomes, processes, and balancing measures. The outcome measure is typically a clinical outcome, such as nosocomial infection or bronchopulmonary dysplasia. A process measure related to reduction of nosocomial infection could be the use of an insertion checklist. In some instances, a process measure can serve as the main outcome of a quality improvement project, when that process measure has been clearly linked to a benefit in clinical outcomes. Examples are a focus on improving the rate of antenatal steroid administration for premature birth or on increasing breast milk provision for premature infants. A balancing measure for increased breast milk provision for premature infants may be growth velocity, which may have a negative correlation.[114] The idea behind a balancing measure is to ensure that the quality improvement intervention does not generate unwanted secondary effects.

The third question, which corresponds to the strategic changes that will lead to improvement, is "What changes can we make that will result in improvement?" These changes should be evidence based, but must also take into account local cultural and organizational characteristics. Plsek has coined the term "potentially better practices" rather than "better" or "best" practices to stress that no change idea is truly better or best until it has been adapted, implemented, and tested in the local context in which it will be applied. This is consistent with the ideas surrounding "context" described by Pawson and Batalden, as noted in the previous section on frameworks for quality. The PDSA cycles in the Model for Improvement can be conceptualized as an application of the scientific method (see Fig. 5.2). Each PDSA cycle is a test of a hypothesis of how a specific change will affect the system.

Integrated Quality Management

Another method for quality improvement in health care focuses on the elimination of process variation. This approach derives from Deming's work and has been adapted with success for health care by several organizations. For example, Dr. Brent James, former Chief Quality Officer and Executive Director, Institute for Health Care Delivery Research, Intermountain Healthcare, helped refocus the health systems quality improvement efforts on process standardization, active management, and ongoing organizational learning. Work units identify high-value clinical processes and set up multidisciplinary provider teams to develop evidence-based detailed care pathways (shared baselines) to execute these processes in a consistent, reliable manner. The name *shared baseline*, rather than protocol or guideline, highlights its development and ongoing refinement by the local work unit. Control rests with frontline care providers, not managers. The purpose of these shared baselines is to minimize the variation that is driven by providers and not accounted for by patient need. Providers are encouraged to deviate from the shared baseline as warranted by the needs of individual patients. This approach allows providers to bring their expertise to bear on the clinical situations that truly warrant an alternative treatment approach. It also effectively ameliorates concerns regarding "cookbook" medicine, given an explicit expectation that no guideline perfectly fits any patient. On the contrary, providers are asked to assess situations where they have deviated from the shared baseline. This information is then used to modify the shared baseline when appropriate. Overall, the use of shared baselines makes the workflow more predictable, efficient, safer for patients, and less stressful for nursing staff.[18,54,94]

Similar to the Model for Improvement, the modified Deming approach uses key measures to track cornerstones of the process, clinical outcomes, service outcomes (such as patient satisfaction), and cost. The shared baseline is eventually integrated into the electronic medical record and managed according to results. The key to promote organizational learning and standardization is tracking of process deviations and systems to modify the shared baselines according to ongoing provider input. To facilitate the success of local projects, strategic staff from clinical work units receive training and technical support for their improvement work from a centralized quality improvement institute.[54] Institutional commitment is foundational to achieving excellence in care delivery in the NICU. Neonatal providers often embark on grass root QI efforts that may not align with hospital leadership priorities. Close communication and support is necessary to assure that efforts are properly prioritized, aligned with frontline and leadership needs, and executed. Sufficient resources for QI management are critical for their staff to carry out "two jobs," their primary work duties, as well as efforts to do their jobs better.

Lean

Lean methodology has become increasingly popular with health care administrators and providers. Lean focuses on reducing process waste and improving process flow.[169] The seven wastes on focus with Lean are overproduction, inventory, waiting, transportation, defects, staff movement, and unnecessary processing. Lean has an intense focus on customer, patients, and families, and encourages users to examine their process steps and eliminate those that do not provide value to customers. A focus on flow attempts to optimize the use of time and resources.

These approaches and others are guiding practical and theoretical improvement work. Although meaningful in

their differences, their common thread lies in the centrality of managing work processes while optimizing the care delivery environment. Organizational goals for high-quality care delivery and patient safety are undergirded by strategies that encourage continuous monitoring of processes and outcomes, facilitate continuous learning, and minimize unwarranted waste and process variation.

Data and Methods for Quality Improvement

Not everything that can be counted counts.
Not everything that counts can be counted.

—ATTRIBUTED TO ALBERT EINSTEIN

It is essential that quality improvement be data driven. First, to identify opportunities for quality improvement, data are necessary to determine performance relative to historical performance or peer-derived benchmarks. Second, once quality improvement is undertaken, data are used to track the effect of changes and interventions, both to assess the impact of quality improvement and also as an essential component of the improvement process to determine next steps. Third, data are essential to further the knowledge of how specific processes and factors may influence quality measures. In addition to traditional concepts of data in the context of quality improvement, there is also an increasing need to be aware of the environment in which quality improvement occurs.

Data Elements for Assessment

A strategic component of quality improvement is a standardized data collection system to create benchmarks for performance, both historically and across centers. In following Donabedian's framework, the main data types in such collections can be categorized as structural or contextual measures, process measures, and outcome measures (including medical outcomes, cost, and service outcomes such as family satisfaction with care). Characteristics of infants and their families may have important influences on clinical outcomes and are discussed in conjunction with these measures.

Structure and Institutional Context

Although the focus of quality improvement has largely been on changing processes of care, often narrowed down to a list of things "to do," there is an increasing awareness of the importance of the context in which improvement activities occur. A focus on care context features prominently in several of the frameworks discussed in the preceding. Because quality improvement in our field often relies on changing systems of care as well as the behavior of many individuals who are part of the health care team, including leaders, frontline staff, and administrators, the organizational environment may be an important aspect of performance. The goal of ascertaining measures of the structure and context of care delivery is an attempt to identify elements that if modified lead to better outcomes of care. Such data are typically obtained through surveys of either essential informants or frontline care providers.

Maybe the best-examined aspect of structure is the patient-to-nurse ratio. In adult and pediatric intensive care unit settings,[3] rising patient-to-nurse ratios have been linked to worse clinical outcomes and higher mortality. In neonatology, this link is less well understood.[64] Although most studies imply a benefit of greater staffing ratios, this finding is not uniform.[140] Nurse staffing ratios may be suboptimal in general and associated with nosocomial infection rates.[122] Other examples of structural measures include academic teaching status, 24-hour coverage by an in-house intensivist, patient volume, and level of care.

Contextual measures are different from traditional measures in that they attempt to assess the links between how care delivery is organized and supported by the institution and quality of care. Kaplan and colleagues developed a framework for examining these linkages and coined it Model for Understanding Success in Quality (MUSIQ).[57] This article highlights different components that support improvements in the processes and outcomes of care delivery at various levels of the institution, including characteristics of the improvement team (diversity, physician involvement, leadership) and the NICU, as well as higher-level organizational functions (quality improvement leadership and administrative support).[59] Validation studies in support of this model are currently underway.[37]

One well-researched aspect of care context is safety culture. NICU safety culture describes the shared norms of leadership, staff, and the organization with regard to patient safety, or simply, the "way we do things around here." Culture influences quality of care in important ways. Whether a process is failure-proof depends on how reliably it is implemented. Non-adherence to care standards may reflect a clinical need but also lack of a standard or willful disregard. Safety culture assessments attempt to capture safety context through surveys that ask about health worker perceptions. The measured domains are called climates (i.e., teamwork climate or safety climate). The term "climate" reflects that perceptions are shared among health workers (i.e., they cluster more strongly within a work unit, e.g., the NICU) than between work units.

Ongoing assessment of safety culture is a requirement for hospital accreditation by the Joint Commission, an accreditation agency that assesses safety and quality of care. There are several validated survey tools to measure safety culture.[24,113,144] The Safety Attitudes Questionnaire (SAQ) reflects caregiver attitudes on safety culture, is psychometrically sound, and has demonstrated wide interinstitutional variation across NICUs.[112,113] Safety culture, as measured by the SAQ, has been linked to a variety of clinical and organizational outcomes. Most famously, this instrument was used by Pronovost and co-workers in their implementation of the Comprehensive Unit-based Safety Program

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

(CUSP) in 103 adult ICUs in Michigan, where through implementation of a checklist and a focus on teamwork and safety, median catheter-related bloodstream infection rates were reduced to zero.[115] This program has been endorsed for implementation in all ICUs by the US government. In a study of 44 NICUs and over 2000 respondents, teamwork was associated with health care–associated infections among very low birth weight infants, such that the odds of an infant contracting an HAI decreased by 18% with each 10% rise in NICU respondents reporting good teamwork.[109] Of note, physicians tend to rate safety culture significantly higher than nurses and other personnel, highlighting an apparent disconnect in perceptions, which should prompt some reflection on behalf of physicians.

Various approaches to improving safety culture have been described. Among them are leadership engagement via Leadership WalkRounds[131] and a teamwork training curriculum developed by the Agency for Healthcare Research and Quality called "Team Strategies and Tools to Enhance Performance and Patient Safety" (TeamSTEPPS). The intervention includes assessment, training, and sustainment phases focused on four core competencies: (1) team leadership, (2) situation monitoring, (3) mutual support, and (4) communication.[17] This approach has been used in multiple health care settings,[84,124] including one reported intervention, which included NICU providers and demonstrated an improvement in perceptions of teamwork.[7]

Safety culture, its improvement, and associations to outcomes of care for sick newborns are topics of active research. Instructions on how to use the Safety Attitudes Questionnaire for the promotion of safety and teamwork goals have been published.[132]

Another emerging aspect of care context is caregiver resilience, operationally often defined as the absence of burnout. Burnout describes a condition of fatigue, detachment, and cynicism resulting from prolonged high levels of stress.[108] In the critical care setting, burnout rates may be consequent to high workload and frequent changes in technology and guidelines, as well as emotional challenges of dealing with critically ill patients and their families.[13,103,120,154] Burnout affects between 27% and 86% of health care workers,[87,137,151] with over half of physicians reporting burnout and around one-third of nurses and physicians meeting criteria for severe burnout.[8,134,136,137] Burnout has negative consequences for health care providers, organizations, and patient care (Box 5.4).

Burnout is usually measured through validated survey tools, such as the Maslach Burnout Inventory[83] or abbreviated versions thereof.[108] A recent systematic review identified that both organizational as well as individually focused interventions are effective in reducing physician burnout.[162] Additional research is being conducted to further test and refine measurement and interventions, and health care systems are increasingly recognizing the need and benefits of supporting staff resilience (for an example, see http://wellmd.stanford.edu).

• BOX 5.4 Impact of Burnout in Health Care

Health Care Professionals

Higher mortality rates[1]
More arteriosclerotic disease[61]
Worse work-life balance[14,29,38]
More depression[26]
More post-traumatic stress[87]
Worse sleep quality[19]

Organizational Functioning

Lower job satisfaction[135,139,170]
Lower safety and teamwork[108,130,131]
More turnover[86,88,139]
Lower sense of control at work[86,139]

Patients

Higher rates of medical errors[104,133,135,159,163]
Higher rates of suboptimal care[120,135]
More medical lawsuits[38]
Higher infection rates[16,135,149]
Less family support[120]
Higher mortality[2]

Overall, context provides the soil on which efforts for high quality of care either thrive or wither. Leadership recognition of these factors is critical; to provide high quality of care of our patients, we must also care for ourselves and our colleagues.

Processes

Process measures are an important element of quality assessment as certain processes of care may be linked to the quality of outcomes. As noted, reducing process variation has been a strategic component of quality improvement, going back to Shewart and control charts to detect deviations. The study of how certain process measures relate to outcomes can also contribute to the broader evidence basis for best clinical practices. An example of processes and practices that could relate to the reduction of line infection in the NICU is shown in Box 5.5.

In those cases in which there is a clear evidence base for the link between a process and a desirable or undesirable clinical outcome, the process measure itself can serve as a quality measure. Antenatal steroids have been demonstrated in clinical trials to prevent respiratory distress and reduce morbidity, and their use in eligible populations is considered an important measure of the quality of perinatal health care delivery.[70] Thus, a goal of using process analysis for quality improvement is to detect the underuse of processes that have been shown to improve outcomes, such as the use of antenatal steroids. Process analyses can also detect the overuse of processes that have been demonstrated to be detrimental, such as the provision of postnatal steroids for chronic lung disease.

In addition to therapeutic processes, preventive measures and screening tests can also be a component of measuring

• BOX 5.5 Processes to Reduce Central Line Infections in Neonates

Checklists	• Cognitive tool to ensure best practices in insertion and maintenance
Dedicated Line Cart	• To have supplies readily available for line insertion
Insertion Practices	• Assessment of need for catheter • Maximal sterile barriers—patient sterile covering and clinician sterile precautions (gown, gloves, mask, hat) • Hand hygiene • Appropriate site preparation and dressing
Maintenance Practices	• Daily assessment of line necessity • Daily assessment of line site to check for signs of infection or infection risks • Dressing change practices • Appropriate catheter access practices, including hub scrub and hygiene • Appropriate tubing change practices

quality of care. Because impaired vision or blindness from retinopathy of prematurity is a potentially preventable condition, timely screening exams are an important measure of the quality of care delivery.[5]

The study of the relationship of processes to outcomes can be an ongoing aspect of quality assessment. The clinical impact of various processes may help to prioritize resources and quality improvement activities when it can be demonstrated that improving processes leads to improved outcomes. Breast milk for premature infants has been shown to have a protective effect for necrotizing enterocolitis. When a quality improvement activity to increase breast milk expression and provision for premature infants leads to decreased rates of necrotizing enterocolitis, the process measure of breast milk provision can be considered a crucial quality measure.[73]

Another use of process measure collection may be for compliance tracking. This can be particularly useful when certain clinical outcomes are rare but are known to be associated with certain practices. For example, vertical infection of a newborn with hepatitis B may be quite rare, but rates of appropriate maternal and newborn testing and prophylactic treatment and immunization can be tracked and may serve as a risk signal.

In addition, compliance measurement is critical to institutional learning. Providers that do not comply with care guidelines may either do so unintentionally, a signal that the default pathway has not been instituted effectively, or intentionally. Intentional noncompliance may lead to eventual improvement of the care guideline as the provider group learns about an aspect of patient care not previously so considered, or in the case of a provider's willful refusal to adhere to the group standard, may have implications for personnel management.

Outcomes

Outcomes are the end results of the clinical care delivery process and represent what patients, families, and providers truly care about. Pragmatically, outcomes are negative events such as death and morbidity, and quality is inferred on the basis of a lower-than-expected negative event rate. It is important to record a wide spectrum of outcomes, but for an outcome to serve as an effective quality indicator, evidence must be strong that variations in process or structure can change its occurrence. A widely used outcome measure is health care–associated infections or their more specific cousin, central line–associated bloodstream infections. These infections are important quality indicators because they cause significant morbidity, and incorporating certain processes of patient care (e.g., hand hygiene and intravenous line care) has been shown to reduce their occurrence.

The effort to reduce such infections, although still a work in progress, has served as a success story and model for other quality improvement activities. Studies of health care–associated infections in the NICU have shown wide variation by hospital, signifying opportunities for improvement, leading to successful efforts to reduce infections at collaborative levels, and contributing to identification of high performers who can serve as role models for other NICUs.[72,96,128,168]

Balancing Measures

In addition to the main outcome measures that are the targets of quality improvement, it is also important to consider which balancing measures to track. In the midst of improving quality for one aspect of clinical care, it is possible that a related outcome may be adversely affected. For example, a decrease in growth velocity may be observed with a focus on improving breast milk feeding rates. Balancing measures may be clinical outcomes such as growth or morbidities but can also include other aspects of quality such as cost or patient satisfaction. These balancing measures should be collected in or close to real time to detect any unintended consequences of quality improvement projects. Although traditionally balancing measures were developed to assess the possibility of negative effects, they are also emerging as important motivational indicators that the new way of doing things is safe. This is an important facilitator of change in that a major roadblock to adopting a new way of practice is the concern that the new approach will fall short, leading to missed or ineffectively treated cases.

Assessing the Total Impact of a Quality Improvement Initiative

In the preceding discussion, the essential role of data in conducting a quality improvement initiative has been stressed. Although a successful initiative typically presents data on the extent to which processes ("hand washing has increased 50%") and outcomes ("catheter-related infections decreased by 50%") have been improved, these statistics fail to capture

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

the initiative's total impact and economic consequences. Successful initiatives have significant impact across many domains. For example, a decrease in catheter-related infections might reduce the need for high-intensity nursing, equipment (infusion pumps), materials (catheter setups), laboratory and radiographic studies, blood products, antibiotics, and parenteral nutrition solutions. It might also decrease the mortality, pain, and discomfort experienced by the infant and the stress experienced by the family, and may improve responses to satisfaction surveys. By working in collaboration, many of these impacts can be objectively measured, with quantitative data obtained from routine administrative sources used by nursing, central supply, pharmacy, laboratory, and radiology. Presenting the total impact of a quality improvement initiative is an effective way to demonstrate its value to hospital administration as well as to the many individuals and departments whose support is essential to the NICU. The impact on resource utilization can also be translated to dollar savings.[121]

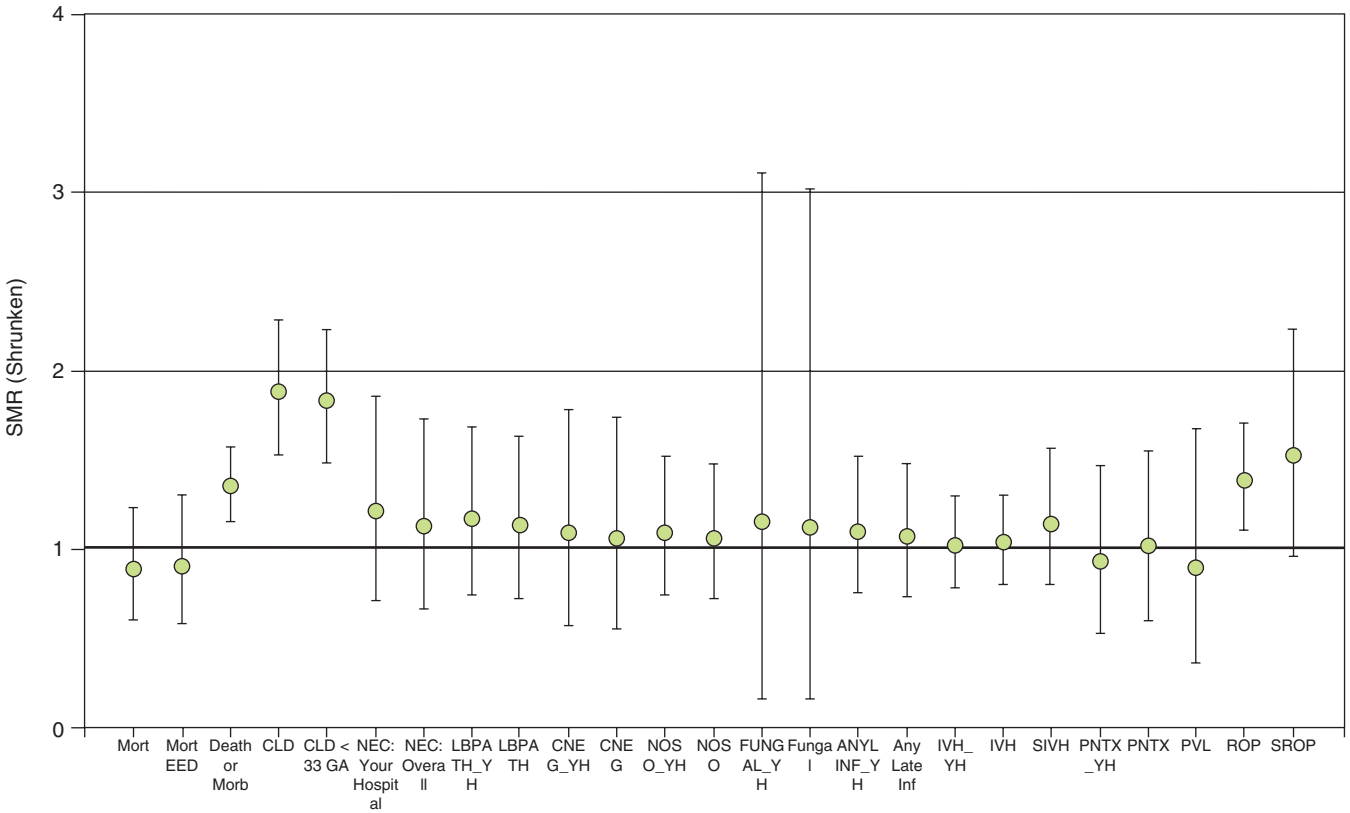
Risk Adjustment/Fair Comparisons

For performance assessment *within* an organization, tracking a process or outcome measure over time may be sufficient to spur quality improvement activities and assess their impact. However, for comparative performance assessments *between* organizations, as currently applied for purposes such as setting benchmarks, pay-for-performance, or public reporting, further statistical and methodologic considerations are required to ensure fair comparisons.

The use of risk adjustment levels the playing field regarding the reporting of patient outcomes by accounting for expected rates of positive or negative outcomes. Expectation is pivotal to the notion of quality, because quality may be inferred from the relation between an observed and an expected outcome. In the context of clinical medicine, expected outcome includes the extent of risk features and co-morbidities that are not under the control of the clinician. Does hospital A with an observed neonatal mortality rate (NMR) of 5 provide better care than hospital B with an observed NMR of 10? Without knowing the expected rate of mortality at these two hospitals, it is impossible to assess their relative quality of care. For example, hospital B might be a tertiary care center, in which an observed NMR of 10 is much lower than its expected NMR. Hospital A could be a primary care hospital, in which an observed NMR of 5 is much higher than its expected NMR.

Mathematically, risk-adjustment methods level the playing field regarding comparisons through the use of one of the variants of multivariate regression. A model is generated in which not only the outcome of interest among the sample (NICUs) is assessed, but also statistically or clinically important characteristics of the NICU and its patient population are taken into account simultaneously.

To illustrate, patient characteristics used in risk adjustment for neonatal quality assessment will encompass both maternal sociodemographic and clinical factors as well as infant factors. In considering what variables to use in risk adjustment, there are two essential requirements. First, the variable should be a risk factor for the outcome of interest. Second, the variable should not be under the control of the entity being evaluated. Birth weight, gestational age, plurality, intrauterine growth, birth defects, and gender are risk factors that are commonly used as risk adjusters to control for institutional differences in case mix so as to make fair comparisons across NICUs.[118] They are highly predictive of morbidity and mortality and are not under the control of clinicians in the NICU. Mode of delivery and antenatal steroid use are also important predictors of mortality. Although not under the control of the neonatologist, they may be under some control of the obstetrician. If neonatal mortality is used to compare the quality of care across NICUs, one can include these two factors in the risk adjustment. However, if the goal is to use neonatal mortality to compare the quality of care across perinatal services, these factors should probably not be included, because they are at least partially under the control of the obstetrician and perinatal system.



Using this approach, the expected number of deaths (or adverse outcomes) at each NICU can be determined based on the characteristics (risk-adjustment variables) of infants treated at that NICU. The ratio of the observed number of deaths (or adverse outcomes) to the expected number of deaths (or adverse outcomes), called the standardized mortality (or morbidity) ratio (SMR), can then be calculated.

Rather than reporting the SMR as a measure of performance, an alternative approach is to calculate the difference between the observed and expected number of cases (O-E), where the expected number can be determined using the same regression approach described earlier. The Vermont Oxford Network routinely reports the O-E for mortality and major morbidities to its members using a method that accounts for risk using regression models and accounts for chance variation using an empirical Bayesian shrinkage method. These data are reported with 95% confidence intervals in table and graphic form to give an individual center an estimate of its performance in relationship to the overall group (Fig. 5.3). It is important to recognize that all estimates of risk-adjusted performance must be interpreted carefully and that these estimates are only the first step in assessing the quality of care.[127]

Because the statistical power to detect quality of care outliers using multivariate risk-adjustment methods based on a single year may be low, it may be useful to consider performing analysis on data combined from several years. Even employing very accurate predictive models and combining several years of data might not be able to overcome the problem of a small sample size in some NICUs. In this case, multivariate risk models may be useful for identifying individual infants who died despite having a low predicted probability of death. The medical records of such infants can then be chosen for detailed review and audit.

Recognizing that risk adjustment based on infant characteristics is imperfect, there is value in reporting comparative

• **Fig. 5.3** Data report from the Vermont Oxford Network. This sample screenshot from the Vermont Oxford Network Nightingale Internet Reporting System for a fictitious center displays risk-adjusted estimates for key performance measures for infants 501 to 1500 grams. The figure displays standardized ratios (SMR = Observed/Expected) and 95% confidence intervals. Estimates are calculated using an empirical Bayesian method.[98,99] Authorized users at network member centers have secure access to confidential reports for their own center. SMR, Standardized mortality (or morbidity) ratio. (Courtesy of the Vermont Oxford Network, Burlington, VT.)

performance data stratified by the type of NICU. The Vermont Oxford Network provides such stratified comparisons to its members. The Committee on the Fetus and Newborn of the American Academy of Pediatrics has proposed a NICU classification system that may be useful for this purpose.[4] In addition to reporting standardized ratios of observed-to-predicted rates for mortality, the Vermont Oxford Network and the CPQCC provide their members with the opportunity to compare important morbidities with similar centers, with the goal of using these data to identify opportunities for improvement. However, there is a caveat to this approach. In certain situations it may be quite appropriate to compare outcomes based on only patient characteristics and not on NICU characteristics. This is especially true in investigations that focus on whether infants are born and receive care at appropriate-level NICUs. Studies have shown that lower level of care and patient volume is associated with neonatal mortality for preterm infants.[60,99] In this situation, it would be critical to directly compare NICU performance based on patient characteristics and not adjust for level of care at the hospital of birth. Otherwise, a NICU that inappropriately retains patients beyond its capacity would get an unwarranted "free ride." In situations in which lower-level NICUs are always only compared with each other, there may be no poor performers identified in that group, even if they are all performing worse than higher-level NICUs. Therefore, if entire strata of NICUs are performing poorly, it may be worth questioning the stratification of quality comparisons. For example, the CPQCC provides both level of care adjusted and level of care unadjusted estimates. It also allows comparison with hospitals within one's perinatal region.

Although multivariate prediction models that are based on admission variables perform well for infants with very low birth weights for whom gestational age or birth weight is highly predictive of mortality, physiologic measures of disease severity have been felt to be necessary to achieve similar predictive performance for larger, more mature infants. In addition to stratification and multivariate modeling based on patient characteristics that are present before therapy is initiated, it is also possible to perform case mix adjustment based on comparable severity of illness.

Several physiology-based severity scores have been developed for use in neonatal intensive care, including the Clinical Risk Index for Babies (CRIB),[148a] which uses infant characteristics within the first hour after birth; the CRIB

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

II[95a] score (a five-item version of the CRIB score); the Score for Neonatal Acute Physiology (SNAP), a physiology-based illness severity score based on measurements of 26 routine clinical tests and vital signs; the SNAP-PE, an additive score based on birth weight, 5-minute Apgar score, size for gestational age, and SNAP; and SNAP II (a six-item score based on variables collected during the first 12 hours after admission).[119]

Zupancic and co-workers compared the SNAP and SNAP-PE scores, which include physiologic measures with the Vermont Oxford Network risk adjustment based on basic patient descriptors. Unexpectedly, the authors found that models based on perinatal descriptors perform similarly to those based on physiologic measures.[172]

These illness severity scores are potentially useful for comparing mortality rates and other outcomes at different NICUs. One drawback of such scores is their use of variables that are measured up to 12 hours or more after NICU admission. This raises two potential problems. The first problem, as stated by Richardson and associates, is that the longer the period of observation, "the more contaminated it becomes with the effects of successful (or unsuccessful) treatment and thus no longer reflects admission severity."[118] The second problem is that the observed severity of illness in the first hours of life may differ from the observed severity of illness in the very same infant in the first 6 hours following transfer and admission to another unit.

The Transport Risk Index of Physiologic Stability (TRIPS) is a scoring system that was developed to assess infant transport care. Based on the collection of only four variables (temperature, respiratory status, systolic blood pressure, and response to noxious stimuli), this approach predicted 7-day survival (area under the receiver operating curve [AROC] of 0.83) and severe intraventricular hemorrhage (AROC of 0.74).[75] This scoring system has also been used to evaluate the effectiveness of different Canadian transport systems. An advantage of this score is that it assesses infant condition in a time frame that is not limited to the first 24 hours of life with very high prediction characteristics. CPQCC modified TRIPS to take into account the use of cardiac pressor medications and the level of oxygen in intubated infants and obtained an AROC for prediction of 7-day survival of 0.88 in all infants and 0.86 in infants transported after day 7 (calculator available at http://www.health-info-solutions.com/CPQCC-CPeTS/tripsmobile/tripsmobile.html). CPQCC also developed a quality of transport estimate, the Quality Change Point 10th Percentile (QCP 10), a benchmark of the greatest deterioration in TRIPS score seen in 10% of the transports by top performing teams. The risk of death increased 2.4-fold in infants whose deterioration exceeded the QCP 10.[34]

Tyson and colleagues have used the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network database to develop a multivariable model to predict survival and neurodevelopmental outcome for preterm infants of 22 to 25 weeks' gestation based on birth weight, gestational age, gender, multiplicity, and antenatal steroid status.[153] This estimation has been validated in a population-based cohort that includes a diverse group of community and academic NICUs.[69] An online calculator is available to estimate survival and survival free of disability for specific values of the five variables in the model (http://www.nichd.nih.gov/about/org/cdbpm/pp/prog_epbo/epbo_case.cfm). While the data used for the calculator are dated, an updated version is under construction.

Another group of variables that may be included in datasets are identifiers. Because of the requirements of Health Insurance Portability and Accountability Act (HIPAA), it may be safer to remove personal identifiers such as name and medical record numbers when using data for quality improvement. However, at stages of development when identifiers are available, the opportunity exists for linkage to other datasets so as to increase the breadth of data for quality assessment and risk adjustment. However, even when identifiers are not available, strategies for data linkage in perinatal care exist by using combinations of variables such as birth weight, gender, hospital of birth, and maternal data, as described in the next section.

Although the importance of risk adjustment for fair comparison of quality among providers has been discussed, there are two other important aspects regarding patient characteristics. Intrinsic to the risk-adjustment process is estimation of the contribution of risk factors to the outcome of interest. First, by identifying certain characteristics that are associated with an adverse outcome, we may learn about the physiology of a disease process, as well as identify high-risk groups for study or intervention. Second, in some instances, it may be beneficial to use observed rates in assessment without considering patient characteristics for risk adjustment. This may be true for processes in which health care systems and clinicians would play a larger role than biologic factors. For example, regardless of patient characteristics, it may be argued that processes such as antenatal steroid administration or retinopathy of prematurity screening may be a reasonable goal for all eligible infants, regardless of sociodemographic factors. For example, risk adjustment for race/ethnicity for these measures could have the potential to perpetuate disparities in care.

Data Sources

Considering the data elements that are required for quality improvement, we can consider the concept of "green data" or recycling of existing datasets for several purposes. Although quality improvement in health care may have started as an "extra" component of clinical care or a hobby for interested doctors, nurses, and administrators, it has now become an integral component of daily workflow. Because of this increasing emphasis on quality improvement, there has also been a demand for data collection for this purpose. Although some data may be collected specifically for the purpose of quality improvement, currently available data such as hospital administrative data and vital statistics may allow for increased efficiency.

Administrative Data

Examples of secondary datasets that have been used to evaluate quality of care are the hospital discharge database, billing data, and files that link birth certificates and death certificates. Although these secondary databases were not primarily designed for evaluating perinatal care, they contain data elements that have made it possible to examine risk-adjusted perinatal complication rates, maternal morbidities,[80] cesarean delivery, and neonatal readmission rates. Although secondary datasets can provide useful information, the accuracy and completeness of reporting poses a potentially important limitation.

A major advantage of using secondary data is the potential for increased efficiency. However, there are also several potential disadvantages. Because the original design may not have considered its use for quality improvement, secondary data sources may not have all of the desired data items. Data definitions might not be appropriate or the same as those used in other NICUs. In some instances, there may be inadequate standards for accuracy. For example, demographic information, prenatal care, mode of delivery, and birth weight tend to be fairly reliable on birth certificates.[31] However, the presence of congenital anomalies, an important item because of the high degree of complexity and mortality in this group, is markedly underreported on both birth and death certificates.

Linked birth and death certificate files are an important source of population-based studies of factors that affect perinatal outcomes. These studies span a wide range of areas (e.g., the effect of the increase in multiple births on infant mortality, labor outcomes at advanced maternal age,[95] factors associated with the birth of infants with very low birth weight at non-NICU hospitals,[33] trends in cesarean delivery for various conditions,[68,71] and quality assessment of perinatal regionalization). There are both advantages and disadvantages of using vital records for quality improvement purposes.[31] However, to maximize the potential usefulness of vital records, clinicians must become actively involved in ensuring their uniformity of definition, accuracy, and completeness.

The hospital discharge abstract can be a useful data source for evaluating neonatal care. The US Department of Health and Human Services mandates that a uniform hospital discharge dataset, which includes 14 core data items, be submitted for each acute patient whose care is paid for by Medicare or Medicaid. Introduced in 1992, the most widely used format for these submissions is the Uniform Bill. UB-04 contains data items for patient identification, insurance coverage, total charges, and entries for up to five diagnostic and three procedural codes. These codes are assigned based on the International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-10-CM). UB-04 is required for hospitals submitting claims to Medicare, Medicaid, Blue Cross, and other commercial insurers. Although hospitals are not required to submit UB-04 for all neonates, most hospitals do complete this form. The Uniform Bill can provide useful information on procedures, diagnoses, and charges. The major advantage of this data source is its widespread use at a large number of institutions and its ready availability as a computer dataset at many hospitals.

Several weaknesses of this source of data must be considered, however. The Uniform Bill was designed for reimbursement, not for monitoring institutional performance or for clinical research. As a result, distortions in the data may result from attempts by hospitals to code diagnostic and procedural data with the goal of maximizing reimbursement. Significant errors in diagnostic coding may occur. For example, although some perinatal conditions such as third- and fourth-degree lacerations appeared to be coded fairly completely, the validity of a variety of perinatal conditions and procedures was quite variable, ranging from quite good to very poor. The accuracy of coding for neonatal conditions has not been studied in detail. Another problem with hospital discharge abstract data is the absence of birth weight as a data item.

One solution to the limitation of important missing variables is linkage to other data sources. Highly successful links can be established without using personal data such as names, hospital numbers, or social security numbers; instead, links can employ virtual identifiers such as postal code of residence, clinical factors, and demographic factors. California's Office of State Health Planning and Development sponsored a project to link the state-linked infant birth and death file with a modification of the UB-92 file (predecessor to the UB-04). This database allowed one to select outcomes from the ICD-9-CM and procedure codes available on the discharge billing file and adjust these outcomes based on the birth weight and clinical, demographic, and socioeconomic information from the birth certificate. Further links to this database have included the mother's discharge file for the current pregnancy as well as all infant readmission discharge files during the first year of life.

Examples of population-based studies using this linked database include the relationship between discharge timing after birth and infant readmission, shoulder dystocia, risk factors and neonatal outcomes, and neonatal outcomes in childbearing beyond the age of 40.

Preliminary analyses suggest that the ICD-10 codes contained within the UB-04 will have similar analytic functionality to their ICD-9 counterparts (personal communication, Elliot Main M.D., medical director, CMQCC).

Diagnosis-related groups or DRGs are another example of secondary data used to evaluate perinatal care. Defining case mix to be able to compare outcomes and resource use across institutions is of great importance to payers. Diagnosis-related group systems are classification schemes that use data that are routinely available in hospital discharge abstracts to group patients into relatively homogeneous categories. Outcomes and resource use are compared for similar DRGs across institutions. Because of the widespread use of DRGs, it is important for neonatologists to

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

be familiar with these systems. However, there are several serious limitations in using DRGs to assess quality. First, even with numerous DRG groups to choose from, the heterogeneity of patients within a single DRG can still be quite broad. Second, the DRG is not assessed before the clinical course of the infant and therefore can actually be influenced by the quality of care received.

Strategies to improve the collection and recording of quality indicators on secondary datasets may be an important approach to building a primary data collection system.

The California Maternal Quality Care Collaborative (www.cmqcc.org) is applying this approach by giving hospitals close to real-time (within 45 days from discharge) data based on linking the infant's birth certificate to the mother's and infant's discharge ICD-10 codes.

In addition to perinatal quality metrics, CMQCC also provides a near real-time assessment of data quality as part of an ongoing initiative to improve its administrative data sources. The confidential reports include Joint Commission perinatal metrics, which can display data on an adjustable time frame with a resolution that allows the creation of run charts to track quality improvement initiatives. The reports also contain confidential drill down analyses to identify ways to improve performance. For example, if there was an increase in early term elective delivery for a hospital (Fig. 5.4), one could examine cases over a period of time to check if there are certain diagnoses that may be contributing to an increase in the elective delivery rate. The rate of elective delivery can also be calculated by provider to see if there are opportunities to work with individuals who may be contributing most to an increased rate. A demonstration site with artificial data is available at https://demo.datacenter.cmqcc.org.

Clinical Data

Primary clinical data collection is necessary for assessing quality of care when existing data are not sufficient. However, because primary data collection is labor intensive, it is important to minimize the collection of data elements to essential components that are critical for the assessment and work of quality improvement. These data elements will consist of outcome and process measures, as well as patient characteristics for risk adjustment as described in the preceding.

Data elements should be clearly and systematically defined for both data abstractors and users of data in a manual of operations to facilitate both coding and interpretation of the data. Fair and useful benchmarking of quality measures and the study of variation in care are dependent on uniform definitions across institutions.

There are several methods for transferring these items to a database. The most efficient technique is to download information that has already been collected via an electronic medical record. In addition to its potential to provide data to inform quality improvement, the electronic medical record can also be used to facilitate standardized practice. Examples include prompts and/or requirements to perform and report ROP eye examination in preterm infants and notification that an infant with a central line has reached an enteral intake of 120 mL/kg and requires justification for continued use. Such systems will allow for the close alignment of clinical care and quality assessment.

Although this will doubtless be a major component of the standard method in the future, it is still in the early stages of development. This approach will need to be informed and iteratively improved by studies on accuracy and consistency for algorithms across centers. For example, the diagnosis of patent ductus arteriosus may be different at individual NICUs, and an objective and consistent assessment of such a variable may or may not be possible from electronic medical records.

When data are collected primarily for the purpose of quality assessment, computer-based data entry systems using local or Web-based data entry interfaces allow for efficiency in checking for errors such as missing fields or out-of-range entries. Examples include the Vermont Oxford Network, which provides members with dedicated software, eNICQ, to collect, manage, and submit standardized data, and CPQCC, which supports data submission and management with a dedicated online tool. An advantage of these systems is that they detect errors in completeness, range, and consistency as the data are being abstracted and entered. When the data entry program detects an error, it requests a valid value and does not allow data entry to proceed until it receives the correct value. The result is a clean record at the point of data entry that avoids costly off-site error detection and correction cycles. However, even with this system, it is important to use methods to minimize data entry errors, such as visual verification.

Qualitative Data

Because not everything that counts can be counted, qualitative techniques are an important set of tools that can provide practitioners with valuable insights regarding the design, execution, and outcome of quality improvement interventions. These techniques may include strategic informant interviews, focus groups, written evaluations, and observations directly or by video. So-called "mixed methods" approaches may use a variety of research tools to explore underlying themes that impact quality of care and help to discover strategies for improvement. Research in this area can address aspects of care that may not be readily collected in the medical record, such as a parent's ability to speak up to promote safety for their child in the NICU.[79]

• BOX 5.6 Lessons Learned in Quality Improvement Through Qualitative Research

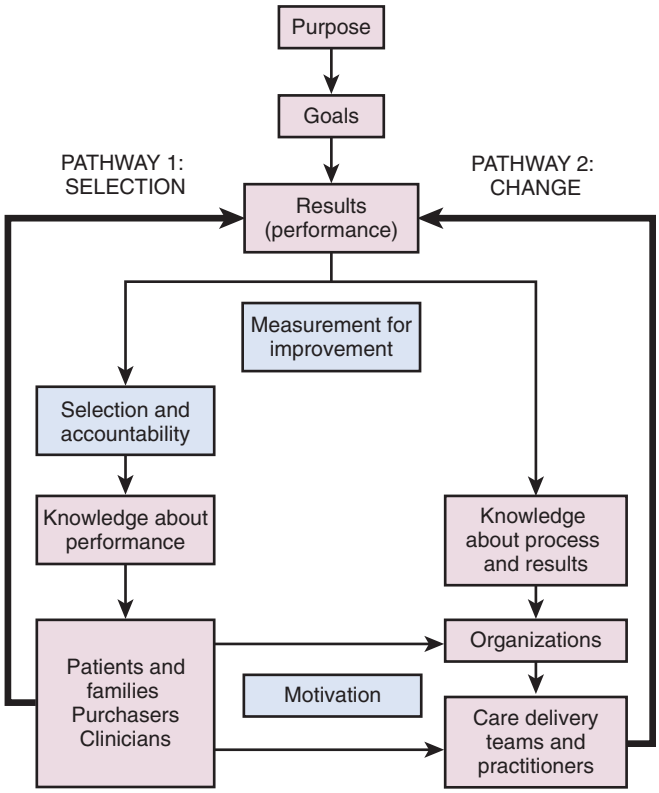
Facilitators

- Organizational structure and culture
- Previous experience with quality improvement
- Adequate resources
- Clinician engagement
- Comparative process measurement and data tracking
- Active communication among stakeholders

Barriers

- Shifting priorities
- Interruption of usual workflow
- Challenges to debriefing
- Lack of physician buy-in
- Disparities

During a quality improvement initiative or in the evaluation phase, qualitative research can help to discern which aspects of a project were the key drivers of change and what steps might be taken for similar subsequent projects. While the subject matter and aim of the project may differ, there may be common barriers and facilitators for implementation in quality improvement projects. A summary of such findings undertaken in three different projects (maternal hemorrhage, breast milk nutrition for preterm infants, delivery room management) is shown in Box 5.6.[66,73,78]



Evaluation of these data can be labor intensive in a research environment, but quality improvement teams can often rapidly extract meaningful and usable information. When there is a deficiency in care or perhaps when things are going well from a quality perspective, these approaches may help to better understand the reasons underlying the results.

Quality Measurement and Improvement

Now that the different types of data that may be available to improve quality of care delivery have been reviewed, it is necessary to consider what data are needed for what purpose and how best to present the data for each of those purposes. Quality measurement is necessary for improvement but not sufficient. Although all stakeholders, such as providers, consumers, payers, or policymakers, have an interest in improving quality of care delivery, they have different information needs and different levers to motivate or effect improvement. Berwick, James, and Coye developed a framework that divides quality measurement according to purpose into two pathways (Fig. 5.5).[12]

Pathway 1 highlights the purpose of selection. One of the main interests of stakeholders in this pathway is to gain knowledge about provider performance and to either

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• **Fig. 5.5** Pathways to Quality Improvement. (Adapted from Berwick, James, and Coye[12] to the NICU setting.)

seek out care for themselves or their constituents accordingly. Stakeholders have the ability to "motivate" providers by either forgoing care or paying less to low-performance providers.

Pathway 2 highlights the pathway of change. The stakeholders here are the organization and the frontline care providers themselves. Motivation for measurement is derived from an internal desire to optimize care delivery for organizational improvement. In the following sections, practical and theoretical considerations regarding quality measurement in these different pathways are provided, including what types of measures may be appropriate for each, recognizing the substantial overlap between them.

In general, the information need regarding the *process* of care delivery is highest for frontline providers (pathway 2), whereas stakeholders who are further removed from the organization are more interested in *outcomes* of care (pathway 1). This is not to say that frontline providers do not care about outcomes of care, rather that the process of care executed in the local care context is what delivers the outcome. Because local contexts differ, a focus on outcomes by external stakeholders and consumers sets guideposts for quality expectations and provides NICUs space for experimentation and innovation to meet them. External stakeholders should avoid a proscriptive focus on process measurement, unless the supporting scientific evidence is strong (e.g., antenatal steroid administration for preterm infants <34 weeks' gestational age).

It is important to recognize that data collection costs of individual institutions are significant, potentially diverting resources from other care priorities. Possibly with the advent of functional electronic health records, these collection costs will drop. However, until then, it is necessary for external stakeholders and quality improvement practitioners to be parsimonious in their choice of quality measures.

Data for Selection

There is an increasing demand for transparency and public reporting of quality in health care to spur consumer choice, allow for performance-based reimbursement, and ultimately improve processes and outcomes of care. Further research is required to identify the best models for predicting neonatal risk and to determine their precision in identifying individual cases or institutions with poor quality of care. However, even without a firm foundation in research, risk-adjusted comparisons of NICUs will become more common. The public release of risk-adjusted comparisons of a variety of safety and quality measures using administrative and claims data for US hospitals by the Centers for Medicare and Medicaid Services is an example of this phenomenon (http://www.cms.gov/Medicare/Quality-Initiatives-Patient-Assessment-Instruments/HospitalQualityInits/OutcomeMeasures.html).

The Leapfrog Group, a consortium of Fortune 500 companies, provides hospital-specific performance data to the public. Although measurement of perinatal care is limited, the group does provide a rating of quality of care for high-risk deliveries, defined as the care provided for VLBW infants (http://www.leapfroggroup.org/). Neonatologists must understand the strengths and weaknesses of different methods for making risk-adjusted comparisons of neonatal outcomes as they attempt to assist the public in understanding these data and to use the data themselves to monitor, evaluate, and improve the quality of care that they provide.

One of the rationales for public reporting of health care quality is the concept that the existence of such reports motivates and influences providers and organizations to improve their quality of care. The Agency for Healthcare Research and Quality has promoted the use of public reporting and guided its implementation for many organizations (http://www.talkingquality.ahrq.gov/about.htm). Although there needs to be continued research on the impact of public reporting on health care quality, thus far results are mixed. Public reports do not appear to inform consumer choice significantly, and improvements in quality measures are moderate at best.[116]

Another source of ratings of health care quality is lay press sources such as *US News & World Report,* which has produced a popular series of "Best Hospitals" and "Best Children's Hospitals." Consumer Reports (www.consumerreports.org) is another consumer-oriented organization that presents hospital quality assessments. These sources have not been well validated and have shown conflicting results with other measurement tools.[93] These publications generally use league tables (rank ordering of institutions) and can

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

provide an idea of how one center might compare with other similar centers for specific measures. However, the interpretation of league tables must be informed by the context of reliability of measurements, adequate risk adjustment, and consistency of results as what may appear to be an orderly ranking may not ultimately denote significant differences between NICUs. For example, in a league table the difference between a top and middle performer may not be clinically or statistically significant. Nevertheless, hospitals feature such ratings prominently in marketing their services, and substantial intramural efforts are devoted to maximizing ratings.

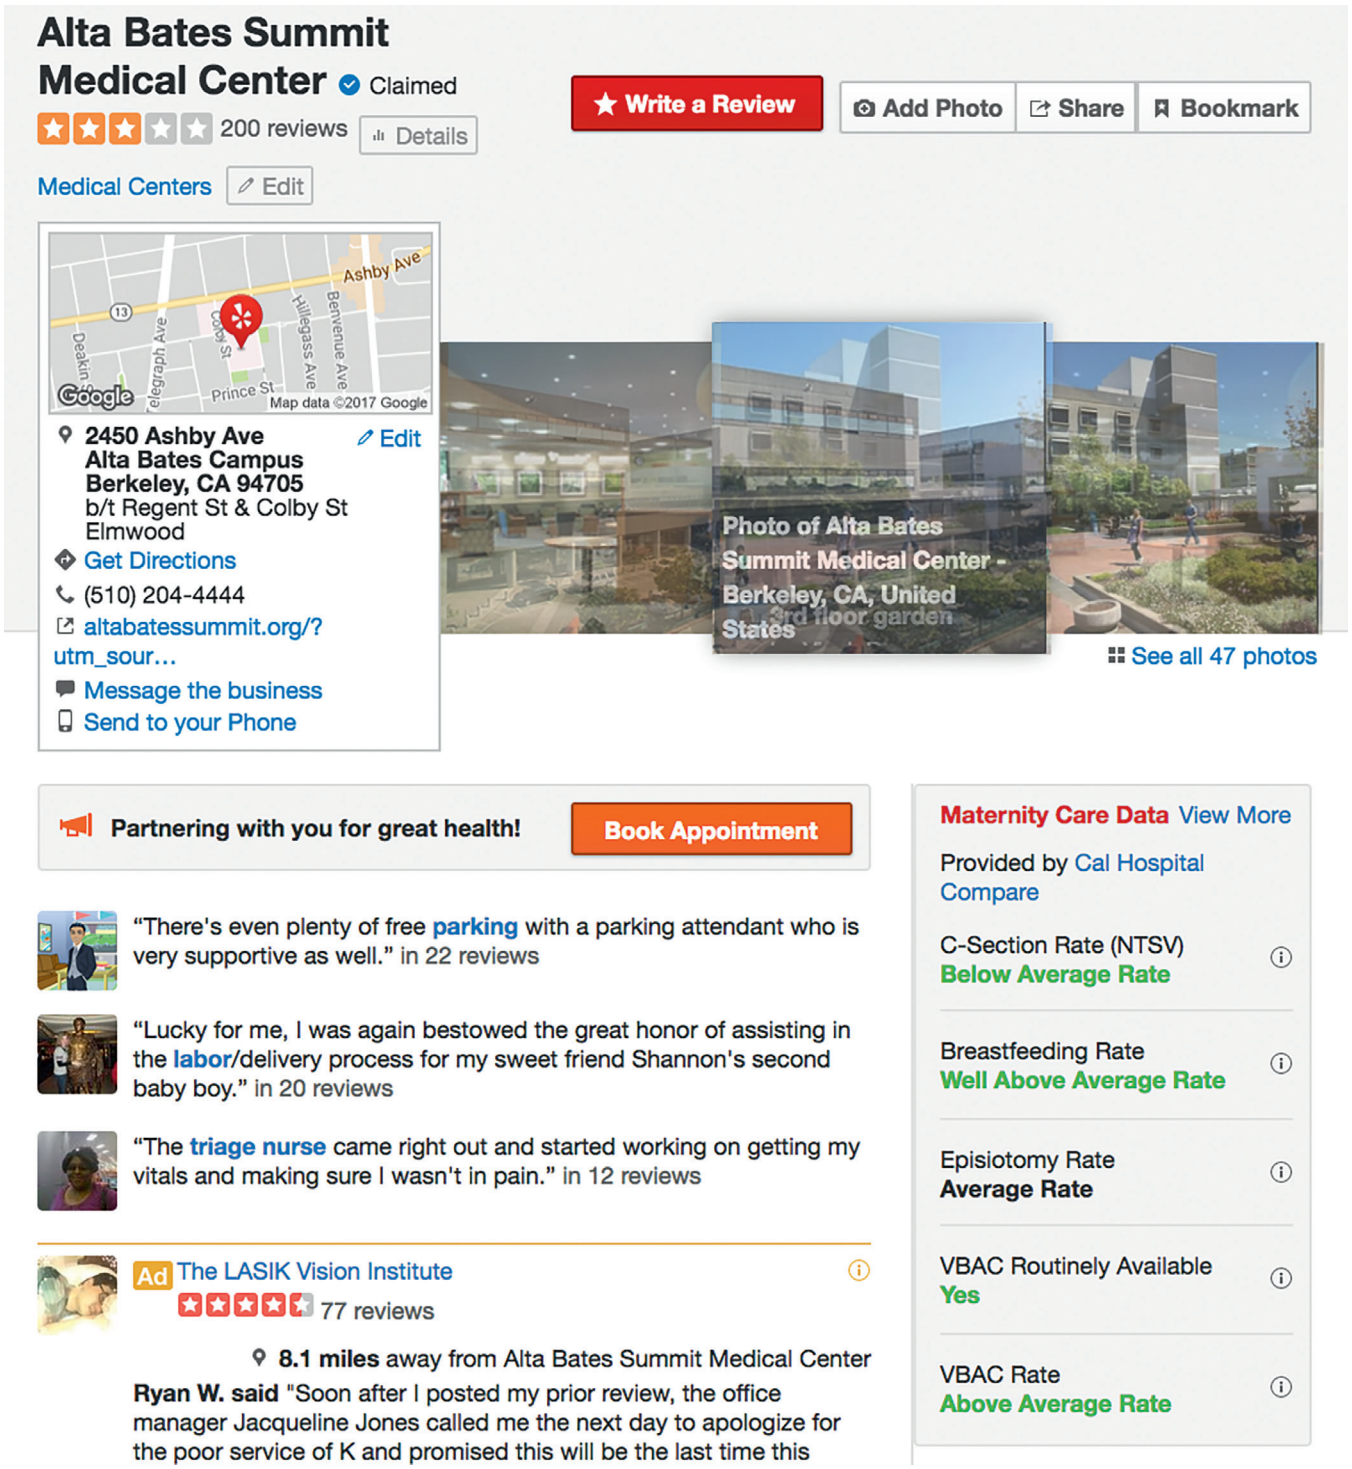
The use of public reporting for perinatal care is relatively underdeveloped. However, it may be an untapped strategy for improving quality. Women of childbearing age are among the most frequent users of the Internet, and pregnancy is the featured topic of many websites geared toward this group. Studies have shown that women in general, and specifically expectant and current mothers, view the Internet as a way to connect to other women having similar experiences and to share information with one another so that each woman who finds a public reporting website useful may communicate that experience to others. Although providers may be wary of the validity of publicly reported quality information on neonatal and maternal care and outcomes, websites are increasingly making such information available. For example, Yelp is now showing several perinatal indicators as a standard feature (Fig. 5.6).

National Quality Measures

Interest in quality assessment continues to increase for perinatal medicine. An important development in ensuring that proposed measures can actually reflect the quality of care has been the work of the National Quality Forum (NQF) (www.qualityforum.org), a multi-stakeholder group that evaluates proposed quality measures. In considering measures, several important areas are assessed, including the importance of the measure to making significant gains in health care quality, the measure's reliability and validity, the extent to which the results can be understood and be useful for decision making, and the feasibility of collection. The Joint Commission published a list of core perinatal measures in 2007. A list of current measures from the NQF is noted in Table 5.1. When considering a potential measure for widespread use, it is important to have evidence that the aspect of care that the measure reflects has been shown to be malleable, that is, shown to be improvable, in at least one multi-institutional quality improvement initiative.

Although the list of quality measures continues to grow, it may become overwhelming for stakeholders, including clinicians, payers, and consumers, to extract a meaningful global picture of quality of care delivery at a given NICU. In addition, Profit and colleagues demonstrated that correlations between quality measures of the care provided to VLBW infants are generally weak, meaning that it is difficult to infer overall quality of care delivery based on a small subset of clinical measures. Strategies for global assessments of quality may provide a more comprehensive assessment.[90] Two of these are explored in the next section.

Data for Improvement



Although so far the collection and presentation of data for provider selection has been discussed, the active work of quality improvement requires different considerations. First, as the purpose of data collection for quality improvement is geared toward identifying potential areas of need and tracking change as soon as possible, there may be a lower threshold for identifying what might be considered an outlying value. In other words, data that are "good enough" to expose areas sorely in need of improvement may be better than waiting for "perfect" data. Second, there may be additional demands for data collection. Although some of the data sources noted in the preceding may allow for facilitation of quality improvement activities to some extent, there are several other aspects of data necessary for active quality improvement, or data collections that may allow a specific question in quality improvement to be answered.

When data are analyzed for the purposes of benchmarking and comparisons, historical data that are collected over a stable period of time may be optimal. However, in the midst of an effort to improve quality for specific processes or outcomes, data will need to be collected and presented in or close to real time.

A strategic aspect of data collection for quality improvement may be the need for additional process measures to be collected. For example, in an effort to increase temperature of very preterm infants at delivery, there may be several important variables that could contribute to this effort, including delivery room temperature, use of devices such as plastic wrap or chemical warming mattress, and use of checklist or noting of adequate team communication before delivery. Another example could be a project to reduce central line infections, in which the team may want to collect data on whether a line insertion or maintenance checklist is being followed, number of line days, and whether the line necessity is being assessed regularly. Although temperature and the presence of an infection may already be part of real-time data collection, the other data elements may not be typically collected or even noted in the medical record in a systematic fashion but may be crucial in the quality improvement process. During the quality improvement project, this data may be collected to facilitate the quality improvement cycle and identify areas for improvement. These data can be tracked and assessed on a regular basis by the quality improvement team.

When several groups participate together in a collaborative to improve quality, an extranet may serve as a common data repository and serve several useful purposes. First, it allows for the systematic collection of data as described in the preceding in real time and for the specific purpose of the quality improvement project. Second, it allows each center to assess how it is doing compared with other groups and therefore to identify areas for improvement. Third, it

• **Fig. 5.6** Yelp ratings of maternity care in California.

can give insight into what processes may be most important to the main outcome of interest for the quality improvement project. The Institute for Healthcare Improvement (IHI) provides the opportunity for multicenter collaborative groups to enter and track data in real time (www.ihi.org).

An essential purpose of data assessment of provider performance is to serve as an agent for change. To fulfill this purpose, data must be available in a timely manner. Data that are too old cannot inform decision making reliably. Because of the lengthy hospitalization of the very premature infant, it may be useful to review data at the end of the first 28 days as well as at discharge. This strategy facilitates the timely analysis of neonatal outcomes.

The format in which data reports are produced and distributed is evolving from fixed, periodic (i.e., annual) reports to more flexible reporting that also allows for user

TABLE 5.1 Perinatal and Reproductive Health Measures Endorsed by the National Quality Forum (2016)

Quality Measures	Brief Description	Source
Reproductive Health		
Chlamydia screening in women	The percentage of women 16-24 years of age who were identified as sexually active and who had at least one test for chlamydia during the measurement year.	National Committee for Quality Assurance
Contraceptive care	Three measures (for women aged 15-44 years): a) Most & moderately effective methods b) Postpartum c) Access to long acting reversible contraception	US Office of Population Affairs
Labor and Delivery		
Elective delivery	Patients with elective vaginal deliveries or elective cesarean sections at ≥37 and <39 weeks of gestation completed.	Joint Commission
Incidence of episiotomy	Rate of episiotomy.	Christiana Care Health System
Cesarean section	Nulliparous women with a term, singleton baby in a vertex position delivered by cesarean section.	Joint Commission
Labor and Delivery – High Risk Pregnancy		
Antenatal steroids	Patients at risk of preterm delivery at ≥24 and <32 weeks' gestation receiving antenatal steroids before delivering preterm newborns.	Joint Commission
Newborn		
Unexpected complications in term newborns	Hospital level performance score reported as the percent of infants with unexpected newborn complications among full-term newborns with no preexisting conditions.	California Maternal Quality Care Collaborative
Hepatitis B vaccine coverage	Hepatitis B vaccination coverage among all live newborn infants before hospital or birthing facility discharge.	Centers for Disease Control and Prevention
Newborn Premature/Low Birth Weight		
Percentage of low birth weight births	The percentage of births with birth weight <2,500 grams.	Centers for Disease Control and Prevention
Late sepsis or meningitis in VLBW infants	Risk-adjusted rate of late-onset sepsis or meningitis in very low birth weight neonates.	Vermont Oxford Network
Neonatal blood stream infection rate	Infection rate for VLBW infants.	Agency for Healthcare Research and Quality
Health care–associated bloodstream infections in newborns	Staphylococcal and gram-negative septicemia or bacteremia in high-risk newborns.	Joint Commission
Retinopathy screening	Proportion of infants 22 to 29 weeks' gestational age screened for retinopathy of prematurity.	Vermont Oxford Network
Postpartum		
Exclusive breast milk feeding	Exclusive breast milk feeding during the newborn's entire hospitalization.	Joint Commission

VLBW, very low birth weight.

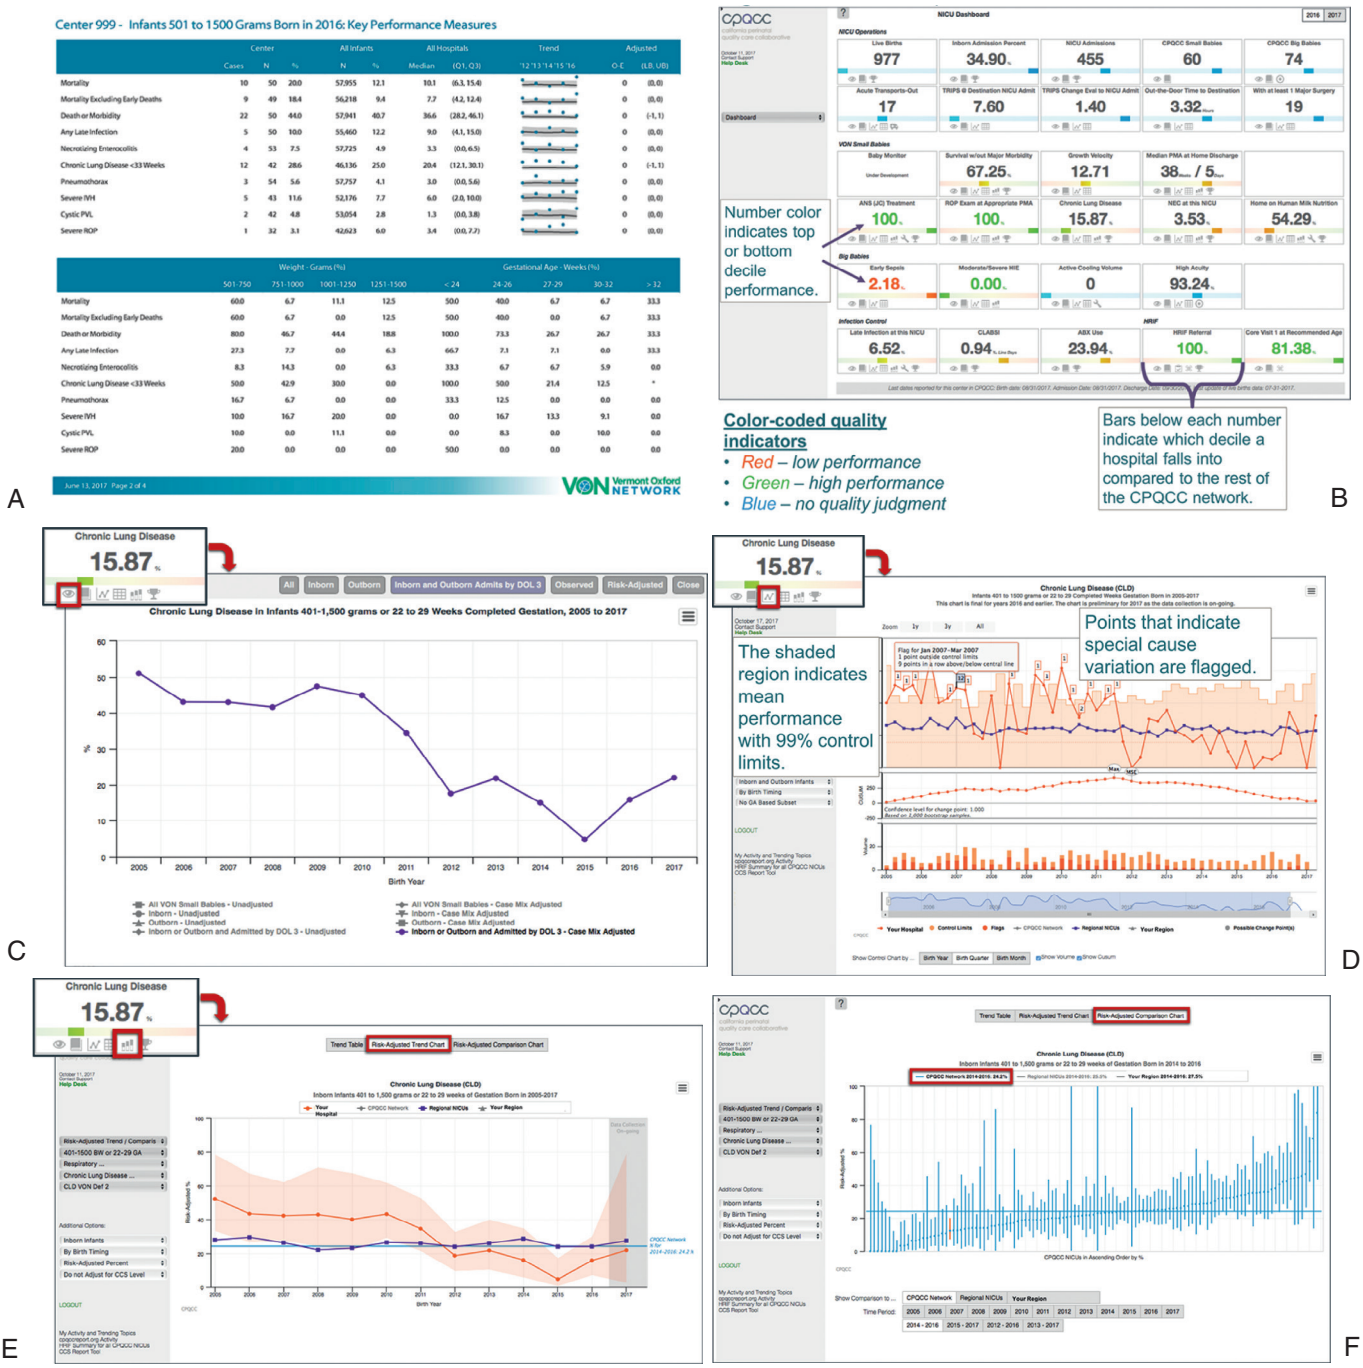
choice in measures presented, time period, comparison groups, and type of presentation. The Vermont Oxford Network Nightingale Internet Reporting System provides users with secure real-time access to all data submitted since 1990, allows users to track trends over time, and enables them to compare their unit's performance with the Network as a whole and with predefined subgroups of units similar to their own. Annual center-specific reports provide additional information on rates of key performance measures compared with the Network, trends over time, and estimates of the Observed minus Expected (O-E) number of cases (see Fig. 5.7*A*). The CPQCC also provides its members with Web-based reports (www.cpqccreport.org). The CPQCC Web-based system has an integrated data entry and report structure that generates confidential individual member reports and network-wide benchmark metrics in real time. Advantages of electronic media reports are the ease of performing local secondary data analysis as well as the ability to easily incorporate the report's tables and figures into local customized presentations. The presentation of a hospital's data in comparison with that from other NICUs in a network plays an important role in motivating quality improvement activities.[167] Although the user can take advantage of the multiple features for selection of data presentation, there is also the option of a simpler "NICU dashboard" that presents crucial quality measures for recent years (Fig. 5.7*B*). This dashboard shows case mix–adjusted individual NICU's performance in comparison to its peers. Other features of CPQCC's online reports are shown in Fig. 5.7*C-F*.

Run charts (Fig. 5.7*C*) and standardized process control (SPC) charts (Fig. 5.7*D*) are powerful tools for quality improvement.[98] A run chart displays a series of data according to a criterion, usually time. Time is recorded on the x-axis, and the quality indicator is shown on the y-axis. This simple run chart can provide important insights regarding trends and variation in the process that results in the quality indicator. A Shewhart chart or SPC chart similarly tracks a quality indicator over time. This chart utilizes the mean or median and statistical control limits (two [95%] or three standard deviations [99%]). Run charts and SPC charts may differ in identifying a significant change in the process[98]; the following rules are used at the CPQCC to identify trends and special cause variation: observed point is outside the control limit (external disturbance); nine points in a row above or below the central line (process shift); six points in a row steadily increasing or decreasing (process shift); fourteen points in a row alternating up and down (source of variability).

To further aid with the interpretation of a control chart, the method of change point analysis was adopted.[164] Change point analysis looks at the trend observed over a period of time and attempts to find likely points of change. For the CPQCC change point analysis, CUSUMs (cumulative sum control charts) are calculated, which use cumulative derivations from the mean over time to identify changes in underlying trends. A segment of a CUSUM chart with an upward slope indicates a period where the values tend to be above the overall average; a segment of a CUSUM chart with a downward slope indicates a period where the values tend to be below the overall average. A change in direction of the CUSUM might indicate a sudden shift or change in the average. Whether such a change point represents a significant new trend is extracted using statistical methods.

In addition to these charts, which are not case mix adjusted, users are able to query risk adjusted trend charts (Fig. 5.7*E*) and comparison charts (Fig. 5.7*F*). Various subgroup analyses can be conducted to provide further specificity.

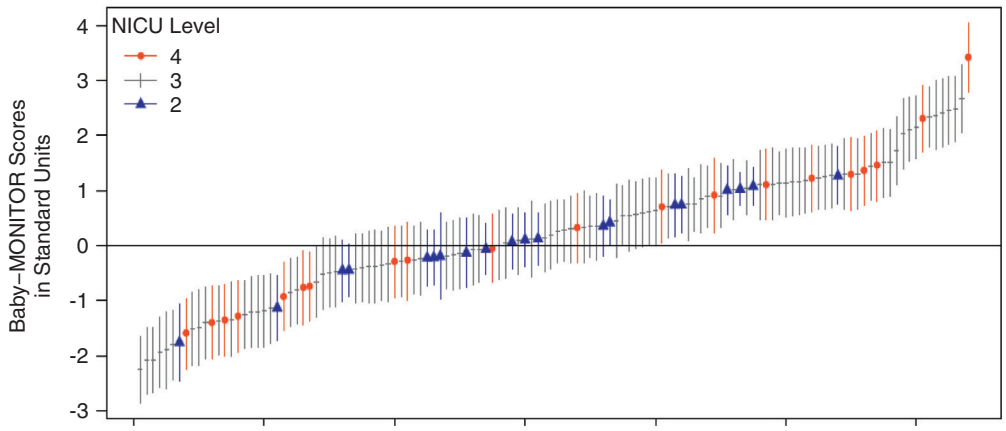
Global Assessments of Perinatal Quality: The Value Compass



One approach to comprehensively monitor quality of care delivery is via a balanced scorecard. In a scorecard, measures are generally displayed in various separate care domains. A particularly refined and comprehensive adaptation of this approach is the Value Compass by Nelson and colleagues.[91] The four value compass directions are: clinical status, functional capacity, satisfaction, and costs. Through the inclusion of patient satisfaction and cost, the value compass pays deliberate tribute to the informational needs of nonclinical stakeholders, including families and administrators. The aim of the Value Compass is to provide stakeholders with a balanced set of variables that enables them to design, implement, and sustain meaningful improvements that all stakeholders recognize as important. The ability to assess performance on individual measures and potential tradeoffs in performance is a strength of the balanced scorecard. However, the scorecard's granularity may also limit the user's ability to assess overall quality progress. Such a global assessment requires a further level of aggregation.

Global Assessments of Perinatal Quality: The Baby-MONITOR

Another method to cut through the thicket of individual quality measures is to combine them meaningfully into a composite indicator. To simplify the presentation of quality assessment, a composite quality rating may ultimately serve as a simple way to quickly assess quality. The Baby-MONITOR, developed by Profit and colleagues, is an attempt at providing such a simplified global assessment tool.



Composite indicators of quality are aggregates of individual measures of quality. During the aggregation process, developers have to make certain editorial choices with regard to the quality measures combination. For example, measures have to be normalized to a common unit. Each measure in the composite needs to assume a weight relative to the others. Most commonly, an equal weighting scheme is applied by developers, but this need not be so. Users may have differential preferences for individual measures. Finally, during the aggregation phase developers might consider to

• **Fig. 5.8** Distribution of composite scores in 22 California NICUs.

what degree they might allow NICUs to compensate for poor performance in one area with good performance in another. Addition of measures would allow full compensation; multiplication of measures allows only partial compensation, giving preference to NICUs that perform average to those with positive and negative outliers. There are also noncompensatory techniques. These choices require that the development of composite indicators proceed in an explicit, systematic, and transparent manner, and that the impact of the developers' choices on NICU performance ratings is subjected to sensitivity analysis.

The Baby-MONITOR is an aggregate of nine measures of quality routinely collected by members of the VON and the CPQCC. The nine measures were selected by an expert panel and validated by a sample of clinicians.[62,111] Quality measures are risk-adjusted, standardized by calculating an observed-expected event ratio, and equally weighted and averaged. Fig. 5.8 shows an example of a distribution of composite scores among 22 California NICUs. Sensitivity analysis invoking different aggregation and weighting schemes showed the Baby-MONITOR to be robust. Subsequent use has shown large variation across California NICUs by level of care[106] and by race/ethnicity.[107]

Another composite measure of NICU outcomes developed by Kaempf aggregates eight measures in a "benefit" measure and divides these by length of stay in a "value" measure.[55] These first formal iterations of composite indicators need to be validated against neurodevelopmental outcomes but provide a yardstick for the future development of multidimensional quality measures.

Although composite measurement is still in its early days, such a tool may prove useful in a variety of ways. It may allow users to monitor overall progress on key quality measures as well as to summarily assess the effect of quality interventions on performance. Through a more holistic focus, composite measurement may provide an incentive for NICUs to engage in systems-based quality improvement efforts that have the potential to affect multiple aspects of quality simultaneously. In addition, it may facilitate discussions with other stakeholder groups on quality of care. Without a comprehensive assessment tool of quality of care delivery, external stakeholders may increasingly subject NICUs to piecemeal appraisals that may not do justice to their overall performance.

Quality and Safety Applied

The previous sections have focused on the history, theoretical frameworks, and data necessities that underpin quality improvement work either at the individual unit or the health system level. Neonatology has been at the vanguard of the quality improvement field. Experimentation and refinement of applied methods occur in a large variety of formats. Neonatal providers undertake improvement work at the individual unit level and in collaboration with vast networks. Formats include in-person or Web-based collaboration, and methods for improvement use quantitative as well as qualitative techniques. Neonatology has also been a leader in engaging families in improvement work (Box 5.7).[39] Over time, there has been a transition from efforts of individuals to NICU-wide efforts to network-based efforts. Increasingly, these efforts engage multiple stakeholders, including families, providers, payers, purchasers, and regulators. In this section is an example of a practical real-world quality improvement project that highlights some of the successes and failures that beset many similar projects. This example also makes use of a small subset of management tools used in such projects.

Local Quality Improvement Applied: An Example

The example NICU experienced an unexpected string of inadvertent extubations after introduction of a new

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• BOX 5.7 Family Engagement in Quality Improvement

There is an increasing recognition that involving family members in health care decisions and processes can improve safety and quality. This is particularly evident in the NICU, where the families, however they are defined, are essential to an infant's health and well-being and are allies for quality and safety within the health care system. The importance of the parental perspective in quality and safety in the NICU makes it imperative to include parents in multiple roles in quality improvement activities. Strategies for promoting family engagement in hospital safety and quality are to:

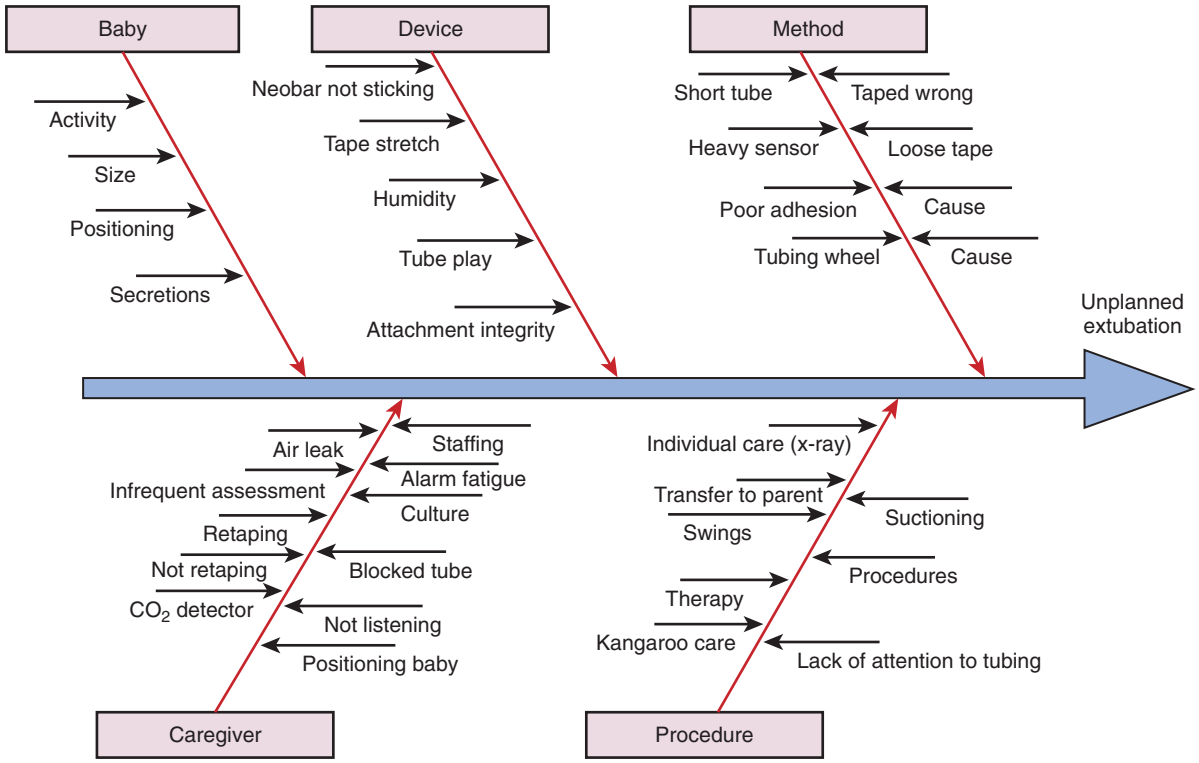
- Engage parents to participate as advisors, working team members, leaders, and faculty in all quality improvement activities.
- Promote effective communication among families and health care professionals so that family knowledge, values, beliefs, and cultural backgrounds are incorporated into the planning and delivery of care.
- Provide timely, complete, and accurate information to families to enhance their participation in care and decision making.
- Involve families in discharge planning throughout the hospital stay.

Adapted from Agency for Healthcare Research and Quality: Guide to patient and family engagement in hospital quality and safety. https://www.ahrq.gov/professionals/systems/hospital/engagingfamilies/index.html; Conway JB, Celenza J, Abraham MR. Advancing patient- and family-centered newborn intensive care. In: Horbar JD, Leahy K, Handyside J, eds. *NICQ 2007: Improvement in Action*. Burlington, VT: Vermont Oxford Network; 2010. http://www.vtoxford.org/quality/ebook/NICQ_2007_Chapter_1.pdf. Accessed November 3, 2017.

endotracheal tube securement device, prompting an effort to reduce such events. A multidisciplinary team, composed of a physician champion, a neonatal nurse practitioner, a nurse, a respiratory therapist, and a parent advisor was formed. The team developed the following aim statement: "To reduce the inadvertent extubation rate in infants in the Newborn Center by 50% within 12 months." Inadvertent extubations were defined as those not ordered by a physician or nurse practitioner.

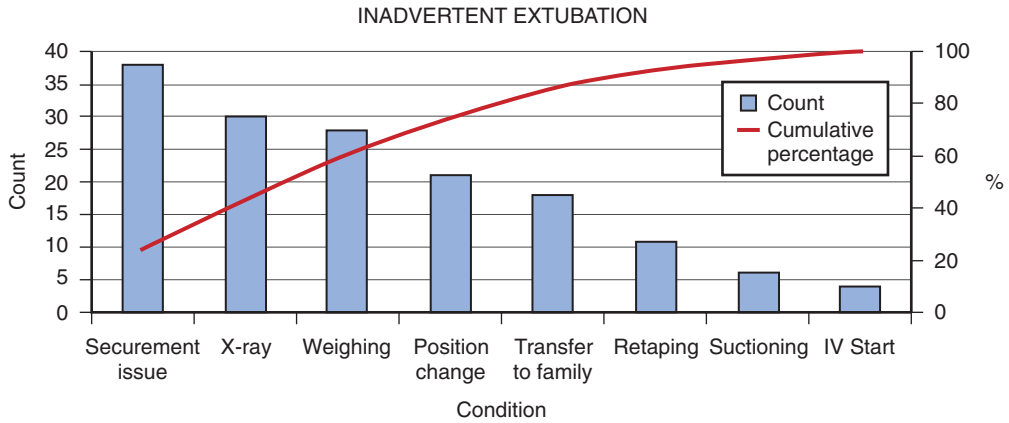
The team began with a brainstorming session, in which members considered factors that contributed to inadvertent extubations. All ideas were collected and grouped in themes, such as baby, device, method, caregiver, and procedure. These themes were then graphed in a fishbone diagram (Fig. 5.9) for clarity. Factors were then assessed with regard to whether they were amenable to intervention and with regard to their likely importance as contributors to inadvertent extubations. A resulting small set of factors was extracted, and over the course of the next several weeks, the team followed up each inadvertent extubation with a key informant interview (usually the bedside nurse present during the extubation). Results were tallied and graphed in a Pareto chart (Fig. 5.10). Based on this information, the team developed a driver diagram (Fig. 5.11), a version of a cause-and-effect diagram, which clarified the team's perceived linkages between the overall aim and key change strategies for achieving the aim as well as change hypotheses. The change strategies were introduced in successive PDSA cycles.

The primary outcome measure was the number of inadvertent extubations per 100 ventilator days. The team recognized several barriers to change, including staff resistance to the new securement method and concern regarding increased mobility of the endotracheal tube with this device, as well as its cost. Because of the recognition of potential risks of fewer inadvertent extubations, such as prolonged intubation, several balancing measures, including the number of days on nasal continuous positive airway pressure and the rate of chronic lung disease, were followed. These measures were already being collected as part of the NICU's membership in the Vermont Oxford Network.



The planned interventions were presented to the service, revised as needed, and approved for implementation. A staff education plan was devised and implemented. Small cycles of change were used to further refine process details. A process control chart was set up (Fig. 5.12), and caregivers received intermittent project updates. As can be gleaned from Fig. 5.12, introduction of the securement device led to a further spike in extubation rates beyond the control limit, indicating special cause variation. The new baseline is displayed. After successive implementation of the change ideas, extubation rates dropped substantially (again special cause variation), prompting another resetting of the baseline. After these initial successes, a renewed deterioration in inadvertent extubation rates occurred when caregiver attention was diverted by the introduction of a new electronic health record. This period spotlights a common concern for quality improvement practitioners, the difficulty of holding the gains, bringing us to our next section.

Sustainability



While there are now many examples of successful quality improvement projects, less is known about sustainability, particularly after resource-intensive projects. The goal to sustain improvement may rely on two potential strategies. One is to design an intervention such that new processes are seamlessly integrated into unit workflows and do not rely on extra effort by staff. Another approach may be to create a culture of improvement rather than just focusing on the intervention itself, where improvement becomes "the way we do things around here." Quality improvement, as with many other skills, may benefit from practice and experience. Indeed, hospitals participating in a California Maternal Quality Care Collaborative project had greater improvement if they had experience participating in a previous quality improvement project.[81]

In a qualitative study of CPQCC NICUs, factors perceived to give the best chance for sustained improvement included the following themes: incorporation into daily work flow, advanced approach to staff education, multidisciplinary team involvement with emphasis on physician buy-in, and a data-driven feedback system.[146] As quality

• **Fig. 5.12** Sample process control chart. U-chart demonstrating the weekly extubation rate per 100 ventilator days. The type of chart used depends on the type of data collected. Breaks in the baseline are shown based on the introduction of new interventions or with signs of "special cause variation," that is, weekly extubation rates exceeding the upper or lower control limits. (To maintain clarity, we elected to reset the baseline at each special cause event.) EHR, Electronic health record; ETT, endotracheal tube; LCL, lower control limit; UCL, upper control limit; X bar indicates the mean.

leaders consider how to advance overall quality in their institutions, attention to both the project at hand and the culture of a unit may be beneficial. Focusing too intensely on just the main aim of the project may lead to team members concluding that their quality work is complete after achieving that aim.

The Institute for Healthcare Improvement has published a White Paper on "Sustaining Improvement," which provides further theoretical frameworks for sustainability and some practical suggestions.[129] This resource focuses primarily on organizational structure and management and how that context can provide optimal opportunities for sustained improvement.

As quality improvement science advances, sustainability will increasingly be considered as part of the goal. A few potential strategies could be tested. One may be to "wean down" from a complete intervention to a lighter version, such as reducing the set of measurements to a minimal set needed to track progress. Another strategy could be to keep motivation going by periodic "reunions" of staff to celebrate accomplishments. Another could be training the whole staff in a specific quality improvement methodology, with forums for staff to implement their own projects. Sustainability is an active topic of quality improvement research.

Quality Improvement Research

The evidence-based movement in medicine has been a hallmark of our time, and the randomized controlled trial has emerged as the gold standard by which research studies are judged and whereby clinicians adopt certain practices. However, the dissemination and implementation of evidence-based practices is not always an easy task. It has been noted that the time for new knowledge generated by clinical trials to be incorporated into general practice may be 17 years. Therefore, one could argue that the study of the translation of evidence into practice is a crucial subsequent step in maximizing and expediting the impact of the discoveries made in clinical trials.[67] The study of quality improvement activities may sometimes not be amenable to a traditional trial, and such a trial may not be the optimal approach. Nevertheless, rigorous research is needed to avoid the adoption of inferior or ineffective practices in the name of quality improvement.

The importance of publishing and, therefore, disseminating the results of quality improvement projects has been recognized by the pediatric community, with the journal *Pediatrics* establishing a "Quality Reports" section since 2011. Another recognition by the broader medical community of the importance of quality improvement research has been the formation of the Standards for Quality Improvement Reporting Excellence (SQUIRE) guidelines (Table 5.2). These guidelines and their 2.0 iteration were established to promote rigor in designing and reporting quality improvement research.[92] Although the usual conventions for publishing scientific papers largely apply, the SQUIRE guidelines recognize several relatively unique aspects of quality improvement research. First, although a rigorous clinical trial requires prespecification of patient groups and interventions, the course of a quality improvement study may be somewhat dynamic. Improvement strategies may be modified in response to feedbacks from the ongoing project. The results of a clinical trial are "hidden" until the end of the study to avoid bias and change of behavior from the investigators. On the other hand, the clinicians involved in a quality improvement project may continuously try to learn from the contextual environment and ongoing results and subsequently modify their behavior to increase the impact of the intervention.

For the mentioned reasons, Berwick has referred to randomized controlled trials as being "an impoverished way to learn" in the context of quality improvement, suggesting that learning from experience "while doing" can be an important part of improving the quality of care.[9] In a simulation study comparing "learning" and putting into practice findings from significant randomized trials only versus quality improvement collaborative projects, the quality improvement model was found to be a potentially superior approach.[23]

In addition to the aspect of learning while doing, a patient-level randomization study for quality improvement may not be feasible as improvement activities on intervention subjects in a single NICU, whether patients or clinicians are likely to contaminate the control group. Approaches such as cluster randomization or step wedge

TABLE 5.2 SQUIRE 2.0 (Standards for Quality Improvement Reporting Excellence) Guidelines

Title and Abstract	
1. Title	Indicate that the manuscript concerns an initiative to improve health care (broadly defined to include the quality, safety, effectiveness, patient-centeredness, timeliness, cost, efficiency, and equity of health care).
2. Abstract	a. Provide adequate information to aid in searching and indexing. b. Summarize all key information from various sections of the text using the abstract format of the intended publication or a structured summary such as: background, local problem, methods, interventions, results, conclusions.
Introduction	***Why Did You Start?***
3. Problem description	Nature and significance of the local problem
4. Available knowledge	Summary of what is currently known about the problem, including relevant previous studies
5. Rationale	Informal or formal frameworks, models, concepts, and/or theories used to explain the problem, any reasons or assumptions that were used to develop the intervention(s), and reasons why the intervention(s) was expected to work
6. Specific aims	Purpose of the project and of this report
Methods	***What Did You Do?***
7. Context	Contextual elements considered important at the outset of introducing the intervention(s)
8. Intervention(s)	a. Description of the intervention(s) in sufficient detail that others could reproduce it b. Specifics of the team involved in the work
9. Study of the Intervention(s)	a. Approach chosen for assessing the impact of the intervention(s) b. Approach used to establish whether the observed outcomes were due to the intervention(s)
10. Measures	a. Measures chosen for studying processes and outcomes of the intervention(s), including rationale for choosing them, their operational definitions, and their validity and reliability b. Description of the approach to the ongoing assessment of contextual elements that contributed to the success, failure, efficiency, and cost c. Methods employed for assessing completeness and accuracy of data
11. Analysis	a. Qualitative and quantitative methods used to draw inferences from the data b. Methods for understanding variation within the data, including the effects of time as a variable
12. Ethical considerations	Ethical aspects of implementing and studying the intervention(s) and how they were addressed, including, but not limited to, formal ethics review and potential conflict(s) of interest
Results	***What Did You Find?***
13. Results	a. Initial steps of the intervention(s) and their evolution over time (*e.g.*, timeline diagram, flow chart, or table), including modifications made to the intervention during the project b. Details of the process measures and outcome c. Contextual elements that interacted with the intervention(s) d. Observed associations between outcomes, interventions, and relevant contextual elements e. Unintended consequences such as unexpected benefits, problems, failures, or costs associated with the intervention(s) f. Details about missing data
Discussion	***What Does It Mean?***
14. Summary	a. Key findings, including relevance to the rationale and specific aims b. Particular strengths of the project
15. Interpretation	a. Nature of the association between the intervention(s) and the outcomes b. Comparison of results with findings from other publications c. Impact of the project on people and systems d. Reasons for any differences between observed and anticipated outcomes, including the influence of context e. Costs and strategic trade-offs, including opportunity costs
16. Limitations	a. Limits to the generalizability of the work b. Factors that might have limited internal validity such as confounding, bias, or imprecision in the design, methods, measurement, or analysis c. Efforts made to minimize and adjust for limitations
17. Conclusions	a. Usefulness of the work b. Sustainability c. Potential for spread to other contexts d. Implications for practice and for further study in the field e. Suggested next steps
Other Information	
18. Funding	Sources of funding that supported this work; role, if any, of the funding organization in the design, implementation, interpretation, and reporting

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

designs may be better suited for experimental studies of quality improvement.[50,157] The Canadian Neonatal Network conducted a cluster randomized trial of 12 NICUs in which half of the units focused on nosocomial infections, whereas the other half focused on reducing bronchopulmonary dysplasia rates.[76] Although bronchopulmonary dysplasia was reduced only in the corresponding group, nosocomial infections decreased in both groups. Their findings may suggest that quality improvement activities in one area may also influence quality in other areas, making the interpretation of such trials challenging. Walsh and colleagues conducted a cluster randomized controlled trial on the effect of benchmarking and multimodal quality improvement at 17 member NICUs of the National Institute of Child Health and Human Development on bronchopulmonary dysplasia rates. Three NICUs were selected as best performers, and the remaining 14 NICUs were randomized to intervention or control. Changes in rates of survival free of bronchopulmonary dysplasia were compared between study year 1 and year 3. Intervention NICUs did change practices related to bronchopulmonary dysplasia, but no statistically significant difference in the primary outcome was found.[157] Horbar and colleagues conducted a cluster randomized controlled trial in 114 NICUs (57 intervention units and 57 control units) alongside a quality improvement collaborative of surfactant timing at delivery. Eligible infants at 23 to 29 weeks' gestational age cared for in the intervention NICUs received surfactant in a more timely manner (median of 21 minutes versus 78 minutes, $p < .001$).[50]

The literature surrounding the effectiveness of quality improvement collaborative activities is still in its infancy. However, relative to other specialties, neonatal-perinatal medicine is at a relatively advanced stage. In a systematic review of the impact of quality improvement collaborative studies by Schouten and co-workers, four of the nine studies considered in the main analysis concerned neonatal outcomes.[125] There are still many opportunities for studying many aspects of quality improvement: its effectiveness as well as optimal designs for broader implementation. Furthermore, although infection reduction has been a success story for health care quality improvement in the NICU, it is perhaps time to focus further on other areas for advancing the science and improving care.

Quality and Safety in the International Context

Although this chapter has focused on some of the quality work done in the United States, similarly sophisticated regional and national collaborative networks as well as quality efforts by individual NICUs are underway throughout the developed world, including, among others, some in Canada, Europe, Australia, and New Zealand.

In addition, there has been increasing appreciation of the high value for money provided by NICU care in low- and middle-income nations. For example, one cost-effectiveness analysis found NICU care in Mexico to be effective in saving healthy life years and to be providing excellent value for the money for infants greater than 23 weeks' gestational age.[110] In many middle-income countries, mothers and newborns have access to medical care, but substantial opportunities for improvements in the quality and safety of care delivery remain. Although in low-income nations access to health care delivery is often a predominant problem, for those who do gain access, high quality of care delivery has been achieved using quality improvement methodologies (http://www.hciproject.org/node/1397). This is because many effective quality improvement interventions such as checklists are low technology and low cost, and patients in middle- and low-income countries have much to gain from applying these techniques.[42]

The World Health Organization and numerous countries have recognized these opportunities and have initiated efforts to train providers in patient safety and quality improvement skills, as well as in ways to conduct basic monitoring of clinical outcomes. These approaches should be complemented by a better understanding of the sources of quality gaps in the care delivery for sick newborns in resource-constrained settings, including potential lack of materials and equipment, workforce training, and availability, as well as institutional context for quality. In addition, a systematic accounting of improvement efforts that work and that do not is necessary to leverage and spread existing knowledge.

Conclusion

The miracles of modern medicine are maybe nowhere as apparent as in the progress of the fields of neonatology and perinatology. However, the impact of these advances can be limited by the performance of providers at the systems and clinician levels. The recognition that there is widespread variation among physicians and hospitals in clinical practice and patient outcomes and the growing pressure to increase the quality, safety, and cost effectiveness of medical care have resulted in unprecedented interest in assessing, evaluating, and improving medical practice. If health professionals are to function successfully in this environment, they must understand how to evaluate their own performance and how their performance will be evaluated by others. These evaluations require accurate and reliable information.

Most important, neonatologists and other health care professionals must learn how to use the information to improve the quality and safety of the medical care they provide. Although neonatologists should not be expected to become experts in industrial quality improvement theory, database management, and evaluation methods, they do need to develop a basic understanding that will allow them to work effectively with other professionals in the changing health care environment.

In this "era of assessment and accountability," we must all develop the knowledge, skills, and motivation necessary

to assume leadership roles in multidisciplinary collaborative quality improvement within our institutions, in larger health care organizations, and across regions. Only then can the potential benefits of modern databases and information systems be translated into better medical care for newborn infants and their families.

Acknowledgments

The authors would like to acknowledge Amy Clarke, RN; Suzanne Iniguez, RCP; Ashleigh McClendon, DO; and Alfred Gest, MD, from Texas Children's Hospital for their efforts in this project.

Key Points

- There continue to be many opportunities for addressing gaps in quality and safety in neonatal care, whether in underuse, overuse, or misuse of various therapies.
- Collaborative networks, including at the state level, have allowed for benchmarking of quality to promote better outcomes.
- Accurately and efficiently derived data that is available in a timely manner provides the framework for assessing and tracking measurements in quality and safety.

Simulation and Debriefing in Neonatal-Perinatal Medicine

LOUIS P. HALAMEK

Introduction

Whereas teaching is something that is (passively) done to trainees, learning is something that trainees must (actively) do themselves.[39] Because not everything that is *taught* is necessarily *learned*, programs that best facilitate skill acquisition in trainees are those that focus on learning rather than on teaching. Traditional didactic programs are passive by nature, and the settings in which they are held are typically isolated from realistic cues, distractors, and time pressure; thus, such programs are unable to prepare learners adequately for all of the challenges inherent when working in the real environment. Learning is best facilitated when the learning opportunities are tailored to meet the needs of the learners. Training models that offer the same content in the same fashion to all learners (thus implying that competency can be attained and maintained simply by spending a particular, often arbitrary, amount of time at a task) fail to recognize that adults have different strengths, weaknesses, and life experiences and acquire and maintain different skills at different rates. Some characteristics of effective adult learning strategies include the following:

- Focus on active rather than passive learning activities.
- Integration of skill sets while performing under realistic conditions.
- Emphasis on competency/proficiency (the ability to perform successfully) rather than compliance (adherence to rules, such as participation in an activity for a predetermined period of time).

Although learning in a real environment may appear ideal at first glance, a deeper analysis reveals otherwise. The most obvious problem with using the real environment as the primary source of skill acquisition and maintenance is that any mistake could negatively affect (even prove lethal) to the human beings in that environment. The pace of actual work in the real environment is often too fast to allow trainees to take full advantage of the learning opportunities therein. Moreover, typically there is no way to ensure that all important learning opportunities will present themselves in the real environment during the time that the trainee is present. Finally the real environment is also typically a very expensive environment and is populated with a number of professionals whose job description may not include providing learning opportunities for trainees.

Simulation may be defined broadly as any exercise that allows an individual to experience a situation that, although not real, nevertheless generates authentic responses on his or her part.[38] The best simulations realistically recreate the key visual, auditory, and tactile cues of actual situations to provide experiences that closely mimic the conditions encountered when working in the real environment. Provision of these key cues creates a high level of fidelity to the real environment. As a result of this degree of realism, those participating in the simulation respond as they would to a real-life situation; thus, their performance during a simulated situation can be hypothesized to resemble what it would be in the real world. In general, the term *simulation* is typically reserved to describe more comprehensive learning, assessment, and research activities that occur in realistic physical and virtual environments; activities conducted in less comprehensive environments (case studies, role-playing, and practice of one particular skill in isolation from other elements associated with that skill) may be better labeled as task training. By suspending their knowledge that they are working in a contrived situation, participants display knowledge, skills, and behaviors similar or identical to those manifest when working in the real environment. The closer a participant in a simulation mimics real-life performance, the more likely he or she will be able to identify and address any weaknesses that become apparent. Identification and remediation of weaknesses is the raison d'être of simulation.

What are the features of the best simulation-based learning programs that make them effective in facilitating the acquisition and maintenance of cognitive, technical, and behavioral skills? Each element of a successful program, including the scenarios, is built around specific learning objectives that are tailored to meet the needs of the participants. Every effort is made to ensure that the scenarios to which they are exposed are realistic in detail, challenging in

Abstract

The delivery of safe, effective, and efficient care to ill neonates is the goal of every neonatologist. Preparation for delivery of neonatal care can be facilitated by the application of simulation-based training coupled with objective debriefing. Simulation-based training is, at its core, practicing doing the right thing under realistic conditions to elicit true-to-life responses from those undergoing this training. When such responses are evoked, trainees have the opportunity to discover their strengths and weaknesses during a debriefing. Debriefings should focus on the actions of the individual team members, how those actions contributed to the performance of the team, and how team performance influenced the care of the patient. In addition, strategies for replicating actions that facilitate successful human and system performance and avoiding those that are ineffective or harmful should be developed during debriefings. The combination of realistic simulated clinical scenarios with objective debriefings provides many advantages over more traditional training methodologies and is ideal for the acquisition and maintenance of the cognitive, technical, and behavioral skills necessary for modern neonatal care.

In addition to its use for training, simulation can be used to create highly standardized clinical environments that allow the investigation of issues that are difficult to study in the real health care environment. It is also likely that, over time, simulation will play a steadily increasing role in the delivery of care to actual patients.

scope, and relevant to their daily work. Finally, expert feedback and facilitated debriefings assist the participants in their critical self-reflection on performance. Effective simulation is not dependent on the purchase and use of highly complex and expensive technology; more important are carefully designed scenarios that align with the needs of the participants, provision of *important* (not necessarily *all*) cues, and conduct of skillfully led debriefings.

Simulation-Based Training in High-Risk Industries

Simulation-based learning opportunities are the standard for skill acquisition in industries such as commercial aviation, aerospace, nuclear power, and the military, in which the risk of death or severe injury to human beings is very real. The use of simulation in these domains is characterized by an emphasis on probing human beings and the systems they design (both technological and social) for weaknesses and then designing and testing solutions to address those weaknesses. This type of learning is the result of a culture that not only fosters but also demands a willingness to learn from mistakes made during simulated events, thus decreasing the chances of repeating such mistakes when working in the real environment.

The National Aeronautics and Space Administration (NASA) was established in 1958 to conduct aeronautical research and administer the human and robotic exploration of space. Space travel is an inherently risky business; how else can one describe a process that places human beings in a rocket filled with tons of liquid fuel and then ignites that fuel in the hope that it will propel those humans into the vacuum of space? The value of simulation was made clear during the Apollo 13 mission, launched on April 11, 1970, as the third mission to land humans on the moon. To prepare for this mission, the three members of the prime crew, Jim Lovell (captain), Tom Mattingly (command module pilot), and Fred Haise (lunar module pilot) trained in NASA's flight simulators for months. One week before launch, Mattingly was exposed to the measles; because he was not immune to the disease, his backup, Jack Swigert, was given simulator time with Lovell and Haise in the week preceding launch to "ensure that Lovell, Swigert, and Haise could function with unquestioned teamwork through even the most arduous and time-critical simulated emergency conditions."[31] A decision by the flight surgeon only one day before launch scrubbed Mattingly from the prime crew and placed Swigert in the left-hand seat as command module pilot for the mission. Fifty-six hours into the flight, as Apollo 13 was approximately 200,000 miles away from the earth en route to the moon, an explosion in the service module's cryogenic oxygen system resulted in the uncontrolled venting of oxygen into space, creating a situation that threatened not only the success of the mission, but also the lives of the crew (oxygen was the source of the crew's breathing air and substrate for the fuel cells that generate electrical power). As has been thoroughly documented, the crew did return safely to earth. What is less well known is that, years before Apollo 13 launched, the procedures that allowed the crew to survive and recover from this devastating event were devised by engineers charged with envisioning every possible failure and then designing procedures to address these failures.[27] These procedures were tested under current mission parameters in the flight simulators almost continuously during the crisis and when deemed reliable were relayed to the crew.[10] In the formal postmission debriefing, the crew referred to their experiences in flight simulation in excess of 40 times.[3] The successful track record of simulation, established over decades in other domains, serves as a model for its use in health care.[35]

Simulation-Based Training in Health Care

Any discussion of training in health care must start with what it is that can be learned. There are three sets of skills that may be acquired and refined by health care professionals:

- What we know in our brains (cognitive skills—content knowledge and decision making)
- What we do with our hands (technical skills)
- How we employ the first two skill sets while caring for patients and working under realistic time pressure with our colleagues (behavioral skills)

Content knowledge is the skill set most familiar to trainees and is typically the major (or only) skill set that is formally evaluated, usually through written or online tests. Decision making may also be evaluated in this manner through the use of clinical vignettes followed by questions as to appropriate next steps to be taken. Technical skills such as intubation are critical to many aspects of health care delivery. Despite their importance, such skills are most commonly practiced at skills stations using models that poorly represent human anatomy and physiology; in addition, they are typically evaluated by subjective rather than objective criteria. Behavioral skills (including but not limited to leadership, teamwork, and effective communication) are also important to successful patient outcomes (Box 6.1). Unfortunately, these skills are rarely, if ever, specifically addressed in learning programs directed at health care professionals. Many patient care tasks actually incorporate elements of all

• BOX 6.1 Key Behavioral Skills

- Know your environment.
- Anticipate and plan.
- Assume the leadership role.
- Communicate effectively.
- Delegate workload optimally.
- Allocate attention wisely.
- Use all available information.
- Use all available resources.
- Call for help when needed.
- Maintain professionalism.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• BOX 6.2 Skills Necessary for Successful Intubation

Cognitive Skills

- Know the indications for intubation.
- Know how to recognize these indications when present.
- Know what equipment (e.g., size of endotracheal tube, laryngoscope blade) to use to accomplish intubation.
- Know the indications of a successful intubation.

Technical Skills

- Assemble the laryngoscope.
- Hold the laryngoscope in the left hand.
- Expose the airway to view.
- Insert the endotracheal tube into the airway.
- Assess for proper placement of the endotracheal tube in the airway.
- Secure the endotracheal tube in the airway.

Behavioral Skills

- Communicate effectively with team members regarding the need for intubation, specific pieces of equipment, and other needs.
- Distribute the workload so that specific tasks are assigned to the team members most likely to carry them out successfully.
- Delegate responsibility and supervise appropriately.
- Call for help when necessary.

three of these skill sets. Intubation is one such example. Far from being simply a technical skill, effective and safe intubation requires coordination and integration of multiple cognitive skills (knowing the indications for intubation and the signs of successful and unsuccessful intubations), sequential discrete technical skills (assembling, testing, and inserting the laryngoscope), and a number of behavioral skills (effectively communicating observations and needs, evenly distributing the workload, and delegating responsibilities), all of which must also be accomplished in a time-efficient manner (Box 6.2).

Much has been made of the importance of the concept of *fidelity* in simulation-based training in health care. Simulation fidelity is typically thought of in terms of its physical, biologic, and psychological elements. Physical fidelity refers to the realism of the physical space in which training occurs; this space is made to look real by including appropriate working medical equipment, fluids, pharmacologic agents, beds, and the other elements necessary for patient care. Biologic fidelity includes the patient simulators and standardized patients as well as the human beings acting as confederates during the simulation, playing roles designed to assist the evolution of the scenario. Patient simulators have been described as high, medium, and low fidelity; unfortunately, there is no standardized definition of simulator fidelity in health care. In reality, no physical patient simulator currently in use bears close resemblance to a human being, either in terms of anatomy or physiology. The use of the term *high fidelity* when describing the current generation of patient simulators more likely refers to high complexity or high cost rather than any intrinsic similarity to a living human being. Finally, all of the previously mentioned elements interact with the mindset brought into the scenario by the trainees to create a sense of realism or psychological fidelity. The overall goal of simulation-based training is to provide experiences that closely mimic the conditions encountered when working in the real clinical environment. The major difference between the simulated environment and the real environment is the absence of real human patients. Although debate continues in the health care simulation community as to how much fidelity is necessary, and although some may argue that the higher the fidelity of the scenario to real life, the better the learning opportunity, it should be understood that as long as sufficient attention is paid to providing the key (not all) visual, auditory, and tactile cues for trainees, allowing them to form a shared mental model of the nature of the situation that they are facing, they will have the opportunity to work effectively to resolve the clinical problems that become manifest during the scenario and, therefore, achieve the learning objectives.

In health care simulations, the patient may be represented by a human being (actor or standardized patient), physical model that can be touched and handled (mannequin or patient simulator), virtual models that are created via software and exist only in the memory of a computer, or hybrid models that require participants to interface with both physical and virtual elements. Simulation in health care encompasses a wide spectrum of activities ranging from computer-based interactive *virtual* environments populated by virtual patients and computer-generated representations (avatars) of oneself and one's human colleagues to highly realistic *physical* environments in which real human health care professionals work as a team providing care for sophisticated patient simulators while using real working medical equipment.

Simulation-based training provides many obvious advantages over more traditional training methodologies. Because patient simulators replace human beings, there is no risk to patients; invasive procedures can be practiced without the fear of patient harm or medical liability. Unlike what happens in the real environment, learning opportunities using simulation can be scheduled at convenient times and structured so that specific learning objectives are consistently achieved. Simulation-based training is an ideal methodology for allowing participants to practice integration of multiple skill sets while working under highly realistic and often stressful conditions. Rather than being directed solely at the individual, simulation accommodates the learning needs of multidisciplinary teams. Simulation-based training activities can be scaled in intensity to meet the needs of participants at all levels of experience, and they can be used to foster both the acquisition and maintenance of particular skills. It can also be hypothesized that those who participate in simulation-based exercises likely will be better prepared and will need less supervision when entering or re-entering the real environment (Box 6.3).

• BOX 6.3 Advantages of Simulation

- Presents no risk to human patients
- Permits training in environments usually inaccessible to less experienced trainees
- Can be tailored easily to the needs of individual trainees regardless of level of experience
- Allows practice without interruption or interference
- Fosters integration of cognitive, technical, and behavioral skills
- Facilitates multidisciplinary team training
- Creates training opportunities for rarely encountered but highly challenging or risky situations
- Provides structured training opportunities with defined learning objectives
- Can be scheduled at times convenient to trainees and instructors
- Permits formal objective performance assessment
- Facilitates use of debriefings as a source of detailed constructive feedback
- Provides a very rich training experience in a relatively short period of time
- Optimizes use of time, money, and other resources

Simulation-based training in its broadest sense has been used for decades in domains outside of health care in which the risk to human life is high, and it is a core component of maintenance of certification programs in those domains. Historically in health care, the emphasis has been on evidence-based practice, and the gold standard of evidence has consisted of the prospective, randomized, controlled, sufficiently powered clinical trial in which the results focus on patient outcomes. However, the debate about the type and extent of evidence required to adopt quality assurance/improvement efforts in health care continues. At one end of the spectrum are clinicians and investigators who insist that quality initiatives must be subject to the same rigorous testing that precedes the introduction of new pharmacologic therapies and medical instrumentation to prove that they actually improve quality and enhance patient safety. Alternatively, others note that requiring randomized controlled trials to assess the safety of innovations with high face validity may place humans at undue risk and, therefore, prove impossible to conduct. In fact, some authors are of the opinion that to not use simulation-based training methodologies, relying instead solely on practice on real patients, is ethically indefensible.[69] Thus, we are left with a situation in which the need for more definitive evidence, although desirable, is felt by at least some members of the health care education and training community not to be necessary or practical. Although numerous studies across multiple health care domains have shown that simulation is capable of producing short-term improvement in skills, and the body of objective data supporting the use of simulation in health care continues to expand, little evidence has been published that definitively documents its effect on patient outcome or its return on investment. That said, it should be emphasized that no one working in other high-risk domains would consider conducting a prospective, randomized, controlled trial with subjects who are randomized to the "no simulation" group; indeed, simulation-based training remains standard operating procedure for these professionals.[53]

Simulation-Based Training in Neonatal-Perinatal Medicine

Approximately 4 million babies are born in the United States every year; of these, around 10% require some degree of resuscitation, with 1% needing extensive resuscitative efforts such as chest compressions, intubation, and delivery of medication.[65] Many different types of health care professionals are responsible for caring for newborns at the time of birth and in the days and weeks that follow. These professionals include, but are not limited to, neonatologists, pediatricians, family practitioners, obstetricians, midwives, neonatal nurse practitioners, nurses, and trainees at all levels in these disciplines. Given the large number of births, the frequency of resuscitation, and the diversity of professionals bearing responsibility for caring for patients in the neonatal period (the first 28 days of life), the need for effective means of acquisition and maintenance of the skill sets necessary to deliver safe and competent care is of tremendous importance. Traditionally the apprenticeship model of assuming graduated responsibility for the care of real patients has been used to address this need. Unfortunately, the assumption underlying this model—that placing a trainee in a supervised clinical environment for a set period of time will allow him or her to experience a sufficient number and breadth of clinical cases to ensure the ability to practice independently and safely in the community—does not always prove to be true. Similarly, maintenance of skill cannot be guaranteed by the routine, nonmentored delivery of patient care.

In 1999, the Institute of Medicine (IOM) published *To Err Is Human: Building a Safer Health System*, a report on human error and patient safety in the United States.[46] In this report, the authors estimated that between 44,000 and 98,000 Americans die each year as a result of medical errors. Although this figure has been highly debated, it is based on extrapolation of the data contained in studies out of Colorado, Utah, and New York published in peer-reviewed literature. The 1999 report was followed in 2001 by another from the IOM, *Crossing the Quality Chasm: A New Health System for the 21st Century*, in which the types of interventions (including training methodologies) necessary to improve patient safety were discussed.[17] Subsequently in 2004, the Joint Commission (JC) published a *Sentinel Event Alert* describing ineffective communication as a major cause in almost 75% of the 47 cases of neonatal mortality or severe neonatal morbidity (lifelong serious neurologic compromise) reported to that agency; since that time, an additional 62 cases have been added.[44] In response to these root cause analyses, the JC recommended that all health care organizations responsible for delivering newborns "conduct team training in perinatal areas to teach staff to work

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

together and communicate more effectively" and "for high-risk events, such as shoulder dystocia, emergency cesarean delivery, maternal hemorrhage, and neonatal resuscitation, conduct clinical drills to help staff prepare for when such events actually occur, and conduct debriefings to evaluate team performance and identify areas for improvement."

The ever-expanding body of knowledge of the basic processes underlying normal and abnormal neonatal physiology has allowed those clinicians responsible for caring for newborns to generate evidence-based clinical practice guidelines under the auspices of the International Liaison Committee on Resuscitation (ILCOR) and its member organizations (Neonatal Resuscitation Program of the American Academy of Pediatrics, the American Heart Association, the Heart and Stroke Foundation of Canada, the Inter-American Heart Foundation, the European Resuscitation Council, the Australian and New Zealand Committee on Resuscitation, and the Resuscitation Councils of Southern Africa). ILCOR was founded in 1992 to facilitate international collaboration on issues involving neonatal, pediatric, and adult cardiopulmonary resuscitation and emergency cardiovascular care.[11] As knowledge about the physiologic processes underlying neonatal cardiorespiratory decompensation and the list of therapeutic interventions grow, so too do the expectations for mastery of this knowledge and associated skill sets that are placed on those responsible for caring for the neonate in distress. In 2010, ILCOR noted that a number of studies have demonstrated that the use of simulation-based learning methodologies enhances performance during simulated resuscitations. Although acknowledging that the interpretation of data generated by these studies is often complicated by their inherent heterogeneity and limitations, ILCOR nevertheless recommended that simulation, briefing, and debriefing techniques should be used during training when caring for simulated patients and in the course of clinical activities involving real patients to facilitate the acquisition and maintenance of the skills necessary for effective neonatal resuscitation.[45,50] This recommendation continues to remain in effect with the publication of the 2015 ILCOR guidelines.[5]

Neonatal care occurs in environments that are extremely dynamic and complex, and the nature of the work performed in those environments requires that correct decisions be made and appropriate interventions be carried out, often while working as a member of a multidisciplinary team in the context of intense time pressure. Simulation is an ideal learning methodology to allow teams of learners to practice working in these types of environments.[2] The first simulation-based learning program in neonatal-perinatal medicine (and one of the first in all of health care) is the NeoSim program developed at the Center for Advanced Pediatric and Perinatal Education (CAPE) located at Packard Children's Hospital on the campus of Stanford University in Palo Alto, California. Launched in 1997, NeoSim has been a very successful innovation in training in the cognitive, technical, and behavioral skills necessary for optimal care of the newborn in distress.[40] Subsequently, the NeoSim program was adopted as the model for extensive ongoing revision of the Neonatal Resuscitation Program (NRP) of the American Academy of Pediatrics (AAP).[37] Since 1987, the NRP of the AAP has set a national standard and an international example for training in the resuscitation of the newborn and has enjoyed tremendous success by claiming more than 3.9 million trainees and more than 23,000 instructors in the United States alone. The NRP's *Textbook of Neonatal Resuscitation* has been translated into 24 languages, and the NRP has been taught in 130 different countries around the world. In the past decade the NRP has undergone a major shift in learning methodology. Instructors are now required to shift their role from that of a teacher responsible for imparting knowledge to learners to that of a facilitator who fosters acquisition of skills by trainees as these trainees accept primary responsibility for their own learning. The NRP Steering Committee also developed a list of the characteristics desired in a cost-effective human neonatal patient simulator and published this online in 2005 as a request for proposals to industry. This marked the first time in the history of health care simulation that a professional body, rather than industry, drove development of a realistic patient simulator based on established learning objectives. Since that time, a number of full-term and preterm neonatal patient simulators have been developed by several commercial companies, indicative of the growth of the simulator industry at large and the field of neonatal simulation in particular. Development of a career-long learning program in neonatal resuscitation that is relevant to professionals from multiple disciplines at all levels of experience and is embedded with robust learning opportunities and valid performance metrics is the ongoing focus of the NRP as it continually adapts to stay relevant and provide optimal simulation-based training experiences.[1]

In addition to resuscitation, simulation has been used to facilitate the acquisition and maintenance of the skills necessary for successful delivery of multiple aspects of neonatal care. Simulation-based training programs have been developed in areas of neonatal care as diverse as reducing central line-associated infections, extracorporeal membrane oxygenation (ECMO), transport medicine, conducting difficult discussions, and outreach.[6,7,8,23,32,43,60,61,67]

The subspecialty of neonatal-perinatal medicine is unique in that one patient (the fetus) exists inside of another patient (the pregnant woman); in the case of multiple gestations, two or more fetal patients await birth inside of the pregnant female patient. The possibility of a sick woman delivering a sick newborn creates a situation in which optimal preparation occurs only when the neonatology and obstetric teams train together.[4] The multitude of events that can complicate human birth and the neonatal period make this an especially appealing target for simulation-based learning. Thus it makes sense that the neonatologists, obstetricians, and nurses from labor and delivery units and newborn nurseries who work closely together in the delivery room caring for patients also conduct joint simulation-based training exercises.[48]

Some of the most convincing work published to date regarding the value of simulation-based training involves the reduction in the incidence of serious sequelae of shoulder dystocia after implementation of comprehensive simulation-based training. In the Obstetrics Emergency Training Programme at Southmead Hospital, Bristol, United Kingdom, Draycott and colleagues used a variety of patient simulators in several simulated environments to show that simulation-based learning resulted in enhanced content knowledge and improved technical management of shoulder dystocia.[19,20,21,22,24] In addition, the same group found in a retrospective multicenter cohort observational study of 19,460 infants that (1) the incidence of infants born with 5-minute Apgar scores of 6 or lower decreased from 86.6 to 44.6 per 10,000 births ($p < .001$), and (2) encephalopathy decreased from 27.3 to 13.6 per 10,000 births ($p < .032$) over a 5-year period following the introduction of a training program consisting of a review of fetal heart rate tracings and hands-on drills in the management of shoulder dystocia, postpartum hemorrhage, eclampsia, twin delivery, breech presentation, and maternal and neonatal resuscitation.[25] This work has been replicated and shown to produce similar improvements in clinically relevant outcomes, serving to document the value of rigorous immersive training.[9,18,58,62,64] The rationale for employing simulation-based training in neonatal-perinatal medicine is clear. The management of serious neonatal pathology is one example of the classic low-frequency, high-risk event that lends itself well to simulation-based training. Many health care professionals who care for newborns have the opportunity to manage serious or rare disease processes on an infrequent basis. Even for those for whom a sufficient number of opportunities do exist, one must question whether it is acceptable to essentially practice on real living patients who are not capable of providing informed consent on their own. Although parents do act as surrogate decision makers for children below the age of consent, few want to contemplate that their child will be the first one on whom someone will perform their first spinal tap, first intubation, or first thoracostomy tube placement. Therefore, it may be argued that the ethical imperative for simulation is stronger in pediatrics in general, and in neonatal-perinatal medicine in particular, than in any other field of health care.

Debriefing Simulated Events

A debriefing is defined as a discussion of events that have already occurred and may be led by an individual or a group; this is in contrast to a briefing which is held to discuss planned or future events. In a debriefing of a health care team the flow of information is both between the leader(s) and the members of the team, as well as among the members of the team. Feedback is the provision of information (from a person or a device) to a person where the flow of that information is one way. While not as interactive as a debriefing, it is important to note that not all learning requires the type of interaction typically ascribed to debriefing. For example, the acquisition and maintenance of a technical skill such as intubation does not require debriefing; rather, the provision of feedback as to appropriate finger and hand position on the laryngoscope and other aspects of intubation technique can be provided by an instructor experienced in intubation without the extensive interaction with trainees ascribed to debriefing.

Much of the health care literature has been devoted to the theoretical underpinnings of debriefing, rather than actual practical strategies and techniques, and focused on relatively inexperienced trainees rather than experienced health care professionals. Most of the models described in that literature use a very similar approach consisting of three primary phases:

1) An individual trained in debriefing who is not a member of the team leads the discussion;
2) the discussion typically includes reaction, description, analysis, and summary phases; and
3) patient outcome is not routinely emphasized (and may actually be avoided if felt to potentially produce negative reactions in team members).

This stands in contrast to how debriefing is conducted in other industries in which the risk to human life is high. In these industries the emphasis of debriefing is on facts, not feelings, and objective outcomes, not subjective interpretations.[13,26,28,29,30,42,47,68]

The debriefing model that has been adopted by the NRP for use after simulated neonatal resuscitation originated at CAPE. The CAPE debriefing model focuses on the actions of the individual, how those actions contribute to the performance of the team, and ultimately how team performance influences the care of the patient, therefore aligning closely with debriefing methods used by aerospace, commercial aviation, and the military. In this model, the person(s) leading the debriefing draws the assessment of individual and team performance from the team members themselves as they evaluate patient outcome in response to their actions and objectively critique those actions. Upon the conclusion of the debriefing, team members must understand how actions beneficial to the patient can be replicated and how any actions that were nonproductive or harmful can be avoided. The guiding principles and specific strategies that facilitate delivery of this model of debriefing are listed in Box 6.4 and Box 6.5, respectively.

It is very important to understand the difference between a technical performance debriefing (used to assess human and system performance) and a critical incident stress debriefing (conducted to provide emotional/psychological support). A critical incident is defined as "an event that has the potential for people to experience significant physical, cognitive, emotional, and behavioral reactions immediately after the incident or days, weeks, months, and even sometimes years later."[63] If simulated clinical scenarios are well-designed and the associated debriefings are conducted in an appropriate manner, a critical incident stress debriefing

• BOX 6.4 Guiding Principles for Technical Performance Debriefing

- Debriefers should set a professional, business-like, matter-of-fact tone for the debriefing and maintain that tone whether the performance of the team members was exemplary or highly flawed.
- The role of the debriefer in a debriefing is to facilitate, rather than dominate, discussion among team members.
- Debriefings should be focused on the actions of the individual, how those actions contributed to the performance of the team, how team performance influenced patient outcome, and developing strategies for replicating actions that facilitate successful human and system performance and avoiding those that are ineffective or harmful.

should very rarely be required; if it is, appropriate professional counseling should be arranged.

While the few studies conducted to date have not consistently shown clear benefits to the use of video during debriefing, it must be acknowledged that in order for the cognitive, technical, and behavioral skills of the team members to be effectively debriefed, an accurate record of the display of those skills must be available.[14,41,56,59] Reliance on memory alone to provide such an accurate record is dubious at best. The ability to display a video stream illustrating key viewing angles coupled with an audio stream that picks up communication among team members provides an objective record of events that is capable of effectively bridging any gap between team members' memories and the actual facts of the scenario.

Debriefing Actual Clinical Events

While the guiding principles and specific strategies remain the same, there are several important differences between debriefing simulated clinical events and real clinical events.[54] Actual patient care events are spontaneous, unlike scripted simulated events, and thus those debriefing real events must do so without the benefit of written checklists of debriefing points. Those debriefing actual clinical events are often members of the team who were intimately involved in delivering care to the patient; this can make it more difficult to create a mental log of issues to be debriefed and offer objective input during the debriefing. Effective time management is critical when debriefing real clinical scenarios because the health care professionals involved in the debriefing must return to patient care as soon as the debriefing is concluded. Because the time that can realistically be devoted to debriefing actual clinical events is limited, it may be necessary to concisely debrief the single most important issue and defer others for review at a later time. Finally, the legal issues inherent in clinical medicine mandate absolute confidentiality when discussing the care of real patients, and consultation with professionals in risk management should be undertaken prior to developing a formal process for debriefing real clinical events.

• BOX 6.5 Specific Strategies for Technical Performance Debriefing

- Preparation of learners: Clearly communicate expectations.
- Initiating debriefings: "What happened in 10 words or less?"
- Sequencing debriefings: Chronological order is easiest to follow.
- Pacing debriefings: Maintain awareness of time remaining for debriefing.
- Facilitating discussion: Target a question-to-statement ratio of 3:1.
- Formulating pertinent questions: Create lists of debriefing points.
- De-emphasizing the instructor's viewpoint: Limit use of first person pronouns.
- Avoiding qualitative statements: Draw performance assessment from learners.
- Minimizing personal anecdotes: Focus on learner (not instructor) experiences.
- Eschewing hindsight bias: Debrief as if experiencing the event for the first time.
- Using silence: Wait approximately 10-15 seconds for a response.
- Deconstructing defensiveness: Limit use of second person pronouns.
- Dealing with emotion: It is not necessary to assume all learners need to ventilate.
- Listening for "red flags": Listen for phrases that indicate a need to drill down.
- Drilling down: Use a series of four questions—
  a. What happened/what did you notice (at that point in the scenario)?
  b. What circumstances led to that?
  c. What happened to the patient as a result?
  d. What can be done to:
     i. facilitate the recurrence of that positive event?
     ii. prevent that negative event from happening again?
- Debriefing with video: Scroll to segments of interest and pause playback for discussion.
- Deciding when to intervene:
  e. inability to recognize performance gaps
  f. talking over one another
  g. lack of gravitas
  h. inappropriate laughter
  i. harsh criticism
- Debriefing novices and experts: Employ the same strategies regardless of experience.
- Debriefing simulated and real clinical events: Formal process is required for real events.
- Terminating debriefings: "Any final questions/comments?"

Simulation-Based Assessment

Simulation is most frequently used in health care as a learning tool to facilitate the initial acquisition of cognitive, technical, and behavioral skills by relatively inexperienced trainees. Although not a frequent occurrence as of yet, it can also be used by experienced professionals to maintain (or reacquire) skills.[55] Regardless of experience level, simulation may in addition be used to objectively assess and document whether a physician or other health care professional can competently deliver care to patients. Appropriate metrics

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

capable of objectively assessing all three skill sets (cognitive, technical, behavioral) must be developed and validated if simulation is to be used for formal evaluation of human performance in the health care domain.[34] Although the objective assessment of content knowledge has long been achieved through written and oral responses to multiple-choice and open-ended questions, the evaluation of technical and behavioral skills remains poorly defined. For example, although the technical skill of intubation can be broken down into a number of discrete steps and each step evaluated in great detail, in the end what is most clinically relevant is whether the patient is intubated successfully and safely, not the summary of the scores on each individual step of the procedure. This implies that there may be steps in the procedure that are so critical that failure in any one of them produces a "fatal error"; such errors result in overall failure in the task, even if all of the other steps are completed successfully. The assessment of behavioral skills presents similar issues. How does one define and score skills such as leadership and communication? Another challenge is the evaluation of performance over time. Providing a single comprehensive score of performance is difficult if that performance varies from minute-to-minute; dividing the event into discrete epochs of time may not completely resolve difficulties with scoring. Before working with a patient simulator can be used for high-stakes assessment, it must be shown to accurately predict performance with real human patients. An evidence-based approach to skill assessment will require collaboration with professionals in fields such as psychometrics, human factors, psychology, and others. If undertaken in a rigorous manner, it will be possible in the future to use simulation for high-stakes assessments such as hospital privileges, state licensure, and board certification in much the same way as flight simulators are used today to determine whether a pilot is capable of safely flying a particular type of aircraft.

Simulation-Based Research

Because all of the elements of the simulated environment (e.g., structure of the physical space, location and function of equipment, amount of various supplies, level of the ambient noise, appearance and reactions of the patient simulator, actions of human confederates in the environment) can be standardized, simulation provides an extremely powerful research methodology for studying clinically relevant issues in a highly controlled manner. The advantages of simulation as a research methodology are illustrated in a study conducted by Chitkara and co-workers.[15] In this study of the ability of human health care professionals to accurately detect heart rate via auscultation and palpation, the following elements were standardized:

- Heart beat: rate, volume, tone, location
- Umbilical cord pulsations: frequency, amplitude, location
- Stethoscope: quality
- Reaction of the simulated neonate to interventions
- Responses of the bedside nurse
- Responses of the bedside respiratory therapist
- Environmental noise
- Other distractors

Unlike the actual clinical environment in which all of these elements would be variables, in the simulated environment they were controlled with great precision; thus, differences in the performance of the subjects could be ascribed to intrinsic human factors rather than extrinsic aspects associated with their environment.

Simulation is especially well-suited to conduct research that is difficult to accomplish in the real clinical environment. Many aspects of neonatal-perinatal medicine are characterized by decisions that carry life-or-death outcomes, procedures that must be successfully completed under intense time pressure, and highly charged emotional situations that challenge both family members and health care professionals alike. Obtaining informed written consent in these situations, even if technically possible, is nevertheless made extremely difficult in that parents who are in a time of crisis must be asked for their willingness to allow their newborn to participate in a research protocol. Even when those involved conduct themselves in a competent and compassionate manner, this remains a challenging situation for all. A number of studies involving comparisons of various procedures during resuscitation and design of devices such as code carts have been published in recent years, illustrating the utility of conducting research in simulated, rather than real, environments.[12,16,49,51,52,57,66]

Simulation as the Basis of Clinical Care

Simulation will be playing a steadily increasing role in the delivery of care to actual patients. Radiologic data are currently being used by surgeons and interventional radiologists to create simulated anatomic models for use in planning and practicing invasive procedures such as tumor removal, catheter placement, and pinpoint delivery of therapeutic agents. Similarly, mathematical models of human physiology allow testing of experimental devices and pharmaceuticals in vitro/in silico rather than in vivo. Although a sophisticated comprehensive virtual model of human physiology, complete with all of its nuances and interdependencies, does not currently exist, virtual models of single organs and organ systems have been developed and are currently being used to assess the potential effects of various technologies and drugs in research and development settings around the world today. Continued work in this area will lead to the accurate simulation of human physiologic responses at the tissue, organ, cellular, and molecular levels and holds tremendous promise for revolutionizing health care on many fronts. The foreseeable future will bring the ability to integrate fetal imaging and biomarkers obtained from maternal blood or amniotic fluid with sophisticated anatomic and physiologic models to produce true high-fidelity simulations capable of accurately predicting the type and severity of eventual neonatal pathophysiology and thereby allow for patient-specific, evidence-based choices of pharmacologic

agents, ventilator strategies, and other clinical interventions during postnatal life.[36]

The Future of Simulation in Neonatal-Perinatal Medicine

Human birth is characterized by nearly continuous changes in the physiology, anatomy, and spatial relationships among various physical structures in both the pregnant woman and fetus, and simulation of the process of labor and delivery is, therefore, a technically complex endeavor. Purely mechanical devices are not able to simulate vaginal birth in a manner akin to real life in a cost-effective manner or to allow practice of highly invasive procedures such as cesarean section. Development of hybrid technologies that combine materials similar to the plastics used for physical patient simulators with visual displays and haptic interfaces capable of generating the images and tactile sensations associated with patient care will create training opportunities that are currently impossible to achieve in the absence of a real patient. Thus, combinations of physical whole body simulators with virtual reality interfaces designed to compensate for the physical simulators' limitations will play a major role as neonatal and obstetric simulation evolves. In addition to physical and hybrid patient simulators, highly interactive web-based virtual environments will allow multiple professionals located in geographically distinct regions to participate in simulated clinical scenarios tailored to meet their specific learning needs. Following the example of the NRP, close collaboration among physicians, computer scientists, biomedical engineers, medical artists, and others will allow the technical challenges that currently exist to be overcome in a timely and cost-efficient manner.

Simulation in neonatal-perinatal medicine has made great strides in the past decade; however, the temptation to become content should be avoided, as much remains to be accomplished to reach the levels of safety, effectiveness, and efficiency that have been achieved in other industries where simulation and debriefing are integral components of daily work.[33] Although a number of technical, financial, and cultural challenges must be met to realize the full potential of this powerful methodology, none of these challenges is insurmountable. Failure to embrace simulation and debriefing will impede the practice of safe and effective health care and lead to harm of the smallest and most vulnerable patients.

Key Points

- Simulation-based training is practicing doing the right thing under realistic conditions.
- Simulation-based training is integral to safety programs in many high-risk industries.
- The key to effective simulation is the display of true-to-life responses by those experiencing it, allowing them to understand both their strengths and weaknesses.
- Debriefings should be focused on the actions of the individual team members, how those actions contributed to the performance of the team, and how team performance influenced the care of the patient.
- Debriefings should also facilitate the development of strategies for replicating actions that make possible successful human and system performance and avoiding those that are ineffective or harmful.
- Standardized simulated clinical environments allow the investigation of issues that are difficult to study in the real health care environment.

Practicing Evidence-Based Neonatal-Perinatal Medicine

SUZANNE M. LOPEZ AND JON E. TYSON

This chapter focuses on five strategic processes in practicing evidence-based, neonatal-perinatal medicine: (1) asking a focused clinical question; (2) searching MEDLINE, the Cochrane Library, and other sources for high-quality evidence (primary reports and systematic reviews); (3) critically appraising the retrieved evidence for its validity; (4) extracting the data; and (5) applying the results to patient care. The role of the Cochrane Collaboration in the preparation, dissemination, and timely updating of systematic reviews of evidence from randomized clinical trials is highlighted. Strategies for promoting evidence-based clinical practice are presented.

Evidence-based medicine (EBM) has been described as "the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients."[34] The practice of EBM requires efficient access to the best available evidence that is applicable to the clinical problem.

It is essential, however, to make two disclaimers. First, not every clinical decision can be based on strong evidence, because such evidence might not exist. In a study at McMaster University Medical Centre, the primary intervention for the primary diagnosis of admissions to the neonatal intensive care unit (NICU) was evaluated for category of supporting evidence as a treatment. Only 34% of cases were prescribed treatment based upon good randomized controlled trial (RCT) evidence. The majority of patients' primary (96%) and secondary (86%) diagnoses were managed with interventions based upon sound evidence.[6] Similar findings were found by Ellis and co-workers in the care provided on a general medicine inpatient service in England.[13] The estimated principal treatments prescribed for patients' primary diagnoses were based on strong evidence from RCTs in about 50% of cases, convincing non-RCT evidence in about 30% of cases, and no substantial evidence in about 20% of cases. These findings were based on evaluations of institutions emphasizing the practice of EBM. The proportion would undoubtedly be substantially lower than 50% in other institutions. Many widely used therapies have not been well evaluated with respect to either effectiveness or safety.[1]

Second, evidence provides a necessary but insufficient ground for clinical decisions. Clinical expertise is no less important under the evidence-based approach; an accurate history, physical examination, and clinical diagnosis are crucial to a properly directed search for evidence that is directly applicable to the patient's problem. In addition, for some treatment decisions, it is essential to consider the values and preferences of parents with respect to the probable clinical outcomes of the treatments being considered for their infant.

Asking a Focused Clinical Question

A focused clinical question should contain the following elements:

- Patients of interest
- Treatment or exposure of interest
- Nature of any comparisons to be made
- Primary outcome of interest and other important outcomes

The exact form of a focused clinical question depends on whether the question concerns treatment or prevention, etiology, diagnosis, or prognosis.[17,46] For questions concerning treatment or prevention, a focused question has the following form: In (patient, problem, or risk factor) does (treatment of interest) compared with (control or alternative treatment) reduce (adverse outcome[s])?

Two examples follow: (1) In women carrying fetuses of 24 to 34 weeks' gestation who are at risk of delivering, does corticosteroid (dexamethasone or betamethasone) compared with no treatment reduce the incidence of respiratory distress syndrome (RDS) in their infants? (2) In infants ≥36 weeks with hypoxic ischemic encephalopathy, does hypothermia treatment using either whole body hypothermia or selective head cooling, compared with no hypothermia treatment, reduce the frequency of moderate to severe neurodevelopmental impairment or death at 18 to 24 months of age?

Armed with a focused clinical question based on an accurate delineation of the clinical problem, the treatment

alternatives being considered, and the important clinical outcomes, a targeted search can be conducted for valid evidence that is applicable to the problem.

Finding Evidence

Sources of Evidence

Clinical evidence that is relevant to problems in neonatal-perinatal medicine is appearing at an accelerating rate and can be found in journals, conference proceedings, online databases, and other sources. Many published reports provide only weak evidence because strong research designs were not used. Evidence-based recommendations are constantly changing as new evidence becomes available. The challenge for a busy clinician is to be able to identify evidence that is valid, up-to-date, and applicable to the clinical problem using strategies that are comprehensive and yet efficient. These strategies are usually directed at retrieving primary reports and systematic reviews.

Recent review articles might seem like an efficient source of best available evidence. Because most review articles do not use explicit review methods, however, systematic reviews (discussed later) are a better source of summarized evidence. Although textbooks can provide valid evidence that is based on systematic methods of review, very few textbooks (except books that focus on evidence-based practice[8,14,30,38]) require contributors to use explicit and systematic methods when reviewing evidence and making treatment recommendations. There tends to be a long time gap between the appearance of new evidence and its impact on therapeutic recommendations found in textbooks.[2] In neonatal-perinatal medicine and other fields in which new evidence is rapidly accumulating, it is especially important to be able to access systematic reviews that are frequently updated.

Efficient Strategies for Searching for Evidence

Primary Reports

Primary reports that are relevant to neonatal-perinatal medicine are published in numerous journals. Most of these journals are indexed in MEDLINE, but additional reports may appear in journals indexed in other computerized databases, including CINAHL and EMBASE. With access to the Internet, one can now search MEDLINE for clinical evidence using PubMed; other databases maintained by the National Library of Medicine also can be accessed. PubMed can be accessed at www.ncbi.nlm.nih.gov/pubmed. An increasing number of full-text articles are available through PubMed Central (accessible through PubMed).

To define the topic of a search, one uses medical subject headings (MeSH terms), text words, or a combination, combining them appropriately in a Boolean search with *AND* or *OR* (a medical librarian can quickly teach the logic of this). Help is also available online in the PubMed tutorial. Search terms for the patient population, the intervention, the comparison, the outcome of interest, or all of these may be included.

Often the clinician finds that a MEDLINE search based only on topic descriptors yields a long list of reports that he or she does not have time to scan or read. Busy clinicians need to prune potentially cumbersome lists by incorporating into the search a strategy for limiting the retrieval to reports that are likely to be of high methodologic quality and more likely to provide valid evidence. This strategy includes using methodologic filters that have been validated against hand-searching[20,21,50] to identify articles that, depending on the type of focused question posed, have the methodologic quality attributes shown in Table 7.1. These methodologic filters are used together with topic descriptors (with the use of *AND*) so that only articles that are clinically relevant and satisfy the methodologic criteria are retrieved.

By choosing different methodologic filters, the clinician can maximize either the sensitivity (for comprehensiveness) or the specificity (for fewest methodologic false-positive results) of his or her search. To do this, one uses PubMed's Clinical Queries page (click on Clinical Queries on the PubMed page or access directly at https://www.ncbi.nlm.nih.gov/pubmed/clinical). After entering the clinical search terms, one is asked to click on the category of the question one is asking (therapy, diagnosis, etiology, prognosis, or clinical prediction guide) and on whether the scope of the search should be broad or narrow. If a clinician is reviewing a topic and wants to be comprehensive in retrieval of sound clinical studies, he or she would select a broad filter. If the clinician has limited time and wants

TABLE 7.1 Searching MEDLINE for Sound Clinical Studies Using Methodologic Filters

Type of Question	Criterion Standard for Methodologic Quality
Treatment	Random or quasi-random allocation of participants to treatment and control groups
Etiology	Formal control group using random or quasi-random allocation; nonrandomized concurrent controls; cohort analytic study with matching or statistical adjustment; or case-control study
Diagnosis	Provision of sufficient data to calculate sensitivity and specificity of the test, or likelihood ratios
Prognosis	Cohort of subjects who, at baseline, have the disease of interest but not the outcome of interest

Modified from Haynes RB, et al. Developing optimal search strategies for detecting clinically sound studies in MEDLINE. *J Am Med Inform Assoc*. 1994;1(6):447-458.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

urgent access to perhaps only one or two reports that are likely to be methodologically sound, he or she would select a narrow filter.

Reviews

Systematic reviews[7,40] are distinguished from other types of reviews by the rigor of the review methods. The objectives and methods are explicitly planned a priori, and they are documented in the review. A review without a methods section is unlikely to be a systematic review.

Systematic reviews of RCTs attempt to identify all trials that have compared a defined therapy against an alternative in a defined population. Trials are included or excluded from the review on the basis of methodologic rigor (without consideration of the trial results). If the populations and the contrasting interventions are similar, the results may be summarized quantitatively by calculating a typical effect based on the results of all eligible trials. This latter step, called a *meta-analysis,* increases the precision of the estimates of treatment effect. A meta-analysis is not a necessary part of a systematic review, however; if there is clinical or statistical heterogeneity across trials, it may be inappropriate to calculate a typical effect. Systematic reviews can be found in MEDLINE by limiting the publication type to "Meta-Analysis" or by using PubMed's Clinical Queries (Systematic Reviews column).

An example follows: The clinician wishes to find a systematic review, with meta-analysis, of studies of women at risk for preterm delivery that assesses the effect of antenatal corticosteroids on the incidence of RDS in their infants. Using PubMed, the search terms are entered: corticosteroid *AND* respiratory distress syndrome. The search is limited by publication type to meta-analysis. Alternatively, topic descriptors could be entered into the Clinical Queries page, and the output would be viewed under "Systematic Reviews."

Cochrane Systematic Reviews

The Cochrane Collaboration is an international organization that prepares, maintains, and disseminates up-to-date systematic reviews of health care interventions. The reviews are prepared by members of collaborative review groups, including the Pregnancy and Childbirth Review Group and the Neonatal Review Group. The reviews are published electronically in the *Cochrane Library,*[9] which is published every 3 months and allows the reviews to be updated as new evidence appears. The reviews prepared by the Neonatal Review Group formally maintained by the National Institute of Child Health and Human Development can now be found at www.neonatal.cochrane.org/our-reviews. Cochrane reviews are indexed in MEDLINE, so they can also be identified using PubMed searches (using the topic descriptor alone or limiting the search by using the topic descriptor *AND* Cochrane). A description of these reviews has also been published.[41]

Critically Appraising Evidence for Its Validity

The fundamental goal of clinical research is to obtain an unbiased answer to the question posed. Bias leads to an answer that is systematically different from the truth. Guides to assessing the validity of clinical research in the realms of therapy, etiology, diagnosis, prognosis, and reviews are available.[18,19,22,24,25,32] Box 7.1 provides a simple distillation of the major methodologic issues to be considered. More comprehensive guides, with specific applicability to therapeutic studies in neonatal-perinatal medicine, have been published.[33,48]

Most studies on treatment or prevention use designs that can be classified into one of four categories, listed in order of increasing methodologic rigor:

1. Case series without controls
2. Nonrandomized studies using historical controls

• BOX 7.1 Readers' Guides for Appraising the Validity of Clinical Studies

Therapy

- Was the assignment of patients to treatments randomized?
- Was randomization concealed (so that the decision to enroll a patient could not be influenced by knowledge of planned group assignment)?
- Were all patients who entered the trial accounted for and attributed at its conclusion?
- Were outcomes assessed "blindly," without knowledge of treatment group?
- When possible, were patients and caretakers blind to treatment?

Etiology or Harm

- Were there clearly defined comparison groups, similar with respect to important determinants of outcome, other than the one of interest?
- Were the outcomes and exposures measured in the same way in the groups being compared?
- Was follow-up sufficiently long and complete?
- Is the temporal relationship correct?

Diagnosis

- Was there an independent, blind comparison with a criterion standard?
- Did the patient sample include the kinds of patients to whom the diagnostic test would be applied in practice?
- Were the test results prevented from influencing the decision to perform the criterion standard (workup bias avoided)?
- Can the test be replicated on the basis of the method reported?

Prognosis

- Was there a representative, well-defined sample of patients at a uniform point in the course of the disease (inception cohort)?
- Was follow-up sufficiently long and complete?
- Were objective and unbiased outcome criteria used?
- Was there adjustment for important prognostic factors?

Criteria from references 17, 18, 22, 24, and 25.

3. Nonrandomized studies using concurrent controls
4. RCTs

The randomized trial is the strongest design for evaluating the effect of treatment. It offers maximum protection against selection bias that can invalidate comparisons between groups of patients. The allocation process should be truly random (not quasi-random, e.g., alternate) and masked so that the person(s) making enrollment decisions cannot discern the next group assignment. In addition, follow-up should be complete, with all randomized patients being accounted for in the primary analysis, and outcome measurements should be made by observers who are masked to the treatment allocation. When feasible, masking of the caretakers, the patient, and the patient's family to the treatment allocation should be accomplished. When reading reports of therapeutic studies, the clinician should scan the "Methods" section to assess validity using these criteria.

Extracting the Data and Expressing the Effect of Treatment

Table 7.2 displays the structure of a typical study that assesses the effectiveness of a treatment. There are two exposure groups (labeled *treated* or *control*) and two possible outcome categories (labeled *event* or *no event*). An event is a categorical adverse outcome, such as occurrence of disease, adverse neurodevelopmental outcome, treatment side effect, or death. The effect of treatment is given by comparing the event rate in the treated and control groups, which can be accomplished using either relative or absolute treatment effect estimators.

The relative risk (RR) is the ratio of risk in the treated group to the risk in the control group, [a/(a + b)] / [c/(c + d)]. This is a relative, but not absolute, measure of risk in the event rate. The complement of the relative risk is the relative risk reduction (RRR). Relative risk reduction (1-RR) is the percent reduction in risk in the treated group compared with the controls. Relative risk of 0.75 represents 25% RRR. The risk difference (RD) or absolute risk difference (ARD), [c/(c + d)] − [a/(a + b)], indicates the absolute magnitude of reduction or increase in risk between the control group and treatment group. A risk difference of 0.05 represents an absolute 5 percentage point reduction of the event rate in the treated group.

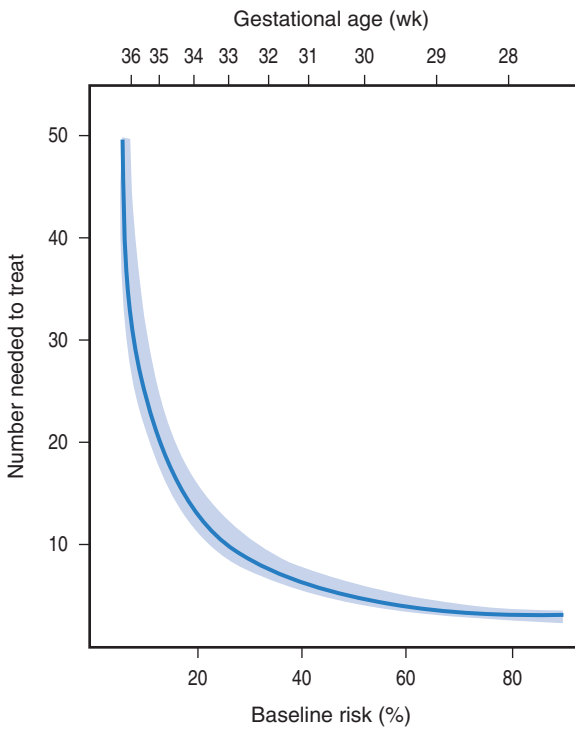
The ARD can be termed absolute risk reduction (ARR) when the risk is decreased with treatment or absolute risk increase (ARI) when the risk is increased with treatment. The reciprocal of the absolute risk reduction (1/ARR) indicates the number of patients who must be treated to expect to prevent the event in one patient. For an ARR of 5% or 0.05, 20 patients (1/0.05) need to be treated to prevent the event in one patient. The number needed to treat (NNT) is particularly relevant when deciding whether to use a treatment that is effective but causes important clinical side effects or is very expensive. The patient's expected event rate in the absence of treatment may be a crucial determinant of this decision. When outcome data are reported on a continuous scale (e.g., blood pressure measured in mm Hg), a different measure of effect, the mean difference, is computed.

TABLE 7.2 Structure of a Study to Assess the Effect of a Treatment and Measures of Treatment Effect

	Outcome	
Exposure	**Event**	**No Event**
Treated	a	b
Control	c	d
Treatment Effect Measures		
Relative risk (RR)	a/(a + b) / c/(c + d)	
Relative risk reduction (RRR)	1 – RR	
Odds ratio	ad/bc	
Risk difference (RD) or absolute risk difference (ARD)	c/(c + d) – a/(a + b)	
Number needed to treat (NNT) or number needed to harm (NNH)	1/RD = 1/ARD	

Applying the Results to Patient Care

The results of randomized trials of therapy indicate the likely effects of the therapy—beneficial and adverse—on important clinical outcomes. These effects are average effects in the patients who are entered in the trials, however, and they may or may not accurately predict the net benefit to be expected in specific subgroups or individual patients.[12,15] This problem becomes especially important when a treatment produces benefits and harm. Often, patients at high risk of the primary outcome are more likely than patients at low risk to benefit from an effective therapy. Because patients at high risk and patients at low risk are exposed to the adverse side effects of that treatment, the balance between likely benefits and harm can shift. This problem is compounded because individual patients may place different values on the relative importance of benefits and harm caused by treatment.



In deciding whether to use an effective therapy in an individual patient, particularly when the therapy results in important clinical side effects, one must consider the relative likelihood that the therapy would actually prevent the adverse target event, or cause adverse side effects, in that individual patient. One way of approaching this decision is to determine whether the report of the relevant trial or systematic review of trials described the size of risk reduction for the primary outcome, and risk increases for any side effects caused, according to patient subgroups defined by patient characteristics at entry. If outcomes are reported for sufficient numbers of patients in these subgroups, it may be possible to derive a relative likelihood of being helped or harmed from the subgroup most similar to the individual

patient. More often, however, either RRR across subgroups is not clearly different, or the clinician cannot judge this because data by subgroups are not presented, or the groups are too small for meaningful comparisons.

Assuming that RRR is constant across the range of baseline risk, one can calculate a patient-specific ARR using the formula ARR = RRR × PEER, where *PEER* is the patient's expected event rate in the absence of treatment. In neonatal-perinatal medicine, such information may often be available from cohort studies reporting risk based on gestational age, birth weight, and postnatal age. Using this approach, ARR (and its inverse, NNT) would be shown to vary with PEER. In patients at high risk, ARR would be high and NNT would be low, whereas in patients at low risk, the reverse would be true.[16,19,39,44]

An example of this form of analysis is shown in Fig. 7.1. A systematic review of randomized trials of antenatal corticosteroid for the prevention of RDS in infants of mothers at risk of delivering prematurely showed that this therapy was effective in reducing the incidence of RDS, with RRR of 41%.[11] Relative risk reduction was fairly constant across subgroups based on gestational age. Because the expected risk for RDS is high at short gestation, but decreases markedly with increasing gestation, NNT to prevent one case of RDS is low when gestation is less than 30 weeks, but it increases sharply after 34 weeks. Although the trials did not show short-term harmful effects, few of them undertook the assessment of long-term effects. Given the uncertain balance at gestation periods beyond 34 weeks between the small likelihood of short-term benefits and the undocumented but not well-studied possibility of long-term risks, the National Institutes of Health (NIH) Consensus Conference on prenatal corticosteroids recommended that women carrying fetuses of 34 weeks' gestation or less who threaten to deliver prematurely be considered candidates for steroid treatment (see Chapter 19).[31] Subsequently, administration of betamethasone to women at risk for late preterm delivery (34 wks 0 days-36 wks 4 days) was shown to significantly reduce the rate of neonatal respiratory complications.[19a] Other examples and a more detailed discussion of how to balance the risks and benefits in prescribing therapies for individual patients have been published.[44]

• **Fig. 7.1** Number of fetuses who must be treated (number needed to treat [NNT]) with antenatal corticosteroid to prevent one case of respiratory distress syndrome (RDS) as a function of baseline risk. The NNT is derived from the typical relative risk reduction of 41% calculated from the data of the trials included in the systematic review of Crowley. The *shaded zone* indicates the 95% confidence interval. As the gestational age increases, baseline risk for RDS decreases and NNT increases. (From Crowley P. Antenatal corticosteroid therapy: a meta-analysis of the randomized trials. *Am J Obstet Gynecol*. 1995;173(1):322-335.)

Promoting Evidence-Based Clinical Practice

The evidence-based practice paradigm places responsibility on the physician to develop and maintain the skills needed to find relevant evidence efficiently, appraise it critically for its validity, and apply it to the clinical problem. The development of these skills should begin in undergraduate medical education, and there is evidence that teaching critical appraisal skills can be incorporated successfully into clinical clerkships.[3] A useful tool for acquiring these skills and enabling evidence-based care is the critically appraised topic,[37] which comprises asking a focused question about a patient, finding and appraising relevant articles quickly, and synthesizing the evidence into a one- or two-page summary.

Attainment of the required skills by individual practitioners poses a challenge. A survey of English general practitioners[28] revealed that although they were favorably disposed to the concept of evidence-based clinical practice, they believed they lacked the necessary knowledge and skills to carry it forward. Only 16% had formal training in searching for evidence, and only about 33% believed they had sufficient understanding of key terms, such as *relative risk* and *number needed to treat,* that they could explain them to others. Most believed that the best way to promote evidence-based practice was the introduction of evidence-based practice guidelines or protocols.[28] Experts in Europe have developed a formal electronic-based curriculum (www.ebm-unity.medmonash.edu/index.html) designed to improve the skills of busy clinicians to integrate EBM at the bedside and other clinical settings.[10,47] Once fully implemented, the project will lead to a specialist qualification in teaching EBM. Utilizing a self-directed electronic-based curriculum alone has demonstrated only similar effectiveness in teaching evidence-based medicine skills as formal teaching methods.[5,49]

The preparation and dissemination of practice guidelines or consensus recommendations does not ensure their use in

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

practice.[4,29] Several strategies aimed at promoting behavioral change among clinicians have been tested, and some have been found successful. Two of these strategies—introducing guidelines through opinion leaders and providing audit and feedback—were included in an intervention package designed to encourage the use of antenatal corticosteroids in eligible women, in accordance with the NIH Consensus recommendations.[31] In a randomized trial in which this package was compared with a control intervention consisting of the usual dissemination of recommendations, the evidence-based use of antenatal corticosteroids was increased in the experimental group.[26,27] Cluster randomized trials are being increasingly used to evaluate competing strategies for promoting the use of evidence in clinical practice.[27,42] More of these studies are needed.

There is also a need for the further development of practical methods for measuring the importance or value that patients, caregivers, and the lay public attach to clinical outcomes.[44,45] In neonatal-perinatal decision making, these values are usually sought from the parents by using informal and unsystematic approaches. Formal systematic methods for measuring preferences,[23] including rating scales and the standard gamble, have been developed. These were used to measure quality of life as perceived by adolescent survivors of extremely low birth weight and their parents.[35] Such methods for rating health outcomes could be used increasingly in the future to assess the importance that parents attach to the probable outcomes of neonatal-perinatal treatment alternatives and to help guide evidence-based decision making for individual patients or patients in specific risk categories.[36,43] For assistance in applying the evolving standards for evaluating and applying evidence to perinatal care, obstetricians, neonatologists, and pediatricians are encouraged to consult the Grading of Recommendations Assessment, Development and Evaluation (GRADE) criteria.[16a,17a]

Acknowledgments

The authors wish to acknowledge the contribution of Dr. Kathleen Kennedy to previous versions of this chapter.

Key Points

- The practice of evidence-based medicine requires efficient access to the best available evidence that is applicable to the clinical problem.
- There are limitations to EBM in that evidence may not exist about the specific clinical problem in question.
- Evidence is necessary but not sufficient to provide clinical care. Clinical judgment must be linked with the evidence to provide optimal treatment.

Perinatal and Neonatal Care in Developing Countries

WALDEMAR A. CARLO

The science and practice of modern neonatology evolved as a medical specialty in the United States and the Western world over the last 70 years. Neonatology as a specialty in developing countries is still evolving. The increased attention to improving newborn care at a global level can be traced to the recognition by the World Health Organization (WHO) of unacceptably high infant mortality in low- and middle-income countries (LMICs).[96,97] The Alma Ata Declaration was the first serious effort by WHO to address the problem of high infant mortality rate (IMR) among developing countries.[27] Since then, several policies have been proposed and implemented to decrease the IMR and neonatal mortality rate (NMR) across the globe. Since the latter part of the twentieth century, there has been steady improvement in overall global newborn care resulting in the reduction of NMR and IMR in LMICs. These developments can be attributed to rapid globalization of health-related information and technology from developed high-income countries (HICs) to LMICs. Also, increased awareness of health and change in health care–seeking behavior among women during the past decade has improved maternal and child health. The major factors responsible for overall improvements in maternal and child care in LMICs probably include: (1) improved access to medical and technical information, (2) rapid transfer of technology, and (3) international campaigns such as the advocacy of the Millennium Development Goals (MDGs)[95] and the Sustainable Development Goals (SDGs).[94] Several large controlled trials have demonstrated the benefits of selected interventions, including packages of care such as the Mother-Baby Package[61] and the Essential Newborn Care program.[15,16,55,96,97] Considerable progress is being made in reducing maternal and child mortality in developing countries; however, many challenges remain. This chapter provides an overview of global neonatal and perinatal problems, presents data on the changing trends in IMR and NMR, and discusses strategies to decrease the IMR and NMR in developing countries.

Global Initiatives to Reduce Infant Mortality Rate and Neonatal Mortality Rate

Historical Perspective

Because of concerns of high global IMR, numerous interventions have been proposed and implemented by world organizations over the past four decades (Table 8.1). The Alma-Ata Declaration of 1978 by the WHO and the United Nations Children's Fund (UNICEF) set a goal to achieve "Health for all by the year 2000."[54] The declaration included a goal for the reduction of maternal and infant mortality through primary care. In 1987, the International Conference on Safe Motherhood drew attention to high maternal mortality rates (MMRs) in developing countries and encouraged policymakers to develop new strategies to reduce maternal mortality.[104] This action led to the worldwide program of Safe Motherhood, placing an emphasis on antenatal care. A similar resolution, the Bamako Initiative, was instituted at the annual meeting of the African Ministries of Health in 1987.[32] The objective was the achievement of universal maternal-child health coverage at the periphery by 2000. In 1988, the Task Force for Child Survival set objectives for a reduction in MMR and IMR.[90] One of these objectives was a worldwide reduction in mortality by at least half, or by 50 to 70 per 1000 live births, whichever can be achieved first, for children 5 years old and younger. Another objective was the reduction of MMR worldwide by at least half.

In 1994, WHO developed the Mother-Baby Package to help reduce MMR and NMR further.[61] Recognizing that MMR remained high, in 1999 WHO re-emphasized the need for an acceleration of national and international efforts to decrease MMR and perinatal mortality rate through the Safe Motherhood program. At the 48th World Assembly of WHO, the concept of integrated management of childhood illness was adopted to improve the well-being of the whole

Abstract

Developing countries continue to share the major burden of neonatal and infant mortality including about 98% of the deaths worldwide. The most frequent causes of neonatal mortality in low- and middle-income countries are preterm birth complications, birth asphyxia, and sepsis/meningitis. The major causes responsible for such disparity between countries are a lack of health facilities, lack of skilled personnel, and lack of access to health care. Considerable progress is being made in reducing maternal and child mortality in developing countries; however, many challenges remain. By the end of the twentieth century, a significant decrease in maternal and infant mortality was reported to be one of the top health achievements of the century. The Sustainable Development Goals program declared in 2015 is the single most influential program bringing the world community, governments, scientists, and policymakers together to address the issues of high neonatal and infant mortality in low- and middle-income countries. There is evidence-based data that show which antenatal, intrapartum, and neonatal interventions are most effective. Several large controlled trials have demonstrated the benefits of selected interventions, including packages of care such as the Mother-Baby Package, Helping Babies Breathe (resuscitation), and the Essential Newborn Care programs. Neonatology is a work in progress in low- and middle-income countries.

TABLE 8.1 Global Initiatives to Decrease Neonatal, Child, and Maternal Mortality

Initiative	Organization	Year and Occasion	Goals
Declaration of Alma-Ata	WHO, UNICEF	Sept 1978, USSR, International Conference on Primary Health Care	Health for all by 2000
Safe Motherhood Initiative	WHO, UNICEF, UNFPA, World Bank, and others	1987, Nairobi, International Safe Motherhood Conference	Reduce maternal mortality to half the present rate by 2000.
Bamako Initiative	UNICEF, WHO	September 1987, Bamako, Mali, Annual Meeting of African Ministers of Health	Achieve universal maternal and child health coverage at the peripheral level by 2000. Revitalize peripheral public health systems. Supply basic drugs. Establish revolving funds. Involve communities in health care.
Task Force for Child Survival	WHO, UNICEF, World Bank, UNDP, Rockefeller Foundation	March 1998, Talloires, France, Protecting the World's Children, an Agenda for the 1990s	Global eradication of polio. Virtual elimination of neonatal tetanus, 90% reduction in cases of measles and 95% reduction in its fatalities, 25% reduction in fatalities owing to ARI. Reduction of IMR and MMR by half or 50-70/1000, whichever is greater. Reduction of MMR by at least half.
Mother-Baby Package	WHO	Sept 1994, Cairo, International Conference on Population and Development	Reduce maternal mortality to half of 1990 levels by 2000.
			Reduce perinatal and neonatal mortality from 1990 levels by 30%-40% and improve newborn health.
Making Pregnancy Safer	WHO	1999, Safe Motherhood Initiative	Accelerate reduction of high maternal and perinatal mortality and morbidity by refocusing WHO strategies in national and international health sectors.
Millennium Development Goals	WHO	2000-2015	Reduce child mortality Reduce by two-thirds the mortality rate for children <5 years old between 1990 and 2015.
Newborn Care Training	NIH	2010	Essential newborn care training of community-based birth attendants has reduced the stillbirth rate.*
Sustainable Development Goals	WHO	2015-2030	Reduce the under-5 mortality rate by two-thirds between 1990 and 2015. Reduce the maternal mortality rate by three-fourths between 1990 and 2015. Reduce global maternal mortality to ≤70 per 100,000 live births. Reduce neonatal mortality to ≤12 per 1000 live births. Reduce under-5 mortality to ≤25 per 1000 live births.

ARI, Acute respiratory infection; IMR, infant mortality rate; MMR, maternal mortality rate; NIH, National Institutes of Health; UNDP, United Nations Development Program; UNFPA, United Nations Fund for Population Activities; UNICEF, United Nations Children's Fund (formerly United Nations International Children's Emergency Fund); WHO, World Health Organization.

child younger than 5 years old.[93] This concept included an emphasis on improved care of newborns. By the end of the twentieth century, a significant decrease in MMR and IMR was reported as one of the top 10 achievements of the century.[91] However, the high IMR and NMR in the LMICs continued to be a major concern to global policymakers. The World Bank initiated the Global Burden of Disease study, which showed that perinatal conditions, including infant mortality, form a significant portion (39%) of the global burden of disease. It showed that developing countries are the major contributors to global perinatal and neonatal mortality. Perinatal mortality constitutes one of the 10 leading causes of death in developing countries. Neonatal mortality is the major part of perinatal mortality. These findings underscore the importance of improving perinatal and neonatal care in developing countries, as declared in the MDGs in 2000.[95]

The Millennium Development Goals (MDGs)

In 2000, the United Nations developed eight MDGs to be achieved by 2015.[95] The targets were measured by preset quantifiable measures. The MDGs focus on some specific health issues but also emphasize social, economic, and public health and health-policy matters that affect the "health" of the people and addressed specific indicator goals for perinatal care (Table 8.2).

In addition to these developments, the series of landmark scientific publications in *The Lancet* provided evidence-based scalable interventions that could reduce NMR and IMR in resource-poor countries.[22,41] These publications generated great interest among researchers and health policymakers around the globe. The Child Survival series examined the potential impact of scaling up 43 interventions that could reduce child mortality by 2015. In 2005, the series on newborn survival provided the first systematic estimates of neonatal deaths by cause and identified simple and cost-effective scalable interventions that could reduce neonatal deaths globally. The impact of some of the suggested interventions is described in the later part of this chapter.

The Sustainable Development Goals

In 2015, the United Nations proposed the Sustainable Developmental Goals (SDGs) to be achieved by 2030.[36,94] These goals were adopted to end poverty, protect the planet, and ensure prosperity for all as part of a new sustainable development agenda. Each goal has specific targets to be achieved over the next 15 years. There are 17 goals (Fig. 8.1).[94] Goal 3 is focused on health and aims to ensure healthy lives and promote well-being for all at all ages. This goal includes specific targets for perinatal and childhood health outcomes. The maternal and childhood targets aim to reduce global maternal mortality ratios to less than 70 per 100,000 live births and end preventable deaths of newborns and children under 5 years of age, with all countries aiming to reduce neonatal mortality to at least as low as 12 per 1000 live births and under-5 mortality to at least as low as 25 per 1000 live births. These aspiring goals are ambitious and will require commitment from all stakeholders to achieve them.

Tracking the Global Progress of the Sustainable Development Goals

Worldwide efforts are taking place to implement SDGs and track their impact. There is a need for accurate birth and death data from all participating countries. Unfortunately, collecting accurate NMR, IMR, and under-5 mortality data on a global scale remains a major problem. There are several hurdles to collect these data accurately. Whereas high-income countries have well-established vital statistics of births and deaths, the LMICs do not. Ostergaard and coworkers found that only 60 of the 193 countries studied had fully functioning sources of mortality data[67]; the rest of the countries depend on annual or periodic surveys. There is a need for improvement in accurate vital statistics to establish

TABLE 8.2 Details of Millennium Development Goals (MDG) and Sustainable Development Goals (SDG) Related to Perinatal Care

Goals	Targets	Indicators
MDG Goal 4 Reduce child mortality	Reduce the under-5 mortality rate by two-thirds between 1990 and 2015.	Under-5 mortality rate (deaths per 1000 live births) Infant mortality rate (deaths per 1000 live births) Proportion of 1-year-old children immunized against measles
MDG Goal 5 Improve maternal health	Reduce the maternal mortality rate by three-fourths between 1990 and 2015.	Maternal mortality ratio (deaths per 100,000 live births) Proportion of births attended by skilled health personnel
SDG Goal 3 Good health and well-being	Reduce global maternal mortality to ≤70 per 100,000 live births. Reduce neonatal mortality to ≤12 per 1000 live births. Reduce under 5 mortality to ≤25 per 1000 live births.	Maternal mortality ratio (deaths per 100,00 live births) Neonatal mortality rate (deaths per 1000 live births) Under-5 mortality rate (deaths per 1000 live births)

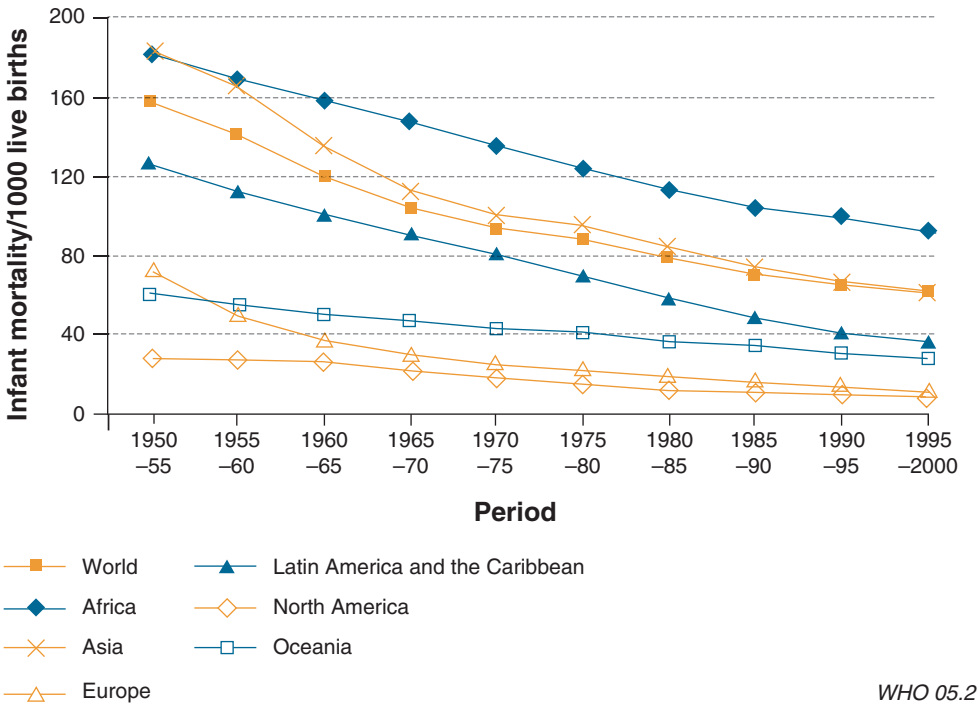
the true burden of MMR, NMR, and IMR and to develop appropriate strategies to monitor progress.

Global Burden of Maternal and Neonatal Deaths

Maternal Mortality

Maternal mortality has been a major global burden of disease.[51] At the time of and preceding the declaration of MDGs, more than 600,000 women were dying annually from causes related to pregnancy and childbirth.[92] Asia and Africa had the highest MMR and the highest number of maternal deaths, compared with only 4000 deaths per year in HICs. The causes of maternal death include maternal hemorrhage (25%), sepsis (15%), abortion (13%), hypertensive disorders of pregnancy (12%), and obstructed labor (8%). More than 50% of the deaths related to pregnancy and childbirth were estimated to be preventable using simple, well-accepted interventions. The MDG #5 aimed at reducing the MMR by 75% between 1990 and 2015.



On a positive note, global MMR in 2010 had decreased by 47% (from 400/100,000 in 1990 to 210/100,000), accounting for 287,000 maternal deaths in 2010.[14,58] Although the overall number of maternal deaths has decreased, only 10 countries have reached the goal, 9 countries are "on track," 50 countries are "making progress," 14 countries have made "insufficient progress," and 11 are categorized as having made "no progress" at all. Sub-Saharan Africa (56%) and South Asia (29%) continue to bear the major burden of global MMR (85%), accounting for 245,000 maternal deaths in 2010. Two countries, Nigeria and India, contribute one-third of the global MMR: India at 19% and Nigeria at 14%.

Neonatal and Infant Mortality

There are limited data on NMR or IMR that go back to the early twentieth century, but there were major reductions in mortality. Fig. 8.2 shows global trends in IMR during 1950 to 2000.[60] In the 1950s, there were wide variations in IMR among different regions of the world. Infant mortality rate was lowest in industrialized Western countries (33 per 1000). It decreased to around 5 per 1000 by 2000, a reduction of 85%. In 1950, sub-Saharan Africa had the highest IMR (157 per 1000) and showed the least reduction (only 32%) among all the regions of the world during the next 50 years. South Asia, the Middle East/North Africa, and Latin America/Caribbean showed 53%, 70%, and 74% decreases, respectively. At the end of the twentieth century, IMR continued to remain significantly high: 70 per 1000 in South Asia, 45 per 1000 in the Middle East, and 27 per 1000 in Latin America.

In an analysis of NMR, out of 193 countries from 1990 to 2009, the investigators found that only 38 countries had a system of civil registration of births and deaths.[67] One hundred fifty-five other countries calculated NMR using statistical models. During the two-decade study, 79 million babies died. More than 98% of deaths occurred in LMICs, the majority of these deaths occur in South Asia and sub-Saharan Africa. The annual reduction rate of NMR was twice as high for the period 1999 to 2009 (2.3%) compared with the period 1990 to 1999 (1.1%). There was a lower

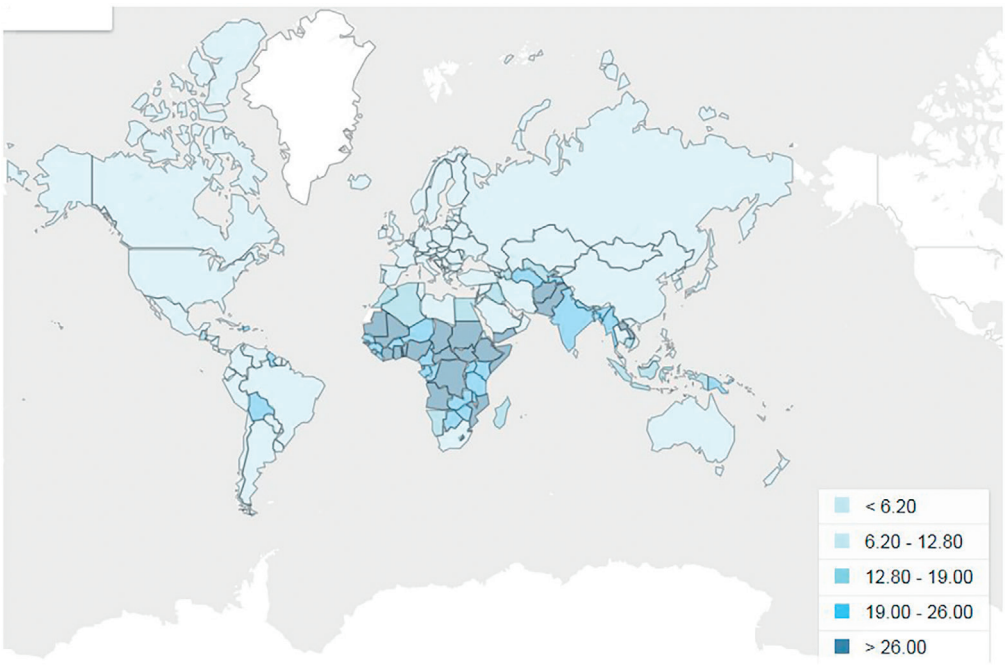
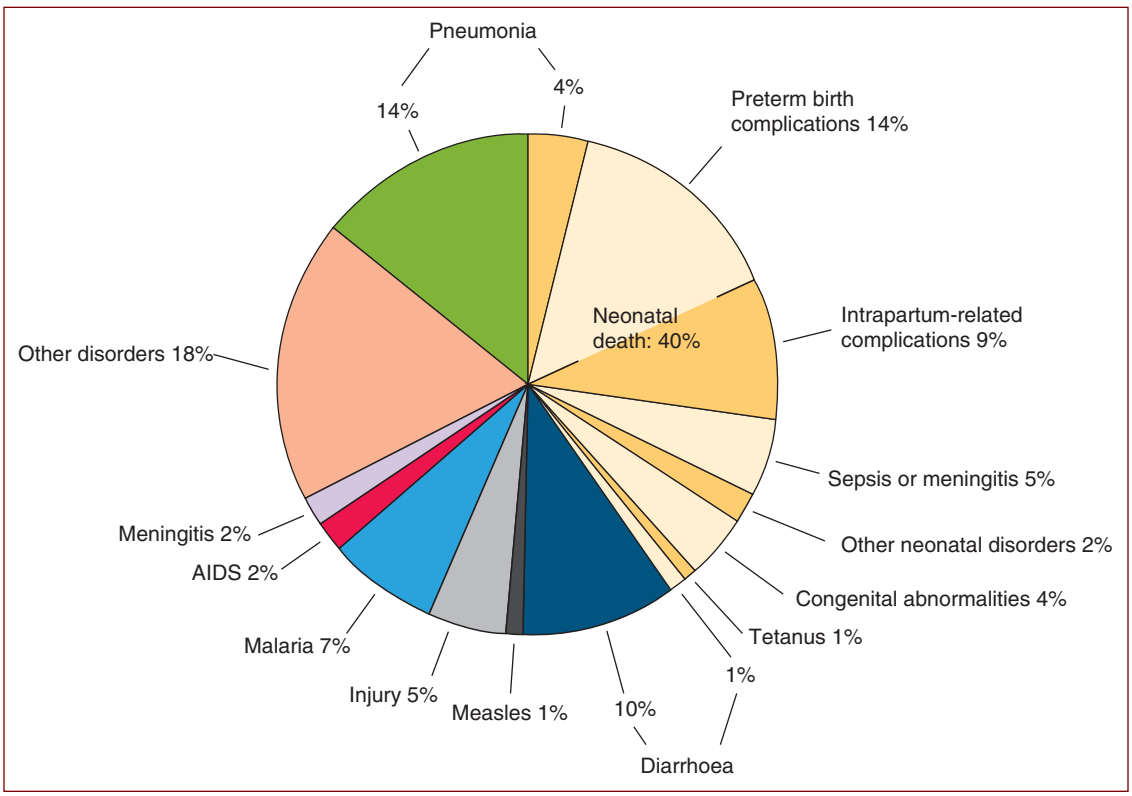
• **Fig. 8.2** Global trends in IMR during 1950 to 2000. Over the past 50 years major demographic changes have affected all regions and countries. As a result of changes in fertility and mortality the world's population has increased from 2.5 billion to 6 billion. Declines in mortality rates, especially during childhood, have been particularly remarkable. (Moser K, Shkolniko V, Leon DA. World mortality 1950-2000: divergence replaces convergence. *Bull World Health Organ*. 2005;83:202-209.)

rate of reduction of NMR in high-income countries (HICs) (1.7% in 1999 to 2009 vs. 3.7% in 1990 to 1999). In spite of these decreases in NMR across the LMICs, the annual rate of NMR reduction was still well below the MDG #4 goal of 4.4% and below the IMR and under-5 mortality rate reductions.[37] Most importantly, NMR varies marginally between countries, with the highest neonatal mortality rates in sub-Saharan Africa and Southeast Asia (Fig. 8.3).



Of the 7.6 million deaths in children under 5 years in 2010, 40% were neonatal deaths (Fig. 8.4).[49] Preterm birth complications (14% of under-5 deaths), birth asphyxia (also called intrapartum-related) complications (9%), and sepsis/meningitis (5%) were the most frequent causes of death in the neonatal period. About 35% of the neonatal deaths occured on the day of birth with another ~35% occurring during the rest of the first week after birth[69] (Fig. 8.5). After a month of age, pneumonia (14%), diarrhea (10%), and malaria (7%) were the most frequent causes of death. To decrease under-5 mortality the most, efforts should concentrate on these causes of death, particularly soon after birth.[48,49,50]

Compared with NMR, the under-5 mortality rate (U5MR) decreased considerably from 1990 to 2010. Fig. 8.6 shows trends in U5MR and NMR in 193 countries from 1990 to 2010.[45] The U5MR showed a steady decrease during the period, whereas the NMR, although decreasing, did so at a slower rate. The NMR thus constituted a higher proportion of U5MR from 2000 to 2010 compared with 1990 to 2000. South Asia accounts for more than half of under-5 deaths. Almost 30% of global neonatal deaths occurred in India. Sub-Saharan Africa accounts for 38% of global neonatal deaths, with the highest NMR (34/1000 live births) and least progress in reducing that rate over the last two decades. Neonatal deaths in sub-Saharan Africa account for about one-third of U5MR (1.1 million neonatal deaths). Taking into consideration the current slow rate of reduction in NMR among the LMICs,[100] the authors also calculated the number of years it will take various countries in different regions to achieve NMR levels similar to those currently in HIC (Fig. 8.7).[67] It is disconcerting to note that for some countries, it will take several decades to reach the low levels of HIC, whereas others may take more than 100 years to reach the low levels of HICs. These disappointing findings underscore the need for serious efforts with a stronger health policy to decrease NMR and IMR in sub-Saharan countries.



Causes of Global Maternal and Neonatal Mortality

Factors that influence MMR and NMR include commonly known maternal and neonatal medical problems, socioeconomic conditions, gender inequality, environmental factors, and economic and political instability. Socioeconomic factors greatly influence the health of mother and baby, in particular, in LMICs, as discussed in the following section.

Neonatal mortality levels for 193 countries in 2009 with trends since 1990: a systematic analysis of progress, projections, and priorities. *PLoS Med*. 2011;8:e1001080.)

Socioeconomic and Cultural Factors

The socioeconomic factors adversely influencing IMR include gender bias against women, maternal education, and economic dependence. SDG #5 is aimed at eliminating gender inequity. Gender bias against women has a negative effect on every phase of a woman's life, interfering with her education, economic power, and health.[71] Gender-biased discrimination begins its influence early in life, leading to poorer nutrition and health in girls compared with boys.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

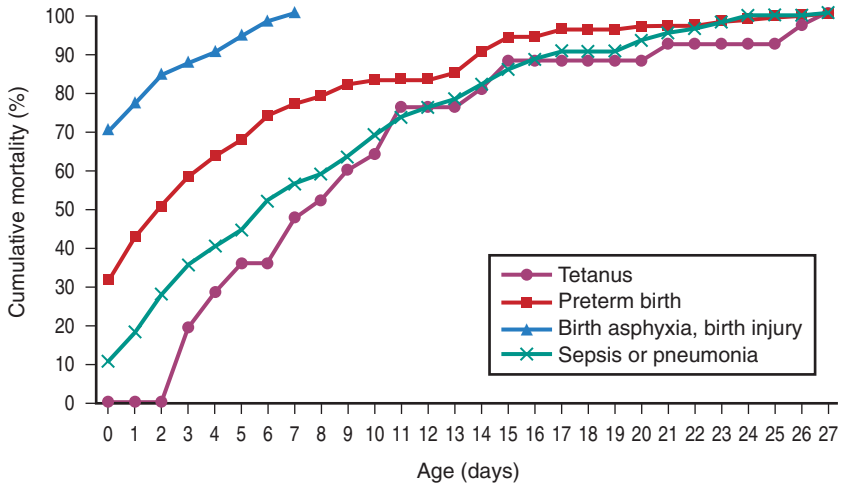
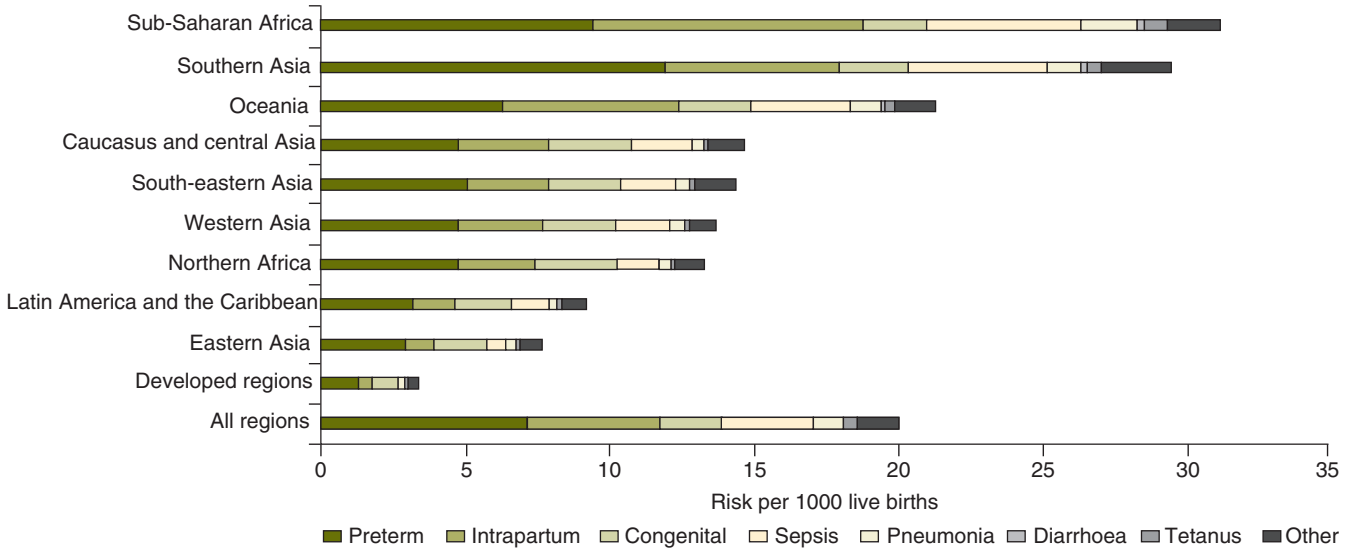
Gender inequalities persist worldwide, depriving women and girls of their basic rights and opportunities. SDG #1 aims to end poverty in all its forms everywhere. SDG #4 aims to ensure inclusive and equitable quality education and promote lifelong learning opportunities for all. Evidence shows that a woman with more education has fewer children, better economic status, lower fertility rate, lower IMR, and improved quality of life. Even in developed countries, every additional year of education for women is associated with lower mortality rates at all ages.[26] Education increases earning potential, and higher income is associated with lower mortality. Earning power provides women with economic, social, and political empowerment. In short, education is seen as a means of ensuring health. Health-seeking behavior during pregnancy, childbirth, and the neonatal period is influenced by regional, religious, and ethnic differences and by cultural beliefs. Understanding the cultural beliefs and their influences on care of the mother and infant is crucial to providing appropriate counseling to mothers.[81] Health strategies to improve MMR and IMR in LMICs include implementation of programs that eliminate gender inequities, end poverty, and ensure equitable education will enable women to improve their health and that of their children. In addition, increasing awareness of maintaining health, improving health-seeking behavior, and improving access to health care will improve health outcomes.



Influence of Political Instability, War, and Conflict

Economic stability alone does not guarantee better health of the mother and child. For example, many oil- and mineral-rich countries in Middle East, Africa, and Latin America with a sizeable global income are a unique group with wide disparities of wealth and health.[12] Despite high gross national product, some of these countries have high IMR, high U5MR, high MMR, and low life expectancy.[60] Although the overall IMR has decreased from ~200 per 1000 in the 1950s to ~50 per 1000 in 2000, in some countries, IMRs are far higher than in Latin America and East Asia.[78]

Women and children account for a disproportionate morbidity burden among conflict-affected populations. Political instability and wars have adversely affected perinatal and neonatal outcome. For example, infant mortality rate and under-5 mortality rate increased during the recent conflict in Syria.[28] Similarly, natural disasters such as Hurricane Katrina and tsunamis call for preparedness to care for pregnant women, parturient mothers, and neonates.[67,68] Pediatricians and neonatologists serving in areas of war conflicts and those working in the armed forces should be well-prepared to manage these situations.



Medical Causes of Neonatal Mortality Rate

In developing countries, prematurity, birth asphyxia, and sepsis/pneumonia continue to constitute a major portion of NMR and IMR (see Fig. 8.4).[49] About 40% of U5MR is due to NMR. Neonatal death due to prematurity is the number one cause of U5MR. Birth asphyxia and sepsis are the other major causes of neonatal mortality.[37,38,49,70] The WHO estimates that 40% to 60% of neonatal deaths are preventable. The time of death is dependent on these causes of death (Fig. 8.8).[5] Furthermore, specific causes of death vary substantially by regions of the world (Fig. 8.9).[70] In contrast to the major contributions of prematurity, birth asphyxia, and sepsis in LMIC settings, congenital malformations and prematurity are the dominant causes of neonatal mortality in HICs. The major causes of neonatal mortality are discussed in detail in the following section.

• **Fig. 8.8** Distribution of deaths by diagnostic categories during the first 28 days of life in a rural population. Lines show cumulative percent deaths for each diagnostic cause. Most deaths in babies with birth asphyxia occur during the first week of life. Prematurity is the second-highest cause of deaths, followed by sepsis and tetanus-related deaths start occurring by the second day of life. (Baqui AH, Darmstadt GL, Williams EK, et al. Rates, timing and causes of neonatal deaths in rural India: implications for neonatal health programmes. *Bull World Health Organ*. 2006;84:706-713.)

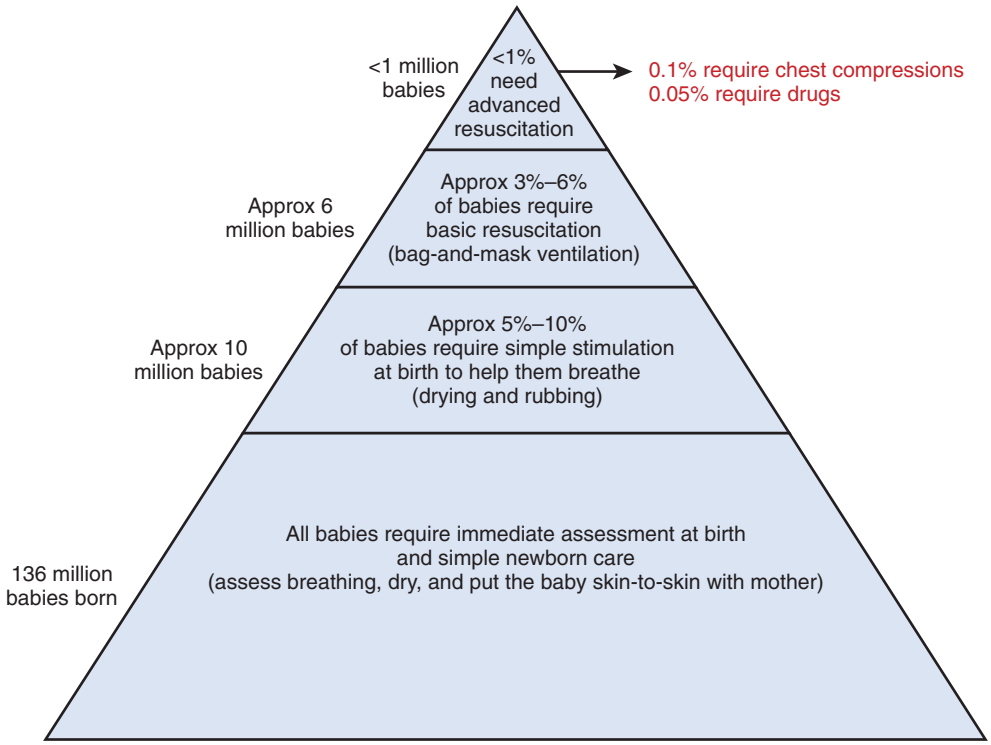
• **Fig. 8.9** Cause-specific risk of neonatal death by Millennium Development Goal (MDG) region in 2013. In every MDG region, preterm birth is the leading cause of neonatal death, with the highest risks in southern Asia (11.9 per 1000 live births) and sub-Saharan Africa (9.5 per 1000 live births). (Oza S, Lawn JE, Hogan DR, Mathers C, Cousens SN. Neonatal cause-of-death estimates for the early and late neonatal periods for 194 countries: 2000-2013. *Bull World Health Organ*. 2015;93:19-28.)

Prematurity



While prematurity is the most frequent cause of death in neonates, the specific cause of death in premature babies worldwide is not known. Respiratory distress syndrome is the most common cause of death in HICs, but in LMICs it is likely that lack of neonatal intensive care accounts for most of the deaths from prematurity. A meta-analysis conclusively demonstrates that surfactant administration reduces mortality in LMIC settings with neonatal intensive care units.[78,79] There are many other effective therapies, such as thermoregulation, nutrition, and prevention and treatment of sepsis, that may have a large impact in LMIC settings. It is likely that most interventions that reduce neonatal mortality in neonatal intensive care units in HICs will reduce neonatal mortality in similar settings in LMICs also.

Birth Asphyxia

Failure to achieve a smooth postnatal transition may lead to various degrees of birth asphyxia. Death due to birth asphyxia is defined as death due to the inability to breathe or sustain breathing soon after birth. Of the 136 million births per year globally, almost 1 million babies die of birth asphyxia. Most of these deaths occur in LMICs where an estimated 4 to 9 million infants per year experience birth asphyxia. Birth asphyxia contributes to 20% to 40% of all neonatal deaths depending on the setting.

The burden of birth asphyxia and the number of babies requiring resuscitation at birth at a global level are shown in Fig. 8.10.[47] It is estimated that of the 136 million annual births, about 10 million (5%–10%) respond to simple stimulation to initiate breathing efforts, 3% to 6% require basic resuscitation with bag and mask (6 million), and only less than 1% (<1 million) require advanced resuscitation (0.1% chest compression and 0.05% require drugs). Causes of birth asphyxia include poor maternal health, inadequate antenatal care, high-risk pregnancies and intrapartum complications, and inadequate care during labor and delivery. Prematurity also contributes to the problem of birth asphyxia. Lack of skilled birth attendants and lack of availability of proper equipment at the time of delivery are the major contributing factors for higher birth-asphyxia–related morbidity and mortality in developing countries. It is heartening to note that in recent years great strides have been made to overcome these deficiencies. Many countries have initiated training programs to improve resuscitation skills at the grass-roots level. In addition to the earlier efforts of WHO and UNICEF, the Neonatal Resuscitation Program (NRP), developed by the American Academy of Pediatrics and American Heart Association, has been adopted in its full or modified form by more than 72 countries worldwide, including India and China. Helping Babies Breathe (HBB) is a simplified version of neonatal resuscitation that advocates proper assessment of baby at birth, stimulation to breathe, and assisted ventilation for all newborns who are not breathing adequately by 1 minute after birth—"The Golden Minute."[84,85] The main life-saving skill is ventilation with a bag and mask. Because of the simplicity of the skill training, it is easily adoptable to train health care workers attending deliveries at a health facility in rural settings. Two large-scale trials that enrolled almost 200,000 deliveries showed that Essential Newborn Care (now simplified as Essential Care for Every Baby and Essential Care for Small Babies) and resuscitation programs reduced early neonatal mortality by over 60%[16] and fresh stillbirth by over 30%,[15] markedly reducing perinatal mortality. These programs are being implemented by many global partners (UNICEF,

• **Fig. 8.10** The global burden of neonatal resuscitation demonstrating the potential number of babies that require various degrees of resuscitation at birth. Many babies (approximately 10 million) respond to simple resuscitation using skills of "Helping Babies Breathe," and approximately 6 million will need bag and mask ventilation. About 1 million may require intubation and full resuscitation. (Lee AC, Cousens S, Wall SN, et al. Neonatal resuscitation and immediate newborn assessment and stimulation for the prevention of neonatal deaths: a systematic review, meta-analysis and Delphi estimation of mortality effect. *BMC Public Health*. 2011;11[suppl 3]:S12.).

WHO, and USAID) in many LMICs.[102] In India, the NRP has become a standard skill-training module since 1990.[29] A significant reduction in deaths related to birth asphyxia after NRP training of health professional was reported.[30] China also has introduced NRP across the country.[107] It is anticipated that HBB will help further reduce birth-asphyxia–related mortality among LMICs. Lee et al. studied the impact of implementation of neonatal resuscitation on neonatal mortality and morbidity at different facilities around the globe.[47] The investigators identified 24 studies: 20 observational, two quasi-experimental, and two cluster randomized controlled trials. The results showed that resuscitation at birth was associated with significant improvement in overall survival (RR = 0.70, 95% CI 0.59–0.84). They also showed that resuscitation in the delivery room significantly decreased early NMR (see Fig. 8.10).[47] It was estimated that immediate newborn assessment and stimulation would reduce both intrapartum-related and preterm deaths by 10%. Facility-based resuscitation would prevent a further 10% of preterm deaths, and community-based resuscitation would prevent a further 20% of intrapartum-related deaths and 5% of preterm deaths. Many intrapartum deaths are classified as stillbirths who are not included in vital statistics in some countries. Many stillbirths are preventable including with postnatal resuscitation.[15,25,46] Stillbirths are very prevalent worldwide and need to be given a higher priority on the global health agenda.[75,76] These encouraging projections regarding the benefits of training health professionals are supported by the large-scale trials (Fig. 8.11).[15,16] The overwhelming majority of survivors following birth asphyxia in low-resource settings have been found to have normal neurodevelopment.[16] This is likely due to the difficulty in keeping alive the most severely asphyxiated newborns. Therapeutic hypothermia reduces mortality and morbidity from hypoxic-ischemic encephalopathy (HIE) in HICs.[39] Using innovative inexpensive methods, body cooling in HIE is showing promise even in LMICs.[40]

Hypothermia

Neonatal hypothermia is a common and important potentially life-threatening condition.[104] Neonatal hypothermia occurs in 32% to 85% of newborn infants, especially in rural primary health centers.[10,52] The incidence of neonatal hypothermia is substantially higher in LMICs compared to HICs.[19,42,43,44,56,88] Neonatal hypothermia (core body temperature <97.7°F [36.5°C]) is common in LMICs even during summer months. In Ethiopia, 67% of high-risk infants and infants of low birth weight (LBW) were hypothermic on admission. In Nepal, more than 80% of infants became hypothermic at birth and 50% remained hypothermic at 24 hours after birth.[62] Hypothermia is associated with higher risk of neonatal mortality.[62,86] When adequate

• **Fig. 8.11** Meta-analysis of three studies examining the effect of additional training of health professionals in neonatal resuscitation on deaths of infants not breathing at birth. There is a significant decrease in mortality of "infants not breathing at birth following the training of health professionals in neonatal resuscitation." (Lee AC, Cousens S, Wall SN, et al. Neonatal resuscitation and immediate newborn assessment and stimulation for the prevention of neonatal deaths: a systematic review, meta-analysis and Delphi estimation of mortality effect. *BMC Public Health*. 2011;11[suppl 3]:S12.)

warmth is not provided, both preterm and term infants are at risk of developing hypothermia.

The causes of neonatal hypothermia in LMICs are many, starting from low ambient temperature of delivery rooms. Inadequate clothing and giving routine baths soon after birth are causes of neonatal hypothermia. Newborns may also experience heat losses within the hospital during transport from delivery room to the postnatal ward and during transport home from the hospital or from hospital to hospital. Neonatal hypothermia increases metabolic demand, oxygen consumption, and neonatal mortality. In the absence of sophisticated and expensive incubators, simple techniques can be adopted to abate hypothermia.[101]

To reduce neonatal hypothermia, the World Health Organization (WHO) recommends the "warm chain," a thermoregulation protocol that should be implemented in every nursery and with every newborn during the first several days and weeks after birth. The warm chain includes warm delivery rooms, immediate drying, uninterrupted skin-to-skin contact as much as possible, early breastfeeding, delayed bathing and weighing, appropriate bundling, mother and baby together, warm transportation, warm resuscitation, and training and awareness raising.[105] However, not all the elements recommended in the WHO thermoregulation protocol are practiced routinely in many birth facilities around the world.[53] Plastic bags and wrapping with plastic wrap at birth are effective in decreasing hypothermia in term and preterm infants.[7] This is a very inexpensive and effective method of providing thermal protection to the newborn in the immediate neonatal period. Kangaroo mother care (KMC) is becoming a universal practice,[87] and in addition to keeping the baby warm, the immediate initiation of breastfeeding provides early provision of calories. However, two Cochrane reviews showed that while KMC in preterm and LBW infants reduces mortality at the time of discharge,[21] early KMC did not reduce hypothermia in healthy late preterm or term infants.[59]

Infections

It is estimated that worldwide 20% of newborns die of neonatal infection. The incidence of sepsis is estimated to be 5 to 6 per 1000 live births (600,000 to 750,000) among hospitalized patients. Meningitis accounts for 0.7 to 1 per 1000 live births (88,000 to 126,000 cases per year), and acute respiratory infections account for 800,000 deaths in neonates. Among these deaths are cases of pneumonia, bronchiolitis, and laryngotracheitis. Cord infections and neonatal tetanus are preventable causes of acquired infection. The maternal transmission of HIV to the newborn was a major factor contributing to neonatal deaths in some countries, particularly in sub-Saharan Africa, but effective prevention is largely available.[103]

Burden of Neonatal Sepsis

Infections in the neonatal period can manifest at birth but most often occur within the first few days, peaking at 2 weeks after birth (see Fig. 8.8).[5] Estimating the burden (incidence) of neonatal infections in developing countries is challenging because of several factors: (1) Most births take place at home, and those newborns with sepsis rarely seek medical attention. (2) Hospital-derived information does not represent true incidence of sepsis in the community. (3) Laboratory facilities for cultures are inadequate or nonexistent. Population-based studies from developing countries have reported clinical sepsis rates ranging from 49 to 170

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

per 1000 live births.[33] Among 18 studies from developing countries, the median incidence of blood culture–confirmed sepsis was 16 per 1000 live births. A study from Bangladesh found the incidence of clinically suspected neonatal sepsis to be 50 per 1000 live births, and the incidence of culture-confirmed sepsis was 3 per 1000 live births.[18] The incidence of culture-confirmed neonatal sepsis was 5.5 per 1000 live births among neonates presenting to a first-level health facility in rural Kenya.[8] However, the absence of active community surveillance suggests that the true burden is probably higher. A review of early-onset neonatal sepsis in developing countries found only five studies.[34] The incidence of clinical sepsis ranged from 20.7 to 50 per 1000 live births, and the incidence of culture-confirmed early-onset neonatal sepsis ranged from 2.2 to 9.8 per 1000 live births. Only two of these studies reported case fatality rates, of 18% and 19%, respectively. These observations contrast with neonatal culture-confirmed sepsis rates of 1 to 3 per 1000 live births reported from industrialized countries,[13] indicating the huge preventable burden of neonatal infections in LMICs.

Diagnosis of Neonatal Sepsis

As noted, although blood culture is the gold standard for diagnosis of neonatal sepsis, lack of laboratory facilities is a major barrier to diagnosis and treatment of neonatal sepsis in LMICs. Therefore, clinicians and health care workers depend on clinical signs of sepsis for diagnosis and treatment. Several clinical scores have been described to facilitate the diagnosis by health care workers in the field. Bang and co-workers have described a simple set of clinical criteria to recognize sepsis in a rural setting.[4] The Young Infants Clinical Signs Study Group conducted a large multicountry study to identify clinical signs with high sensitivity and specificity for predicting sepsis.[106] They identified seven common clinical signs that could be identified easily by health care workers in primary care settings. Other investigators have used slight modifications of these signs for clinical diagnosis of neonatal sepsis in community-based neonatal programs. The WHO also has developed guidelines for the Integrated Management of Childhood Illnesses for resource-limited countries.[9] Using the aforementioned background information, an algorithm may be used by health care workers in LMICs to assess infants at home or in health facilities, initiate treatment for sepsis, and triage infants to higher levels of care.

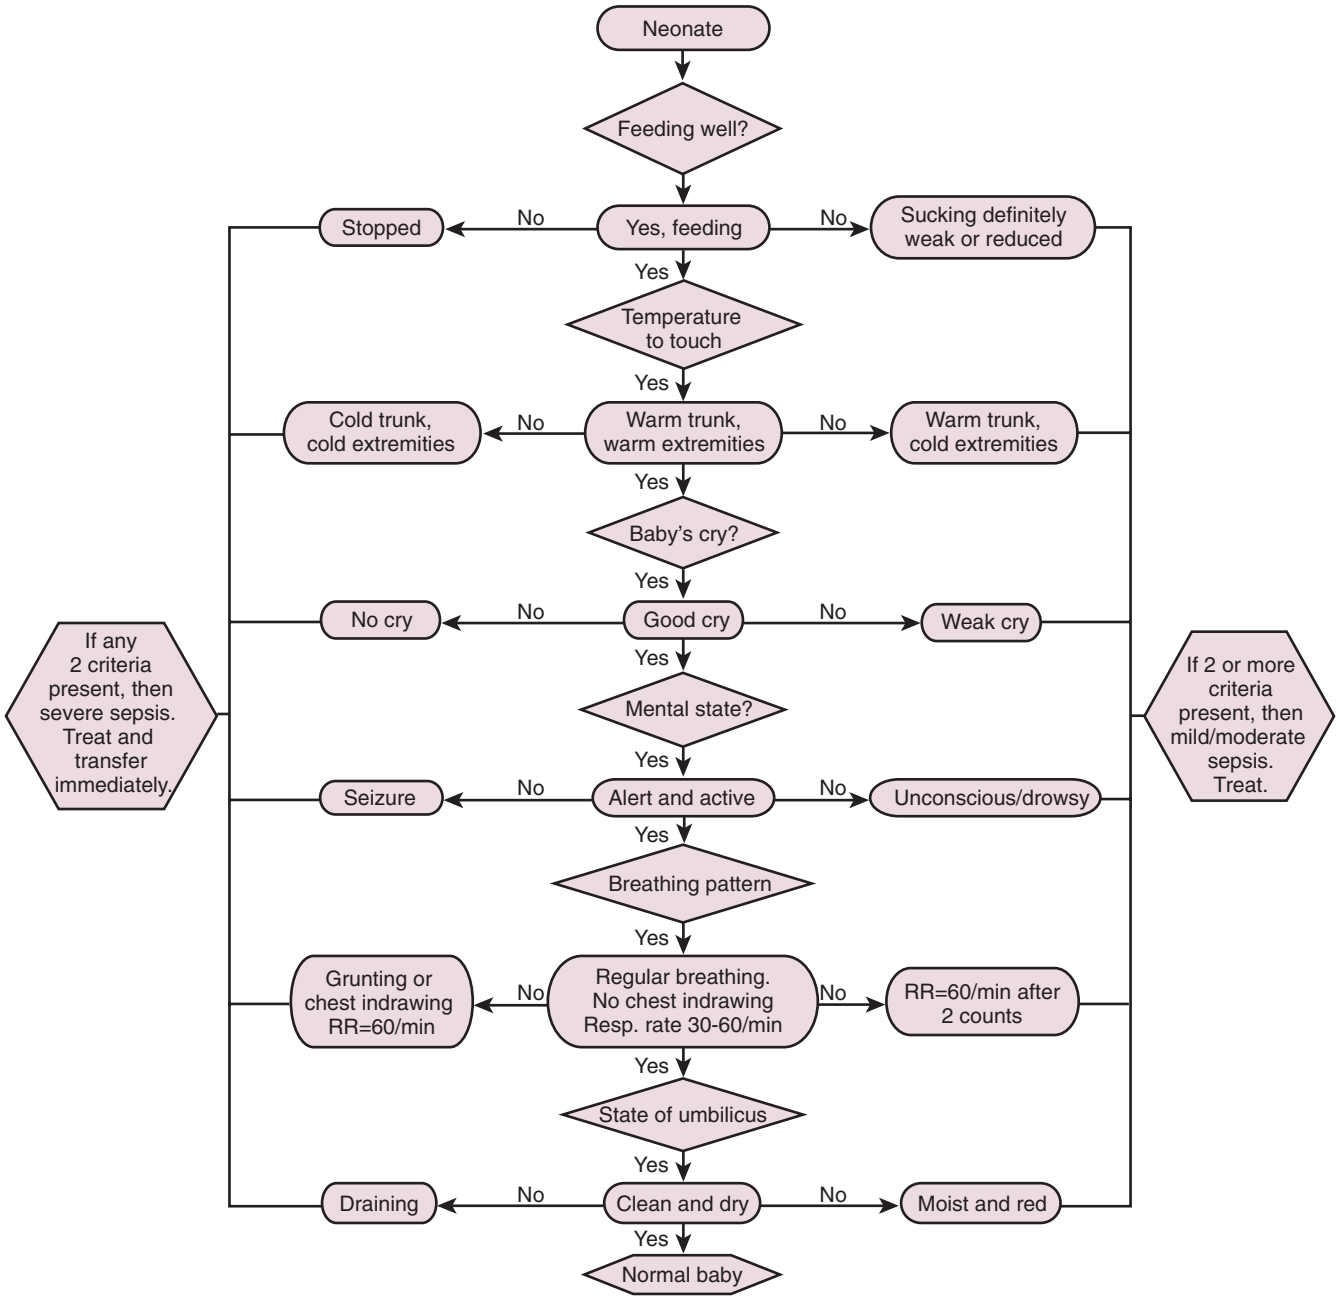
Fig. 8.12 shows the elements of observation and action based on common clinical findings: feeding, crying, variations in skin temperature on touch, activity, breathing pattern, and condition of the cord. These findings can be graded from mild to severe. Any two milder forms of distress can be treated and managed at home by the health care worker. Infants showing more severe forms of distress must be treated and transferred to a referral health center. Recent randomized controlled trials by the African Neonatal Sepsis trial group showed feasibility of community-based diagnosis of clinical signs of possible serious bacterial infection and simplified antibiotic regimens including injectable and oral combinations.[1,2]

Evidence-Based Interventions to Reduce Maternal Mortality Rates, Neonatal Mortality Rates, and Infant Mortality Rates

Although the global health policies described in the beginning of this chapter are being adopted by many countries, researchers are also actively investigating the causes of high global maternal and neonatal mortality and gathering information for evidence-based effective interventions that are adoptable and scalable in reducing MMR, NMR, and IMR in LMICs. Three series of landmark publications, popularly known as *The Lancet* series (described earlier), provided evidence-based, scalable interventions that reduced MMR, NMR, and IMR in resource-poor countries.[17,22,41] *The Lancet* Child Survival Series conducted comprehensive reviews of 23 interventions with a focus on under-5 child survival. Interventions were introduced in preconception, antenatal, intrapartum, and postpartum periods. Sixteen major community-based interventions were analyzed for their efficacy in reducing NMR.[23] Increasing coverage of these 16 interventions to 90% of the population could save 590,000 to 1.08 million lives in South Asia annually at an additional cost of US $900 million to $1.76 billion. In sub-Saharan Africa, it could save up to 450,000 to 800,000 lives at a cost of US $680 million to $1.32 billion.

Many antenatal, intrapartum, and neonatal interventions may be very effective in reducing NMR.[6] The 11 major evidence-based effective antenatal and neonatal interventions are listed in Box 8.1. These include two major antenatal interventions, antenatal steroids, and antibiotic therapy for premature rupture of membranes (PROM).

• BOX 8.1 Evidence-Based Cost-Effective Interventions That Increase Neonatal Survival



Intrapartum Interventions

- Antibiotics for premature rupture of membranes (PROM)
- Prophylactic antenatal steroids for mothers in premature labor

Neonatal Interventions

- Delayed cord clamping
- Vitamin K supplementation at delivery
- Resuscitation at birth
- Hospital-based kangaroo care
- Early breastfeeding and probiotics
- Thermal care
- Early continuous positive airway pressure (CPAP) in infants with respiratory distress syndrome (RDS)
- Surfactant therapy in RDS
- Case management for sepsis

• **Fig. 8.12** An algorithmic approach to assessment and management by health care workers of newborns with suspected sepsis.

Also described are nine neonatal interventions, including late cord clamping[89] and neonatal resuscitation.[15,16] After birth, surfactant therapy and application of continuous positive airway pressure (CPAP) reduce mortality in infants with respiratory distress syndrome. Probiotics decrease necrotizing enterocolitis, sepsis, and all-cause mortality in LMICs.[31] These findings are of great clinical importance to practitioners as well as health policymakers because they provide a basis for adoption of new cost-effective interventions in saving many high-risk newborns.

Prematurity is a major cause of neonatal deaths in developing countries, and respiratory distress syndrome (RDS) is the leading cause of neonatal death in this population in HICs. The goal should be to consider preventive antenatal care and proven interventions, such as antenatal steroid therapy in preterm labor, implementation of delivery room neonatal resuscitation, early use of CPAP, and surfactant therapy.[72] Using antenatal steroids as a preventative measure will be the least expensive. Antenatal steroid treatment of mothers in premature labor has been estimated to save 500,000 lives a year.[63] Infants with RDS can be best managed with inexpensive nasal CPAP devices. Evidence suggests that in LMICs, postnatal CPAP followed by surfactant therapy can significantly reduce mortality and morbidity from RDS.[44,99] Use of nasal CPAP as a first choice of treatment decreases the need for surfactant replacement

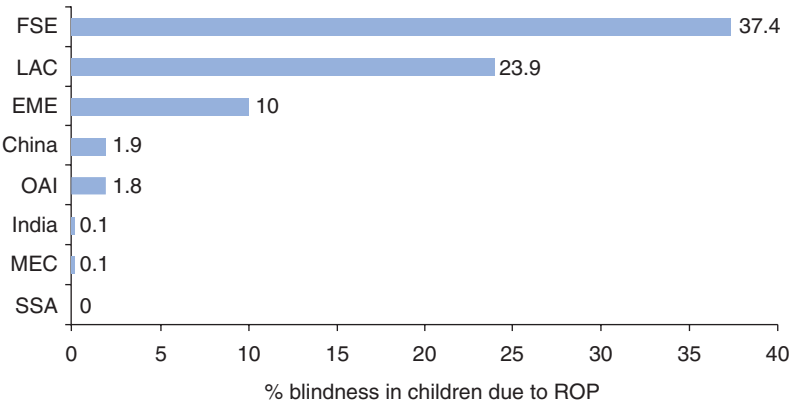
therapy and reduces mortality and bronchopulmonary dysplasia (BPD) compared to early surfactant.[77] Therefore, outcomes can be improved by using early CPAP and reducing the use of surfactant for infants who respond to CPAP as is done now in HICs.[20]

The Impact of Progress

With the increased access to neonatal intensive care and improved survival of preterm and VLBW infants, there is a financial burden on families and risk of associated morbidities among survivors. Three major neonatal emerging challenges in developing countries are of great concern. They include (1) BPD, also known as chronic lung disease (CLD);[66] (2) retinopathy of prematurity (ROP)[35,74]; and (3) neurodevelopmental delays.[64,83] All three conditions are related to prematurity, and as survival of preterm infants increases, so does the incidence of CLD, ROP, and neurodevelopmental delays. Data regarding the prevalence of these morbidities in LMICs are lacking.



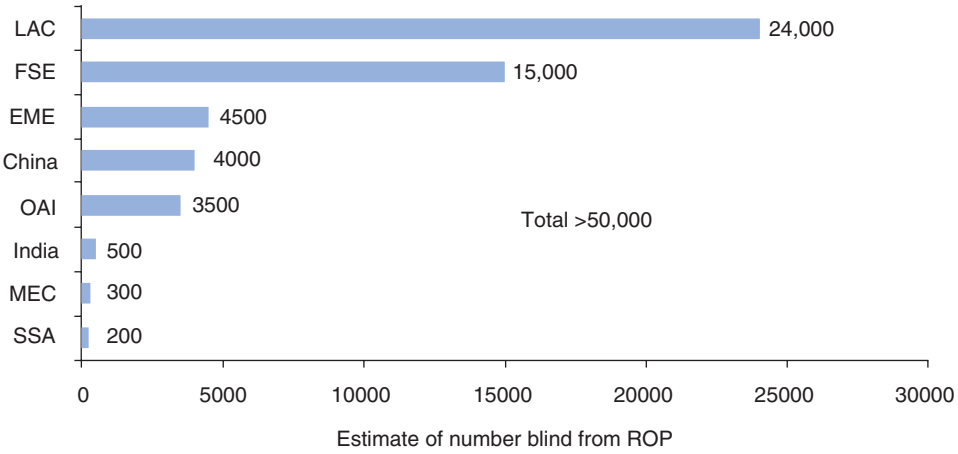
BPD is a newly emerging disease in LMICs.[66] LMICs contemplating the development of modern NICUs should be well-prepared to recognize these complications and associated costs. Strategies need to be developed to minimize the overall burden of disease on the community. In this regard, the application of CPAP as the first approach to managing respiratory distress syndrome is to be encouraged in LMICs.[99]

Retinopathy of prematurity was first encountered in the early 1950s in HICs with the introduction of high oxygen therapy and again with the introduction of ventilator care and increasing survival of extremely premature infants. Although the rate and severity of ROP is decreasing in HICs, it is beginning to increase in LMICs. As NMR is steadily decreasing, it is estimated that globally at least 50,000 children are blind from ROP. This observed large number of ROP worldwide has come to be known as the *third epidemic*.[35] Fig. 8.13 shows the estimated absolute number of ROP-related blind population by global regions. As is seen, ROP is being increasingly reported from India and China, home to more than one-sixth of the world's population. Fig. 8.14 shows the relationship of IMR rate and ROP-related blindness.[35] Blindness caused by ROP begins to rise as the IMR of a country continues to decrease. These data suggest the influence of increased survival of preterm infants with the introduction of NICU care, oxygen therapy,[24,100] and ventilation: the lower the IMR, the higher the rate of ROP-related blindness. Retinopathy of prematurity will soon become a public health issue in these countries unless control activities keep pace with the increased survival of premature babies at risk.

There is a need to develop and implement educational programs to avoid the potentially hazardous practices of high oxygen therapy, to promote early detection of ROP, and to pursue a multidisciplinary approach to prevent ROP. LMICs also have the additional problem of lack of awareness of ROP among pediatricians, whereas ophthalmologists may be inadequately trained in the recognition and management of ROP.[74]

The Burden of the High Cost of Advanced Neonatal Care

The overall cost of neonatal intensive care at the tertiary level in developing countries is very high and sometimes affordable only to middle- and upper-income groups. Bhutta from Pakistan showed that infants with RDS can be successfully managed with ventilator support.[11] In that study, the overall mortality of infants with RDS treated with assisted ventilation was 39%, the average length of stay was 25 ± 21



FSE = Former Socialist Economies
LAC = Latin America and the Caribbean
EME = Established Market Economies
OAI = Other Asia and Islands
MEC = Middle East Crescent
SSA = Sub Saharan Africa

Note: Data from South Africa showed that ROP only affected Caucasian and Asian children. As no other countries in the region had any child blind from ROP the proportion for the region has been put as 0%.

days, and the average cost was US $1391 per survivor. Shanmugasundaram and colleagues in India reported similar costs associated with NICU care.[82] Narang and co-workers reported the per-day cost of NICU care of neonates in a government teaching hospital to be US $125/day, although the family shared 25% of the total cost of NICU care.[65] Profit and co-workers showed that NICU care for infants born at 24 to 26, 27 to 29, and 30 to 33 weeks' gestational age in Mexico prolonged life expectancy by 28, 43, and 34 years and averted 9, 15, and 12 disability-adjusted life years (DALYs) at incremental costs per infant of US $11,400, US $9,500, and US $3,000, respectively, compared to infants with no intensive care.[73] These data provide strong evidence that even in LMICs, provision of NICU care is cost effective in improving survival and decreasing morbidity. Unfortunately, in many LMICs, parents have to bear 80% of hospital costs out of pocket, which may exceed their resources.[57]

Long-Term Neurodevelopmental Outcome

Data on long-term outcomes in LMICs are limited. Lack of a uniform database of surviving infants, lack of expertise in assessing developmental disabilities, and the lack of a support system for needy families and children are the major barriers to develop meaningful information regarding the morbidity of surviving infants. Mwanki and co-workers reviewed 153 studies from around the world suitable for inclusion for analysis of developmental outcome of high-risk newborns.[64] Altogether, there were 2161 survivors of intrauterine or neonatal insults. The overall median risk of at least one sequela in any domain was 39% (interquartile range [IQR] 20% to 55%), with a risk of at least one severe impairment in any insult domain of 18% (8% to 33%), at least one moderate impairment of 5% (0% to13%), and at least one mild impairment of 10% (1% to 18%).

The pooled risk estimate of at least one sequela associated with one or more of the insults studied (excluding HIV) was 37% (95% CI 27% to 48%). The most common deficits were learning difficulties, cognition, or developmental delay ($N = 4032$; 59%); cerebral palsy ($N = 1472$; 21%); hearing impairment ($N = 1340$; 20%); and visual impairment ($N = 1228$; 18%). Only 40 studies included data for multidomain impairments. These studies (26%) included 2815 individuals, of whom 1048 (37%) had impairments, with 334 (32%) having multiple impairments. These findings show that in developing countries, perinatal adverse insults have a high risk of causing substantial long-term neurologic morbidity.

Shillcott and co-workers[83] studied the estimates of long-term disabilities following neonatal illness in a district of Bangladesh. They found that "a significant burden of disability results from neonatal conditions." They also projected that their national newborn project might have averted several years lost to disability.

The preceding two studies provide important information on the impact of advanced care and increasing survival of at-risk infants in LMICs. Comparable cohort studies in other resource-poor regions should be done to assess the burden of long-term outcome effects of improved neonatal survival.

Ethical Dilemmas

The issues of the high cost of hospital care and uncertain outcomes of LBW and critically ill newborns pose ethical dilemmas to practicing neonatologists in LMICs. Most poor populations cannot afford the high cost of care. In these countries, although public sector health care caters to the care of the poor, the private sector is rapidly expanding services to selected families able to afford the cost of NICU care.

Because of changing economic demographics among LMICs, there will be two divergent situations regarding the care of the sick newborn in the NICU, with one group of families who cannot afford the high cost of NICU care. As stated by Singh, undue emphasis is being placed on saving an individual infant with an uncertain outcome at any cost to the family.[84] He suggests that to ensure the principle of cost-effectiveness in resource-poor countries, the narrow principle of the "best interests" of the child should be replaced by the concept of a broader benefit to the family, society, and state. His point is valid and should be considered when counseling resource-poor families. In recent years, rapid demographic and economic transitions have changed the expectations of middle-class and upper-middle-class families in countries such as India, China, and other LMICs. When the families and parents with adequate economic resources are willing to avail themselves of such care in spite of the high cost, the care cannot be denied. The neonatologist, therefore, has the responsibility to prepare parents with prenatal counseling and provide realistic evidence-based treatment options to parents.[3] There is a need for a larger debate and development of ethical guidelines for practitioners among LMICs.

Strategies to Improve Global Neonatal and Perinatal Outcome

Strategies to reduce perinatal mortality in LMICs should include social and medical programs that are integrated into national plans. Box 8.2 outlines the steps involved in developing a plan to improve neonatal-perinatal outcome. Even though the objectives and goals of the MDG declaration have been universally accepted, strong commitment and leadership on the part of professional groups, nongovernmental organizations (NGOs), and the governments are necessary for successful implementation of programs aimed at reducing NMR.

Schiffman and Sultana noted that the factors that led to national advocacy for newborn health in Bangladesh were both a strong commitment of the government to achieving the MDG targets and donor resources.[80] They note that the emergence of successful policy to improve newborn survival involved interactions between global and national agencies rather than either alone. To quote the authors, "In Bangladesh, newborn survival emerged from obscurity to relative prominence on the government's health policy agenda." These observations are applicable to other LMICs. Many LMICs are developing similar programs to scale up maternal and neonatal services.

Summary

Developing countries continue to share the major burden of neonatal and infant mortality. The major causes responsible for such disparity between HICs and LMICs are a lack of health facilities, lack of skilled personnel, and lack of access to health care. The SDGs declared in 2015 are the single most influential program bringing the world community, governments, scientists, and policymakers together to address the issues of high neonatal and infant mortality in LMICs. The publication of *The Lancet* series also evoked great interest among researchers to explore the causes of high NMR and find evidence-based cost-effective interventions to reduce MMR, NMR, and IMR in LMICs. A review of the literature clearly identified several evidence-based effective antenatal, intrapartum, and neonatal interventions. It remains to be seen how well these interventions will be implemented in LMICs. It is recognized that successful implementation of the MDGs requires both commitment

• BOX 8.2 Strategies to Develop Sustainable Programs to Improve Maternal and Neonatal Health in Low- and Middle-Income Countries

Step I

- Identify a region to be covered.
- Assess the current situation: data gathering on MMR, NMR, and IMR.
- Involve regional governmental and nongovernmental agencies and local stakeholders.
- Develop a local perinatal advisory committee.
- Identify gaps in services.
- Develop programs that provide continuums of care: preconceptual/conceptual/post-delivery services.

Step II

- Improve and achieve optimal perinatal-neonatal coverage with available services.
- Introduce innovative approaches to overcome deficiencies.
- Introduce capacity-building programs for health professionals.
- Improve local health facilities with proper equipment for keeping the baby warm and providing resuscitation at birth.
- Establish links between health facilities within the region: from basic level of care to tertiary-care level for consultation and transport of highest-risk babies.

Step III

- Develop outreach educational services in the community.
- Increase public awareness of the importance of safe motherhood and newborn care.
- Coordinate with other health initiatives in place at local/regional/state levels.
- Systematically scale up the preceding activities as these programs take root.
- Share results with stakeholders, and gain confidence in the program.

Step IV

- Measure impact annually.
- Share information with stakeholders.
- Make innovative changes as needed.
- Continue activities defined in steps II to IV to achieve goals defined in MDG #4 and #5 for the region.

IMR, Infant mortality rate; MDG, Millennium Development Goals; MMR, maternal mortality rate; NMR, neonatal mortality rate.

of national governments and collaboration of international agencies. It is encouraging to note that some LMICs have reached their targets of MDGs #4 and #5, but many countries have not reached their MDGs. There is lot more to be done in a large number of LMICs. Neonatology is a work in progress in LMICs.

Acknowledgments

The author would like to acknowledge the contributions of Drs. Dharmapuri Vidyasagar and Anil Narang, who were authors of this chapter in previous editions.

Key Points

- More than 98% of the neonatal deaths worldwide occur in low- and middle-income countries. The majority of these deaths occur in South Asia and Africa.
- Neonatal deaths constitute approximately 40% of global under-5 childhood mortality, of which the highest proportion is related to complications of preterm birth, intrapartum-related complications, and sepsis.
- Preterm birth complications (14% of under-5 deaths), birth asphyxia (also called intrapartum-related) complications (9%), and sepsis/meningitis (5%) were the most frequent causes of death in the neonatal period.
- The increased attention to improving newborn care at a global level can be traced to the recognition by the World Health Organization of unacceptably high infant mortality in low- and middle-income countries.
- Several large controlled trials have demonstrated the benefits of selected interventions including packages of care such as the Mother-Baby Package, Helping Babies Breathe (resuscitation), and the Essential Newborn Care programs.
- Considerable progress is being made in reducing maternal and child mortality in developing countries; however, many challenges remain. By the end of the twentieth century, a significant decrease in maternal and infant mortality was reported to be one of the top health achievements of the century.
- One of the Sustainable Development Goals metrics aims to reduce neonatal mortality to at least as low as 12 per 1,000 live births.

Social and Economic Contributors to Neonatal Outcome in the United States

RENATE D. SAVICH AND MOBOLAJI FAMUYIDE

Epidemiology of Health Disparities in Neonatal and Perinatal Medicine

While there have been significant improvements in neonatal and infant mortality in the United States over the past 50 years, compared to other high income countries in the world, the United States alarmingly lags behind these other countries in infant mortality rates.[60] Infant mortality and morbidity rates are commonly used as an important indicator worldwide of overall population health. Recent research has focused on why the United States has not seen continued improvements in these public health indices as have other countries, and indeed several markers of US infant health have actually worsened in recent years. It is important to understand recent US trends and contributing factors to provide optimal care and public health planning in the prenatal, perinatal, neonatal, and post neonatal periods to improve these outcomes. One major factor contributing to these poor perinatal and infant outcomes in the United States is the significant health disparities seen among women and infants related to race and ethnicity. Other disparities in health outcomes in the perinatal period in the United States are related to poverty, lack of health care access, and other overall indicators of poor socioeconomic status.

Infant Mortality

While the United States had a steady decline in infant mortality over the past decade, declining 15% from 6.86 deaths per 1000 live births in 2005 to 5.82 per 1000 in 2014,[62] this rate is still almost twice that of other comparable countries in the world.[60] Data comparing infant mortality from 2010 indicated that the United States had 2 to 3 times the infant mortality rate of countries such as Germany and Sweden, in spite of significantly larger health care expenditures in the United States per capita compared to these other countries. Multiple studies have attempted to delineate the factors unique to the United States that might explain this discrepancy. One possible explanation is the high number of infants born and resuscitated at 22 and 23 weeks' gestation in the United States compared to many countries in Europe. However, excluding these infants still indicates a US infant mortality rate twice that of these countries.[60] Addressing prematurity is a significant health and financial priority. Although only 9.1% of birth hospitalizations were among preterm or low birth weight infants, these births accounted for 43.4% of total costs of neonatal care.[6]

Prematurity (infants born at less than 37 weeks) in the United States has a major impact on high infant mortality rates. Studies show that the United States has rates of prematurity up to two times that of other developed countries.[60] Clearly, this is a significant contributor to the high infant mortality seen in the United States. During the 1990s and early 2000s, the US preterm birth rate steadily increased from 10.6% in 1990 to 12.8% in 2006.[39] The United States overall saw a steady decrease in the prematurity rate over the past decade, with a decrease from 10.44% in all births in 2007 to 9.57% in 2014.[40,61] Disturbingly, this trend in the prematurity rate has reversed in recent years with a small but significant increase to 9.63% in 2015 and 9.84% in 2016, primarily due to an increase in late preterm births.[40] It is unclear how this will impact the recent improvements in US infant mortality.

Addressing the causes of prematurity is critical to reducing the US infant mortality rate. However, a higher rate of prematurity alone does not explain the higher US infant mortality rate, as the gestational-age-specific infant mortality rates are also increased above other countries at gestational ages 32 weeks and above, the category with the highest number of preterm births.[60]

It is now well established that major contributors to infant mortality rates in the United States are the significant health disparities. The major health disparity is related to racial and ethnic differences of perinatal health outcomes in all states in the United States, with a wide variation state to state.

Epidemiologic studies have shown that non-Hispanic black infants have an infant mortality rate over two times that of non-Hispanic white infants (10.93 deaths per 1000 live births in 2014 vs. 4.89 per 1000 live births) (Fig. 9.1).[59,62]

Abstract

While there have been significant improvements in neonatal and infant mortality in the United States over the past 50 years, compared to other high income countries, the United States lags behind in infant mortality rates. Infant mortality and morbidity rates are commonly used as important indicators worldwide of overall population health. One major factor contributing to these poor perinatal and infant outcomes in the United States is the significant health disparities seen among women and infants related to race and ethnicity. Other disparities in health outcomes in the perinatal period in the United States are related to poverty, lack of health care access, and other overall indicators of poor socioeconomic status. In the United States, non-Hispanic black infants have the highest rates of infant mortality and prematurity compared to other races and ethnic groups. Non-Hispanic black mothers also have extremely high rates of maternal mortality and morbidity, as well as obesity, leading to other poor outcomes. Native American/Alaska Natives also suffer from a disproportionate share of infant mortality and prematurity as well as higher rates of sudden unexpected death of infancy. Hispanic mothers also suffer from adverse outcomes such as obesity, yet seem somewhat protected from other neonatal adverse outcomes. In the United States, optimal social determinants of health that are lacking in minority races and ethnicities play a major role in the poor outcomes seen in the perinatal and neonatal period suffered by these groups. Specific interventions targeting racial and ethnic disparities in neonatal mortalities and morbidities will be needed to improve current US perinatal and neonatal outcomes.

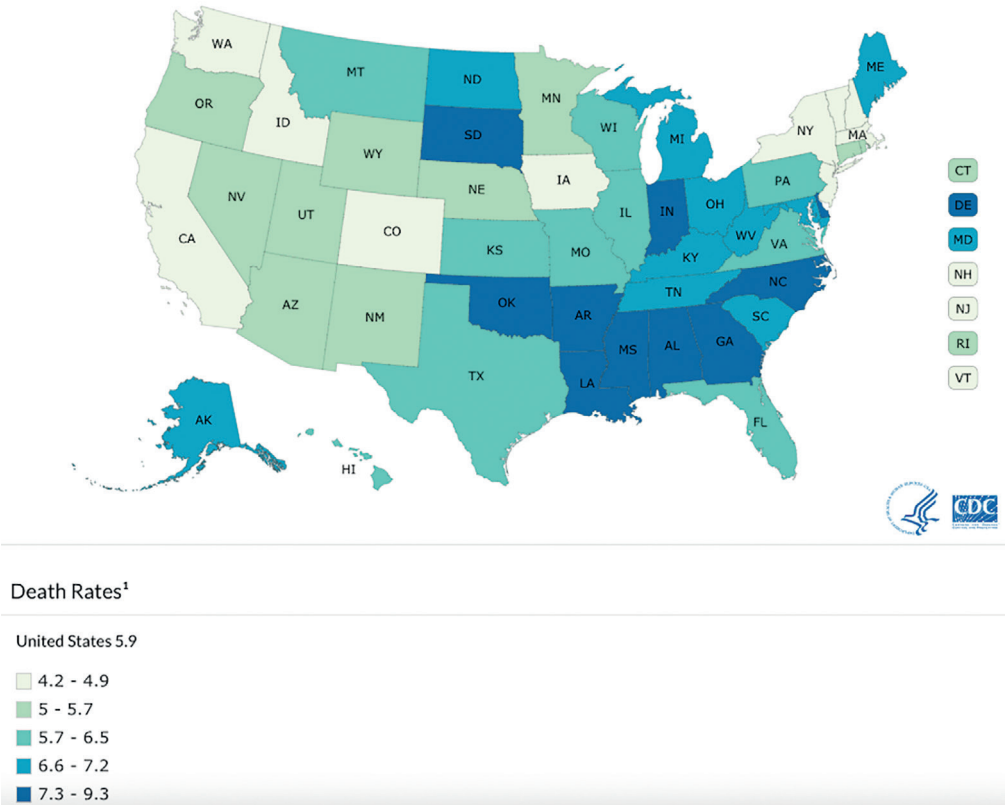
American Indian or Alaskan Native infants also exhibit substantially higher infant mortality rates than non-Hispanic whites.[59,62] Interestingly, Asian or Pacific Islander infants have consistently exhibited the lowest neonatal and infant mortality rates for many years, while Hispanic infant mortality rates track close to non-Hispanic white infant mortality rates in spite of economic disadvantages and poor health care access.[62]

From 2005 to 2014, infant mortality rates overall and for each race or ethnic group had decreased each year.[62] However, in recent years, this decline has plateaued. It appeared that the United States was making great strides in reducing the discrepancies in infant mortality rates related to race with a 16% decline from 2005 to 2011 seen in non-Hispanic black rates compared to the overall US decline of 12% during those years. A closer look at recent US infant mortality data shows disturbingly that from 2013 to 2014, only non-Hispanic whites had a significant 3% decrease; other groups did not show a statistically significant improvement.[62] In fact, the 2015 data indicate that for non-Hispanic black infants the infant mortality rate actually increased from a low of 11.4 per 1000 in 2014 to 11.7 per 1000 in 2015.[75] This is in sharp contrast to the infant mortality rate of 4.8 per 1000 in non-Hispanic white infants in 2015.[59,75] Thus, it appears that in the United States, these disparities by race are worsening. In addition, there are significant differences in infant mortality by state, with the southern states having the highest infant mortality. These are also the states with the highest percentage of non-Hispanic black women in their population (Fig. 9.2).



Similar to significant disparities seen in infant mortality, the incidence of prematurity varies greatly by race and ethnicity, with the provisional 2016 percent of births under 32 weeks for non-Hispanic blacks at almost three times that of non-Hispanic whites (3.16% vs. 1.26%)[40] (Table 9.1). Disturbingly, US prematurity rates for less than 37 weeks gestation are slightly increased in 2016 compared to 2015 and 2014 for the United States.

The five leading causes of infant mortality in the United States are congenital malformations, short gestation and low birth weight, SIDS (sudden infant death syndrome) or SUID (sudden unexpected infant death), maternal complications, and unintentional injuries.[62] Data show that these causes of death vary by racial and ethnic group. For example, death due to low birth weight/preterm-related causes is over 3-4 times higher in non-Hispanic blacks compared to non-Hispanic whites. In contrast, the high infant mortality seen in Native Americans and Alaska Natives occurs in those babies born at much higher birth weights and would appear to be less impacted by prematurity.[33] There are also differences in mortality noted within certain ethnic groups. For Puerto Rican infants, the rate of infant mortality due to preterm causes is almost twofold that of non-Hispanic whites and is the highest among all of the Hispanic subgroups.[33,62] This could reflect the longer-term presence of the Puerto Rican population in the United States compared to more recent Hispanic immigrants and the cumulative toxic effect in the United States of low socioeconomic states (SES) over time on adverse pregnancy outcomes.

Congenital anomalies and subsequent infant mortality are also impacted by health disparities. Bassil et al. found that socioeconomic inequities lead to a significant increase in major congenital anomalies in babies born to mothers in areas of highest deprivation.[7] Further analysis revealed that there were higher odds of chromosomal and multiple systems anomalies in the highest deprivation areas. These findings could be explained by higher exposure to teratogens or to poor health of these disadvantaged mothers.

Post-neonatal mortality also exhibits racial and ethnic disparities as seen in SIDS/SUID, a leading and increasing

TABLE 9.1 Selected Maternal and Birth Characteristics by Race and Hispanic Origin of Mother, 2016 Provisional Data

	Unmarried (%)	First Trimester Prenatal Care (%)	Late or No Prenatal Care (%)	Gestational Age Under 37 Weeks (%)	Gestational Age Under 32 Weeks (%)	Low Birth Weight (%)	Very Low Birth Weight (%)
TOTAL	39.7	77.2	6.2	9.84	1.59	8.16	1.39
White	28.4	82.3	4.3	9.04	1.26	6.97	1.07
Asian	12.0	80.6	5.4	8.63	1.19	8.43	1.09
Hispanic	52.5	72.0	7.7	9.44	1.45	7.31	1.23
Black	69.7	66.6	10.0	13.75	3.16	13.33	2.94
American Indian/ Alaska Native	68.1	63.0	12.5	11.38	1.74	7.77	1.38
Native Hawaiian or Pacific Islander	47.7	51.9	19.2	11.51	1.79	7.65	1.44

National Center for Health Statistics.[5]

cause of infant mortality. The vast majority of infant autopsies identifying the cause of death due to SIDS or SUID are from infants born at 37-42 weeks.[71] For American Indian or Alaska Natives, the largest difference in mortality outcomes when compared to non-Hispanic whites is the two- to threefold increase in deaths due to SUID (American Indian: 177 per 100,000 live births, non-Hispanic white: 84.5 per 100,000 live births).[71] Non-Hispanic blacks also have an extremely high rate of mortality from SUID (172.4 per 100,000 live births),[71] only slightly lower than the rate for Native American infants. The lowest rate of SUID is seen in Hispanic and Asian/Pacific Islander infants (Hispanic: 49.3 per 100,000 live births, Asian/Pacific Islanders: 28.3 per 100,000 live births), even lower than the non-Hispanic

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

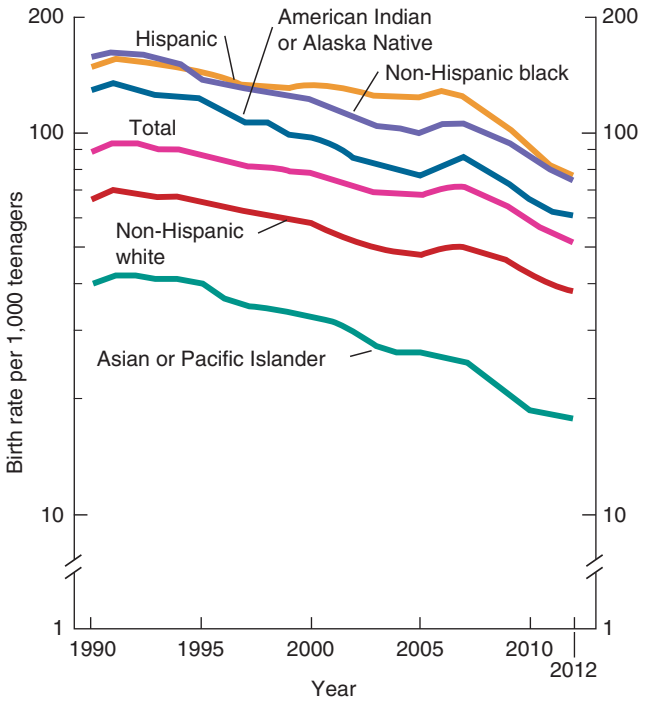
white rate. A significant impact on SUID is decreasing gestational age at birth, with infants born at 24-27 weeks having a 3.5–5-fold increase in the rate of SIDS compared to term infants.[70] Again, racial disparities are seen, with an SUID rate in non-Hispanic blacks at less than 28 weeks of 382.3 per 100,000 live births compared to the lowest group, Asian/Pacific Islanders: 126.6 per 100,000 live births at less than 28 weeks.[71] Given that the highest rate of prematurity is seen in non-Hispanic blacks, this contribution to SIDS/SUID also negatively impacts this population and infant mortality. In addition, overall, the SUID group had twice the percentage of African American mothers and was independently associated with this adverse outcome. There are racial and ethnic differences in positioning of babies for sleep, with Hispanic and non-Hispanic black infants and infants in southern states being placed supine much less often than non-Hispanic white infants. Premature infants are also positioned more often in the prone position as well.[46a] Alarmingly, many states have reported a recent increase in deaths due to SIDS/SUID in the non-Hispanic black population for unclear reasons. Again, it is unclear what impact genetic versus cultural factors may play in this adverse outcome. This would imply that both genetic and cultural aspects of race and ethnicity contribute to differing SIDS/SUID outcomes as well as lower SES.

Mirroring the infant mortality rates, fetal deaths and perinatal mortality rates show wide variation by race and ethnicity. Non-Hispanic black fetal mortality rates are twice as high as non-Hispanic white rates, with American Indian or Alaska Native fetal and perinatal mortality rates intermediate.[58] Poorer maternal health and decreased access to prenatal care may have an impact on this.

Maternal Mortality

Maternal mortality related to pregnancy has been steadily increasing in the United States over the past 20 years[56,57] despite significant decreases seen in other high income countries during this same time period.[86] Again, alarming racial and ethnic disparities are seen in pregnancy-related mortality in the United States, with non-Hispanic black women dying at a rate almost four times that of non-Hispanic white women (42/100,000 live births vs. 12/100,000).[9,25,26] While the reasons for the dramatic increase in US pregnancy-related mortality are not clearly understood, underlying poorer maternal health, obesity, lack of prenatal care, teen pregnancies, and single mothers without support systems all are likely contributors to this high mortality rate. All of these indicators of poor health care during pregnancy are significantly higher in non-Hispanic black women and American Indian and Alaskan Native women compared to non-Hispanic white women.[26,61] As a reflection of the increasingly overall poor health of the United States, maternal deaths due to hemorrhage, hypertensive disorders of pregnancy, emboli, and anesthesia complications have declined, while contributions from cardiovascular conditions, cardiomyopathy, stroke, and non-cardiovascular medical conditions have increased.[9,25,26] For non-Hispanic black women over the age of 40, pregnancy is particularly dangerous, with the rate of almost 192 deaths per 100,000 live births, compared to an average mortality ratio of 17 maternal deaths per 100,000 live births for all women at all ages.[26] Racial disparities impact a variety of maternal morbidities, with non-Hispanic black and American Indian and Alaska Native women having the highest rates of blood transfusion, heart failure, shock, eclampsia, and renal failure, as well as an overall rate severe maternal morbidity over twice that of non-Hispanic white women during delivery hospitalization.[23] Pre-eclampsia during pregnancy is a particularly dangerous condition leading to maternal morbidity and death as well as several neonatal complications, especially preterm birth and its associated complications for the neonate. Pre-eclampsia is highest in non-Hispanic black mothers but lower in Hispanics and Asians compared to non-Hispanic white women. A recent study also noted that American Indians/Alaska Natives also had a significant higher pre-eclampsia risk. However, the authors noted that higher pre-pregnancy body mass index (BMI) in American Indians/Alaska Natives may contribute to this morbidity.[89]

Determinants of Prematurity and Adverse Outcomes



A significant body of research has focused on the high teen pregnancy rate in the United States compared to other high income countries. Encouragingly, rates of teen pregnancies have significantly decreased for all races and ethnicities in the United States[41,61,77,81] (Fig. 9.3). However, two groups with some of the highest teen pregnancy rates, non-Hispanic black women and Native American women, have the highest infant mortality rate and prematurity rate; teen pregnancies may play a factor in these outcomes. There are also significant regional differences in the United States in teen birth rates, with the south having much higher rates of teen pregnancies (Fig. 9.4).

Previous studies have shown that infants born to Hispanic women have outcomes for prematurity and mortality similar to non-Hispanic white women.[59,62,78] Although many Hispanic women are also economically disadvantaged and have poor access to prenatal care, their rates of prematurity and infant mortality are low, suggesting a genetic component and unexplained protective effect of Hispanic ethnicities in birth outcomes. However, even within women who identify as Hispanic, there is large variation in infant outcomes with Puerto Rican infants having much higher mortality rates than other Hispanic infants.[59] In addition, even within race and ethnicity, there may be an additional genetic component, as Hispanic women who identify as black Hispanic have outcomes such as low birth weight, preterm birth, and small for gestational age intermediate of Hispanic and non-Hispanic black women.[8] Interestingly, women of Mexican origin who were born and delivered in Mexico were much less likely to deliver preterm or low birth weight infants compared to US-born

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

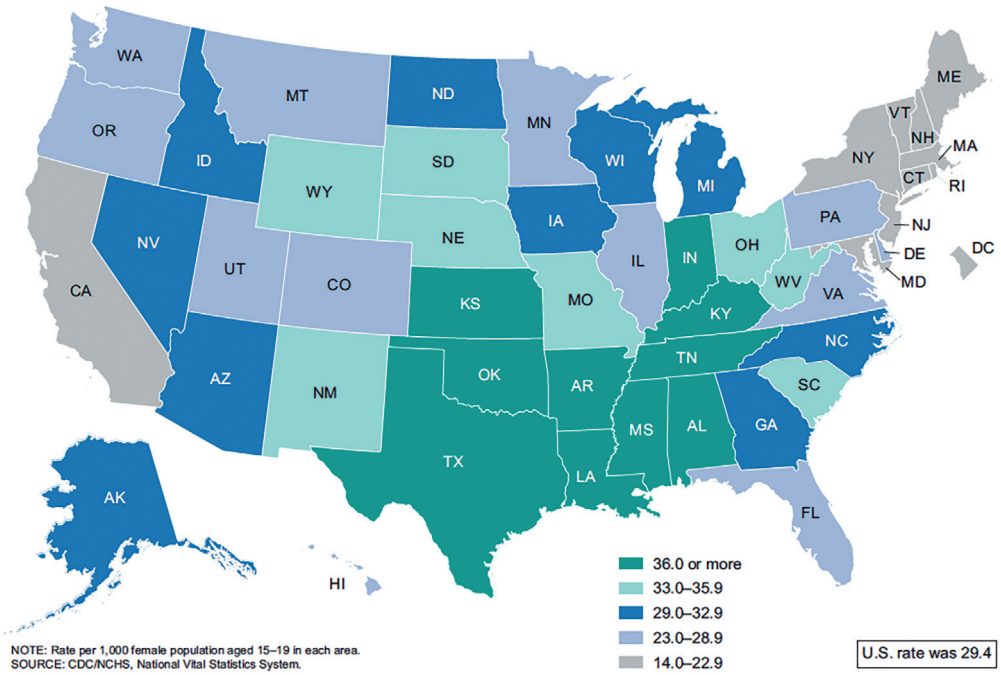
Mexican-origin women who delivered in the United States. Even those women who delivered in the United States but were born in Mexico appeared to have some protective effect.[45,78]

Prematurity rates vary widely in the United States by state, with those in the Deep South—states with the highest percentage of non-Hispanic black mothers—showing the highest rates of prematurity and infant mortality. The highest mortality states include Mississippi, Alabama, Louisiana, North Carolina, Arkansas, Georgia, Oklahoma, and South Dakota, states with either very high non-Hispanic black or Native American populations. These are also the states with the highest rates of preterm births (see Fig. 9.2). Encouragingly, many of these states in the Deep South also had the biggest recent decreases in infant mortality.[62] This may be partially explained by the state-level progress made by many of the southern states in reducing the black-white infant mortality gap in recent years.[13] However, within the Mississippi Delta, those counties with the poorest health outcomes also have a significantly higher percentage of African American females and low birth weight infants.[37] It is unlikely that poverty and low SES, or higher rates of teen pregnancy alone, can explain the poorer outcomes of low birth weight seen in non-Hispanic black women. A recent study by Coley et al. found that even after adjusting for a multitude of maternal factors encompassed in a "neighborhood risk" score, racial disparities persisted as a cause of low birth weight in North Carolina.[20]



Note: Rates are plotted on a logarithmic scale.

Social Determinants of Health

Health care disparities are differences in health care quality, access, and outcomes adversely affecting members of racial and ethnic minority groups and other socially disadvantaged populations.[34,67] The World Health Organization (WHO) defines social determinants of health as the conditions in which people are born, grow, live, work, and age.[87] They consist of policies, programs, and other aspects of societal structure, including government and private sectors,

• **Fig. 9.4** Standardized birth rates for teenagers aged 15–19, by state: United States, 2012.

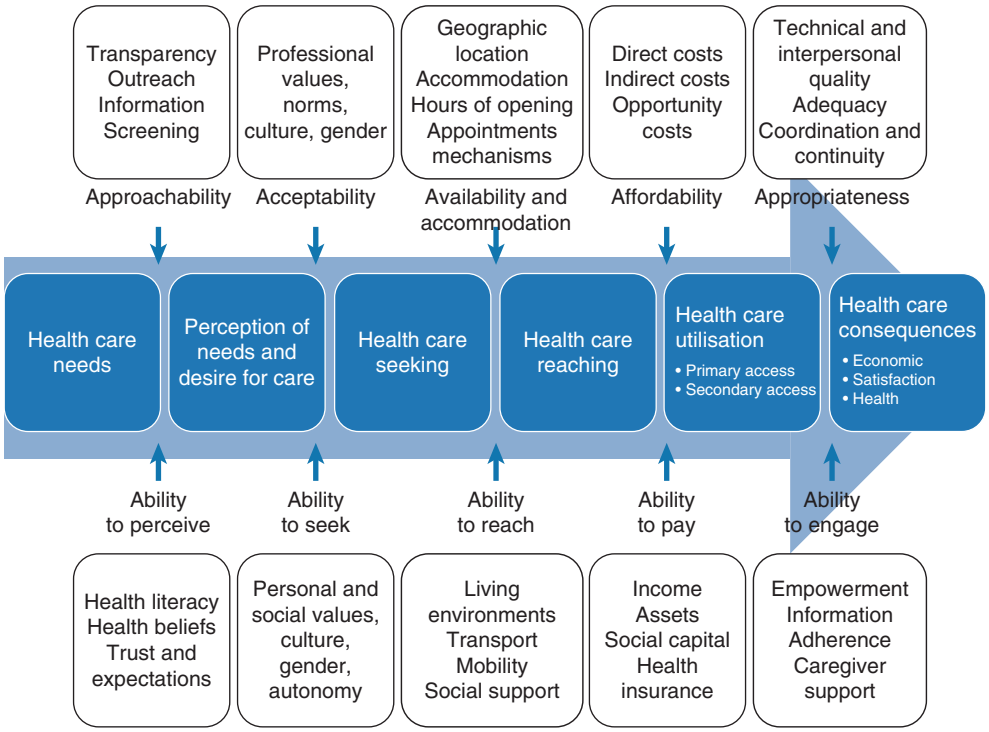
as well as community factors.[44] Health is determined in part by access to social and economic opportunities; the resources and supports available in homes, neighborhoods, and communities; the quality of schooling; the safety of workplaces; the cleanliness of water, food, and air; and the nature of social interactions and relationships (Box 9.1). These circumstances are shaped by the distribution of money, power, and other resources at global, national, and local levels.[44] Social determinants greatly impact perinatal outcomes[55] and are largely responsible for preventable health inequities.[18,48] Poverty limits access to healthy foods and safe neighborhoods and education resources, a known predictor of better health.[10,18,82]

A "place-based" organizing framework, reflecting five key areas of social determinants of health (SDOH), was developed by Healthy People 2020.[44] These five key areas (determinants) include: (1) economic stability, (2) education, (3) health and health care, (4) neighborhood and built environment, and (5) social and community context.[44] Each of these five areas reflect several critical components/key issues that make up the underlying factors.

The complex history of race and ethnicity in the United States may affect individual responses to medical recommendations for screening tests and adherence to treatment plans, contributing to disparate outcomes along racial lines.[84] Numerous examples exist of racial and ethnic groups being targeted for forced medical procedures or experimentation.[54] These past atrocities in the United States have left a lasting mistrust in minority communities. Distrust of the health care system has not been well studied in the prenatal/obstetric/neonatal context. In other settings, health care system distrust is associated with a greater burden of racial discrimination and not explained by differences in individual socio-demographics, health care access, or residential segregation.[4,35] Experiences of racism and discrimination likely play a role in health system engagement and prenatal care utilization. In a survey of mothers, non-Hispanic black or Hispanic race/ethnicity was associated with almost three times higher odds of discrimination due to race, language, or culture, and uninsured women had nearly twice the odds of experiencing any perceived discrimination.[35]

Creanga et al. noted that non-Hispanic black-serving hospitals performed worse than other hospitals on 12 of 15 delivery-related indicators, highlighting the impact of the access to quality health care as a determinant of delivery outcomes.[24] Adequacy of prenatal care has been found to be significantly associated with infant outcomes, particularly gestational age at delivery and birth weight.[16,19,35] Race and living in a distressed neighborhood are associated with late presentation to prenatal care. Proximity to the hospital is a key mediator in prenatal care utilization, and transportation to appointments and affordability of transportation are key factors in adherence to prenatal care. The impact of the neighborhood of residence on prenatal care disparities has not been explained by provider or physician supply alone. Neighborhood factors are thought to explain up to two-thirds of observed black–white differences in the preterm birth rate.[20,35]

Social determinants such as insurance status, availability of social support in the form of childcare and adequate housing, neighborhood, and transportation likely play some role in prenatal care utilization and ultimately neonatal outcomes.[35] Community-based research has shown that bundling prenatal care with other services such as child care that specifically aimed to reduce known disparities in social determinants improves outcomes.[35] Non-Hispanic black women are three times more likely to be homeless during their pregnancy or preconception period, and prenatal homelessness is associated with higher odds of low birth weight and preterm delivery.[28,83]



Access to health care is central to the delivery of health care services. Access is defined as the opportunity or ease with which consumers or communities are able to use appropriate services in proportion to their needs. Levesque et al.[53] conceptualized five dimensions of accessibility of services: approachability; acceptability; availability and accommodation; affordability; and appropriateness. Five corresponding abilities of persons interact with these dimensions of accessibility to generate access; these dimensions of abilities include: ability to perceive; ability to seek; ability to reach; ability to pay; and ability to engage. The various dimensions of access identified are not independent constructs (Fig. 9.5).

Although the Children's Health Insurance Program (CHIP) has increased the number of US children with coverage,[31,32] insurance coverage alone does not guarantee access to needed health care. Angier et al. found affordability and lack of availability to be the most commonly reported barriers to health care access in a cohort of parents with incomes less than 133% of the federal poverty level; despite their child having health insurance, parents were unable to receive necessary health care services.[1,2,50] Low socioeconomic status is associated with poor health status before, during, and after pregnancy. Homelessness during pregnancy in particular leads to worse birth outcomes due to a variety of factors.[28]

• BOX 9.1 Examples of Social Determinants of Health

- Availability of resources to meet daily needs: safe housing and local food markets
- Access to educational, economic, job opportunities, health care services, and job training
- Availability of community-based resources for recreational and leisure-time activities
- Transportation options and public safety
- Social support, social norms, and attitudes (e.g., discrimination, racism, and distrust of government)
- Exposure to crime, violence, and social disorder
- Socioeconomic conditions (e.g., concentrated poverty and the stressful conditions that accompany it)
- Residential segregation, language/literacy, and culture
- Access to mass media and emerging technologies (e.g., cell phones, the Internet, and social media)

• **Fig. 9.5** A conceptual framework of access to health care. (From Levesque J-F, Harris MF, Russell G. Patient-centered access to health care: conceptualizing access at the interface of health systems and populations. *Int J Equity Health*. 2013;12:18.)

The increase in ethnic differences in neonatal mortality may be related to additional inequities in the provision of health care. Alabama's 2011 omnibus immigration law resulted in a reduction in service availability for Latina immigrants and their US and foreign-born children. Affordability and acceptability of care were also adversely affected because of economic insecurity and women's increased sense of discrimination.[85] A mental health diagnosis, poor relationships with health professionals, and environmental barriers can compromise women's utilization of maternity services.[12]

Before the Affordable Care Act (ACA) spurred major expansions in health insurance coverage, non-Hispanic black and Hispanic working-age adults were far more likely than non-Hispanic whites to be uninsured.[43] Uninsured women are 77% less likely to use obstetrical services, have higher rates of severe morbidity, and are more likely to have inadequate prenatal care.[35] Having health insurance makes it easier to gain access to and afford care, but insurance alone is unlikely to eliminate differences in access among all groups.[43] Increased state level Medicaid reimbursement for care increases adequate prenatal care utilization.

Even within the hospital setting, there may be unrecognized and unintended disparities in the delivery of health care to pregnant mothers and neonates. Profit et al. found clinically and statistically significant racial and/or ethnic variation in quality of care between neonatal intensive care units (NICUs) as well as within NICUs.[74] Earlier work in the California Perinatal Quality Care Collaborative suggested that Hispanic mothers, mothers younger than age 20, and those without prenatal care were less likely to receive antenatal steroid treatment for impending preterm delivery.[51] A recent review of three New York hospitals suggested that non-Hispanic white infants were more likely to receive surfactant by 4 hours (85%) than non-Hispanic black infants (61%) or Hispanic infants (67%).[46]

Chronic stress and worry by disadvantaged mothers likely has a significant impact on poor perinatal and neonatal outcomes. Braveman et al. found that non-Hispanic black women reported significantly higher chronic worry about racial discrimination compared to non-Hispanic white women.[11] Surprisingly, rates of worry for non-Hispanic black women were highest in those with higher income and education levels. Those with the highest rates of worry also had the highest rates of preterm birth. Even more intriguing is the evidence for continued generational effects of racial disparities with non-Hispanic black mothers who were small for gestational age or preterm themselves having a higher risk than non-Hispanic white mothers to deliver a subsequent small for gestational age or preterm infant.[17]

Interventions to Reduce Neonatal Health Outcome Disparities

It is unlikely that improving care in the NICU alone will have a dramatic impact on reducing the US neonatal and infant mortality rates. Research has demonstrated the areas of greatest impact that will result in improved neonatal health. First, all women, but especially those at highest risk

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

such as non-Hispanic black women and Native American/Alaskan women, must have improved health status even before conception. Programs that can screen and identify women at risk must be easily accessible. This is certainly a challenge in very rural/remote areas where health care access is limited or non-existent. In addition, many urban settings have a maldistribution of health care providers, making access difficult for those most in need.

The massive rise in obesity in the US population over the past years has been well documented. Of significant concern to those in the public health arena is how this has negatively impacted women of reproductive age and their future children. Maternal obesity is another aspect of health disparities in that those races and ethnicities exhibiting worse perinatal and neonatal outcomes also have significantly higher rates of obesity than the general population. Recent data indicate that in the last decade, non-Hispanic black women over the ages of 20 have an extremely high incidence of obesity at 56.9%, compared to non-Hispanic white women at 35.5%.[69] Hispanic women also suffer from this epidemic of increased weight with an incidence of 45.7%. Disparities in the incidence of obesity during pregnancy also are seen in non-Hispanic black women, having the highest rates of prepregnancy obesity in the general population, especially at the highest categories of obesity.[49,52,79] Obesity is known to increase the risk of gestational diabetes from a baseline of 2.8% to a high of 14.6% in pregnant women with class III obesity.[49] Other morbidities of pregnancy such as gestational hypertensive disorders (increasing fourfold at highest obesity classes), infection, cesarean section rates, and cardiovascular events are all higher in obese pregnant women. While obesity has its own risks of increased morbidity on pregnant women, obesity is also associated with increased infant mortality and morbidity. Infant mortality increases with each increase in obesity category.[49] Declerq et al. found that with a normal prepregnancy weight as a reference, the odds ratio (OR) for an infant death rose from 1.32 (95% confidence interval [CI] 1.27–1.37) for mothers in the obese I category up to 1.73 (95% CI 1.64–1.83) for obese III category pregnant mothers.[29] Lemon et al. reported that compared with non-Hispanic white women, non-Hispanic black women were more likely to be obese and experienced a higher rate of stillbirth (8.3 vs. 3.6 stillbirths per 1000 live-born and stillborn infants) and infant death (8.5 vs. 3.0 infant deaths per 1000 live births).[52] In addition, obesity during pregnancy is associated with increased neonatal morbidities such as prematurity,[79] sepsis, large-for-gestational-age infants, and NICU admission.[49] Increasing obesity also results in an increased risk of major malformations in the neonate and were the highest as the severity of obesity increased.[73] Congenital malformations were seen in the cardiovascular system, malformations of the nervous system, and limb defects. It is also likely that to reduce these adverse outcomes, intervention begin before conception.

The causes of obesity are multifactorial, but chronic maternal stress related to racial and ethnic disparities seen in the United States may play a significant role.[72] Screening and health promotion for obesity, diabetes, and hypertension are critical to improving the health of the mother. Current models of physician reimbursement discourage the significant time needed for such interventions. Innovative models, such as mobile clinics, group counseling, and specially trained health care workers have all shown to improve health outcomes in women of child-bearing age. Chronic conditions, such as hypertension and diabetes, must be well controlled over time, with continued and affordable access to medications that are known to be effective. The current dramatic increase in obesity, especially in the south and among non-Hispanic blacks, Native Americans, and Hispanics in the United States, is a particular challenge. Not often recognized is the lack of healthy food available in underserved and rural areas, which contributes to obesity.

Another public health initiative that will have a significant impact on health care disparities in the perinatal and neonatal period is in pregnancy delay and prevention of unintended pregnancies[36] and associated short interpregnancy intervals. Teen births, while significantly decreasing, are still highest in some of the populations at highest risk for prematurity and infant mortality. Improved education about pregnancy prevention, including in schools, as well as easier access to contraception, is critical. In addition, long-acting reproductive contraception (LARC) has been shown to be particularly effective and is reversible at the time of desired pregnancy. Contraception for those that desire it must be more readily available, especially immediately after delivery of a baby. Contraceptive counseling is rarely done during postpartum care, or while a baby is in the NICU, but these are valuable missed opportunities to improve the health of the mother and her future children. Improved access to contraception will increase interpregnancy intervals. Short inter-pregnancy intervals less than 6 months are more common in non-Hispanic black mothers (7.1%) compared to non-Hispanic white mothers (4.1%) and Hispanic mothers (5.0%).[80] The shortest interval of inter-pregnancy conception (less than 6 months) has been shown to have the highest adverse outcomes, especially in teen mothers.[68] Access to contraception, especially for teen pregnancies, of which 75% are unintended, is critical to lengthen interpregnancy intervals and prevent adverse outcomes associated with teen pregnancy. Local legislation will be needed to implement this public health intervention. Because of limited access to contraception, there are racial disparities in abortion rates for women of lower socioeconomic status and women of color. Hispanic women and non-Hispanic black women have 2–3.5-fold higher rates of abortion than non-Hispanic white women.[47] However, efforts to decrease access to abortion for these women may only widen the health disparities for future generations.[30]

As noted above, there are significant disparities in rates of prenatal care related to race and ethnicity, with non-Hispanic blacks overall having the lowest rates of adequate prenatal care and the highest rates of no prenatal care (see Table 9.1). Statewide Medicaid-enhanced prenatal care

programs have been shown to reduce infant mortality risk.[64,65] Implementation of such a program in Michigan reduced the odds of infant death by 27%, with the highest reduction in black infant mortality (29%). The greatest reduction was seen in those women who fully participated in the program using a population-based home visitation program. For non-Hispanic black women, this program resulted in lower odds of low birth weight (0.76), very low birth weight (0.42) and very preterm birth (0.41) compared with matched nonparticipants.[76]

Access to insurance coverage before, during, and after pregnancy is also a vital piece of health care. Having health insurance reduces racial and ethnic disparities in key measures of health care access and affordability, even after adjusting for income and other factors.

Women often qualify for Medicaid coverage once the pregnancy is identified but cannot access the health care system before the pregnancy to improve their health, thus putting them at greater risk. As noted above, the Affordable Care Act (ACA) has significantly decreased the uninsured rate of people in the United States, with varying improvements in insurance coverage based on the degree of states' Medicaid expansion. This program has also mandated insurance coverage by all health plans for prenatal, postnatal, and infant care. The Children's Health Insurance Program (CHIP) funded by the United States has increased coverage of uninsured children. Survey-based research shows positive associations between CHIP expansions and children's health care utilization. After Oregon's 2009-2010 CHIP expansions, newly insured patients' utilization rates were more than double their pre-expansion rates (adjusted rate ratios [95 % confidence intervals]); increases were 2.10-fold (1.94–2.26) for primary care visits.[5] Thus, continued access to insurance for women and children may have a significant impact on reducing the disparities seen. Unlike other developed countries, the United States has no universal health care and the ACA has been a significant, albeit controversial, improvement in this area. Those in health care, both providers and insurers, must advocate for the most vulnerable in the population to maintain and expand this coverage.

Other modifiable factors must be addressed for women at risk of becoming pregnant. Tobacco, alcohol, and illicit substance use/abuse all have negative impacts on pregnancy outcomes and are often disproportionately used by those at highest risk of adverse outcomes.[66] Culturally specific and appropriate educational materials and interventions must be available in a variety of settings, including schools. Tobacco cessation programs specifically during pregnancy, especially quitting early in pregnancy, have been shown to decrease the risk of preterm birth.[66] Alcohol use and abuse is particularly high among Native American and Alaska Natives and results in high rates of fetal alcohol syndrome.[15] Fetal alcohol syndrome and fetal alcohol spectrum disorder is the largest cause of preventable long-term neurodevelopmental disability in children. Treatment of those ingesting alcohol during pregnancy is particularly difficult. However, intensive interventions have made some impact.[42] Finally, the current opioid epidemic has been well publicized, as has the impact on those at the lowest socioeconomic populations. Pregnant women are often the least likely to get medical help given the highly punitive nature of some state programs, even to the point of arresting and incarcerating pregnant women, especially those women of minorities. However, programs that deal with multiple aspects of maternal drug use with known effective interventions and a less punitive approach have been shown to significantly improve neonatal and maternal outcomes, including more controlled or even cessation of drug use.[88] Other innovative prenatal care programs such as group-based centering, easier access to care during pregnancy, and the use of novel IT platforms for patient access and information also have been shown to have a significant impact on avoiding adverse outcomes of pregnancy.[27]

While the underlying cause of prematurity is multifactorial and not clearly understood, certain interventions have been shown to reduce preterm birth. For those women identified with a singleton pregnancy and a previous history of spontaneous preterm birth, 17 alpha-hydroxyprogesterone caproate (17OHP) has been shown to reduce the risk of subsequent preterm delivery by up to 30%.[22] However, access to this medication requires weekly injections, and the current drug delivery and reimbursement model is problematic for both physicians and women at risk. Many state Medicaid plans are investigating novel methods to deliver this drug to mothers at risk.

Breastfeeding has been shown to have important benefits to both the mother and infant, including decreased breast and ovarian cancer rates, less postpartum depression, and osteoporosis in the mother, as well as fewer infections, less risk of diabetes, heart disease, and asthma in the infant. However, significant disparities exist in the rates of breastfeeding among different races and ethnicities.[63] Non-Hispanic black women have the lowest rates of initiation of breastfeeding, exclusive breastfeeding at 6 months, and any breastfeeding at 12 months.[3] In addition, certain areas of the United States with the highest poverty levels such as the Deep South and Appalachian States have the lowest rates of breastfeeding. Successful implementation of breastfeeding must begin before delivery with targeted and appropriate education. Baby Friendly initiatives in the United States have resulted in increased awareness of the importance of this public health measure but more must be done. Lactation specialists must be available to all mothers immediately after delivery and during the postnatal period to improve initiation of and adherence to breastfeeding.

The American Academy of Pediatrics (AAP) and March of Dimes (MOD) have initiated the Safe Sleep campaign in an effort to reduce SIDS. While the Safe Sleep program is effective, key measures must be stressed, such as the lack of separate sleeping spaces for the infant and co-bedding in minority populations. It is often difficult to intervene in those families with limited finances. Programs such as Back to Sleep and Baby Sleeping Boxes are simple and effective

interventions. However, continued local and state educational efforts must be maintained and supported.

State Perinatal Quality Collaboratives have been an extremely successful model for health care providers and families interested in improving prenatal and postnatal outcomes, primarily using Quality Improvement methodology. Areas successfully addressed have been increased administration of antenatal corticosteroids to mothers at risk of preterm delivery, decrease in elective late preterm deliveries, and antibiotic stewardship.[38] State collaboratives identify best practices within each state and work together to improve maternal and neonatal outcomes through quality improvement processes.

Finally, improving the overall health and economic status of those most disadvantaged in the United States will result in improved perinatal and neonatal/infant outcomes. In enhanced programs, implementation of measures that increase educational opportunities, job creation, and statewide early intervention programs have been shown to be beneficial in other countries. Canada implemented unconditional prenatal income supplements to mothers already receiving prenatal social assistance and observed reductions in low birth weight (21%), preterm births (17.5%), and increases in breastfeeding.[14] Every baby deserves a first birthday. Effective interventions exist that will help more to reach this goal.

Key Points

- The United States has high infant mortality and prematurity rates compared to other high income countries.
- Health disparities are seen in maternal outcomes with non-Hispanic black mothers having the highest rates of maternal mortality and morbidity, obesity, and teen pregnancy.
- The United States has significant health disparities in measurements of perinatal and neonatal outcomes with non-Hispanic black infants leading in prematurity and infant mortality.
- American Indian/Alaska Native infants suffer from high infant mortality rates compared to non-Hispanic white infants.
- Public health interventions to address health disparity outcomes by race and ethnicity are needed to improve US neonatal outcomes.

Genetic Aspects of Perinatal Disease and Prenatal Diagnosis

SUSAN J. GROSS AND CIPRIAN P. GHEORGHE

The genetic basis of human disorders is a fundamental cornerstone of modern medicine. Recent advances in our understanding of complex genetic disorders coupled with technical developments have allowed genetics to become an invaluable part of clinical practice. This chapter highlights essential concepts regarding the genetic basis of disease and issues surrounding prenatal evaluation and diagnosis. Principles of inheritance, teratogens, genetic screening, and diagnostic modalities are discussed.

Principles of Inheritance

Chromosomal Disorders

In humans, normal gametes are composed of 23 chromosomes each. A normal human somatic cell contains 46 chromosomes. In both genders, 22 pairs of chromosomes, also known as *autosomes,* are identical. Women have a homologous pair of sex chromosomes, known as the X chromosome. Men have a nonhomologous pair, an X and a Y chromosome.

A chromosome is composed of a linear DNA molecule that is complexed with structural proteins known as *histones* to form chromatin. Each chromosome has a centromere, which divides the chromosome into a short arm (the *p* arm) and a long arm (the *q* arm). Where the centromere is located helps describe chromosomes as metacentric, submetacentric, and acrocentric. In *metacentric* chromosomes the arm length is equal, whereas in *submetacentric* chromosomes, one arm is larger than the other. If the p arm contains such small amounts of genetic material that it is almost negligible, the chromosome is considered *acrocentric*. In humans, the acrocentric chromosomes are 13, 14, 15, 21, and 22. The ends of each chromosome are known as *telomeres*. During cell division the chromosomes condense more than 10,000-fold, resulting in compact structures that can segregate.

To analyze chromosomes, a karyotype is produced (Fig. 10.1). The chromosomes are paired and organized according to size. The overall structure and banding pattern is evaluated and is reported according to the International System for Cytogenetic Nomenclature. According to this nomenclature, a karyotype designation includes the total chromosome number followed by the sex chromosome constitution. Females are 46,XX and males are 46,XY. If there are any variants or abnormalities, this is reported after the sex chromosomes (Table 10.1).[35] Chromosome disorders can be either structural or numerical. The consequence of the abnormality depends on the amount of genomic imbalance and the genes involved.

Maternal Age Considerations

Epidemiologic studies suggest that women are having fewer children, often later in life. The National Center for Health Statistics (NCHS) reported that from 2000 to 2014, the proportion of first births to women aged 30-34 rose 28% (from 16.5% to 21.1%), and first births to women aged 35 and over rose 23% (from 7.4% to 9.1%).[19] With the advent of assisted reproductive technology (ART), women in their 50s and 60s can achieve pregnancy. Although it cannot be emphasized enough that the effects of increasing age occur as a continuum, the term *advanced maternal age* has historically referred to pregnant women who will be 35 or older on their expected date of confinement.

Chromosomal analysis of samples from spontaneous abortions, prenatal diagnosis, and live births reveals that there is a steady increase in aneuploidy as a woman ages (Fig. 10.2). The basis for this increase is unknown, although it may be related to a decrease in the number of normal oocytes available or cumulative oxidative stress on the finite number of oocytes with which females are born. Along with chromosomal abnormalities, it has been observed that congenital anomalies increase with increased maternal age. The FASTER trial reported rates of congenital anomalies for women younger than 35 years old as 1.7%; women 35 to 39 years old and 40 years old or older had rates of 2.8% and 2.9%, respectively.[29]

Abnormalities of Chromosome Number

The mere presence of additional genetic material, albeit of normal makeup, can result in clinically significant

phenotypes. Following is a discussion of the various types of numerical abnormalities.

Triploidy and Tetraploidy

Triploid fetuses have three sets of chromosomes for a total number of 69. Triploid fetuses are rarely born alive; when they are, survival is poor. Most triploidy is the result of fertilization by two sperm. Tetraploids, fetuses with 96 chromosomes, are usually miscarried in the first trimester.

Aneuploidy

In humans, the term *aneuploid* is used to describe any genotype in which the total chromosome number is not a multiple of 23. Most aneuploid patients have either a monosomy (only one representative of a particular chromosome) or a trisomy (three copies of a particular chromosome). As a rule, monosomies tend to be more deleterious than trisomies. Complete monosomies are generally not viable except for monosomy X (Turner syndrome). Trisomies for chromosomes 13, 18, 21, X, and Y are compatible

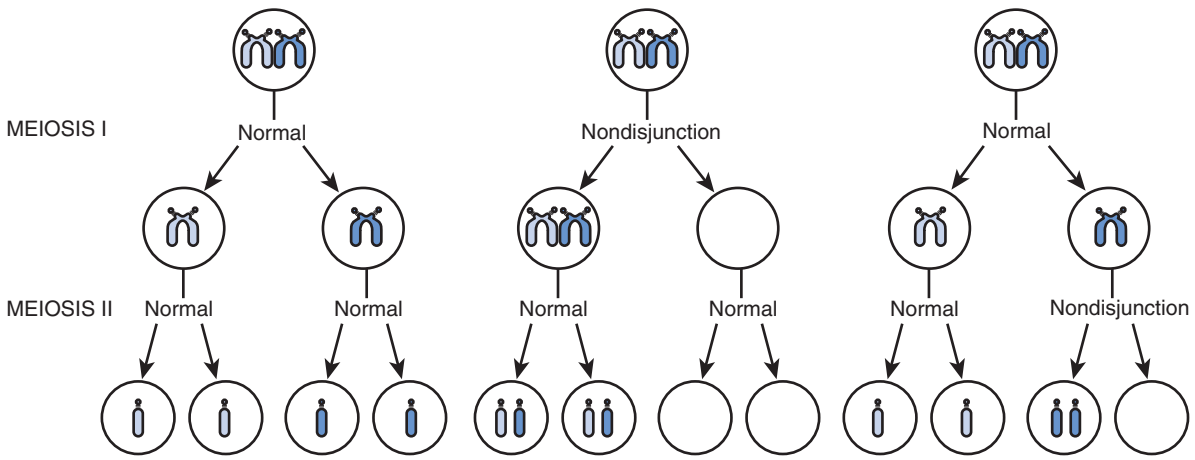
with life, with trisomy 21 (Down syndrome) being the most common trisomy in live-born infants.

The most common mechanism for aneuploidy is meiotic nondisjunction, in which a pair of chromosomes fails to separate during either of the meiotic divisions (Fig. 10.3). Nondisjunction can rarely occur during a mitotic division after the formation of the zygote. If this happens early in cleavage, mosaicism may occur. In this situation, two or more different chromosome complements are present in one individual. The clinical significance of mosaicism is difficult to evaluate and depends on the developmental timing when the mosaicism occurred, the tissues affected, and the proportion of tissue affected.

Abnormalities of Chromosome Structure

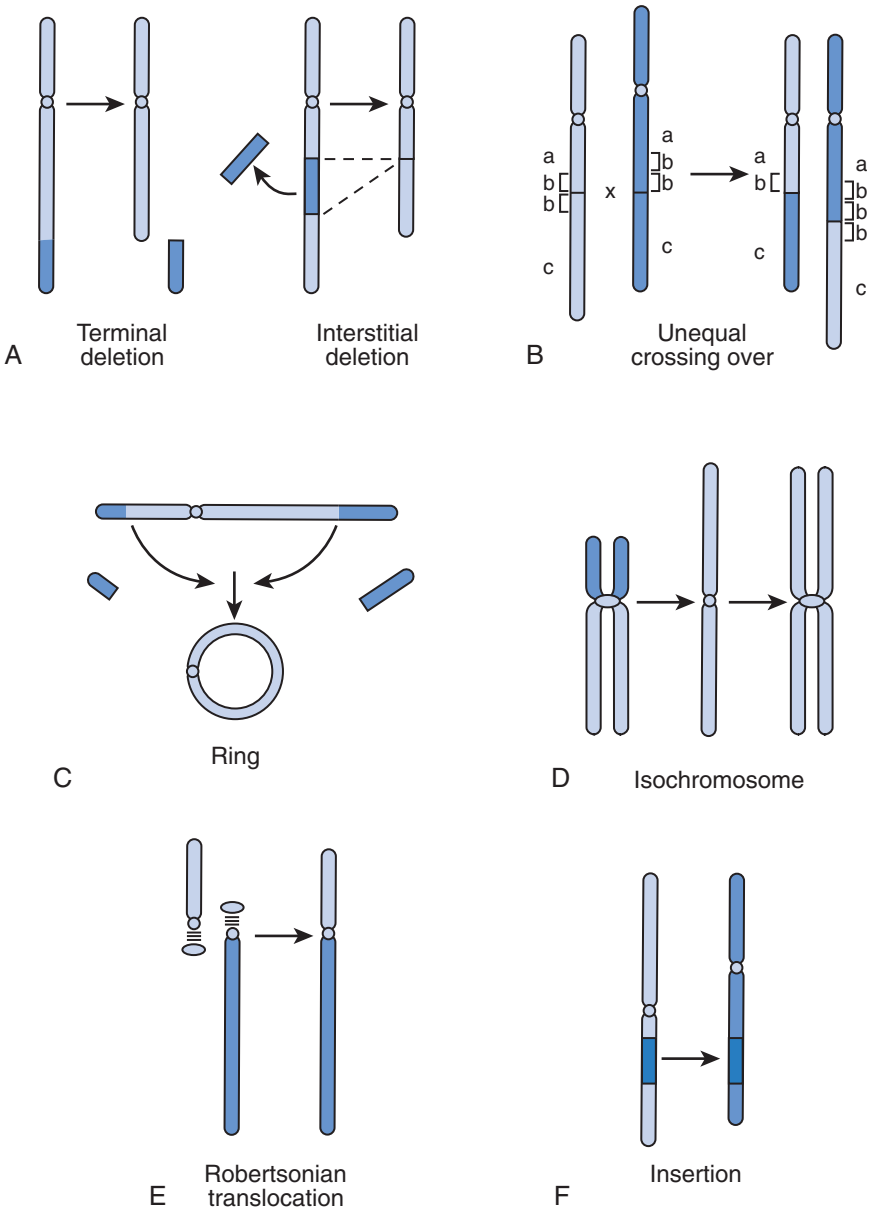
Chromosomal structural abnormalities are the result of chromosome breakage followed by anomalous reconstitution.



• **Fig. 10.2** Risk of fetal aneuploidy as a function of maternal age.

Rearrangements result spontaneously or are due to inducing agents, such as ionizing radiation. Structural abnormalities can be divided into two categories—balanced and unbalanced. Balanced rearrangements have the normal complement of chromosomal material. Also, a balanced rearranged chromosome must have a functional centromere and two functional telomeres. Unbalanced rearrangements are either missing or have additional genetic information.

Structural rearrangements include deletions, insertions, ring chromosomes, isochromosomes, and translocations (Fig. 10.4). One unique type of translocation is the Robertsonian translocation, in which two acrocentric chromosomes lose their short arms and fuse near the centromeric region. Because the short arms of acrocentric chromosomes contain only genes for ribosomal RNAs, loss of the short arm is rarely deleterious. The result is a balanced karyotype with only 45 chromosomes, including the translocated chromosome, which comprises the long arms of two chromosomes. Carriers of Robertsonian translocations are phenotypically normal but have the risk of producing unbalanced gametes. The main clinical relevance of a Robertsonian translocation is that one involving chromosome 21 could result in a child with Down syndrome. About 4% of cases of Down syndrome have 46 chromosomes, one of which is a Robertsonian translocation between chromosome 21 and another chromosome.



Single-Gene Disorders

Mendel studied the offspring characteristics of garden peas and observed that certain phenotypic characteristics occurred in fixed proportions. Single-gene traits for which mutations cause predictable disease are described as exhibiting *Mendelian inheritance*, because they follow the rules that he originally described. Currently, almost 4000 diseases are known to exhibit Mendelian patterns of inheritance.

• **Fig. 10.3** Consequences of nondisjunction at meiosis I (*center*) and meiosis II (*right*) compared with normal disjunction (*left*). If the error occurs at meiosis I, the gametes either contain a representative of both members of the chromosome 21 pair or lack chromosome 21 altogether. If nondisjunction occurs at meiosis II, the abnormal gametes contain two copies of one parental chromosome 21 (and no copy of the other) or lack chromosome 21. (From Nussbaum RL, et al. *Thompson and Thompson Genetics in Medicine*. 7th ed. Philadelphia: Saunders; 2007:68.)

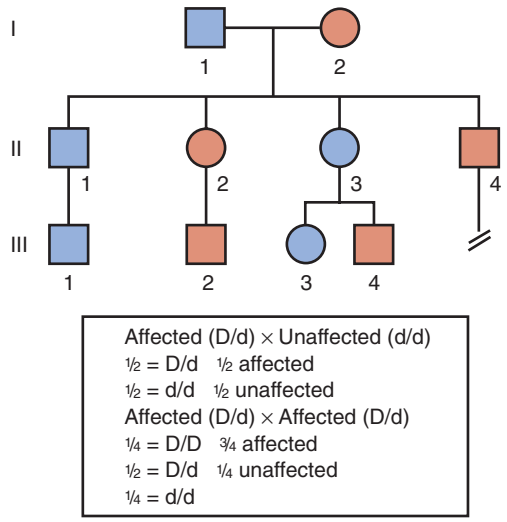
• **Fig. 10.4** Structural rearrangements of chromosomes. **A,** Terminal and interstitial deletions, each generating an acentric fragment. **B,** Unequal crossing over between segments of homologous chromosomes or between sister chromatids (duplicated or deleted segments indicated by *brackets*). **C,** Ring chromosome with two acentric fragments. **D,** Generation of an isochromosome for the long arm of a chromosome. **E,** Robertsonian translocation between two acrocentric chromosomes. **F,** Insertion of a segment of one chromosome into a nonhomologous chromosome. (From Nussbaum RL, et al. *Thompson and Thompson Genetics in Medicine*. 7th ed. Philadelphia: Saunders; 2007:69.)

Among hospitalized children, 6% to 8% are thought to have single-gene disorders.

Variants of a gene are called *alleles*. For many genes, there is one prevailing allele, which is referred to as the *wild-type* allele. The other versions of the gene are *mutations,* not all of which may cause disease. Mutations can be inherited or de novo, meaning that neither parent possessed the mutation. Instead, the mutation occurred as a random error during gametogenesis. To distinguish between benign and deleterious mutations, the professional genetics community now calls the latter pathogenic variants.

Autosomal Dominant Disorders



Approximately half of Mendelian disorders are inherited in an autosomal dominant fashion. Inheritance usually exhibits a vertical pattern of transmission, meaning that the phenotype appears in every generation, with each affected person having an affected parent (Fig. 10.5). For each offspring of an affected parent, the risk of inheriting the mutated allele is 50%. An example of a disorder inherited in an autosomal dominant fashion is osteogenesis imperfecta. Biochemical defects in either the amount or the

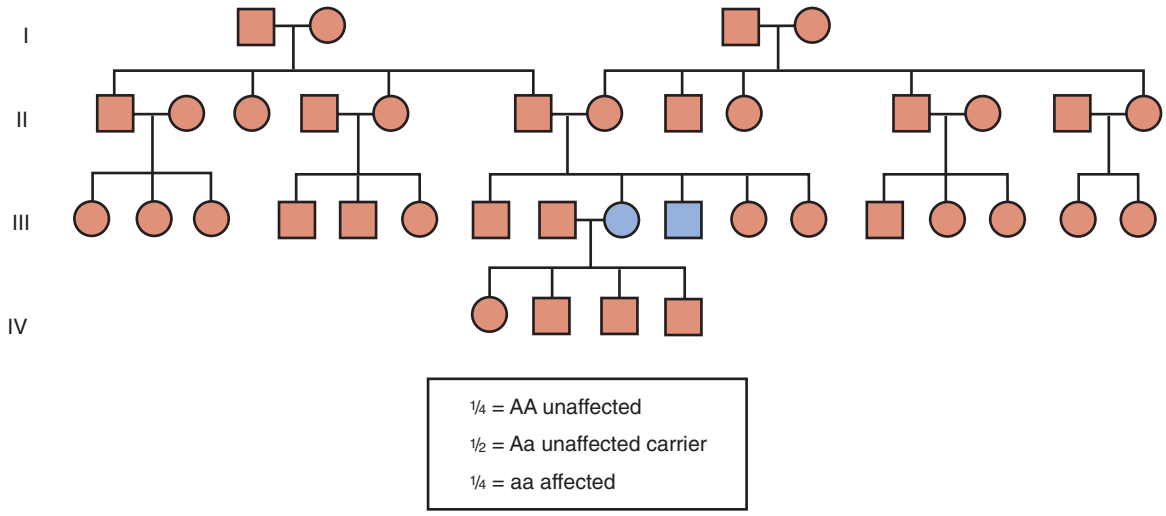
structure of collagen result in various clinical phenotypes depending on the mutation.

Advanced Paternal Age

The link between advanced maternal age and genetic abnormalities has been well-established. The role of advanced paternal age, defined as 40 or older, is not as clear. It has been established that the rate of base substitution mutations during spermatogenesis increases as a man ages. The risk of de novo autosomal dominant disorders in offspring of fathers 40 years old or older is estimated at 0.3% or lower.[26] Some evidence has suggested that advanced paternal age is associated with an increased risk for complex disorders such as schizophrenia, autism, and congenital anomalies. The relative risk for these conditions is 2% or less. Although there may be slightly increased risk for a range of disorders associated with advanced paternal age, the overall risk remains low. No screening or diagnostic tests target conditions associated with advanced paternal age. Pregnancies that are fathered by men 40 years old or older should be treated according to standard guidelines established by the American College of Medical Genetics (ACMG) and the American College of Obstetrics and Gynecology (ACOG).[38]



• **Fig. 10.5** Pedigree showing the typical inheritance of an autosomal dominant disorder. ■ affected male; ● affected female; ■ unaffected male; ● unaffected female.

Autosomal Recessive Disorders

An autosomal recessive condition occurs when an individual possesses two mutant alleles that were inherited from heterozygous parents. For autosomal recessive diseases, an individual with one normal allele does not manifest the disease, because the normal gene copy is able to compensate. Autosomal recessive disorders exhibit horizontal transmission, meaning that if the phenotype appears in more than one family member, it is typically in the siblings of the proband, not in parents, offspring, or other relatives (Fig. 10.6). If both parents are carriers of a mutated allele, 25% of offspring have the autosomal recessive disease. Consanguineous unions (mating between individuals who are second cousins or closer) are at increased risk for an autosomal recessive disorder, because there is a higher likelihood that both individuals carry the same recessive mutation. A common autosomal recessive disease is cystic fibrosis. Carrier screening and prenatal implications are discussed in a later section.

Sex-Linked Disorders

X chromosome inactivation is a normal process in females in which one X chromosome is randomly inactivated early in development. Females are normally mosaic with respect to X-linked gene expression. Disorders of genes located on the X chromosome have a characteristic pattern of inheritance that is affected by gender. Males with an X-linked mutant

• **Fig. 10.6** Typical pedigree showing autosomal recessive inheritance. allele are described as being hemizygous for that allele. Males have a 50% chance of inheriting a mutant allele if the mother is a carrier. Females can be homozygous wild-type allele, homozygous mutant allele, or a heterozygote.

An X-linked recessive mutation is phenotypically expressed in all males but is expressed only in females who are homozygous for the mutation. As a result, X-linked recessive disorders are generally seen in males and rarely seen in females. An example of such a condition is hemophilia A. X-linked dominant disorders may manifest differently among heterozygous females in the same family because of different patterns of X chromosome inactivation. X-linked inheritance is classically characterized by the lack of male-to-male transmission, because males transmit their Y chromosome to their sons, not their X chromosome (Fig. 10.7).

Non-Mendelian Patterns of Inheritance

Mitochondrial Inheritance

Mitochondrial DNA (mtDNA) is organized as a 16.5-kb circular chromosome located in the mitochondrial organelles of a cell, not the cell nucleus. mtDNA contains 37 genes that encode for important proteins, including proteins involved in oxidative phosphorylation.

• **Fig. 10.7** Pedigree pattern showing X-linked dominant inheritance. ■ affected male; ● affected female; ■ unaffected male; ● unaffected female. (From Nussbaum RL, et al. *Thompson and Thompson Genetics in Medicine*. 7th ed. Philadelphia: Saunders; 2007:133.)

Mitochondrial inheritance has a few distinct features that differ from Mendelian inheritance: maternal inheritance, replicative segregation, and heteroplasmy. Because sperm mitochondria are eliminated from the forming embryo, mtDNA is inherited entirely from the maternal side, with very rare exception. At cell division, the mitochondria sort randomly between two daughter cells, a process known as *replicative segregation*. A cell containing a mix of mutant and wild-type mtDNA can distribute variable proportions of mutant or wild-type DNA to daughter cells. By chance, a daughter cell may receive all wild-type or all mutant mtDNA, a state known as *homoplasmy*. Heteroplasmic daughter cells can result in variable penetrance and expression depending on the amount of mutant mtDNA present.

More than 100 different mutations in mtDNA have been identified to cause disease in humans and with new technologies, that number is growing.[10] Most of these involve the central nervous system or musculoskeletal system (Table 10.2).

Mitochondrial disease typically manifests as dysfunction in high energy-consuming organs such as the brain, muscle, heart, and kidneys. Poor growth, muscle weakness, loss of coordination, or developmental delay not explained by more common causes should alert a neonatologist or pediatrician to the possibility of a mitochondrial disease. When a mitochondrial disease is suspected, the child should be referred to a specialized medical center wherein comprehensive evaluation, including genetic studies, can be performed.

Epigenetics and Uniparental Disomy

Epigenetics refers to modification of genes that determines whether a gene is expressed or not (see Chapter 16). These modifications, an example of which is methylation, affect the expression of a gene, but not the primary DNA sequence itself. *Imprinting* refers to a phenomenon in which genetic material is differentially expressed depending on whether it was inherited from the father or the mother. A different phenotype can result depending on the parent of origin,

TABLE 10.2 Common Mitochondrial Diseases and Their Manifestations

Name	Abbreviation	Disease Characteristics
Myoclonic epilepsy associated with ragged red fibers	MERRF	Progressive myoclonic epilepsy, short stature, clusters of diseased mitochondria accumulated in subsarcolemmal region of muscle fiber (appear as "ragged red fibers" when stained)
Mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke	MELAS	Muscle weakness, headaches, loss of appetite, seizures, lactic acidosis, stroke
Neuropathy, ataxia, and retinitis pigmentosa	NARP	Numbness and tingling in limbs, muscle weakness, ataxia, deterioration of light-sensing cells of retina
Leber hereditary optic neuropathy	LHON	Acute onset of visual loss and optic atrophy usually in early young adulthood
Myoneurogastrointestinal disorder and encephalopathy	MNGIE	Ptosis, progressive external ophthalmoplegia, diffuse leukoencephalopathy, gastrointestinal motility dysfunction

because for certain genes, only the allele from one parent is transcriptionally active.

Uniparental disomy is the inheritance of a pair of homologous chromosomes from one parent rather than the normal scenario in which one chromosome is inherited from each parent. This situation is thought to arise most commonly by a process called *trisomy rescue,* during which a trisomic cell is converted into a disomic cell. It is a matter of chance as to which chromosome drops out. When trisomy rescue occurs, both chromosomes are from one parent a third of the time.

Classic examples of disorders related to genomic imprinting are Prader-Willi and Angelman syndromes. Both these syndromes involve the long arm of chromosome 15 (15q11-15q13). At birth, Prader-Willi syndrome is characterized by hypotonia, low birth weight, and almond-shaped eyes. During childhood, other features such as short stature, obesity, indiscriminate eating habits, small hands and feet, mental retardation, and hypogonadism develop. In most of these cases, there is paternally derived deletion, which means that all the genetic information in the region is maternal in origin. Angelman syndrome, characterized by mental retardation, short stature, abnormal facies, and seizures, is the opposite situation, in which the deletion is maternally derived, and the genetic information in the region is paternal only in origin. Approximately 30% of Prader-Willi cases and 5% of Angelman cases are the result of uniparental disomy. In this scenario, there is no cytogenetically detectable deletion. Because of imprinting, Prader-Willi syndrome results from uniparental disomy in which both chromosomes derive from the mother. The loss of the paternal contribution results in Prader-Willi syndrome. Paternal uniparental disomy in the same region results in Angelman syndrome because of the loss of maternal contribution of genes in the 15q11-q13 region.

Another aspect of epigenetics that has become an exciting avenue for research is the fetal origin of adult disease hypothesis. This is also known as the Barker Hypothesis, named after British epidemiologist David Barker, who proposed that intrauterine stress in the form of growth restriction and prematurity can predispose the individual to hypertension, cardiac disease, and diabetes. The initial evidence was provided by epidemiologic data that correlated low birth weight with poor health outcomes in adulthood.[7] Since then, several animal and human studies have shown that a harsh intrauterine environment can lead to a host of changes in DNA methylation and ultimately influence gene expression and metabolic dysregulation in adulthood.[27]

Trinucleotide Repeat Expansion

Most mutations, when they occur, remain unchanged as they get passed from one generation to the next. There is a subset of disorders, however, for which an expansion of an area of DNA containing repeating units results in disease. In this case, as the gene is passed on, the number of repeats (usually consisting of three nucleotides each) can increase to beyond polymorphic range and begin to affect gene function. Although the mechanism of how this expansion occurs is not completely elucidated, it is thought to be the result of a slipped mispairing mechanism in which an insertion occurs when a newly synthesized strand temporarily dissociates from the template strand. A dozen or so diseases, including congenital myotonic dystrophy, Huntington disease, Friedreich ataxia, and fragile X syndrome, are the result of unstable repeat expansions.

Fragile X syndrome, the most common hereditary form of mental retardation, has an incidence of approximately 1 in 4000 births. The normal number of triplet repeats in the Xq27.3 region (*FMR1* gene) is less than 45; a full mutation is considered to be greater than 200 repeats. Individuals with 45 to 54 repeats are referred to as intermediate carriers—these individuals are not at risk for any phenotypic abnormalities and are not at risk for expansion to a full mutation in their offspring. Individuals with 55 to 200 repeats are known as premutation carriers. Besides the risk of having an offspring with the full mutation, these premutation carriers are also at risk for adult-onset cerebellar dysfunction (known as fragile X-associated tremor/ataxia syndrome) and premature ovarian failure.[25]

Individuals who have any family or personal history of developmental delay, mental retardation, ovarian dysfunction, or tremor should be offered screening for fragile X syndrome. There has been increasing adoption of prenatal screening for fragile X in the general population, despite not being recommended by professional bodies.[13]

Multifactorial Inheritance

There are disorders that affect certain families more than others but do not follow Mendelian patterns of inheritance or fit into the non-Mendelian inheritance phenomenon. These disorders are thought to be the result of interplay between genetic and environmental factors and gene–gene interactions. Known as *multifactorial* or *complex* inheritance, these disorders have a greater incidence than disorders secondary to chromosomal or single-gene mutations. These disorders provide unique genetic counseling dilemmas regarding recurrence risks, because although genotypes predisposing to disease may aggregate in families, the phenotypic expression is discordant, owing to differences in nongenetic exposures.

An illustrative example of multifactorial inheritance is the occurrence of neural tube defects (NTDs). Spina bifida and anencephaly are NTDs that cluster in families and are a leading cause of fetal loss and handicap. Spina bifida is the result of incomplete fusion of vertebral arches and manifests in various degrees of severity. Anencephaly is a devastating condition in which the forebrain, overlying meninges, bone, and skin are absent. Most fetuses with anencephaly are stillborn. Although some NTDs can be explained by teratogens, amniotic bands, or chromosomal disorders, most are multifactorial. Decreased levels of maternal folic acid have been inversely correlated with the risk of NTDs. Folic acid levels are affected by two factors—dietary intake and enzymatic processing. Folic acid levels are detrimentally affected by

a mutation in the enzyme 5,10-methylenetetrahydrofolate reductase (MTHFR). Fifteen percent of the population is homozygous for the mutation. It has been shown that the mothers of infants with NTDs were twice as likely to have MTHFR mutations than controls. Preconceptual supplementation of folic acid has been shown to decrease the risk of NTDs.[42] All reproductive-age women should consume 0.4 mg of folic acid daily. Prenatal screening for NTDs is discussed later in this chapter.

Teratogens

Environmental exposures—medications, maternal conditions, or infections—are the etiology of malformations in 10% of cases. The impact of the agent relates to the timing and amount of exposure (duration and dosage). The susceptibility of a fetus depends on its stage of development when an exposure takes place (Fig. 10.8)[34] (see Chapter 14).

Exposure during the first 2 weeks after conception usually either is lethal to the embryo or has no adverse effect. This window is known as the "all-or-none" period. During organogenesis, teratogenic exposure may result in major morphologic abnormalities because of disruption of the forming organ systems.

Most commonly prescribed medications can be used with relative safety during pregnancy. For the medications that are suspected or known teratogens, genetic counseling should emphasize relative risk. That is, risk increases should be presented in relation to a woman's baseline risk of a birth defect, which is 2% to 3%. The possibility that certain medical conditions if left untreated pose greater threat to the fetus than the medications used to treat the condition should be addressed. The US Food and Drug Administration, in 2014, removed the letter categories for drugs in pregnancy, and labeling now includes information on whether a drug is absorbed systemically and relevant information to help providers manage and counsel patients.[20]

Use of these drugs in pregnancy ultimately requires expertise and access to up-to-date databases specializing in teratogenesis, available through a prenatal genetics service. Certain drugs may be a significant risk, but only during a particular trimester. Trimethoprim-sulfamethoxazole should be avoided in the third trimester to avoid kernicterus in the newborn but may be used in the first and second trimesters. Likewise, a certain drug may be a genuine teratogen, but the risk of stopping the drug would be of even greater consequence. Lithium use during the first trimester of pregnancy has been associated with cardiac malformations, including Ebstein anomaly. Although efforts should be made to avoid lithium during the first trimester, if an alternative therapy is inappropriate, the lowest possible lithium dose should be used. Finally, certain drugs are known teratogens, but the underlying disorder may contribute to birth defects independently. Women with epilepsy are at increased risk of fetal malformations such as orofacial clefts, independent of whether or not they are taking anticonvulsant therapy.

Diagnostic Imaging

Radiographic imaging modalities are widely used in inpatient and outpatient settings. Safety of ionizing radiation exposure in pregnancy is an important concern because of the association of ionizing radiation with prenatal death, malformation, and carcinogenesis. It is necessary to weigh the risk of exposure versus the risk to the mother and fetus of a delayed diagnosis. With proper test selection, shielding, and procedure modifications, fetal risk can be significantly reduced or eliminated.

Common radiologic studies such as chest or dental x-rays typically expose the fetus to much less than 5 rad of radiation (Table 10.3). At these levels, there has been no evidence of increased risk of mental retardation, fetal anomalies, or pregnancy loss. The risk of childhood leukemia with an exposure of 1 to 2 rad increases to 1 in 2000, a 1.5-fold increase above the baseline risk of 1 in 3000.[14]

Exposure greater than 10 rad has been associated with an increased risk of malformations. Diagnostic imaging rarely, if ever, exposes the fetus to this level of radiation, however. Iodinated contrast materials can cross the placenta and produce transient effects in the developing fetal thyroid. Although not contraindicated, iodinated contrast material should be used with great care.

Magnetic resonance imaging (MRI), which uses electromagnetic radio waves to generate images, has not been associated with any harmful effects to the developing fetus. Gadolinium, the contrast agent most commonly used in MRI, crosses the placenta. There has been limited evaluation of its safety, and it is not recommended for use in pregnancy.

Ultrasonography is an important tool in obstetrics. Although there has been some concern regarding elevation of tissue temperature with prolonged use, there is no reliable evidence of harm to the human fetus as a result of standard, medically indicated ultrasonography. When used appropriately, ultrasonography can provide important information regarding gestational age and fetal anatomy. The casual use of ultrasonography for fetal pictures or sex determination is not justified.[1]

Airline Flights

The amount of cosmic radiation received during commercial flights is much less than the levels associated with fetal risk and is considered negligible. Air travel should be avoided if the woman suffers from a condition that may require emergency care. Pregnant women should keep well hydrated and move their lower extremities when possible to avoid venous stasis and thromboembolic events.[2]

Congenital Anomalies and Ultrasonography

Ultrasonography has become an important tool in obstetrics and gynecology over the past two decades. Geneticists

TABLE 10.3 Estimated Average Fetal Exposure From Select Imaging Studies

Procedure	Fetal Dose (mrad) for an Average Study
Chest x-ray (PA and lateral)	<1
Abdominal plain film	200-300
Intravenous pyelogram	400-900
Barium enema	700-1600
Cervical spine x-ray	<1
Dorsal spine x-ray	<1
Lumbar spine x-ray	400-600
Lumbosacral area x-ray	200-600
Upper GI series	50-400
Dental x-rays	0.01
Mammography	Negligible
CT scan of chest	30
CT scan of abdomen	250
Perfusion lung scan with Tc 99m	6-12
Ventilation lung scan	1-19
Pulmonary angiography via femoral route	221-374
Pulmonary angiography via brachial route	<50

CT, Computed tomography; GI, gastrointestinal; PA, posteroanterior.

use ultrasonography as a way to characterize dysmorphology in utero.

Congenital abnormalities occur in 3% to 4% of live births and have several causes—single-gene defects, chromosomal abnormalities, teratogens, multifactorial, or unknown reasons. Congenital anomalies can be divided into three categories depending on the mechanism underlying the defect: malformations, deformations, and disruptions. Malformations involve intrinsic abnormalities in the genetic programs controlling development. The syndactyly that is associated with Apert syndrome is the result of a mutation in a gene encoding for fibroblast growth factor receptors. Conversely, deformations are caused by extrinsic factors physically impinging on otherwise normal tissue. An example of this is arthrogryposis, or contractures of the extremities. This condition can be caused by a prolonged leakage of amniotic fluid, resulting in fetal crowding. Disruptions, the final category, are the consequence of fetal tissue destruction. They can be the result of vascular insufficiency or mechanical damage. Amniotic band syndrome results in the partial amputation of a limb.

Assessment of an infant with birth defects requires a careful review of prenatal exposures and maternal illnesses. When evaluating birth defects, it is important also to consider whether a defect occurred in isolation or is part of a pattern, which may suggest a syndrome. Imaging studies or laboratory examinations may also help elucidate the underlying pathophysiology of an anomaly.

Ultrasound examinations fall into three categories: limited, standard, or specialized. A limited examination is one that is performed to address a specific question, such as placental location, or to confirm fetal cardiac activity. It cannot replace a standard ultrasound examination, which is ideally performed between 18 and 20 weeks' gestation. A specialized ultrasound examination, which may include fetal echocardiography, fetal Doppler studies, or additional biometry, is performed when an anomaly is suspected based on family history, laboratory aberrations, or discovery during standard ultrasound examination. An abnormality seen on ultrasound examination is a common reason that patients opt to undergo invasive prenatal diagnosis.

An example of the utility of ultrasonography is the case of fetal pyelectasis, or hydronephrosis. Defined as a renal pelvic diameter of greater than or equal to 4 mm, this finding is present in up to 3% of euploid fetuses and is a relatively common finding. Postnatal evaluation shows that although most cases resolve, conditions such as ureteropelvic junction obstruction and vesicoureteral reflux may be identified in some infants.[44] The fact that the potential issue can be identified prenatally and results in postnatal follow-up obviates the possibility of a child with chronic renal impairment owing to silent infection and inflammation.

In a review of 36 published studies including 900,000 fetuses, the overall sensitivity for detecting fetal anomalies was 40% (range 15% to 80%), indicating that these detection rates greatly depend on the incidence of anomalies in the population studied and sonographer experience. It has been observed that 50% of fetuses with Down syndrome have no findings on prenatal ultrasound examination. When an examination is performed, the patient should be counseled regarding the benefits and limitations of ultrasonography.

First-trimester ultrasonography has been traditionally used to confirm an intrauterine pregnancy, to estimate gestational age, and to evaluate pelvic anatomy. Since the introduction of first-trimester aneuploidy screening, there has been interest in screening for structural anomalies in the first trimester. There is now extensive literature on the use of first-trimester testing in the detection of fetal anomalies and, in expert hands, a very thorough examination is possible. Older studies had shown a 44% to 50% detection rate of major anomalies in the first trimester[17] with the latest reports indicating that 95% of the common aneuploidies could be detected with detailed sonography between 11 and 13 weeks.[39] First-trimester sonography is becoming more widely adopted among centers with appropriate expertise, although in the United States, detailed anatomy is still preferentially assessed in the second trimester.

TABLE 10.4 Elevation and Depression of Parameters Used in First-Trimester and Second-Trimester Screening Tests

	First-Trimester Screen			Second-Trimester Screen			
	Nuchal Translucency	PAPP-A	Free β-hCG	uE3	AFP	Free β-hCG	Inhibin
Trisomy 21	Increased	Decreased	Increased	Decreased	Decreased	Increased	Increased
Trisomy 18	Increased	Decreased	Decreased	Decreased	Decreased	Decreased	Unchanged
Trisomy 13	Increased	Decreased	Decreased	Decreased	Decreased	Decreased	Unchanged
Neural tube defect	NA	NA	NA	Unchanged	Increased	Unchanged	Unchanged

AFP, α-fetoprotein; β-hCG, human chorionic gonadotropin β subunit; NA, not applicable; PAPP-A, pregnancy-associated plasma protein A; uE_3, unconjugated estriol.

Three-dimensional ultrasonography has some unique advantages over two-dimensional ultrasonography. Its ability to acquire and manipulate an unlimited number of planes allows for the quantification of organ volume and the ascertainment of images inaccessible by two-dimensional technology. Despite these technical advantages, however, consistent utility has not been determined. Potential areas of clinical benefit include evaluation of NTDs and facial anomalies.

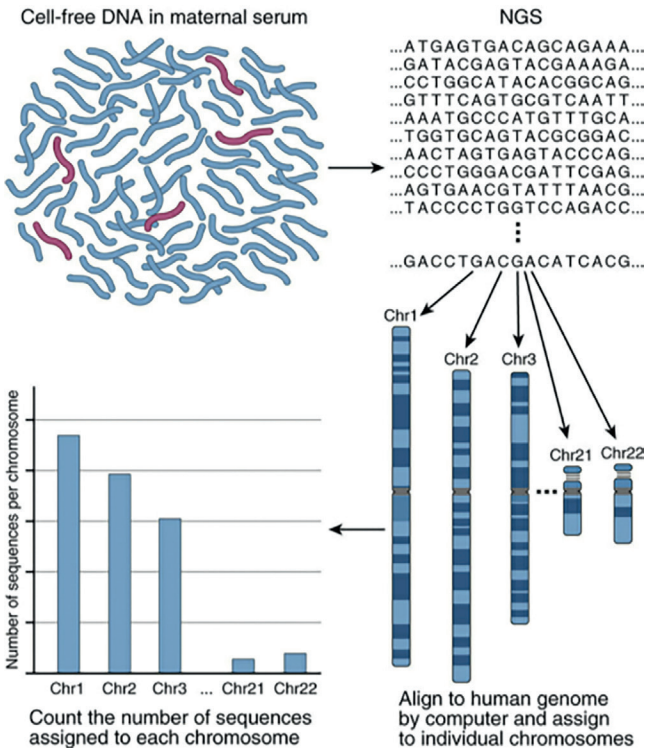
Screening Modalities

Screening for Aneuploidies

Current guidelines from ACMG and ACOG recommend that all pregnant women, regardless of age, have the option to undergo invasive diagnostic testing for fetal aneuploidy. After reviewing the benefits and limitations of screening and diagnostic modalities with their health care provider, patients have the option to undergo screening tests for fetal aneuploidy and NTDs (Table 10.4).

First-Trimester Screening

First-trimester screening, which involves an ultrasound examination and ascertainment of serum markers, is performed between 10 0/7 weeks and 13 6/7 weeks' gestation. The ultrasound examination involves measurement of the nuchal translucency, a fluid-filled space behind the fetal neck. An increased nuchal translucency is significantly associated with aneuploidy, including Down syndrome. The ACOG recommends that patients with a fetal nuchal translucency of 3.5 mm or greater be offered targeted ultrasonography with or without echocardiogram. Detection of Down syndrome with nuchal translucency alone is 70%. When combined with two serum markers, pregnancy-associated plasma protein A (PAPP-A) and human chorionic gonadotropin (hCG), the detection rate increased to 82%-87%. Results are reported as an adjusted risk for Down syndrome. It is recommended to offer maternal serum alpha-fetoprotein (AFP) as an isolated test in the second trimester to screen for NTDs (see later).



Second-Trimester Screening

The second-trimester maternal serum screen for aneuploidy, particularly trisomies 18 and 21, and NTDs is performed between 15 0/7 weeks and 22 6/7 weeks of pregnancy. Maternal serum AFP, hCG, and unconjugated estriol, known as the "triple screen," has an aneuploidy detection rate of 65%. With the addition of a fourth marker, inhibin-A, to create the "quad screen," the detection rate increases to approximately 80%. The detection of NTDs is discussed subsequently. Results are reported as age-adjusted risks and, similar to first-trimester screening, should be reported to patients to make decisions regarding their desire for invasive testing.

Cell Free DNA Screening

Fetal DNA of placental origin is present and detectable in maternal blood. Taking advantage of this biologic phenomenon, fetal DNA can be isolated and screened for aneuploidy using either sequencing or SNP detection methods (Fig. 10.9). A recent meta-analysis has shown that cell free DNA (cfDNA), also known as non-invasive prenatal screening (NIPS), performs best in detecting trisomy 21 (99% detection and a false positive rate <1%), while performing less well for trisomy 18 and 13. Multiple recent studies have demonstrated superior performance of NIPS compared to standard screening. In a major multi-centered, blinded, prospective study, a positive NIPS result was correct 80.9% of the time compared to only 3.5% using traditional first-trimester screening. Most labs offer NIPS for trisomy 21, 18, and 13, with the option of sex chromosome screening as well. The ACOG now recommends that "no one test is superior for all test characteristics and not every test is available at all centers. Each test has advantages and disadvantages that should be discussed with each patient, with the appropriate test offered based on her concerns, needs, and values." NIPS is not yet a universal first-line test due to issues related to cost and accessibility, but uptake continues to grow rapidly. It is important to note that the ACOG still recommends that all women, regardless of risk, have the option of invasive testing if they so choose.

• **Fig. 10.9** NIPS screening using next generation sequencing. Cell free fetal DNA is isolated and sequenced using next generation sequencing technology. Output consists of short sequences that are then counted and aligned to known sequences in the reference genome. Sequences are then counted and loss or gain of genetic material is determined by number of probes counted.

Initially, the excellent sensitivity and specificity of NIPS led to some confusion that this new technology is a diagnostic test when in fact it is simply an improved screening modality. In the prospective study mentioned above, despite excellent sensitivity and overall performance compared to standard testing, the positive predictive value (PPV—the chance that a positive test is truly positive) in a general population was only 80.9% and not 100%. In a large retrospective study of 712 women, while testing for trisomy 21 still performed well with a positive predictive value (PPV) of 85%, trisomy 13 was only diagnosed correctly in 45% of cases, trisomy 18 in 77%, monosomy X (Turner syndrome) in 26%, and 47,XXY (Klinefelter syndrome) in 86% of cases. These findings underscore the importance of properly interpreting screening results and following professional guidelines that universally call for confirmatory testing of all positive NIPS results prior to initiating any clinical management plan.

The other limitation is that the circulating DNA originates from placental trophoblast, which can have isolated placental mosaicism and does not always reflect the true fetal phenotype. For this reason, there has been some controversy regarding the best way to confirm a positive NIPS test. A chorionic villus sampling (CVS) procedure samples the same tissue that is the origin of the circulating DNA, while a karyotype from an amniocentesis is fetal-derived. An unfortunate example of not being attuned to the implications of placental mosaicism is reflected in a case report of a positive trisomy 13 on NIPS. The NIPS result was confirmed via rapid aneuploidy analysis using fluorescence in situ hybridization (FISH) probes and consequently, a termination of a fetus was performed. The final fetal karyotype was normal. A systematic study has shown that after a high-risk NIPS result for trisomies 21, 18, 13, and monosomy X (Turner syndrome), there is still a substantial likelihood of finding CVS mosaicism and need for amniocentesis. Chromosomes 13 and X in particular seem to have a higher rate of placental mosaicism and, therefore, especially for positive trisomy 13 and monosomy X results, amniocentesis is the preferable confirmatory approach. Other confounding factors that can lead to false positives are maternal occult malignancy or undiagnosed translocations as well as the vanishing twin phenomenon.[10,32] Trophoblast tissue can remain viable following a demise of one twin, which is more likely in the twin with an abnormal karyotype. Thus, DNA reflecting an abnormal karyotype (or sex in the case of Y chromosome) may be detected by NIPS, resulting in a false diagnosis. In summary, while NIPS performance characteristics are far superior to traditional screening approaches for common aneuploidies, this technology cannot yet replace prenatal diagnosis.

To summarize, although the benefits of a non-invasive method of sampling fetal DNA are easy to grasp, certain caveats must be pointed out. NIPS is a screening test, therefore, the patient must be counseled regarding the inherent limitations compared to diagnosis. There are multiple other chromosomal anomalies aside from basic aneuploidies that will not be detected with NIPS, even if the test had a perfect detection rate. For women who want to know not just about trisomy 21 but all clinically detectable chromosomal anomalies, invasive testing may be a better option.

Future Directions for Non-Invasive Screening and Diagnosis

Microdeletions

While NIPS covers the majority of clinically significant aneuploidies, this technology can also detect microdeletions and larger genomic deletions and duplications. Although an advance over previous standard screening methodologies that cannot detect these changes, screening performance for microdeletions is substantially inferior to that of the standard aneuploidies. In a retrospective review, detection rates were as low as 0% for Cri-du-chat syndrome and as high as 21% for 22q11.2 deletion syndrome.[36] It is possible that NIPS screening for microdeletions and structural rearrangements perform better in higher risk populations. However, currently there are no clinical validation or utility studies to support the use of NIPS for these chromosomal anomalies. Guidelines may differ on the use of NIPS for microdeletions, but ACOG and SMFM have come out clearly that until there are appropriate population-based studies, NIPS is not recommended as a screening test for fetal microdeletions.

The Role of First-Trimester Ultrasound

The fetal medicine community has been concerned that if NIPS continues to move forward as a first-line test, the benefits of the first trimester ultrasound used in standard screening may be lost. An approach that may be adopted in the future is a detailed anatomic fetal ultrasound in the first trimester for all pregnant women. Those who have an ultrasound finding would be referred to a fetal medicine center. The remaining women would have NIPS and, if positive, referred to a high-risk center as well. A recent study looked at this strategy and found that this new approach had a significant reduction in the false positive rate compared to standard screening for trisomy.[23] While this study may not be sufficient to advocate for a new screening mechanism, it does give a window into what the near future may look like for prenatal aneuploidy screening.

Non-Invasive Prenatal Diagnosis (NIPD)

Several technological advances have shown promise in moving the field from NIPS to NIPD. If fetal or placental cells could be derived in a non-invasive way, they could be tested using the same genetic analyses currently used for blood, CVS, or amniocentesis. A new technique has been proposed that allows for direct isolation of circulating fetal cells and subsequent amplification and analysis of the fetal DNA. This technique eliminates the risk of maternal contamination of the sample and allows for more granular analysis such as microdeletion detection.[24] Researchers have isolated fetal trophoblast from a cervical scraping akin to a Pap smear.[8] This technique would eliminate the procedural risks associated with CVS but suffers from the same limitation of not being able to distinguish an aneuploidy from a placental mosaicism. However, with multiple research centers and technologies that allow for precise cell sorting as well as single cell analyses, NIPD that assesses the fetal genome may soon be a reality.

Screening for Multifactorial Disorders

Serum Alpha-Fetoprotein

Maternal serum AFP is an important tool in screening for NTDs; AFP is a fetal-specific molecule that is synthesized by the fetal yolk sac, gastrointestinal tract, and liver. The maternal serum AFP concentration is usually significantly lower than in fetal plasma or amniotic fluid and generally offered to women between 15 and 20 weeks.

Although it is intended as a screening test for open NTDs, other abnormalities such as ventral wall defects may also cause an increase in maternal serum AFP. Results from the examination are reported as multiples of mean (MoM) based on gestational age. A value greater than 2.5 MoM is considered abnormal, although cut-offs may vary based on the laboratory. Clinicians may opt to repeat the test after one moderately elevated result, because one-third are below the threshold on repeat analysis. If this occurs, a return to below threshold has not been associated with an increase in false-negative results.[16]

If the value remains persistently elevated or if the clinician opts not to repeat the test, the next step is to perform a detailed ultrasound examination and discuss the option of amniocentesis with the patient. Amniotic fluid AFP and amniotic fluid acetylcholinesterase (AChE) are the two main analytes evaluated for detection of NTDs. An elevation of AFP and AChE values suggests an open fetal NTD with 96% accuracy, with a false-positive rate of 0.14%. Contamination of the amniotic fluid sample with blood accounts for half of false-positive results.[40] Fetal karyotype should also be performed using the amniotic fluid obtained. An elevated maternal serum AFP in the second trimester that cannot be explained by a fetal structural abnormality or underlying maternal condition is associated with poor fetal outcome, including increased risk of intrauterine fetal demise, placental abruption, and preeclampsia.[33] In some centers, with appropriate equipment and expertise, ultrasound is being used as the first-line screening test for NTDs.

Screening for Mendelian Disorders

Preconceptual and prenatal parental carrier screening is an effective way to prevent or prepare for neonatal diseases. Discussions of testing strategies for common Mendelian disorders follow.

Screening for Hemoglobinopathies

As part of routine obstetric care, all women in the United States have a complete blood count early in pregnancy. This simple test helps identify women at risk for hemoglobinopathies and thalassemias. According to ACOG guidelines, women with an MCV <80 and normal iron indices should have a follow-up hemoglobin electrophoresis (if normal, follow-up testing may still be needed to rule out alpha-thalassemia). A baseline hemoglobin electrophoresis should be performed in women from high-risk groups (African, Middle Eastern, Southeast Asian, West Indian, and Mediterranean ancestry). If a hemoglobin variant or thalassemia is discovered, the woman's partner should be evaluated. When the father is determined also to be a carrier or is unavailable for testing, the patient should be offered genetic risk assessment and prenatal testing.

Carrier Screening for Cystic Fibrosis

Cystic fibrosis, the most common autosomal recessive disease in live-born infants, is a multisystem disorder that is the result of mutations of a large gene on chromosome 7 that encodes the cystic fibrosis transmembrane conductance regulator (CFTR) protein. The condition is characterized by chronic pulmonary disease, pancreatic insufficiency, and liver disease. CFTR is a complex gene, with more than 2000 mutations identified (800 additional mutations were added

TABLE 10.5 Cystic Fibrosis Detection and Carrier Rates Before and After Testing

Racial or Ethnic Group	Detection Rate	Carrier Rate Before Testing	Carrier Risk After Negative Test Result
Ashkenazi Jewish	94%	1/24	1/380
Non-Hispanic white	88%	1/25	1/200
Hispanic white	72%	1/58	1/200
African American	64%	1/61	1/170
Asian American	49%	1/94	1/180

From ACOG Committee Opinion #691. Available at https://www.acog.org/-/media/Committee-Opinions/Committee-on-Genetics/co691.pdf?dmc=1&ts=20170309T1313372850. Accessed December 9, 2017.

to the database since this book's last publication) and the frequencies of certain deleterious mutations vary based on ethnicity. Likewise, the carrier rate differs based on ethnic origin; individuals of Asian descent have the lowest and Ashkenazi Jewish and non-Hispanic white individuals have the highest carrier rates (Table 10.5).[15] The ACOG recommends that carrier screening be offered to all couples regardless of ethnicity. It is important for providers to discuss with their patients that a negative screen decreases the risk of being a carrier, but does not eliminate it completely because screening does not test for all possible mutations. Expanded screening beyond the usual 23 mutations tested by the ACMG panel can be offered to improve sensitivity, especially in non-Caucasian populations. Finally, guidelines recommend that complete sequencing of the *CTFR* gene should not be routinely offered but can be performed in specific cases: family or personal history of CF, newborn with CF that had negative maternal screening, or males with congenital bilateral absence of the vas deferens.

Jewish Carrier Screening

The *founder effect* refers to the overrepresentation of specific alleles in an inbred population. This mechanism has been documented in the Jewish community, particularly individuals of Ashkenazi heritage (eastern European). Tay-Sachs disease is the most well-known of these disorders. Because of communal efforts and professional guidelines, the incidence of this disease has declined remarkably, however, to the point that most children born with this disorder are not of Jewish heritage. Carrier screening, prenatal diagnosis, and culturally sensitive marital planning in regard to this autosomal recessive disease all were applied in this effort dating back to the 1970s. Since that time, the underlying genetic mutations are now known for several more similar diseases known collectively as the *Jewish genetic disorders*. As a group, the carrier frequency is very significant—one in four Ashkenazi Jews carries a mutation for one of these autosomal recessive disorders.

Culturally sensitive preconceptual and prenatal carrier screening is an important tool in preventing or preparing for these devastating diseases. The current recommendation from ACOG is to offer carrier screening to individuals who identify their background as Ashkenazi Jewish for at least the following diseases: cystic fibrosis, Canavan disease, familial dysautonomia, and Tay-Sachs disease. Screening should be considered for mucolipidosis IV, Niemann-Pick disease type A, Fanconi anemia group C, Bloom syndrome, Gaucher disease type I, familial hyperinsulinism, glycogen storage disease type 1, Joubert syndrome, maple syrup urine disease, and Usher syndrome. In couples with one partner of Ashkenazi Jewish background, that partner should be screened first, and if he or she is found to have a positive result, the other partner (regardless of background) should be screened for that disorder. One Ashkenazi Jewish grandparent is sufficient to offer someone testing. As mentioned in the above discussion on CFTR, expanded panels well beyond guidance recommendations have arrived for Jewish ethnicity panels as well.

Carrier Screening for Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is a progressive neuromuscular disease resulting from degeneration of spinal α motor neurons. Childhood SMA is divided into three clinical groups, types I, II, and III SMA, depending on age of onset and clinical sequelae. With a live birth rate of 1 in 10,000, SMA is the second-most common fatal autosomal recessive disorder after cystic fibrosis. The SMA-determining gene, *SMA1,* is located on 5q13. The carrier rate of an abnormal allele varies widely between races. In 95% of cases, this abnormality is a deletion in exon 7 of *SMA1*. In a recent change, the ACOG has joined the ACMG and recommends that SMA carrier testing be offered to all couples regardless of race or ethnicity.[13] The sensitivity of the carrier screening test is approximately 95% in Caucasians and as low as 71% in African Americans, although with new molecular tests, false negative rates are improving.[28] A negative screening test for both partners reduces the possibility of an affected offspring significantly but does not eliminate it entirely, as 2% of cases result from de novo mutations.[43] Because of advances in genetic science, there have been some recent SMA treatment breakthroughs, including a medication, nusinersen, that is now FDA approved. In addition, researchers have just reported a successful gene therapy study. Of note, neither approach is curative, but research is ongoing and more advances are expected in the future.

Diagnostic Modalities

The ACOG recommends that all women, regardless of risk, have the option of invasive prenatal diagnosis. However, the

majority of tests are still performed in a high-risk setting. After genetic counseling, some couples may opt to undergo diagnostic testing as opposed to prenatal screening. Others choose diagnostic testing after an abnormal screening result or ultrasound finding.

Chorionic Villus Sampling (CVS)

CVS involves procuring a small sample of the placenta for genetic diagnosis. Although not fetal tissue, the placenta is embryologically derived from the same trophoblastic cells as the fetus and most often has the same karyotype as the fetus. Usually performed between 10 and 13 weeks' gestation, CVS is an ambulatory procedure. Using ultrasound guidance, the placental villi can be obtained through a transcervical or transabdominal approach depending on placental location. Chorionic villus sampling enables diagnosis of genetic disorders in the first trimester, giving patients more time to make decisions about the pregnancy, including the opportunity for first-trimester termination if they choose.

When the villi have been obtained, the medium is placed onto a plastic tissue culture dish to evaluate the sample. If the sample appears inadequate, the operator may opt to take a second pass to obtain more villi. Blood clots and maternal decidua can be separated from the villi, and these cleaned villi can be transferred to different media for further evaluation, including FISH studies and long-term culture. Alpha-fetoprotein testing cannot be performed on CVS tissue samples. It is impossible to assess risk of NTDs through CVS.

The most serious complications associated with CVS are damage to the fetus and pregnancy loss. It has been associated with an increased risk of transverse limb and oromandibular defects. It is hypothesized that these defects are caused by disruption of the vascular system. The overall risk for transverse limb defects after CVS is approximately 1 in 3000, with most defects occurring if CVS is performed before 9 weeks' gestation.[9] Women contemplating CVS can be reassured that if performed after 9 weeks' gestation, the risk of limb defects associated with CVS is low and approaches the baseline population risk.[4]

The pregnancy loss rate after CVS is complicated by the fact that the background risk of pregnancy loss in the first trimester is greater than in the second trimester. Operator experience, number of insertions, and gauge of catheter used all play a part in determining the procedure-related risk of CVS. More recent data suggest that the pregnancy loss rate attributable to both CVS and amniocentesis is quite low and is no more than 0.1%-0.3% in skilled hands.[5]

An important concept related to CVS is that of confined placental mosaicism, discussed earlier in the section on NIPS. Culture of mesenchymal cells of CVS samples reveals the existence of trisomies not present in the conceptus in approximately 1% of cases. In this scenario, an amniocentesis is warranted to confirm the fetal karyotype. Patients should be informed of the small risk of an inadequate sample or the need for additional testing secondary to placental mosaicism during their genetic counseling session, before opting for diagnostic testing.

Amniocentesis

Amniocentesis, a procedure to withdraw amniotic fluid from the uterine cavity, is most commonly performed either for prenatal genetic studies or for evaluation of fetal lung maturity (performed in the third trimester). It can also be used as a diagnostic tool for evaluation of intra-amniotic infection or as a therapeutic procedure to remove excess amniotic fluid. The rest of this section focuses on amniocentesis for the purposes of genetic diagnosis.

Although technically possible after 11 weeks' gestation, an amniocentesis is usually performed between 15 and 22 weeks' gestation. Before 14 weeks' gestation, the complication rate, particularly orthopedic malformations, is higher because of incomplete fusion of the amnion, chorion, and decidua parietalis. After 22 weeks, two potentially serious scenarios exist: (1) the procedure provokes labor or rupture of membranes resulting in a periviable delivery, or (2) abnormal results arrive after the fetus has entered into the 24th week of gestation, eliminating the option of termination in most states.

Similar to a transabdominal CVS, the patient is placed in supine position. An ultrasound survey is done to assess viability, fetal position, placental location, and a gross anatomic survey is performed before the procedure. Amniotic fluid, 20 to 30 mL, is aspirated into sterile syringes. The amniocytes and desquamated fetal cells floating in the amniotic fluid provide a source of mitotically active cells for cytogenetic evaluation and culture. Levels of AFP and AChE in the amniotic fluid can help identify fetuses at high risk for NTDs. Results of FISH (see Technical Advances in Molecular Cytogenetics) are usually available in 2 days, whereas results from cell culture take approximately 7 to 14 days.

The fetal heart rate is assessed and documented after the procedure. It is normal for a patient to experience uterine cramping during the procedure, but cramping should resolve soon after the procedure is over. Patients are encouraged to keep themselves well hydrated and to avoid strenuous physical activity, including intercourse, for 2 days.

Fetal loss is the most devastating potential complication. As mentioned above, data strongly suggest that procedure-related loss is low at 0.1%-0.3% for otherwise normal pregnancies. Increased maternal age, a history of bleeding associated with pregnancy, and abnormal serum screening results all increase the risk of fetal loss. Patients are cautioned regarding fetal injury, although this is an extraordinarily rare event with the advent of ultrasound guidance. Leakage of fluid can occur in approximately 1% of cases; however, in contrast to spontaneous rupture of membranes that occurs outside the setting of amniocentesis, 90% are self-limited and resolve spontaneously within 1 week. If a patient reports leakage, a conservative approach—one that

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

monitors amniotic fluid volume, fetal growth, and signs of infection—should be adopted because the prognosis is excellent. Overall, long-term follow-up on offspring of women who underwent amniocentesis did not show a significantly higher rate of major disabilities compared with matched controls.[6]

Cordocentesis

A third and much more infrequently used modality of diagnostic testing is cordocentesis, also known as *percutaneous umbilical blood sampling*. This procedure involves puncturing the umbilical vein under ultrasound guidance to obtain fetal blood cells for genetic analysis. Usually performed after 18 weeks, the procedure-related pregnancy loss rate is approximately 1 in 100 when the procedure is performed for genetic diagnosis.[30] Given the high loss rate compared with CVS or amniocentesis, use of this test for genetic diagnostic purposes is limited to further evaluation of chromosomal mosaicism discovered on a CVS or amniocentesis result. Instead, most cordocenteses are performed in the setting of fetal transfusions to evaluate and treat fetal anemia, especially in the case of Rh sensitization.

Technical Advances in Molecular Cytogenetics

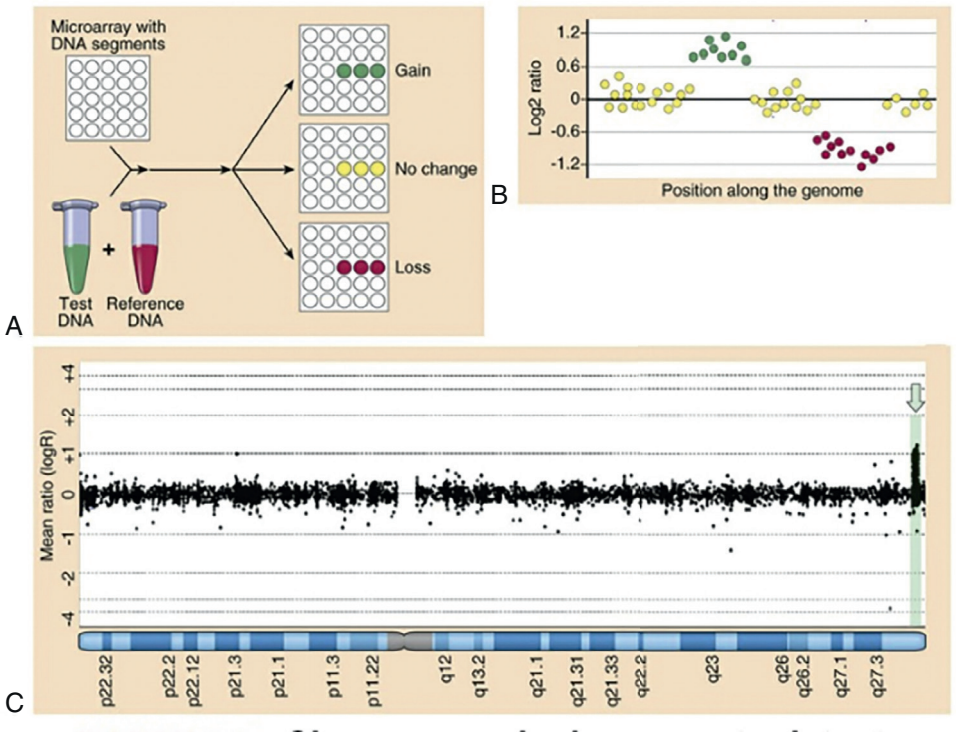
Molecular and cytogenetic diagnostics are an important part of genetic counseling. Increasing understanding of the human genome has led to the development of efficient, accurate testing modalities. Following is an overview of the most commonly used diagnostic tools.

Chromosomal analysis, or karyotyping, is best performed when the cell is in prometaphase or metaphase and the chromosomes are condensed. The most common staining technique, a Giemsa stain, results in a distinct pattern of alternating light and dark bands that is dependent on the composition of the underlying DNA sequence. Each chromosome has a unique banding pattern. Analysis of this banding pattern can show structural abnormalities. The disadvantage of this technique is that the sensitivity of banding is limited, which means that small structural abnormalities or mutations would go undiagnosed. The advantage of this technique is that the whole genome is visualized at one time.

As a diagnostic tool, FISH has better resolution than traditional chromosomal banding. After denaturation, a DNA probe labeled with a fluorochrome is directly hybridized onto cells that have been fixed onto a glass slide. The fluorescent signal is immediately visible by fluorescence microscopy. A double signal corresponds to one signal on each chromosome pair. Cells with one nuclear signal are monosomic for the chromosomal region being evaluated. Conversely, trisomic cells have three nuclear signals.

The advantage of FISH is that it can be applied to nondividing and dividing cells. It can identify several different types of mutations—deletions, duplications, and aneuploidy. Its major disadvantage is that structural abnormalities are missed, because the DNA probe detects only the presence of a genetic sequence, not its location. Although FISH is a rapid test, its use is currently limited to a few aneuploidy and deletion syndromes. However, FISH is an important tool for patient care in labor and delivery and the neonatal intensive care unit when quick decision making is required. Because of its limitations, however, a full karyotype is still performed before formulating a definitive report.

Polymerase chain reaction (PCR) is a process to amplify a single DNA molecule into thousands of copies in a matter of hours. The double-stranded DNA of interest is heated to separate into two single strands. Single-stranded primers, usually 20 to 30 nucleotides in length, are mixed in to allow them to anneal to the opposite DNA strands of the desired target. Next, a thermostable DNA polymerase and single nucleotides are introduced, and the complementary strand is synthesized using the primers as sites of initiation.



The advantage of PCR is that it is fast and extremely sensitive, meaning that PCR can amplify DNA from a single cell. Because of this sensitivity, however, contamination with even small amounts of other DNA can produce an erroneous result. To design appropriate primers, the nucleotide sequence information of the target region must be known.

Quantitative PCR is a newer application of standard PCR in which the accumulation of PCR products over time is measured directly with the use of fluorescent probes that hybridize to the target sequence. This probe begins to fluoresce when the DNA polymerase cleaves it. The fluorescent signal increases proportionally to the amount of PCR product, and this signal is quantified by comparing the cycle number at which the sample reaches a predetermined level of fluorescence with a standardized curve of a control. In some countries, this technique is preferred over FISH analysis.[25]

Microarray Technology

Since their development in the 90s as research tools for gene expression analysis, microarray technologies have quickly become important clinical tools. They allow for quick and thorough interrogation of chromosome structure and integrity. The technology consists of two array types: comparative genomic hybridization (CGH) arrays and single nucleotide polymorphism (SNP)–based arrays. The major benefit of microarrays is that they can provide important information on copy number variants (CNVs). These are the gains and losses of "pieces" of chromosomes that can have significant clinical implications. A routine karyotype can only detect losses or gains of up to 5 MB (megabases), while microarrays can detect much smaller changes (Fig. 10.10). 22q11.2 Deletion syndrome (also known as DiGeorge syndrome) is an important example of a common disorder that would be missed on karyotype without microarray, as the common deletion is only 3 MB in size. A detailed review of the

• **Fig. 10.10** NIPS screening using array comparative genomic hybridization (aCGH). **A,** Fetal DNA and a reference DNA are both labeled with different fluorescent dyes and co-hybridized to an array containing probes aligned along all chromosomes. **B**, An excess of fetal sequence represents a DNA gain such as a triploidy and a loss represents a monosomy. **C**, The sequences are then aligned according to their position along the chromosome and excess or loss of genetic material can be seen as points above or below the median.

various technologies is beyond the scope of this overview but can be found elsewhere.[37]

Clinically, the benefit of microarrays has been demonstrated by several studies. A landmark study of 4340 fetal microarray samples showed that they correctly identified all aneuploidies and unbalanced translocations identified by traditional karyotyping. The researchers identified additional clinically relevant deletions and duplications in 6% of samples from fetuses with ultrasound anomalies and 1.7% of fetuses referred for advanced maternal age.[41] Due to the technical limitations of the microarray platform, they could not identify balanced translocations.

Additionally, a meta-analysis of 17 studies demonstrated that in fetuses with an increased nuchal translucency, microarray analysis provided clinically valuable information in 5% of fetuses over conventional karyotyping.

The question remains regarding where microarray fits within the various modalities available for prenatal diagnosis. The SMFM published guidelines in 2016 that recommend that it be offered in cases of fetal malformations or stillbirth and should replace conventional karyotyping in these situations. The guidelines also allow for the consideration of microarrays even in the setting of normal fetal anatomy due to the 1.7% detection rate beyond karyotype in this population. The other recommendations involve best practices such as appropriate counseling regarding the limitations of the technology in regard to the non-detection of single gene disorders and the potential detection of fetal variants of uncertain significance or cases of non-paternity.

One constant issue that has plagued microarray studies is the large quantity of data that can be difficult to interpret. Variants that are not associated with a known disorder or do not cover a known coding region of the genome are often detected, and their interpretation can be challenging. With further research, some of these have been reclassified as benign or likely pathologic, but the problem will likely persist into the foreseeable future and continue to pose a dilemma for the clinician and the parents presented with these results.

Future Directions for Prenatal Diagnostic Testing

Next generation sequencing (NGS) is a technology that has revolutionized medicine. There is now the capability to sequence all 3 billion base pairs of the human genome. While whole genome sequencing (WGS) is used only sporadically by clinicians, its role in research laboratories is well established and critical to identifying new pathogenic variants or multiple variants that together may result in disease. Whole exome sequencing (WES), however, is a key technology used to identify causative pathogenic variants in children with undiagnosed syndromes or to screen adults at risk

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

for cancers. There are studies that are currently ongoing regarding the use of WES and WGS in the prenatal setting as well as a new approach to newborn screening.[18] The benefit of these technologies is the ability to detect genetic changes that would be missed otherwise. Conversely, the additional data can also result in the same problems clinicians are struggling with when it comes to microarrays—providing an abundance of data that may not be actionable or even interpretable. Currently, guidelines do not recommend the use of these technologies in the prenatal period if outside the parameters of a clinical trial.

Assisted Reproductive Technologies (ART)

More than 60,000 infants born in the United States each year are conceived through ART. The outcomes of techniques such as in vitro fertilization (IVF) and intracytoplasmic sperm injection have been well examined. The risks of ART can be divided into two categories—obstetric risks and fetal risks.

Thirty percent of ART pregnancies are twins or higher order multiples, which inherently carry an increased risk of premature delivery. Even when compared to spontaneous twinning, IVF twins carry a higher risk of preterm birth (RR of 1.23) and low birth weight (RR or 1.14).[31] Singleton IVF pregnancies are at an increased risk of preterm delivery and perinatal mortality when compared with spontaneously conceived singleton pregnancies. Singleton IVF pregnancies also have increased risk for other morbidities, including abnormal placentation, preeclampsia, and cesarean delivery.

There is an overall increase in birth defects associated with ART (1.32 RR).[22] The risk of de novo chromosomal abnormalities seems to triple, however, if intracytoplasmic sperm injection is performed. It has been observed that pregnancies that are the result of ART are at an increased risk for rare imprinting disorders, such as Beckwith-Wiedemann syndrome, suggesting that epigenetic changes may occur as a result of ART.[18,44]

Although there may be increased morbidity related to ART, there is some evidence that couples suffering from infertility that end up conceiving spontaneously also have an increased rate of birth defects, which points to potential underlying conditions leading to both issues.[45]

As a result, couples contemplating IVF must be informed of the small increased risk of birth defect and pregnancy complications associated with IVF and must receive appropriate screening and close evaluation during the pregnancy.[3]

Genetic Evaluation and Counseling

Genetic counseling is an ever-evolving field that has become an important part of clinical practice. Full of ethical and practical challenges, genetic counseling focuses on assessing a patient's genetic risk to provide individualized information and options. Some level of genetic counseling is provided by health care professionals in all fields of medicine. Obstetricians spend time with their pregnant patients discussing prenatal screening and diagnosis, whereas oncologists review hereditary cancer susceptibility. Patients can also be referred to genetic counselors, formally trained professionals who have received a Master's level degree and are certified by the American Board of Genetic Counseling. Genetic counselors are trained not only in pedigree construction and analysis, but also in communication education and counseling skills, and are a distinct discipline from medical geneticists who are certified by the American Board of Medical Genetics after completing a residency program. Although such physicians also provide counseling, their focus is more on diagnosis, treatment, and management of genetic disease.

In many centers, physicians and counselors work as a team to provide comprehensive genetic services. Indications for referral are varied but include (1) family history of early-onset cancer, (2) personal or family history of known or suspected hereditary disease, (3) ethnic background associated with an increased risk of a heritable disorder, (4) teratogen exposure during pregnancy, (5) abnormal prenatal ultrasound or abnormal first-trimester or second-trimester screening results, and (6) recurrent pregnancy loss. Any pregnancy at risk of birth defects warrants such a referral.

A genetic counseling visit entails obtaining a detailed medical and family history, including the age and health status of first-degree, second-degree, and third-degree relatives. For the prenatal patient, additional information such as genetic screening results, ultrasound findings, and possible teratogenic exposures is discussed. This information allows for a targeted discussion regarding the likelihood of developing disease, testing options for the condition, the impact that an illness could have on the patient and family, and the possible interventions available to modify the disease.

Ideally, genetic counseling is provided in a nondirective manner; emphasis is placed on educating the patient on his or her options and the consequences of those options. Before initiating any testing, a provider should ensure that proper consent is obtained. It is up to the provider to ensure that the patient understands the nature of the test, its limitations, and its potential sequelae. This becomes more complex when testing of children or adolescents is considered. In this situation, the benefits of timely genetic testing should be the primary justification. The American Society of Human Genetics (ASHG) suggests that "counseling and communication with the child and family about genetic testing should include advocacy on behalf of the interests of the child." Generally, if there is no immediate benefit to the child, testing is usually deferred until adulthood, when the individual can make his or her own choices.[11]

Another ethical dilemma of genetic testing that clinicians face is the balance between maintaining patient confidentiality and the duty to protect other family members who might be affected. An individual's genetic testing results have implications for an entire family. The ASHG encourages voluntary disclosure by the person tested (proband) whenever possible. If this does not happen, the ASHG recommends that the degree of disclosure to other family

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

members depends on the magnitude and immediacy of risk faced, stating that disclosure is acceptable if "harm is likely to occur, and is serious, immediate, and foreseeable."[12]

A concern that many patients have is the impact of their genetic testing results on future employment and ability to obtain health insurance. In 1995, the Equal Employment Opportunity Commission issued guidelines that individuals discriminated against based on their genetic testing had the right to sue. A year later, the Health Insurance Portability and Accountability Act was enacted to prevent insurance companies from denying coverage based on genetic testing. On a federal level, the Genetic Information Nondiscrimination Act (GINA) was passed in early 2008.[21] It prohibits US insurance companies and employers from discriminating on the basis of information derived from genetic tests. Insurers and employers are not allowed under law to request or demand a genetic test. The GINA prevents insurance companies from discriminating through reduced coverage, and it prohibits employers from making employment decisions based on an individual's genetic code. State laws that have an impact on the provision of genetic services also exist, and there may still be issues with respect to procurement of life insurance despite the aforementioned laws.

Key Points

- An understanding of the genetic basis of disease and the tools available for prenatal genetic evaluation is vital in the management of patients and their offspring in the peripartum and newborn period.
- Reproductive genetic counseling and diagnostic techniques are a vital means of defining a potential clinical dilemma, allowing for seamless coordination between obstetricians and neonatologists.
- Medical genetics is a rapidly evolving field, with new advances and discoveries reported frequently. However, the underlying genetic core principles and the clinician's respect for patient autonomy to make good choices based on complete information have remained unchanged.

Perinatal Ultrasound

NOAM LAZEBNIK, NANCY E. JUDGE, AND PE'ER DAR

Ultrasound has permanently changed imaging in perinatology, increasing expectations of success and improving outcomes in maternal and neonatal care. The method is safe, real time, relatively inexpensive, and readily available in hospitals and clinics worldwide.[19] Fetal imaging is the most common ultrasound study. Identifying anomalies related to fetal and placental development or dating errors is crucial. Sonographic genetic screening, cervical assessment, Doppler vascular measurements, and three-dimensional (3D) examinations have evolved from investigational techniques to accepted diagnostic tools. In the past two decades, magnetic resonance imaging (MRI) has joined sonography for the prenatal diagnosis of a broad spectrum of disorders.

Ultrasound Equipment

In an ultrasound exam, a transducer (probe) is placed directly on the skin, inside the vagina or other body cavity, or directly on the organ of interest intraoperatively. A thin layer of water-based gel acts as a coupling agent to potentiate sound wave transmission.

Obstetric studies may be performed by either the transabdominal or transvaginal approach, using transducers of the appropriate frequency, usually between 1.5 and 10 MHz. Choice of transducer is a trade-off between penetration with lower frequencies (essential in the obese patient) and resolution at the higher end (required for the smallest fetal structures).

Fetal Imaging Techniques

Real-time ultrasound, in which image brightness varies with the intensity of returning signals (B-mode), is the standard method of fetal imaging (Fig. 11.1). It is required for confirmation of cardiac activity and fetal movement in living gestations. Brief signal bursts are followed by relatively long receptive intervals (1 : 10 ratios or greater); lower signal frequencies encounter less interference but reflect from fewer informative interfaces. Image quality varies with distance to the target, structure size, movement relative to the signal, and tissue transmission characteristics. Ideally, the transducer is close to its target; the transvaginal approach is preferable in early gestation for cervical studies and for gynecologic investigations. Suboptimal images are common with obesity, limited fluid interfaces, intervening structures, gas-filled viscera, scar tissue, and poor positioning relative to the sound beam. Diagnostic difficulty arises when different materials have similar echo characteristics, as do blood, urine, ascites, and the contents of many cysts.

M-mode ultrasound is a direct representation of beam reflection by moving edges (e.g., in cardiovascular imaging). Interpretation requires standardized, often hard-to-achieve, stable views. M-mode is useful in assessing arrhythmias, myocardial contractility, and pericardial effusions. M-mode "snapshots" efficiently document cardiac activity and rate (Fig. 11.2).

Doppler ultrasound uses the frequency shift that occurs when sound beams are reflected off moving objects to demonstrate the presence, velocity, and direction of blood flow (Fig. 11.3). Direct calculations from narrow, tortuous fetal and uterine vessels lack accuracy; to compensate, prenatal Doppler findings ideally are obtained at beam angles less than 35 degrees relative to umbilical vessels and 15 degrees for middle cerebral arteries. The flow indices are generally expressed as ratios, relative to median values. Color Doppler semiquantitatively assigns direction to blood flow; by convention, warm colors (red) denote movement toward the transducer, and saturation is keyed to velocity. Color Doppler illuminates cardiac, arterial, and venous structures (Figs. 11.4 and 11.5). Color Doppler energy (power Doppler) reflects signal intensity; amplitude corresponds to blood cell motion. Power Doppler is sensitive to very low flow and effective independent of angulation; it is helpful for mapping vascular beds and for quick visualization of any fetal vessel (Figs. 11.6 and 11.7).

Three-dimensional ultrasound analyzes returning echoes along a third axis. Images are manipulated electronically to render surfaces and volumes from multiple perspectives, both as static and real-time ("four-dimensional") views. Surface rendering of subtle organ details enhance detection of anomalies, partially overcoming positional limits of standard scans and permitting a comprehensive review of fetal organs and skeleton (Fig. 11.8). Three-dimensional studies have improved volume calculations, facilitated analysis of complex spatial relationships, and have better explained

Abstract

The field of perinatal imaging and diagnosis has been exponentially growing for the last 30 years using both ultrasound and magnetic resonance imaging (MRI). It has revolutionized diagnosis of fetal anomalies in different organ systems, enables fetal well-being assessment, accurately determines gestational age, and uncovers potential uterine, placental, and ovarian disorders that might negatively affect maternal and fetal outcome. Apart from imaging, other techniques, for example, DNA analysis from chorionic villus samples, amniocentesis, and free fetal DNA circulating in the maternal blood can be used to diagnose specified fetal anomalies. The aim of this chapter is to share with pediatrician and neonatologist the current modalities of prenatal imaging as well as its limitations. The chapter includes descriptions of abnormalities paired with their sonographic images. The template includes a brief description of the anomaly, the relevant findings, and information regarding management and prognosis.

• **Fig. 11.8** Two-dimensional profile (compare with normal profile in Fig. 11.1) and three-dimensional coronal rendering of a 26-week fetus with a large, right-sided cleft lip and palate. The fetus is in a frank breech position with the foot (*arrow*) visible on the head.

abnormal findings.[5] Spatiotemporal correlation (by a database managing both space and time inputs) of heart movement with color and power Doppler augments standard cardiac imaging (Fig. 11.9).

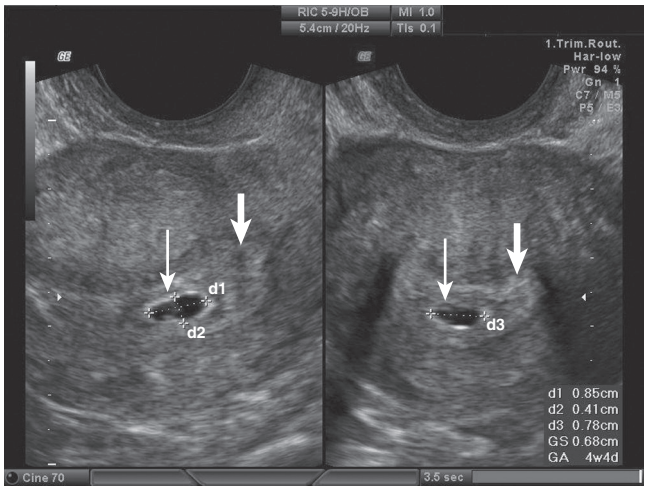
In spite of challenges, the most clinically mature applications for volume ultrasound technology are within the realm of obstetrics. The ability to reorient the active view for optimal visualization permits rapid identification of normal and abnormal structures. Advantages to volume imaging also include presentation of recognizable fetal anatomy and anomalies to parents, aiding informed decision-making, and aid in maternal-infant bonding.

Magnetic resonance studies of pregnancies are usually performed after the first trimester, in spite of lack of identified biologic adverse effects.[48] Maternal oblique positioning prevents undesirable inferior vena cava compression, and images are obtained with ultrafast sequences in less than 1 second; claustrophobia can be difficult for some patients, even after sedation or anxiolytic use. The wide field of

• **Fig. 11.9** Spatiotemporal color flow imaging of normal four-chamber heart at 18 weeks. Transverse chest with four-chamber view. Upper left: Cardiac apex facing right. Upper right: Axial view. Lower left: Coronal view. Lower right: Cardiac apex facing left (three-dimensional).

view, extremely high resolution, excellent soft tissue contrast, and multiple potential planes of construction make MRI an appealing imaging modality, particularly useful when ultrasound studies are compromised by obesity or oligohydramnios.[29]

MRI is often used to elucidate problems initially identified by ultrasound examinations. Images are acquired in the axial, coronal, and sagittal planes relative to the fetus or orthogonal to the maternal pelvis. Gadolinium is placentally transferred and is contraindicated during pregnancy because of its exceptional persistence in tissue and known potential for adult renal injury. Its use rarely may be justified for assessment of placenta accreta or serious maternal disease.[48]



Bioeffects and Safety

As part of the Food and Drug Administration's (FDA's) initiative to reduce unnecessary radiation exposure from medical imaging, health care providers are advised to consider techniques with little or no ionizing radiation, for example, ultrasound or MRI, and only if medically appropriate.

Diagnostic ultrasound energy has the potential for affecting tissues (bioeffects); two recognized mechanisms are heating and cavitation.[38] Data collected during routine studies show that "gray-scale" B-mode ultrasound is associated with a negligible rise in temperature.[40] To date, there has been no convincing evidence of harm to the human fetus.

By definition, ultrasound is inaudible to humans; moreover, oncogenic effects have not been identified. At nonclinical levels, ultrasound energy causes cell lysis, intracellular shearing, streaming effects, altered membrane permeability, and abnormal chromosome function. Heat exposure triples with each change in modality: from 2- or 3D, B-mode to M-mode, then color flow, before peaking during pulsed Doppler. Harmful levels should not be attained routinely but might occur during focal cranial pulsed Doppler

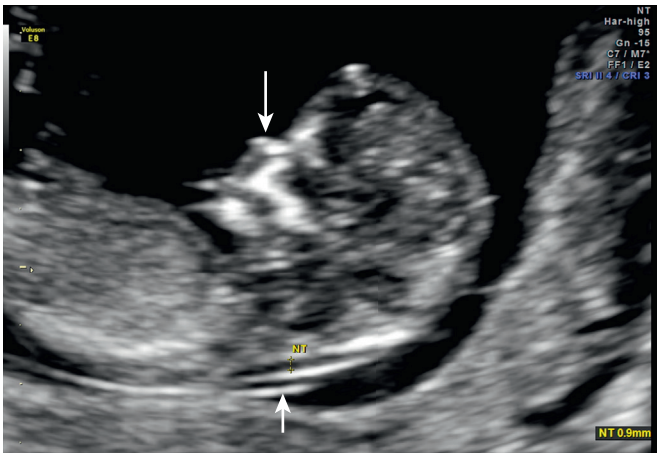
• **Fig. 11.10** Transvaginal longitudinal and transverse axis ultrasound images of a 4 4/7-week intrauterine pregnancy, showing a small yolk sac (*thin arrows*) within the gestational sac (*calipers*) and echogenic surrounding decidual reaction (*thick arrows*). The embryo is not yet visible. Note MI and TI notations at top center.

interrogation or in a febrile patient, without unusually long exposures. Mechanical disruption from cavitating gas bubbles is improbable in the fetus. Both temperature and disruption risks are now displayed on equipment (Fig. 11.10); thermal index (TI), a ratio between transducer output and the energy needed to warm up tissue temperature by 1°C, with a desired value below 2, is also categorized by tissue type: TI soft tissues, TI cranial structures, and TI bone. Mechanical index (MI) references pulse amplitude effects of compression and decompression, ideally maintained below 0.4 in fetal studies. Publication standards now usually require that these indices be displayed on submitted images. For safety, only medically essential examinations should be performed; settings and duration should be the minimum required to achieve adequate views.

Strong magnetic fields and radiofrequency waves are used in MRI with no known harmful effects, but large longitudinal studies are lacking. As with ultrasound, heat delivery to the fetus is a recognized hazard; in MRI, however, the maternal surface receives the greater thermal exposure. Noise from the magnetic coils (up to 120 dB) is, in theory, capable of causing acute hearing damage; fortunately, maternal tissue attenuation decreases fetal intensities by 25% to relatively safe levels. Direct magnetic bioeffects remain unproven; the FDA states that safety to the fetus "has not been established."

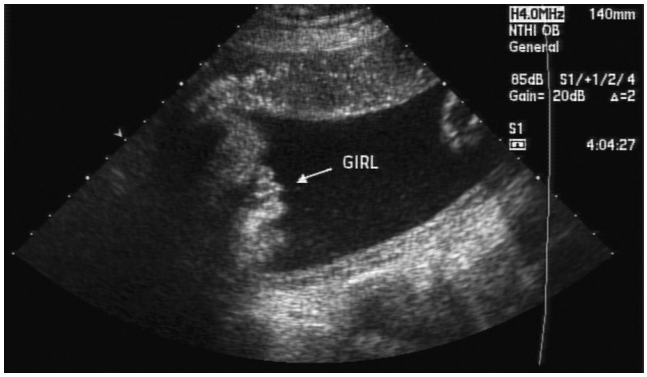
The FDA has recommended that health care providers attempt to minimize exposure while maintaining diagnostic quality when using ultrasound. The lowest possible ultrasound exposure settings that obtain adequate image quality and gain the necessary diagnostic information should be used, following the as-low-as-reasonably-achievable (ALARA) principle.[20] Spectral or "flow" Doppler should not routinely be used to "auscultate" the fetal heart rate in the first trimester because of its higher energy delivery; instead, adequate documentation of viability can be obtained with use of M-mode or conventional two-dimensional real-time ultrasonography with video or cine archiving.

Who Should Perform Fetal Ultrasound Examination?



Evaluating the unborn fetus is an enormous responsibility. A true hazard of performing obstetrical ultrasound studies lies in the potential for error in image interpretation. Either under- or over-diagnosis may trigger a chain of events with tragic consequences. Some radiologists who perform ultrasound studies may have had relatively limited exposure during training to obstetrical imaging; in contrast, obstetrical services may offer extensive bedside experience but fewer didactic hours, particularly for complex cases. As a result, many practitioners prefer to delegate the task of scanning to sonographers, themselves of variable competencies, choosing instead to emphasize image interpretation and case management.

All practitioners who perform or supervise the performance of obstetric ultrasonography should be licensed medical practitioners, with specific training in obstetric ultrasonography; this is especially necessary when providing specialized obstetric ultrasound examinations.[49] Certification programs, continuing education and credentialing for both sonologists and the interpreting sonologists, are important steps toward improving safety and diagnostic accuracy. To ensure the highest quality and accuracy in interpretation of obstetric imaging, the American Institute of Ultrasound in Medicine and the American College of Radiology offer ultrasound facility accreditation. The process involves a review of submitted case studies, practice volume, equipment use and maintenance, report generation, image storage, and qualifications of all providers. Practices, not individuals, are accredited for obstetrics, gynecology, or both; practices maintaining ultrasound accreditation have been shown to demonstrate improved compliance with published standards and guidelines for the performance of ultrasound examinations.



Ethical Considerations

The education of physician sonologists encompasses visual recognition and interpretative tasks common to diagnostic imaging but also demands mastery of specific mechanical skills (or, at least, an ability to assess the latter in sonographers). Both ultrasound and MRI have rapidly evolved; clinically relevant frontiers are often explored by collaborators with pooled data, prerelease technology, and funding for staff and statistical analysis. Nuchal translucency measurement, a deceptively simple sonographic method for aneuploidy screening, provides a cautionary example (Fig. 11.11).[41] Its orderly dissemination, including certification courses, ongoing audits, professional society, and laboratory coordination, stands in sharp contrast to the viral dissemination of most techniques, yet erosion of competency, once achieved, remains a concern.

• **Fig. 11.11** Nuchal lucency measurement (*calipers*) in a 13-week fetus. The nasal bone is visible (*down arrow*), and the amnion (*up arrow*) is clearly distinguished from the skin fold.

• **Fig. 11.12** Vulvar skin folds (*arrow*) of normal female fetus in the midtrimester.

Ethical practitioners should be candid when informing patients of their ability to provide a requested service and assiduous in improving their skills. Professional judgment remains paramount in deciding how and when to incorporate new developments into personal clinical practice. The ability to conduct a knowledgeable, balanced discussion regarding interventions both local and international is essential when counseling patients overwhelmed by online information.

Prenatal identification of fetal sex for the purpose of selective termination is available for serious X-linked disorders but has been more widely applied to abort normal female fetuses because of a lower perceived value (Fig. 11.12).[53] The addition of preimplantation genetic evaluations and non-invasive prenatal screening has redistributed the onus without fully resolving the problem.

Nonmedical fetal ultrasound (also known as "keepsake" ultrasound) uses ultrasound to provide nondiagnostic pictures or to determine the sex of a fetus (for a "reveal" party) without a practitioner referral, directly paid for by the patient. Notwithstanding governmental and professional guidelines and warnings regarding ultrasound safety, the popularity with prospective parents, evident profitability, and absence of proven harm have provided keepsake businesses with the impetus for rapid expansion. A number of ethical issues are raised, including conflicts of interest for the commercial enterprise, the fetus, and the parents with respect to long-term effects. Current epidemiologic evidence is not synchronous with advancing ultrasound technology; a lack of evidence of harm is not the same as lack of harm. Applying four major theories of ethics and principles (the precautionary principle, theories of consequentialism and impartiality, duty-based theory, and rights-based theories) leads to the conclusion that obstetric ultrasound practice is ethical only if the indication for use is based on medical evidence, rendering "keepsake studies" ethically unjustifiable.

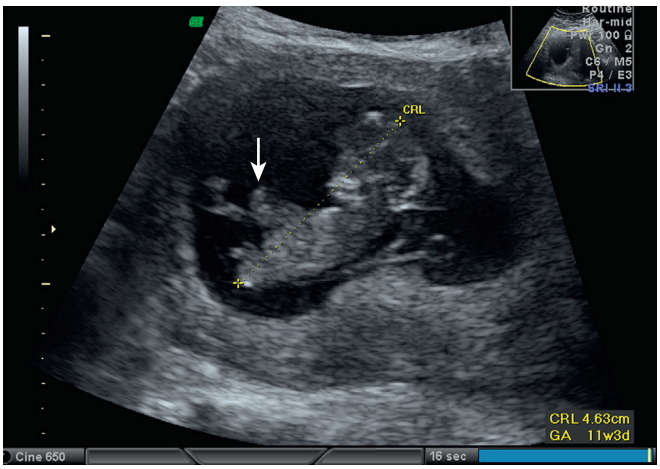
Multiple gestations may result in a number of ethical dilemmas. Advances and regulation in assisted reproductive technology (ART) have decreased the incidence of multifetal pregnancies, but fetal reduction remains a painful choice for parents facing the prospect of extreme prematurity in higher order multiples. Management of twin–twin transfusion syndrome (TTTS), anomalous co-twins, discordant growth, or distress far from term also necessitates choosing among unsatisfactory alternatives. An excellent review of the psychosocial consequences and the ethical issues associated with selective termination of pregnancy has been published.[25]

Non-diagnostic studies, varying prognoses for a given diagnosis, and the inherent limitations of ultrasound and MRI studies lead to ethical issues in management and counseling. Patients and physicians alike may share unrealistic expectations for the predictive accuracy of targeted diagnoses.

Anomalies and variants linked to Down syndrome and other serious conditions (sonographic "markers") identified during routine studies present patients and caregivers with unanticipated, unwelcome options, particularly if patients had previously explicitly refused serum screening or direct genetic testing.[19] Ideally, informed consent discussions addressing risks, benefits, consequences, alternative strategies, and limitations of ultrasound and MRI should be provided to all patients before performing such imaging. Given the irreversible nature of both birth and abortion, prospective parents must ultimately judge for themselves their tolerance for uncertainty in diagnosis and for imperfection in their offspring.

Classification of Fetal Sonographic Examinations

A. First-Trimester Examination



First trimester transvaginal scans exclude ectopic implantation by demonstrating an intrauterine asymmetric or "double sac" gestational sac with yolk sac or embryo, ideally with visible cardiac activity; identifiable embryos in the fallopian tubes are uncommon. Heterotopic pregnancy occurs in less than 0.1% of spontaneous conceptions, leading to the pragmatic conclusion that finding an intrauterine pregnancy excludes an ectopic one, except after assisted reproductive technic (ART). Nevertheless, careful study of the

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

adnexa, ovaries, and cervix is generally prudent. A "double sac" is usually seen transvaginally at levels of 1000-1500 international units of human chorionic gonadotropin before 5 1/2 menstrual weeks (see Fig. 11.10); but serum human chorionic gonadotropin (hCG) and visualization thresholds are variable. Finding a yolk sac or embryo confirms an intrauterine site, with growth of the gestational sac diameter of about 1 mm daily in early pregnancy. The embryonic disc is usually visible transvaginally once sac diameters exceed 15 mm. Embryonic length also increases daily by 1 mm; transvaginally identified cardiac activity is customary by the end of the sixth week (4 mm embryonic length) and obligatory by the seventh. Current practice postpones diagnosing a failed pregnancy until well past the accepted normal thresholds for appearance and progressive development of these structures.

Embryonic heart rates, slower at initiation, increase to more than 160 beats per minute (bpm) by the 9th week, declining slightly through the 13th week. Persistent rates below 100 bpm have been linked to risk for missed abortion, aneuploidy, and anomalies.[15] When an embryonic heart rate (below 80 bpm) is detected between 6 and 7 weeks, a first-trimester demise is anticipated in approximately 25%, even if the rate subsequently normalizes. In such pregnancies, a follow-up scan is warranted. Prior to 6 weeks, an embryonic heart rate below 100 bpm is not necessarily indicative of a poor prognosis. Likelihood of survival into the second trimester is also significantly higher when there is concordance between biometrically calculated gestational age and menstrual dating.[3]

Embryonic anatomic surveys are limited and necessarily provisional; however, early fetal period scans diagnose a number of entities accurately (Fig. 11.13). First-trimester screening for early detection of abnormalities decreases the need for invasive testing (previously offered to every woman over 35 years old, thereby missing abnormal pregnancies in younger women), the associated risk of miscarriages, and enabled first-trimester invasive testing and diagnosis in high-risk pregnancies using chorionic villi sampling rather than a second-trimester amniocentesis. It also allowed the safer and more private option of first-trimester termination of an abnormal pregnancy before the pregnancy was visible, decreased anxiety, and provided reassurance about pregnancy well-being in both high-risk and low-risk situations. Progress in the field of first-trimester sonography continues in two intertwined directions: One is finding additional sonographic markers that increased the accuracy and sensitivity of detecting chromosomal abnormalities, especially Down syndrome. The other is improving the early detection of congenital anomalies. Midtrimester confirmation continues to be prudent for the majority of first-trimester findings (see Fig. 11.13). Later studies retain advantages with respect to the natural history of many anomalies and for visualization of heart, spine, and other problematic structures.

• **Fig. 11.13** Eleven-week embryo with a thickened nuchal lucency and an omphalocele (*arrow*) containing fetal liver. The fetal liver does not undergo physiologic herniation. A study at 18 weeks identified a lumbosacral spina bifida in addition to confirming the omphalocele.

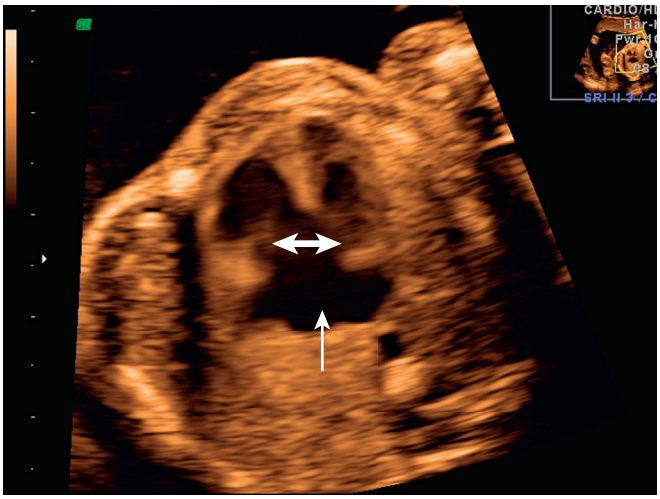
B. Standard Second- or Third-Trimester Examination

A standard second- or third-trimester sonogram includes an evaluation of fetal number, presentation, cardiac activity, fetal biometry, amniotic fluid and placental characteristics, and fetal organ survey. Second trimester transvaginal cervical measurement is encouraged for patients at risk for prematurity; however, the role of universal screening remains controversial. Examination of the maternal pelvic structures is otherwise performed transabdominally at this time, if feasible.

C. Limited Examination

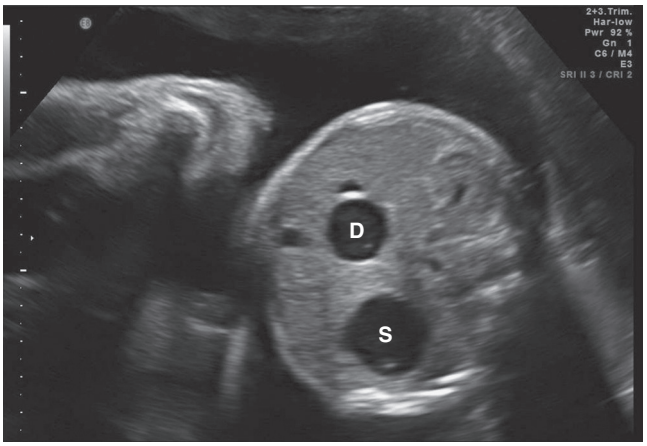
A limited examination is performed to investigate a specific concern, usually under exigent circumstances. For example, a limited examination might identify fetal cardiac activity in the presence of bleeding or confirm presentation in early labor. Abbreviated sonographic studies are more acceptable when there has been a prior complete study; pragmatically, a full examination should be documented once the acute situation has stabilized for ongoing pregnancies.

D. Specialized Examinations



A detailed "targeted" anatomic examination is performed when an anomaly is suspected on the basis of history, biochemical or genetic results, or findings on prior scans. Other specialized examinations include fetal Doppler ultrasound, 3D imaging, biophysical profile, fetal echocardiogram, detailed neurosonography, and additional biometry or evaluation of organs not usually imaged on routine studies.

Applications of Ultrasound Studies



Genetic Screening

Genetic screening combines ultrasound study and biochemical testing to enhance the detection of chromosomal abnormalities. This approach has resulted in greater scrutiny of younger patients and less frequent age-based invasive

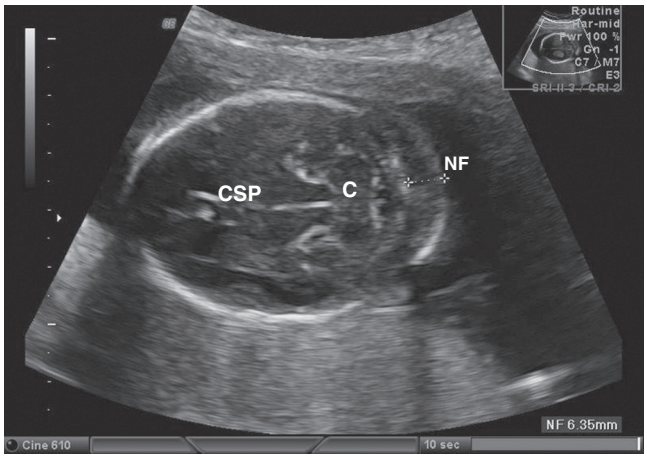
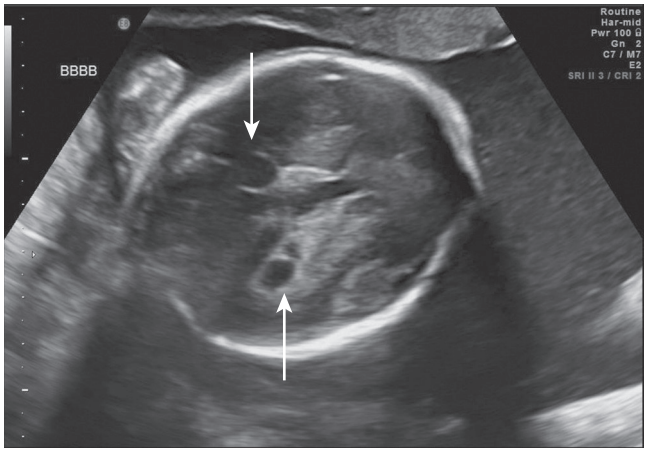
• **Fig. 11.14** Fetus with trisomy 21 and large atrioventricular canal defect on transverse thoracic view. Note the absence of a normal crux. Common atrium (*thin arrow*) connecting into a common ventricle (*thick, double-headed arrow*) can be seen.

• **Fig. 11.15** "Double bubble" sign of duodenal atresia in a 35-week pregnancy, with the dilated stomach (S) and the obstructed proximal duodenum (D) seen on transverse abdominal view, spine to right of image. The finding is uncommon before the late second trimester.



• **Fig. 11.16** Ventriculoseptal defect (*arrow*) demonstrated by color flow Doppler in 28-week fetus. LA, Left aorta; LV, left ventricle; RA, right aorta; RV, right ventricle.



testing.[2] Presently, noninvasive screening for fetal aneuploidy (trisomies 13, 18, 21) is encouraged for all low-risk patients. Common noninvasive screening options include: (1) first-trimester screening (nuchal translucency measurement and maternal serum biochemical marker algorithm), (2) first- and second-trimester cell-free fetal DNA fragment analysis from maternal blood, (3) second-trimester serum screening (maternal age and serum biochemical marker algorithm), or (4) two-step integrated screening, which includes first- and second-trimester serum screening with or without nuchal translucency (integrated prenatal screen, serum integrated prenatal screening only, contingent and sequential screening variations). Different algorithms noticeably affect sensitivity, specificity, and predictive values; cost or convenience may factor in choosing a strategy.[12] Analysis of cell-free fetal DNA, found at concentrations almost 25 times higher than those from intact nucleated fetal blood cells extracted from similar volumes of maternal blood. Cell-free fetal DNA (cfDNA) noninvasive prenatal screening is now in wide use for specific targeted chromosomal abnormalities, especially trisomy (an extra copy of a chromosome) or monosomy (a missing chromosome), and numerous commercial products are currently marketed for this indication.[42] Patient acceptance has been high, perhaps in part because of early identification of fetal sex. Insufficient fetal fractions and indeterminate results appear more frequently in obese patients but may also occur with chromosomal abnormalities. Direct prenatal diagnosis by chorionic villus biopsy or amniocentesis should be routinely recommended for at-risk individuals on the basis of age, family history, abnormal screening, or ultrasound findings.

One-third of fetuses with Down syndrome will have anomalies, characteristically endocardial cushion defects (Fig. 11.14), duodenal atresia (Fig. 11.15), and more subtly, small atrioseptal and ventriculoseptal cardiac defects (Fig. 11.16). Two-thirds may have second-trimester sonographic markers: for example, increased nuchal lucency, hypoplastic or absent nasal bones, and abnormal cardiovascular Doppler patterns in the first trimester, thickened nuchal fold (Fig. 11.17) and nasal hypoplasia, ventriculomegaly, choroid cysts (Fig. 11.18), hypoplasia of the fifth digit, decreased long bone ratios, enhanced echogenicity of papillary muscles and bowel, and renal pyelectasis (Fig. 11.19). The predictive value of screening components is affected by ethnicity, habitus, maternal diet, and fetal sex, as well as by device and operator-dependent detection rates. The permutations may confound counselors attempting to elucidate (and patients trying to grasp) the difference between screening and diagnosis, and basic descriptions of risks

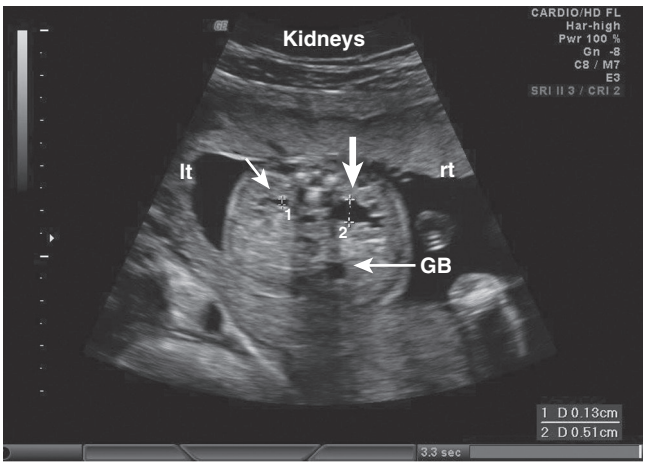
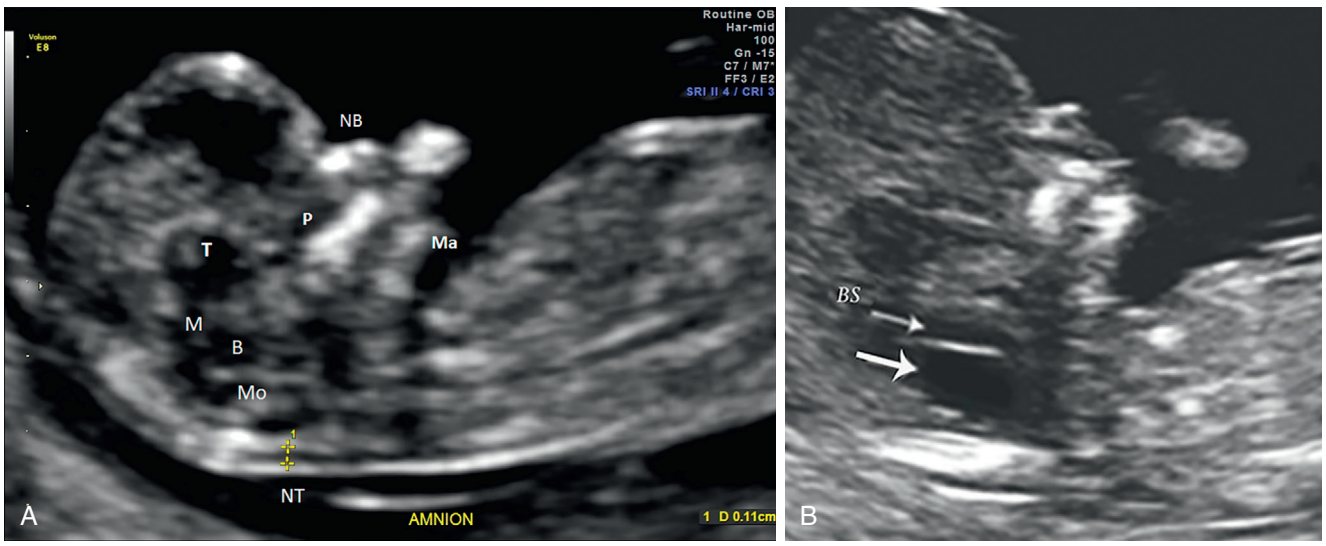
• **Fig. 11.17** Thickened nuchal fold (NF) (*calipers*) at a level demarcated by the cavum septum pellucidum (CSP) and the cerebellum (C), here noted at 18 weeks, is considered a marker for trisomy 21 (Down syndrome) and cardiac and other anomalies. The finding is infrequent, even in affected infants, limiting its utility.



• **Fig. 11.18** Choroid plexus cysts. Coronal view of the brain shows bilateral choroid plexus cysts (*arrows*).



and benefits. Recently described first-trimester evaluation of the posterior brain (intracranial translucency) provides an additional screening tool for open neural tube defects and other intracranial abnormalities (Fig. 11.20*A* and *B*).[21] Second-trimester sonographic follow-up and genetic evaluation may add critical information to the assessment of these abnormal findings. First-trimester identification of tricuspid regurgitation and increased ductus venosus resistance seems a promising, albeit technically challenging, addition to early screening protocols.[26]

Assisted Reproduction

Ultrasound is essential for timing and guiding oocyte retrieval and helpful in embryo transfer; its role in judging

• **Fig. 11.19** Transverse abdominal view, backup. Gallbladder (*arrow GB*) at right, with asymmetric renal pelves (*calipers*) illustrating the normal left renal appearance (1) (*short, thin arrow*) and right pyelectasis/caliectasis (2) (*thick arrow*). Between 1% and 5% of normal fetuses have pyelectasis, limiting its utility as an isolated marker.

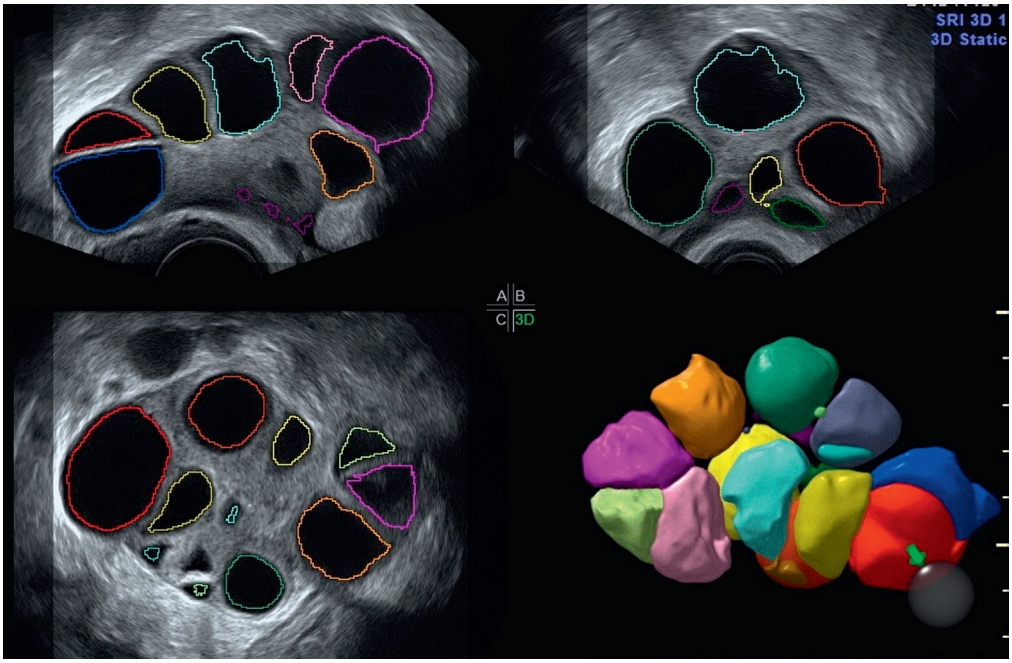
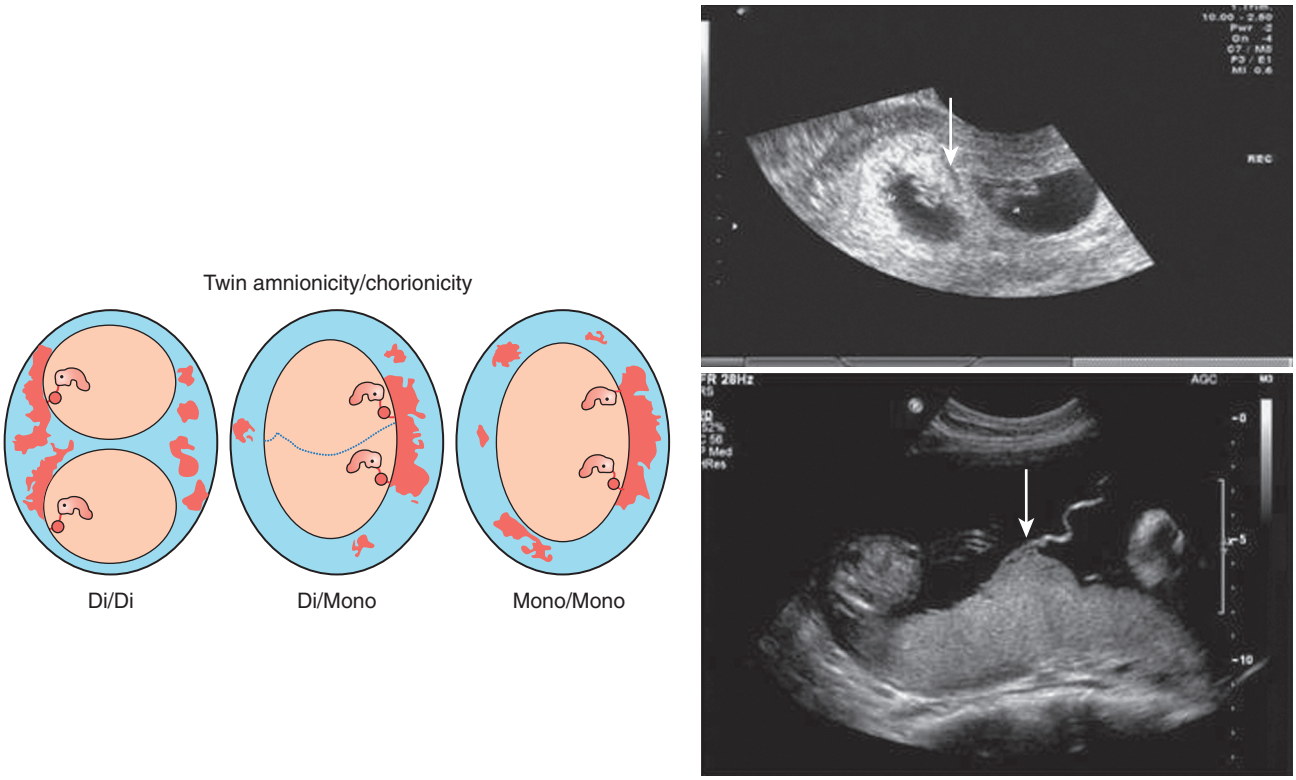
endometrial receptivity is less clear. Saline ultrasound studies prior to fertility treatments routinely complement or replace hystero-salpingogram in assessment of the uterus and adnexa. Use of MRI may play an expanded role in structural and functional evaluation in the future.



Assisted reproductive technology results in more twins and higher-order multiples; early ultrasound study of embryos, amnionicity, and chronicity is essential to subsequent management. With the increasing popularity of ART, obstetricians and radiologists are more likely to encounter associated complications, especially in an emergency setting. These complications include ovarian hyperstimulation or torsion, ectopic or heterotopic pregnancy, and pregnancies of unknown location or undetermined viability. Ovarian hyperstimulation syndrome may occur following ovulation induction or ovarian stimulation and is characterized by bilateral ovarian enlargement, by multiple cysts, and third-spacing of fluids (Fig. 11.21). Additional clinical findings may range from gastrointestinal discomfort to life-threatening renal failure and coagulopathy. Ovarian torsion should be excluded in any woman undergoing ART who presents with severe abdominal pain. Ectopic pregnancy resulting from ART has a relatively increased frequency of rarer and more lethal forms, including interstitial and cervical locations. Heterotopic pregnancies, simultaneous intrauterine and ectopic implantations, are more common in ART patients.

Ultrasonography is the first-line choice for identifying ART complications, although lack of specific symptoms may first trigger other approaches. Familiarity with characteristic strengths and limitations of these and other techniques will facilitate accurate, timely diagnosis and avert potentially serious consequences.

Multiple Gestations



Multiple gestation accounts for about 3% of all pregnancies. With an increase in the number of fetuses, scans become more complex, time consuming, and error prone; additionally, determination of zygosity is essential. The management of anomalous, discordant, or moribund co-twins differs significantly based on chorionicity (Fig. 11.22). Monochorionic twins occur with a relatively constant frequency (1:250 pregnancies), unlike dichorionic twinning that may be influenced by race, heredity, maternal age, parity, and ART. Ultrasound assignment of chorionicity is most accurate for different-sexed dizygotic twins, but by evaluating sac appearance in early gestation, approaches this accuracy in gender-concordant pairs. Successful identification may occur throughout gestation by examining the dividing membranes at their placental origin. Dichorionic diamniotic twins are usually (95%) dizygotic, with independent risks for anomalies and placental malfunction. Monochorionic pairs are predictably monozygotic; attrition rates exceed 30% from early abortion, anomalies, and prematurity. Matched and isolated anomalies are both more common in monochorionic gestations; because of shared vasculature, loss of a co-twin may kill its sibling outright or produce severe neurologic damage in up to one-third of survivors.[27]

Monochorionic TTTS, more common in females, is characterized by unbalanced, shared perfusion that restricts

• **Fig. 11.21** Three-dimensional color-enhanced volume rendering of seven follicles in the right ovary. The echo-free follicles are outlined by the operator in orthogonal planes. The generated volumes are then displayed in the three-dimensional rendering (*lower right*) with color correlation.

• **Fig. 11.22** Diagram (*left*) of variations in appearance of the dividing membrane for dichorionic, monochorionic, and monoamniotic twins. Upper-right image shows typical thick first-trimester appearance of the chorion (*arrow*) in dichorionic diamniotic twins. Lower image shows the peaked dividing membrane (*arrow*) of dichorionic twins in the latter half of pregnancy.

growth and amniotic fluid production in the donor and causes volume overload, cardiac dysfunction, and polyhydramnios in the recipient. Ultrasound staging has been used to time and to guide a variety of vascular ablation strategies. Serial amniocentesis may be helpful in milder cases. Management by these approaches has been modestly effective in decreasing stillbirths and prematurity in TTTS. Monoamniotic twins rarely experience TTTS but routinely encounter cord entanglements, resulting in high lethality rate of both fetuses (Fig. 11.23). Management usually consists of a scheduled preterm cesarean prior to onset of labor. For all multiple gestations, serial ultrasound monitoring of growth, well-being, placental performance, and cervical length is common practice.

Twin reversed arterial perfusion (TRAP) sequence is another complication of monochorionic twinning, complicating approximately 1% of monozygotic pregnancies.[32] Placentation among TRAP cases has been predominantly reported to be monochorionic diamniotic and to a lesser degree monochorionic monoamniotic twins. The proposed pathogenesis is the association of paired artery-to-artery and vein-to-vein anastomoses through the placenta combined with delayed cardiac function of one of the twins early in pregnancy. This situation allows blood pumped from the healthy twin "pump twin" to perfuse retrogradely the heart of the other twin, also known as the "acardiac" twin or "parabiotic twin." Thus, flow in the artery and vein are

• **Fig. 11.23** Monochorionic monoamniotic twins with entangled umbilical cords at 10 weeks' gestation.

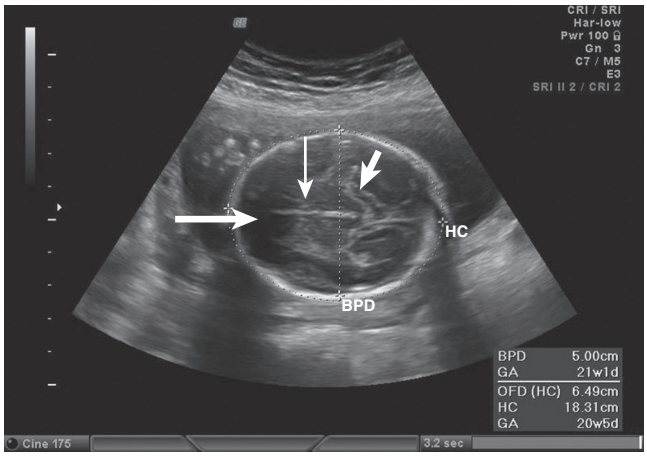
reversed in the umbilical cord of the acardiac twin, giving rise to the acronym TRAP. Retrograde perfusion interferes with normal cardiac development, which rarely goes beyond the stage of tubular heart. Common abnormal findings in the "acardiac twin" include impaired or absent development of the cephalic pole, rudimentary or absent heart, abnormal or absent upper limbs, relative preservation of the lower limbs although clubbing and abnormal toes are common, abnormal viscera, and single umbilical artery. A common finding is massive edema around the upper body including the neck of the acardiac twin (Fig. 11.24*A-C*).

Pregnancy Evaluation



One of the most powerful applications of prenatal ultrasound is using biometrics to establish or confirm gestational age.[9] Through 22 weeks of gestation, most genetically normal individuals cluster closely on normographic curves. Sonographic measurements of fetal ultrasound parameters are the basis for accurate determination of gestational age and detection of fetal growth abnormalities. It has been shown that a fixed error of about 8% (plus or minus) can be anticipated when determining gestational age by ultrasound, consistent with the observation that the earlier gestational age is determined, the lower the margin of error in days. If accelerated or restricted growth supervenes, however, biometric markers are generally compromised accordingly.

Selection of the most useful single parameter depends on the timing and purpose of measurement and is influenced by specific limitations. Commercial equipment has a variety of preinstalled normograms, biometry-based dating, and weight estimation formulae. Embryonic pole and crown-rump lengths are considered most precise for early dating of pregnancy, becoming more variable with fetal flexion effects at the end of the first trimester. Biparietal diameter (BPD), obtainable after parietal bone calcification in week 12, maintains the closest correlation with gestational age in the second trimester. BPD is measured from the outer to the inner table of the skull, perpendicular to the parietal bones and central falx cerebri. The proper plane contains the cavum septum pellucidum, thalami, third ventricle, and tentorial hiatus, within the bony table of a complete head circumference (Fig. 11.25). In cases of variation in the shape of the skull, a head circumference (HC) measurement obtained in the same plane may be an effective alternative. Microcephaly may be suspected when the HC measurement is more than 3 standard deviations (SD) below the mean but is rarely diagnosed prenatally. Additionally, antenatal sonographic estimation of HC is associated with significant underestimation compared with the actual postnatal HC. This discrepancy may have important clinical implications and should be taken into account in the interpretation of sonographically measured HC.[30] BPD and HC are relatively spared in nutritional and perfusional disorders of growth, although cranial measurements may also be distorted by compression effects. The abdominal circumference (AC), measured along the outer margin of the abdominal skin line at the level of the gastric bubble and the intrahepatic portion of the umbilical vein at the bifurcation of the portal veins, is the best single predictor of growth aberrations but is less helpful for dating (Fig. 11.26). Femoral length (FL) is the fourth measurement commonly included in biometric

AC, Abdominal circumference.

formulae, less affected by hypoperfusion but potentially influenced by familial stature. Extraocular and transcerebellar diameters, humeral and pedal lengths are common additional dating parameters. Special curves are available for non-Caucasian ethnicity and multiple gestations, although not universally accepted as essential.

Use of multiple predictors improves the accuracy of estimates, with an individualized approach recommended for fetal growth assessment. The various epidemiologic factors influencing fetal growth should be considered. Clinical application of fetal biometry is of utmost importance in recognizing dating errors, growth abnormalities, chromosomal anomalies, and skeletal dysplasias.

Fetal Growth

Serial measurements over time are the best way to judge fetal growth. The sac and embryo grow perceptibly each day; by the second trimester, intervals of 2 or 3 weeks between studies are more reliable. Problems arise when attempting simultaneously to assign age and weight percentile without reliable dating. The abdominal circumference (AC) is a better indicator of decreased perfusion or increased glycogen storage than the cranial measures; ratios of AC to the HC and FL amplify differences but have poor sensitivity and specificity. Strategies to identify small-for-date fetuses have included risk panels, Doppler ratios, amniotic fluid volume, placental scores, and biometry-based weights; none have had completely satisfactory results, although outcomes appear to have improved.

Correctly identifying fetal growth abnormalities remains an elusive goal despite their major contribution to adverse perinatal outcomes and stillbirth. Current clinical screening relies on the symphyseal–fundal height measurement, but fewer than 25% of small-for-gestational-age (SGA) infants will be identified using this methodology in a low-risk population. Routine third-trimester ultrasound study for growth assessment has a better detection rate, ranging from 50% to 80%, but the impact on perinatal outcome is unclear.[43]

Several common findings, in addition to risk panels, underlying maternal diseases (particularly with vascular components) and prior stillbirth or growth-restricted outcomes may raise concern for fetal growth restriction.[11] These include a modest size–dates discrepancy (within method error) on a first-trimester study, abnormal maternal serum levels of pregnancy-associated plasma protein-A (PAPP-A), and free β-human chorionic gonadotropin at 9-13 weeks, usually obtained as part of genetic screens; early elevation of maternal blood pressure and abnormal uterine artery resistance by Doppler at 11 0/7 to 13 6/7 weeks; a hypoglycemic response to glucose testing may be an early third-trimester observation. By combining uterine artery Doppler findings and baseline maternal characteristics, detection rates for early-onset fetal growth restriction have reached clinically acceptable levels. Unfortunately, fetal growth restriction developing later in pregnancy still goes largely undetected.[7]

Placental Abnormalities

Placental conditions affecting the mother and/or fetus include gestational trophoblastic diseases, placental hematoma, chorangioma, abruption, placenta previa, placenta accreta/increta/percreta, vasa previa, choriocarcinoma, chorioamnionitis, viral and parasitic villitis and placentitis, decidual and thrombotic vasculopathies, infarction, polyps, and retained products of conception. Although gross inspection and histopathology provide the ultimate diagnosis, ultrasonography is the definitive prenatal modality for the evaluating the majority of these conditions. MRI

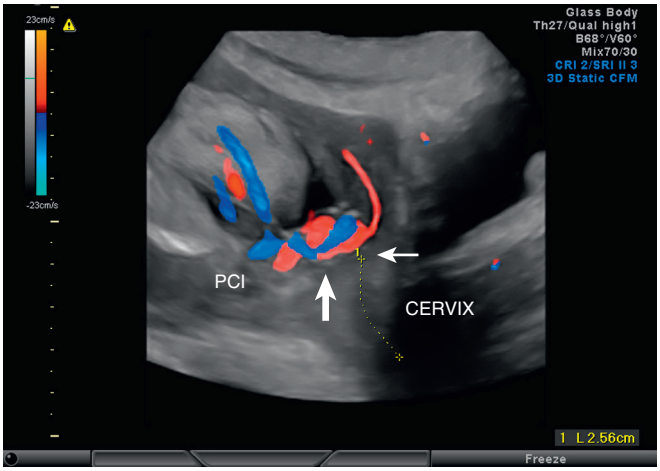
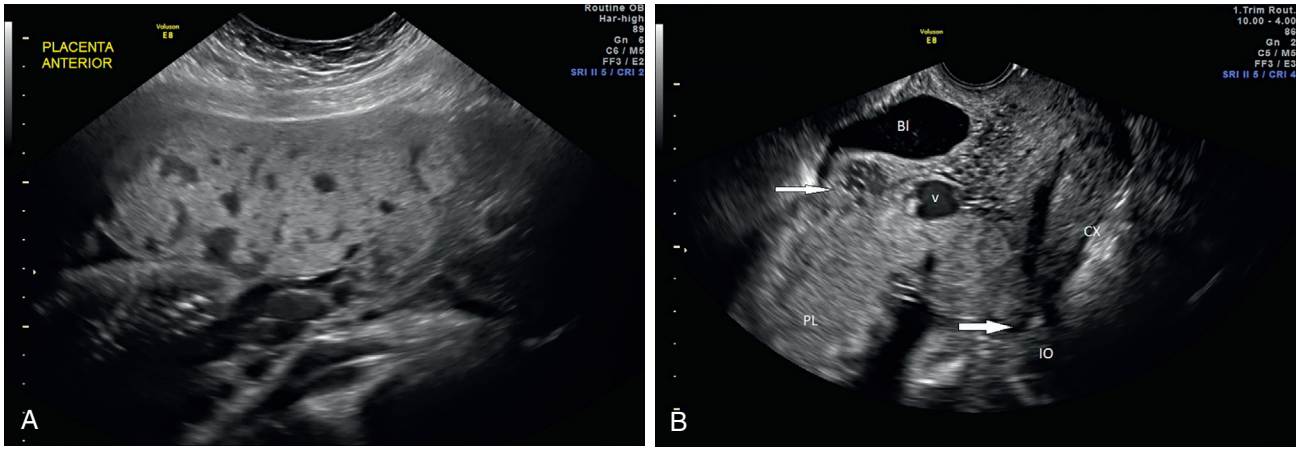
and computed tomography are infrequent adjunctive measures, with the latter occasionally helpful in tumor staging or trauma cases.[31]

Placental Location



Placental location can be confidently established by abdominal and transvaginal ultrasound studies. Low-lying placentation, present in up to 60% of early second-trimester studies, persists as placenta previa in only 1% to 2% of patients at term (Fig. 11.27). Fetal vessels near the cervix can be visualized using color Doppler, facilitating the diagnosis of funic (umbilical cord) presentation and vasa previa (fetal vessels overlying the os) (Fig. 11.28). Normally inserted centrally in the placenta, the umbilical cord may later, as a result of asymmetric placental growth, be located marginally or even on adjacent membranes; in the latter position, traumatic lacerations, hemorrhage, and compression-linked heart rate changes are potential consequences.

Abnormally invasive placenta is a spectrum disorder encompassing the histopathologic diagnoses of placenta accreta (a small focus or more generalized muscular invasion), placenta increta (deeper myometrial invasion up to the uterine serosal layer), and placenta percreta (through the serosa to adjacent visceral or vascular structures). It is potentially life threatening, as forced removal of an abnormally invasive placenta can lead to catastrophic maternal hemorrhage; management of all but the most circumscribed lesions usually requires hysterectomy (Fig. 11.29*A* and *B*).



Invasive placentation was previously diagnosed only when failed attempts to remove the placenta were followed by massive bleeding. Placental accretion is significantly more likely in women with the combination of placenta previa and a history of one or more cesarean sections,[36] after myomectomy or curettage, and with high parity.[18] The frequency of accretion, now complicating 1/2500

• **Fig. 11.27** Placenta previa: the internal os (*arrow*) is completely covered by the placental tissue (P) in this transabdominal view.

• **Fig. 11.28** Fetal vessels (*thick arrow*) within the membranes overlying the internal os (*thin arrow*) are termed vasa previa. Rupture of the vessels can rapidly exsanguinate the fetus; artificial membrane rupture and labor are contraindicated.

• **Fig. 11.29 A,** Anterior placenta accreta showing multiple cysts (vascular lacunae). The hypoechoic interface between the placenta and the myometrium is not seen. **B,** Anterior wall placenta previa and percreta. The wall of the maternal bladder (Bl) is invaded by placental vessels (*narrow arrow*). A sizable venous lake (V) is seen where one would normally expect to view the placental myometrial interface. The placental margin covers the internal cervical os (IO) (*wide arrow*). Cx, Cervix.

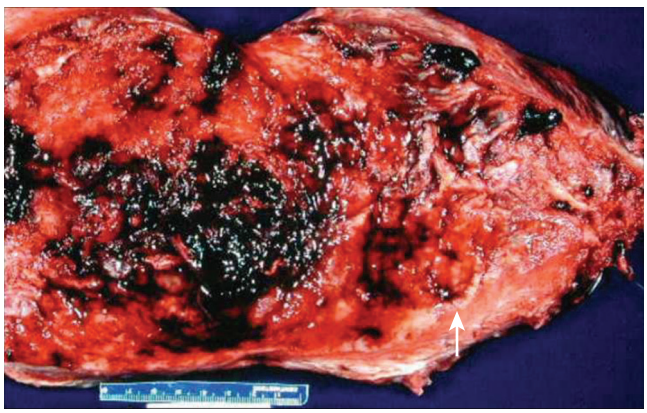
deliveries, has increased more than 10-fold in the past 20 years, echoing rising cesarean rates.[50] Sonographic criteria for placenta accreta were developed using conventional gray-scale, 2D, and 3D color and power Doppler transabdominal and transvaginal ultrasonography. The sonographic characteristics identified are loss/irregularity of the echo-free "clear space" between the uterus and the placental basal plate; thinning or interruption of the hyperechoic interface between the uterine serosa and the bladder wall (increasing concern for percreta), and Doppler findings that included the presence of turbulent placental lacunae with high-velocity flow, as well as hypervascularity of the uterine serosa–bladder wall interface and irregular intraplacental vascularization. Diagnostic ultrasound findings of indistinct placental margins, attenuated myometrium, and large turbulent placental vessels (mainly veins) have sensitivity and specificity for accretion in the range of 85%.[18] The presence or absence of the listed findings has been shown to be very helpful in diagnosing placental accretion and in differentiation of placenta accreta from percreta.[8] In a recent study, the European Working Group on Abnormally Invasive Placenta sought to increase diagnostic capabilities of abnormally invasive placenta.[10] The researchers have suggested a total of 10 sonographic findings detected by 2D gray-scale and color Doppler study to be very helpful in diagnosing an abnormally invasive placenta. Similar sonographic findings with 81% sensitivity and 98.9% specificity were recently reported.[35]



Antepartum diagnosis of abnormal attachment permits multidisciplinary planning for prematurity management, anesthesia, transfusion, hemostatic and uterotonic medications, balloon tamponade, arterial embolization, or scheduled preterm (around 34 weeks) cesarean-hysterectomy prior to onset of labor (Fig. 11.30). MRI mapping is most helpful when there is posterior placentation, suspected lateral extension, after myomectomies, for evaluation of adjacent viscera with percreta, or when ultrasound findings are ambiguous.[35]

The diagnosis of placental abruption remains a clinical one. The role of imaging in this disorder is to exclude placenta previa, an equally common source of severe third-trimester bleeding. Subchorionic hematomas are often noted on transvaginal scans early in gestation; symptomaticity, size, and persistence have been linked to poorer outcomes.[17] Later abruptions are more difficult to visualize; acute bleeding is isoechoic with placenta and can be mistaken for placentomegaly. Hypoechoic fluid collections and hyperechoic infarcted areas appear in more chronic presentations.

Grading placental appearance to detect disturbed growth or maturation is of limited benefit. Persistent immaturity is linked to hydrops fetalis, although not as often as increased echogenicity and thickening. Precociously mature placentas may presage growth restriction (Fig. 11.31).

Amniotic Fluid Volume

Amniotic fluid is initially secreted by the amnion; by the 16th week of pregnancy, fetal renal production accounts for the majority, with nearly complete turnover during a 24-hour period. Malformations of the esophagus and upper gastrointestinal tract, inhibited fetal swallowing, aneuploidy, intermittent renal obstruction, maternal diabetes, twin–twin transfusion syndrome, some forms of dwarfisms, and fetal hydrops are associated with marked polyhydramnios. Severe growth restriction with polyhydramnios carries a poor prognosis. Polyhydramnios is idiopathic in almost half of the cases; associated complications include maternal respiratory compromise, premature membrane rupture, preterm labor and delivery, malposition, abruption, cord prolapse, preeclampsia, amniotic fluid embolism, and puerperal hemorrhage. Maximum vertical pocket or summed depths across quadrants conveniently serve as proxies for volume calculation in clinical settings (Fig. 11.32). Oligohydramnios may occur after membrane rupture; after fetal renal compensation for placental hypoperfusion; from functional or obstructive urogenital anomalies; with maternal dehydration; or following exposure to some medications, including indomethacin and angiotensin-converting-enzyme inhibitors. Maternal obesity is associated with underestimation of amniotic volumes. Amniotic fluid measurements may be

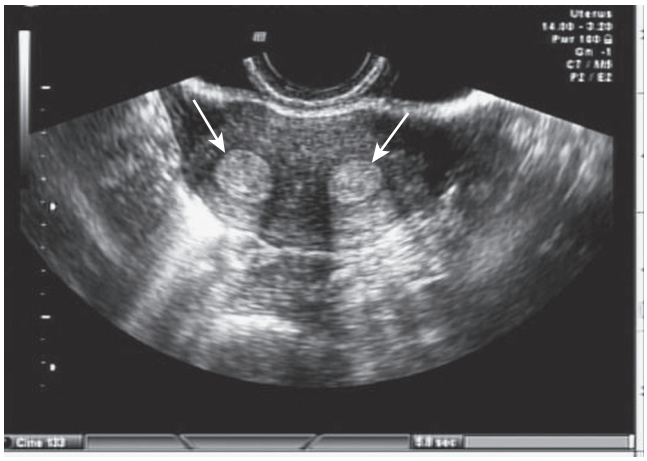
combined with non-stress and fetal biophysical testing to provide reassurance of fetal well-being.

Cervical Length and Pelvic Structures

Cervical length and appearance is frequently assessed during routine antenatal ultrasound; transvaginal measurements (Fig. 11.33) are more reliable and reproducible than transabdominal views. The closed endocervical canal length is positively correlated with duration of gestation in a continuous fashion. Moreover, once values fall below 25 mm, preterm deliveries increase. In patients with prematurity risks, shorter cervical length is strongly predictive of delivery before 36 weeks; in combination with fetal fibronectin and other biomarker assays, ultrasound aids in identifying those at highest risk for imminent delivery.[6]

Attempts to prevent premature births by tocolysis have been ineffective; postponing delivery for 48 hours to permit steroid enhancement of lung maturity has proven more feasible. First-trimester ultrasound prediction of the need for cervical cerclage has not been reliable. Specific candidates may benefit from either preventive or "rescue" cerclage procedures on the basis of midtrimester cervical lengths. Progesterone prophylaxis against prematurity by intramuscular injection or vaginal preparation has increased in recent years; the former has supporting evidence for effectiveness after a short cervix has been noted by ultrasound.[6]

The gravid uterus is conveniently studied by ultrasound. Congenital Müllerian anomalies, including duplications and septations, occur in about 0.5% of the population (Fig. 11.34). Patients with bicornuate uteri may experience irregular bleeding in early pregnancy, altered cervical



• **Fig. 11.33** Transvaginal study showing cervix (*dotted line*) with MacDonald cerclage (*arrows*) in situ.

competency, and, rarely, torsions or ruptures of the horn in which the gestational sac is located. Poorly vascularized septations are etiologically associated with abruption and pregnancy failure. Myomas complicate 1% to 2% of pregnancies with more frequent cesareans and prematurity, abruption, degeneration, and fetal malpresentation; less common complications include fetal deformation, dystocia (7.5%), puerperal hemorrhage, and hysterectomy.[22] Adverse obstetric outcomes are rare; studies are confounded by age, ethnicity, and other differences in those who develop myomas. Generally good maternal and neonatal outcomes are expected in most pregnancies with uterine fibroids.[22]

Normal adnexal structures are not palpable after the first trimester; ultrasound is the first choice for ovarian

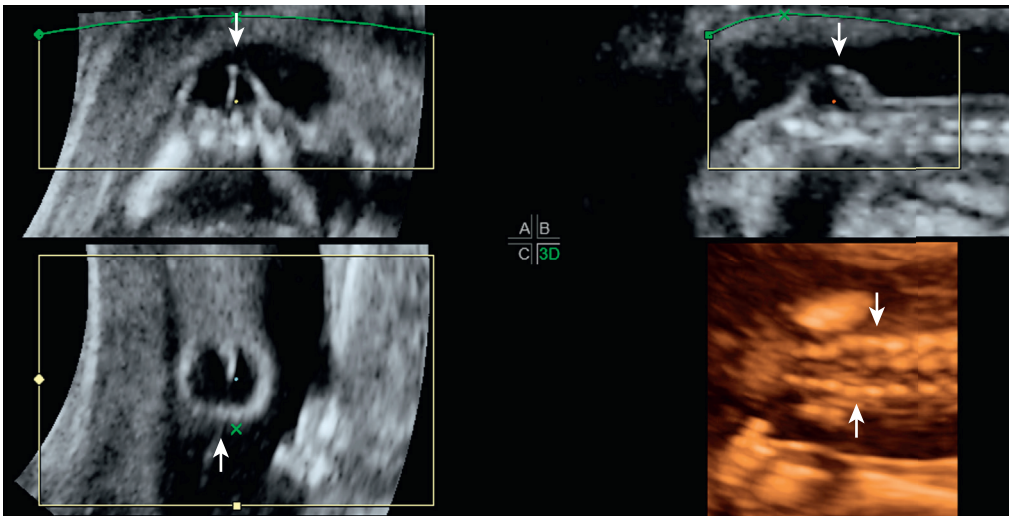
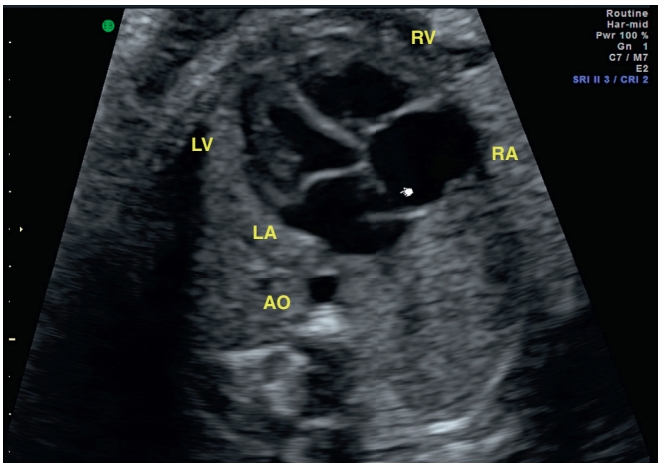
evaluation during pregnancy, although often augmented by MRI and computed tomography (CT). Ovarian torsion is a rare but acute surgical emergency; it is more likely with ART, ovarian cysts, and adnexal masses, favoring first-trimester or puerperal onset. Once an adnexal mass has been discovered by ultrasound, better characterization by MRI may be essential in avoiding unnecessary surgery during pregnancy. Asymptomatic lesions, even when quite large, are now generally expectantly managed until delivery or the postpartum period if malignancy is not suspected. Ultrasound is frequently sufficient for a secure diagnosis of corpus luteal cysts, benign cystic teratomas, and endometriomas. Use of MRI for atypical lesions can confirm the presence of fat, key to the diagnosis of teratoma and the exclusion of endometrioma. MRI aids in identification of hydrosalpinges and nongynecologic lesions. Expectant management of many adnexal masses past delivery is now more common, based on benign ultrasound, Doppler, and MRI characteristics.[51]



• **Fig. 11.34** Müllerian anomaly: Bicornuate uterus in transverse view with two decidualized cavities (*arrows*) and indented external contours.

Second-Trimester Ultrasound Study of the Fetus



During second-trimester studies, a number of normal fetal structures are routinely identified and anomalies excluded. Basic anatomic surveys usually include documentation of fetal cranial integrity and central nervous system anatomy: midline brain structures, cavum septum pellucidum and thalami, lateral and third ventricles, choroid plexus, cerebellum, and posterior fossa.

Views confirming facial symmetry, intact orbits, clear lenses, paired nares, intact lips and hard palate, and normal profile are part of comprehensive studies. Fetal swallowing, respiratory movements, and nuchal structures may be noted. The spinal column is normally imaged in the long-axis, transverse, and coronal views. Distinct advantages in the visualization of the facial features, small parts, and spine are provided by 3D imaging (Fig. 11.35). Views of the thorax, including the axis, site, and relative proportions of cardiac and mediastinal structures with respect to the lungs and pulmonary vessels, yield indirect support for the integrity of the diaphragm. Over time, the basic cardiac examination has expanded from obtaining the axis, laterality, and rate to requiring symmetric four-chamber apical views and, as feasible, images of normal outflows, ductal and aortic arches, and additional arterial and venous tracts (Fig. 11.36). Prenatal echocardiography adds M-mode rhythm, color flow Doppler, and structural studies capable of details and diagnostic accuracy approaching those of postnatal examinations, subject to predictable limitations. Fetal abdominal views confirm the closure of the ventral wall; presence, normal size, and site of hepatic, gastric, splenic, pancreatic, vascular, and choledochal structures; renal and adrenal contours; normal bowel dimensions and echogenicity; bladder filling; and umbilical cord appearance. Accuracy of fetal sex assignment exceeds 99% by the midtrimester (Figs. 11.12 and 11.37). Fetal digits, small parts, cerebellar vermis, and

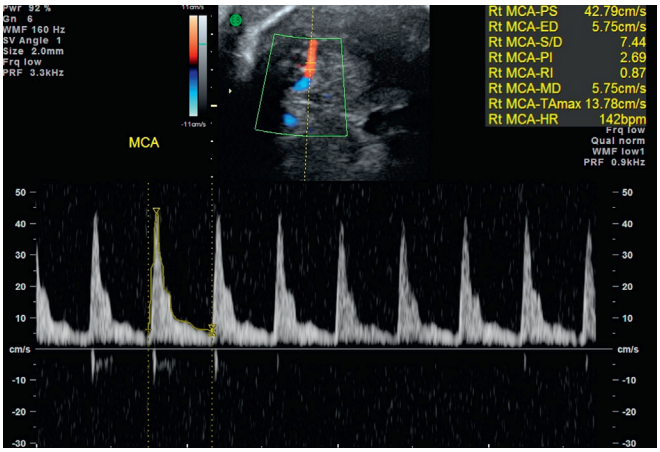
• **Fig. 11.36** View of the thorax showing a normal four-chamber heart; apex is up and to the left of the picture. The right and left atria (RA, LA) and corresponding ventricles (RV, LV) are seen in the transverse plane of the fetal chest.

palatal components are often imaged by a combination of 2D and 3D. As gestation progresses, neurosonography may identify additional features of intracranial architecture and cerebral maturation.

Doppler Ultrasound

Initially considered revolutionary, obstetric Doppler has been hampered by costs, time constraints, safety concerns, and lack of clear utility for most patients. Currently accepted applications, originally employed in research and referral centers, commonly include identification and localization of blood flow, resistance to flow, vessel patterns, and directionality and velocity in cardiopulmonary structures and in a wide range of additional vessels, most commonly the uterine arteries, umbilical vessels, ductus venosus, and middle cerebral artery.

Uterine blood flow patterns reflect both maternal vascular resistance and placental site. Abnormal Doppler results in these and other vessels precede growth restriction and maternal hypertensive complications. Paired umbilical cord arteries are readily shown by color Doppler to bifurcate around the bladder (see Fig. 11.5). Absence of one umbilical cord artery may have associated cardiac and renal anomalies, aneuploidies, or growth restriction. Abnormally high umbilical artery resistance is more often characteristic of uteroplacental constraints on fetal growth than of anomalies or aneuploidy. Doppler findings may suggest the origin of a size/date discrepancy, but weight estimation more reliably identifies the small-for-gestational-age fetus. Persistent absence or reversal of end-diastolic flow, albeit rare, is associated with severe growth restriction, and perinatal morbidity and mortality. Middle cerebral artery resistance and umbilical venous patterns usually change later in the course of compromised perfusion; paradoxical ductus venosus and umbilical venous patterns are considered premorbid. Schemes combining clinical risks, biometry, Doppler



• **Fig. 11.37** The male fetus (**A**) can reliably be distinguished from the female fetus (**B**) by ultrasound after the first trimester. **C**, A female fetus with hydrometrocolpos. The arrows point to sediment of red blood cells in the uterus. B, Bladder; UT, uterus.

measurements of the umbilical and middle cerebral vessels, and biophysical testing appear to have improved outcomes for growth-restricted fetuses while reducing the frequency of iatrogenic prematurity.[2]

Doppler measurement of peak systolic velocity in the middle cerebral artery has become integral to detection of fetal anemia and management of isoimmunization

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• **Fig. 11.38** Middle cerebral artery (*in trapezoid*) Doppler flow velocity in a fetus with Rhesus sensitization. The peak systolic velocity (PSV shown in lower portion) increases as fetal anemia progresses. Doppler measurements in the fetus are often expressed as ratios to compensate for inaccuracies introduced by narrow, tortuous vessels.

(Fig. 11.38). Previously, discovering hydrops or elevated maternal erythrocyte antibody levels triggered obligatory cord blood sampling or amniocentesis. The former is complicated by technical challenges, prematurity, and fetal losses; the latter is informative for only some hemolytic anemias. Peak velocities of the middle cerebral artery by noninvasive Doppler, relatively easily obtained, are inversely correlated with hemoglobin values. At a cutoff of 1.5 multiples of the median, the sensitivity for clinically significant anemia approaches 100%, with a false-positive rate from 0% to 28%; reliability decreases near term.[28] Severe growth restriction may contribute to false-positive results but is usually distinguished by clinical context.

Color flow Doppler distinguishes between cystic and vascular lesions, confirms the presence or site of organs, and aids in evaluating brain, cardiac, and pulmonary vasculature. When combined with 3D, color flow generates dramatic virtual vascular casts, although with more limited prenatal applications.

Doppler Studies of the Growth-Restricted Fetus

Placental dysfunction leading to fetal growth restriction (FGR) is an important risk factor for neurodevelopmental delay. Observations clarify that FGR evolves prenatally from a preclinical phase of abnormal vascular, nutrient, and endocrine milieu to a clinical phase differing in characteristics in preterm versus term pregnancies. Relating childhood neurodevelopment to prenatal characteristics may aid in identifying mechanisms and timing of critical insults. Based on available studies, lagging head circumference, degree of FGR, gestational age, umbilical artery (UA), aortic and cerebral Doppler parameters may be independent prenatal predictors of infant and childhood neurodevelopment. Head circumference is meaningful independent of gestational age, but a generalized growth delay has greater impact in early-onset FGR. Gestational age at delivery becomes the chief determinant of neurodevelopment before 32 to 34 weeks' gestation. Doppler evidence of placental resistance to flow is increasingly important after 27 weeks, with maximum concern when flow reversals are noted in the umbilical artery, aorta, ductus venosus, or the umbilical vein. These findings predominate in early-onset FGR; cerebral vascular impedance changes, sometimes expressed as a ratio between the pulsatility indices of the middle cerebral and umbilical arteries, are important in later FGR. Abnormal motor and neurologic delays occurring in preterm FGR give way to cognitive effects and abnormalities related to specific brain areas as gestation advances, suggesting different pathophysiologies or evolving vulnerabilities of the fetal brain. Current studies do not suggest that fetal deterioration has an independent effect on neurodevelopment in early-onset FGR; the role of intervention in late FGR requires more research: risks for damage and patterns of deterioration may differ in the third trimester.[49]

Ultrasound-Guided Procedures

Real-time ultrasound is well suited by virtue of safety, economy, and convenience for guiding placement of needles, cannulae, catheters, and other devices used in fetal diagnosis and therapy. The range of procedures includes oocyte retrieval and embryo transfers, embryonic and fetal reduction, chorionic villus sampling, placental and skin biopsies, amniocentesis and amnioreduction, cord blood sampling, intrauterine transfusion, aspiration of fluid from various fetal and maternal sites, and an adjunct to fetoscopy and vascular ablation. The effectiveness as well as complications from procedures are often apparent in real time. Determinations of fetal status; relative fetal and umbilical cord positions during external version for malpresentations, labors, and immediately before transfusions; surgical interventions; and the EXIT (EX utero intrapartum treatment) procedure are important accepted applications.

Fetal Well-Being Assessment

A tenet of antepartum testing is that more accurate predictions of fetal wellness are achieved in proportion to the number of variables considered. See also Chapter 12. The biophysical profile (BPP) is a noninvasive ultrasound-based clinical tool that integrates levels of dynamic biophysical activities into a usable standard. The BPP attempts to predict the presence or absence of fetal asphyxia to prevent progression to metabolic acidosis and fetal death. The BPP seeks to identify four parameters in a 30-minute period, each of which is assigned two points: (1) observation of continuous tidal fetal breathing for 30 seconds, (2) a vertical amniotic fluid pocket of at least 2 cm (or 2 cm in 2 planes), (3) three obvious fetal movements, and (4) fetal tone, manifested by brisk flexion of small parts or hands. Death or injury within 1 week is more likely with scores below six, with loss of tone considered a late finding. Conversely, scores of eight

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

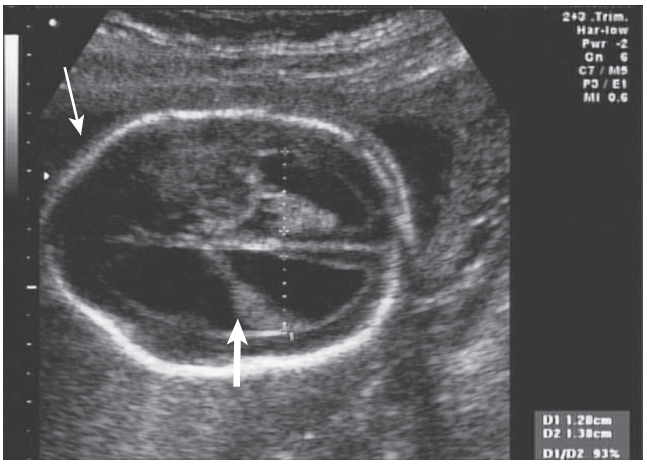
are considered highly reassuring for well-being during the same period. A fetal non-stress test, sometimes included for an additional 2 points (total score of 10), does not usually affect the predictive value of the BPP.

Antepartum testing by BPP should not be performed prior to viability or when fetal or maternal conditions preclude successful intervention. Cautious interpretation is appropriate for extreme fetal prematurity; in the presence of anomalies; maternal metabolic abnormalities; during labor; and with some drugs, including opiates, sedatives, and antenatal corticosteroids.

Fetal Anomalies

Neonatal outcomes can be optimized by forewarning and timely preparation when fetal abnormalities are present. Unfortunately, more than one-third of birth defects remain unrecognized prenatally. False-positive diagnoses are less frequent, but up to 10% discordancy with autopsy findings highlights the inherent uncertainties of prenatal diagnosis. Familiarity with imaging pitfalls associated with common anomalies is imperative to avoid misdiagnosis. Suspected structural defects should always be visualized in the correct plane with attempted confirmation in other planes. Precise measurements using specific criteria, appropriate gain settings, and additional modalities may be required for correct interpretation and management. Expert second opinions by patient referral or image review are available for most findings. Despite acknowledged limitations, prenatal ultrasound is the standard method for recognition of fetal anomalies.

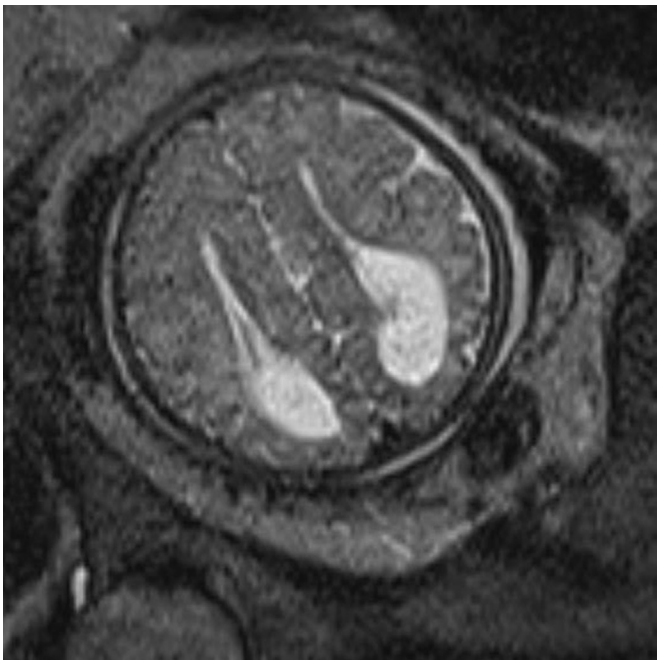
Central Nervous System



Fetal Ventriculomegaly

Hydrocephalus and ventriculomegaly are not strictly synonymous. Hydrocephalus connotes raised intracranial pressure, a functional observation not directly amenable to ultrasound. Prenatal enlargement of lateral ventricles (Fig. 11.39) may occur without altered pressure because of developmental abnormalities. Enlargement of the atria and posterior horns of the lateral cerebral ventricles (colpocephaly) may be associated with agenesis of the corpus callosum or type II Chiari malformations. Dilated lateral ventricles may also result from obstructed cerebrospinal fluid flow by hemorrhage or from brain destruction by a variety of causes, including ischemia and infection (e.g., cytomegalovirus, toxoplasmosis, or Zika virus). A single measurement over 10 mm at the level of the posterior atria of the lateral ventricles defines ventriculomegaly.

Atrial widths tend to decrease slightly during pregnancy. Choroid plexus positioning is gravity-dependent; on axial views, the choroid, attached at the level of the foramen of Monro, rests on the dependent wall of the lateral ventricle, marking the limit of the lateral ventricle, even when the wall cannot be visualized. A "dangling" choroid plexus conveys the extent and severity of ventricular enlargement (Fig. 11.40).



• **Fig. 11.39** Fetal MRI at 23 weeks' gestation. Massive enlargement of the lateral ventricles with a thin rim of remaining brain parenchyma.

• **Fig. 11.40** "Dangling choroid" (*thick arrow*) with bilaterally dilated lateral ventricles secondary to an open neural tube defect. The latter is signaled by the frontal depression "lemon sign" (*thin arrow*) in up to 90% of cases.

Clinical outcomes of severe ventriculomegaly (atrial size greater than 15 mm) are discouraging; survivors are often mentally and physically impaired. Hydrocephalus associated with arachnoid cyst, atresia of Monro, absence of the corpus callosum, or minor intracranial hemorrhage may have a better prognosis. By contrast, hydrocephaly seen with holoprosencephaly, encephalocele, congenital syndromes, or infection generally leads to loss or greater disability. Formal diagnostic and management algorithms, combining ultrasound, MRI, genetic diagnosis, and infectious disease screening play an essential role in counseling and care when hydrocephaly is identified.[52]

• **Fig. 11.41** Fetal MRI at 35 weeks' gestation demonstrating agenesis of corpus callosum. Axial scan shows parallel lateral ventricles enlarged posteriorly (colpocephaly) in a teardrop shape.

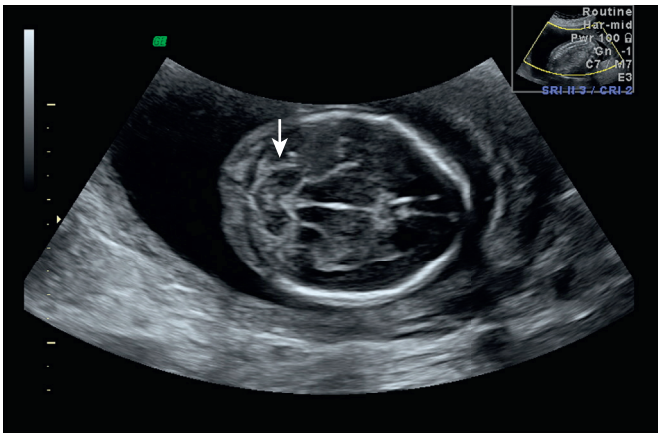
In utero shunting has no current role in the treatment of prenatal ventriculomegaly. Asymmetric or rounded lateral ventricles and mild ventriculomegaly (widths between 10 and 12 mm) convey an uncertain prognosis, as most infants are normal, particularly when resolution occurs; slightly wider dimensions (12-15 mm) carry an intermediate prognosis.

Agenesis of the corpus callosum can be isolated but is commonly associated with other anomalies of abnormal neuronal migration. Midtrimester diagnosis of many brain lesions is hampered by ongoing differentiation and growth of the central nervous system; third-trimester transvaginal cranial ultrasound and MRI are particularly helpful in assessing the progressive development of gyri and sulci of the brain (Fig. 11.41).

Meningomyelocele and (Type II) Chiari Malformation

Meningomyelocele (Fig. 11.42) may be associated with a Chiari II malformation, that is, downward displacement of the hindbrain, as well as with other brain anomalies, including ventriculomegaly (Fig. 11.43). Often, hydrocephalus does not develop in children with neural tube defects (NTD) until after birth or lesion repair. Open NTD (Fig. 11.44) is usually accompanied by markedly elevated alpha fetoprotein levels in both maternal serum and amniotic fluid. A meningomyelocele appears on ultrasound as splaying or divergence of the posterior ossification centers, best appreciated on axial spinal views. A fluid-filled sac may be seen and the integrity of the overlying skin can be visibly disrupted on axial and sagittal images. The level

• **Fig. 11.42** MRI of sacral meningomyelocele (*thick arrow*) at 21 weeks' gestation; normal posterior fossa including cerebellum and fourth ventricle (*thin arrow*).



• **Fig. 11.43** Fetal MRI at 19 weeks demonstrates Chiari II malformation. Note dilated lateral ventricle (*straight arrow*) and communication between lower lumbar spinal canal and amniotic fluid–open neural tube defect (*curved arrow*).

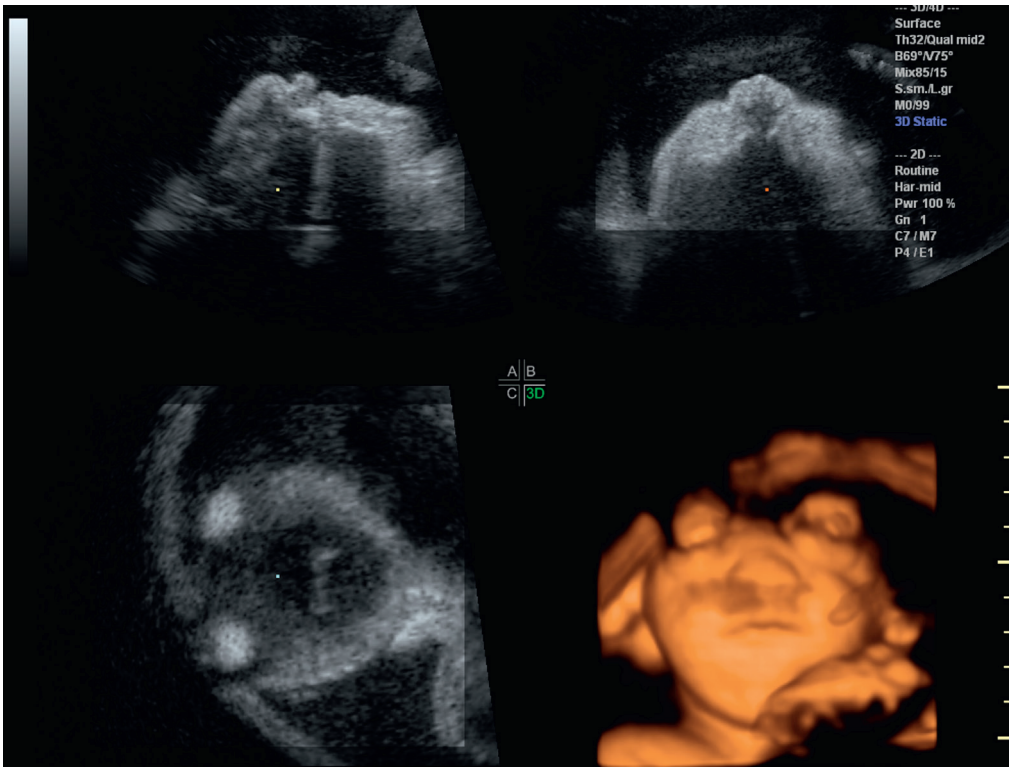
of the meningomyelocele can be ascertained more accurately with 3D ultrasound and MRI (see Figs. 11.35 and 11.42), helpful for predicting the outcome in affected children. Severe cases may be associated with kyphoscoliotic spinal deformity or clubbing of one or both feet. Prenatally, extremity movement may seem to be preserved; however, absence of normal activity better correlates with postnatal motor function.

The Skull and Brain in Spina Bifida



The "lemon sign" refers to the altered appearance of the calvarium, similar in shape to a lemon, on an axial view of the skull and brain (see Fig. 11.40). Biconcave frontal bones produce the calvarial distortion. The sign is best demonstrated between 18 and 24 weeks but is not specific, appearing sometimes in otherwise normal children. The "banana sign" refers to abnormal cerebellar positioning, curled in a crescent (banana-like) around the brainstem (see Fig. 11.44). Obliteration of the cisterna magna and cerebellar distortion are secondary to type II Chiari malformation. One or both signs are seen in the majority of spina bifida cases during the midtrimester and should prompt a more detailed examination of the spine. Prenatal surgical closure of defects may improve outcome in appropriate candidates, particularly with respect to preservation of motor function and prevention of hindbrain displacement.

• **Fig. 11.44** Open neural tube defects may be associated with an obliterated posterior fossa "banana sign" (*arrow*) in 60% of cases.

Anencephaly

Anencephaly, the absence of normal brain and calvarium superior to the orbits, can be detected as early as 10 weeks but is recognizable throughout gestation (Fig. 11.45). Maternal serum alpha fetoprotein is usually very elevated. About half of cases have associated anomalies, for example, meningomyelocele, cleft palate, or clubfoot. Occasionally, the typical appearance is altered by the presence of echogenic material superior to the orbits, identified pathologically as angiomatous stroma ("area cerebrovasculosa"). Polyhydramnios and malpresentation are common later findings. Abnormal prolongation of pregnancy may occur, presumably secondary to lack of fetal neurohormonal cues for labor. Anencephaly is considered incompatible with

• **Fig. 11.45** Three-dimensional orthogonal image of anencephaly at 17 weeks' gestation. The cranial vault is absent above the orbits.

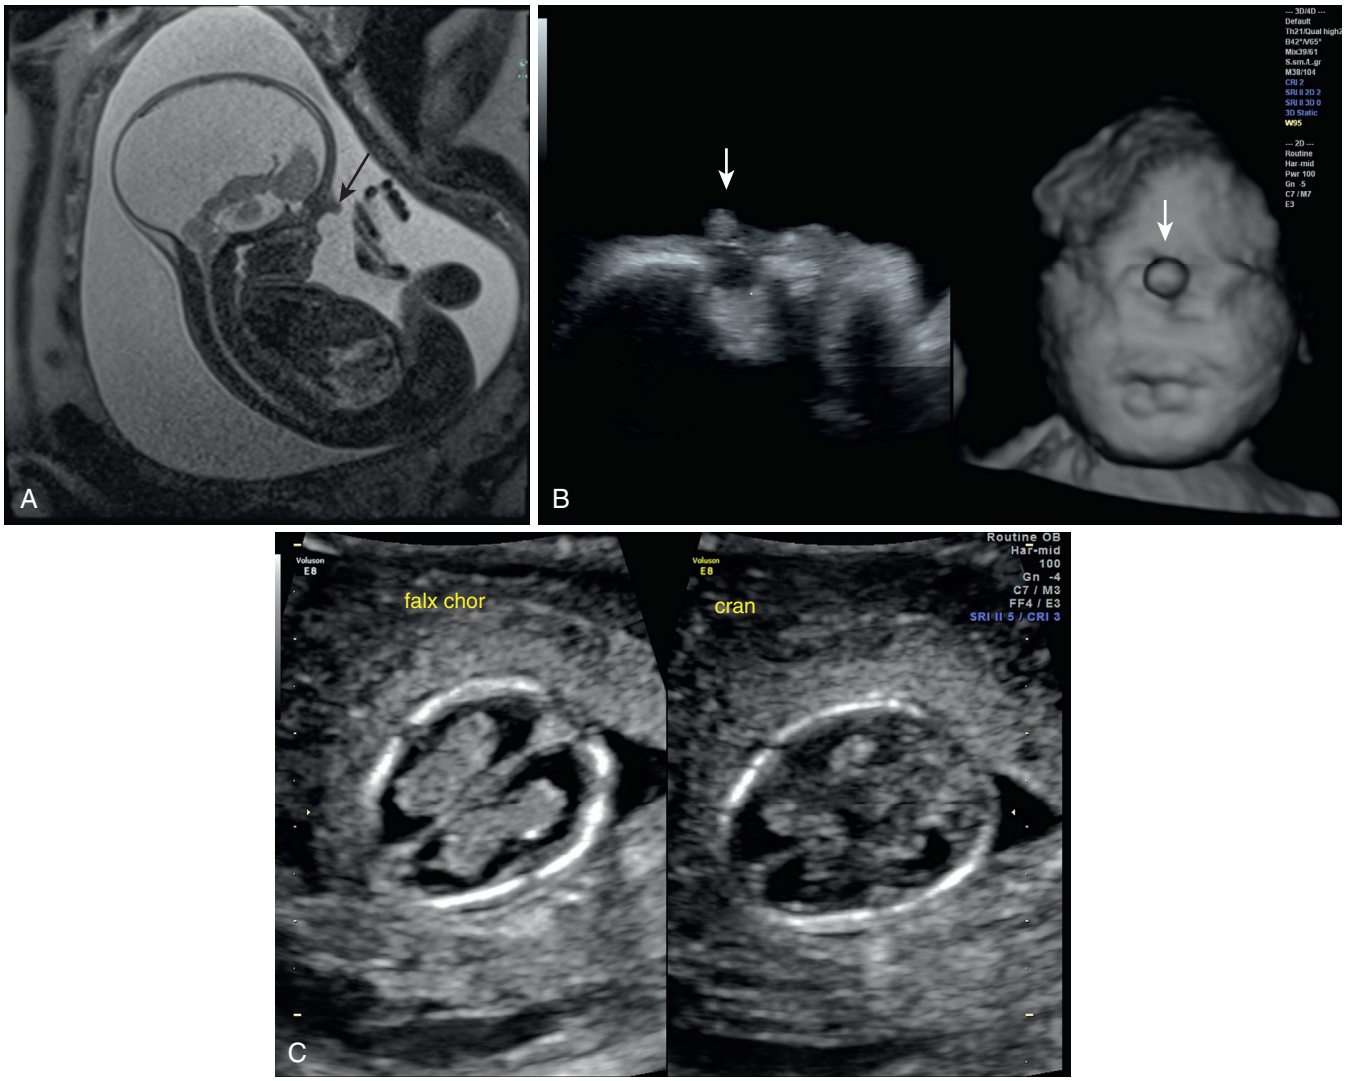
meaningful survival; most affected live-borns succumb in the immediate neonatal period. Intervention for purely fetal indications is futile and is not recommended.

Encephalocele

The extracranial protrusion of brain tissue within a meningeal sac is a straightforward ultrasound diagnosis, although dependent on site and size of lesion and appropriate visualization. Most encephaloceles in the Western world are occipital and midline and should be distinguished from soft tissue edema or lymphangiomata of the neck. The identification of a calvarial defect allows a specific diagnosis (Fig. 11.46). Encephaloceles may be isolated or associated with amniotic band syndrome (when off midline) and genetic syndromes such as Meckel-Gruber. Prognosis is affected by site, size/amount of extruded tissue, and adversely affected by ventriculomegaly, microcephaly, and syndromic etiology. Anterior sites are more common in Asian populations; small nasal or frontoethmoidal encephaloceles may initially elude even postnatal detection.

Holoprosencephaly

Holoprosencephaly, a malformation resulting from early failure of division of the embryologic prosencephalon or forebrain, is frequently associated with facial abnormalities (Fig. 11.47*A*). Its incidence ranges from 0.6 to 1.9 per 10,000 live births, although this is likely an underestimate because many cases spontaneously abort and milder variants can be unrecognized. In cases without chromosomal abnormalities, recurrence risk is estimated to be 6%. The etiology of holoprosencephaly is heterogeneous and not fully known with most cases being sporadic. Environmental, mechanical, and genetic factors have all been implicated. Several chromosomal disorders are linked to this anomaly, most notably trisomy 13, with 70% exhibiting holoprosencephaly. Holoprosencephaly in association with extra-cephalic malformations strongly suggests aneuploidy; there are also autosomal dominant and recessive familial forms. The condition has been induced by a variety of teratogenic agents in animal models. In alobar holoprosencephaly, the most severe form, there is a complete failure of cleavage of the forebrain into two hemispheres. The cerebral hemispheres are fused and enclose a single prosencephalic ventricle. In addition to a single ventricular cavity, the thalami are fused, and the cavum septum pellucidum (CSP), corpus callosum, falx cerebri, optic tracts, and olfactory bulbs are all absent. The alobar condition is often associated with fetal loss; the vast majority of live-borns experience severe neurologic dysfunction or death in early infancy; less severe variants have a wider, less predictable range of outcomes. Partial cleavage results in semilobar holoprosencephaly, with posterior separation of the cerebral hemispheres, variable degrees of thalamic fusion, and absent olfactory bulbs and corpus callosum. In lobar holoprosencephaly, the abnormalities may be confined to absence of the CSP and corpus callosum with fusion of the lateral ventricles and cingulate gyrus; hemispheres are separated anteriorly and posteriorly. The mildest form, septal optic dysplasia, lacks only the CSP. Severe forms of holoprosencephaly may exhibit cyclopia (median mono-ophthalmia) with or without proboscis, cebocephaly (ocular hypotelorism and a blind single nostril), ethmocephaly (ocular hypotelorism with proboscis) (see Fig. 11.47*B*), and median facial clefts. The diagnosis of holoprosencephaly was typically made during the midtrimester anatomic survey by noting fused lateral ventricles and thalami and the absence of normal midline structures. Early prenatal detection of holoprosencephaly can occur between 11 and 14 weeks' gestation by obtaining transverse cranial images in which the normal "butterfly sign" of choroid and ventricles is absent (see Fig. 11.47*C*).



• **Fig. 11.46** Upper image: Occipital encephalocele with herniation of meninges through the defect (*arrow*). Lower images: Posterior encephalocele with meninges and neuronal tissue.

Dandy-Walker Malformation

The Dandy-Walker malformation is a fluid-filled posterior fossa cyst, with variable occurrence of lateral ventriculomegaly; the posterior fossa is always enlarged and the tentorium uplifted.[46] The cerebellar hemispheres, separated by the cyst, are rudimentary. Agenesis of the cerebellar vermis is difficult to confirm before 20 weeks because wide variations in developmental timing mean that full formation may not yet be present. The Dandy-Walker variant consists of direct communication between the fourth ventricle and cisterna magna, without posterior fossa enlargement and with only mild hypoplasia of the inferior vermis. The subtle ultrasound findings can be associated with serious abnormalities

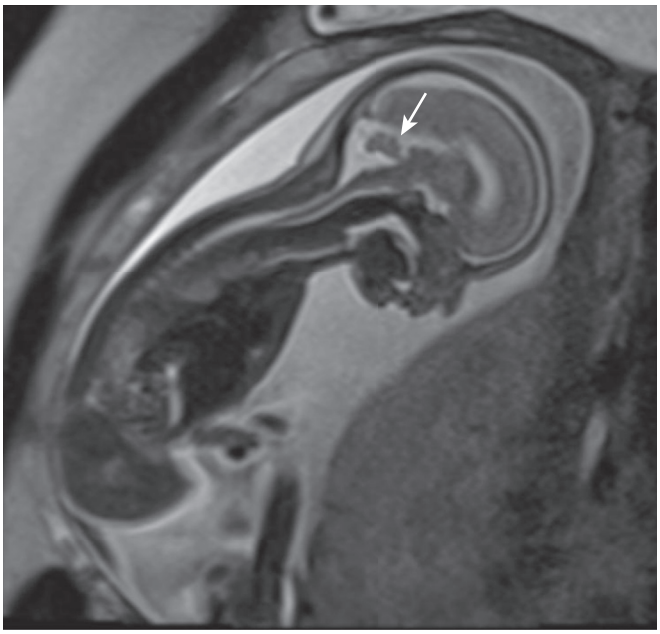
Massive single ventricle with little remaining brain. **B,** Reconstructed three-dimensional image of a fetus with alobar holoprosencephaly. A proboscis (*arrows*) is seen but no orbits. **C,** The fetal choroids are seen to be symmetrical and intact in this 12-week fetus.

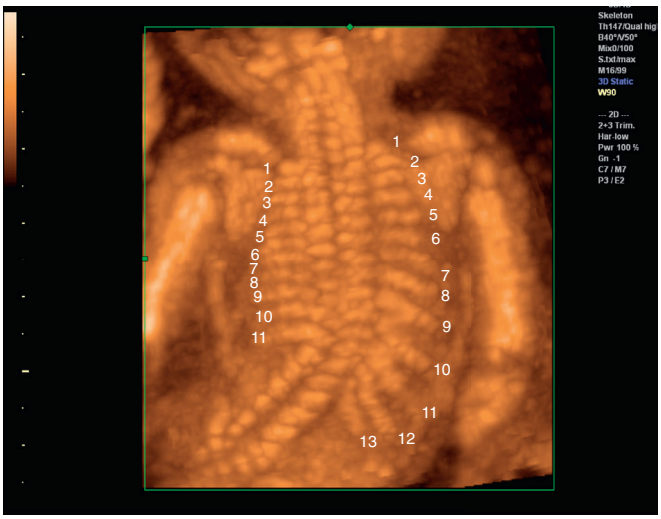
of neuronal migration; confirmation from MRI is helpful (Fig. 11.48).

Choroid Plexus Cyst



Cysts in the choroid plexus, noted in 1% to 2% of normal second-trimester pregnancies, usually resolve by the early third trimester (see Fig. 11.18). Cyst number, size, or persistence impart no additional clinical significance. Isolated choroid plexus cysts are generally associated with normal karyotype, do not require follow-up to confirm resolution, and do not affect postnatal development.[14] Choroid cysts have been associated with trisomy 18.

Spine



3D imaging is extremely useful for studying fetal spine, vertebrae, ribs, pelvic bones, and spinal cord. Operators can simultaneously visualize three orthogonal planes, scroll through volumes along any given orientation, and precisely locate abnormalities by use of stable anatomic reference points (Fig. 11.49).

Sacrococcygeal teratomas (SCTs) are congenital germ cell tumors, usually benign but often large, arising posteriorly at the medial spinal base. Posterior bony elements of the lumbosacral spine are typically intact. Often SCT is associated with polyhydramnios, prematurity, and more rarely with anemia, high output cardiac failure, and hydrops. Maternal serum alpha fetoprotein is usually elevated. Generally, SCTs are not related to aneuploidy, although rare cases of chromosomal abnormalities have been reported. The typical teratoma is a complex cystic and solid mass protruding from the fetal rump, with arterial and venous flow seen by color Doppler. Uncommonly, it may be entirely cystic or solid, extend into the fetal pelvis (Fig. 11.50) and abdomen, or undergo malignant degeneration. Some SCTs have unique characteristics, including those found

in the Currarino syndrome (presacral SCT, sacral malformation, and anorectal anomalies, with or without associated Hirschsprung disease and cloacal anomalies). Prenatal diagnosis is extremely important in planning timing and route of delivery, given tumor size and potential for hemorrhage, and in anticipation of postnatal surgery. Critically ill fetuses distant from term may benefit from referral to a fetal surgery center. Emergency delivery may be precipitated by tumor hemorrhage, mass effects, or by obstetric mirror syndrome, a rare maternal complication simulating severe preeclampsia. The prognosis for uncomplicated SCT is generally excellent, although anterior extension and high levels of circulating AFP and other markers, particularly in

• **Fig. 11.50** Fetal MRI of sacrococcygeal teratoma at 27 weeks' gestation. Tumor (*thick arrow*) extends into fetal pelvis between the spine (*thin arrow*) and the urinary bladder (*curved arrow*).

• **Fig. 11.51** Fetal retrognathia (recessed chin) is a feature of a variety of syndromes and aneuploidies, as noted in this fetus with trisomy 18.

immature teratomas, convey elevated risks for recurrence or malignancy.[33,34]

Head and Neck

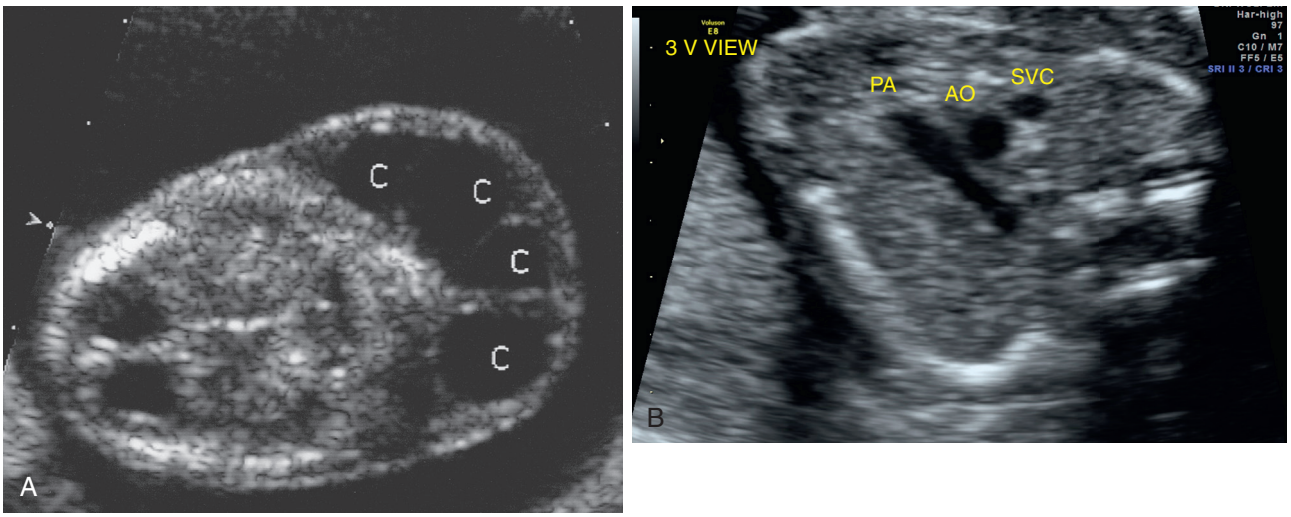
After 14 weeks, visualization of the nose, nares, orbits, forehead, lips, eyes, and ears is feasible. Orbits are clearly seen axially; the ocular diameters, and interocular and binocular distances (defining hypertelorism and hypotelorism) are measurable. The profile reveals the forehead, nose, and jaw sagittally (contrast Fig. 11.1 with Fig. 11.51). The coronal view, best for facial structures, includes the orbits (and lenses), eyelids, nose, and lips. Coronal and 3D views identify facial clefting, including cleft lip and palate; clefts may be central or lateral, unilateral or bilateral, involving nasal structures or, more subtly, the soft palate. Sagittal views should include the nasal bones; nasal bone hypoplasia or absence is associated with an increased risk for Down syndrome. The complex anatomy of the fetal face is shown exquisitely by 3D sonography. The distinction between

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

normal and abnormal facial features can be seen clearly by comparing Fig. 11.8 with Fig. 11.52.

Cystic hygroma is a septate, cystic mass arising from the neck and occipital region secondary to lymphatic malformation; it may extend over the entire trunk (Fig. 11.53*A*). Posterior septation of the nuchal ligament and bony integrity distinguish this lesion from neural tube defects. Associated aneuploidies, particularly monosomy X (45,X), are common. When associated with generalized edema, cystic hygromas carry a grim prognosis; when small, isolated, and with normal karyotype, more favorable outcomes, including regression, are well documented. Less common neck lesions include teratomas, hemangiomas, branchial cleft cysts, and anteriorly, thyroid goiters and thymic absence.

Increased nuchal translucency (see Fig. 11.11) and nuchal fold thickness (see Fig. 11.17) are associated with aneuploidies, including trisomies 21 and 18, cardiac malformations, diaphragmatic herniation, dwarfisms, a wide range of other anomalies and genetically inherited disorders (Noonan syndrome), lymphatic obstruction sequence, and fetal loss. With normal karyotypes and reassuring midtrimester surveys, outcomes are generally good.[47]

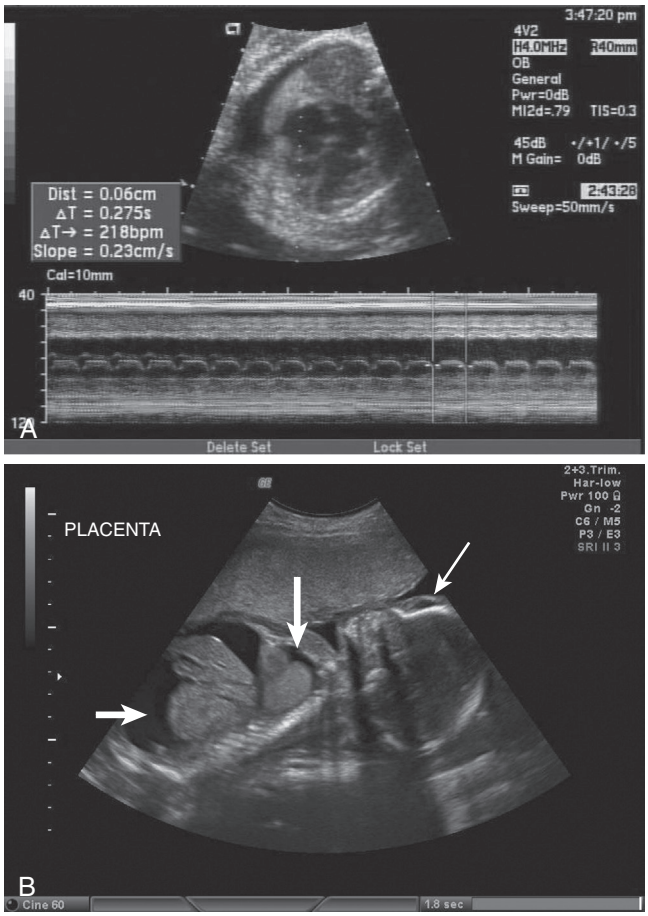


• **Fig. 11.52** Unremarkable fetal face shown on 3D imaging at 34 weeks' gestation. Views are optimized by adequate fluid interface, lack of fetal movement, limited maternal adipose and scarring tissues, and posterior placentation.

Heart

Optimal timing of the fetal heart study is a compromise between finding defects as soon as possible and accurately assessing complex anatomy, recognizing that some lesions manifest late in pregnancy. Basic heart evaluation is now an integral part of anatomic surveys at 18 to 22 weeks' gestation. Initial appreciation of first-trimester cardiac anatomy is feasible by either a transvaginal or transabdominal approach, augmented by color Doppler; however, the best timing for early imaging of the four chambers and great arteries is usually at 13 to 14 weeks. In experienced hands, first-trimester fetal echocardiography is quite sensitive for the detection of major structural cardiac abnormalities. Some features useful in combination with nuchal measurements for aneuploidy screening include abnormal flow patterns in the ductus venosus and tricuspid valve; these are also early markers for cardiac abnormalities and should prompt more detailed assessment. A focused cardiac examination should be performed for known medical or historical risks, with teratogen exposures, and when any significant extra-cardiac anomaly or chromosomal defect has been identified. Cardiac defects should also be excluded in the presence of an aberrant right subclavian artery or other vascular anomalies.[47]

Screening for fetal cardiac abnormalities was introduced more than 30 years ago, yet prenatal detection remains challenging. Most major congenital heart defects are amenable to prenatal identification, with tertiary centers reporting high diagnostic accuracy; however, overall detection rates remain low and highly operator dependent. Pregnancies



• **Fig. 11.53 A,** Transverse image through the head showing a posteriorly located cystic hygroma with multiple septate cysts (C). **B,** Three-vessel view of the fetal heart. The pulmonary artery (PA), aorta (AO), and the superior vena cava (SVC) can be seen.

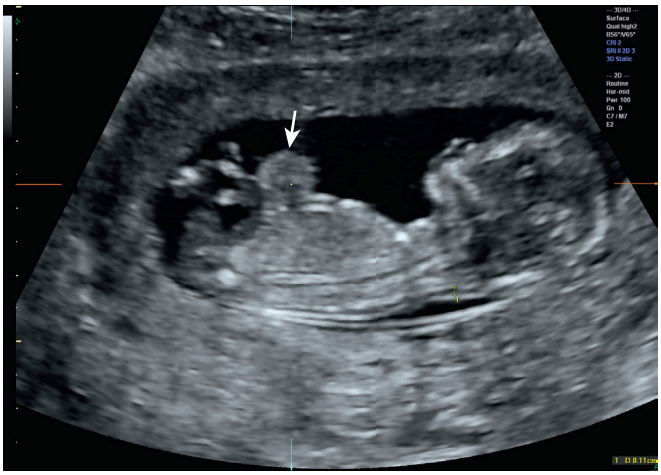
with predisposing factors are usually referred for echocardiogram, but most cases of congenital heart disease occur in low-risk pregnancies. Prenatal diagnosis, particularly for babies at risk for acute cardiovascular collapse, for example, with ductal dependent or restrictive lesions, could reduce both morbidity and mortality.[39]

Basic cardiac studies attempt to obtain symmetric, appropriately oriented four-chamber views of the fetal heart (see Fig. 11.36), showing pulmonary veins, atrioventricular valves, intra-atrial and intraventricular septa, as well as aortic and ductal arches and normal outflow views that link the aorta and neck vessels with the left ventricle and the bifurcating pulmonary artery with the right. The echocardiographic three-vessel view (see Fig. 11.53*B*) allows assessment of the superior vena cava, ascending aorta, and main pulmonary artery. These views aid in identification of transposition of the great arteries, tetralogy of Fallot, truncus arteriosus, and some aortic abnormalities.

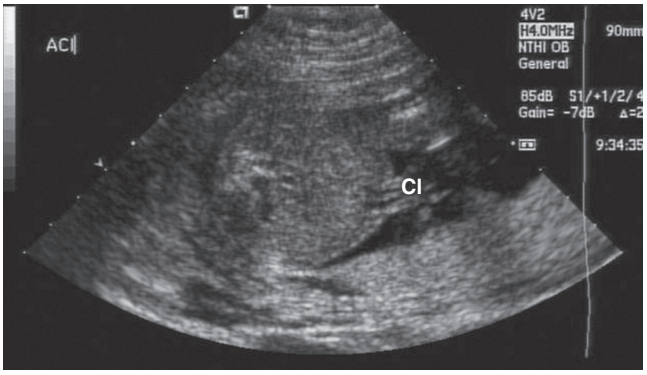
Fetal arrhythmias may also be analyzed (Fig. 11.54). Sensitivity for complex cardiac lesions exceeds that for isolated septal defects; accurate diagnosis remains dependent on experience and the absence of obstacles posed by poor resolution or unfavorable fetal position.

• **Fig. 11.54** Fetal arrhythmia by M-mode (**A**), consistent with paroxysmal atrial tachycardia at 218 bpm. Sustained rates greater than 200 bpm may be associated with fetal hydrops (**B**). The fetus has ascites (*short arrow*), pleural effusion (*long arrow*), and skin edema (*thin arrow*).



Gastrointestinal Tract

Normal Bowel Appearance



Physiologic migration of the gut into the proximal umbilical cord occurs between gestational weeks 7-10 and may be seen on first-trimester scans (Fig. 11.55) up to 12 weeks. The normal liver always remains intra-abdominal; bowel migration should not be mistaken for a ventral abdominal wall defect.

The fetal stomach, seen transvaginally by 9-10 weeks of gestation, is an echo-free structure in the upper left abdomen, varying in size as it empties and fills.

Fetal small bowel is not undifferentiated in appearance early in gestation but appears as central abdominal fluid-filled loops by the late second trimester (Fig. 11.56). Fetal colon is clearly evident by the third trimester as a hypoechoic, haustrated tube at the abdominal periphery. Meconium in the large bowel is normal in the third trimester; second-trimester meconium normally may have transiently increased echogenicity. Hyper-echogenic bowel, bright as adjacent osseous structures, is a concerning but nonspecific finding associated with trisomy 21, cystic fibrosis,

• **Fig. 11.57** Massive dilation of bowel loops secondary to in utero volvulus with obstruction. The stomach and duodenal bulb are marked with arrows. Polyhydramnios is present.

• **Fig. 11.58** Dilation of small bowel loops associated with ileal obstruction and perforation. The echogenic material (*arrow*) is a meconium pseudocyst.

bowel atresia, congenital infections (e.g., cytomegalovirus), growth restriction, placental abruption, and poor outcome.[1]

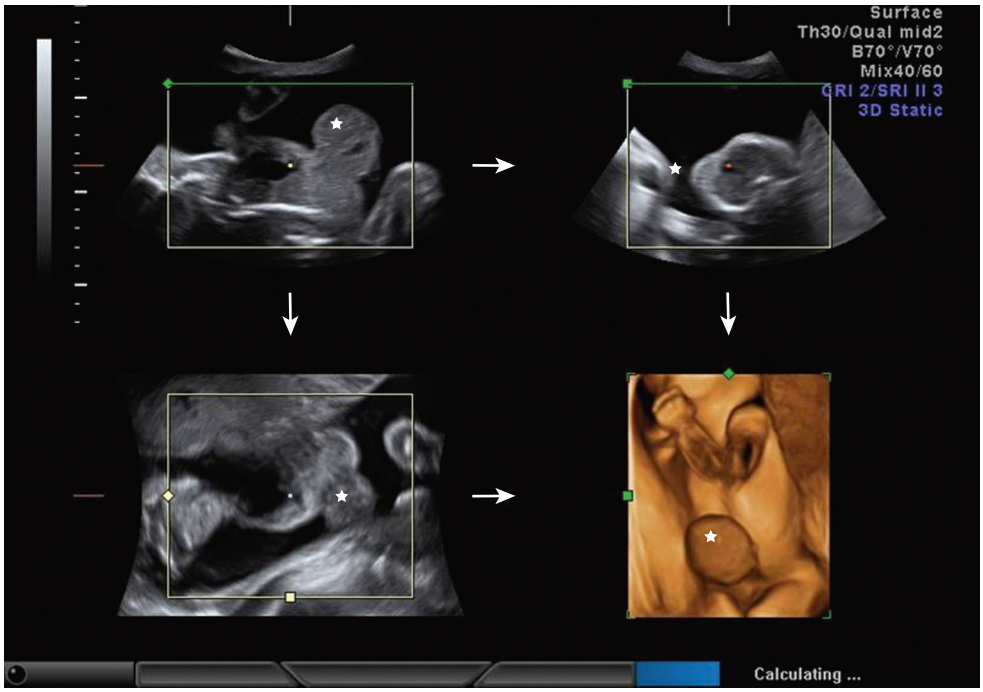
Gastrointestinal tract obstruction can often be diagnosed by ultrasound. Blockage of the proximal alimentary canal interferes with normal amniotic fluid regulation by fetal swallowing and gut absorption. In complete proximal obstructions, assuming intact membranes and normal renal production, polyhydramnios is invariable.

Esophageal Atresia and Tracheoesophageal Fistula

A nonvisualized fetal stomach combined with polyhydramnios should alert the examiner to the possibility of esophageal atresia. Unfortunately, these signs coincide in only 40% of cases. Nonvisualization of the stomach is not specific for esophageal atresia; proximal esophageal pouches are rarely visualized. Polyhydramnios, although present in two-thirds of cases, may not develop until the third trimester. The VACTERL complex consists of vertebral, anal, cardiovascular, tracheal, esophageal, renal, and limb malformations; these systems should be scrutinized if tracheoesophageal fistula is suspected. The stomach may also fail to fill when there is little fluid to swallow (e.g., as in oligohydramnios, or secondary to neuromuscular conditions like Pena-Shokeir syndrome that interfere with swallowing).

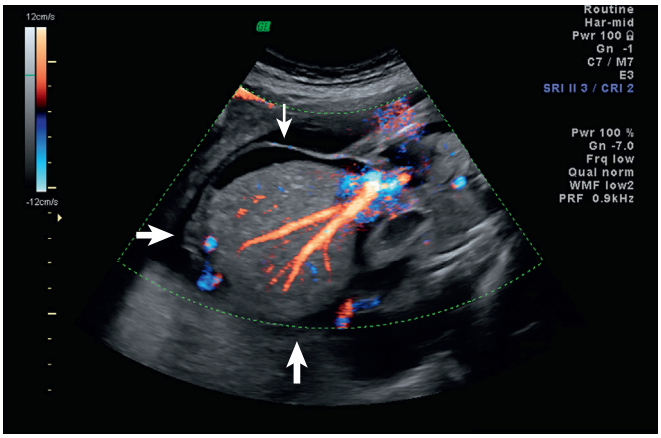
Small Bowel Obstruction

In duodenal atresia, the distended stomach and proximal duodenum produce a "double-bubble" sign akin to the neonatal radiologic finding (see Fig. 11.15). A strong (25%) association with trisomy 21 warrants genetic testing when duodenal atresia is suspected. Other etiologies include annular pancreas, duodenal web, malrotation, and severe duodenal stenosis. Ileal and jejunal atresias usually cause multiple distended bowel loops, often exhibiting exaggerated peristalsis (Fig. 11.57). More distal obstruction, as seen in meconium ileus, Hirschsprung disease, and anal atresia, may not result in visible bowel dilation until third trimester or postpartum. Meconium peritonitis, a sterile but morbid chemical response to intrauterine bowel perforation, is characterized by echogenic peritoneal calcifications and free intraperitoneal fluid (Fig. 11.58); some cases progress to echogenic pseudocysts.



Anterior Abdominal Wall Defects

A midline ventral abdominal wall defect involving the base of the umbilical cord is characteristic of omphalocele (Fig. 11.59). A sac surrounds the herniated viscera and may include the liver (Figs. 11.60 and 11.61). Omphaloceles are often associated with other anomalies (Beckwith-Wiedemann syndrome, pentalogy of Cantrell) and aneuploidies (trisomies 13 and 18). In gastroschisis, herniated bowel loops float freely in the amniotic cavity without a covering membrane (Fig. 11.62). Defects are usually to the right of the umbilical insertion; aneuploidy, extra-intestinal abnormalities, familial forms, and recurrence are not customary with gastroschisis. Gastroschisis is thought to be caused by a vascular accident with wall infarction; young maternal age, use of vasoactive substances, and NSAIDs have been related to increased risk for this lesion.



Diaphragmatic Hernia and Thoracic Lesions

Congenital diaphragmatic hernia (Fig. 11.63) is diagnosed when abdominal organs (usually stomach and bowel) are seen in the thorax. Fluid-filled intrathoracic bowel loops with visible peristalsis help confirm the diagnosis. Associated congenital heart disease, other structural defects, and chromosomal abnormalities worsen a guarded prognosis. Hernia contents produce a mass effect, shifting the mediastinum and compressing the lungs (Fig. 11.64); the resulting pulmonary hypoplasia and secondary pulmonary hypertension are major determinants of mortality. Polyhydramnios and lagging abdominal circumference are common associations. Estimation of lethality is usually based on lung measurements at the level of the four-chamber heart (expressed as

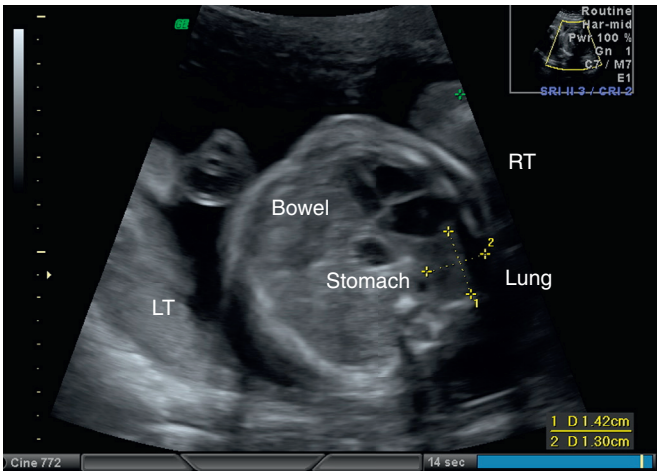
• **Fig. 11.61** Fetal MRI of omphalocele at 24 weeks' gestation. Note membrane (*thin arrow*) covering the omphalocele that includes the liver. Fetal stomach and bladder are shown by *thick arrows*. Note normal smooth brain surface at 24 weeks without gyri or sulci.



observed to expected lung/head circumference); the process is unreliable, largely because most lesions are in an intermediate prognostic category. Calculated 3D lung volumes by ultrasound study and MRI provide more precise measurements of the lungs but with only minor impact on prognostic accuracy. Liver herniation into the chest (Fig. 11.65) is common but carries a worse prognosis; right-sided hernias are harder to recognize and may also increase mortality. Bilateral herniation is generally lethal with few documented exceptions.

Congenital pulmonary adenomatoid malformations (Fig. 11.66) may have cysts with a similar appearance to bowel but lack peristalsis and displacement of identified abdominal organs. Microcystic forms are echogenic and resemble sequestrations; the latter usually have systemic arterial feeding vessels (Fig. 11.67), although blended forms have been described. Growth is variable, with spontaneous regression during pregnancy commonly reported. "Vanishing" lesions, not identified by postnatal x-rays, are always present on chest CT. Fetal hydrops may develop; fetal surgery

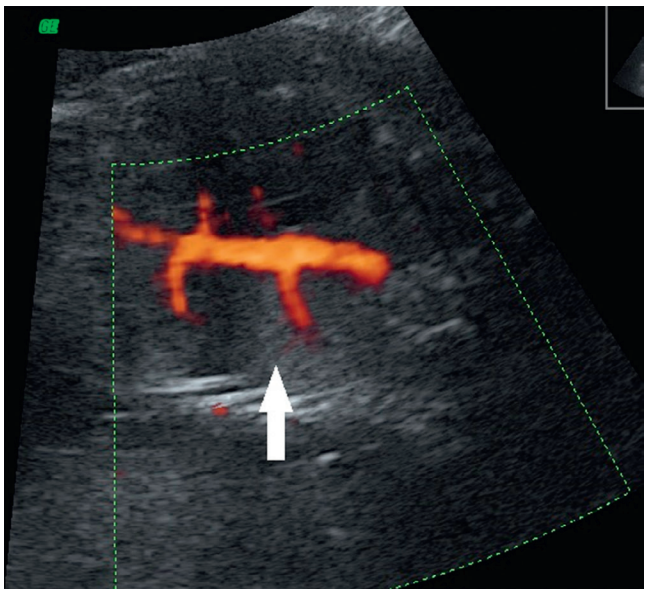
may be indicated to avert this potentially fatal complication. Gestational age-normalized congenital pulmonary airway malformation volume and congenital cystic adenomatoid malformation volume ratios have been proposed as methods for anticipation of hydrops. The latter ratio has been used to identify the need for fetal intervention. In predominantly microcystic lesions, maternal betamethasone therapy has been reported to lower risks for polyhydramnios and fetal hydrops.[13]



Gallbladder and Bile Ducts

A choledochal cyst is a localized circular dilation of the biliary system, often involving the common bile duct and located in the upper right abdominal quadrant, separate from the gallbladder. Echogenic gallstones and sludge are noted in the gallbladder lumen on third-trimester scans (Fig. 11.68) in one out of every 200 fetuses. The prognosis of fetal gallstones and biliary sludge is favorable. Follow-up studies in neonates generally confirm resolution once separated from the maternal hormonal milieu; infants are usually asymptomatic. The fetal gallbladder can often be seen after 14 weeks' gestation; its rare absence, suspected by persistent nonvisualization, is associated with a variety of abnormal conditions, most notably biliary atresia and cystic fibrosis.[16]

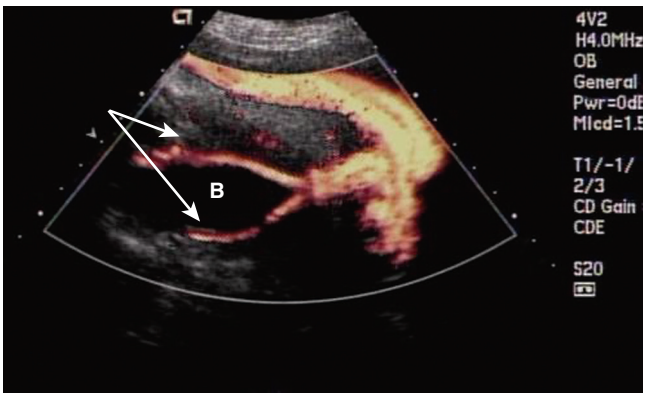
Genitourinary Tract



The kidneys, readily visible by 12-14 weeks' gestation, are located lateral to the fetal spine (Fig. 11.69) below the diaphragm and prominent fetal adrenal glands. Normal renal size and volume can be plotted against gestational age. By the late third trimester, fat deposition creates an echogenic border, enhancing visualization. The bladder, may be seen by 11 weeks of gestation, flanked by paired umbilical

• **Fig. 11.68** Fetal gallbladder (*GB*) (*arrow*) with echogenic sludge and small calculi in the third trimester. Findings usually resolve once maternal hormonal levels decrease. Compare with normal echo-free appearance in Fig. 11.19.

• **Fig. 11.70** Power Doppler demonstration of two umbilical cord arteries (*arrows*) outlining the fetal bladder (B).

arteries (Fig. 11.70). Normal fetal ureters are not visible by ultrasound. Fetal adrenal glands are usually identifiable because of a relatively large cortex and unique, contrasting echo textures.

Lethal renal malfunctions, including bilateral multicystic dysplasia, bilateral agenesis, and some cases of congenital

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

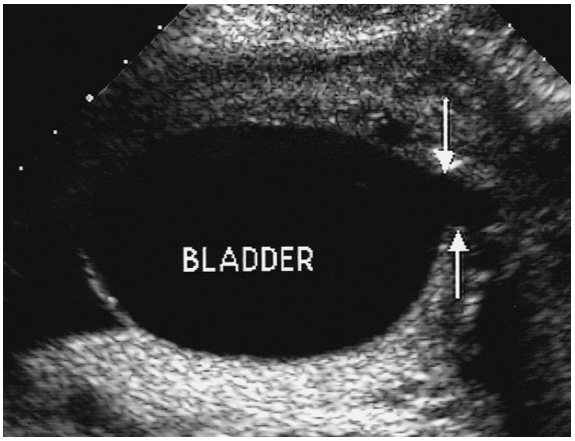
autosomal recessive polycystic kidney disease result in failure of fetal urine production. After 16 weeks, amniotic fluid is almost entirely fetal urine, but oligohydramnios may not become apparent until 18-20 weeks of gestation. Infants born after prolonged oligohydramnios have a characteristic facial appearance, limb deformities, and pulmonary hypoplasia, termed Potter syndrome (or sequence). The finding of oligohydramnios should direct attention to the fetal urinary tract with rescanning at 30-minute intervals for confirmation if the fetal bladder is not initially visualized. Anhydramnios (no measurable fluid), a persistently empty bladder, and an inability to identify fetal kidneys or renal arteries are strongly suggestive of bilateral renal agenesis. Unfortunately, absence of amniotic fluid may impede making a secure diagnosis with its associated implications for management, particularly because fetal adrenal glands, losing their normal angulation in renal agenesis, may be mistaken for kidneys. Fetal MRI can be ideal in establishing this lethal diagnosis. Care must be exercised when suspecting unilateral renal agenesis to exclude renal ectopy (pelvic kidney); color Doppler may reveal the aberrant course of the renal artery (see Fig. 11.4).

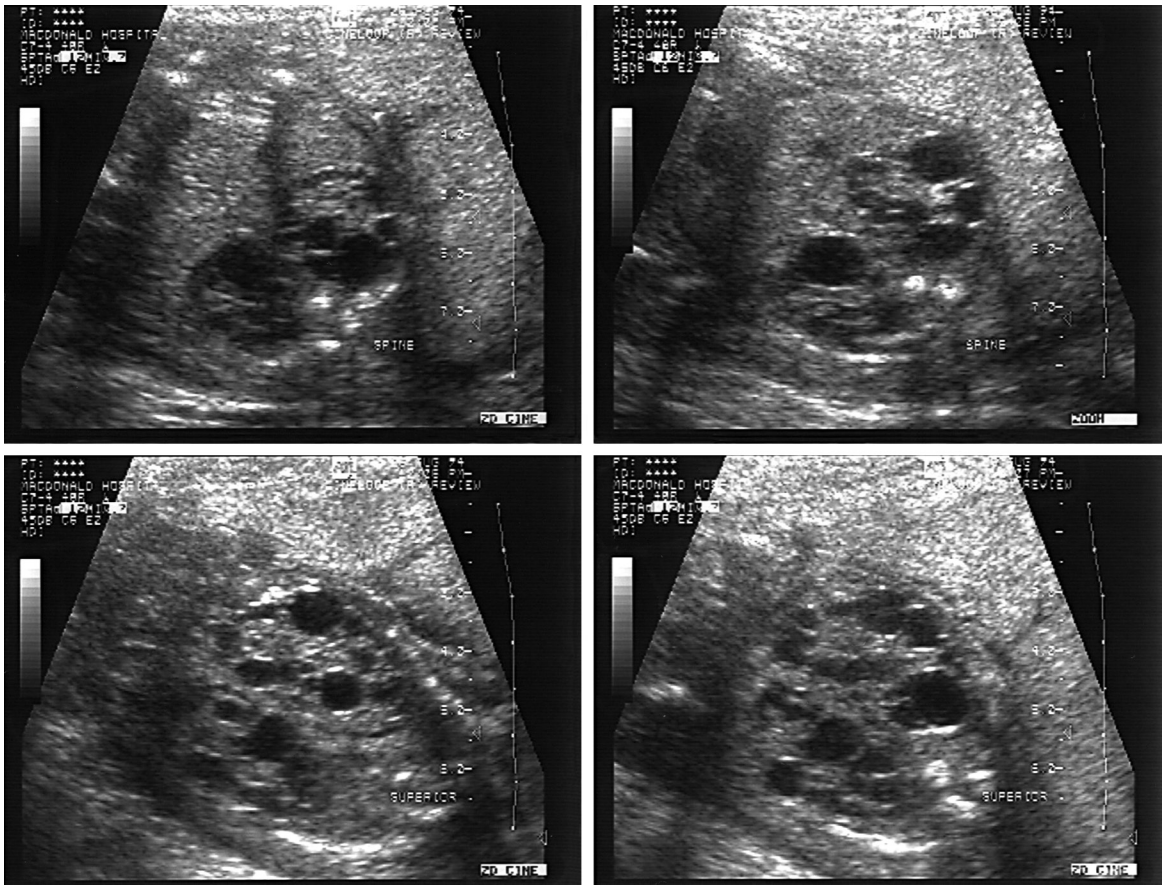
Pyelectasis (dilation of the renal pelvis), occurring in up to 5% of pregnancies, is a variant that should not be misinterpreted as hydronephrosis. Pyelectasis is considered a minor marker for trisomy 21 but when isolated is not usually an indication for amniocentesis; transient urinary reflux is a common underlying cause. Measurements of anteroposterior views of the kidneys and renal pelves in the transverse plane are used to identify both pyelectasis and hydronephrosis. Upper limits of 4 mm and 7 mm in second and third trimesters respectively define pyelectasis, with normalization by the third trimester routinely anticipated. Pelvic dilation above 1 cm is suspicious for hydronephrosis, particularly with calyceal involvement. Vague correlation exists between the magnitude of fetal renal pyelectasis and renal abnormalities. Persistent pyelectasis should be confirmed neonatally and followed until either resolved or an etiology established.[44]



Urinary tract obstruction may have a variable sonographic appearance, depending mainly on timing of onset. Renal dysplasia, sometimes with cyst formation, is the consequence of early obstruction; obstruction occurring later in gestation is more likely to result in dilation of the collecting system (Fig. 11.71).

Hydronephrosis may be unilateral, resulting from obstruction of the ureteropelvic or ureterocystic junctions, or bilateral, secondary to lower tract obstruction by posterior urethral valves or urethral agenesis. A distended, thick-walled bladder may be seen in males with posterior urethral valve, along with hydroureters; urinary ascites may occur as a result of calyceal or bladder rupture with intraperitoneal accumulation of urine. "Keyhole" dilation of the posterior urethra helps in distinguishing this lesion from Eagle-Barrett (prune-belly) syndrome (Fig. 11.72).

Multicystic dysplastic kidney disease (MCDKD) is commonly an incidental unilateral finding on prenatal examination. Bilaterality is less frequent but lethal. In unilateral cases, abnormalities of the contralateral kidney are common.[24] Associated nonrenal abnormalities occur frequently with both unilateral and bilateral MCDKD, increasing risks for chromosomal abnormality. Males predominate in unilateral MCDKD (ratio of 2.4:1), but females are four times more likely to have chromosomal abnormalities and twice as likely to have nonrenal anomalies or lethal bilateral disease.[24] The option of chromosomal analysis should be discussed whenever there are extrarenal abnormalities or bilaterality. Unilateral isolated MCDKD with normal amniotic fluid is not associated with abnormal genetic studies and usually has a favorable outcome; however, a neonatal work-up to exclude reflux in the unaffected kidney should be performed.[37]



• **Fig. 11.71** Fetal MRI at 35 weeks' gestation. Note massive hydronephrosis with dilated tortuous ureter on contralateral side (*thick arrow*). Fetal urinary bladder is shown (*thin arrow*).

• **Fig. 11.73** Multiple views of bilateral multicystic dysplastic kidneys. This diagnosis is considered incompatible with postnatal survival and is always associated with severe oligohydramnios in the second half of gestation. Note lack of fluid interface.

Severe hydronephrosis, in contrast to MCDKD, is an orderly arrangement of the enlarged renal pelvis with connecting, dilated calyces. Bilateral renal anomalies (including bilateral secondary multicystic renal dysplasia) are common (4%) in the fetus (Fig. 11.73). Dilated ureters occur in ureterovesical junction obstruction, primary megaureter, or secondary to reflux. Infantile autosomal recessive polycystic kidney disease causes bilaterally enlarged, echogenic reniform kidneys (Fig. 11.74). Other renal and urogenital anomalies identified prenatally include cysts, masses, duplicated collecting systems, and bladder exstrophy; in the last, a nonvisualized bladder coincides with normal amniotic fluid and renal appearance. A short or bifid male phallus is sometimes associated.

Reliable identification of male and female sex is anticipated after 16 weeks' gestation (see Fig. 11.37) by external genital examination, with interposition of uterus noticeably separating the fetal bladder from the rectum. Fetal ovarian cysts, fluid-filled or septate, are often abdominal and hard to distinguish from gastrointestinal and other lesions. Hydrometrocolpos may also produce a complex fluid-filled pelvic structure (see Fig. 11.37*C*).

Identification of genes involved in sex differentiation, noninvasive prenatal genetic screening, measurements of

• **Fig. 11.74** Congenital infantile polycystic kidney disease. Transverse abdominal scan shows echogenic, enlarged kidneys filling the fetal abdomen (*arrows*). The renal pelvis (P) is seen in the superior kidney. Oligohydramnios is present.

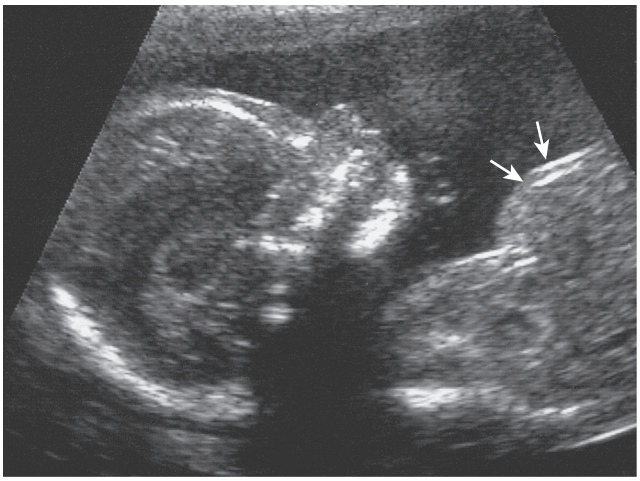
key mediating hormones, combined with ultrasound, have allowed multidisciplinary teams to identify cases of ambiguity, conduct detailed prenatal evaluations, and provide informed parental counseling.

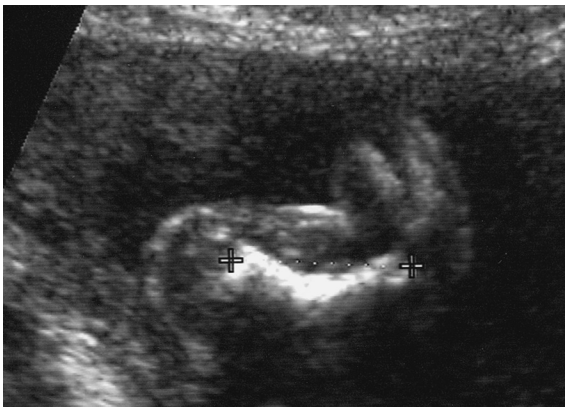
Following the characterization of the sex-determining region on the Y chromosome in 1990, there have been a number of genes found to play a role in sex development. The most common disorders of sex development (DSD) result from disruption of androgen levels and activity affecting later embryonal development, for example, congenital adrenal hyperplasia and androgen insensitivity syndrome. Available powerful genetic techniques can interrogate the entire genome for causative changes; it is important to critically assess the flood of genetic data for meaningful information. Recent discoveries have clarified roles of various transcription factors in DSD, including SOX9, SF1, and WT1 genes. Disruption of signaling molecules, such as hedgehog, WNT, cyclin-dependent kinase, and Ras/MAP kinase is known to cause some DSD. Dosage dependence of genes involved in gonadal development is a recurrent theme; genetic changes in promoter and repressor regions are being probed by microarray analysis and other techniques. Multiple phenotypes result from deletion, duplication, homozygous, heterozygous, and regulatory region changes in the same gene. Ongoing studies may yield clinically applicable insights into DSD and its underlying genetic basis.[23]

Musculoskeletal System



Examination of all four extremities and determination of femur length is routine in prenatal studies. Normograms exist for all fetal long bones, feet, and many other skeletal components. Measurements falling more than three standard deviations below the mean for age are very suspicious for skeletal dysplasia. Because normal individuals by definition populate the fifth percentile, it is reassuring that most skeletal dysplasias are dramatic; an abnormal femur-to-foot ratio (<0.89) provides additional diagnostic support. The biparietal diameter usually continues to reflect gestational age unless the skull is also involved.

Careful measurement of all bones in the peripheral skeleton is required in suspected cases, first to define the category of dysplasia and then, if possible, to make a diagnosis. Extreme generalized limb reduction or absence is termed *phocomelia*; overall limb shortening is *micromelia*; *rhizomelia* refers to proximal (femurs and humeri) reduction; *mesomelia* to more distal (forearms and lower legs); and *acromelia* to the most distal (feet and hands) dysplasias. Fractures and curvatures; altered bone density; the appearance of the spine, skull, and ribs; and extraskeletal anomalies may be keys to more specific diagnoses. Polyhydramnios may also be present and is often a poor prognostic sign.



Pulmonary hypoplasia from restrictive thoracic deformation is often the cause of death in severe skeletal dysplasias. Lung volume can be assessed by MRI or by 3D imaging, but a ratio of FL/AC below 0.16 functions as a convenient proxy for more cumbersome estimators for lethality.[37]

Thanatophoric dysplasia is uniformly fatal and relatively common, often recognizable in utero by severe micromelia, curved femurs, and narrow thorax (Fig. 11.75). Useful for diagnosis, when present, is a cloverleaf-shaped skull. Achondrogenesis, also lethal, manifests severe micromelia with poor vertebral ossification. Lethal type II osteogenesis imperfecta presents with short, angulated fractures of long bones and ribs (Fig. 11.76). Bone density, particularly calvarial, is decreased. Fatal forms of hypophosphatasia may have similar severe demineralization with strikingly clear resultant central nervous system imaging and easy compressability of the skull. Short-ribbed polydactyly syndrome, also lethal, is characterized by a small chest with hypoechoic truncated ribs, postaxial polydactyly, and polyhydramnios (Fig. 11.77).

Heterozygous achondroplasia is the most common nonlethal skeletal dysplasia; homozygous status is incompatible with survival. Shortening of the femur, frontal bossing, trident hand shape and increased amniotic fluid volume characterize this autosomal dominant rhizomelic disorder, rarely apparent prior to the third trimester. Prenatal genetic diagnosis is limited to known carriers. Eighty percent of

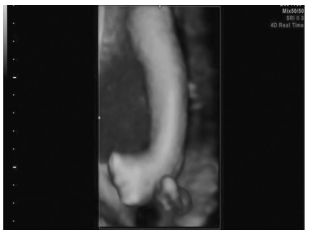
• **Fig. 11.77** Fetus with short-ribbed polydactyly syndrome. Multiple images show a small chest with hypoechoic ribs, large amounts of amniotic fluid, and postaxial polydactyly.

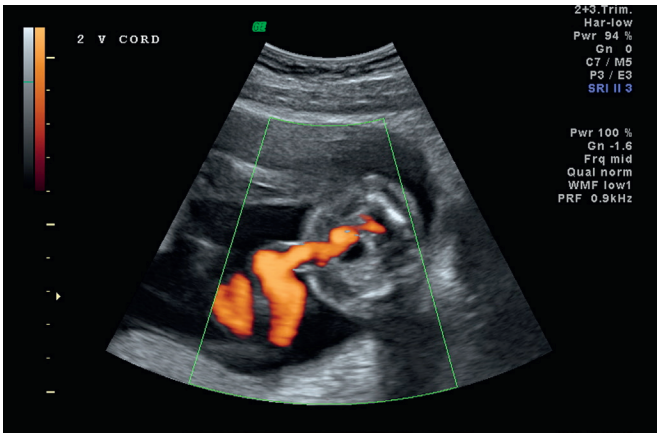
cases are new mutations; some are associated with advanced paternal age.

Other abnormalities of the musculoskeletal system include the malformation or absence (dysostosis) of various skeletal portions; for example, limb reduction anomalies including radial-ray syndromes (hypoplasia or absence, often affecting thumb development) and hemimelia. Amniotic band syndrome (Fig. 11.78) asymmetrically amputates or truncates an extremity, although the narrow strand may not persist. Valgus deformities of the feet (Fig. 11.79) may be isolated, familial, positional, or secondary to central nervous system and spinal cord abnormalities.

Pitfalls in the diagnosis of skeletal dysplasia are appreciable. Complete current classification from the International Skeletal Dysplasia Society is available online.[45] Classification of skeletal dysplasias is constantly being altered by new genetic information.



• **Fig. 11.78** Truncated fetal arm (*arrow*) secondary to amniotic band.



Two-Vessel Umbilical Cord

A single umbilical artery may be identified on transverse views of free cord loops or at the bladder bifurcation based on color Doppler (Fig. 11.80). Single umbilical arteries have been linked to other anomalies, unfortunately without a consistent pattern. Lack of normal coiling and short cords are also linked to abnormalities, particularly those affecting movement. It is unclear whether an isolated single umbilical artery is associated with aneuploidy, nor does the laterality of the absent vessel have significance. Being small-for-gestational age is more common in neonates with single umbilical artery. Counseling, selective use of amniocentesis, and serial third-trimester examinations to document fetal growth may be helpful in management.

Summary

As sonography nears maturity, it has had gratifying success in fulfilling its early potential. Initial limitations have yielded to advances in technology and technique or have been augmented by genetic and biochemical breakthroughs. MRI is now well established as a versatile partner to ultrasound in prenatal diagnosis. The future of imaging holds immense promise for continued progress in improving neonatal outcomes.

Key Points

- All practitioners who perform or supervise the performance of obstetric ultrasonography should be licensed medical practitioners, having received specific training in obstetric ultrasonography.
- Gray-scale B-mode ultrasound is associated with a negligible rise in temperature. Strong magnetic fields and radiofrequency waves are used in MRI with no known harmful effects. Large longitudinal studies confirming the safety of ultrasound and MRI are lacking.
- A standard ultrasound study should follow the guidelines published by the American Institute of Ultrasound in Medicine.
- An important application of prenatal ultrasound is using biometrics to establish gestational age and the utility of the biophysical profile to confirm fetal well-being.
- Genetic screening of the fetus should combine ultrasound study and biochemical testing or cell-free fetal DNA to enhance the detection of chromosomal abnormalities.
- Neonatal outcomes can be optimized by forewarning and timely preparation when fetal abnormalities are present.
- Nondiagnostic studies, varying prognoses for a given diagnosis, and the inherent limitations of ultrasound and MRI studies might lead to ethical issues in management and counseling.

Estimation of Fetal Well-Being

DAVID N. HACKNEY

In high-risk populations at increased risk of perinatal mortality, antenatal fetal surveillance is often employed in an attempt to prevent stillbirth. Pregnancies at risk for progressive deterioration of placental function leading to fetal hypoxemia and acidosis are most likely to benefit from the methods currently in use. The various modalities, including non-stress test (NST), contraction stress test (CST), biophysical profile, and Doppler velocimetry, rely on fetal biophysical parameters that are significantly associated with the presence or absence of fetal hypoxemia. Because all tests are associated with a false-positive rate, each test result should be interpreted within the clinical context presented by the patient.

Despite the inherent stress of labor, most fetuses are able to tolerate the transient episodes of hypoxemia without harm. Rarely, the process of labor and delivery places a fetus in jeopardy of long-term neurologic damage or death as a result of profound hypoxemia and metabolic acidosis. Since the 1970s, electronic FHR monitoring has emerged as the most common technology to monitor fetuses during labor in the hopes of identifying at-risk fetuses to achieve delivery before permanent harm. Although not without benefit, monitoring has also likely resulted in a dramatic increase in cesarean deliveries without reducing the rate of cerebral palsy. Strategies to prevent fetal harm while reducing the incidence of cesarean delivery have been difficult to achieve, although potential benefits can be derived from standardization of practice.

Introduction

Antepartum testing entails the evaluation of fetal health through a variety of modalities, including fetal heart rate monitoring and ultrasound, occurring at points in pregnancy that are remote from delivery, as opposed to *intrapartum* testing, which is performed in the patient experiencing labor. A false-negative test will be one that fails to identify a fetus at risk of death or major morbidity, which could have been prevented by delivery. False-positive results, however, can lead to iatrogenic preterm birth, which itself can be associated with significant morbidity. Even if testing does not lead to delivery, positive results can also generate significant maternal anxiety and stress, as well as cost. The optimal antepartum fetal testing strategy would appropriately identify an at-risk fetus prior to an irreversible event while minimizing maternal anxiety, cost, and iatrogenic prematurity. Such optimization, however, has been difficult to achieve.

Antepartum Fetal Surveillance

Indications for Surveillance

Intrauterine fetal death may result from a wide range of potential etiologies, including congenital structural malformations, genetic abnormalities, fetomaternal hemorrhage, infection (TORCH and chorioamnionitis), umbilical cord obstruction, placental abruption, and uteroplacental insufficiency.[20] The methods commonly used for antenatal fetal surveillance rely on fetal biophysical parameters that are sensitive to hypoxemia and acidemia, such as heart rate and movement. Thus, it is primarily useful in a fetus at risk for hypoxemia specifically because of chronic uteroplacental insufficiency. Intrauterine demise from sudden catastrophic events, such as abruption, maternal trauma, or cord occlusion, is likely not predictable by antepartum monitoring.

The indications for antenatal testing are those that increase the risk of uteroplacental insufficiency, many of which are listed in Table 12.1. The optimal antenatal testing strategy for each of these would be beyond the scope of a single chapter, and additionally in many circumstances the exact strategy is controversial, because there is often little or no prospective or randomized data from which to determine an optimal approach. Many conditions for which testing has been suggested are those for which epidemiologic studies have identified an increased risk of intrauterine demise. However, in some circumstances the risk of stillbirth, although achieving statistical significance in large studies, may remain small in actual magnitude. Additionally, an association between a particular risk factor and stillbirth alone does not necessarily demonstrate that there is a benefit from antenatal surveillance, because that would require a specific study of antepartum testing for the given risk factor. For example, maternal obesity is associated with an increased risk of stillbirth,[4] but because there are few or

TABLE 12.1 Indications for Antenatal Surveillance

Maternal Conditions	Pregnancy-Related Conditions
• Antiphospholipid syndrome • Hyperthyroidism (poorly controlled) • Pre-gestational diabetes mellitus • Cyanotic heart disease • Systemic lupus erythematosus • Chronic hypertension • Chronic renal disease • Hemoglobinopathies (hemoglobin SS, SC, or S-thalassemia)	• Pre-eclampsia • Decreased fetal movement • Oligohydramnios • Polyhydramnios • Intrauterine growth restriction • Complicated multiple gestation • Gestational diabetes with poor control • Premature rupture of membranes

From American College of Obstetricians and Gynecologists. *Antepartum Fetal Surveillance, ACOG Practice Bulletin 9*. Washington, DC: ACOG; 1999.

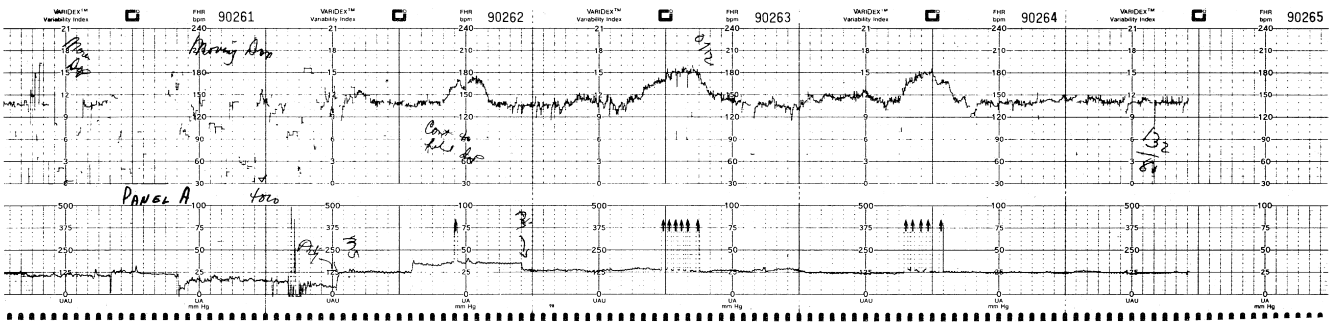
no prospective interventional studies, exact recommendations for monitoring are not available from professional societies.[19]

Of note, uterine contraction monitoring (tocometry) is performed simultaneously with electronic fetal cardiac monitoring as part of the non-stress and contraction stress test. This is primarily to allow for the interpretation of fetal heart rate decelerations relative to uterine contractile activity. Uterine contraction monitoring alone as a method of identifying patients at increased risk of preterm birth is of low clinical utility.

Physiologic Basis for Antenatal Surveillance

The application and interpretation of antepartum fetal monitoring necessitates an understanding of the progressive fetal changes that occur secondary to increasing placental insufficiency progressing to intrauterine demise. In experiments involving animal and human fetuses, hypoxemia and acidosis have been shown consistently to alter fetal biophysical parameters such as heart rate, movement, breathing, and tone. The fetal heart rate (FHR) is normally controlled by the fetal central nervous system (CNS) and mediated by sympathetic or parasympathetic nerve impulses originating in the fetal brainstem. The presence of intermittent FHR accelerations associated with fetal movement is believed to be an indicator of an intact fetal autonomic nervous system. In historic studies of fetal blood sampling of pregnancies resulting in healthy neonates, Weiner and colleagues established a range of normal fetal venous pH measurements.[22] In this population, the lower 2.5 percentile of fetal venous pH was 7.37. Manning and colleagues showed that fetuses without heart rate accelerations had a mean umbilical vein pH of 7.28 (±0.11), and fetuses with abnormal movement had a mean pH of 7.16 (±0.08).[16] These and similar observations were the basis for the development of antenatal fetal testing modalities that are currently in use.

Patient Assessment of Fetal Movement



The patient's own subjective assessment of the fetal activity is perhaps the simplest and most universal of antepartum surveillance methods, although its subjective nature leads to difficulty in quantification and empiric evaluation. As described above, fetal movement decreases with increasing hypoxia, which also serves as the physiologic basis of the biophysical profile as described below. As a result, a decrease in subjective fetal movement should usually be evaluated. Beyond this generalized recommendation, various formalized strategies of fetal monitoring (colloquially referred to as "kick counts") have been proposed. One of the more common is to determine the time it takes for the perception of 10 movements during a period of specific, restful evaluation and to contact one's provider if the duration is 2 hours or more. However, systematic reviews have identified neither an optimal strategy nor clear evidence that routine, quantified fetal movement assessment can prevent stillbirth.[14]

Non-Stress Test

In most institutions, the first-line assessment tool for fetal surveillance is the non-stress test (NST). In the outpatient setting, the patient typically rests in a reclining chair with a lateral tilt or semi-Fowler. Ideally she should have not recently smoked. Although commonly provided in antepartum testing units, the maternal ingestion of juice or food has not been demonstrated to increase the probability of a reactive non-stress test. The FHR is monitored with an external transducer for up to 40 minutes and observed for the presence of accelerations above the baseline. A reactive test is one in which there are at least two accelerations that peak 15 beats/min above the baseline and last (not at the peak) for at least 15 seconds before returning to baseline (Fig. 12.1), colloquially referred to as "15 × 15." Most NSTs are reactive within the first 20 minutes. For tests that are not, possibly because of a fetal sleep cycle, an additional 20 minutes of monitoring may be needed. A nonreactive NST is one in which two such accelerations do not occur within 40 minutes.

The optimal gestational age at which to begin antenatal surveillance depends on the clinical condition. In making this decision, the physician must weigh the risk of intervention at a premature gestational age against the risk of intrauterine fetal death. Initiation at 32-34 weeks' gestation is reasonable for most at-risk patients, with the acknowledgment that some situations may warrant testing earlier at 26-28 weeks of gestation. FHR variability and reactivity vary with gestational age, with an increasing frequency of tracings that lack "15 × 15" accelerations with decreasing gestational age under 32 weeks. Thus, prior to 32 weeks, non-stress tests are considered reactive if there are two

• **Fig. 12.1** Reactive non-stress test showing accelerations occurring with fetal movement. Note the arrows on the contraction channel. (From Freeman R, Garite T. *Fetal heart rate monitoring*. Baltimore: Williams & Wilkins; 1981.)

accelerations that peak 10 beats/min above baseline and last for at least 10 seconds ("10 × 10"). Of note, the magnitude of accelerations in fetuses less than 32 weeks can vary normally over time, thus a fetus at less than 32 weeks is reactive by 10 × 10 criteria even if it had previously demonstrated 15 × 15 accelerations.[9]

Although the NST is noninvasive and easy to perform, it is limited by a high false-positive rate. Normal fetuses often have periods of nonreactivity because of benign variations such as sleep cycles. Vibroacoustic stimulation may be used safely in the setting of a nonreactive NST to elicit FHR accelerations without compromising the sensitivity of the NST. In this situation, the operator places an artificial larynx on the maternal abdomen and activates the device for 1-3 seconds. This technique is often useful in situations in which the FHR has normal beat-to-beat variability and no decelerations but does not show any accelerations. If the test remains nonreactive, further evaluation with a biophysical profile or contraction stress test (CST) is warranted as long as the FHR is otherwise reassuring. However, if the tracing is overtly concerning (see Category III later in this chapter), additional testing may need to be deferred in favor of delivery depending upon the exact gestational age and clinical circumstance.

Contraction Stress Test

The CST is designed to evaluate FHR response to maternal uterine contractions. The principles that are applied to the evaluation of intrapartum FHR monitoring (see FHR Monitoring) are used here. In response to the stress of the contraction, a hypoxemic fetus shows FHR patterns of concern, such as late decelerations.

Similar to the NST, for the CST the patient is placed in a recumbent tilted position, and FHR is monitored with an external fetal monitor. The FHR pattern is evaluated while the patient experiences at least three contractions lasting 40 seconds within a 10-minute period. If the patient is not contracting spontaneously, contractions may be induced with nipple stimulation or intravenous oxytocin. Nipple stimulation can be self-administered by the patient or a breast pump can be used. If no late or significant variable decelerations are noted on FHR tracing, CST is considered to be negative. If there are late decelerations after at least 50% of the contractions, CST is positive. If late decelerations are present less than 50% of the time, or if significant variable decelerations are present, the test is considered to be equivocal. Contraindications to the performance of CST include clinical situations in which labor would be undesirable (e.g., placenta previa or previous classic cesarean section).

• BOX 12.1 Biophysical Profile Scoring System

1. Fetal breathing movements (one or more episodes lasting at least 30 seconds)
2. Fetal movement (three or more discrete body or limb movements)
3. Fetal tone (one or more episodes of active extension with return to flexion of a limb or trunk, or the opening and closing of a fetal hand)
4. Amniotic fluid volume
5. Reactive non-stress test

Biophysical Profile

The biophysical profile is based upon the general principle that a progressively hypoxic fetus will be less likely to engage in elective activities such as breathing or body motions, while an active fetus is likely also healthy. As originally described, it combines NST with four components evaluated by ultrasound (Box 12.1). In a 30-minute period, either 2 or 0 points are assigned depending upon if the criteria are fulfilled or unfulfilled. The final score will thus range from 0-10 with no odd numbers (either 0 or 2; 1 point is never awarded for each criteria). A combined score of 8 or 10 indicates fetal well-being. A score of 6 is considered to be equivocal; it usually merits delivery if the pregnancy is at term or additional or repeat (24 hours) testing if the pregnancy is preterm. A score of 4 or less is considered to be abnormal, and in the absence of reversible causes, consideration would need to be given to delivery except in uncommon extenuating circumstances. Of note,

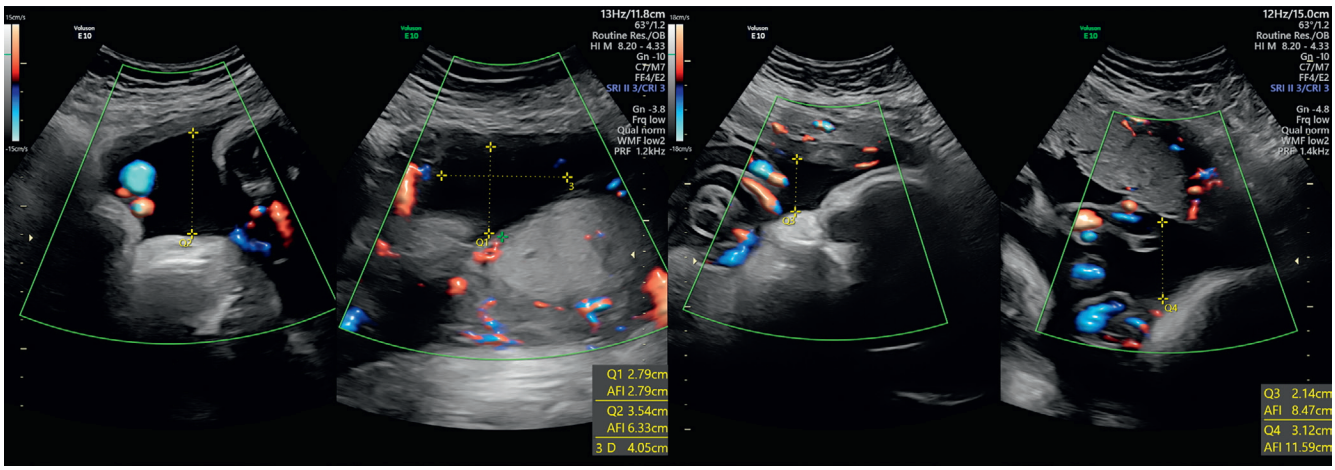
one of the five criteria in the BPP is the amniotic fluid volume. This can complicate interpretation of the testing in situations where the fluid volume is low for reasons that are independent of placental function, such as membrane rupture or congenital anomalies of the urinary tract.

Of note, fetal breathing is not usually present during active labor, to the extent that the absence of fetal breathing on ultrasound had previously been evaluated as an assessment tool for the presence of "true" preterm labor. Thus, biophysical profiles are not performed in patients who are actively laboring.

Amniotic Fluid Volume Assessment

Amniotic fluid volume is commonly estimated by ultrasound via one of two primary methods. The amniotic fluid index (AFI) is calculated by measuring and adding the maximal vertical pockets of fluid (without loops of umbilical cord) in each of the four quadrants of the maternal abdomen as demarcated by the umbilicus (Fig. 12.2). Alternatively, the single deepest vertical pocket of fluid alone can be measured. Decreased amniotic fluid volume, or oligohydramnios, is defined as either an AFI of 5 cm or less or no single measurable vertical pocket greater than 2 cm. Gestational age-specific nomograms are also available although are less commonly used. Neither AFI nor single deepest pocket is perfectly sensitive or specific for the detection of oligohydramnios.[13] Oligohydramnios can occur secondary to a range of causes including rupture of the fetal membranes and congenital fetal anomalies of the urinary tract. In the absence of membrane rupture or congenital anomalies, however, the most concerning etiology would be decreased fetal urine production secondary to the shunting of blood flow away from the fetal kidneys in the context of uteroplacental insufficiency.



When oligohydramnios is diagnosed, the first step is to rule out membrane rupture and congenital anomalies and, if not present, assess the fetus for other evidence of uteroplacental insufficiency, including fetal biometric measurements to assess growth restriction. Delivery is usually performed for oligohydramnios at term, although at preterm gestations, delivery decisions will involve multiple factors, including the exact gestational age and presumed etiology of the decreased fluid, with conservative management being reasonable in many circumstances. More information on the management of amniotic fluid disorders is covered in Chapter 24.

Doppler Flow Velocimetry

Quantitative evaluation of maternal and fetal blood vessels by Doppler sonography has been the focus of intense research over the last several years and is continuing to evolve rapidly. The list of clinical scenarios in which it has been utilized includes the evaluation of the fetal middle cerebral artery in cases of red blood cell isoimmunization, monochorionic twins with twin–twin transfusion syndrome, the screening and diagnosis of congenital cardiac anomalies, and the diagnosis of congenital vascular anomalies. These indications will likely continue to expand. However, the primary utility of Doppler sonography is in the evaluation of a fetus with possible intrauterine growth restriction. In normal pregnancies or when the fetus has demonstrated normal growth, there is no current role for Doppler sonography of fetal vessels, because they have not been found to convey benefit in a low-risk population. Use of Doppler velocimetry in the setting of intrauterine growth restriction is presented in Chapter 15.

Interpretation of Test Results

The realistic goal of antepartum testing is to decrease the risk of intrauterine fetal demise or perinatal mortality in the tested population so that it approaches the rate for a low-risk population without an excessive or unacceptable false-positive rate that may result in unnecessary intervention. The false-negative rate for commonly employed antepartum tests is very low, with residual stillbirth rates after reassuring

• **Fig. 12.2** Ultrasound image of the maximal vertical pocket measured as part of either the biophysical profile or the amniotic fluid index. Note the absence of umbilical cord in the measured pocket.

testing approximating those of the general population. The false-positive rate, however, is more difficult to ascertain because a positive test usually results in obstetric intervention, significantly decreasing the likelihood of intrauterine death. However, babies delivered after abnormal testing do not always demonstrate abnormal findings such as acidemia or low Apgar scores. For example, Manning et al. reported on a cohort of 913 infants delivered after biophysical profile score of 6 or less.[15] Nearly 40% of infants with scores of 6 showed no markers of fetal compromise at delivery, as defined by fetal distress in labor, admission to the neonatal intensive care unit, a 5-minute Apgar score of 7 or less, or an umbilical cord pH less than or equal to 7.20. There was a significant inverse linear association, however, between biophysical profile score and these markers, and all fetuses with scores of 0 had at least one of these markers at delivery.

In a clinically stable situation, reassuring tests (reactive NST, negative CST, and biophysical profile of 8 or 10) are considered reliable for 1 week, and so testing is usually performed on a weekly basis. Labile conditions may merit more frequent testing; the frequency is left to the discretion of the physician. In certain high-risk populations, the false-negative rate of NST may be unacceptably high. The stillbirth rate within 1 week of a reactive NST is markedly higher for patients with diabetes mellitus and fetal growth restriction. Boehm and co-workers found that the stillbirth rate decreased from 6.1 per 1000 to 1.9 per 1000 in their high-risk population when the frequency of testing was changed from once weekly to twice weekly.[5] For this reason, testing twice weekly may be appropriate in certain populations, such as those described.

Clinically, one should always give consideration to maternal illness as a cause of nonreassuring fetal status. For example, if the mother is acidemic from any etiology, placental equilibration will eventually lead to acidemia in an otherwise healthy fetus, which in turn can lead to abnormal antenatal testing results. A classic example is maternal diabetic ketoacidosis. In such circumstances, the appropriate course of action is to correct the maternal condition first and not to necessarily directly intervene on behalf of the fetus despite the nonreassuring antenatal testing. The fetal status will improve as the maternal status is improved, thus avoiding iatrogenic delivery, and cesarean sections or other efforts to deliver the fetus may not be safe if the mother is critically ill.

Evaluation of the Intrapartum Fetus

The process of labor and delivery is a period of significant metabolic stress for both the laboring mother and her baby, although in the great majority of cases these stressors are easily tolerated, and labor results in a healthy mother and child. In some cases, however, the process is tolerated poorly, and the fetus develops a degree of acidosis that places it at risk of multiorgan dysfunction or even death. Thus, in the 1970s, FHR monitoring during labor was introduced, with the hope of identifying heart rate patterns that were predictive of adverse outcomes and would allow for intervention prior to irreversible events. Subsequently, continuous electronic FHR monitoring during labor has been used in the majority of laboring patients in developed countries for the last several decades. The initial hopes and promises of continuous FHR monitoring, however, have not been fulfilled during this time. The incidence of cerebral palsy has remained stable, whereas the cesarean section rate has progressively increased, in part because of operative deliveries being performed for FHR patterns that may or may not be sufficiently predictive of adverse outcomes.[11] The contemporary practitioner utilizing FHR monitoring during labor must thus be cautious to both intervene prior to an irreversible event and to avoid iatrogenic operative delivery. This has proved to be a difficult balance.

Intrapartum Oxygenation and Neurologic Morbidity

The strongest correlate to adverse outcomes is decreased tissue concentrations of oxygen (*hypoxia*) and decreased tissue pH (*acidosis*). What is more easily and often evaluated, however, is decreased oxygenation or pH in the peripheral blood, referred to respectively as *hypoxemia* and *acidemia*. These are what is measured when the blood from the umbilical artery and vein is sampled after delivery, and thus serve as common surrogate outcomes in clinical research. Although significant hypoxemia will eventually lead to tissue-level hypoxia and acidosis, the presence of the former does not necessarily guarantee the latter. Although hypoxemia and acidemia can be easily evaluated by laboratory methods, determining the presence or absence of hypoxia or acidosis is more complex and often involves physical and clinical more so than laboratory assessments.

Another important differentiation is between respiratory and metabolic acidosis in the fetus and neonate. The concept of a "respiratory" acidosis in a fetus may seem unusual, because they are not literally using their lungs to exchange air, although the same concepts that are useful outside of the uterus can be applied to the transplacental exchange of oxygen and carbon dioxide. A respiratory acidosis occurs when carbon dioxide accumulates secondary to impaired clearance by the lungs or, in the case of a fetus, the placenta. A fetal metabolic acidosis will be the result of a prolonged or severe deprivation of oxygen, triggering lactate production in fetal tissue. A respiratory or metabolic acidosis, although often occurring in combination, can be differentiated from one another by the measurement of base deficit, with a high base deficit indicating a metabolic process. Metabolic processes are more concerning than respiratory ones for several reasons. First, an umbilical artery acidemia with an increased base deficit strongly implies excess tissue lactate generation. Thus there is probable acidosis and not just acidemia. Additionally, a respiratory acidemia can rapidly correct itself once normal ventilation is established and excessive carbon dioxide is cleared, whereas the correction

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

of a metabolic acidosis requires the cessation of lactate generation at a tissue level and is thus delayed relative to the onset of appropriate oxygenation. Clinically, the newborn with an isolated respiratory acidosis (or acidemia) will have a low umbilical cord pH at birth and low 1-minute Apgar score, although once ventilation is established, will enjoy rapid clinical improvement and a subsequent uneventful newborn period. By contrast, the neonate who remains clinically depressed through the first several minutes of life despite adequate ventilation is more likely to have a metabolic acidosis and an increased umbilical artery base deficit.

As discussed previously, various findings in the FHR patterns have been correlated with fetal hypoxemia and acidemia. The outcomes of hypoxemia and acidemia, however, are in and of themselves surrogate outcomes. Although fetal risks increase with increasing metabolic derangements, many fetuses with hypoxemia and acidemia, especially if it is a purely respiratory process, will subsequently have a normal newborn course. If an operative delivery is performed in a fetus that has hypoxemia or acidemia but that would have, if left alone, delivered vaginally without permanent neurologic injury, then the intervention has not been clearly beneficial. The most meaningful clinical question then is if continuous FHR monitoring can predict the fetus that will not survive the labor process or survive with permanent neurologic injury secondary to intrapartum events. Given the multitude of complex factors that contribute to neurologic injury, it is perhaps not unsurprising that an evaluation of FHR alone has not proved to be sufficiently predictive in this regard. Using cerebral palsy as an endpoint, the positive predictive value of FHR monitoring is very low.

The overall determination of neonatal health following the stress of delivery is not determined by a single laboratory value, but a combination of laboratory and clinical evidence of metabolic acidemia with a clinical course that is consistent with a hypoxic event. For the child who is subsequently diagnosed as having cerebral palsy, a multitude of other potential etiologies (anatomic, infectious, genetic, thrombotic, and metabolic, among others) needs to be ruled out as well, because intrapartum hypoxic events account for only a small percentage of cases of neonatal neurologic injury. To provide guidance in these complicated issues, the American College of Obstetricians and Gynecologists and American Academy of Pediatricians convened a joint task force that in 2003 established criteria to define an acute intrapartum event as having been sufficient to cause cerebral palsy[17] with an update in 2014.[18] These criteria are outlined in Box 12.2, and the evaluation of neonatal encephalopathy is covered in detail in Chapter 54. In the absence of these explicit criteria, it is not optimal for a provider to ascribe neurologic outcomes to a potential intrauterine event, and appropriate caution should always be applied to the potentially inappropriate use of the expressions *asphyxia*, *newborn encephalopathy*, and *hypoxic-ischemic encephalopathy* in the medical records.

• BOX 12.2 Criteria to Define an Acute Intrapartum Event as Sufficient to Cause Cerebral Palsy

- Apgar score of less than 5 at 5 minutes and 10 minutes
- Evidence of a metabolic acidosis in fetal umbilical cord arterial blood obtained at delivery (pH <7 and base deficit ≥12 mmol/L)
- Evidence of acute brain injury on neuroimaging
- Multisystem organ failure consistent with neonatal encephalopathy
- A sentinel hypoxic event occurring immediately before or during labor and delivery
- Cerebral palsy of the spastic quadriplegic or dyskinetic type
- Exclusion of other identifiable etiologies such as trauma, coagulation disorders, infectious conditions, or genetic disorders

Adapted from *Neonatal encephalopathy and cerebral palsy: defining the pathogenesis and pathophysiology*. Washington, DC: American College of Obstetricians and Gynecologists; 2003.

Continuous Versus Intermittent Fetal Heart Rate Monitoring

Two options for fetal monitoring are available for laboring women: continuous and intermittent fetal monitoring. Provider and patient opinions vary regarding which is optimal, although for low-risk patients guidelines exist for both, and both options are considered acceptable and within usual standards of care. A meta-analysis by the Cochrane Collaborative identified 12 studies that compared continuous electronic FHR monitoring to either no monitoring or intermittent monitoring during labor.[1] The use of continuous FHR monitoring was not associated with a decreased risk of perinatal mortality or cerebral palsy. There was, however, a significant reduction in neonatal seizures. This benefit was balanced against a significant increase in the risk of undergoing either cesarean section or operative vaginal delivery. Thus, the optimal mode of fetal monitoring is unclear. The occurrence of neonatal seizures, low Apgar scores, and hypoxemia at the time of birth can all cause significant emotional distress for new parents even in the absence of clear differences in long-term neurologic outcomes or survival, and many parents would potentially be willing to accept an increased risk of operative delivery to prevent neonatal seizures. On the other hand, many patients are highly motivated to have a spontaneous vaginal delivery and would be willing to accept a risk of transient neonatal seizures if there are no significant differences in longer-term neurologic outcomes. For low-risk patients who would be candidates for either approach, the most optimal approach may be to discuss the relative advantages and disadvantages of either early in pregnancy and allow the patients to then make the choice that works best for them.

Continuous electronic FHR monitoring may be performed externally or internally. Telemetry units are available so that a patient need not be confined to a bed to be monitored. Additionally, many modern units are waterproof and

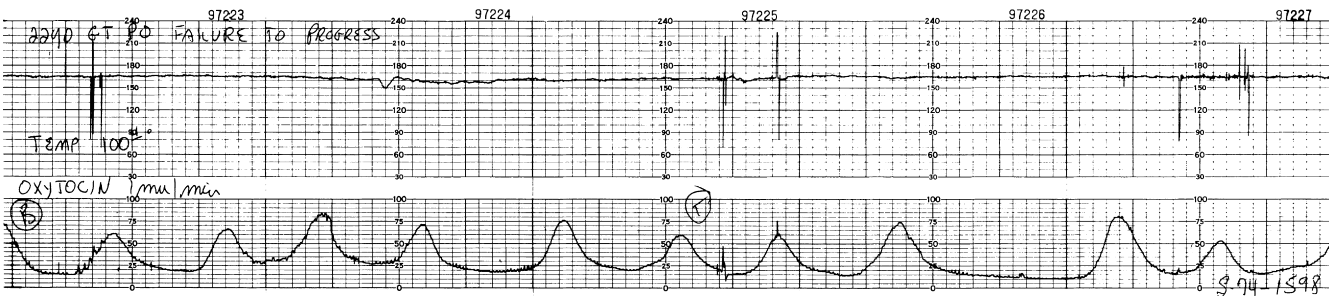
would thus allow for continuous monitoring while a patient is laboring in a bath or tub. Most external monitors use a Doppler device with computerized logic to interpret and count the Doppler signals. Internal FHR monitoring may be performed in circumstances in which external monitoring is technically difficult, such as maternal obesity. Internal monitoring uses an electrode that is attached to the fetal scalp, and contraindications to fetal scalp puncture (transmittable maternal infections such as hepatitis or HIV) are likewise relative contraindications for internal fetal monitoring. Internal monitoring also necessitates rupture of the fetal membranes. If the membranes are intact and internal monitoring is determined to be necessary, they can be artificially ruptured to facilitate monitoring, although this can carry a risk of umbilical cord prolapse if the fetal presenting part is not engaged.

Internal fetal scalp electrodes also have the advantage of overcoming monitoring difficulties secondary to maternal obesity. The rates of obesity have been steadily increasing throughout the world and present technical difficulties for external Doppler monitoring when the amniotic membranes are still intact. However, electrohysterography (EHG) and fetal electrocardiograms are expanding alternate technologies that can provide similar degrees of monitoring through maternal abdominal electrodes and are less sensitive to differences in maternal habitus.[7,8]

Interpretation of Continuous FHR Recordings

Baseline Fetal Heart Rate

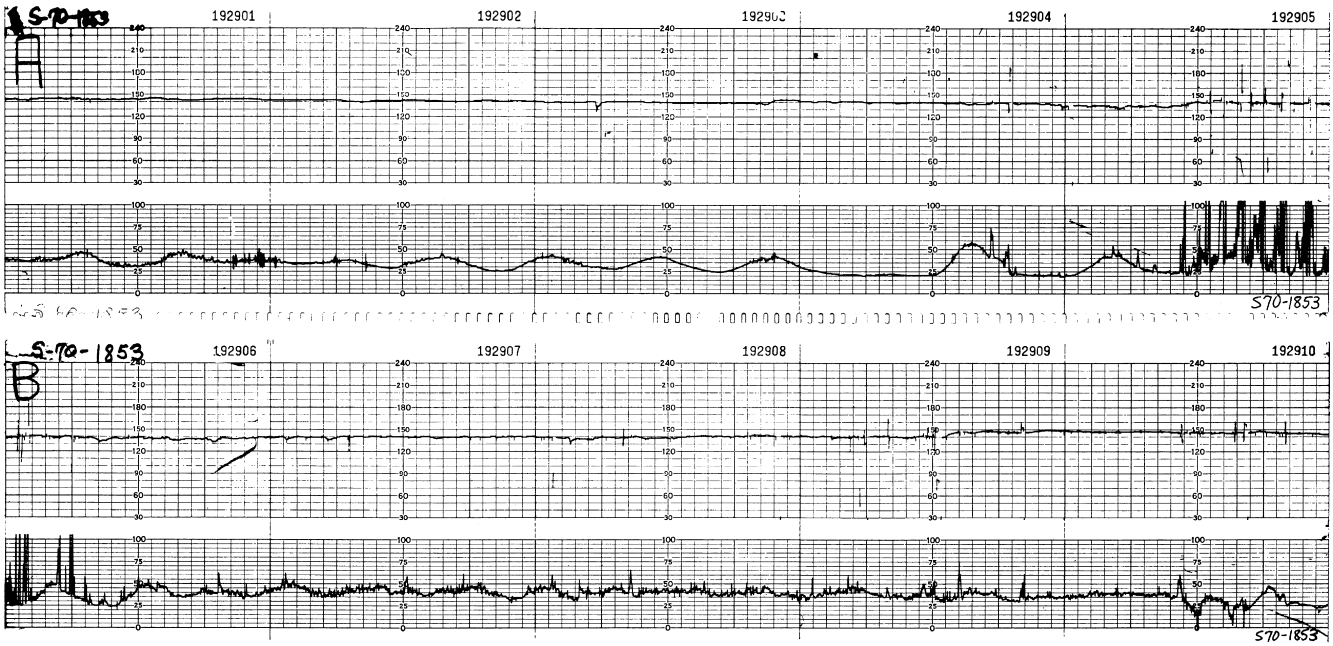
Baseline FHR is the average FHR rounded to increments of 5 beats/min during a 10-minute segment, excluding periodic or episodic changes, periods of marked variability, or baseline segments that differ by more than 25 beats/min. In any given 10-minute window, the minimal baseline duration must be at least 2 minutes or the baseline is considered indeterminate. A normal FHR baseline rate ranges from 110-160 beats/min. If the baseline FHR is less than 110 beats/min, it is termed *bradycardia*. If the baseline FHR is greater than 160 beats/min, it is termed *tachycardia* (Fig. 12.3). Of note, although rates of 110 and 160 beats/min are the accepted cutoff values for FHR, many fetuses with heart rates above or below these values will be otherwise healthy outliers. For example, a fetus that is experiencing otherwise uncomplicated labor with a fetal heart rate tracing that is perfectly reassuring other than a baseline in the 100s is likely normal.



As described later, events that can be associated with hypoxemia or the later development of hypoxemia, such as umbilical cord compression, produce decelerations of the fetal heart rate. However, it is worth noting that the primary response to hypoxemia is not bradycardia but tachycardia secondary to sympathetic discharges. A progressive increase in the heart rate baseline during labor can raise concern for hypoxemia if other FHR anomalies, such as decreasing variability, become progressively apparent over the same time period. Tachycardia may also be associated with conditions other than hypoxia, such as maternal fever, intra-amniotic infection, thyroid disease, the presence of medication, and cardiac arrhythmia.

Fetal Heart Rate Variability

The presence of baseline FHR variability is a useful indicator of fetal CNS integrity. Variability is defined as fluctuations in FHR baseline of two cycles per minute or greater, with irregular amplitude and inconstant frequency. Of note, although the fetus will normally have beat-to-beat heart rate variation, the actual PQRS complexes themselves are normal, differentiating this healthy phenomenon from atrial fibrillation or other pathologic arrhythmias. The variation represents alternating responses to sympathetic and parasympathetic inputs. If either the sympathetic or parasympathetic system instead predominates, such as would be the case of vagal nerve stimulation or increased sympathetic activity owing to hypoxia, this variability would be lost (Fig. 12.4). Thus, moderate FHR variability is strongly associated (98%) with an umbilical pH greater than 7.15, and in combination with a normal FHR baseline, generates a high degree of reassurance regardless of the presence or absence of accelerations or decelerations.



FHR variability is visually assessed as the amplitude of the peak to trough in beats per minute as follows:

Amplitude Range	Classification
Undetectable	Absent
1-5 beats/min	Minimal
6-25 beats/min	Moderate
>25 beats/min	Marked

• **Fig. 12.3** Fetal tachycardia, with a baseline fetal heart rate of 165 beats/min. This was in the setting of a maternal fever. (From Freeman R, Garite T. *Fetal heart rate monitoring*. Baltimore: Williams & Wilkins; 1981:70.)

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

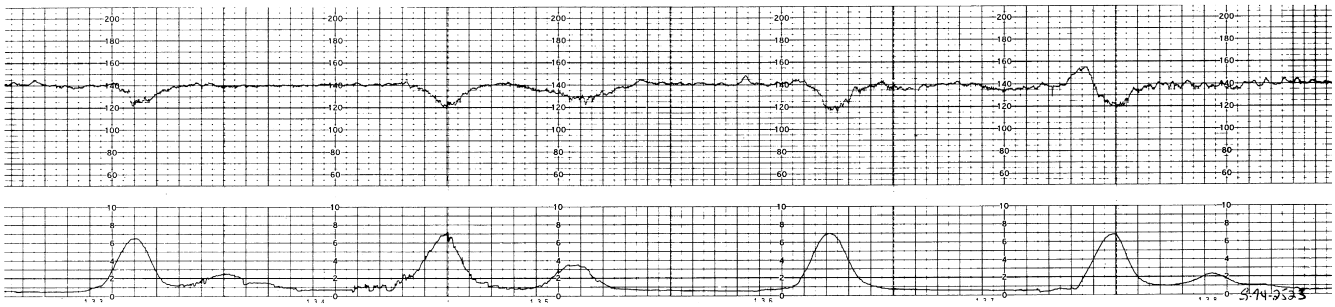
• **Fig. 12.4** Abnormal (absent) fetal heart rate (FHR) variability. Because there are no decelerations present, this would qualify as a category II FHR tracing. (From Freeman R, Garite T. *Fetal heart rate monitoring*. Baltimore: Williams & Wilkins; 1981:138.)

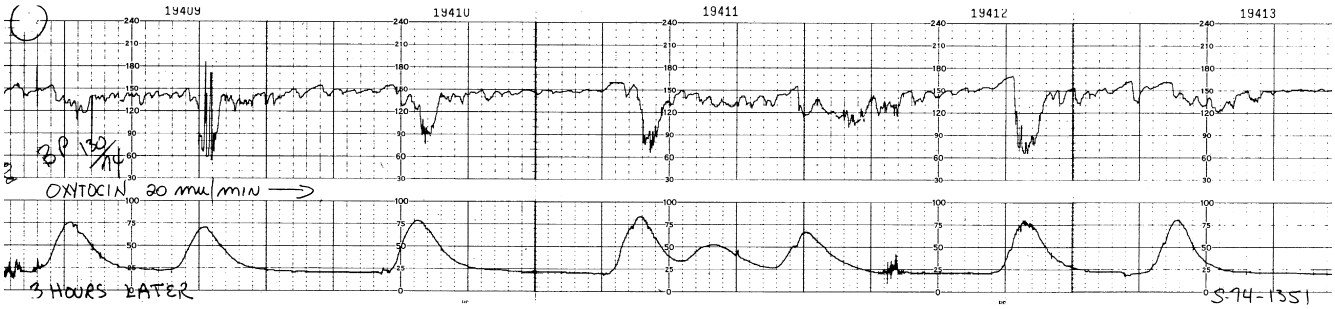
Accelerations

Accelerations in FHR are periodic elevations above the baseline, and they are usually associated with fetal movement. The presence of FHR accelerations during labor is always reassuring, as it is in a nonlaboring patient. Their absence during labor, however, is not necessarily concerning if other aspects of the FHR pattern are reassuring (see subsection Category I). Unlike a non-stress test in an antepartum patient, a "reactive" FHR tracing with "15 × 15" accelerations is not required for reassurance in the laboring patient.



Decelerations

Decelerations in FHR are episodic decreases below the baseline. Most decelerations are mediated through parasympathetic stimulation from the vagal nerve. These, in turn, are triggered by a variety of stimuli, including transient increases in intracranial pressure ("early" decelerations), increased systemic vascular resistance ("variable" decelerations), and hypoxemia (some "late" decelerations). Thus, most decelerations do not specifically signify the presence of fetal acidosis, and in fact many are simply interesting demonstrations of human physiologic reflexes. A portion of "late" decelerations, however, occurs secondary to the suppression of myocardial function by tissue-level hypoxia, which is clinically concerning. Clinically differentiating these from other deceleration patterns, however, is often imprecise.



Decelerations are classified by their morphology and then by whether they are recurrent or prolonged. Decelerations are defined as "recurrent" if they occur with at least 50% of the contractions. A "prolonged" deceleration is one that lasts for more than 2 minutes. Three types of decelerations are described: early, variable, and late. Early decelerations are shallow and symmetric, gradual in onset and recovery, and associated with a contraction such that the nadir of the deceleration occurs at the same time as the peak of the contraction (Fig. 12.5). Physiologically, early decelerations are a demonstration of Cushing reflex, in which increased intracranial pressure generates bradycardia through stimulation of the vagal nerve. Because of the unfused cranial fontanelles, pressure applied to the fetal cranium, such as when the head is pressed against maternal tissue during a contraction, is translated into increased intracranial pressure and can trigger activation of the vagal nerve. Like most reflexes, the response is virtually instantaneous and the magnitude of vagal nerve stimulation correlates with the magnitude of pressure applied against the fetal head. This is why "early" decelerations appear as mirror images of the contractions. This entire process is unrelated to fetal oxygenation and acid-base balance, which is why early decelerations, although conceptually interesting, are not of clinical importance.

Variable decelerations are typically associated with an abrupt onset and abrupt return to baseline. They vary in shape, depth, and duration and in the occurrence of contractions. They are also frequently preceded and followed by small accelerations in FHR (Fig. 12.6 and Fig. 12.7). Variable decelerations are usually associated with compression of the umbilical cord and represent physiologic changes in response to alterations in vascular resistance and preload. The umbilical cord contains a single large, thin-walled vein and two smaller, muscular arteries. When the umbilical cord is initially compressed, the umbilical vein is thus occluded first. This causes a decrease in venous blood returning to

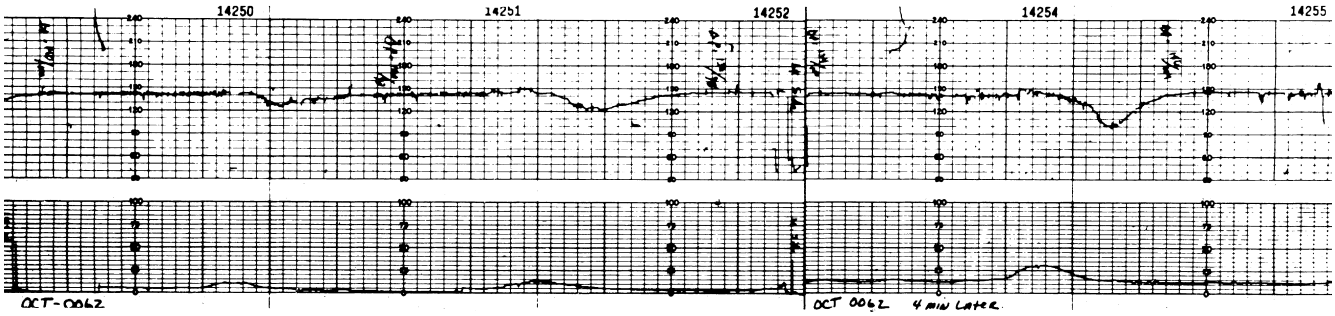
• **Fig. 12.5** Early decelerations. Note the way in which the decelerations appear to "mirror" the uterine contractions. (From Freeman R, Garite T. *Fetal heart rate monitoring*. Baltimore: Williams & Wilkins; 1981:74.)

• **Fig. 12.6** Variable decelerations. Note the normal fetal heart rate baseline and variability between the decelerations. (From Freeman R, Garite T. *Fetal heart rate monitoring*. Baltimore: Williams & Wilkins; 1981:78.)



• **Fig. 12.7** Variable decelerations. In contrast to Fig. 12.8, note the tachycardic fetal heart rate (FHR) baseline and absent variability between the decelerations. Also note the prolonged FHR "overshoot" in the middle portion of the panel. This FHR tracing is more concerning for the presence of fetal hypoxia and acidosis and would be considered category III.

the fetal heart and, thus, a decrease in preload, which in turn triggers tachycardia. This is why variable decelerations are often preceded and followed by small increases in FHR, referred to colloquially as "shoulders." As increasing compressive force is applied to the umbilical cord, the muscular arteries are eventually compressed as well. This then leads to a significant increase in vascular resistance, which in turn generates bradycardia via vagal nerve stimulation via baroreceptors. Although variable decelerations can sometimes occur normally during the labor process or even antenatal testing, their presence should alert the practitioner to the potential presence of umbilical cord compression, causes for which could include low amniotic fluid (oligohydramnios) or prolapse of the umbilical cord through the cervix. Overall, variable decelerations represent anticipated physiologic reflexes to umbilical cord compression and not the presence of hypoxemia or acidemia per se. However, severe and repetitive compression will eventually compromise oxygenation and overall health, and thus interventions (which can be as simple as maternal positional changes) would be warranted in this circumstance. Additionally, some fetuses can develop hypoxemia during periods of umbilical cord compression, which then normalizes after the compression is released. This can present as a period of tachycardia that follows resolution of the variable deceleration, owing to a sympathetic response to the hypoxemia. These are referred to as "overshoots" (see Fig. 12.7).

Late decelerations, by contrast, have a more gradual onset and return to baseline—typically 30 seconds or more from onset to nadir. The onset, nadir, and recovery of the

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

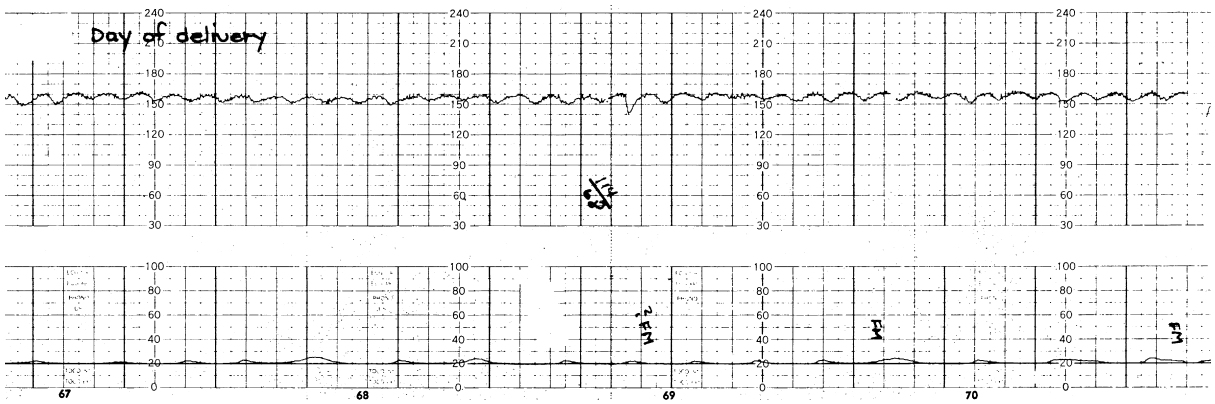
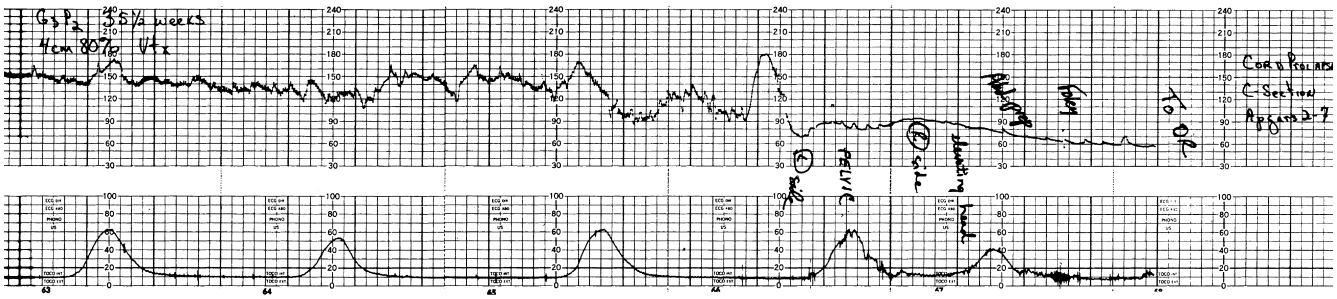
• **Fig. 12.8** Late decelerations. Note the timing of the onset, nadir, and recovery of the deceleration, which occur after the onset, peak, and end of the contraction. (From Freeman R, Garite T. *Fetal heart rate monitoring*. Baltimore: Williams & Wilkins; 1981:201.)

deceleration occur after the onset, peak, and end of the contraction (Fig. 12.8). During a uterine contraction, placental perfusion is temporarily impaired secondary to myometrial compression of the spiral arteries, which lose their muscularis in early pregnancy and are thus compressible. In a fetus that is undergoing the labor process normally, however, this transient event is well tolerated without clinically meaningful hypoxemia. For fetuses that are experiencing a decreasing oxygen reserve, however, the perfusion reduction during a contraction can have more significant effects, albeit not always tissue acidosis or multiorgan dysfunction. These effects and their resolution will always be delayed relative to the contraction itself, because the impact of decreased perfusion will be progressive and then require time to resolve once the contraction is complete. This is why "late" decelerations have their characteristic appearance relative to uterine contractions.



The actual mechanism of late decelerations occurs secondary to two separate although interrelated processes, one of which is related to hypoxemia and the other to tissue-level hypoxia. Although hypoxemia generates a sympathetic response that leads to tachycardia and thus an increasing FHR baseline, it can also generate bradycardia through a more indirect pathway: the decrease in peripheral oxygen concentration triggers a sympathetic output, which in turn transiently increases the blood pressure, which in turn triggers baroreceptors, which in turn stimulate the vagal nerve, which then decreases the heart rate. Thus, the presence of late decelerations can signify transient hypoxemia during and resolving after uterine contractions. In this situation, it would be optimal to resolve the transient hypoxemia, and interventional measures such as positional changes and supplemental oxygenation are usually undertaken. The fetus in this scenario, however, is not necessarily acidotic (or even has tissue-level hypoxia) and, presuming it can recover appropriately between contractions, can still possibly proceed with a normal labor course and uncomplicated vaginal delivery. The other potential mechanism for late decelerations, however, involves direct suppression of myocardial activity secondary to tissue-level changes in which the bradycardia reflects the inability of the myocardium to function properly in the setting of hypoxia. Secondary to differences between respiratory and metabolic acidosis and all of the other complex variables involved in organ function, many of the fetuses in this scenario will still have normal long-term outcomes, although this is the scenario of greatest clinical concern and the one in which consideration could be given to expedition through operative delivery. For the patient experiencing late decelerations, however, it can be difficult to determine if they are occurring secondary to which of these two underlying pathways. Context is important in this regard, such that in the case of a persistently hypoxic fetus, other FHR changes, such as progressive tachycardia and loss of variability, should accompany the late decelerations. The fetus who is experiencing late decelerations, but for whom the FHR has a normal rate and variability between contractions, is more likely to be experiencing only transient hypoxemia.

A sinusoidal heart rate pattern consists of a regular oscillation of the baseline variability in a smooth undulating pattern. This pattern typically lasts at least 10 minutes, has a relatively fixed period of three to five cycles per minute, and an amplitude of 5-15 beats/min above and below the baseline (Fig. 12.9). This pattern is quite rare but can be associated with severe chronic anemia or severe hypoxia and acidosis, although rarely can also be an incidental finding.



Interpretative Systems for Classification of Fetal Heart Rate Patterns

Since its introduction, the utility of electronic fetal monitoring has been limited by the subjective nature of its interpretation. Despite continual efforts at standardization, interpretation of FHR tracing is subjective and prone to significant interobserver and intraobserver variation.[3] Although many interpretative systems exist for FHR tracings, the 2008 National Institutes of Child Health and Human Development (NICHD) workshop dealing with Standardization of Nomenclature for Intrapartum Electronic Fetal Monitoring, jointly sponsored by NICHD, the American College of Obstetricians and Gynecologists, and the Society for Maternal Fetal Medicine, has been an important step toward standardization.[12] In this system, fetal tracings are divided into three categories.

• **Fig. 12.9** Sinusoidal fetal heart rate pattern. This fetus was severely anemic and hydropic because of maternal Rh isoimmunization. (From Freeman R, Garite T. *Fetal heart rate monitoring*. Baltimore: Williams & Wilkins; 1981:166.)

• **Fig. 12.10** Prolonged deceleration associated with acute prolapse of the umbilical cord. Note the reassuring fetal heart rate tracing leading up to the deceleration, indicating an acute event. (From Freeman R, Garite T. *Fetal heart rate monitoring*. Baltimore: Williams & Wilkins; 1981:83.)

Category I

These are "normal" tracings, which are strongly predictive of normal fetal acid-base status at the time of observation and can be followed in a routine manner without any specific action required. They necessitate all of the following:

- Baseline rate of 110-160 beats/min
- Moderate variability
- Absence of any late or variable decelerations
- Early decelerations may or may not be present.
- Accelerations may or may not be present.

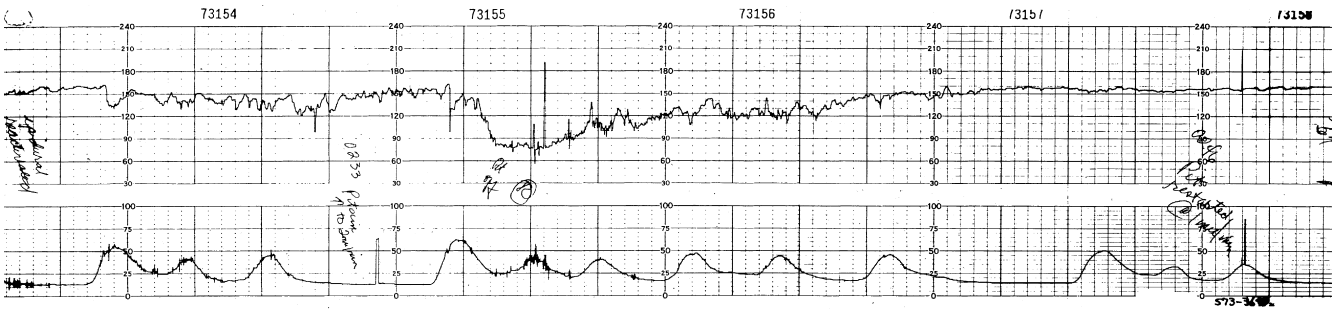
Of note, an FHR pattern during labor does not have to have accelerations that would meet the "reactivity" criteria of an antepartum non-stress test to still be a category I tracing.

Category II

These are indeterminate tracings that, although not predictive of abnormal fetal acid-base status, cannot be classified as category I or III and require evaluation and continued surveillance and reevaluation. These tracings are frequently encountered in clinical care and include any tracing that does not meet the more specified criteria for category I or III. Except for patterns that are sinusoidal, category III tracings require the combination of absent variability plus one more additional finding as described below. Thus, a tracing that has appropriate variability but has other findings, such as late or variable decelerations that would exclude it from category I, would fall into category II.

Category III

These are abnormal tracings that are potentially predictive of an abnormal fetal acid-base status at the time of observation. As such, they require prompt evaluation and initiation of attempts at correction. These tracings include *either*:



1. Absent baseline FHR variability along with *any* of the following:
   a. Recurrent late decelerations
   b. Recurrent variable decelerations
   c. Bradycardia
2. Sinusoidal pattern

"Recurrent" decelerations would be those that occur with greater than 50% of contractions.

Management of Non–Category I FHR Patterns During Labor

The evaluation of a category II or III pattern begins with a search for an underlying etiology that would itself require immediate delivery. For example, an acute change in the FHR pattern with prolonged deceleration (Fig. 12.10) could have occurred secondary to umbilical cord prolapse,

• **Fig. 12.11** Prolonged deceleration associated with uterine hyperstimulation. Note the recovery of the deceleration after discontinuation of the oxytocin infusion. (From Freeman R, Garite T. *Fetal heart rate monitoring*. Baltimore: Williams & Wilkins; 1981:85.)

placental abruption, or uterine rupture. In the absence of such events, one should search for a remediable cause of the concerning FHR tracing. Uterine perfusion is very sensitive to maternal blood pressure, and even relative redistributions of maternal blood flow, such as can occur after the initiation of regional anesthesia, can impact the FHR pattern. Abnormal FHR patterns may also result from contractions that are too frequent in timing to allow for recovery between them. The occurrence of uterine contractions more frequently than 5 in 10 minutes, averaged over 30 minutes, is generally referred to as tachysystole (Fig. 12.11) and can occur as a consequence of labor induction agents. When the tachysystole is resolved, either by discontinuing or decreasing an oxytocin infusion or administering a tocolytic, the fetal status typically improves. Maternal position in labor can affect the FHR tracing, because the supine position decreases uterine blood flow and placental perfusion. Repositioning a patient to the lateral recumbent position can improve a concerning FHR pattern with no other intervention. Supplemental oxygen therapy for the mother should also be administered. When recurrent variable decelerations are present, amnioinfusion, in which fluid is infused into the uterine cavity, has been shown to decrease the rate of variable decelerations and cesarean delivery for nonreassuring fetal status.[10] When faced with a concerning FHR tracing with no clear secondary cause and which persists despite attempts at conservative management, some options do exist for additional reassurance, because many of these fetuses will still have a normal acid-base status secondary to the imprecision of continuous FHR monitoring. An acceleration in FHR after vibroacoustic stimulation or fetal scalp stimulation with a digital examination provides reliable reassurance of a normal fetal pH and allows labor to continue. Blood sampling from the fetal scalp can be used to assess the fetal pH or lactate directly, although this is invasive and uncommonly performed in contemporary practice.

Many FHR tracings will remain indeterminate without either a reversible cause or additional reassurance from scalp stimulation or pH measurement. Management of these cases is complicated and depends upon the exact clinical circumstances, including the stage and progress of labor. Because of this common scenario there has been longstanding interest in technological advancements to provide additional information regarding the fetal status. The two areas of greatest promise had been the fetal pulse oximetry and ST segment analysis. Unfortunately, neither of these technologies has demonstrated a reduction in cesarean delivery or neonatal outcomes in large clinical trials. Specifically, a randomized trial of ST segment analysis in 11,108 subjects was published in 2015 and demonstrated no differences in either composite neonatal morbidity or cesarean delivery between open and masked monitoring.[2]

Although research in this important area is continuing, at this time there are no technologies available for additional fetal reassurance that are either evidence-based or standard of care. In lieu of current or future technological advancements, there has been increased focus on optimizing our available fetal monitoring protocols through the increased use of guidelines and practice standardization. In particular, there is interest in increasing the uniformity of management for category II tracings, since these are both common and of indeterminate significance. For example, the occurrence of any late deceleration would exclude a designation of category I, and thus a tracing that was otherwise entirely reassuring with the exception of a single late deceleration would be category II. On the other end of the spectrum would be a tracing with absent variability and four late decelerations out of 10 contractions in a 30-minute period, since category III requires "recurrent" late decelerations, which would be greater than half of contractions. In addition to the wide range of severity, the overall clinical context needs to come under consideration as well, including the course of labor and degree to which longitudinal changes may be occurring within category II.[21] It would be more reasonable to continue with a category II tracing in a patient with normal labor progress who is nearing delivery than it may be for the same tracing for a patient who is either early in the latent phase or experiencing abnormal labor progress. Thus, attempts have been made at guideline development for category II management, including the publication of collaborative exert opinion.[6] These provide useful guidance although have not been formally adopted as national standards of care.

Key Points

- Antepartum testing can decrease the risk of stillbirth in many pregnancies at risk of fetal compromise secondary to uteroplacental dysfunction.
- The most common strategy for antepartum testing is the weekly non-stress test performed after 32 weeks. A non-stress test is reassuring if the fetal heart rate demonstrates two accelerations that are 15 seconds in duration and 15 beats per minute above the baseline.
- The biophysical profile is an alternate antenatal testing modality that uses ultrasound to track fetal activity using a scoring system from 0-10. Values of 8 and 10 are reassuring and values of 6 are indeterminate.
- Low-risk fetuses during labor can be monitored with either intermittent or continuous monitoring.
- Continuous electronic fetal monitoring has not clearly resulted in a decreased incidence of cerebral palsy and may increase the risk of cesarean and operative delivery.
- A three-category scoring system is utilized for the interpretation of fetal monitoring during labor.

Surgical Treatment of the Fetus

JARRETT MOYER, COREY W. IQBAL, SHINJIRO HIROSE, AND HANMIN LEE

Summary

Over the past half-century, implementation of high-resolution screening prenatal imaging, coupled with increasingly nuanced understanding of embryology and human fetal development, have created a new surgical patient: the fetus. Through decades of rigorous scientific investigation and technical innovation, congenital anomalies that previously carried a grim prognosis are now candidates for fetal intervention. As experience has grown with fetal surgical intervention, we have been able to quantify survival benefit and reduction in morbidity to the fetus for many conditions, while also coming to understand the specific risks for the fetus and the mother.

In fact, the potential impact of fetal surgery on the mother presents difficult ethical decisions. By undergoing general anesthesia, a surgical operation, postoperative recovery, and the remainder of pregnancy, the mother is subject to significant risk but can expect no direct health benefit from fetal surgical intervention. Specifically, short-term morbidity after fetal surgery includes preterm labor, the potential risk of anesthesia, the potential need for blood transfusion, premature rupture of membranes, chorioamniotic separation, chorioamnionitis, and placental abruption. Long-term morbidity related to the hysterotomy used in open fetal cases includes infertility, uterine rupture during future pregnancies, and mandatory cesarean section with future pregnancies. Therefore, it is crucial that the obstetric, medical, and surgical teams consider the protection of the pregnant woman as the utmost priority when making treatment decisions. Additionally, comprehensive discussion of the potential benefit to the fetus and the unique risks to the mother is required while obtaining informed consent. Specifically, women should be informed of and provided access to alternative treatment modalities, including postnatal therapy, palliative delivery, or pregnancy termination.[8,19]

Fetal Access

Access to the fetus can be considered in three general categories: percutaneous, fetoscopic, and open hysterotomy. Preoperative and intraoperative ultrasound are critical for defining the anomaly (or anomalies), delineating the placental anatomy, determining the position of the fetus, detecting the location of the maternal blood vessels, and monitoring the fetal heart rate during the procedure. Ultrasonography is particularly vital in percutaneous and fetoscopic procedures owing to limited direct visualization of the fetus, placenta, and uterus during the procedure.

Percutaneous Interventions

Needle-based interventions were first reported in 1963, when Liley performed the first fetal transfusion by inserting a 16-gauge needle into the fetal peritoneal space.[64] Since then, advances in imaging and instrumentation have broadened the application of percutaneous techniques in the treatment of the fetus. Percutaneous procedures are performed through small skin incisions on the mother's abdominal wall, utilizing real-time ultrasound to visualize the fetal and maternal anatomy and guide the intervention.[109] Cystic masses, ascites, pleural fluid, or other fluid collections can be aspirated as a diagnostic or therapeutic maneuver. Shunts can be inserted for more definitive drainage of fluid into the amniotic space. Other devices such as radio frequency ablation (RFA) probes can be deployed to treat complications of twin gestation. The needles used to place these catheters, as well as the RFA device, are approximately 1.5 to 2 mm in diameter, minimizing morbidity to the mother and irritation of the uterus.

Fetoscopic Surgery

Fetoscopic procedures are performed using a 1.2- to 3.0-mm fetoscope with or without a working channel, inserted through a 2.3- to 4.0-mm cannula placed into the uterus.[103] For procedures performed through a single port with a fetoscope containing a working port, the uterus can be accessed through a small incision on the mother's abdomen. Procedures requiring multiple instruments and ports may proceed either via multiple small abdominal incisions or a maternal laparotomy allowing port placement directly into the uterus. Fetoscopy permits direct visualization of the lesion at the time of intervention but is still facilitated by the use of fetal ultrasound. Additionally, access to the uterus is performed under ultrasonographic guidance to locate a

Abstract

Fetal surgery is a developing field, with scientific, clinical, and ethical questions still under investigation, and innovation forging new paths forward. In all cases, the well-being of the expectant mother must be considered the top priority when making treatment decisions. Informed consent is especially vital, as any fetal intervention carries substantial risk of obstetric complications, including preterm labor, PPROM, membrane separation, and chorioamnionitis, and open hysterotomy necessitates eventual delivery by cesarean section. Fortunately, innovation in surgical instrumentation and technique has led to effective percutaneous and fetoscopic minimally invasive therapies for most conditions amenable to prenatal intervention. Given the risk of obstetric morbidity, fetal interventions are usually reserved for the fetus at risk of intrauterine or early neonatal demise, as is the case in congenital diaphragmatic hernia, congenital pulmonary airway malformations (CPAM), hydrothorax, sacrococcygeal teratoma, fetal neck mass, urinary tract obstruction, abnormalities of twin gestation, and congenital heart defects. Fetal repair of myelomeningocele is unique in that fetal intervention aims to minimize postnatal morbidity rather than mortality. In this chapter, the authors describe the indications, techniques, and outcomes of fetal interventions for the conditions listed above, as well as other congenital lesions that threaten the fetus.

"window" in the uterus that is devoid of the placenta in hopes of reducing the risk of maternal bleeding, placental abruption, and fetal morbidity. Occasionally, the amniotic fluid is not clear enough for adequate direct visualization with the fetoscope. In such cases, an amnio-exchange may be performed with warmed isotonic crystalloid solution to optimize visualization.

Open Hysterotomy

The early experience in surgically correctable fetal anomalies in utero was conducted through an open hysterotomy. Fortunately, continuing advancements in imaging and minimally invasive techniques have reduced the need for open fetal procedures. Open fetal procedures are usually performed through a low, transverse maternal skin incision. The fascia can be opened in a vertical or transverse fashion, depending on the exposure needed. Preoperative and intraoperative ultrasound is crucial to map out the placenta and determine the ideal placement of the uterine incision to optimize fetal exposure and avoid injury to the placenta. Uterine staplers with absorbable staples were developed specifically for fetal surgery to allow a hemostatic hysterotomy yet avoid infertility from permanent staples functioning as an intrauterine device. Typically, fetal exposure is limited to the site specific to the intervention to avoid hypothermia and unnecessary manipulation of the umbilical cord, which is prone to spasm that can result in fatal fetal ischemia. A fetal extremity may also be exposed for placement of an intravenous cannula if indicated. The uterus should be stabilized within the maternal abdomen to minimize tension on the uterine blood vessels that could impede placental flow. Amniotic fluid volume is maintained using warm, isotonic crystalloid solution. At the conclusion of the procedure, the amniotic fluid is completely restored, and the uterus is closed in multiple layers using absorbable sutures. Postoperatively, the mother and fetus are monitored continuously for uterine contractions and heart rate, respectively. Patients are often discharged with oral nifedipine as a tocolytic.

Open fetal surgery requires cesarean section for the current pregnancy and all future pregnancies owing to the potential for uterine rupture during labor. Although vaginal delivery after cesarean section (VBAC) may be considered for routine, lower uterine segment hysterotomy, VBAC is not an option after hysterotomy for fetal surgery owing to the increased risk of uterine rupture.

Exit Procedure

Ex-utero intrapartum therapy (EXIT) allows for a fetal intervention to be conducted while maintaining uteroplacental circulation, followed by immediate delivery. EXIT procedures are most commonly indicated for airway issues but have been described for extracorporeal membranous oxygenation, separation of conjoined twins, and resection of fetal neoplasms.[50] An EXIT procedure is performed similarly to the open fetal procedure described above. However, at the conclusion of the case, with an established fetal airway, the fetus is delivered. Since uterine relaxation is critical during any fetal intervention, the EXIT procedure carries a significant risk for maternal hemorrhage at the time of delivery, and coordination between the anesthesiologist and the surgeon is critical, as discussed below.

Anesthetic Considerations

In addition to providing amnesia, analgesia, and patient monitoring that are central to all anesthetic encounters, successful maternal-fetal anesthesia must maintain uteroplacental relaxation and circulation. The only exception to this is the EXIT procedure, in which uterine contraction after delivery of the fetus is necessary to prevent bleeding secondary to uterine atony.

In all cases, the mother is positioned supine with her left side down to minimize compression of the inferior vena cava by the gravid uterus. Commonly administered preoperative medications include indomethacin for tocolysis and an antibiotic, such as cefazolin, for infection prophylaxis. The maternal bladder is decompressed by either straight catheterization for short procedures or an indwelling bladder catheter for longer or open procedures.

For minimally invasive percutaneous interventions and fetoscopic procedures, locoregional anesthesia can be administered via epidural, spinal, or local injection, depending on the mother's preference and anticipated length of the procedure. Spinal and epidural anesthesia are especially useful for complex fetoscopic procedures requiring multiple ports or in cases when emergency cesarean section may become necessary.[107] Regional anesthesia can produce maternal hypotension and negatively impact uteroplacental blood flow; therefore, with spinal anesthesia normotension is maintained with a phenylephrine infusion. Both phenylephrine and ephedrine are effective vasopressors that maintain maternal blood pressure while minimizing the effect on umbilical cord blood flow.[53,100] Additional conscious sedation can be provided intravenously using propofol or inhaled nitrous oxide. Nitrous oxide has the added benefit of enhanced uterine relaxation.

For open fetal procedures, including EXIT, deep maternal general anesthesia is required to ensure adequate uterine relaxation. Volatile inhaled anesthetics are used at high concentrations (usually 2.0 minimal alveolar concentration), but the subsequent relaxation of the myometrium can lead to a drop in placental blood flow.[27] Therefore, maternal blood pressure is augmented in these cases with either ephedrine or phenylephrine. The surgeon should be vigilant about repeated assessment of uterine tone. When the uterus is open, amniotic fluid volume is maintained with warm, isotonic crystalloid solution to prevent compression of the umbilical cord.

For open fetal cases, as the hysterotomy is being closed, the inhaled anesthetic is reduced or turned off and tocolysis with magnesium sulfate is initiated. Amniotic fluid volume

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

is restored. Alternatively, after delivery during an EXIT procedure, the inhaled anesthetic is reduced, and oxytocin is administered to enhance uterine contraction prior to closure of the hysterotomy.

For procedures performed directly on the fetus, additional fetal anesthesia and analgesia is required. In the fetus experiencing pain, systemic vascular resistance can increase, which may decrease umbilical cord blood flow and fetal perfusion. While transplacental passage of the volatile anesthetics does occur, the time needed for fetal levels to reach a therapeutic dose precludes maternal anesthesia from being an adequate source of fetal anesthesia. Furthermore, inhaled anesthetics do not provide analgesia. Thus, additional fetal anesthesia is administered intramuscularly and typically consists of opioid analgesics and non-depolarizing paralytic agents such as rocuronium or pancuronium.[65,107] Rocuronium and pancuronium have the added benefit of vagal inhibition that can abate bradycardia, which may result from opioid administration; however, atropine is often administered for additional protection against bradycardia.[102]

Transplacental passage of anesthetic from mother to fetus places the fetus at risk for demise. Inhaled anesthetics produce myocardial depression, which can augment the fetal bradycardic response to stress and contribute to malperfusion, as fetal cardiac output and end organ perfusion are primarily determined by heart rate.[13] Other environmental factors such as hypothermia and umbilical cord compression increase the risk for fetal demise. Accordingly, continuous fetal monitoring should be undertaken via transcutaneous pulse oximetry, intraoperative fetal echocardiography, and monitoring of amniotic fluid temperature.

Finally, in light of in vitro and animal data demonstrating lasting neurotoxic effects associated with exposure to all general anesthetics tested,[94] the Food and Drug Administration (FDA) issued a Safety Communication in 2016 acknowledging the potential for adverse effects on fetal brain development and postnatal learning with anesthetic exposure to the pregnant woman.[87] Clinical studies have not demonstrated worsened neurodevelopmental outcomes with brief anesthetic exposure,[26,101] but data suggest the effect may be dose-dependent, with prolonged and repeated anesthetic exposure placing the developing brain at higher risk. Further clinical studies characterizing the effects of anesthesia on developing brains are necessary and ongoing.[84]

Anomalies Amenable to Fetal Surgery

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) is a defect in the fetal diaphragm allowing herniation of abdominal contents into the thoracic cavity. This occurs in roughly 1 in 2500 live births[91] and leads to abnormal development of the lung parenchyma and pulmonary vasculature. The resultant pulmonary hypoplasia and associated pulmonary hypertension can lead to persistent fetal circulation (also known as persistent pulmonary hypertension, PPHN), cardiorespiratory failure, and neonatal death. Despite significant advances in neonatal cardiac and respiratory support, children born with CDH in the United States have a mortality rate of 20%-30%.[31,99] Prenatal diagnosis and poor prognosis have made CDH a primary target for effective fetal intervention, and this entity was one of the primary driving forces in the genesis of fetal surgery at the University of California, San Francisco.

Prenatal imaging with ultrasonography and MRI allows both diagnosis and risk-stratification of fetuses with CDH. The most reliable predictor of poor prognosis on ultrasound or MRI is the presence of liver herniation. A systematic review of 710 cases of CDH demonstrated 75% survival without liver herniation, compared to 45% with liver herniation.[79] An additional predictor of poor prognosis is a low lung-to-head ratio (LHR), which is calculated as the area of the contralateral lung at the level of the cardiac atria divided by the head circumference. In a retrospective case series, LHR correlated with survival: 100% survival with an LHR greater than 1.35, 61% survival with an LHR between 0.6 and 1.35, and 0% survival with an LHR less than 0.6.[72] This finding was corroborated in multiple subsequent trials.[59,66] As an adjunct to LHR, in order to account for discrepant growth rates between the head and lung throughout gestation, some centers use the observed-to-expected LHR (O:E LHR), represented as a percentage of the expected LHR based on a normal fetus of the same gestational age.[55] For left-sided defects, an O:E LHR less than 25% is associated with an 18% survival, whereas an O:E LHR greater than 45% correlates with 89% survival.[54]

Finally, MRI allows calculation of total lung volume and percent-predicted lung volume (PPLV) in CDH as an additional method of risk-stratification.[9,21] Different centers have described different outcome thresholds for PPLV in CDH, but generally a PPLV greater than 20%-35% offers an improved prognosis.[111]

Fetal repair of CDH was first conceptualized after reversal of CDH in the fetal lamb model resulted in increased lung growth and development, allowing survival of the lamb neonate.[4] Based on these results, open fetal surgery was investigated in human fetuses diagnosed with CDH. The first successful case was reported by investigators at the University of California, San Francisco, in 1990 using a two-step approach that involved creation of an abdominal silo to accommodate the reduced viscera and prevent compression of the umbilical vessels.[45] However, a prospective trial comparing open fetal repair to medical management followed by postnatal repair found that fetuses with poor prognosis (liver herniation) suffered from high mortality rates despite in utero correction, and fetuses with good prognoses (no liver herniation) had no difference in survival or need for extracorporeal membrane oxygenation (ECMO).[42,43]

These disappointing results were tempered by the subsequent observation that pulmonary hyperplasia developed in fetuses with congenital high airway obstruction syndrome (CHAOS).[48] This observation was applied to treatment of

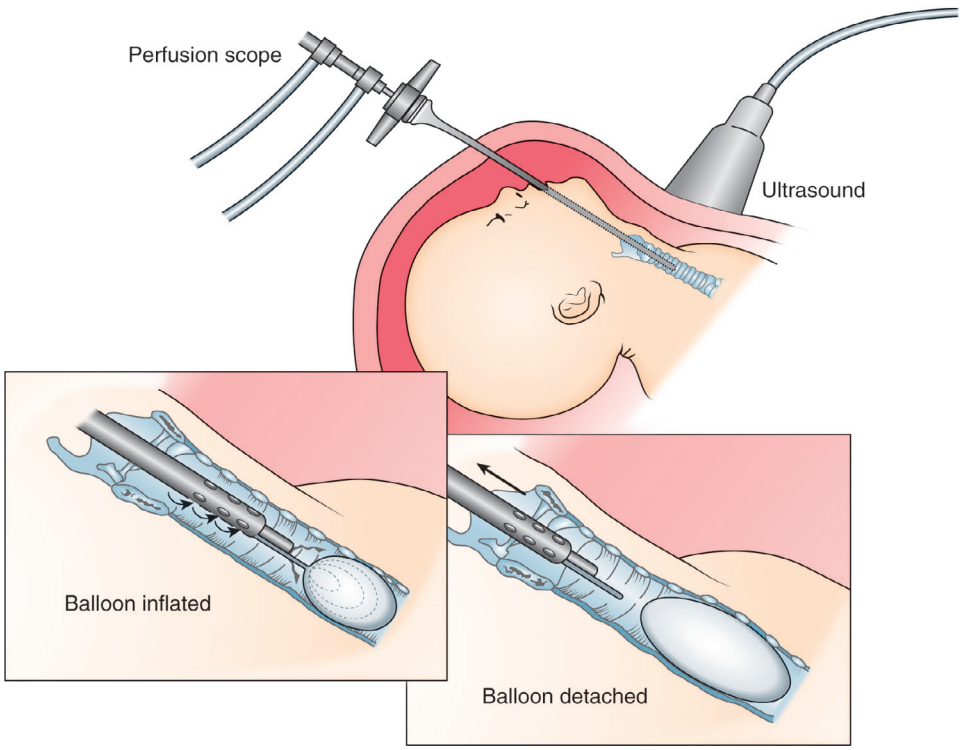
CDH first in the fetal lamb model, where tracheal occlusion was achieved by suture ligation, foam-cuffed endotracheal tubes, or expandable foam inserts, and led to increased lung volume, decreased herniation of abdominal contents, and improved postnatal cardiopulmonary function.[10,30,47]



Based on these findings, in utero tracheal occlusion was applied in humans first in 1996, with placement of a metallic tracheal clip via maternal laparotomy and open hysterotomy.[44] The clip was then removed during EXIT procedure (Fig. 13.1). This approach suffered from a high rate of mortality and morbidity related to hysterotomy and preterm labor, as well as tracheal stenosis. To reduce morbidity related to open hysterotomy, fetal surgeons developed a minimally invasive technique for tracheal clipping, first performed in 1997.[110] However, clipping still suffered from frequent airway complications, including stenosis and vocal cord paralysis.

Despite these initially disappointing results, investigators remained optimistic that tracheal occlusion could improve outcomes for high-risk CDH lesions. Ongoing advancements in fetal surgery led to less invasive means for fetal tracheal occlusion, namely fetal endoscopic tracheal occlusion (FETO) via deployment of an obstructing tracheal balloon (Fig. 13.2).[46] FETO offers the benefits of being achieved through a single maternal fetoscopic port, as well as the avoidance of fetal neck dissection. FETO is performed between 26 and 30 weeks' gestation, and, when initially described, the balloon remained in place until delivery, with removal during EXIT procedure. However, relief of tracheal occlusion in utero via a second procedure in utero demonstrated increased type II pneumocyte differentiation, leading to increased surfactant production in the fetal lamb model,[14] and enables vaginal delivery, obviating the need for EXIT procedure. Currently, FETO is relieved at 34-36 weeks' gestation via a second fetoscopic procedure.[91]

The multicenter FETO consortium has reported an overall 48% survival rate among 210 cases of severe CDH (liver herniation, LHR ≤1.0) treated with temporary fetal tracheal occlusion compared to an 11% survival in historical

• **Fig. 13.1** The airway is established during an ex-utero intrapartum therapy (EXIT) procedure after relief of fetal tracheal occlusion in the treatment of congenital diaphragmatic hernia. controls, based on CDH registry data.[56] A meta-analysis compiled series compared survival after FETO to contemporary control groups, demonstrating markedly improved survival after FETO in fetuses with isolated severe CDH (LHR <1.0).[7] Specifically, 46.3% of the cases undergoing FETO survived to discharge, compared to 5.9% in controls, translating to a survival odds ratio of 13.3 with FETO. While these results are promising, the true benefit of FETO is difficult to assess from retrospective case series and meta-analyses due to differences in assessment of CDH severity as well as postnatal care. Currently, international prospective randomized trials comparing FETO to expectant management in both moderate and severe lung hypoplasia secondary to CDH are ongoing (TOTAL trial, www.totaltrial.eu).[28]

Congenital Pulmonary Airway Malformations

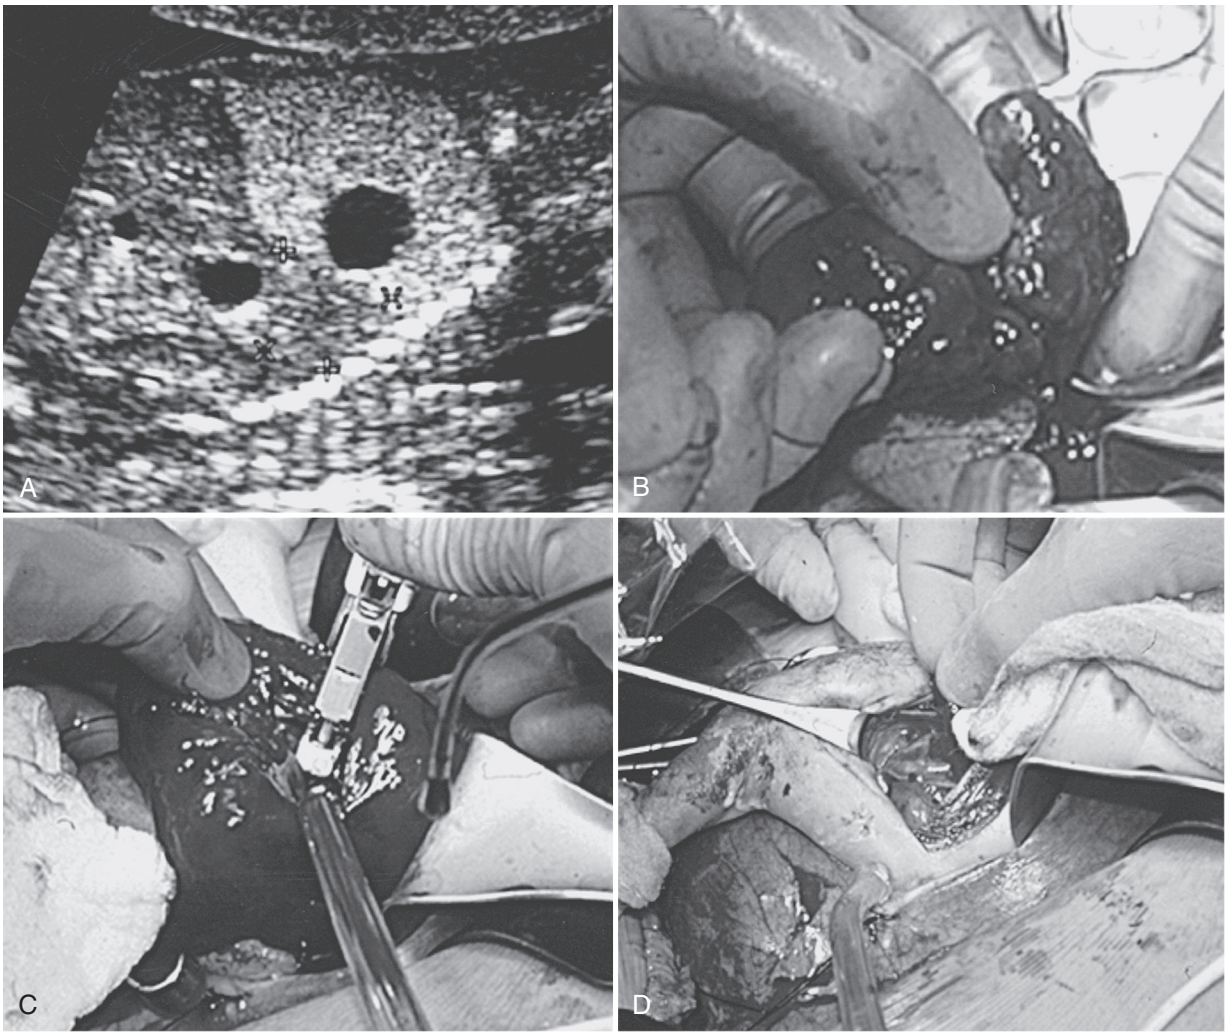
Congenital pulmonary airway malformations (CPAM) are benign cystic pulmonary lesions with widely variable clinical presentations. Most CPAM are diagnosed in utero on screening ultrasound, and the majority of fetuses proceed to live birth with the absence of neonatal respiratory symptoms.[3,92] However, 5%-30% of prenatally diagnosed CPAM produce mediastinal shift, polyhydramnios, and nonimmune hydrops,[3,18] leading to certain fetal demise without prenatal intervention. The risk for development of nonimmune hydrops increases with lesion size. The cyst volume ratio (CVR) is a sonographic marker normalizing lesion volume to head circumference and is a widely used risk-stratification tool for the eventual development of nonimmune hydrops. Fetuses diagnosed with CPAM with CVR greater than 1.6 have an 80% risk for the development of hydrops.[22,118] Fetuses with CVR >1.6 should be monitored with weekly ultrasound exams, as hydrops is associated with near 100% fetal mortality if left untreated.[1,18]

The morphology of the lesion is also an important consideration in determining risk. Microcystic lesions have a more predictable course, with steady growth that tends to plateau at 26-28 weeks' gestation, at which point fetal growth exceeds that of the CPAM. For this reason, patients with microcystic or solid CPAMs should be followed closely up to 26-28 weeks' gestation, at which point the interval between ultrasound examinations can be lengthened if the pregnancy has been otherwise uncomplicated. In contrast, macrocystic CPAMs can undergo abrupt enlargement caused by rapid fluid accumulation in a dominant cyst regardless of the CVR. Therefore, macrocystic CPAMs require close follow-up with serial ultrasound throughout the duration of the pregnancy.[74]

The development of hydrops necessitates fetal intervention. Maternal betamethasone administration is especially effective in treating microcystic lesions producing nonimmune hydrops, with survival rates to delivery as high as 92%.[25,67,105] Current practice is to initiate maternal betamethasone for nonimmune hydrops or a CVR greater than 1.6 whether or not hydrops is present for microcystic lesions. Predominantly macrocystic lesions are not routinely treated with steroids, as they are less likely to respond. Maternal steroids can be re-dosed, but care should be taken because repeated courses of maternal steroids beyond three to five courses can result in untoward effects such as reduced birth weight.[37]

Given the effectiveness of prenatal steroids in the treatment of hydrops, there are few clinical scenarios in which invasive fetal intervention is indicated. However, in CPAM with a predominant macrocyst or large pleural effusion at less than 32 weeks' gestation, in utero drainage can relieve mass effect, leading to resolution of hydrops and improved surrounding lung development.[114] In a series of 75 cases of thoracoamniotic shunt placement, shunts produced a 55% decrease in CPAM volume.[83] This led to resolution of hydrops in 83% of cases, survival to birth of 93%, and long-term survival of 68%. Thoracoamniotic shunting is not without complications, which can include shunt migration, development of chest wall abnormalities, shunt occlusion, hemorrhage, membrane separation, placental abruption, and/or preterm labor.[71] Furthermore, the majority of neonates born after in utero thoracoamniotic shunting experience respiratory distress requiring intubation for >24 hours[83] and thus should be delivered at a tertiary referral center.

Open fetal thoracotomy for resection of the CPAM is no longer routinely performed due to the success of maternal betamethasone administration and thoracoamniotic shunting. Historically, the procedure was performed through an open hysterotomy and a thoracotomy through the fifth intercostal space, followed by resection of the lobe containing the CPAM (Fig. 13.3).[2]



Fetal Hydrothorax

Fetal hydrothorax can be classified as either primary or secondary. Primary fetal hydrothorax occurs because of a lymphatic malformation, predominantly of the thoracic duct, that results in a chylous effusion. Secondary hydrothorax can be caused by immune or non-immune hydrops, chromosomal anomalies, or infections. Overall survival for fetal hydrothorax has been reported to be between 45% and 78%; therefore, close surveillance of these pregnancies is required, with the possible need for diagnostic and therapeutic fetal interventions that include thoracentesis and thoracoamniotic shunting.[68]

Percutaneous thoracentesis is both a diagnostic and therapeutic maneuver in the setting of fetal hydrothorax. Roughly one-quarter of fetuses undergoing an initial percutaneous thoracentesis for primary fetal hydrothorax will not require further intervention. The pleural fluid that is obtained can be sent for differential cell count and culture to determine the etiology of the effusion. Typically a lymphocyte count ≥85% is consistent with a chylothorax.

The majority of fetal hydrothoraces will reaccumulate after aspiration, with ongoing compression of the lung placing the fetus at risk for progression to hydrops and/or lung hypoplasia. In these cases, placement of a thoracoamniotic

shunt for definitive decompression of the hemithorax is indicated. Currently, two devices are available for shunt placement. The Harrison catheter was developed at the University of California, San Francisco, and is a polyurethane double coil stent deployed through a trocar, allowing the distal coil to be deployed within the fluid-filled cavity and the proximal coil to be deployed within the amniotic cavity. The alternative shunt is the Rocket catheter, which is larger than the Harrison catheter.

In a retrospective cohort of 88 pregnancies complicated by primary fetal hydrothorax, 74 (80.7%) neonates were born alive, with 52 (70.3%) surviving the neonatal period.[117] Fifty-nine fetuses had developed hydrops prior to shunt insertion, with these cases exhibiting survival of 52.5%. In fetuses in which hydrops resolved, 71% survived past the neonatal period. These results compare favorably to historical data from noninvasive management of hydropic fetuses. Although decompression of the hydrothorax via shunt placement is minimally invasive and may offer improved perinatal outcomes, complications related to fetal intervention persist. In the series described above, 11.4% of pregnancies experienced complications related to shunt insertion, including emergency cesarean for fetal distress, fetal demise due to cord laceration, PPROM within 7 days of shunting, and preterm delivery.[117]

Amniotic Bands

Amniotic bands are difficult to identify with standard prenatal imaging, including ultrasound and MRI. Often, the diagnosis is made by deformities that are consistent with amniotic bands (such as limb deformities) in the absence of visible bands. Although many believe that the bands result from membrane disruption, a recent single-institution review found that only 40% of cases have associated membrane separation.[52] The clinical manifestations of amniotic bands are determined by the anatomic location affected. Simple bands involving the extremities can cause

TABLE 13.1 Distribution of Amniotic Bands From the University of California, San Francisco, Single-Center Experience

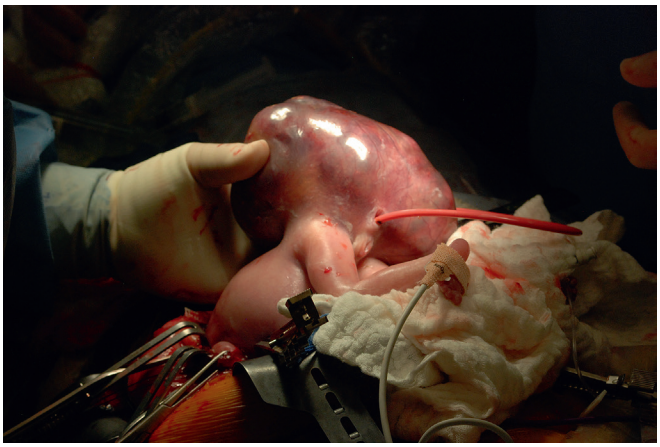
Anatomic Location	N (%)
Extremity	20 (71)
Single extremity	16 (57)
Multiple extremities	4 (14)
Umbilical cord	7 (26)
Abdomen	5 (19)
Limb-body-wall-complex	5 (19)
Head	1 (4)
Chest	1 (4)

deformity or amputation of the affected limb, whereas more complex bands involving the abdominal wall can lead to large abdominal wall defects mimicking gastroschisis or omphalocele.

Extremity involvement can account for more than 70% of cases, but any other anatomic region of the fetus can be involved (Table 13.1). Fetoscopic release of amniotic bands affecting one or more extremities can prevent limb loss and preserve limb function when distal flow is still identifiable on preoperative ultrasound.[29] In fact, amniotic bands isolated to the extremities remain the primary indication for fetoscopic band release. The procedure is performed using a 10 French cannula, similar to fetoscopy for laser ablation in TTTS. A 3-mm fetoscope is introduced, and the amniotic bands are then visualized. Through the side channel of the fetoscope, endoscopic instruments can be used to release constricting bands.

Bands involving other anatomic regions have usually resulted in irreversible defects at the time of diagnoses, and currently there does not appear to be any indication for fetal intervention in those cases. One exception is umbilical cord involvement, which may be an evolving indication for fetoscopic amniotic band release. A mortality rate of 67% with umbilical cord involvement compared with only 19% when the cord is not involved has been observed. In two patients, amniotic band release was performed for umbilical cord involvement identified at the time of fetoscopy for release of extremity bands, with both patients doing well and delivering at 40 weeks' gestation.[29]

Neoplastic Mass Lesions



Sacrococcygeal Teratoma

Sacrococcygeal teratoma (SCT) is a rare germ cell tumor that can grow to a large size in utero. Its rapid and disproportionate growth leads to high risk for perinatal complications and fetal demise secondary to nonimmune fetal hydrops as a result of high-output cardiac failure, hemorrhage, and obstetric complications, including preterm labor and polyhydramnios. Delivery can be particularly dangerous when the diagnosis has not been made prenatally, resulting in traumatic delivery causing tumor rupture and/or life-threatening hemorrhage. A nationwide Japanese survey of 97 cases of SCT from 2000–2009 found an overall fetal mortality of 26%, reduced to 16% when elective terminations were excluded.[106] However, 21% of fetuses with SCT were delivered before 32 weeks' gestation, with mortality of 44% in this cohort. Previous case series have shown perinatal mortality as high as 43%.[115] Surgical intervention is centered upon providing temporizing measures to relieve cardiovascular compromise through debulking, ablation, or devascularization, usually followed by definitive resection in the neonatal period.

To guide prenatal surveillance and potential intervention, investigators discovered the tumor volume to fetal weight ratio (TFR) as an important prognostic indicator for fetuses with SCT.[89] Tumor volume is assessed by ultrasound or MRI, and fetal weight is calculated by ultrasound using the Hadlock formula. Originally, TFR was applied to 10 fetuses with SCT, and a TFR greater than 0.12 was associated with an 80% incidence of fetal hydrops and 60% mortality. However, a TFR less than 0.12 was associated with 100% survival.[89] Subsequent multi-institutional case reviews validated TFR >0.12 as a poor prognostic sign.[6,98] In addition to TFR, case series have shown cystic SCT to have better perinatal outcomes than solid SCT.[98]

Despite the development of TFR and tumor characterization (solid vs. cystic) as an overall prognostic indicator, there is not a universally accepted indication for fetal surgical intervention. Most commonly, fetal surgery is considered in the presence of nonimmune hydrops or evidence of impending cardiac failure at a gestational age too young for delivery and neonatal care.[60] This is best assessed via fetal echocardiography to measure the combined cardiac output, which increases dramatically prior to the development of hydrops, with a value of 550 mL/kg/min associated with poor outcome in SCT.[17,95] As mentioned above, the goal of surgical intervention is to relieve the hemodynamic impact of the large mass on the fetal cardiovascular system. The most frequently utilized approach is a debulking resection via maternal laparotomy and open hysterotomy (Fig. 13.4). Minimally invasive techniques are also described and include both interstitial ablation and vascular interruption techniques with radiofrequency or laser energy sources. A recent systematic review of case reports of both open and minimally invasive interventions for SCT in the setting of nonimmune hydrops found a survival of 55% (6/11) after open hysterotomy and SCT debulking, compared to 30% (6/20) after minimally invasive interventions, including radiofrequency and laser ablation.[108] However, given reporting bias, survival is likely to be over-represented in these series, making a true comparison of open and minimally invasive techniques difficult. Additionally, while survival rates were poor in both cohorts, these interventions were performed in fetuses in the presence of hydrops, which confers a very high risk for fetal demise without intervention.[41] Finally, in both open and minimally invasive cohorts,

• **Fig. 13.4** Open fetal debulking of sacrococcygeal teratoma.

mean gestational age at delivery was less than 30 weeks, emphasizing the risk for preterm birth after surgical intervention and the need for intensive neonatal care after birth.

Additional experience is needed with minimally invasive techniques before they are abandoned in favor of open resection. Typically, lumped together as "minimally invasive," there is some suggestion that not all techniques employed are equal. A recent review sought to compare interstitial ablative procedures and vascular disruption procedures.[93] Eleven fetuses underwent devascularization procedures, with a survival of 63.6%. This compared favorably to a survival of 40.9% in 22 fetuses who had interstitial ablation. The authors hypothesized that the sudden tumor necrosis and subsequent risk for hemorrhage contributed to decreased survival with interstitial ablation.

Cystic SCTs are usually amenable to percutaneous drainage or shunt placement, which may not be indicated given the favorable prognosis for cystic SCTs and the lower incidence of fetal hydrops with cystic SCTs.[98] However, immediate decompression of an SCT may be indicated just prior to delivery to prevent dystocia, to facilitate cesarean delivery, and to prevent rupture with spillage of neoplastic cells.

Fetal Neck Mass

The fetal neck mass poses a significant risk to the fetus with a nearly 20% risk of intrauterine fetal demise (IUFD) and a 35% risk of death due to airway obstruction immediately after delivery.[11] Obstruction of the trachea and esophagus can result in polyhydramnios and preterm labor; local compression can lead to craniofacial defects and cranial nerve injury. Highly vascular lesions can result in high-output cardiac failure with nonimmune fetal hydrops and subsequent IUFD.[51] The primary histologic lesions encountered are cervical teratoma, cystic hygroma, or other vascular malformations. Rarely, neck masses can include thymic cysts or congenital neuroblastoma.[40]

Fetal neck masses are readily identified on prenatal ultrasound, and upon diagnosis, fetal MRI should be obtained to better characterize the mass—specifically to distinguish between a cystic hygroma and teratoma based on the presence of fat. Fetal MRI can also aid in the identification of the fetal trachea. Ultrasound imaging can help in diagnosis and prognosis by demonstrating polyhydramnios, the lack of a fluid-filled stomach indicating esophageal compression, and a dilated hypopharynx. The tracheoesophageal displacement index (TEDI) is a useful prognostic measurement described by the group at Texas Children's Hospital.[62] This measurement is defined as the sum of the lateral and ventral displacement of the trachea and esophagus from the ventral most aspect of the cervical spine. In their series of 24 prenatally diagnosed neck masses, all patients with a TEDI of greater than 12 mm had a complicated airway, whereas only 46% of those with a TEDI less than 12 mm had a complicated airway. Furthermore, the authors found that the presence of a cervical teratoma or polyhydramnios also increased the risk for a complicated airway.

Pregnancies complicated by a fetal neck mass require very close surveillance. Large masses that cause significant extension of the neck require delivery via cesarean section due to the risk of dystocia. In the presence of fetal hydrops prior to 30 weeks' gestation, successful open fetal resection has been reported.[51] In all cases, at the time of delivery, immediately securing the airway is paramount, as 35% of cases in which the neonate dies immediately are a result of airway compromise.[11] For this reason, the EXIT-to-airway procedure should be considered to permit safe establishment of the airway prior to delivery. However, it is important to keep in mind that most cystic neck masses do not cause airway obstruction, and judicious use of EXIT procedures for these patients is required.

If delivery is pursued via EXIT-to-airway procedure, strict adherence to anesthetic principles are required. Deep maternal anesthesia is required to maintain complete uterine relaxation and preserve uteroplacental circulation so that the fetus does not undergo premature transition from fetal to neonatal circulation. During an EXIT-to-airway procedure, the uterus is exposed and a hysterotomy is made to deliver the fetus's head and neck.[50] Direct laryngoscopy can be attempted for endotracheal intubation. Airway management can be escalated using bronchoscopy or tracheostomy if laryngoscopy is not successful. In the presence of a large neck mass, the trachea is often deviated, and this displacement must be recognized prior to tracheostomy. In cases of large cystic lesions, decompression of the cyst may facilitate establishing an airway by relieving any airway compression. When an airway still cannot be obtained, resection of the mass while still on uteroplacental circulation may be necessary, converting the procedure to an EXIT-to-resection. Once an airway has been established and confirmed (usually by flexible bronchoscopy), the umbilical cord can be divided and the baby completely delivered.

Post-delivery and post-resection hypothyroidism and hypoparathyroidism are the most common non-airway complications. Therefore, an endocrine evaluation should be initiated with specialist consultation as indicated. Given the small malignant potential for cervical teratomas, screening for recurrence should also be implemented by following alpha-fetoprotein levels and obtaining surveillance imaging.

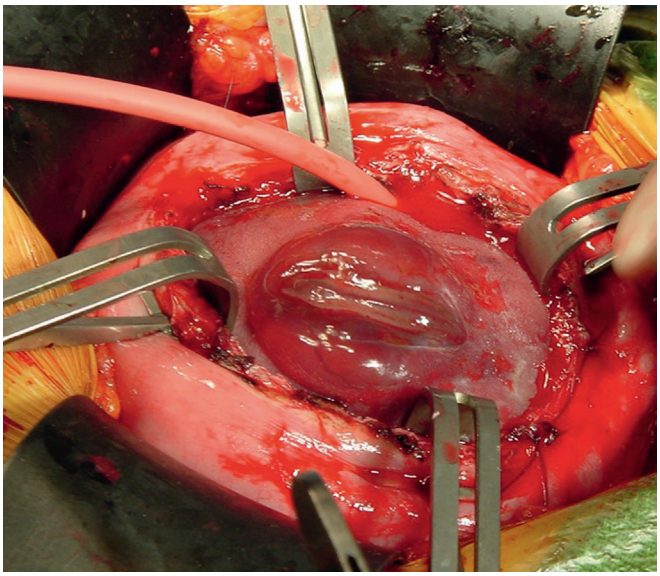
Cystic hygromas and other vascular malformations presenting as fetal neck masses can be difficult to manage postnatally given that these lesions have a propensity for significant cervical, oral, and intrathoracic extension, making complete resection difficult, recurrence rates high, and disfigurement likely.



Myelomeningocele

Myelomeningocele (MMC), or spina bifida, is characterized by incomplete closure of the neural tube resulting in exposure of the spinal canal elements. This can occur anywhere along the spine but most commonly occurs at the lumbar or cervical vertebral levels. The primary manifestations include neurologic deficits with motor and somatosensory abnormalities that correspond to the level of the spinal defect, autonomic nervous system injury resulting in impaired bowel and bladder function, and the Chiari II malformation of the hindbrain leading to hydrocephalus and the need for ventriculoperitoneal (VP) shunting. Contrary to most targets for fetal surgical intervention, fetuses with MMC do not have high risk for perinatal mortality. However, MMC confers severe long-term morbidity to the child, and up to 30% of patients with MMC die before reaching adulthood, owing to respiratory, urinary, or central nervous system complications.[49]

The rationale for fetal intervention in MMC is centered on a "two-hit" hypothesis for development of morbidity, in which the first hit is the original neural tube defect that results in an open spinal canal, and the second hit is postulated to be trauma to the exposed neural elements while the fetus is in utero.[73] By minimizing secondary trauma to the exposed neural elements through fetal repair, it was hypothesized that neurologic outcomes for MMC could be improved.[113] Indeed, early results from animal studies showed improved neurologic outcomes with prenatal closure, which was confirmed in the first human studies along with a decreased need for VP shunting.[16,34]

Initial attempts at minimally invasive techniques of MMC repair resulted in high rates of fetal death,[15] leading to further development and refinement of open surgical techniques. Thus, fetal repair of MMC is performed most often through a maternal laparotomy and open hysterotomy (Fig. 13.5) with either primary repair of the defect or coverage of larger defects using allografts.[5] Recently, two minimally invasive approaches have been described,[61,81] but outcomes are not extensively studied.

Initial success with open surgical repair prompted a multi-institutional prospective randomized trial, known as the Management of Myelomeningocele Study (MOMS), comparing open fetal repair at 19-26 weeks' gestation to postnatal repair.[5] For the MOMS trial, a power analysis based on the initial, nonrandomized human studies indicated 200 patients were required to adequately study the primary outcome, which was the need for a VP shunt within the first 12 months of life. However, the study was terminated early after demonstrating superiority of prenatal repair. Patients undergoing fetal repair had decreased need for VP shunt placement (40% compared to 82% in the postnatal repair group) and improved motor function, as 42% of the fetal repair group could walk by 30 months of age, compared to 21% in the postnatal repair group.

• **Fig. 13.5** Open fetal myelomeningocele repair. (From Fetal therapy. In: Holcomb GW III, Murphy JP, eds. *Ashcraft's Pediatric Surgery*. 5th ed. St Louis: Elsevier; 2010:125-132.)

Despite demonstrating a convincing benefit to the fetus in terms of neurologic outcomes, the excitement for fetal repair of MMC has been tempered by the incidence of obstetric morbidity demonstrated in the MOMS trial. Complications included a 38% incidence of preterm labor, with a mean gestational age in the prenatal repair group of 34 weeks compared to 37 weeks in the postnatal group. Furthermore, premature rupture of membranes occurred in 46%, chorioamniotic membrane separation in 26%, and placental abruption in 6%. Additionally, fetal demise occurred in 3% of the prenatal repair group. For these reasons, extensive counseling should be provided to families to ensure that they fully understand the risks and benefits of prenatal MMC repair.

Urinary Tract Abnormalities

Hydronephrosis

Hydronephrosis is a common prenatal diagnosis. In most cases, especially when the extent of hydronephrosis is mild, there is complete resolution. However, 10% will have persistent or progressive disease and require postnatal evaluation.[77] In the setting of minimal hydronephrosis, an ultrasound should be obtained in the third trimester to determine if there has been resolution or progression, which will help determine the need for postnatal evaluation.

In more severe cases of hydronephrosis, ureteropelvic junction (UPJ) obstruction, ureterovesical junction obstruction, or an obstructing ureterocele should be suspected. If the obstruction is unilateral, there is no indication for fetal

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

intervention, because the unaffected contralateral collecting system functions normally, maintaining adequate amniotic fluid volume. However, bilateral obstruction leading to hydronephrosis can produce severe oligohydramnios, placing the fetus at risk for developing pulmonary hypoplasia leading to neonatal death. Improved survival with urinary tract decompression and restoration of amniotic fluid volume via shunting has been demonstrated.[23] Yet, further postnatal care is still complicated by dysplastic change of the kidneys from chronically elevated hydrostatic pressure in the collecting system. The first fetal intervention for hydronephrosis was for bilateral UPJ obstruction in 1982[39]; fortunately, UPJ leading to oligohydramnios is uncommon and the need for fetal intervention with shunting is rare.

Lower Urinary Tract Obstruction

Lower urinary tract obstruction (LUTO) is most commonly caused by posterior urethral valves (PUV) but can also result from urethral atresia and Eagle-Barrett syndrome (prune belly).[35] LUTO is most commonly diagnosed on screening prenatal ultrasound at 20 weeks' gestation, with observance of the classic triad of a dilated keyhole-shaped bladder, bilateral megaureters, and bilateral hydronephrosis.[69] The fetus with LUTO is at high risk for the development of oligohydramnios as a result of mechanical obstruction of urinary flow and dysplastic changes in the kidneys. Resultant development of pulmonary hypoplasia is associated with a perinatal mortality around 50%, with surviving neonates placed at a 20% to 30% risk of developing end-stage renal disease in their lifetime.[12,85] Additionally, chronic distention of the bladder is associated with a 45% incidence of neurogenic bladder, with most babies developing at least a mild degree of permanent bladder dysfunction.

Oligohydramnios in the setting of LUTO is considered an indication for fetal intervention, with the aims of preventing pulmonary hypoplasia by restoring the amniotic fluid volume and preventing further kidney injury, as animal models of LUTO suggest renal dysplasia is more severe the earlier it occurs and the longer it is sustained.[36]

Fetal interventions employed in the treatment of LUTO include vesicoamniotic shunting (VAS), fetoscopic cystoscopy with PUV ablation, and open fetal vesicostomy. VAS is the most common modality in use today. A meta-analysis of early case reports found improved perinatal survival, especially in fetuses with poor prognoses.[20] However, the Percutaneous Vesicoamniotic Shunting versus Conservative Management for Fetal Lower Urinary Tract Obstruction (PLUTO) trial, an international prospective randomized trial aimed at characterizing benefit in renal function over long-term follow-up, showed that patients in both the VAS and control groups had poor renal function at 1 and 2 years of age.[78] The study ended early due to poor enrollment, and survival to 28 days showed a trend toward improvement in the VAS group in intention to treat analysis. These results suggest irreversible damage to the renal parenchyma occurs prior to diagnosis, and that surgical intervention may only provide a small benefit, if any, to long-term outcome.

TABLE 13.2 Normal* Values for Fetal Urine Electrolytes

Measurement	Normal Values
Osm	<210 mEq/L
Na	<100 mEq/L
Cl	<90 mEq/L
Ca	<2 mmol/L
PO_4	<2 mmol/L
β_2-microglobulin	<2 mg/L

*Validated after 20 weeks' gestational age.

Furthermore, vesicoamniotic shunting can be complicated by shunt dislodgment, shunt occlusion, iatrogenic gastroschisis, and obstetric complications.

Imaging and fetal urine electrolyte studies are well-described but are not definitive in identifying those fetuses with LUTO that do not have oligohydramnios and have not yet developed irreversible renal injury, making them optimal candidates for intervention. Fetal urine electrolytes are only interpretable after 20 weeks' gestation,[80] and the initial bladder needle aspiration may be a misrepresentation of renal function because that urine may have been in the bladder for some time. Thus, serial taps are usually more helpful in determining the presence of renal dysplasia, especially if the β_2-microglobulin is elevated. Established normal values for other fetal urine electrolytes are outlined in Table 13.2; these values are representative of fetal urine electrolyte composition after 20 weeks' gestation. On ultrasound, findings of echogenic calyces and loss of corticomedullary differentiation may be early indicators of renal dysplasia. Cystic changes or the presence of a perinephric urinoma are late findings.[69] Further investigation to identify at-risk patients and more effective therapies is needed. Whether intervention is undertaken or not, these pregnancies require close monitoring, especially regarding the amniotic fluid volumes. Delivery should occur in a tertiary center.

Abnormalities of Twin Gestations

Monochorionic twin gestations carry up to a 50% incidence of developing a complication (see Chapter 21). This is predominantly because of the unpredictable nature in which the two umbilical cords are implanted in the uterus and how the placental circulation is shared. Of the multiple complications that arise from the shared placenta, twin–twin transfusion syndrome (TTTS) is the most common complication, occurring in 10% of all monochorionic twin pregnancies.[96]

Twin–Twin Transfusion Syndrome

TTTS occurs when vascular connections (which can be arterial-to-venous, venous-to-arterial, or arterial-arterial)

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

form between the umbilical cord vessels of both fetuses, resulting in a bypass of maternal circulation and an imbalance of umbilical flow. If the net blood flow from one twin (the donor) exceeds flow from the other twin (the recipient), then TTTS ensues. The donor twin develops hypovolemia, manifesting in oliguria and oligohydramnios secondary to decreased renal perfusion, while the recipient twin suffers from volume overload leading to polyuria and polyhydramnios.[58] These physiologic alterations place the donor twin at risk for hypoxic-ischemic injury and restricted growth while the recipient can suffer from nonimmune hydrops. The pathognomonic diagnostic finding in TTTS is oligohydramnios, defined as a deepest vertical pocket (DVP) less than 2 cm in the donor twin, with concurrent polyhydramnios, defined as a DVP greater than 8 cm in the recipient twin. It is also common to see growth discordance between the twins, with the donor being smaller than the recipient. Growth discordance becomes worrisome in any twin pregnancy when the estimated weights are greater than 20% discordant. Quintero et al. developed sonographic criteria widely utilized as a staging system for TTTS (Table 13.3).[86] If severe TTTS is left untreated, mortality for both twins is greater than 90%.

Two primary modes of therapy have been offered for TTTS: amnioreduction and fetoscopic laser ablation. Amnioreduction of the polyhydramniotic sac was initially used to reduce the amniotic volume and decrease the risk of preterm labor. Based on survival outcomes for TTTS treated with amnioreduction reported through the International Amnioreduction Registry, high-volume amnioreduction was associated with a 60% single twin survival rate.[88] However, fetoscopic laser ablation for TTTS has largely replaced amnioreduction as the primary therapy for TTTS. Fetoscopic laser ablation is performed through a 10 French cannula using a 3-mm fetoscope that is equipped with a side channel for deployment of a laser fiber. Under direct fetoscopic visualization, intertwin vascular connections are readily identified on the surface of the placenta and are all ablated.

The use of amnioreduction versus laser ablation in the treatment of TTTS has been comparatively studied in multiple retrospective studies that prompted prospective trials. Initial studies varied in whether or not laser ablation was associated with a survival benefit, but overall neurologic outcomes favored those twins undergoing laser ablation.[112] Two large prospective trials comparing amnioreduction to laser ablation have been conducted, primarily favoring laser ablation. The first trial, conducted by the Eurofetus group, enrolled 70 women for treatment with amnioreduction and 72 women for treatment with laser ablation.[97] Early interim analysis showed a clear survival advantage for laser therapy—76% versus 51% single survivor and 36% versus 26% for dual survivors—and the study was closed prior to full enrollment. A North American trial sponsored by the NIH was also closed early after 42 mothers were randomized: 20 in the amnioreduction arm and 22 in the laser ablation cohort.[24] There was no demonstrable survival benefit in this underpowered study, but it was stopped early due to poor recruitment. The data obtained in these two trials was pooled in a 2014 Cochrane review, which showed a nonsignificant trend toward improved survival with laser ablation (overall survival of 66% for laser ablation compared with 48% for amnioreduction).[88] Additionally, a higher percentage of children alive at 6 years had no neurologic abnormality in the laser group. Given these findings, laser ablation has to become the treatment of choice for advanced TTTS; however, when laser ablation is not available or not possible for technical reasons, amnioreduction is an appropriate alternative.

At what stage to intervene for TTTS is highly controversial. There is wide agreement that cases of stage II or greater require intervention; however, there is no consensus regarding the management of stage I TTTS. Favorable outcomes with expectant management for stage I TTTS are possible, with laser ablation reserved for those cases with stage II or more advanced disease; this strategy has been supported in multiple observational studies.[90] However, a multicenter retrospective review demonstrated improved outcomes with prenatal intervention (amnioreduction or laser) over observation.[33]

TABLE 13.3 Quintero Stages of Twin–Twin Transfusion Syndrome

Stage	Description
I	Polyhydramnios (DVP >8 cm) with oligohydramnios (DVP <2 cm) with bladders present in both twins
II	Bladder not visible in the donor twin
III	Changes in umbilical cord or ductus venosus end-diastolic flow; tricuspid regurgitation in the recipient twin
IV	Evidence of hydrops in either twin
V	Fetal death

Selective Fetal Reduction

In addition to TTTS, monochorionic twin pregnancies are subject to complications, including selective intrauterine growth restriction, structural anomalies, twin anemia polycythemia sequence, and twin reversed arterial perfusion sequence (TRAP).[104] In complicated monochorionic pregnancies at high risk for hemodynamic compromise or intrauterine fetal death, fetal reduction may prevent secondary neurologic injury or demise of the co-twin.[82] Selective termination can be achieved via umbilical cord ligation, fetoscopic laser coagulation, ultrasound-guided bipolar cord coagulation, or radiofrequency ablation (RFA).[116]

Selective reduction is especially beneficial in TRAP sequence, a rare complication occurring in 1% of monochorionic pregnancies. In TRAP sequence, one twin has an absent or nonfunctional heart, and receives blood flow from arterial-arterial anastomoses between the twins, resulting in

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

one twin acting as a "pump," providing blood flow to the acardiac twin.

Because the normal twin is maintaining blood flow for itself as well as the acardiac twin, TRAP sequence can lead to high-output heart failure with progression to hydrops and fetal demise. Untreated, there is a 50% to 75% mortality rate in the pump twin, owing to cardiac failure and nonimmune hydrops.[76] Generally, intervention is indicated when there is evidence of high-output cardiac failure or hydrops in the pump twin, or when the estimated fetal weight of the acardiac twin is 50% or more relative to the pump twin.[57]

Selective reduction occurs most commonly via RFA of the acardiac twin's umbilical cord. A 2013 review of 98 cases of RFA for TRAP across 12 centers in the North American Fetal Therapy Network found survival of the pump twin in 80% of cases to 30 days of life.[63]

Congenital Heart Disease

Advancements in the prenatal care of congenital heart disease include fetal interventions in cardiac bradyarrhythmias and valvular stenosis resulting in evolving hypoplasia of the right or left ventricle. Bradyarrhythmias occur in 9% of cases, and the outcome is best determined by the etiology of the bradyarrhythmia. In nearly half of the patients, the heart is structurally normal, but transplacental antibodies from mothers with collagen vascular disease affect the fetal heart. These patients may benefit from maternal steroid administration to lower maternal antibody titers; however, if that is not successful, the only alternative that has been explored is fetal pacemaking. Unfortunately, the best reported outcome to date was 5 days post-implantation with no survivors to delivery.[32]

Critical outflow stenosis of the fetal aortic or pulmonary valves can progress to complex congenital heart defects, namely, hypoplastic right and left heart, respectively. Hypoplastic congenital heart defects require multiple, staged procedures to achieve double ventricular physiology, and even then, the outcomes are poor. Therefore, attempts at correction in utero have been made and focus solely on early relief of the obstructive lesion to prevent hypoplasia of the affected ventricle. In 1991, Maxwell described the first percutaneous balloon fetal aortic valvuloplasty (FAV) in a fetus with evolving hypoplastic left heart syndrome (HLHS).[70] In this procedure, ultrasound guidance was used to advance a guidewire through the apex of the heart and across the stenotic aortic valve. Using a Seldinger technique, a balloon catheter was deployed across the valve and inflated to relieve the obstruction.

In a recent retrospective review of 100 cases of FAV between 2000 and 2013, 88 fetuses survived to birth, and 38 had biventricular circulation.[38] Fetuses who progressed to birth with biventricular cardiac physiology had an 84% cardiac death-free survival to 10 years. However, even in patients who developed biventricular physiology, 37 of 38 required postnatal interventional procedures. While these results are promising, multiple complications have been reported with percutaneous balloon valvuloplasty. These include IUFD, pericardial effusions requiring aspiration, fragmentation of the device in the heart, significant valvular regurgitation, need for pressor support intraprocedurally for hemodynamic instability, and all of the other risks associated with percutaneous procedures.[75]

Conclusion

The application of in utero correction for fatal fetal anomalies has existed for more than three decades, and over that time the indications and techniques have evolved dramatically, showing great promise to improve outcomes for anomalies that historically have been poor and increasing our understanding of the natural history of most congenital anomalies. Traditionally, fetal surgery had been reserved for the fetus in distress, but the improved outcomes for myelomeningocele with open fetal repair have challenged this paradigm and beg the question: what other anomalies might benefit from prenatal therapy? Despite this growing optimism and interest in the utility of fetal interventions, maternal and fetal risk should not be underestimated. We should remain critical of our progress by inclusion of multiple areas of discipline, and we should approach innovation in the field of fetal surgery responsibly to minimize unintended harm to our patients, both born and unborn.

Key Points

- Fetal surgery is a developing field, with scientific, clinical, and ethical questions still under investigation, and innovation forging new paths forward.
- The well-being of the expectant mother must be considered the top priority when treatment decisions are made.
- Any fetal intervention carries substantial risk of obstetric complications, including preterm labor, PPROM, membrane separation, and chorioamnionitis; open hysterotomy necessitates eventual delivery by cesarean section.
- Fetal interventions are usually reserved for the fetus at risk of intrauterine or early neonatal demise, as is the case in congenital diaphragmatic hernia, CPAM, hydrothorax, SCT, fetal neck mass, urinary tract obstruction, abnormalities of twin gestation, and congenital heart defects.
- Fetal repair of myelomeningocele is unique in that fetal intervention aims to minimize postnatal morbidity rather than mortality.
- Innovation in surgical instrumentation and technique has led to effective percutaneous and fetoscopic minimally invasive therapies for most conditions amenable to prenatal intervention.

Adverse Exposures to the Fetus and Neonate

ALISON J. FALCK, SANDRA MOONEY, AND CYNTHIA F. BEARER

Exposure to environmental toxicants during pregnancy may have a significant impact on the developing fetus. Fetal adverse exposures are growing in importance as our population expands and the number of women participating in the workforce continues to rise. In 2015, women comprised 47% of the workforce in the United States, and 73.5 million women aged 16 and over were employed. Approximately 75% worked full time.[115] In addition, more pregnant women are staying in the workforce and continuing to work until later into pregnancy. According to the U.S. Census Bureau (2011), 66% percent of women worked during their first pregnancy in 2008, and 88% percent continued into the third trimester.[74]

Environmental exposures increase as the world's population and economic needs expand. In 1900, there were 1.25 billion people on Earth. This number doubled by 1950 and doubled again in 1987 to 5 billion. The world population was estimated at 7.6 billion in 2017; it is projected to increase to 9.8 billion by 2050, and 11.2 billion by 2100.[109] Pressures of population growth are reflected in increasing need for land, water, food, and fuel. With population expansion, economic growth, and technologic advances comes increasing interaction with chemicals in our environment that are developed to support our society. The growth of industry, commerce, and agriculture brings overuse of land; changes to the environment such as global warming; and contamination of air, water, food, and soil. It is inevitable that all humans are exposed to environmental toxicants, including the developing fetus.

The Developmental Origins of Health and Disease (DOHaD) is a field of study that explores the relationship between exposure to environmental stressors during critical periods of fetal development and adverse health outcomes that occur across a lifetime (see also chapter 16). This paradigm suggests that the developing fetus exhibits significant genetic plasticity that may be impacted by the intrauterine environment. Thus, genetic "reprogramming" that occurs prenatally can alter phenotypic expression, both following birth and in generations to come.[4,78,121] The DOHaD is based on work originally published in 1990 by a British epidemiologist, Dr. David Barker. The Barker hypothesis (or fetal origins hypothesis) describes fetal nutritional and metabolic programming as the mechanism linking intrauterine growth restriction to the development of coronary artery disease as an adult.[73,121] Fetal exposure to toxicants is a stressor that has also been implicated in the DOHaD and is the subject of this chapter.[55,121] Toxic environmental exposures may be non-concurrent or concurrent with pregnancy. This chapter describes the role of epigenetics and developmental plasticity, pathways of fetal exposure to environmental toxicants, unique pharmacokinetics of the fetus, and the spectrum of adverse outcomes associated with fetal exposure to specific environmental toxicants (Fig. 14.1).

Exposures Not Concurrent With Pregnancy

Environmental exposures that affect the fetus may occur long before conception and possibly in an earlier generation than the parents. Commonly, the exposure impacts the ovum or sperm. In addition, there are chemicals that bioaccumulate prior to pregnancy and impact the fetus by enhanced elimination during pregnancy. Lipid-soluble toxins and heavy metals such as lead are stored in adipose and bone and mobilized during pregnancy. Some chemicals, such as organohalogens, can affect the fetus by both non-concurrent and concurrent exposure.[4]

Preconceptual Effects

The Epigenome

Epigenetics is the study of phenotypic changes occurring in the absence of modification of DNA sequence. Environmental epigenetics describes the relationship between endogenous and exogenous factors (such as chemical exposure) and the epigenome.[90] Changes to the epigenome are stable, heritable, and a target for environmental toxicants. The term *epimutation* refers to a heritable change in gene expression that does not affect DNA base pair structure.[35,90]

The epigenome is susceptible to dysregulation at any time but is highly vulnerable during fetal life when the

Abstract

Environmental exposures during pregnancy may significantly affect the fetus during critical stages of development. Toxicants can adversely influence phenotypic expression following birth and impact health across a lifetime. In addition, genetic and epigenetic modifications may be transferred to future generations. Both maternal and paternal toxicant exposure that occurs prior to pregnancy and during the periconceptual period may impact fertility and contribute to development of congenital malformations. Other exposures that are non-concurrent with pregnancy include maternal body burden with chemicals such as lead and polychlorinated biphenyls that are mobilized from stores in bone and adipose tissue during pregnancy. Histone modification, expression of microRNA, and DNA methylation are examples of epigenetic mechanisms that alter the fetal phenotype without changing DNA sequence; the epigenome is highly susceptible to environmental toxicants during fetal development. Air pollution, heat, drinking water, and diet represent examples of sources of toxic exposure that occur during pregnancy. Toxicants primarily reach the fetal compartment via passive diffusion across the placenta; lipid solubility, molecular weight, protein binding, and ionization impact placental transport. Other placenta-independent pathways that may be harmful to the developing fetus include heat, noise, and ionizing radiation. The complex physiologic environment during pregnancy impacts absorption and distribution of chemicals to the fetal compartment. Both ontogeny of fetal hepatic metabolic enzymes and genetic polymorphisms are important factors in determining susceptibility of the fetus to toxic effects. Throughout this chapter, specific examples of environmental toxicants, their known effects on pregnancy and the fetus, and preventive strategies are explored.

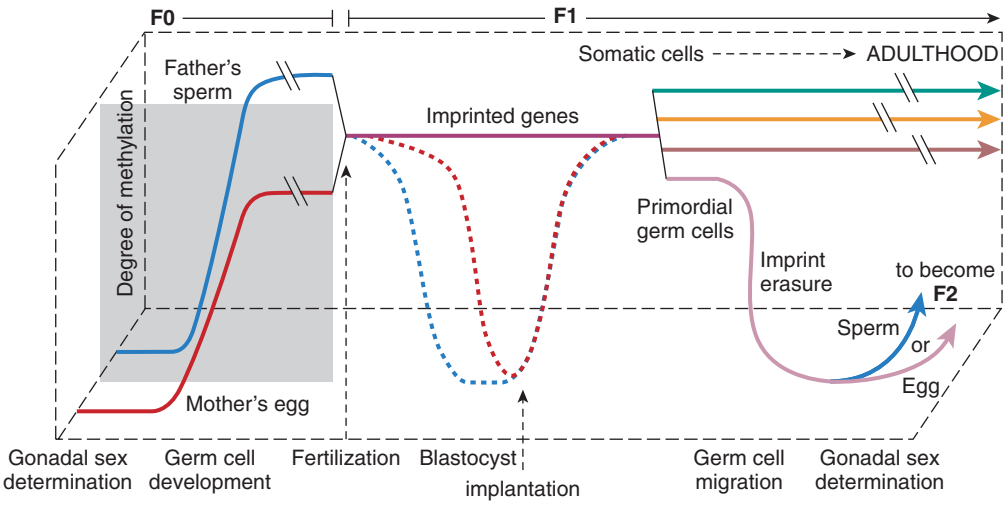
rate of DNA synthesis is high. Epigenetic mechanisms include alterations in expression patterns of microRNAs, modifications of histone proteins, and DNA methylation. These epigenetic mechanisms are described in Fig. 14.2.[102] MicroRNAs are small segments of noncoding RNA that regulate post-transcriptional expression of mRNA.[35,78,90,95,102,129] Histones are a group of eight nuclear proteins that package and tightly compact DNA chromatin into smaller, coiled segments called nucleosomes containing 146 base pairs. Histone modifications such as acetylation and phosphorylation alter the histone protein at the N-terminal tail, changing nucleosome structure, and activating or repressing transcription.[95,102] DNA methylation is a well-described epigenetic modification involving addition of a methyl group to the nucleotide cytosine when it precedes guanine, frequently at the promoter region. Methylated segments of DNA are more tightly coiled, hiding the promoter region and limiting gene expression. In less methylated areas, the promoter is open, allowing for DNA transcription.[4,35,49,95] DNA methylation is the mechanism of X-chromosome inactivation during embryogenesis in females. Aberrant DNA methylation of the X-chromosome is implicated in fragile X syndrome.[90] While DNA methylation is not entirely static across a lifetime, much of the epigenome is established during fetal development.[49]

One of the best-described epigenetic processes is genomic imprinting. Genomic imprinting occurs during early development and involves silencing of one parental allele leading to monoallelic gene expression. Dysregulation of genomic imprinting, potentially due to aberrant methylation of DNA, leads to disorders such as Angelman syndrome, Prader-Willi syndrome, and Beckwith-Wiedemann syndrome, and has been linked to autism and cancer later in life.[90] Imprinted genes are ideal models to study epigenetic modifications. As imprinting occurs early in fetal development, epigenetic adaptations are likely to have a significant effect. For example, adults who were conceived during the Dutch famine of World War II (1944–1945) demonstrate widespread and persistent changes in DNA methylation of imprinted insulin-like growth factor-2 (IGF-2) loci, with diverse biologic functions. These genes are known to be important modulators of growth, and epigenetic modifications are implicated in the development of metabolic and cardiovascular disease in adults.[78] Offspring conceived during the famine have developed these metabolic and cardiovascular conditions more frequently as adults.[129]

Fig. 14.3 illustrates potential periods of fetal development in which environmental toxins may impact the phenotype of the developing fetus.[90] Environmental toxicants have been shown to alter the epigenome during fetal life via modifications in DNA methylation. Measures of global DNA methylation can quantify the methylation state of the epigenome and have been utilized to investigate the relationship between toxicant exposure and epigenetic modifications. Global DNA hypomethylation is correlated with instability of the genome and cancer risk.[58]



An association between prenatal exposure to metals such as arsenic, cadmium, and lead and DNA methylation has been documented in the literature.[4,35,49,78] Buccal samples from children prenatally exposed to maternal cigarette smoking show both global hypomethylation and in specific loci important in modulating cellular proliferation.[49] Polycyclic aromatic hydrocarbons (PAHs) are neurotoxic and carcinogenic chemicals found in fumes from vehicle exhaust, coal, charbroiled foods, and cigarette smoke. PAHs are lipophilic and cross the placenta and fetal blood-brain barrier. Byproducts of PAH metabolism have the capacity to bind DNA, forming PAH-DNA adducts. The fetus is highly susceptible to formation of PAH-DNA adducts and associated genetic mutations, a known cancer risk. In a cohort of 159 children, prenatal airborne PAH exposure was associated with global hypomethylation of umbilical cord WBC DNA, which persisted at 3 years of age. In addition, increased global methylation was associated with the presence of BPH-DNA adducts in cord blood, two independent findings associated with increased cancer risk.[58,90]

• **Fig. 14.2** Examples of epigenetic mechanisms: Histone modification, RNA interference (micro RNA), and DNA methylation. These mechanisms interact with DNA or mRNA to control gene expression. A nucleosome is the building block of chromatin, consisting of 146 base pairs wrapped tightly around nuclear proteins called histones. Histones are modified at the N-terminal tail, altering nucleosome structure and regulating transcription. RNA interference involves regulation of post-transcriptional expression of mRNA by noncoding segments of RNA called microRNAs. DNA methylation is characterized by addition of a methyl group to cytosine when it precedes guanine, frequently at the DNA promoter region. Regions in which methylation occurs are more tightly coiled, hiding the promoter region and limiting gene expression. In less methylated areas, the promoter is open, allowing for DNA transcription. • **Fig. 14.3** Potential periods in which environmental toxicants may impact the phenotype of the developing fetus by epigenetic modifications such as DNA methylation. F0 = parental germ cell development; F1 = the developing fetus; F2 = future generation(s). (From Perera F, Herbstein J. Prenatal environmental exposures, epigenetics, and disease. *Reprod Toxicol*. 2011;31:364.)

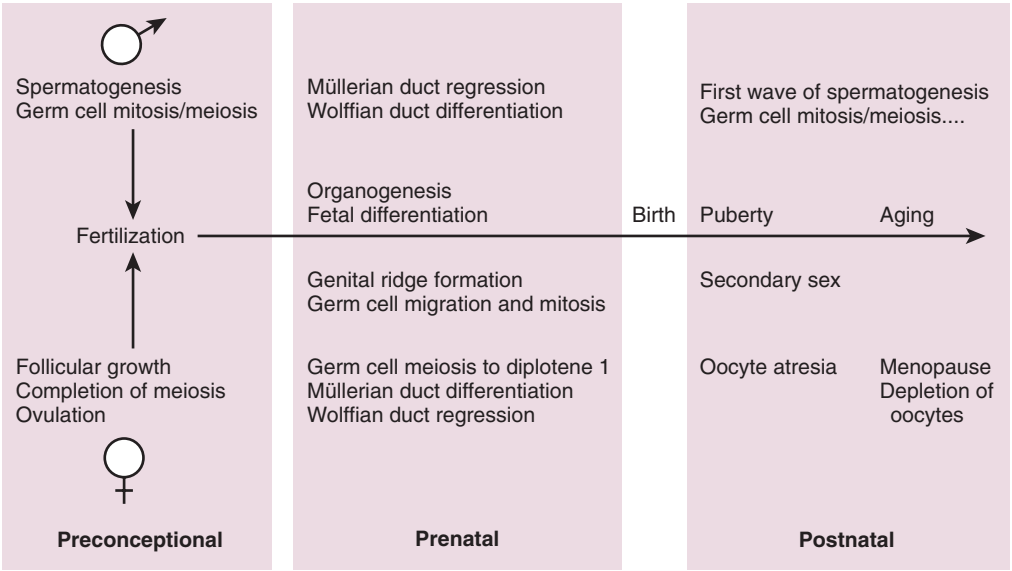
Maternal Exposures

In early fetal life, oogonia are formed by meiotic division. Before birth, oogonia develop into primary oocytes and complete prophase of the first meiotic division.[94] Oocytes remain in this state until puberty. As cells are highly susceptible to environmental toxicants while in active phases of division, fetal life represents a critical period of vulnerability. This hypothesis is supported by the increasing incidence of nondisjunction events with advancing maternal age and prolonged environmental exposures. Exposures impacting regulatory and endocrine functions of the ovum can influence ovarian competence throughout life. Fig. 14.4 represents critical windows of exposures that may impact the male and female reproductive system.[94]

Active smoking during pregnancy is associated with loss of ova in the fetus, which may reduce fertility in women born to mothers who smoke. In animal models, fetal exposure to nicotine results in granulosa cell proliferation, impaired ovarian steroidogenesis and angiogenesis, increased ovarian cell apoptosis, and reduced fertility.[12] Endocrine disrupting chemicals (EDCs) are compounds that act as agonists or antagonists to the endocrine system. Epidemiologic studies demonstrate an association between developmental exposure to EDCs and infertility. Bisphenol A (BPA) is an EDC found in plastic products. An inverse relationship has been found between the number of eggs recovered during in-vitro fertilization and urinary BPA levels.[129]



Developmental exposure to environmental toxicants can have an impact on fertility that may be transmitted to future generations. Inheritance of epigenetic information between generations that leads to phenotypic variation in the absence of direct environmental influence is termed *epigenetic transgenerational inheritance*. Epigenetic transgenerational inheritance requires epimutations to be present in the germline, as it is only sperm and eggs that pass this information to the next generation.[82] Epigenetic transgenerational inheritance has been proposed as a mechanism for phenotypic aberrations that have occurred following fetal exposure to the EDC diethylstilbestrol (DES). DES is an estrogenic drug that was prescribed to 5–10 million women worldwide from the 1940s to the 1970s to prevent miscarriage. Although vaginal clear cell adenocarcinoma has occurred infrequently in daughters of women exposed to DES, infertility and poor pregnancy outcomes are extremely prevalent. In addition, other disorders of the reproductive, cardiovascular, and immune systems have been reported in both male and female offspring and these effects have persisted in the grandchildren of DES-treated women.[55,68,129] The incidence of breast cancer is at least twofold higher in the daughters of DES-exposed mothers.[60]

Paternal Exposures

Environmental toxicants that impact spermatogenesis have been identified. Spermatogonia are highly sensitive to apoptosis after exposure to cytotoxic agents. Toxicants may also impact male fertility by limiting sperm production. Unlike the female, cell divisions in the male that produce mature spermatozoa occur after puberty. However, mature spermatozoa have no DNA repair mechanisms and are vulnerable to the effects of mutagens. Transient aneuploidy of autosomal and sex chromosomes has been reported in sperm of men treated for Hodgkin disease with chemotherapy in the preceding 3 months.[94]

A gradual decline in sperm concentration has been reported in reproductive-age males, and human male infertility is currently approaching 10%. Increased exposure to environmental toxicants has been postulated as a contributing factor. For many of these exposures, findings have been reproduced for several generations, and epigenetic transgenerational inheritance is a proposed mechanism.[77,82] Chronic occupational exposure to the pesticide 1,2-Dibromo-3-chloropropane (DBCP) is associated with cessation or

• **Fig. 14.4** Critical windows of exposure of the reproductive system to environmental toxicants during preconception, prenatal, and postnatal period. (From Pryor JL, et al. Critical windows of exposure for children's health: the reproductive system in animals and humans. *Environ Health Perspect*. 2000;108(3):492.)

reduction in spermatogenesis.[94] In the rat model, exposure of the pregnant female to two EDCs (vinclozolin, a fungicide used in the wine industry, and the pesticide methoxychlor) led to impaired spermatogenesis and infertility in males in four subsequent generations.[77,82,94] Phthalates are plasticizers and known EDCs that are now ubiquitous in our environment. Bis (2-ethylhexyl) phthalate (DEHP) is found in polyvinyl compounds, while dibutyl phthalate (DBP) is used primarily to add flexibility to plastics. Both compounds can adversely affect male reproductive function. In animal studies, prenatal exposure has been linked to spermatogenic cell apoptosis, seminiferous tubule atrophy, and testicular dysfunction. Phenotypic alterations following exposure prenatally included cryptorchidism, hypospadias, ambiguous genitalia, reduced sperm production, and decreased anogenital distance.[77]

The relationship between paternal occupation and cancer in offspring has been extensively studied.[40,99] One study reported increased risk of central nervous system (CNS) tumors with paternal occupational exposure to pesticides (relative risk [RR] 2.36; 95% CI 1.27-4.39) and work as a painter (RR 2.18; 95% CI 1.26-3.78). Increased incidence of childhood leukemia has been associated with paternal periconceptual occupational exposure to woodworking, solvents, paints, pesticides, and motor vehicles (driving, exhaust fumes, and inhaled particulate hydrocarbons).[40] A case control study evaluating paternal exposure to pesticides reported increased risk of astrocytoma in offspring; combining occupational and home exposures significantly elevated this risk (OR = 1.8, 95% CI 1.1–3.1).[99]

Approximately 60% of congenital malformations of unknown etiology are estimated to be secondary to environmental toxicants.[37] Increased prevalence of birth defects in offspring of fathers employed as janitors, painters, printers, agricultural workers, groundskeepers, welders, electrical industry workers, and firefighters have been reported.[23,32,37] In addition, paternal exposure to organic solvents and pesticides was a significant risk factor for congenital anomalies in offspring.[23]

Male fertility diminishes and sperm DNA mutations increase with advancing paternal age. Advanced paternal age is associated with pregnancy loss, birth defects, and autosomal dominant genetic disorders such as Marfan syndrome and achondroplasia. Congenital malformations seen more frequently in fetuses of older fathers include cleft lip and palate, hydrocephalus, neural tube defects, limb reduction defects, tracheoesophageal fistula, congenital cataracts, and congenital heart disease.[50] A possible mechanism for paternally mediated effects is the impairment of a paternal gene necessary for the normal growth and development of the fetus. Replacement of the father's genetic material with a second copy of the mother's genetic material (uniparental disomy), or vice versa, results in a nonviable conceptus.[53] In Prader-Willi syndrome, there is a functional mutation in paternal 15q, resulting in inactivation of the genes in that region of the chromosome. Environmental factors may play a role in uniparental disomy and lead to paternally mediated effects on the fetus. Studies have shown association between paternal exposure to hydrocarbons and Prader-Willi syndrome. In one study, approximately 50% of fathers of children with Prader-Willi syndrome were occupationally exposed to hydrocarbons.[15]

Secondary Fetal Exposure: Maternal Body Burden

The developing fetus may be exposed to xenobiotics (chemicals not naturally produced by the organism) after increased mobilization from maternal storage compartments during pregnancy. Adipose tissue is a storage site for

hydrophobic chemicals, while both lead and fluoride are stored in bone.

Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs) are endocrine disruptors (EDCs) that are mobilized from adipose tissue during pregnancy and readily cross the placenta. They are lipophilic organochlorine chemicals that bioaccumulate in the environment, enter the food chain, and are stored in adipose tissue.[4,28,76] Exposure occurs primarily through ingestion of dairy, animal fat, and fish. PCBs were used as liquid insulators for transformers and capacitors in the 1970s. Because PCBs remain stable in the environment and are resistant to biologic breakdown, they are classified as persistent organic pollutants (POPs).[76] Although use has been banned or limited in many countries, exposure remains a public health concern. Two recent studies (2011, 2014) document the presence of PCBs in blood samples from pregnant women and in breast milk.[76]

Prenatal exposure to PCBs has been correlated with neurodevelopmental impairment and autism.[76] Maternal occupational exposure is linked to low birth weight and prematurity.[28] Human poisonings have occurred through dietary consumption of PCBs. In 1979, an epidemic of PCB poisoning from contaminated rice oil occurred in Taiwan termed *yu-cheng disease*. Adults who were exposed developed hyperpigmentation, acne, and peripheral neuropathy. Of the first 39 hyperpigmented children born to poisoned women, 8 died. Children born up to 6 years after the outbreak of yu-cheng disease had ectodermal defects and developmental delay. Children born 6 years after maternal exposure were as developmentally impaired as those born within 1 year of the epidemic, indicating significant maternal body burden.[21] Cognitive defects seen in Taiwanese children with yu-cheng disease are comparable to those observed in American children prenatally exposed to PCBs. Studies in Michigan and North Carolina showed neurodevelopmental impairment in children prenatally exposed to PCBs through maternal body burden. In Michigan, cognitive deficits were seen in children who had elevated cord blood levels of PCBs and whose mothers had regularly consumed contaminated sport fish.[28]

Lead

The major repository for lead is bone, and chronic exposure results in significant accumulation of lead in the skeleton. Lead stores are mobilized from bone during pregnancy, potentially exposing the fetus during critical stages of brain development. It is postulated that enhanced calcium turnover during pregnancy increases lead mobilization. Maternal tibial and patellar bone lead levels are correlated with low birth weight and decreased head circumference. One study established maternal trabecular bone lead level as an independent risk factor for cognitive delay at 24 months of age. Lead is readily transported across the placenta and blood-brain barrier. Lead is a potent neurotoxin. Developmental exposure is linked to learning disability, cognitive and language deficits, and attention deficit hyperactivity disorder (ADHD). Treatment of pregnant women with calcium supplementation may limit lead mobilization from bone and could decrease circulating maternal lead levels and placental transfer to the fetus.[45]

Maternal Exposures Concurrent With Pregnancy

Biomarkers of fetal exposure have been developed using cord blood and meconium.[27,86] In 2007, The Environmental Working Group measured cord blood levels of 413 chemicals from 10 US newborns. They found 287 toxicants, with an average of 200 chemicals in cord blood of each infant. Chemicals included pesticides, PCBs, and heavy metals such as mercury.[27] Meconium analysis is a sensitive tool utilized to determine antenatal exposure to environmental toxicants. In a study of 426 infants born in the Philippines, exposure rate was 26.5% for lead, 83.9% for mercury, and 53% for the organophosphate pesticide malathion.[86]

Occupation and Paraoccupation

The strongest associations between maternal exposures and adverse pregnancy outcome (spontaneous abortion, miscarriage, and congenital anomalies) have been found for lead, mercury, pesticides, organic solvents, and ionizing radiation. Occupations linked with adverse pregnancy outcome secondary to exposures include anesthesiologists, hair dressers, laboratory technicians, dry cleaners, agricultural workers, and those working in chemical, electronic, or shoe factories.[41]

Specific congenital anomalies have been linked to maternal occupations. For example, cleft lip and palate occurs more frequently in offspring of leather workers, hairdressers, housekeepers, and transport and communication workers. Limb anomalies have been reported in children of agricultural workers, and neural tube defects in children of cleaners and health care providers working with anesthesia and radiation.[59] In a large population-based case control study that examined the relationship between various maternal occupations and 45 birth defects, jobs with the highest number of associated anomalies were janitors/cleaners, scientists, and electronic equipment operators. Teachers and health care workers had the lowest risk of delivering a child with congenital anomalies.[59] However, in health care providers, adverse pregnancy outcomes (miscarriage and congenital anomalies) have been reported with chronic occupational exposure to antineoplastic medications, especially when this exposure occurs during the first trimester.[24]

Paraoccupational exposures occur when others living in the home come in contact with an occupationally exposed individual, or occupational chemicals are brought into the home on clothing or other materials. Paraoccupational exposure to pesticides remains an occupational hazard today. An important route of exposure to neurotoxic organophosphate

pesticides (OPs) occurs in families of farm workers. A systematic review of 10 studies assessing prenatal exposure to OPs reported neurocognitive impairment involving working memory and attention in toddlers and children at school age.[80]

Air Pollution

Many chemicals found in outdoor air pollution are neurotoxic. Exposure is associated with disruption of the blood-brain barrier, chronic CNS inflammation, microglia activation, and white matter injury.[51] The United States Environmental Protection Agency (EPA) established air quality standards in 1971. Although some progress has been achieved, outdoor air pollution continues to carry significant health risks. Particulate matter, ground-level ozone, sulfur dioxide, nitrogen dioxide, carbon monoxide, and airborne lead are examples of outdoor air pollutants with known adverse health outcomes. These air pollutants are the focus of air quality standards, such as the EPA's Clean Air Act. The air quality index (AQI) is an indicator of daily air quality calculated by the EPA for these six major air pollutants that are regulated by the Clean Air Act. Both carbon monoxide and airborne lead are typically meeting safety standards.[112]

Particulate matter pollution consists of fine inhalable particles comprised of many different chemicals found in outdoor air ($PM_{2.5}$ and PM_{10}, 2.5 micrometers and 10 micrometers in diameter, respectively). Particles less than 10 micrometers are readily inhaled into the lungs, interact with the immune system, and are absorbed systemically. Ground-level ozone (the primary component of smog) is formed in the atmosphere by photochemical reactions between sunlight, nitrogen oxide species, and volatile organic compounds (VOCs), which are photochemically reactive hydrocarbons. Sulfur dioxide and nitrogen dioxide are also components of smog. Emissions from industrial facilities, motor vehicle exhaust, gasoline vapors, and chemical solvents are common sources of these toxicants.[112]

Exposure to outdoor air pollution is difficult to avoid during pregnancy, especially in highly polluted areas. There is strong evidence concerning exposure to air pollution to both increased infant mortality and respiratory morbidities such as asthma in early childhood. In addition, there is evidence from epidemiologic studies linking prenatal exposure to air pollution and prematurity, low birth weight, impaired lung and immune function, autism spectrum disorders, and neuromotor impairment in early childhood.[51,93,98]

Drinking Water

The drinking water supply is obtained from a variety of sources that include ground water and surface water from rivers, lakes, reservoirs, and aquifers. Environmental toxicants that contaminate drinking water are associated with adverse health outcomes. Common drinking water contaminants include the heavy metals lead and arsenic, inorganic compounds such as nitrates and nitrites found in fertilizers and livestock manure, pesticides such as atrazine and glyphosate, disinfection byproducts such as chloroform, and organic solvents such as trichloroethylene. Congenital anomalies, specifically cardiac defects, and low birth weight were found in studies evaluating trichloroethylene-contaminated drinking water. The EPA and the Food and Drug Administration (FDA) monitor the safety of drinking water; the EPA is responsible for drinking water standards for public water systems.[113]

Arsenic enters the water supply naturally and is also found in agricultural and industrial chemicals. Arsenic readily crosses the placenta; prenatal exposure is associated with fetal growth restriction and increased infant mortality in animal models. Population studies of health outcomes associated with arsenic exposure have been conducted primarily in countries such as Bangladesh, Taiwan, and Chile, where naturally occurring arsenic levels in groundwater are elevated. A systematic review and meta-analysis of these studies notes an association between prenatal arsenic exposure and spontaneous abortion, stillbirth, low birth weight, and neonatal mortality. While studies on dose response were limited, the strongest correlation was between prenatal arsenic exposure and spontaneous abortion.[96]

Diet

Maternal diet during pregnancy appears to impact the fetal epigenome. In animal models, fetal growth restriction has been linked to cardiovascular disease, including adult-onset hypertension and central adiposity. Diets low in protein or iron and high in saturated fat appear to have the greatest impact on blood pressure. Conversely, several studies have documented the relationship between maternal obesity, gestational diabetes mellitus, and altered epigenome methylation in the placenta and cord blood; findings that may potentially correlate with risk for metabolic conditions in offspring.[73]

The effects of nutritional modification can be selective. Genetically identical agouti mice contain a coat color gene controlled by DNA methylation. If pregnant mice are fed normal rat chow, offspring have either a yellow coat or brown coat. Those with a brown coat have normal weight, while those with a yellow coat are prone to obesity, diabetes, and cancer. Mice fed a diet supplemented with methyl donors such as folic acid tend to develop brown color coat and are not obese.[49,73,90] Maternal exposure to bisphenol A (BPA), an endocrine disruptor, shifts distribution of offspring's coat color to yellow. This effect can be reversed by dietary supplementation with methyl donors such as choline or folate.[35]

Similarly, B12 and folate deficiency during pregnancy have been proposed to impact the fetal methionine-homocysteine cycle via epigenetic alterations in DNA methylation. The methionine-homocysteine pathway is an important regulator of methylation and is dependent on Vitamin B12 and folate as cofactors. Deficiency in

B12 or folate leads to high levels of homocysteine, a well-established risk factor for adult cardiovascular disease. Pregnant sheep exposed to diets restricted in B12, folate, and methionine deliver offspring who develop increased body mass, impaired immune function, insulin resistance, and hypertension as adults.[73]

Inorganic mercury (methylmercury) is an example of a xenobiotic that contaminates our food supply. Methylmercury is a lipid-soluble and potent neurotoxin found in fish and seafood. Methylmercury readily crosses both the placenta and blood-brain barrier.[69] The US EPA has set an oral reference dose of mercury at 0.1 μg/kg/day. Approximately 8% of women have body burdens exceeding this reference dose. The fetus is very susceptible to the neurotoxic effects of methylmercury. Prenatal exposure has been associated with microcephaly, seizures, and cognitive and sensory impairment.[27,69] In 1956, methylmercury contaminated the food chain in Minamata Bay, Japan. Offspring of pregnant women from a local fishing village exposed to methylmercury developed severe neurodevelopmental impairment.[55]

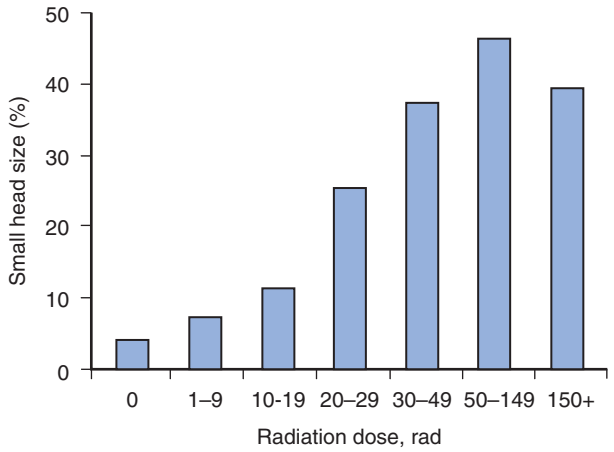
Pathways of Fetal Exposure

Placenta-Dependent Pathways

Two routes of fetal exposure to environmental toxins are placenta-dependent pathways and placenta-independent pathways. Placenta-dependent pathways require chemicals to enter the mother's bloodstream and cross the placenta in significant amounts. Not all environmental toxins meet these criteria; asbestos and radon gas do not, unless they have been ingested. Most xenobiotics cross the placenta by passive diffusion. Therefore, the concentration gradient between maternal and fetal circulation and placental blood flow are the primary determinants of exposure.[3]

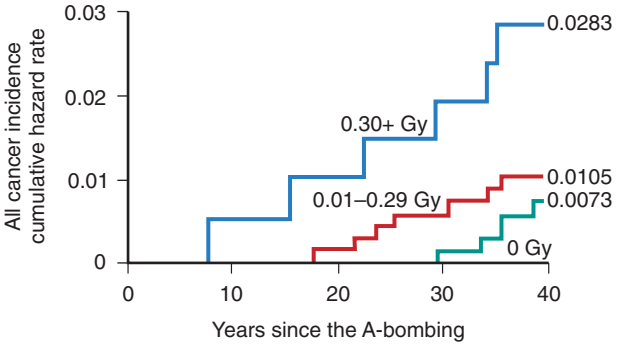
Properties enabling chemicals to cross the placenta more readily are low molecular weight, protein binding, lipid solubility, ionization, and resemblance to nutrients with specific transport mechanisms. An example of a low-molecular-weight compound is carbon monoxide, a constituent of environmental tobacco smoke (ETS). Carbon monoxide has a very high affinity for hemoglobin and displaces oxygen. Accumulation of carboxyhemoglobin leads to hypoxia and impaired cellular metabolism.[34] Examples of lipid-soluble chemicals that readily cross the placenta are PCBs, ethanol, and polycyclic hydrocarbons such as benzo[a]pyrene, a carcinogen in ETS. Lead is actively transported across the placenta via calcium-specific channels; calcium supplementation may reduce the transfer of lead to the fetus.[45]

Placenta-Independent Pathways



Radiation

Ionizing radiation is a well-characterized teratogen that is most harmful to the fetus in the first trimester during organogenesis. Prenatal exposure is associated with infertility, microcephaly, and increased incidence of childhood cancer in offspring.[4] Children of survivors of the atomic bombs in Hiroshima and Nagasaki exposed in utero at <18 weeks' gestation developed microcephaly, with the lowest observable effect at a dose of 1-9 rad (Fig. 14.5).[8]



The brain of a neonate undergoing cranial computed tomography (CT) with settings of 400 mA, 125 kV (peak), and a standard slice thickness of 4 mm receives a dose of 10.5 rad.[125] Therefore, it has been recommended that CT be used sparingly for infants, particularly when other imaging techniques are available. An excess of cancer among Japanese individuals exposed in utero has also been reported (Fig. 14.6).[128] Not all forms of radiation are hazardous to the fetus. Ultraviolet light does not penetrate to the fetus and does not constitute a future cancer risk.[4]

Heat

Heat may directly penetrate to the fetus and cause birth defects. Animal studies demonstrate that both maternal core temperature 2°C above baseline and duration of

hyperthermia are important risk factors. One study showed association between hot tub use after conception and twofold increased risk of miscarriage. In a study of the effects of heat on the outcome of pregnancy, 22,491 women undergoing α-fetoprotein screening were asked about their use of hot tubs, saunas, and electric blankets, and whether they had experienced a fever during the first trimester. The adjusted relative risk for neural tube defects with hot tub use was 2.8 (95% CI 1.2–6.5). With exposure to two of these heat sources, the relative risk increased to 6.5.[20]

Noise

Sound exposure is an important form of sensory stimulation in the developing fetus. At 23-25 weeks, sound begins to produce physiologic changes in fetal state; by 25-29 weeks' gestation the auditory system is functional.[47,48] At 27 weeks, the fetus primarily hears low frequency sounds below 500 Hz; frequencies above 500 Hz are not perceived until closer to 29 weeks due to filtering by the maternal tissues and uterus.[47,72]

Both low- and high-frequency noise can be detrimental and produce physiologic changes in the fetus. Applying vibroacoustic stimulation directly to the maternal abdomen leads to increase in fetal heart rate and movement.[72] Intense and sustained noise exposure during the prenatal period is associated with congenital anomalies, prematurity, and low birth weight.[47] In addition, noise-induced hearing loss may be evident after in utero exposure. The cochlear hair cells are sensitive to low frequency sound. Animal studies show that intense low frequency sound can damage the cochlear hair cells; effects are determined by gestational age and the intensity and duration of sound exposure.[48,72] The Sound Study Group recommends that pregnant women should avoid extended exposure to low frequency sound levels (<250 Hz) greater than 65 dB, and that sources of sound applied directly to the mother's abdomen (headphones) should be avoided because of no clear benefit and potential risks to fetal hearing.[48,72]

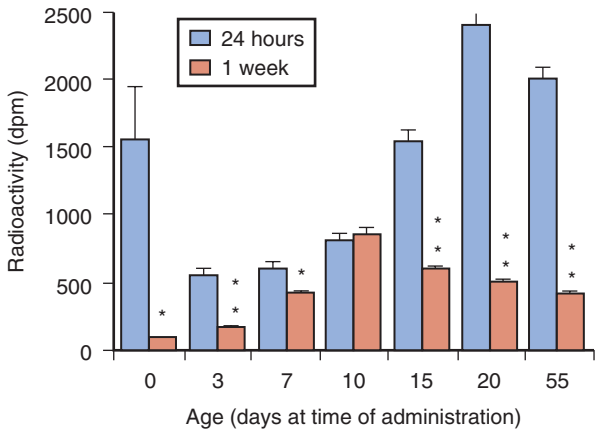
Fetal Pharmacokinetics

Absorption and Distribution

Physiologic changes during pregnancy influence maternal absorption and distribution of toxicants to the fetus. Increases in maternal progesterone concentration prolong gastric emptying time and slow intestinal motility, impacting enterohepatic circulation and absorption of xenobiotics. This results in reduced peak maternal levels of xenobiotics but increased overall exposure.[3] Another maternal physiologic change that affects absorption of xenobiotics occurs in the lungs. Both hyperventilation and increased pulmonary blood flow associated with pregnancy favor uptake of toxicants such as air pollutants into the lungs, where they can be absorbed systemically.[64,88]

Distribution of xenobiotics in the maternal compartment are impacted by increases in fat stores, extracellular fluid volume, and plasma volume during pregnancy. In addition, amniotic fluid represents a third potential compartment for distribution of water-soluble chemicals. This amniotic fluid compartment is characterized by low protein concentration and delayed elimination, resulting in a potential source for prolonged exposure to unbound chemicals that may be harmful to both mother and fetus. As the fetal kidney matures, higher concentrations of xenobiotics may be stored in this compartment.[3,88]

During pregnancy, plasma volume increases by 50%. Dilutional hypoalbuminemia is a result of plasma volume expansion that surpasses albumin production. Dilutional hypoalbuminemia alters the ratio of protein-bound chemicals and the volume of distribution in maternal blood, facilitating both clearance of free fractions of xenobiotics in the liver and placental transport to the fetal compartment.[3,88] Changes in maternal plasma volume also impact excretion of toxicants. Increased renal blood flow, glomerular filtration rate, and tubular transport result in maternal excretion of toxicants before reaching the fetus.[3]



Distribution of xenobiotics in the fetal compartment is also influenced by acid-base status and protein binding. As fetal pH is more acidic than maternal pH, weak bases that are non-ionized in the maternal compartment are readily transported across the placenta. In the fetal compartment, weak bases become ionized, resulting in higher concentration and "ion trapping." While maternal serum albumin gradually declines during pregnancy relative to plasma volume, fetal albumin concentration progressively increases. Thus, unbound xenobiotics that easily cross the placenta become protein-bound in the fetus and can accumulate in the fetal compartment.[88]

While maternal fat stores serve as a reservoir for lipophilic compounds, there is minimal fetal adipose development until after 29 weeks' gestation. Before that time, lipid soluble toxicants accumulate in tissues containing adipose, such as the developing brain. An example is shown in Fig. 14.7. The pesticide DDT (dichlorodiphenyltrichloroethane) was administered orally to mice at ages that correspond to the human brain growth spurt. Radioactivity was measured in brain tissue after 24 hours and 7 days. At 24 hours, 20-day-old mice accumulated more DDT in their brains than at other ages. DDT persisted longest in the animals given DDT at 10 days. Mice treated at 10 days had more behavioral abnormalities than those treated on other days, suggesting that the persistence was more important than initial accumulation. These results reflect the complexities of chemical distribution in the developing fetus.[39]

Metabolism

Maternal basal metabolic rate increases during pregnancy, facilitating hepatic metabolism of xenobiotics. The most widely described hepatic metabolizing enzyme systems are phase I (cytochrome P450 enzymatic oxidation, dehydrogenation, reduction, and hydrolysis) and phase II (enzymatic glucuronidation, sulfation, methylation, and glutathione

Age-dependent retention of [^{14}C]DDT in the brain of the postnatal mouse. *Toxicol Lett*. 1984;22:326.)

conjugation) processes. Approximately 75% of chemicals are toxic in their original state, and the remaining 25% are metabolized to toxic intermediates in the liver. Certain phase I and phase II enzymatic processes have been shown to be activated as a direct response to pregnancy-induced circulating estrogen levels, impacting metabolism and excretion of xenobiotics. Maternal metabolism and clearance of xenobiotics may additionally be reduced by estrogen-induced cholestasis that occurs physiologically during pregnancy.[3,64,85]

Prior to reaching the fetal compartment, some degree of first pass metabolism by phase I and phase II processes occurs in the placenta. In the fetus, expression of metabolic enzymes in the liver matures with advancing gestational age. Metabolism can lead to detoxification and facilitate excretion or activation of a xenobiotic to a more potent toxin.[3,91] The fetus may be protected if the active form of a toxin is its metabolite. An example is acetaminophen, a common drug used in suicide attempts during pregnancy. Acetaminophen is metabolized by phase I enzymes to hepatotoxic and nontoxic intermediates. Expression of the phase I enzymes is developmentally regulated. Because many of these enzymes are poorly expressed in fetal tissues, the fetus may be protected.[104]

Polymorphisms in human drug-metabolizing enzymes have been described that impact the susceptibility of the fetus to environmental toxicants. For example, risk of fetal alcohol spectrum disorder is impacted by genetic polymorphisms in the expression of the enzyme alcohol dehydrogenase (ADH). If the high-activity variant of ADH is inherited, ethanol oxidation and elimination is enhanced, decreasing the teratogenic effects of alcohol on the developing fetus.[91] A second example involves deactivation of organophosphate pesticides by the antioxidant enzyme paraoxonase 1 (PON1). In the liver, certain organophosphates are converted to a biologically active toxic form by cytochrome P450 enzymes. PON1 is responsible for hydrolyzing this toxic intermediate to an inactive metabolite that can be excreted. Genetic polymorphisms in PON1 have been described that impact both expression and catalytic capability of PON1, thus providing enhanced protection or greater susceptibility to toxic effects of these pesticides. When four birth cohorts were pooled (n = 936), negative associations were found between organophosphate metabolites in maternal urine and the Bayley MDI at 24 months in carriers of a particular PON1 allele.[38]

Specific Exposures

Cigarette Smoke

Despite the known consequences of smoking, 15%-20% of women in the United States smoke, and many are of childbearing age.[31] Both active maternal smoking during pregnancy and passive exposure to environmental tobacco smoke (ETS) are harmful to the fetus. ETS consists of smoke coming from the end of a burning cigarette (sidestream smoke) and from smoker's exhalation (mainstream smoke); it is also known as secondhand smoke. ETS contains over 250 harmful chemicals, including carbon monoxide, cyanide, benzene, ethylene oxide, nitrogen oxides, arsenic, formaldehyde, vinyl chloride, toluene, and polycyclic aromatic hydrocarbons such as benzo(α)pyrene. At least 69 are known carcinogens; the amount of each chemical varies with each cigarette.[81] Cotinine is a metabolite of nicotine that has a long half-life (~20 hours) and is the biologic marker used to measure exposure to ETS. There is no safe level of exposure to ETS.[34,81,84]

E-cigarettes are a diverse class of inhaled aerosol devices that have recently increased in popularity. They are battery powered and typically contain nicotine and other flavoring such as mint, fruit, or chocolate. Toxic additives may include particulate matter, solvents such as benzene and toluene, and heavy metals (lead, nickel, and tin). According to the US Department of Health and Human Services, e-cigarettes are the most commonly used tobacco product among adolescents. In 2015, one of every six high school students reported use of e-cigarettes within the past month.[114]

Sources of Exposure

Since smoking in public and the workplace has been restricted, the most common source of ETS exposure is at home. Paternal smoking is the most frequently reported source of environmental exposure.[84]

Toxic Effects

Active smoking is associated with infertility, reduction in successful in-vitro fertilization, and early onset of menopause.[31] Impaired female fertility may be secondary to hormonal imbalance, direct impact on follicular growth and ovulation, or reduced motility in the female reproductive tract.[31,84] Cotinine and benzo(a)pyrene (carcinogen, endocrine disruptor) have been found in follicular fluid and

ovarian granulosa cells; levels correlate with the degree of active and passive exposure.[31,84] Active paternal smoking is linked to decreased production, impaired motility, and altered sperm morphology.[84] Active smoking also impacts the developing fetus. Nicotine leads to vasoconstriction of the uteroplacental blood vessels, reducing delivery of oxygen and nutrients. Additionally, carboxyhemoglobin production from carbon monoxide contributes to fetal hypoxia and chronic hypoxic stress.[34,62] Fetal exposure to active maternal smoking is associated with placental dysfunction, spontaneous abortion, intrauterine growth restriction, preterm delivery, and congenital anomalies such as cleft lip and palate. Active maternal smoking during pregnancy is an important risk factor for sudden infant death syndrome (SIDS).[4,34,84,114] A direct dose-response relationship has been noted between maternal smoking and intrauterine growth restriction; one study suggested a 5% reduction in relative fetal weight per pack of cigarettes smoked daily.[34] Nicotine is toxic to the developing nervous system, impacting neuronal proliferation and differentiation. Maternal active smoking during pregnancy is associated with impaired cognitive functioning, auditory processing deficits, impulsivity, anxiety, depression, ADHD, obesity, and conduct disorders in offspring.[34,49,62] Maternal smoking also appears to impact infant stress response via epigenetic mechanisms. DNA hypomethylation of the placental glucocorticoid receptor promotor region was found in one study to correlate with infant salivary cortisol levels over the first month of life.[49] Epidemiologic studies show a relationship between prenatal maternal active smoking and both reduced lung function and asthma in offspring.[12,34] At present, there is insufficient evidence to decisively link ETS with infertility, spontaneous abortion, or congenital anomalies. However, prenatal exposure to ETS has been associated with increased incidence of both SIDS and low birth weight.[34,84] Evidence is suggestive of a relationship between ETS and preterm delivery. The literature also suggests a relationship between prenatal exposure to both active maternal smoking and ETS and the incidence of childhood cancers; further evidence is necessary to support this relationship.[84]

Prevention Strategies

Smoking prevention programs should focus on education and treatment of preteens, adolescents, and women of childbearing age. As nicotine is a neurotoxin, nicotine replacement should be avoided as a means to quit smoking during pregnancy. Smoking during pregnancy and common sequelae such as preterm birth and low birth weight have been diminished using behavioral therapy programs.

Ethanol

Effects of alcohol on the fetus are extensive, devastating, and often permanent. Approximately 8%-30% of women report drinking alcohol at some time during their pregnancy (CDC MMWR).[16] The incidence of fetal alcohol syndrome (FAS) in the United States is estimated as 0.3 per 1000 live births, and 2%-5% of preschoolers may have a fetal alcohol spectrum disorder (FASD).[79]

Sources of Exposure

While most ethanol exposure is the result of deliberate ingestion, measurable levels of ethanol in the blood after use of hand sanitizers has been documented. There are sporadic reports of people ingesting hand sanitizers.[46,66] Recent data show measurable levels of ethanol in air in NICU incubators following the use of hand sanitizers.[61] Patients are also exposed to ethanol as an excipient in medications; studies in the United States, the Netherlands, and New Zealand report that ethanol is present in 47 pediatric medications with concentrations ranging from 0.6% v/v to 76% v/v ethanol.[1,25,105,119] Measurement of blood ethanol concentrations in samples from 289 neonates show that these mostly remain relatively low (typically 10 mg/dL or lower), although 11 of the 289 blood samples had ethanol concentrations at or above 20 mg/dL.[25]

Toxic Effects

FAS was identified more than 40 years ago. It is defined by craniofacial abnormalities (including smooth philtrum, thin upper lip, and short palpebral fissures), growth deficiency (at or below the 10th percentile), and central nervous system dysfunction (structural, neurologic, and/or functional). FAS is generally considered to be the extreme end of the spectrum of negative outcomes that result from alcohol exposure during pregnancy.[65,75]

Fetal alcohol spectrum disorder (FASD) is an umbrella term that covers all diagnoses that pertain to children who were exposed to alcohol in utero. This includes FAS, as well as partial FAS, alcohol-related neurodevelopmental disorder, and alcohol-related birth defects. Children exposed to alcohol in utero tend to have poor outcomes. They can have lower IQ scores; poor reasoning skills; hyperactivity; poor memory; learning difficulties; speech and language delay; intellectual disability; and/or problems with attention, sleep, vision, or hearing, or with heart, kidney, or bone. Prenatal exposure to ethanol is still the leading known cause of intellectual delay.[65,75] A recent meta-analysis identified 428 comorbid conditions in people with FASD across all organ systems.[92] The top five were: "abnormal results of function studies of peripheral nervous system and special senses, conduct disorder, receptive language disorder, chronic serous otitis media, and expressive language disorder." People prenatally exposed to alcohol are also at risk for epilepsy; a recent study showed that 17.7% of a prenatally alcohol-exposed population have at least one documented seizure[7] and depression and anxiety disorders.[56]

While much of the work examining outcomes after exposure to ethanol is focused on brain development and behavior, other organ systems are also at risk. For example, prenatal alcohol exposure results in smaller, immature lungs as well as disruption of both innate and adaptive immunity in the lung, which increases risk of infection.[44] There is an

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

increased risk of congenital heart disease.[13] The growth deficiency is part of the diagnosis of FAS points to skeletal abnormalities; this deficiency continues at least through early adolescence[30] and is associated with abnormal bone growth.[52] There are also reports of abnormalities in other systems including kidney, liver, and gastrointestinal.[14] However, such associations may not hold up under closer examination. This is partly due to a paucity of case reports and may also reflect the lack of information about alcohol exposure in the child's medical record.

Heavy alcohol consumption increases the risk of miscarriage from ~15% to 45%[54] and increases stillbirths sixfold.[26] It is possible that prenatal alcohol exposure increases the risk for preterm birth, however this is not definitive and the risk may depend on the amount of alcohol consumed.[83,87]

Typically, FAS and FASD are associated with moderate to high levels of alcohol consumption. While there are some reports that low to moderate alcohol consumption is not harmful,[70] these same authors later found deficits in graphomotor skills in 5-year-old children exposed to ~9 drinks per week[63] and participated in a meta-analysis that identified behavior deficits in children exposed to <6 drinks.[42] In both studies that described deficits, these were more pronounced if the alcohol was consumed in a binge.

Prevention Strategies

Certainly, the cause of FAS and FASD is known and has been for many years; however, the rate of alcohol consumption by pregnant women is remarkably stable over time.[16] Although the human literature can be inconsistent regarding outcomes following exposure to alcohol, the best advice remains to abstain from alcohol exposure during pregnancy. Women planning to become pregnant should also consider abstaining as the effects of preconception exposure are not well understood at this time, although the animal literature suggests that preconception exposure can alter gene expression and epigenetic regulation of genes.[97] Intriguingly, work from the preclinical field suggests that some protection against alcohol effects may be provided by omega-3 polyunsaturated fatty acids[122,123] or choline[6]; in humans, choline appears to provide some therapeutic benefit to children with FASD.[127]

Pesticides

Pesticides are applied in agriculture and both in and around our homes. More than one billion pounds of pesticides are applied annually in the United States, and 5.6 billion pounds are used worldwide.[2] Pesticides are defined as any chemical utilized to eradicate insects (insecticides), plants and weeds (herbicides), rodents (rodenticides), and microorganisms (disinfectants, bactericides, fungicides, and algaecides).[2,99,124] Pesticides are classified by the function of their active ingredient and the intended target organism. Some of the more common classifications of pesticides, mechanisms of action, and examples are shown in Table 14.1. In addition to their active ingredient, pesticides contain other chemicals that are not required to be readily available for consumers.[2]

Organochlorines (DDT, methoxychlor, chlordane, aldrin, dieldrin, and lindane) and organophosphates (chloropyrifos, diazinon, and parathion) are neurotoxic insecticides that were historically applied commercially in agriculture. Both classes of insecticides have been restricted because of toxic effects in animals and humans.[17,38,99] Organochlorines are lipid-soluble and bioaccumulate in the environment.

TABLE 14.1 Common Pesticide Classifications and Their Characteristics

Classification	Mechanism of Action	Toxicity	Use and Characteristics	Examples
Organochlorine	GABA antagonist	High	Insecticides Residential and agriculture Many banned in U.S. EPA due to health risk, bioaccumulation Lipid soluble Lindane for lice, scabies	DDT Chlordane Lindane Aldrin
Organophosphates	Acetylcholinesterase inhibitors	High	Insecticides Used in agriculture, residential use banned Water-soluble	Chlorpyrifos Malathion Parathion Phosmet
Pyrethrins and Pyrethroids	Sodium channel antagonist	Low to moderate	Insecticides Residential and agriculture	Permethrin Deltamethrin
Carbamates	Acetylcholinesterase inhibitors	Variable	Insecticides Agriculture and residential	Aldicarb Carbaryl Primicarb
Neonicotinoids	Selective for insect acetylcholine receptors	Lower	Flea control for domestic animals Agriculture	Imidacloprid

DDT, dichlorodiphenyltrichloroethane; GAGA, gamma-aminobutyric acid.

Although the organochlorine DDT was banned by the US EPA in 1972, use continues in some parts of the world for control of diseases such as malaria and for agriculture. Organophosphates are water-soluble and exert their neurotoxic effects via irreversible inhibition of acetylcholinesterase. Residential application of most organophosphates has been restricted or banned due to toxicities in humans.[38,99,110] Pyrethoids, pyrethrins, and piperonyls are insecticides primarily marketed for residential use. Generally, they are less toxic, but health effects have been reported.[17] The CDC conducts a biomonitoring program for many common pesticides. In 2005, 29 of 45 pesticides were identified in samples from random subjects; the most prevalent were organochlorine and organophosphate insecticides.[99]

Sources of Exposure

Important sources of exposure include direct inhalation after application and ingestion of contaminated food. Organochlorine pesticides have a long half-life and bioaccumulate in our food supply.[17] Frequent sources of the organochlorine DDT include meat, dairy products, and fish. DDT and its metabolites have been found in breast milk. The organochlorines aldrin and dieldrin are found in fish, shellfish, root crops, dairy products, and meats. Plants absorb these chemicals directly from the soil; even organic vegetables may contain high levels if grown in contaminated areas.[99] The EPA sets acceptable standards for pesticide residue, which are regulated by the FDA. In 2014, pesticide residues were found in 29% of 1458 domestic and 47% of 4814 imported samples, with violations of EPA standards (residue for which there is no tolerance or residues above the tolerance level) in 1.4% of domestic and 12% of imported samples. The violation rate was greatest for imported grains. Boscalid (fungicide used on food crops), chloropyrifos (organophosphate insecticide), and imidacloprid (neonicotinoid insecticide used in agriculture) were the most frequently reported pesticide residues.[116]

Pregnant women may be exposed in the home environment via indoor use of disinfectants, insecticides, and rodenticides, and outdoor application of herbicides, insecticides, and fungicides. Certain products such as sprays and foggers may lead to prolonged exposure in the home. Another potential source of exposure in the home is drinking water. Herbicides are a frequent contaminant of drinking water in agricultural areas; in urban areas both insecticides and herbicides are known contaminants.[99] Occupational or paraoccupational exposure to pesticides and living in close proximity to pesticide-treated agricultural areas represent other important sources for pregnant women or women of childbearing age.[38,124]

Biomarkers have been identified to evaluate fetal pesticide exposure. In 2004, the Environmental Working Group found 21/28 organochlorine pesticides in cord blood of 10 babies. Amniotic fluid from amniocentesis samples has been used to characterize early fetal exposure; meconium samples have been utilized to determine exposure during the second and third trimester. While organophosphates have been identified in amniotic fluid, both organophosphates and pyrethroid pesticides have been found in meconium samples.[27]

Toxic Effects

While most pesticides are neurotoxins, the degree of toxicity varies between classes. Pesticides also can function as endocrine disruptors, immunotoxicants, and carcinogens in animals and humans.[2,38,124] Epidemiologic data suggest a link between parental pesticide exposure and infertility, spontaneous abortion, fetal demise, preterm birth, intrauterine growth restriction, and congenital anomalies.[99,124] One study demonstrated a relationship between exposure to chloropyrifos and DDE (a metabolite of DDT) and both low birth weight and microcephaly.[27] Additionally, biomarkers for organophosphates found in maternal urine, blood, or umbilical cord samples are associated with low birth weight and preterm birth.[124] A relationship between exposure to organochlorines such as DDT and both cryptorchidism and hypospadias has been reported, suggesting endocrine disruption as a mechanism of toxicity.[99]

The developing fetal nervous system appears to be especially vulnerable to the neurotoxic effects of pesticides. Four case reports have linked exposure to chloropyrifos to multiple congenital anomalies and severe cognitive delay.[110] Evidence supports a relationship between prenatal exposure to organochlorine and organophosphate pesticides and adverse neurodevelopmental and behavioral outcomes that persist into childhood. Findings include increased incidence of cognitive delays and intellectual disability that persist into childhood, and increased incidence of both ADHD and autism spectrum disorders.[9,27,38,76,99]

There is increasing epidemiologic evidence correlating parental pesticide exposure and childhood cancers. Multiple studies report correlation between maternal pesticide use (both occupational and household) before and during pregnancy and childhood acute lymphoblastic leukemia. There is stronger evidence linking maternal exposure to pesticides and leukemia than paternal exposure. Similarly, more than 25 studies have described a relationship between prenatal pesticide exposure and brain tumors. The most consistent risk factors identified are maternal and paternal prenatal exposure to pesticides at home or at work. Two case-control studies specifically report an association between parental pesticide exposure and childhood astrocytoma.[99,108,120]

Prevention Strategies

Dietary changes may decrease contact, and exposure to pesticide residues may be limited by ingestion of organic foods. One study showed that urinary excretion of organophosphate metabolites significantly decreased when children were placed on an organic diet for 5 days.[4,99]

Washing produce may remove pesticide residue, and avoiding animal fat and certain fish can limit exposure to lipid-soluble pesticides such as organochlorines. The EPA recommends integrated pest management (IPM) as a strategy to avoid environmental exposure to pesticides. Maternal

occupational and household exposures should be avoided during pregnancy.[4]

Bisphenol A, S, and F

Bisphenol A (BPA) is a chemical plasticizer that is added to plastic resins to enhance rigidity. It has been used since the 1960s in the production of polycarbonate plastic bottles and in epoxy resins utilized as protective coating inside metal food and beverage cans. It is also used in water supply pipes, medical devices, dental sealants and composites, and many other products that are part of our daily lives.[4,10,11,36,101] BPA is in widespread use worldwide and is pervasive in our environment, with more than six billion pounds manufactured annually.[101,118]

As concerns for the health effects of BPA have been identified and have become widely recognized by the public, alternative products that are "BPA-free" are sought by both consumers and industry. Two BPA analogs, Bisphenol S (BPS) and Bisphenol F (BPF), are utilized as alternatives to BPA with similar physical properties. BPS is used as a coating for thermal paper that allows for inkless printing. Rolled thermal paper with BPS ("BPA-free" paper) is found in cash register and ATM terminal receipts and paper products such as boarding passes and currency. BPF is used in epoxy resins and coating of industrial and consumer materials to increase thickness and durability. Use of BPS and BPF is currently not regulated.[100]

Sources of Exposure

Human exposure to BPA is significant. BPA leaches from plastic bottles and the epoxy resin coating metallic cans and other products; contamination of the food supply and routine ingestion by humans is presumed. Leaching also occurs from dental sealants. Heat and both acidic and basic conditions lead to hydrolysis of BPA polymers and leaching into the food supply.[10,101,117,118] Transdermal absorption and inhalation have been shown to be less common routes of exposure. Studies demonstrate serum concentrations of unconjugated (biologically active) BPA between 0.2 and 20 ng/mL.[117,118] BPA was detected in the urine of 90% of over 2,489 participants ≥6 years of age in the National Health and Nutrition Examination Survey (NHANES) conducted by the Centers for Disease Control (CDC) between 2011 and 2012.[18] BPA has been measured in urine and blood during pregnancy, amniotic fluid, ovarian follicular fluid, placental tissue, fetal blood, and umbilical cord blood.[101,117,118] In one study, there was a fivefold difference in mean amniotic fluid BPA concentration at 15-18 weeks' gestation (8.3 ng/mL), as compared to mean concentration in maternal blood in early pregnancy (1.4 ng/mL). Immature fetal liver function and phase II enzyme activity may explain high levels of BPA documented in amniotic fluid.[117]

Like BPA, BPS and BPF can leach from plastic bottles, epoxy resins, and thermal paper. Both of these BPA analogs have been identified in paper products (commonly store receipts) and personal care products (body wash, hair products, makeup, and toothpaste). Like BPA, BPS and BPF are found in indoor dust particles and can also be inhaled.[100]

Toxic Effects

BPA is a known estrogenic endocrine disruptor. BPA binds to estrogen receptors; recent *in vitro* studies of molecular mechanisms demonstrate a similar potency to estradiol. BPA is primarily unbound to plasma proteins; in this active form BPA may exert estrogenic effects during critical stages of fetal development. In an animal model, hepatic glucuronidation of BPA to its inactive form in pregnant rats was reduced by 40% during pregnancy, suggesting increased susceptibility to endocrine disruption for both the mother and fetus.[49] BPA may significantly impact fetal neurodevelopment, as estrogen plays an important role in the developing brain. Specifically, estrogen is important for sexual differentiation in the brain.[101]

More than 150 studies have documented adverse effects in vivo, many at doses below acceptable reference levels for human daily intake (50 μg/kg). Animals exposed to BPA during gestation develop a wide range of endocrine pathology. In the rodent, low-dose perinatal effects of BPA include urogenital anomalies, accelerated pubertal development, and predisposition to prostate cancer in the male and breast cancer in the female.[101,117,118] Additionally, animal studies have shown that prenatal exposure impacts neurodevelopment and increases behaviors such as aggression and anxiety.[11] In the mouse model, perinatal BPA exposure modifies estrogen sensitivity later in life.[101,117]

The body of epidemiologic literature documenting BPA exposure in humans is increasing. In women, BPA exposure has been associated with recurrent miscarriages, preterm delivery, polycystic ovarian syndrome, breast cancer, and chromosomal anomalies in offspring.[5,101,117] In men, elevated urinary BPA levels have been correlated with low sperm count, poor motility and quality, and increased sperm DNA breakage.[36,101] Decreased anogenital distance has been documented in male infants whose fathers were occupationally exposed to BPA.[36]

Prenatal and childhood exposure is associated with hypospadias, precocious puberty, neurodevelopmental and behavioral impairment, increased adipokine levels, and obesity. Adipokines are a diverse group of secretory proteins that modulate lipid and glucose metabolism.[5,10,36] In one study of 244 mothers and their 3-year-old children, a 10-fold increase in urinary BPA levels during pregnancy was associated with higher scores for anxiety, depression, hyperactivity, and poor emotional regulation in offspring.[11]

BPS and BPF are also estrogenic endocrine disruptors. While the literature documenting the estrogenic effects of these BPA analogs in vivo is limited, in vitro studies indicate similar toxicity and potency to BPA.[36,100] In one study, BPF and BPS administration decreased basal secretion of testosterone in cultured human fetal testis.[36] Another study in which BPF was administered to pregnant rats via a feeding

TABLE 14.2 Phthalates and Their Characteristics

Phthalate	Source	Fetal Effects (Animal Models)
Di(2-ethylhexyl) phthalate (DEHP)	Medical tubing and intravenous fluid bags Food packaging Plastic toys Wall coverings, floor tiles, shower curtains Rainwear, shoes Furniture and auto upholstery	Skeletal malformations, cleft palate, cryptorchidism, hypospadias, testosterone synthesis, sexual differentiation, anogenital distance, neural tube defects, growth restriction
Dibutyl phthalate (DBP)	Nail polish, makeup, perfume Coatings on pharmaceuticals/herbal products	Skeletal malformations, cleft palate, cryptorchidism, hypospadias, testosterone synthesis, delayed puberty, neural tube defects, growth restriction
Dimethyl phthalate (DMP)	Insecticides Adhesives Hair styling products, shampoo, aftershave	
Butyl benzyl phthalate (BBP)	Vinyl flooring and tile, carpet, artificial leather Adhesives and sealants Food packaging Furniture upholstery	Skeletal malformations, cleft palate, cryptorchidism, hypospadias, delayed puberty
Diethyl phthalate (DEP)	Cosmetics, nail polish, deodorant, perfume, lotion Insecticide Pharmaceuticals, herbal products	Skeletal anomalies, decreased testosterone

tube, the active form was found in the placenta, amniotic fluid, and fetal tissue.[100]

Prevention Strategies

To avoid exposure to BPA and its structural analogs, pregnant women can refrain from using plastic materials that contain BPA. Reducing contact with thermal paper receipts can also limit exposure to these chemicals. Resin identification codes are identified by symbols appearing on plastic products that identify the plastic resin out of which the product is made. Many products that contain BPA contain the resin identification code 7. As heat may lead to release of BPA, plastic materials containing BPA should not be boiled, washed in the dishwasher, or placed in the microwave.[4,5]

Phthalates

Phthalates are a class of chemical plasticizers that provide flexibility to plastics such as polyvinyl chloride (PVC). Phthalates are also used as solvents, lubricants, and insect repellants. They are utilized to manufacture toys, vinyl products, plastic bags, plastic food packaging products, and detergents. They are found in medical gloves, blood and intravenous fluid and bags, tubing, the coating of pharmaceuticals, and in cosmetics. Eighteen billion pounds of phthalates are produced annually worldwide. Like BPA, phthalates are ubiquitous in our environment and have become significant environmental pollutants. Certain phthalates are considered toxic chemicals, and their release into the environment is monitored by the EPA's Toxic Release Inventory (TRI) database available at www.epa.gov/tri. Table 14.2 lists some of the more common phthalates used as plasticizers, and products that contain them.[5,29,111]

Sources of Exposure

Like BPA, exposure to phthalates is substantial. Diet is the main source of exposure; phthalates leach from plastic containers and plastic wrap, particularly after heating, and can be ingested. Transdermal absorption from cosmetics, fragrances, lotions, and insect repellents has been reported. In particular, usage of fragrance, nail polish, and eye shadow has been correlated with concentration of phthalate metabolites in the urine of pregnant women. Dibutyl phthalate (DBP) is commonly used in deodorant, cosmetics, and nail polish. DBP levels are significantly higher in women of reproductive age than in men.[5,29] Inhalation is another potential route of exposure. Phthalates have been found in ambient air, household dust, and fumes from new paint or vinyl flooring.[29,111] There is potential for direct intravascular exposure via IV tubing and blood product or IV bags.[111] The National Health and Nutrition Examination Survey (NHANES) conducted by the CDC in 2013–2014 measured 13 phthalate metabolites in the urine of 2685 participants. Of the 13 phthalate metabolites measured, 10 were present in greater than 90% of participant urine samples.[19] Several studies have documented phthalate metabolites in amniotic fluid and cord blood, suggesting that phthalates cross the placenta and may impact the developing fetus.[126] Silva et al. found three phthalate metabolites in samples from amniocentesis during the second trimester.[103] Wittassek et al. measured phthalate metabolites in amniotic

fluid sampled at the time of cesarean section; phthalate metabolites were found in 11/11 samples.[126]

Toxic Effects

Phthalates are anti-androgenic endocrine disruptors. Phthalate exposure during pregnancy has been associated with pregnancy loss, preterm delivery, and adverse neurodevelopmental outcomes.[5] It appears that the most sensitive tissue to phthalates is the male reproductive tract.[29,111] In rats, phthalates and their metabolites cross the placenta. Prenatal exposure to di(2-ethylhexyl) phthalate (DEHP), butyl benzyl phthalate (BBP), and dibutyl phthalate (DBP) results in increased incidence of cleft palate, skeletal malformations, and fetal death in offspring of exposed pregnant rats. Male offspring developed hypospadias and cryptorchidism, low sperm production, and testicular Leydig adenomas as adults.[111] Findings seen in animal studies are similar to testicular dysgenesis syndrome described in humans.[111,126] Data documenting similar anti-androgenic effects of phthalates on the human fetus are increasing. Studies have shown a relationship between phthalate concentration in maternal urine and fetal amniotic fluid and decreased anogenital distance (AGD) in offspring, a marker that has been utilized in vivo to evaluate anti-androgenic endocrine disruptors and male reproductive development.[106] Swan et al. demonstrated that decreased AGD is significantly correlated with small scrotum, reduced penile length, and testicular maldescent. The effect on AGD was noted at levels well below the US EPA reference dose.[106] Similar to animal models, studies have correlated maternal phthalate exposure and hypospadias in male newborns.[29]

Prevention Strategies

Food and products made from PVC plastics represent the most common sources of exposure. PVC plastics are labeled with the resin identification code 3.[5] Processed foods and those individually wrapped in plastic tend to contain the highest concentrations. The FDA recommends careful use of plastic containers, avoidance of reheating plastic containers in the microwave, and only using plastics in the microwave labeled for microwave oven use. One-time-use containers (such as carry out containers) should not be used in microwave ovens. Plastic wrap should not touch foods during microwaving. Avoidance of long-term storage of foods in plastic, heating plastic containers, and consumption of processed foods may decrease exposure.[4] Until more information is available, limiting exposure to phthalates during pregnancy is a reasonable approach.

Organic Solvents

Organic solvents are a large, diverse group of volatile carbon-based chemicals used to dissolve lipids and other high molecular weight compounds in solution. Organic solvents are found in volatile anesthetics, paint and paint thinners, cleaning supplies, dry cleaning solutions, dyes, office supplies such as copier fluid and printer ink, cosmetics, nail polish remover, glues, adhesives, spot removers, and detergents.[32] They can be classified into three families of chemicals: oxygenated solvents, petroleum solvents, and chlorinated solvents.[89] Glycol ethers are oxygenated solvents. Ethylene glycol is found in sunscreen and cosmetics and propylene glycol is a component of antifreeze. Prenatal exposure to glycol ethers is associated with male infertility.[22] Benzene, toluene, and xylene are petroleum solvents. Benzene is a known human carcinogen, and prenatal exposure is linked to neural tube defects in offspring. Chlorinated solvents include perchloroethylene used in the dry cleaning industry, a carcinogen in animals. Many are neurotoxins, as demonstrated by reports of neurotoxicity in adults after acute poisoning and chronic occupational exposure.[67,89]

Sources of Exposure

Organic solvents are ubiquitous in our environment, and concentrations are much greater indoors than outdoors. Many of these chemicals persist in ambient air long after their use. Organic solvents are commonly found in household products such as cleaning supplies, and occupational exposure is significant.[89] As many women continue to work throughout pregnancy, exposure to organic solvents poses a risk to the fetus. Since organic solvents are volatile, inhalation represents the most common route of exposure. Recreational inhalation of toluene found in spray paint and glue has resulted in multiple congenital anomalies and neurodevelopmental delay. Oral ingestion and transdermal exposure also occurs.[43]

Toxic Effects

Organic solvents cross the placenta and, as with other lipophilic chemicals, concentrate in organs with higher lipid content such as the brain.[67] In animals, organic solvents are teratogenic. Spontaneous abortion and congenital anomalies are seen in animals prenatally exposed. Exposure of both chick embryos and fetal rats to chlorinated solvents such as trichloroethylene leads to increased incidence of congenital heart disease.[22,43] Epidemiologic studies in humans link maternal occupational exposure to organic solvents with risk of spontaneous abortion and congenital anomalies. Congenital malformations include cleft lip and palate, neural tube defects, and congenital heart disease (CHD).[22,32,43] The National Birth Defects Prevention Study 1997–2002 was a case control study that enrolled 2951 control mothers and 2047 mothers of infants with CHD. The study demonstrated an association between occupational organic solvent exposure during the month prior to conception through the first trimester and CHD; specifically left ventricular and right ventricular outflow tract obstruction, conotruncal defects, and septal defects.[43] Toluene (methyl benzene) is an aromatic hydrocarbon utilized in industry in paint, glue, and other organic compounds. Toluene embryopathy has been described after maternal abuse of these organic solvents as inhalants, termed "solvent sniffing." Findings include intrauterine growth restriction, microcephaly, facial

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

features similar to fetal alcohol syndrome, and neurodevelopmental impairment.[75] Several studies have investigated maternal prenatal occupational solvent exposure and neurodevelopmental outcome linked exposure to delays in motor skills verbal skills; visual-motor and memory function; and behaviors such as aggression, hyperactivity, and impulsivity.[67,89] The visual system appears to be sensitive to developmental exposure. Till evaluated visual function of 21 infants born to mothers with occupational exposure to organic solvents and found both reduced contrast sensitivity and deficits in color vision in exposed infants, as compared to 27 age-matched controls.[107]

Prevention Strategies

Organic solvents should be used in a well-ventilated area, and partially used containers should be discarded after use. Pregnant women should avoid paint fumes to reduce exposure in both home and occupational settings. Cleaning supplies should be used in well-ventilated areas while wearing protective gloves. There are specific recommendations for nail salon workers and hairdressers that include limiting work hours, wearing gloves and masks when appropriate, ensuring optimal ventilation, covering containers and garbage, and separating areas to handle food and to eat.[4]

Conclusions

In 2014, the leading causes of infant death were congenital malformations and chromosomal abnormalities, short gestation and low birth weight, newborns affected by maternal complications of pregnancy, and sudden infant death syndrome.[71] All have been associated with environmental exposures discussed in this chapter. This chapter has described the many different sources of exposure and the timing of exposure to occupational and environmental chemicals. The complexity of maternal-fetal pharmacokinetics has been outlined, and many of the various types of outcomes have been discussed. The science of environmental medicine continues to evolve. More recently, literature has begun to focus on the impact of co-exposure to environmental toxicants; a growing body of evidence supports the deleterious effect of simultaneous exposure at concentrations lower than known to cause toxicity individually.[57] Genome-wide association studies (GWAS) and epigenome-wide association studies (EWAS) are novel methodologies being utilized to better understand the molecular basis for exposure risk.[55]

When caring for a patient with a diagnosis that may be secondary to an environmental exposure, it can be difficult to demonstrate a causal relationship. Hotlines for teratology information are part of the Organization of Teratology Information Services and are listed online at www.otispregnancy.org. Case Studies in Environmental Health can be obtained from the ATSDR at www.atsdr.cdc.gov/atsdrhome.html.

Key Points

- The fetus is highly vulnerable to environmental toxicant exposures that can alter phenotypic expression, both following birth and in future generations.
- Fetal exposure becomes a growing concern as our population expands and the number of women participating in the workforce during pregnancy increases.
- *Epigenetics* is the study of phenotypic changes occurring without modification of DNA base pair sequence. Epimutations are stable, heritable, and a target for environmental toxicants. Mechanisms include histone modifications, altered DNA methylation, and expression of microRNA.
- *Epigenetic transgenerational inheritance* refers to epimutations in the germline (egg or sperm) that are passed to future generations and leads to variation in phenotypic expression.
- Exposure to environmental toxicants that impacts the developing fetus may be concurrent or nonconcurrent with pregnancy. Certain toxicants, such as lead and polychlorinated biphenyls, are stored in maternal compartments and mobilized during pregnancy. Air pollution and diet (food and water) represent common sources of exposure during pregnancy.
- Toxicants reach the fetus via placenta-dependent and placenta-independent pathways. Certain chemical properties promote transport across the placenta, such as low molecular weight, lipid solubility, protein binding, and ability to utilize nutrient transport mechanisms. Examples of placenta-independent environmental exposures that are potentially hazardous to the fetus include ionizing radiation, heat, and noise.
- Maternal and fetal absorption, distribution, and metabolism of toxicants are influenced by the maternal physiologic environment during pregnancy, ontogeny of fetal phase I and phase II metabolism in the liver, and genetic polymorphisms in drug-metabolizing enzymes.
- Active cigarette smoking during pregnancy is associated with reduced male and female fertility, placental dysfunction, spontaneous abortion, intrauterine growth restriction, preterm delivery, and congenital anomalies. Smoking during pregnancy is a known risk factor for SIDS.
- Fetal alcohol spectrum disorder (FASD) encompasses the entire range of sequelae of prenatal exposure to alcohol; fetal alcohol syndrome (FAS) describes the extreme end of the spectrum with characteristic facial features and neurodevelopmental impairment.

- While most pesticides are neurotoxins, some also exhibit toxic effects as endocrine disruptors, immunotoxicants, and carcinogens. Evidence supports a relationship between prenatal exposure to pesticides and both cognitive impairment and cancer in offspring.
- Bisphenol A (BPA) and phthalates are plasticizers that are ubiquitous in our environment. Both BPA and phthalates leach from plastic containers into our food supply. They are known endocrine disrupting chemicals (EDCs); BPA is an estrogenic EDC, while phthalates are anti-androgenic.
- Organic solvents are a large and diverse group of volatile lipid-soluble chemicals commonly found in household products such as cleaning supplies. These chemicals, many of which are teratogens, readily cross the placenta and concentrate in organs with high lipid content such as the brain.

Intrauterine Growth Restriction

ALISON CHU AND SHERIN U. DEVASKAR

Summary

Intrauterine growth restriction (IUGR) broadly encompasses pregnancies complicated by poor fetal growth, where the fetus's growth is less than its genetic potential. IUGR is an important condition to recognize, as it is a common complication of pregnancy that has both short- and long-term sequelae for offspring. This is a particularly difficult diagnosis to manage in both the prenatal and postnatal periods for a number of reasons. Firstly, definitions and terminology lack consensus among practitioners, researchers, as well as organizations that inform clinical practice. Secondly, the etiologies are multiple, and the pathophysiology remains incompletely understood. Given these challenges, diagnostic criteria and prenatal practice guidelines remain uncertain, no definitive prevention strategy or treatment has been identified, and postnatal management and surveillance guidelines are scant, variable, and ill defined. Despite the major global burden of IUGR, it remains a condition that is difficult to diagnose, prevent, or treat, and further research is essential in this field.

Definitions and Terminology

In clinical practice and in research studies, IUGR can be defined in multiple ways and there remains a lack of consensus regarding terminology. Commonly, "normal" fetal growth results in a neonate whose birth weight falls between the 10th and 90th percentile for gestational age (deemed "appropriate for gestational age" or AGA). Therefore, a birth weight less than the 10th percentile is categorized as "small for gestational age" (SGA) and correlates with a birth weight that is two standard deviations or more below population norms. In contrast, IUGR encompasses all fetuses with evidence of malnutrition or in utero growth restriction, which can still include an infant born with a birth weight above the 10th percentile.[4] Therefore, close communication between the obstetric and newborn medical teams is imperative to accurately identify which neonates exhibited true in utero growth deceleration and not base the label of "IUGR" on birth weight alone. Clinically, this is an essential distinction to make as infants with IUGR are at risk for both short-term and long-term complications, whereas constitutionally small infants that fall into the SGA category but had consistent growth patterns in utero are at much lower risk for long-term adverse outcomes.

The Health Burden of IUGR

Given the difficulties and inconsistencies in defining IUGR, the true prevalence of IUGR is not known. However, it has been estimated that up to 10 percent of live-born infants are characterized as IUGR, and that this percentage is likely higher among stillborn neonates.[70] Globally, IUGR is the second leading cause of perinatal morbidity and mortality after prematurity.[71] The risk of fetal death increases with severity of growth restriction, such that a fetus with a weight less than the 10th percentile for gestational age has a 1.5% risk of fetal death (twice the risk of stillbirth in normally grown fetuses), whereas risk for a fetus with a weight less than the 5th percentile increases to 2.5%.[30]

Not only does fetal growth restriction increase overall mortality by increasing risk of intrauterine demise, stillbirth, and neonatal death,[4] it also carries significant comorbidities for the surviving neonate. After birth, IUGR neonates are at increased risk for admission to the intensive care unit, requiring monitoring and treatment for complications of IUGR, which include but are not limited to hypoglycemia, hyperbilirubinemia, hypothermia, and respiratory distress syndrome. These issues will be discussed more in the management section of this chapter. In the long term, infants born IUGR are at risk for neurodevelopmental delay and cardiometabolic diseases in adulthood, including obesity, type 2 diabetes mellitus, and cardiovascular disease.[7]

Classification of IUGR

Historically, IUGR has been classified into two types: asymmetric versus symmetric (Table 15.1). In asymmetric IUGR, it is believed that decreased fetal growth occurs in response to suboptimal intrauterine provision of nutrients and oxygen. The fetus adapts to this environment by conserving energy and focusing nutrient delivery to vital organs such as the brain and the heart. Therefore, asymmetric IUGR typically manifests as a fetus with a disproportionately high

Abstract

Intrauterine growth restriction (IUGR) broadly encompasses pregnancies complicated by poor fetal growth, where the fetus's growth is less than its genetic potential. IUGR is an important condition to recognize, as it is a common complication of pregnancy that has both short- and long-term sequelae for offspring. This is a particularly difficult diagnosis to manage in both the prenatal and postnatal periods for a number of reasons. Firstly, definitions and terminology lack consensus among practitioners and researchers, as well as organizations that inform clinical practice. Secondly, the etiologies are multiple, and the pathophysiology remains incompletely understood. Given these challenges, diagnostic criteria and prenatal practice guidelines remain uncertain, no definitive prevention strategy or treatment has been identified, and postnatal management and surveillance guidelines are likewise variable and ill defined. Despite the major global burden of IUGR, it remains a condition that is difficult to diagnose, prevent, or treat, and further research is essential in this field.

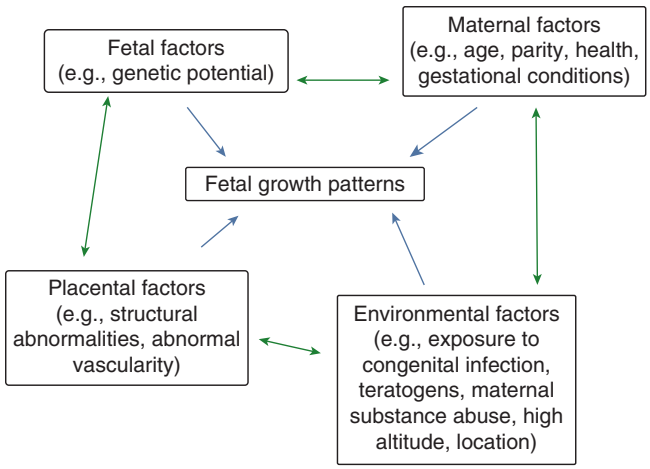
TABLE 15.1 Characteristics of Symmetric Versus Asymmetric IUGR

Characteristics	Symmetric IUGR	Asymmetric IUGR
Typical period of insult and presentation	Earlier gestation (often second trimester)	Later gestation (often detected in the third trimester)
Percentage of all IUGR cases	20%-30%	70%-80%
Etiology	Genetic disorders Congenital infections	Placental insufficiency
Antenatal scan	Proportionately decreased head circumference (HC), abdominal circumference (AC), biparietal diameter, and femur length	Only abdominal circumference decreased
Cell number	Decreased	Normal
Cell size	Normal	Decreased
Postnatal anthropometry	All parameters (HC, length, and weight) reduced	Reduced weight, HC normal, length low to normal
Features of malnutrition	Less pronounced	More pronounced



IUGR, Intrauterine growth restriction.
Adapted from Sharma D, Shastri S, Sharma P. Intrauterine growth restricion: antenatal and postnatal aspects. *Clin Med Insights Pediatr.* 2016;10:67-83.

head circumference percentile compared to percentile for weight. Height can be normal to low normal. Prenatally, fetal growth deceleration in asymmetric IUGR tends to manifest in the third trimester (notably, the period of most rapid fetal growth), when prenatal measurements on growth scans demonstrate a low abdominal circumference, whereas head circumference, biparietal diameter, and femur length often remain within normal ranges. This pattern of growth has also been coined as "head-sparing" IUGR. Asymmetric IUGR is more common than symmetric, accounting for 70%-80% of all IUGR fetuses,[54] and more often than not can be due to maternal, environmental, and/or placental factors that result in placental insufficiency.

Symmetric IUGR, on the other hand, results in a fetus or neonate with proportionately low anthropometric measurements of head circumference, weight, and length. This pattern is less common than asymmetric IUGR, representing 20%-30% of all IUGR cases, and the poor growth rate is often detectable earlier in pregnancy. Often, asymmetric IUGR is seen in association with fetal etiologies such as genetic or chromosomal disorders, and prognosis is generally worse in these cases.[21] It can also be seen with early pregnancy infections resulting in congenital syndromes, such as congenital rubella or congenital cytomegalovirus (i.e., "TORCH" infections). At times, severe maternal malnutrition extending from the first trimester throughout pregnancy can result in symmetrical IUGR, which is also seen with maternal malarial infection.[58,68]

Etiology of IUGR

There are four broad etiologic categories for IUGR: maternal, fetal, placental, and environmental factors. IUGR can also result from a combination of these factors, as inherent genetic potential and the "environment" both determine fetal growth (Fig. 15.1). Although the underlying pathophysiologic mechanisms may differ among and within these categories, the majority of IUGR cases share the same common pathway that results in suboptimal nutrient and oxygen provision to the fetus, oftentimes secondary to poor placental perfusion (Table 15.2). The exception to this common pathway is oftentimes due to "fetal" etiologies, which largely are due to genetic or structural disorders and thought to result from a decreased number and growth of fetal cells.

• **Fig. 15.1** A schematic illustrating the complex interactions between the fetus, mother, environment, and placenta that affect fetal growth patterns.

TABLE 15.2 Etiologies of Asymmetric and Symmetric IUGR

	Asymmetric IUGR	Symmetric IUGR
Fetal	• Genetics	• Chromosomal disorders (e.g., trisomy 13, trisomy 18, trisomy 21) • Structural disorders (specific forms of congenital heart disease, gastroschisis)
Maternal	• Age • Parity • Ethnicity/race • Height • Poor weight gain • Short pregnancy intervals • Medical conditions: pregestational diabetes mellitus, renal insufficiency, autoimmune disease, cyanotic cardiac disease • Diseases related to pregnancy (gestational hypertension, preeclampsia, gestational diabetes) • Thrombophilia (antiphospholipid antibody syndrome)	• Advanced maternal diseases (e.g., severe hypertension, hemoglobinopathies)
Placental	• Multiple gestation • Placental insufficiency • Placental disorders and umbilical cord abnormalities	
Environmental	• Teratogen exposure (e.g., cyclophosphamide, valproic acid, antithrombotic drugs) • Substance use (alcohol, tobacco, cocaine, narcotics) • Altitude • Assisted reproductive technology	• Infectious diseases during early pregnancy (e.g., malaria, cytomegalovirus, rubella, toxoplasmosis, syphilis)

IUGR, intrauterine growth restriction.

Fetal Etiologies

IUGR can be associated with chromosomal abnormalities of the fetus; classically, trisomies 13, 18, and 21 are among the more common chromosomal disorders seen in IUGR, accounting for up to 20% of IUGR cases. Fifty percent of fetuses with trisomy 13 or 18 have evidence of fetal growth restriction.[27] Other chromosomal abnormalities associated with IUGR include placental mosaicism.[74]

Fetuses with certain congenital birth defects (even without chromosomal or genetic underlying abnormalities) may be at increased risk of IUGR,[39] such as those with gastroschisis.

Maternal Etiologies

The overall health and "reproductive potential" of the mother are obviously critical in determining fetal health and outcome. Demographic factors that may affect this potential include maternal age, parity, or last pregnancy interval. In addition to baseline demographics, maternal health conditions prior to pregnancy affect risk for IUGR. In the past, certain health conditions may have precluded the woman's ability to conceive or to carry a viable pregnancy to term. However, with medical advancements, many of these conditions can be managed to the extent that pregnancy can be maintained but may still affect the fetus's growth potential. For example, hypertension and diabetes, either pre-existing or gestational, put the fetus at risk for IUGR. Other maternal diseases that may affect the mother's overall ability to provide optimal nutrition, oxygen, or blood flow to the infant include pulmonary and renal disease, autoimmune disease, thrombophilic disorders (specifically antiphospholipid syndrome but not factor V Leiden or prothrombin mutations),[19,56] and/or congenital heart disease.

In addition, the mother's own diet and access to nutrition affects the fetus's risk for IUGR. Historically, there are numerous large epidemiologic studies that link low birth weight with maternal malnutrition during famine periods.[6,60] In these cohorts, low birth weight was specifically linked to poor protein intake in the first two trimesters and with severe caloric restriction (<600-900 kcal daily). However, it is important to note that in cases of suspected fetal growth restriction in the absence of true maternal malnutrition, additional nutritional supplementation does not increase fetal weight or improve outcomes.[57] In the current era, maternal malnutrition (largely in developing nations) still can lead to IUGR, and conversely, especially in developed nations, maternal obesity can also lead to IUGR. It is also of note that an adolescent mother's own metabolic demands compete for the nutrient supply to the growing fetus, resulting in IUGR. In Western societies, disorders

related to image distortion, such as bulimia, anorexia, or hyperemesis gravidarum, at times can cause IUGR.[68]

Environmental Etiologies

Exposure of the fetus to environmental stressors at various points during gestation may result in IUGR as well.

In early pregnancy, exposure to infectious agents such as *plasmodium* (resulting in malaria), rubella, cytomegalovirus, *Toxoplasma gondii*, and syphilis can result in congenital syndromes with multiple birth abnormalities, including IUGR. Of these, malaria represents the largest portion of global burden of IUGR secondary to infectious etiologies.[24] These infectious etiologies represent approximately 5%-10% of all IUGR cases.

Exposure to teratogens, maternal medications, or maternal substance abuse can also lead to IUGR. The effect of teratogen exposure on fetal growth depends on a number of factors, such as the inherent teratogenicity of the drug, the timing/duration/dosage of exposure during gestation, as well as the mother's particular ability (or inability) to metabolize the drug (whether from genetic disposition or health conditions such as hepatic or renal disease that affect drug metabolism). Teratogens classically associated with IUGR include antiepileptic medications (e.g., valproic acid), antithrombotic agents (e.g., warfarin), and chemotherapeutic/antineoplastic agents (e.g., cyclophosphamide). Heavy substance abuse can also result in IUGR, with alcohol and tobacco use being the most common etiologic agents.[46] It should be noted that tobacco use is associated with a 3.5-fold increased risk of SGA, and that the risk of SGA with alcohol use is increased even with the intake of 1-2 drinks daily. Cocaine, heroin, and narcotic use during pregnancy are also associated with IUGR.[29]

It can also be argued that where the neonate is born affects their risk for IUGR. For example, it is well documented that fetuses gestating at higher altitudes are less likely to reach their growth potential, compared to their counterparts at sea level.[73] Another example of the birth location effect is when comparing developed versus developing nations. The resources available to the low-income populations in developing nations may predispose mothers to poor food availability, air pollution, infectious agents, and poor/limited health care. Poorly resourced nations, such as in the Indian subcontinent and in South Africa, have much higher rates (estimated at six times higher) of IUGR compared to developed nations.[36]

Placental Etiologies

Placental insufficiency resulting from abnormal placentation is the most common pathology associated with IUGR. However, placental insufficiency may have myriad causes, multifactorial etiology, and results in a broad spectrum of severity. Pregnancy disorders such as preeclampsia and preterm birth, as well as IUGR, generally exhibit some degree of placental insufficiency or malperfusion. These placentas are often small in size and are histopathologically characterized by hypovascular villi, fibrin deposition, and/or trophoblast degeneration, which taken together lead to poor nutrient and oxygen provision to the fetus on a physiologic level.[43]

Specific placental disorders such as chronic placental abruption, infarction, circumvallate shape, chorioangioma, and umbilical cord abnormalities such as velamentous or marginal cord insertion have been associated with IUGR.[47] Placenta accreta and previa have not been consistently associated with IUGR, nor is the presence of a single umbilical artery consistently associated with IUGR.

Twin or multiple gestation also is an important consideration in IUGR, as multiple gestation is on the rise secondary to rapidly advancing artificial reproductive technology.[22] It is debated whether or not IUGR in multiple gestation should be considered physiologic or not. In general, growth deceleration is evident and expected to some degree in the third trimester in multiple gestation, as the physical and functional capacity of both the uterus and/or placenta may be exceeded in this period of rapid fetal growth. However, it should be noted that twin gestation disproportionately accounts for adverse neonatal outcomes (10%-15%), while only accounting for 2%-3% of live births in the United States. Multiple gestation is associated with both SGA and prematurity, with the risk of SGA as high as 25% in twin pregnancies and up to 60% for triplet and quadruplet pregnancies.[52] Moreover, monochorionic twin pregnancies are at higher risk of SGA and IUGR because of unequal placental sharing and increased risk of twin-to-twin transfusion syndrome (with the donor born IUGR).

Pathophysiology

The pathophysiology of intrauterine growth restriction remains poorly understood. In the case of chromosomal abnormalities, it is surmised that poor fetal growth is due to decreased numbers of fetal cells and poor cellular growth. Beyond this, little data is available on the pathophysiology of growth restriction in fetal chromosomal disorders.

It should be noted that fetal growth also depends on a number of hormones, including insulin, thyroid hormones, adrenal hormones, and pituitary hormones. Insulin has a number of roles in growth; it has been described to: (1) control cell number via direct mitogenic effects on cellular development, (2) regulate glucose uptake and consumption in somatic tissues, and (3) regulate other metabolic pathways, such as protein breakdown. Hormones such as insulin-like growth factor 1 (IGF-1), insulin-like growth factor-II (IGF-2), insulin-like growth factor binding protein-2 and -3 (IGFBP-2 and -3) have all been implicated in the pathophysiology of IUGR in experimental models. A number of other genes involved in these various hormonal and metabolic pathways have been implicated in IUGR in human genomic studies as well.[58]

The knowledge of pathophysiology underlying placental insufficiency, which is present in the majority of IUGR

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

neonates, especially those with idiopathic IUGR (i.e., not due to chromosomal abnormalities, teratogen exposure, or congenital infection), is limited. Given the difficulty and risks of obtaining human placental samples during an ongoing pregnancy, and that IUGR is often detected late, studies investigating the pathophysiology of IUGR have been largely limited to animal models, tissue explants, or cell culture work. Animal models of IUGR include various stressors to reduce blood flow or nutrient provision to the developing fetus, such as maternal food restriction, gestational hypoxia, or uterine artery ligation. Each of these models have distinct advantages and disadvantages, and the animal chosen also is important in considering the extrapolation of findings in these studies to the human condition of IUGR. Placentation is a unique biological process that varies significantly among different species, and in combination with different stressors, the resulting phenotype can differ greatly between models. The limitation of tissue explant and cell culture work is that in true pregnancy, these tissues and cells do not exist in isolation, as multiple inputs in pregnancy affect cellular biological behavior and function. For cell culture results (such as is utilized in trophoblast or human umbilical vein endothelial cell studies), it is important to consider the characteristics of the cell line utilized (e.g., in what trimester the cells were originally obtained, immortalized versus not, etc.).

Taken together, studies using these various models suggest that placental insufficiency oftentimes results from a disruption in normal early vascularization of the placenta. Specifically, incomplete spiral artery remodeling results in shallow invasion of the placental vasculature. This poor invasion contributes to failure of these vessels to appropriately become low-resistance vessels, thus limiting blood flow to the fetus and nutrient/oxygen provision to the fetus and placenta itself. However, insults during mid to late pregnancy may affect the exchange tissue barrier and the vascular surface area as well.

Antenatal Screening and Prenatal Management

Given the inherent differences and difficulties in how IUGR is defined, in combination with its poorly understood pathophysiology, guidelines for how to screen for IUGR generally lack strong evidence to back them.[31] Subsequently, the outcomes in this high-risk population have improved very little despite advances in obstetric and neonatal care. However, identification of the fetus at risk is essential to providing close prenatal surveillance and to heighten the awareness of the postnatal neonatal care team for complications. Based upon what is known at this time, the components that should be included in antenatal screening for IUGR are (Table 15.3):

1. **A detailed maternal and family history**: Standard diagnostic tools include a thorough maternal and familial history to identify the presence of etiologic risk factors as outlined above. Accurate gestational dating, either by last menstrual period (LMP) or first-trimester ultrasound results, is an essential component in the detection and prenatal management of IUGR. Previous history of an SGA newborn should be sought out, as risk of recurrence is reported as ~20%,[5] and risk of recurrent IUGR is estimated at ~20%-50%.[11]
2. **A detailed maternal physical exam, including fundal height measurements**: Maternal physical examination with close attention to maternal nutritional status as well as fundal height should be performed. Fundal height as measured between 24 and 38 weeks of gestation may be a useful screen for fetal growth less than the 10th percentile.[62] However, the accuracy of fundal height measurement is limited by factors such as maternal obesity, multiple gestation, or uterine leiomyomas.

Once a pregnancy or fetus is identified as at risk for IUGR, evaluation should include:

1. **Fetal ultrasound**: Serial ultrasound evaluation for growth assessment is key in the evaluation of the growth-restricted fetus. Four biometric measures are commonly used to assess fetal growth: (1) biparietal diameter, (2) head circumference, (3) abdominal circumference, and (4) femur length. In combination, an estimated fetal weight can be calculated from these measurements.[32] It should be noted that there is the possibility of significant error in these measurements—estimates of fetal weight may deviate from actual weight up to 20% in the majority of cases.[26] However, used as a screening tool and used serially, prenatal ultrasound is the most powerful screening tool available for identification of fetuses at risk for IUGR. It is recommended that if the estimated fetal weight falls below the 10th percentile for gestational age, a more detailed evaluation including amniotic fluid measurement and Doppler flow studies be performed. In addition, evaluation of fetal anatomy should be completed given the high incidence of structural and genetic abnormalities presenting with fetal growth restriction.[4] Additional testing for chromosomal disorders or infections can also be performed, as indicated (especially in the presence of structural abnormalities identified on imaging, or for growth restriction detected early in gestation). Of the biometric measurements, abdominal circumference appears to have the best "stand-alone" specificity and a negative predictive value of almost 90% for diagnosing IUGR.[10] Decreased abdominal circumference is thought to represent a small liver, which reflects decreased hepatic glycogen stores and subcutaneous fat. The other biometric measurements can help to distinguish symmetric from asymmetric fetal growth restriction, and taken in combination, may improve the sensitivity, specificity, and positive and negative predictive value for IUGR.[10] The optimal interval frequency of growth scans (optimal surveillance regimen) has not been established, although the American College of Obstetricians and Gynecologists (ACOG) suggest every 3-4 weeks to minimize false-positive rates.[4]

TABLE 15.3 Prenatal Management and Testing in Cases of Suspected IUGR

Prenatal Test	Clinical and Diagnostic Utility	Other Recommendations and Specifics
A detailed maternal and family history	Previous history of SGA of IUGR, as recurrence risk is ~20% and ~20%-50%, respectively	Accurate gestational dating is essential
Maternal physical exam	Fundal height measured during the second half of pregnancy may be a useful screen for fetal weight <10% (specificity ~92%-93% and negative predictive value ~92%-98%)[62]	Assess maternal nutritional status Assess fundal height
Fetal ultrasound	An estimated fetal weight based upon biparietal diameter, head circumference, abdominal circumference, and femur length should be obtained, and serial measurements of growth (every 3-4 weeks) are key in the management of IUGR.[32] If estimated fetal weight <10%, include amniotic fluid measurements, full anatomy evaluation, and Doppler studies. Abdominal circumference has the best "stand-alone" specificity, and negative predictive value of almost 90%, for diagnosing IUGR.[10]	
Umbilical artery (UA) Doppler velocimetry	UA Doppler measurements can be helpful in prognosticating severity of IUGR and in guiding clinical management. Absent or revered end-diastolic flow is associated with increased perinatal mortality. When used in cases of suspected fetal growth restriction, the rate of perinatal death decreases by almost 30%.[37]	UA Doppler is less sensitive in mild disease and cannot be used as a screening tool for IUGR.
Doppler studies of fetal circulation	Doppler studies of fetal circulation, such as the ductus venosus, middle cerebral artery, or aortic isthmus may be reasonable predictors of short-term risk of fetal death, neonatal acidosis, and/or increased mortality and neurologic morbidity in the setting of fetal growth restriction.[61]	There can be technical difficulties in obtaining these measurements, and available studies are small, limiting the ability to make conclusive recommendations.
Genetic testing or infectious disease testing	Prenatal genetic testing should be offered in the presence of suspected structural abnormalities seen on fetal ultrasound or for growth restriction detected early in pregnancy.	

IUGR, Intrauterine growth restriction; SGA, small for gestational age.

2. **Doppler velocimetry, especially of the umbilical artery**: Doppler velocimetry, especially of the umbilical artery, is a well-studied measurement in the setting of IUGR and can specifically be a powerful tool in prognosticating severity of fetal growth restriction, potentially dictating prenatal management of IUGR fetuses.[61] Flow in the umbilical artery is a reflection of maternal circulation; normally, the resistance in the umbilical artery should decrease with increasing gestational age. However, with placental insufficiency, resistance will increase and subsequently, diastolic flow will decrease. Based upon data extrapolated from animal models, absent or reversed end-diastolic flow in the umbilical artery is thought to occur when two-thirds of the placental villous tree is damaged.[48] Clinically, absent or reversed end-diastolic flow in the umbilical artery is well documented as a poor prognostic factor, associated with increased perinatal mortality.[40] When included in prenatal testing in cases of suspected fetal growth restriction, the rate of perinatal death is decreased by almost 30%,[2] indicating it is a powerful tool in the management of IUGR. However, umbilical artery Doppler is less sensitive in mild placental disease. Other studies have suggested that measures of fetal circulation such as Doppler of the ductus venosus, middle cerebral artery, and aortic isthmus may be useful predictors of short-term risk of fetal death or increased mortality/neurologic morbidity in early-onset fetal growth restriction.[61] However, not enough evidence is available to routinely recommend that abnormalities noted on these studies dictate clinical care.
3. **Other standard fetal surveillance**: Some studies suggest that the use of Doppler velocimetry in combination

with nonstress tests, biophysical profiles (BPP), or both may improve outcomes in IUGR fetuses,[3] although a Cochrane meta-analysis did not find sufficient evidence that the BPP is an adequate measure of fetal well-being upon which clinical decisions should be based in high risk pregnancies.[42]

The timing of delivery for growth-restricted fetuses remains debated but in general is dependent upon the underlying etiology of growth restriction as well as the estimated gestational age. Early delivery of an IUGR fetus with known aneuploidy or congenital infection is not associated with improved outcomes and may in fact portend worse outcomes. In such cases, nonintervention may be a reasonable option while respecting parental desires. In other instances, such as in IUGR due to placental insufficiency, multidisciplinary input should be considered and each case considered individually. When intervention is preferred, antenatal surveillance may be helpful in guiding the timing of delivery, taking into account risk–benefit ratios. Decisions about the mode of delivery should be based upon other factors, as IUGR in itself does not require cesarean delivery. The overall goal is to balance delivery of the IUGR fetus prior to severe fetal compromise, with early delivery leading to increased incidence of prematurity and its comorbidities. Only two randomized clinical trials to assess timing of delivery of the growth-restricted fetus (in one study, in IUGR fetuses less than 34 weeks' gestation, and in the other, IUGR fetuses greater than 36 weeks' gestation) have been published, and both suggested that earlier delivery versus expectant management did not improve rates of perinatal survival or longer-term outcomes.[12,72] Between 34 and 36 weeks of gestation, no adequately powered randomized trials exist. Based upon these studies, the ACOG recommends delivery at 38 0/7 to 39 6/7 weeks in cases of isolated fetal growth restriction, and delivery at 34 0/7 to 37 0/7 weeks for IUGR fetuses with additional risk factors for poor prognosis (e.g., oligohydramnios, abnormal umbilical artery Doppler velocimetry).[64] For preterm deliveries, delivery ideally should be coordinated and performed at a center with both high-risk maternal fetal medicine teams and a neonatal intensive care unit. Antenatal corticosteroids should be given, and magnesium sulfate administration should be considered when appropriate.[4]

Prevention

There are no to very few "preventative" strategies for IUGR. Counseling regarding modifiable risk factors, for example, cigarette smoking during pregnancy, diet during pregnancy, and malarial prophylaxis in high-risk areas, may be somewhat effective in preventing or mitigating IUGR. Outside of these interventions, no effective preventive strategy has been identified. Nutritional and dietary supplementation regimens such as increased consumption of specific food groups, a low-salt diet, iron, zinc, calcium, protein, or vitamin D[23,35,51,53] supplementation have not been effective. Bed rest is not recommended for suspected fetal growth restriction.[4] The preliminary evidence behind the use of aspirin suggests potential efficacy in mitigating more severe IUGR (with evidence of abnormal umbilical artery Doppler studies), with aspirin-treated groups showing increased birth weight at delivery, prolonged gestation, and decreased need for admission of the newborn to the neonatal ICU, but is not routinely indicated at this time given that existing studies are small.[14]

Postnatal Diagnosis of IUGR

The diagnosis of IUGR postnatally is problematic because of the lack of consensus in how to define IUGR and the unclear and myriad pathophysiologic mechanisms that may be involved. Anthropometric measurements should be taken at birth and considered in combination with the prenatal history. The birth weight "cut-off" that should be used to delineate IUGR is variable, with some clinicians recommending below the 10th and some recommending below the 3rd percentile. However, the percentiles, as defined upon growth curves, are only as good as the population upon which the data is based. Extrapolation from these growth curves may be limited by the specific demographic and genetic make-up of the population measured. As noted earlier, it is imperative to take into consideration the prenatal pattern of growth as well as other prenatal findings (e.g., other placental and fetal structural abnormalities, abnormal genetic testing, family and previous maternal pregnancy history, and pregnancy infections). For example, a neonate with a significant history of poor fetal growth in the third trimester, even if above the 10th percentile in birth weight for gestational age, should be monitored for complications related to IUGR. Histopathologic evaluation of the placenta may be helpful in identifying overall size, shape, presence of structural abnormalities, and large infarctions.

Examination of the infant may also be helpful. Stigmata of "malnourished" fetuses may include: a large and wide anterior fontanelle, absent buccal fat, small and scaphoid abdomen, thin umbilical cord, decreased skeletal muscle mass and subcutaneous fat, disproportionately large hands and feet, and/or loose and dry skin (especially at the nape of the neck, axilla, and gluteal regions) (Fig. 15.2). These physical examination findings may be more consistent with asymmetric, or "brain-sparing," IUGR. In symmetric IUGR, other features may be present, depending upon the underlying etiology. For example, in aneuploidies, dysmorphic facies or other congenital anomalies may be present, or in certain congenital infections, classic stigmata such as microcephaly, petechiae and "blueberry muffin" rashes, cardiac murmurs secondary to congenital heart defects, and/or hepatosplenomegaly may be seen. Historically, there are a number of indices that can be calculated, such as Ponderal index, mid-arm to head circumference ratio (McLaren's index), the clinical assessment of nutrition score, and cephalization index. Cut-off values for each of these measures have been defined as suggestive of fetal malnutrition.

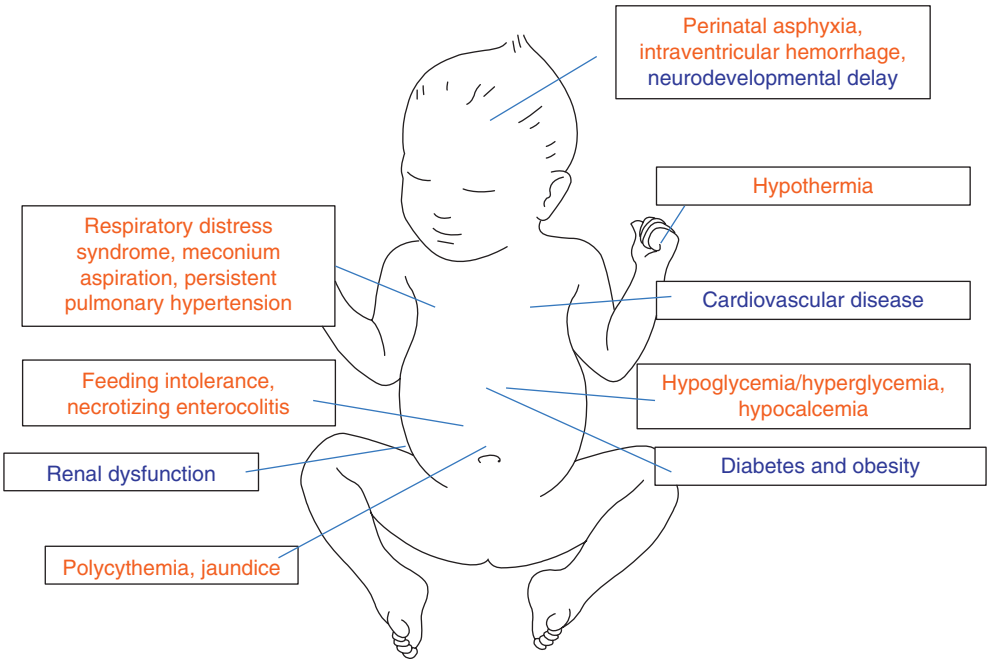
• **Fig. 15.2** This is a 36-week male neonate with a birth weight of 1600 grams who was born to a mother with severe pre-eclampsia. This baby was noted to have asymmetrical intrauterine growth restriction (IUGR). Note the loss of fat over the body, visible rib cage, excessive skin folds noted over the whole body, and relatively large head compared to the body. (From Sharma D, Shastri S, Sharma P. Intrauterine growth restriction: antenatal and postnatal aspects. *Clin Med Insights Pediatr.* 2016;10:67-83.)



Postnatal Management

Clinically, the IUGR infant is at increased risk of stillbirth, neonatal death, and prematurity: estimates are that approximately half of unexplained stillbirths are IUGR; IUGR infants suffer a 5- to 30-fold increase in morbidity and mortality even when born at term; and IUGR infants are 2.5 times more likely to be born premature than their AGA counterparts.[41] These infants also are at increased risk for needing more perinatal intervention, such as cesarean delivery, exposure to antenatal steroids, and admission to the neonatal intensive care unit.[69] A skilled team that is able to resuscitate the newborn should be present at delivery, given that IUGR newborns oftentimes do not tolerate labor well given the acute stress of laboring superimposed upon chronic poor blood flow and hypoxia. Once delivered, the IUGR neonate is at increased risk for a number of neonatal complications (Fig. 15.3), which should be monitored for and managed appropriately (Table 15.4). The problems that these IUGR infants encounter are often due to the fetal adaptations that occur in utero in the setting of poor nutrient and oxygen provision, which are poorly tolerated ex utero. In general, the fetus responds to hypoglycemia and/or hypoxemia by increasing catecholamine concentration, adjusting glucose transport and insulin receptor expression in a tissue-specific manner,[75] decreasing fetal pancreatic insulin secretion,[45] and increasing hepatic glucose production.[25,67] The overall metabolic and hormonal adaptations promote fetal survival and brain development at the expense of other somatic tissues,[67] especially in asymmetric IUGR. The management of the issues that arise postnatally as a result of IUGR results in prolonged hospital stays and increased health care costs for these infants in the short-term.

Hypoglycemia

Postnatal hypoglycemia is common in IUGR neonates, given that they are born with suboptimal glycogen stores, impaired

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

• **Fig. 15.3** A schematic of complications of IUGR. Orange labels indicate short-term complications, and blue labels indicate long-term complications.

gluconeogenesis, decreased fat, and increased sensitivity to insulin. The hormonal and metabolic predispositions in IUGR neonates may be further exacerbated by polycythemia and hypothermia. Clinically, close glucose concentration monitoring of IUGR neonates is warranted, given that over half of infants born SGA have some episode of hypoglycemia (defined as <2.6 mmol/L [46 mg/dL]) postnatally, and that about a third of these infants have severe, prolonged and/or recurrent hypoglycemia.[33] These infants may require formula or oral glucose supplementation shortly after birth, tube feedings, and/or supplementation with dextrose-containing intravenous fluids (IVF) in combination with continued frequent monitoring until hypoglycemia is resolved without supplemental feeding or IVF.

Hypothermia

Hypothermia occurs in IUGR neonates because of decreased brown fat deposition in utero. Thermal regulation should be monitored closely soon after delivery of the IUGR neonate. Although hypothermia can sometimes be managed in a general care nursery with close monitoring and may self-resolve over a matter of hours or minutes, some IUGR neonates require an exogenous heat source or incubator for management of hypothermia, particularly those born premature.

Respiratory Complications

IUGR neonates are at increased risk for both respiratory distress syndrome in the short term and bronchopulmonary dysplasia/chronic lung disease in the long term, which is due in part to both poor in utero growth and concomitant risk for prematurity.[13] Although some believe that fetal growth restriction may accelerate lung maturity (perhaps via catecholamine hormonal adaptations), this effect may be countered by the cellular growth restriction in IUGR that may manifest in the lung as decreased alveolar number and dysfunction, in combination with vascular remodeling (perhaps secondary to altered fetal circulation in IUGR). This pulmonary vascular remodeling also may lead to increased risk of pulmonary hypertension, in combination with chronic lung disease. In later childhood, these infants exhibit lung dysfunction.[49] Supportive care and respiratory support should be provided as needed.

Necrotizing Enterocolitis

Whether or not IUGR predisposes infants, especially those born preterm, to increased risk for necrotizing enterocolitis (NEC) is debated. However, severe cases of IUGR (those with evidence of absent or reversed end diastolic flow on prenatal ultrasound) seem particularly susceptible to necrotizing enterocolitis, although the underlying mechanisms are unclear. Formula feeding seems to increase this risk in preterm IUGR infants,[44] but early initiation of trophic or small-volume feedings is associated with better weight gain and decreased parenteral nutrition exposure and associated cholestasis[55] in these infants. Interestingly, SGA infants seem particularly susceptible to parenteral nutrition-associated liver disease.[55] Taken together, prompt initiation of feeding when possible is prudent, and provision of breast milk instead of formula should be encouraged.

TABLE 15.4 Postnatal Issues in IUGR

Postnatal Concern	Overall Risk and Etiology	Management Recommendations
Perinatal distress/asphyxia	IUGR infants, compared to AGA, have a 5-30x increase in morbidity and mortality, even when born at term, and are 2.5x more likely to be born premature. Overall increased risk for stillbirth and prematurity makes the delivery of an IUGR neonate high risk. Increased risk of perinatal distress given the stress of labor in the setting of chronic poor blood flow and hypoxia.	Attendance at delivery by a skilled team that can resuscitate a low birth weight or premature infant, ideally at a center with a neonatal intensive care unit.
Hypoglycemia	Half of infants with a birth weight <10th percentile have some episode of hypoglycemia, and 1/3 of infants with a birth weight <10% have severe, recurrent, and/or prolonged hypoglycemia. Due to suboptimal glycogen stores, impaired gluconeogenesis. Decreased fat, increased sensitivity to insulin. May be exacerbated by polycythemia or hypothermia.	Serial monitoring for hypoglycemia, initiated soon after birth. If persistent, prolonged, or severe: Formula supplementation, gavage feeding, provision of dextrose-containing intravenous fluids.
Hypothermia	Decreased brown fat deposition in utero.	Temperature monitoring, initiated soon after birth. Provision of an exogenous heat source or incubator may be required.
Respiratory complications	Poor in utero growth and concomitant risk for prematurity put IUGR infants at risk for respiratory distress syndrome in the short term and chronic lung disease in the long term. Some IUGR infants exhibit evidence of pulmonary vascular remodeling, which may result in increased risk of pulmonary hypertension.	Supportive care and respiratory support, as necessary.
Necrotizing enterocolitis/ feeding intolerance	Severe cases of IUGR (those with absent or reversed end-diastolic flow on UA Dopplers), especially with concomitant prematurity, may have increased susceptibility to NEC and/or feeding intolerance.	Breastmilk provision and avoidance of formula. Early initiation of trophic or small volume feeding.
Intraventricular hemorrhage	Increased risk may be due to cerebral vascular remodeling, cerebral autoregulatory mechanisms, and overall hemodynamic instability in IUGR.	Surveillance with head ultrasound. Avoiding fluctuations in cerebral oxygenation using continuous monitoring such as near infrared spectroscopy.
Electrolyte abnormalities	Hyperglycemia and hypocalcemia	Monitor for and correct abnormalities.
Polycythemia/jaundice	May occur as a response to long-standing hypoxia in utero.	Check for underlying hematologic abnormalities, and treat when clinically indicated.
Abnormal innate and humoral immunity	Unclear etiology, although speculated to occur due to bone marrow suppression secondary to chronic hypoxia.	Check for underlying abnormalities with a complete blood count and differential. Low threshold for infectious work-up and aggressive management of infection.

AGA, Appropriate for gestational age; IUGR, intrauterine growth restriction; NEC, necrotizing enterocolitis; UA, umbilical artery.

Seizures, Intraventricular Hemorrhage

IUGR neonates, especially those born premature, may be at increased risk for intracranial hemorrhage (ICH). Some studies have demonstrated an increased association of ICH with IUGR neonates with abnormal cerebral blood flow patterns (as measured by prenatal middle cerebral artery measurements),[20] while others have not demonstrated the same association after correcting for gestational age and other confounding factors.[65] The mechanisms underlying

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

intracranial hemorrhage in IUGR neonates are also debated, as there is evidence to suggest that cerebral vascular remodeling, cerebral autoregulatory mechanisms, and overall hemodynamic instability in IUGR infants may contribute to predisposition toward IUGR. Given the unknowns, recent research into the utility of cerebral oxygenation (via near-infrared spectroscopy) as a marker of brain perfusion suggests that serial measurement may be helpful in predicting neurodevelopmental outcome. When available, avoiding fluctuations in cerebral oxygenation may be helpful in avoiding intracranial hemorrhage,[50] and thus, continuous monitoring of cerebral oxygenation may be a much better marker than the use of blood pressure values alone, which do not extrapolate to adequate tissue perfusion, particularly in the brain.[1]

Other

Other reported complications of IUGR in the immediate postnatal period include perinatal asphyxia, electrolyte abnormalities (e.g., hyperglycemia, hypocalcemia), hematologic issues (e.g., polycythemia, jaundice), feeding difficulties and intolerance, and abnormal innate and humoral immunity.[59] These issues should be closely monitored for, and addressed, as possible.

Long-Term Consequences of IUGR

There is a wealth of evidence that the in utero environment contributes greatly to the fetus's development in a manner that can have long-lasting implications. For IUGR infants, there are long-term neurodevelopmental, as well as cardiometabolic consequences, of poor growth in utero (see Fig. 15.3). This phenomenon is known as developmental programming,[15] a concept that has a foundation built in large epidemiologic studies showing that maternal gestation during periods of famine results in IUGR offspring that are at increased risk for cardiometabolic disease during adulthood.[8]

The neurodevelopmental outcomes of IUGR offspring are known to be worse than those of their AGA counterparts, but the mechanisms by which this occurs remain controversial. IUGR neonates are at increased risk for cerebral palsy and for lower scores across multiple neurocognitive domains including cognition, attention, mood, and social skills,[38] even after correcting for confounders such as socioeconomic status, prematurity, and its co-morbidities. In placental insufficiency underlying asymmetric IUGR, vasoconstriction of the peripheral vascular bed and raised placental vascular resistance in combination with vasodilation of the cerebral arteries preferentially shifts cardiac output toward the brain.[63] It is important to note that brain-sparing appears to be regional, not global, and that patterns of increasing and decreasing blood flow in specific portions of the brain change during the course and chronicity of hypoxia, implying a hierarchical order to blood flow response even within a single organ.[34] It was previously believed that this phenomenon was a brain-protective response in the face of chronic hypoxia; however, other studies suggest that neurodevelopmental outcomes are worse in IUGR subjects with evidence of "brain-sparing"[28] (as measured by blood flow patterns in cranial blood vessels). It has been proposed that increased cerebral blood flow may actually suggest advanced stages of brain injury and that the persistently increased cerebral blood flow seen after birth in IUGR infants despite no longer being in an hypoxic environment[37] may be a maladaptive change resulting from long-standing blood flow changes that alter structure and function of the cerebral vasculature (e.g., loss of cerebral vasoreactivity), leading to hyperoxic and reperfusion injury postnatally.[18] In addition, the contribution of elevated cortisol exposure in utero, as is seen in IUGR,[17] is unknown, although the link between synthetic steroid exposure and altered brain structure and cognitive function is well-established.[66] Studies on human infants born IUGR demonstrate that they have decreased brain volume, gray matter, and hippocampal volumes, and these changes persist into childhood and are associated with neurodevelopmental impairments.[9]

The concern about neurodevelopmental impairment shapes, in large part, the discussion about the benefits and risks of postnatal "catch-up" growth. Although optimized postnatal growth seems to portend better neurocognitive outcomes,[16] it has been associated with increased risk for cardiometabolic syndromes such as obesity, cardiovascular disease, and diabetes.[7] In general, it is believed that the fetal adaptations that allow the IUGR fetus to reallocate energy sources during starvation/undernourishment toward survival in utero manifest a propensity for insulin resistance, the development of diabetes, and obesity when as an adult, the offspring is exposed to abundance in the nutritional environment. The same adaptations occur in the vascular system and the hormonal axis. Fetal development is believed to be a critical window, during which the "programming" of disease is particularly susceptible to environmental influences. It is believed in part that these fetal adaptations occur via epigenetic mechanisms.[15]

There are a number of other long-term sequelae that are being reported in association with IUGR, such as propensity toward cancer, schizophrenia, Alzheimer's disease, polycystic ovarian syndrome, shorter life span, and immune dysfunction.

Conclusions

Given the huge burden of disease, both to an individual and to public health worldwide, intrauterine growth restriction remains a devastating problem for obstetricians and perinatologists alike. There remain many unknowns in how to best define the disease, identify pregnancies at risk, manage these pregnancies antenatally, and minimize complications postnatally. Furthermore, IUGR offspring may contribute significantly toward adult diseases that compromise the majority of adult mortality, including cardiovascular disease,

obesity, diabetes, and cancer predisposition. Monitoring for these long-term morbidities is important as these children enter adulthood. There is a need for improved modalities in detecting IUGR and predicting some of the morbidities. It behooves us to closely monitor these infants not just in the neonatal intensive care unit but throughout childhood to ensure better societal assimilation and care toward prevention of non-communicable chronic disorders.

Key Points

- Intrauterine growth restriction occurs when fetal growth is less than its genetic potential.
- There are many definitions of IUGR and etiologies leading to IUGR, which contribute to difficulties in how to diagnose, prevent, and develop therapies for intrauterine growth restriction.
- The general categories of etiologies causing IUGR are: fetal, maternal, environmental, and placental.
- Prenatal screening for IUGR is largely dependent on serial ultrasound and Doppler velocimetry, although there is still debate as to how these indicators should be used to dictate prenatal care and delivery planning.
- IUGR has significant short- and long-term consequences for the neonate.

Developmental Origins of Adult Health and Disease

JOSEPHINE M. ENCISO AND SHERIN U. DEVASKAR

Fetal Origins of Adult Disease Concept

The concept of fetal origins of adult disease popularized by Barker arose from a robust association between small size at birth and the risk of chronic adult diseases, such as coronary artery disease, hypertension, stroke, type 2 diabetes mellitus, and osteoporosis.[4,9,20,29] These original epidemiologic observations have been extensively replicated by multiple groups in varying populations of different ethnicities employing birth weight as a surrogate for the intrauterine state.[9,20,36] During the 1944-1945 Dutch famine, women who were previously adequately nourished were subjected to low caloric intake and the associated environmental stressors. The offspring that were conceived or were gestating in their mothers' wombs during the famine, as adult survivors at age 50-60 years, showed a higher incidence of hypertension, cardiovascular-related mortality and morbidity, and glucose intolerance/insulin resistance. The culmination of all these epidemiologic associations is referred to as the "Barker hypothesis" or "developmental origins of health and disease (DOHaD)."[4,9]

Although fetal growth and birth weight have served as surrogate markers of fetal nutrition and health, it is clear that fetuses subjected to nutritional perturbations with no resultant change in size or growth also develop adult chronic diseases.[9] Moreover, although in utero calorie restriction serves as a classic example of the far-reaching implications of the "Barker hypothesis," other triggers, including a deficiency or excess of specific nutrients, stress, inflammation, toxins, and drugs, can perturb the fetal hormonal-metabolic milieu and set the stage for the subsequent onset of chronic diseases.[9,20,23,36] These observations support that adaptations in an adverse in utero environment occur to ensure immediate survival, which may or may not interfere with fetal growth depending on the type, timing, and severity of adversity. Although nutritional deficiency is considered to exist only in poorly resourced countries, differential socioeconomic status with varying access to health care and sociocultural and ethnic differences resulting in disparities are rampant in the Western world, including the United States. These situations can lead to malnutrition, overnutrition, and other forms of maternal-fetal stress, which translate into an altered phenotype of this subpopulation.

As more investigations in human and animal models are accumulating, various mechanisms responsible for this fetal-adult association are being unraveled.[9] These adaptive mechanisms, or "thrifty phenotype," combat an adverse nutritional and/or metabolic intrauterine environment by developing safeguards for the energy supply sometimes at the expense of growth, ensuring a reduced fetal demand. After birth, these same adaptive systems can remain masked, however, without much contribution to short-term health or disease. Over time, with or without additional nutritional or metabolic stressors, the finely crafted phenotype may tip toward a disease state. The conventional belief is that these phenotypic features are expressed mainly in aging adults. Given lifestyle changes toward an increased caloric intake and relative inactivity, however, some of these features are seen in childhood or during late teenage years (Box 16.1).[59]

Influences on the Early Embryo

The use of artificial reproductive technology continues to increase worldwide; 1%-3% of live births are secondary to artificial technology.[18] Different culture media and techniques used in artificial reproductive technology can alter the environment of the developing embryo and subsequent phenotype of the offspring.[18,23,41] Even after accounting for confounding factors such as infertility and advanced maternal or paternal age, there is evidence that artificial reproductive technology is linked to an increased incidence of prematurity, growth restriction, congenital malformations, and imprinting disorders.[10,18,23,41] Imprinting refers to the differential expression of specific genes according to parental origin. Genes are "silenced" by epigenetic modifications. In pregnancy, imprinted genes play a critical role in determining placental size and fetal growth. Most paternally expressed genes enhance placental and fetal growth, whereas

Abstract

The "Barker hypothesis" or concept of the developmental origins of health and disease (DOHaD) connects maternal health status and exposure to stress or environmental toxins during pregnancy with later development of disease in the offspring. In this chapter we will review the studies, both animal and human, that provide support for the concept of fetal origins of adult health and disease. We will describe the effects of maternal overnutrition, undernutrition, diabetes mellitus, obesity, and maternal exposure to stress and environmental toxins, as well as how the existence of these adverse conditions during pregnancy can affect fetal growth, organ, and vascular development and predict health problems and chronic diseases later in life, including obesity, metabolic disease, diabetes mellitus, hypertension, coronary artery disease, and cancer. The epigenetic mechanisms that are associated with the fetal programming of disease from one generation to the next will also be discussed.

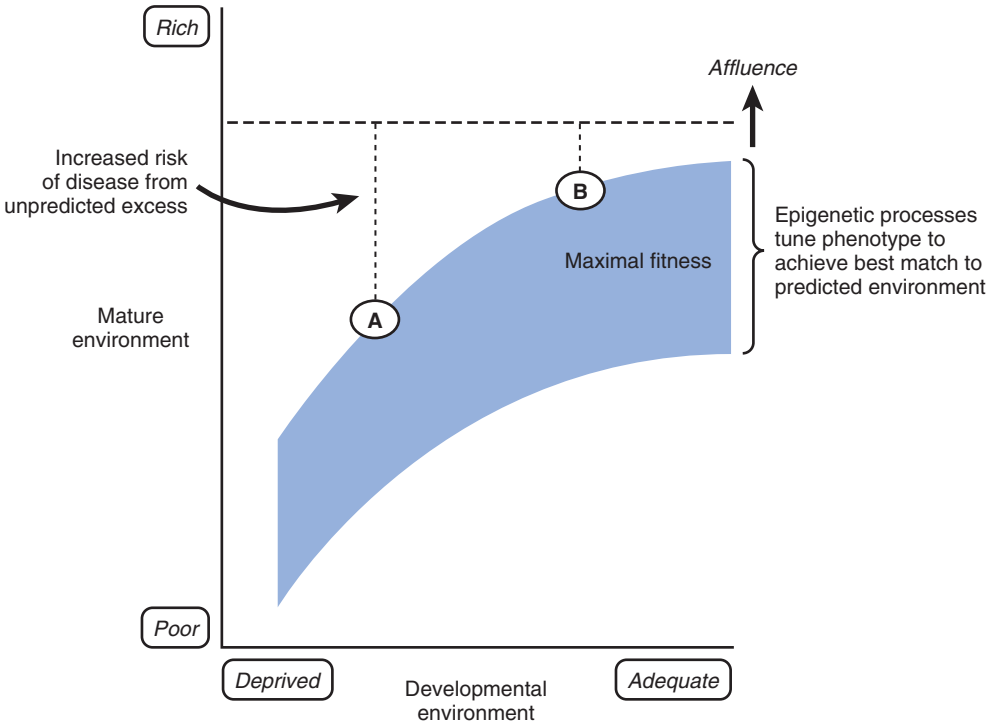
- Poor cognitive performance
- Shortened life span

most maternally expressed genes reduce placental and fetal size. Imprinting disorders, such as Beckwith-Wiedemann, Angelman, Prader-Willi syndromes, and hypomethylation syndrome, appear to be increased in children who are a product of artificial reproductive technology.[41] The incidence of Angelman syndrome is estimated to increase from 1 in 400,000 births to 1 in 20,000 births with artificial reproductive technology.[41] Moreover, artificial reproductive technology may alter the growth patterns of children.[19] Children conceived by in vitro fertilization also have decreased growth early in infancy and then experience "catch-up growth" after about 6 months of age, resulting in higher blood pressures and altered body composition.[10] These alterations in growth patterns and risk for disease illustrate that reprogramming at an early stage can increase the risk for adult disease later on.

Postnatal Growth and Nutrition



The first indication that postnatal stages of development can influence the long-term outcome related to perturbed fetal nutrition came from observations during the Leningrad siege.[9] Exposure in utero and postnatally to nutritional deprivation failed to produce signs of chronic diseases in adults. These findings suggested that postnatal manipulation of nutrition may have a protective effect on the trajectory of fetal origins of adult disease. Investigations have revealed that in girls and boys, low birth weight with a slow growth pattern followed by exponential growth during childhood increases the risk for metabolic syndrome, which is characterized by obesity, insulin resistance, hypertension, and dyslipidemia.[3,59,68] These studies established that postnatal growth patterns were important in modulating the fetal trajectory toward predetermining the adult phenotype. These findings are of particular interest to neonatology, where there continues to be an ongoing dilemma as to what is ideal postnatal growth and whether this growth rate should be the same for infants of varying birth weights, gestations, sexes, ethnicities, and races.

The phenomenon of postnatal catch-up growth seems to reflect intrauterine or early postnatal nutritional deprivation. It is a normal tendency by the body to compensate after a nutritionally restricted period, showing rapid growth. This rapid growth targets short-term benefits, which include survival and protecting the reproductive capacity.[6] It is evident, however, that catch-up growth tends to favor nutrient deposition in white adipose tissue, resulting in adiposity, particularly visceral adiposity; a rearrangement of skeletal muscle mitochondria; and increased oxidative injury.[6] These changes set the stage for metabolic syndrome, diabetes mellitus, and coronary artery disease as the child matures into an adult.[59] This catch-up growth results in a shortened life span with changes in the telomeric length.[19] For "short-term gain," catch-up growth results in "long-term pain" (Fig. 16.1).

The question arises, should postnatal catch-up growth not be fostered? If postnatal nutrition matches intrauterine nutrition, can adult chronic diseases be curbed and result in longevity? Although animal and human studies lend credence to this concept, the absence of catch-up growth, although resulting in glucose tolerance, lean body composition, and reduced coronary artery disease with longevity, may negatively affect cognition and reproductive capacity. Rapid postnatal growth, whether superimposed on low birth weight (LBW) or normal birth weight, seems to have a similar effect in producing adult chronic diseases.[4,6,9] Avoidance of rapid postnatal catch-up growth within a short period may be beneficial if replaced with moderate long-term growth and may be influenced not only by the amount of calories ingested but also by the quality and composition of the nutrition. In a study of small-for-gestational-age (SGA) infants exposed to either maternal breast milk or formula, babies who received breast milk exhibited decreased adiposity and normal serum adiponectin concentrations, while those who received either standard or protein-enriched formula had increased fat mass and lower adiponectin concentrations.[15] Other studies have revealed an association between fortified formulas and elevated blood pressures and insulin resistance during the childhood years.[65]

At the other end of the spectrum, infants born with a heavier birth weight, resulting from either maternal diabetes or obesity, are also prone to adult chronic diseases. These infants are obese during childhood and develop insulin resistance with the associated phenotypic presentations.[68] One can speculate that these infants experience catch-up growth during fetal life after experiencing slow growth during the early embryonic phase. Further postnatal escalated growth leads to earlier acquisition of adult chronic diseases and the associated complications. The weight status in the first 6 months of life predicts obesity at 3 years of age and future mortality (Fig. 16.2).[68]

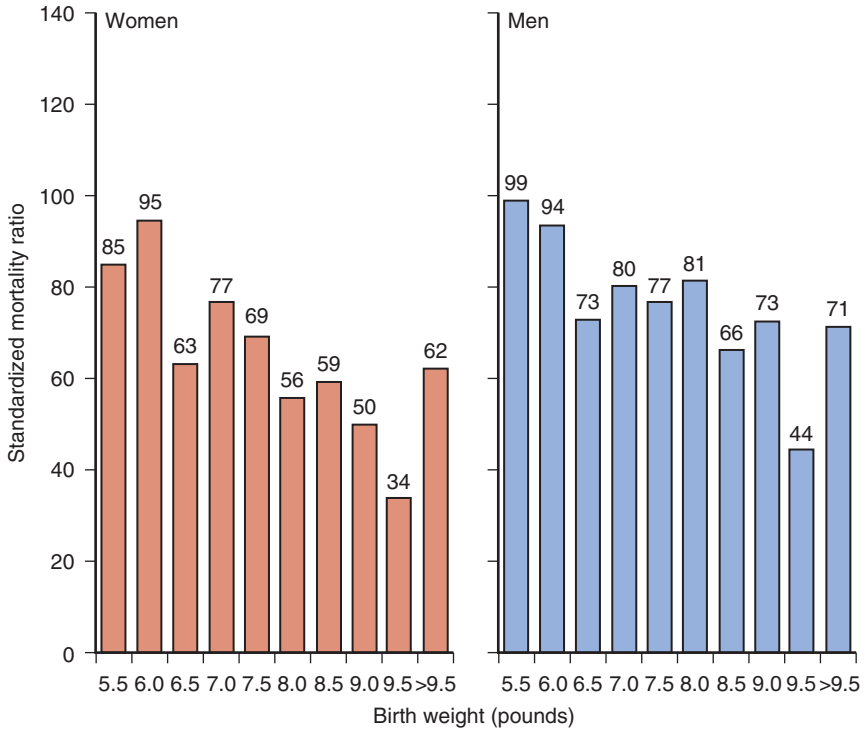
• **Fig. 16.1** Schematic representation of the mismatch concept that emphasizes the degree of disparity between the environment experienced during development and that experienced later (*hatched line on top*), on the risk of disease. During the period of developmental plasticity in prenatal and early postnatal life, epigenetic processes are thought to alter gene expression to produce phenotypic attributes best suited to the environment and based on environmental cues transmitted via the mother (*shaded area*). Greater mismatch gives greater risk of disease from unpredicted excessive richness (high-calorie-density food, sedentary lifestyle) in the environment. Risk is greater with poorer developmental environment (**A** versus **B**) and with socioeconomic transitions to an affluent Western lifestyle. (From Godfrey KM, et al. Epigenetic mechanisms and the mismatch concept of the developmental origins of health and disease. *Pediatr Res*. 2007;61:5R.)



Mismatch Concept

Investigations have solidified the concept of profound effects resulting from a "mismatch" between the early developmental environment and the subsequent environment after birth into childhood and adult life. The degree of mismatch can be increased by deprived environmental conditions during a critical phase of development (prenatal or postnatal) or an excess later or both (see Fig. 16.1). Compromised maternal health, nutrition, toxins, stressors, infections, and inflammation can contribute to the former, whereas energy-dense foods and television watching with reduced physical activity can contribute via the latter pathway, exaggerating the mismatch further. Such a phenomenon has considerable significance to developing societies that are undergoing rapid socioeconomic transitions or to immigrant families in Western countries that came from poorly resourced countries.[36]

Most important to neonatal intensive care units are the neonatal health concerns of nutrition, toxins, stressors, hypoxia, infections, and inflammation during the early phase of life that can have similar effects on the life course of a particular individual. Thought should be exercised before introducing interventions during this period of development that have the potential of altering the life course. The concept of catch-up growth should be reevaluated to determine what is optimal for every subset of the population. At both ends of the spectrum—infants who are large for gestational age (LGA) and intrauterine growth restriction (IUGR)—there is a period of deprivation followed by exposure to excess. In the case of the former, this deprivation usually occurs during the first trimester, with rapid catch-up growth observed during the third trimester, resulting in an infant who is LGA, whereas in the latter category, the deprivation is generally in the third trimester, with rapid catch-up growth postnatally. In premature infants who have very low birth weight (VLBW), the deprivation is in early postnatal life followed by catch-up growth during the post-neonatal stage of development. Very low birth weight children may also be faced with superimposed fetal growth restriction, further increasing their disease risk. Thus, it appears that the earlier the deprivation phase is followed by catch-up growth, the more significant the consequences as an adult.[6]

Although considerable emphasis in most studies has rested on the prenatal or postnatal growth pattern and size at birth or infancy, a perturbation in growth and size is evidence that adaptations are in place to conserve energy at

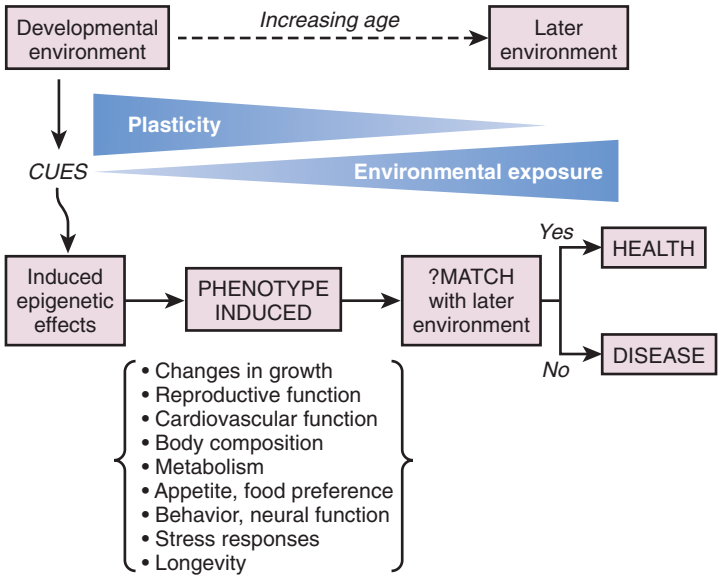
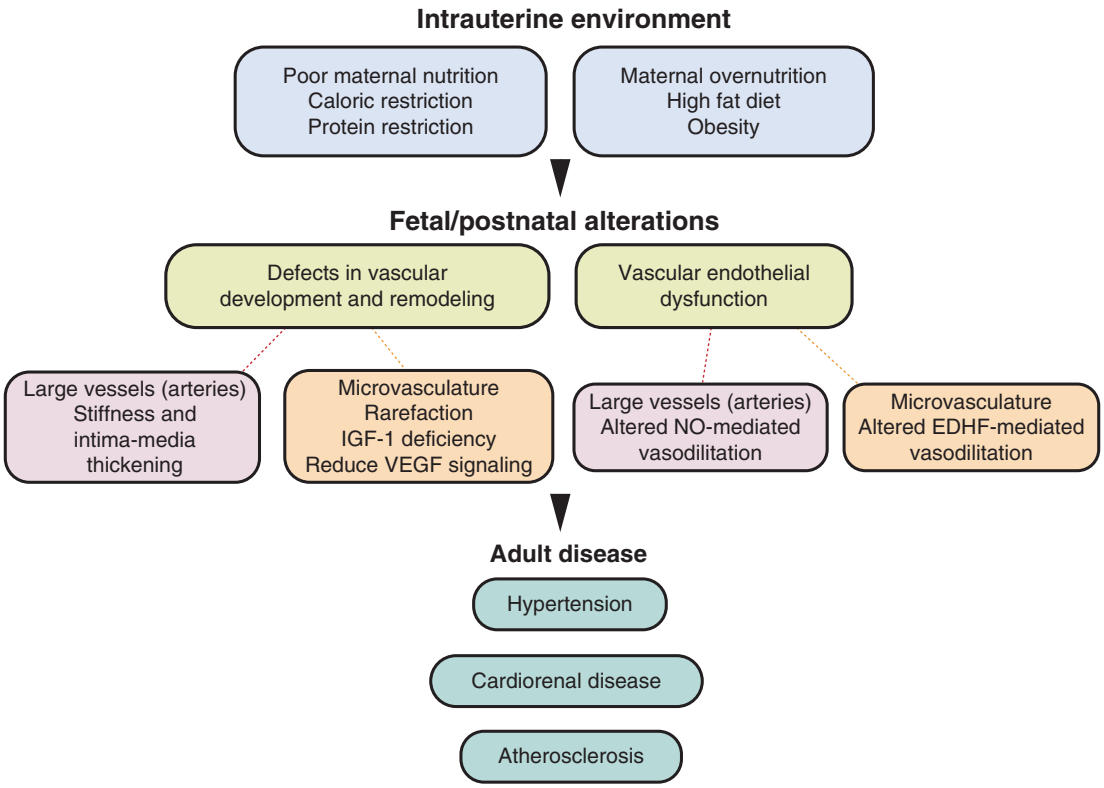
the expense of growth. Situations of deprivation or exposure to stressors can occur, however, in the absence of any effect on the growth potential or size. This makes it difficult sometimes to understand the mismatch concept and its role in the growing incidence of chronic adult diseases. The developmental origins of adult health and diseases are now recognized to have major public health implications worldwide. The World Health Organization states, "The global burden of death, disability, and loss of human capital as a result of impaired fetal development is huge and affects both developed and developing countries." (http://www.who.int/nutrition/publications/fetal_dev_report_EN.pdf, accessed December 18, 2017). This statement advocates for a broader concept of maternal well-being and achieving an optimal environment for the fetus (and newborn) to maximize the potential for a full and healthy life. This concept has widened to include plasticity during childhood, which is being presently investigated in prospective studies consisting of large populations (Fig. 16.3).



Fetal Origins of Vascular Structural Abnormalities and Dysfunction in Adult Cardiometabolic Disease

The Barker hypothesis established a connection between maternal nutrition during pregnancy, low birth weight in the offspring, and development of cardiovascular disease in offspring in adulthood, such as hypertension, coronary heart disease, stroke and metabolic syndrome including insulin-resistance, type 2 diabetes, and obesity. Maternal undernutrition as well as nutritional excess during pregnancy can predispose offspring to later cardiovascular disease. Specifically, maternal caloric intake has been shown to influence vasculogenesis, angiogenesis, barrier integrity, and vascular maturation in the fetus.[38] On the other extreme, maternal obesity and excessive maternal weight gain in pregnancy can predispose offspring to elevated blood pressure and increased adiposity and risk of also becoming obese.[39,52] There is building evidence that maternal nutrition and cardiovascular and metabolic disease such as hypertension, type 2 diabetes, and obesity can have adverse effects on fetal vascular development and function that predispose the fetus to future adult cardiovascular and metabolic disease (Fig. 16.4).[14] Most of the evidence has been based on animal studies and less on human studies.



In regard to larger vessels, arterial stiffness and increased coronary artery intima-media thickness has been described in low birth weight and small for gestational infants.[50,51] Infants with excessive gestational weight gain had correlating postnatal obesity with higher body mass index (BMI) and systolic blood pressures.[39] Animal studies, rodent and nonhuman primate models, also provide evidence that undernutrition as well as a high fat diet prenatally can lead to vascular remodeling in offspring, specifically increased arterial stiffness, and increased arterial wall thickness that can lead to atherosclerosis.[21,27]

Endothelial dysfunction, or loss of normal control of vasodilation by the endothelium, is also seen in hypertension

and metabolic syndrome. The vascular endothelium, the inner lining of blood vessels, has multiple roles including the regulation of vascular tone, trafficking of inflammatory cells, and an antithrombotic role. Vascular tone is regulated by local, neural, humoral, and myogenic factors. Vasoactive endothelium-derived mediators that activate their corresponding receptors on nearby smooth muscle cells include vasoconstrictors such as thromboxane A2, endothelin-1 (ET), and prostaglandin H2 and vasodilators such as nitric oxide (NO), prostacyclin (PGI2), and endothelium-derived hyperpolarizing factor (EDHF).[11,28] In addition to structural remodeling abnormalities, low birth weight infants and infants with poor fetal nutrition have evidence of endothelial dysfunction characterized by impaired vasodilation.[22,66] In human studies, utilization of the noninvasive techniques of flow-mediated dilatation and pulse wave velocity has allowed for the measurement of vascular function in large conductance and resistance arteries.[62] A cohort study showed that abnormal flow-mediated dilatation and findings of early atherosclerosis mediated by elevated blood pressure, triglyceride levels, and inflammation were associated with impaired fetal growth.[66] Endothelial dysfunction in animal models has been studied by measuring endothelium-dependent acetylcholine-induced relaxation of vascular smooth muscle cells by wire myography or measurement of shear mediated dilatation using pressure myography.[72] Multiple animal studies have shown that maternal diet can lead to abnormal acetylcholine-mediated arterial dilatation in adult offspring.[27,64,69] IUGR induced early in pregnancy resulted in adult offspring with abnormal endothelium-dependent and endothelium-independent dilatation and hypertension. Nitric oxide (NO) has a central role in mediating vascular dilatation and is dependent on NO bioavailability. Increased oxidative stress and the presence of reactive oxygen species (ROS) reduce NO bioavailability.[11] The increased oxidative stress and increased ROS production in conditions such as obesity and type 2 diabetes are associated with endothelial dysfunction.[71] Increased oxidative stress and low levels of antioxidant enzymes are associated with SGA and LGA infants.[63] Maternal overnutrition resulted in increased placental expression of ROS and was associated with neonatal insulin resistance and obesity.[57]

The microvasculature, or small resistance arteries, arterioles, capillaries, and venules with diameter less than 200 μm located within tissue parenchyma, has a primary role in regulating tissue perfusion and optimal exchange of gases, nutrients, water, and solutes between the blood and surrounding tissues. The microvasculature has an important regulatory role in maintaining adequate tissue perfusion and controlling blood pressure.[56] Microvascular rarefaction, or decreased vascular density, and dysfunction leading to the development of cardiovascular and metabolic disease in adulthood may be primed by the maternal environment, thus stressing the importance of the pre- and perinatal environment in the development of vascular disease such as hypertension, coronary heart disease, and stroke. Rarefaction has been observed in obesity and hypertension and is thought to contribute to insulin resistance. Rarefaction results in restricted tissue perfusion and longer capillary diffusion distances for metabolic exchange. Studying microvascular structure and function in humans is, however, challenging and limited to accessible vascular beds including skin and retinal microvasculature. Low birth weight has been shown to be associated with rarefaction and impaired endothelium-dependent vasodilatation of skin microvasculature. SGA babies have evidence of decreased retinal vascularization that is known to be mediated by downregulation of vascular endothelial growth factor (VEGF) and associated with insulin-like growth factor 1 (IGF-1) deficiency in preterm and IUGR infants.[33] Although the findings of rarefaction in the skin and retinal vasculature of low birth weight and SGA infants may not be reflective of the microvascular environment in major organs such as the kidney, heart, and skeletal muscle, the data suggests that impaired vasculogenesis and angiogenesis also occur at these sites and may contribute to the microvascular dysfunction and the development of cardiometabolic disease in this risk group. The effect of maternal or intrapartum factors, including high fat diet, calorie restriction, hypertension, and fetal oxygen stress on microvascular structure in animal studies have been demonstrated.[42,48] Reduced microvascular development, specifically in the renal and intestinal microvasculature, in the offspring of mothers with these conditions during pregnancy has been associated with the development of hypertension and cardiometabolic disease in these offspring.[35,54,74,75] Offspring born to dams on a low protein diet had evidence of microvascular rarefaction of arterioles and capillaries at age 7–28 days and later were associated with the development of elevated blood pressure.[54] The reduction in VEGF and VEGF receptor expression has been demonstrated in some of these studies, indicating that the absence of angiogenic signaling from the VEGF pathway may be the mechanism inhibiting microvascular development.

Endothelial dysfunction in the microvasculature can alter normal vasoconstrictor and dilator responses and adversely affect blood flow, perfusion, and glucose uptake and oxygenation. Overall, few studies, particularly human studies, have demonstrated the effects of maternal nutritional status on endothelial function specifically in the microvasculature. In animal models, a reduction in acetylcholine-induced vasodilation in cremaster arterioles has been observed in offspring of mothers fed a high-fat diet.[47] Further, endothelium-derived hyperpolarization (EDH)-mediated vasodilation in the microvasculature can be impaired in the setting of fetal growth restriction and in offspring exposed to both excessive and restrictive calories in utero.[46,69] Data is yet lacking on the effects of excessive nutrition during pregnancy on the microvascular function of the offspring exposed to an adverse in utero environment.[55]

Placental Abnormalities and Association With Adult Disease

The placenta has an essential role in promoting normal fetal development and maintaining pregnancy. Its major functions include providing oxygen and gas exchange; transfer of macro- and micronutrients, vitamins, hormones, and antibodies; elimination of waste products; metabolism of glycogen, cholesterol, and fatty acids; and endocrine secretion of hormones that sustain pregnancy. Fetal growth and infant birth weight not only depend on maternal nutrition but are also dependent on placental function and transport of nutrients from the mother to the fetus.[8] Nutrient transfer by the placenta is reflected in the weight, size, and shape of the placenta, and these placental characteristics have been found to be a marker for later disease in adulthood, including hypertension and coronary heart disease.[5,25] Epidemiologic studies have demonstrated associations between placental size and shape and adult chronic disease.[61] The Helsinki Birth Cohort of 13,345 men and women born between 1943 and 1944 showed the association between low placental weight and surface area with hypertension in adulthood.[5] In this same birth cohort, small placentas, small placental surface area, and placental inefficiency was a powerful predictor of coronary heart disease in the men followed in this study. There is also data to suggest that a large placenta with increased surface area and increased number of lobes can also result in elevated blood pressure. Children in a study from Bristol, United Kingdom (ALSPAC study), had higher birth weights and were found to have elevated blood pressure at age 9.[2] In all, these studies demonstrated that both large and small placentas can limit the flow of nutrients to the fetus and ultimately have long-term effects on cardiovascular health into adulthood.

Gestational Diabetes and Long-Term Metabolic Effects on Offspring

Gestational diabetes is increasingly prevalent in industrialized countries wherein overnutrition leading to obesity and type 2 diabetes is a health concern. Investigations have uncovered an association of type 2 diabetic risk alleles in infants born with a reduced size, linking the genetics of type 2 diabetes with low birth weight.[45] There is evidence from epidemiologic studies that intrauterine exposure to maternal diabetes can lead to adverse metabolic outcomes in offspring, including obesity, insulin resistance, and type 2 diabetes.[3,16,17,73] Data from a population of Pima Indians in Arizona with high rates of obesity and type 2 diabetes revealed that offspring of women who had gestational diabetes were obese and had a higher prevalence of type 2 diabetes.[17] To address the confounding factor that genetics contributes to the development of type 2 diabetes in offspring of diabetic mothers in the same population of Pima Indians, a sibship study was done to compare body mass index (BMI) and the prevalence of type 2 diabetes in siblings born before and after their mother was diagnosed with type 2 diabetes. Among a population of mothers genetically predisposed to type 2 diabetes, it was demonstrated that offspring born to mothers after they had developed diabetes had a significantly higher risk of type 2 diabetes and a higher body mass index (BMI) than their siblings born prior to development of diabetes in the mother.[16] Other studies have provided evidence that intrauterine exposure to hyperglycemia can result in offspring with either type 2 diabetes or type 1 diabetes, obesity, and metabolic syndrome.[73]

Cancer

Although most cancers are diagnosed later in life, the pathogenesis of cancer is multifactorial, and prenatal events may bear some contribution to the disease. Birth weight has been speculated to be associated with the development of breast, ovarian, colon, lung, and some blood cancers.[9,26,60] Although numerous oncogenes have been identified, genetics and environmental triggers cannot completely explain the pathogenesis of many cancers.

Increased or decreased maternal concentrations of estrogen and testosterone may play roles in a tissue's potential for cellular dysplasia. Trichopoulos first proposed that elevated estrogen concentrations during pregnancy increase the risk of breast cancer in female offspring.[70] Estrogen concentrations peak during pregnancy, being 10 times higher in pregnant women. Higher maternal estrogen concentrations are noted with advanced maternal age, twin gestations, and LGA status. Conversely, estrogen is inversely associated with pregnancy-induced hypertension. Fetal mammary gland cells are undifferentiated and particularly vulnerable to the carcinogenic effects of estrogens and other growth hormones such as IGF. As a result, in utero exposure to high estrogen levels increases the risk of mitogenic activity and adult-onset cancer.

Preeclampsia and eclampsia have shown to be protective against breast cancer.[43,70] A clear positive association between breast cancer and higher birth weight, birth length, and placental weight was reported. Further epidemiologic studies have confirmed these findings. In a meta-analysis of 18 studies consisting of 16,424 breast cancer cases, the risk for breast cancer increases 7% for each 1 kg increase in birth weight.[43]

Psychosocial Aspects

When examining psychosocial consequences of low birth weight, the question is raised why suboptimal fetal and neonatal growth are risk factors for a less successful adult life. Low birth weight is associated with poor cognition, increased risk for behavioral disorders such as autism and attention deficit hyperactivity disorder, and adult-onset psychiatric disorders such as depression and schizophrenia.[1,53,58] The fetal programming model provides some answers. Adults who were SGA or VLBW have had remodeling of their hormones and metabolism in early neonatal life from heightened stress responses.[34] Chronic stress, either antenatal

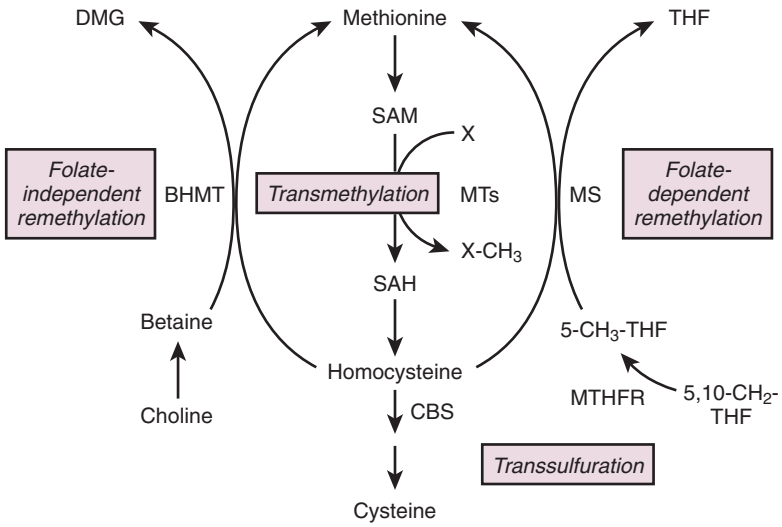
or postnatal, can permanently alter the hypothalamic-pituitary-adrenal axis, resulting in high concentrations of glucocorticoids.[34] Compounding the neonate's hyperactive state, fetuses and premature and critically ill neonates are often prescribed varying doses and types of synthetic glucocorticoids, which may further alter brain development. This hormonal and central nervous system remodeling leads not only to neurodevelopmental impairments and an increased risk for cardiovascular disease but also maladaptive behaviors such as anxiety and depression.[1,34] Malnutrition during a critical time in prenatal and postnatal development may also play a vital etiologic role. In summary, fetal origins of adult disease not only help explain why fetal reprogramming can affect systemic adult disease processes but also explain the difference seen in academic performance, professional attainment, sexuality and reproduction, emotionality, personality, and overall quality of life.[1,34,58]

Improvements in technology and the practice of neonatology have allowed clinicians to adequately resuscitate preterm infants at younger and younger gestational ages. The generations of preterm infants who have survived are now being followed into adulthood, and they provide information on the types of problems facing infants who are SGA and have a VLBW.[58] The particular medical problems these infants experience are well described in the literature. The social implications of being born premature have not been studied that well, however, and are only now beginning to emerge. Countries in Europe and the United States that maintain national databases are reporting their findings on adult outcomes for premature and low birth weight neonates. In a Helsinki cohort, fast postnatal growth superimposed on restricted prenatal growth was also shown to influence development of the anxiety trait in men and women at 63 years of age. This pattern resembled the pattern seen with the development of cardiovascular events, supporting a shared common developmental origin.[37]

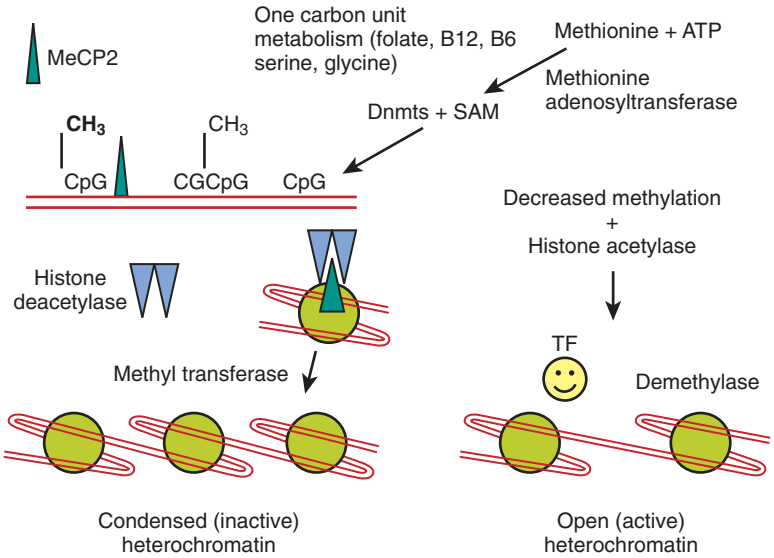
Toxins, Endocrine Disrupters, and Micronutrient Metabolism

(See Also Chapter 14)



Although considerable focus has been on prenatal and postnatal nutrition as the inciting factor, other factors, such as maternal stress, prenatal glucocorticoids, infections associated with inflammation, and hypoxic-ischemic insults secondary to a diminution of fetal blood flow, seem to affect fetal development, resulting in subsequent cardiovascular and metabolic abnormalities.[9,20] Certain endocrine disrupters, such as pesticides, estrogens, antiandrogenic compounds (bisphenol A and phthalates), can affect endocrine function and have far-reaching effects on the phenotype of animals and children.[40,44,49] These changes, which are considered epigenetic in nature, persist into future generations when a pregnant animal is exposed. The fetus (second generation) and the gametes of the fetus (which give rise to the third generation) face the same exposure. Increases in pubertal abnormalities, ovarian and testis disease, and obesity have been observed.[40] The classic example of how an endocrine disruptor can be responsible for tissue and hormonal reprogramming is diethylstilbestrol (DES), a synthetic estrogen. In animal studies, offspring of mothers exposed to low-dose DES exhibit low birth weights, catch-up growth, adult-onset obesity, decreased activity, and abnormal glucose metabolism.[49] Bisphenol A, a chemical used in plastics and an environmental estrogen, is also linked to obesity and insulin resistance.[49] These changes may be sex-specific depending on the time of exposure. Moreover, other airborne toxins can also have a long-term effect on the adult offspring.

Epigenetics



Waddington coined the term *epigenetics* and defined it as a branch of biology that studies the causal interactions between genes and the phenotype. Epigenetics consists of heritable covalent modifications of DNA and histones that affect gene expression without alterations in DNA nucleotide sequence. Epigenetic changes in gene expression form the important link between environment and genome. Environmentally induced epigenetic modifications, in the form of DNA methylation, histone acetylation, or microRNA, can result in permanent changes in gene regulation and expression that are transmitted from parental cells to daughter cells through rounds of somatic cell division and are inherited across multiple generations.

Subtle changes in DNA methylation occur through the rest of fetal development and subsequently during extrauterine life, explaining the phenotypic differences with age in monozygotic twins. Although DNA methylation relies on the one-carbon metabolism involving methyl donors (folic acid, methionine, betaine) (Fig. 16.5), DNA is methylated in specific noncoding regions and at DNA repeats of transposable elements. In particular, CpG islands, DNA regions where a cytosine (C) nucleotide is followed by a guanine (G) nucleotide and linked together by a phosphate (p) group, of a gene promoter are unmethylated in tissues of expression but can undergo methylation in tissues in which that particular gene is not expressed (Fig. 16.6). Hypomethylation of the imprinted locus *IGF2*, a gene that regulates growth and development, was observed six decades later in individuals born during the Dutch hunger winter of 1944 who had developed obesity later in life after periconceptual exposure to famine.[32] Of more relevance today is the transgenerational epidemic of obesity in industrialized countries wherein overnutrition is prevalent. More recent epidemiologic studies have demonstrated epigenetic changes in offspring born to mothers with overnutrition, obesity, metabolic disease, and diabetes mellitus during pregnancy that predispose these offspring to similar conditions. A study using a mass spectrometry–based approach assessing blood methylation in offspring from mothers before and after bariatric gastrointestinal bypass surgery to reduce obesity demonstrated differences in DNA methylation of glucoregulatory, immunologic, and cardiovascular

• **Fig. 16.5** Scheme of the one carbon metabolism showing the folate-dependent and -independent pathways related to transmethylation that provide methyl groups to the CpG islands of DNA. In addition, methionine is a methyl donor. BHMT, Betaine homocysteine methyltransferase; CBS, cystathionine β-synthase; DMG, dimethyl-glycine; MS, methionine synthetase; MTs, methyltransferases; MTHFR, methylene tetrahydrofolate reductase; SAH, *S*-adenosyl-L-homocysteine; SAM, *S*-adenosyl-L-methionine; THF, tetrahydrofolate.

• **Fig. 16.6** Simplistic scheme showing methylation (CH_3) of CpG islands achieved by DNA methyltransferases (Dnmts) and *S*-adenosyl-L-methionine. Methylated DNA attracts methylated CpG binding protein 2 (MeCP2), which recruits histone deacetylases and histone methylases, resulting in histone deacetylation and methylation. When this occurs in a gene promoter, it causes heterochromatin formation, repressing gene expression. This is facilitated further by heterochromatin protein (HP1) binding. In contrast, hypomethylation of DNA attracts histone acetylases and demethylases, which have the opposite effect, resulting in euchromatin formation, transcription factor (TF) binding, and activation of gene transcription. ATP, Adenosine triphosphate. (From Devaskar SU, Thamotharan M. Metabolic programming in the pathogenesis of insulin resistance. *Rev Endocr Metab Disord*. 2007;8:105.)

disease genes.[31] Gene candidate studies have demonstrated hypomethylation of specific genes such as mesoderm-specific transcript (MEST) isolated from fetal cord blood and placenta in offspring born to mothers with either diet-treated or insulin-dependent diabetes mellitus compared to controls without diabetes mellitus.[24] These studies show that epigenetic changes involving DNA methylation can result from prenatal exposure to hyperglycemia and predispose to later increased risk of obesity, metabolic disease, and diabetes mellitus in offspring.

A more recently recognized epigenetic mechanism resulting in altered gene expression is the post-transcriptional

regulation of RNA by short single-stranded, noncoding microRNAs.[12] MicroRNAs indirectly affect translation of key factors or enzymes required for epigenetic processes in the nucleus. MicroRNAs bind to specific complementary sequences in the 3′-untranslated region of a gene suppressing translation. By suppressing DNA methyltransferase enzyme translation, microRNAs indirectly can regulate DNA methylation. In a study of monozygotic twin pairs discordant for type 2 diabetes, 20 microRNAs isolated from skeletal muscle were identified that were downregulated in the twins with diabetes compared to their nondiabetic twin.[7] The downregulation of two microRNAs, miR-15b and miR 16, were found to be the most statistically significant and were shown to target the expression of key proteins in the insulin signaling pathway, including insulin receptor (INSR), IRS1, and PIK3R1.

A few studies have started to identify epigenetic biomarkers that could predict the risk for obesity and developing metabolic disease later in life. Promoter methylation of the retinoid X receptor, alpha (RXRA), a nonimprinted gene, in umbilical cord tissue of healthy neonates was associated with increased adiposity during later childhood.[30] RXRA promoter methylation had a stronger effect in predicting later childhood adiposity than other factors such as birth weight or maternal body composition, supporting the usefulness of this epigenetic biomarker in predicting obesity. Promoter methylation of another gene, peroxisomal proliferator-activated receptor- gamma-co-activator-1 alpha (PPARG-C1A) in blood from children as early as 5-7 years old was found to be stable over time from childhood to puberty, and when detected, was able to predict risk for increased adiposity several years later up to age 14.[13]

Overall, an aberrant environment during a critical phase of development imposes permanent adaptive changes as a mode of survival. These adaptations are mediated by epigenetic alterations of the genome, which change gene expression. Changes in gene expression affect the cell cycle and phenotype and are carried transgenerationally. This phenomenon underlies the concept of developmental origins of adult health and disease.

Translation to Neonatology

How do these epidemiologic associations in humans and mechanistic paradigms discovered in animal models affect neonatology? Epidemiologic associations and human and animal studies continue to demonstrate that a reduction or an increase in birth weight is associated with an array of adult-onset chronic diseases.

In practice, changes of 1 kg in birth weight can be seen in infants with growth restriction and LGA compared with appropriate-for-gestational-age neonates. However, although weight serves as an overall indicator for a fetus's and child's well-being, in utero and extrauterine stressors can trigger later disease without any change in growth. It has become apparent that intrauterine and postnatal nutrition and growth trajectories have far-reaching implications for an individual. Further postnatal interventions (nutritional or otherwise) can cause lifelong perturbations requiring close long-term follow-up. Particularly, postnatal nutrition walks a fine line between guarding against "nutritional excess" while ensuring adequate energy for the developing brain.

The recognition of variability in a given population based on ethnicity, prenatal nutrition, stressors, maternal disease, placental health, infections, and toxin exposure is important. An example is growth rate and nutritional practices that vary based on ethnicity and the country/region of origin. An ideal growth pattern for the West may not be reflected or achieved in certain South Asian countries. Although infants may be smaller in size, their body composition may be entirely different. More evidence is emerging that body mass index measurements may not reflect the whole picture. Fat distribution plays a major role in whether an infant is prone to developing obesity and insulin resistance with time. Individuals who have subcutaneous fat accumulation may be relatively more protected than individuals with visceral adiposity. Further signs of lipotoxicity seen with fat redistribution and accumulation in tissues such as the liver, beta-islet cells of the pancreas, skeletal muscle, and bone marrow are detrimental to metabolic homeostasis. Various biomarkers, such as circulating insulin (C-peptide), leptin, adiponectin, and cytokine concentrations are considered to preempt childhood and adolescent disorders secondary to insulin resistance.

Similar approaches are emerging with respect to the development of other chronic disorders, such as hypertension and neuropsychoses. Although the search for an ideal battery of biomarkers that can predict the adult phenotype of an infant is ongoing, the prenatal and postnatal periods of life form the critical window of developmental plasticity that contributes to the entire life cycle of the individual, including the phenotype of future generations.

Key Points

- The Barker hypothesis identified a link between cardiovascular disease and birth weight.
- Maternal nutrition, diabetes mellitus, obesity, and exposure to stress and environmental toxins during pregnancy can affect fetal growth, organ, and vascular development, and predispose the fetus to cardiovascular and metabolic disease, psychiatric disorders, and cancer in adulthood.
- Epigenetic mechanisms drive fetal programming of adult disease and can have generational effects.

Hypertensive Disorders of Pregnancy

ARUN JEYABALAN

Hypertensive disorders of pregnancy consist of a broad spectrum of medical complications, including gestational hypertension, preeclampsia, eclampsia, and pregestational hypertension. The incidence is estimated to be between 3% and 10% of all pregnancies.[4,26,74] Worldwide, preeclampsia and related conditions are among the leading causes of maternal mortality.[26] Although maternal death caused by preeclampsia is less common in developed countries, maternal morbidity remains high. Hypertensive disorders of pregnancy are also the leading cause of fetal growth restriction and indicated preterm deliveries, with the associated complications of prematurity such as neonatal deaths and serious long-term morbidity being substantial.[26]

Preeclampsia is a pregnancy-specific syndrome that is clinically recognized by new onset hypertension and proteinuria after 20 weeks' gestation. Vascular dysfunction is central to the systemic maternal manifestations of preeclampsia, including increased peripheral vascular resistance, heightened sensitivity to vasopressors, endothelial dysfunction, vasospasm, ischemia, inflammation, activation of the coagulation cascade, and platelet aggregation leading to multiorgan damage.[69] The term *eclampsia* is derived from the Greek, meaning "sudden flashing" or "lightning," and refers to the seizures that can accompany this syndrome. Although the Egyptians and Indians described this disorder more than 2000 years BCE, the only known cure for preeclampsia remains delivery of the fetus and placenta.

Classification of Hypertensive Disorders of Pregnancy

Precise classification of the hypertensive disorders of pregnancy has remained challenging because of the changing nomenclature over time, with terms such as *toxemia* and *pregnancy-induced hypertension* now considered outdated. Furthermore, varying diagnostic criteria are used in different regions of the world.[4,70] The classification system most commonly used in the United States is based on the Working Group Report on High Blood Pressure in Pregnancy published in 2000 and revised in 2013 by the American College of Obstetricians and Gynecologists (ACOG) Task Force for Hypertensive Disorders of Pregnancy.[4,30] The goals of the Task Force were to evaluate the existing evidence and update the classification system as well as the management of hypertensive disorders of pregnancy.[4] Four major categories are described: gestational hypertension, preeclampsia-eclampsia, chronic hypertension, and preeclampsia superimposed on chronic hypertension (Table 17.1).

Gestational Hypertension

Gestational hypertension is defined by elevated blood pressure (≥140 mm Hg systolic or ≥90 mm Hg diastolic) in a previously normotensive woman. High blood pressure should be sustained with documented elevations on at least two occasions 4 hours apart. Blood pressure should be measured in the semi-Fowler or seated position with an appropriately sized cuff. Disappearance of sounds (Korotkoff phase V) is used to determine diastolic pressure. Gestational hypertension is a provisional diagnosis during pregnancy and includes women in three categories: (1) women who will progress to develop preeclampsia, (2) women with "transient hypertension of pregnancy" who do not develop preeclampsia and revert to normal blood pressures by 12 weeks' postdelivery, and (3) women who may have previously unrecognized chronic hypertension. Definitive diagnosis is possible only after reassessment at 6-12 weeks' postpartum.

Preeclampsia

Preeclampsia (see Table 17.1) is defined as new onset of elevated blood pressure and new onset of proteinuria after 20 weeks of gestation; or in the absence of proteinuria, hypertension with any of the following: thrombocytopenia (platelet count of less than 100,000/μL), impaired liver function blood (elevated blood concentrations of liver transaminases to twice the normal concentration), the new development of renal insufficiency (elevated serum creatinine of greater than 1.1 mg/dL or doubling of serum creatinine in the absence of other renal disease), pulmonary edema, or new onset of cerebral or visual disturbances. The term "mild" preeclampsia has been replaced by "preeclampsia without severe features" to emphasize the need for ongoing vigilance

Abstract

Hypertensive disorders of pregnancy, including preeclampsia, are common complications of pregnancy and associated with significant maternal and fetal/neonatal morbidity and mortality.

Keywords

preeclampsia
hypertensive disorders
pregnancy-induced hypertension
HELLP syndrome

TABLE 17.1 Classification of Hypertensive Disorders of Pregnancy

Preeclampsia	• Blood pressure ≥140 mm Hg systolic or ≥90 mm Hg diastolic on at least two occasions at least 4 hours apart after 20 weeks' gestation in a woman with a previously normal blood pressure OR • Blood pressure ≥160 mm Hg systolic or ≥110 mm Hg diastolic; hypertension can be confirmed within a short interval (minutes) to facilitate timely antihypertensive therapy AND • Proteinuria ≥300 mg per 24-hour urine collection (or this amount extrapolated from a timed collection) OR protein/creatinine ratio of ≥0.3 OR dipstick reading of 1+ (used only if other quantitative methods not available) OR in the absence of proteinuria, new-onset hypertension with the new onset of any of the following: • Thrombocytopenia with platelet count <100,000/μL • Renal insufficiency with serum creatinine of >1.1 mg/dL or a doubling of the serum creatinine concentration in the absence of other renal disease • Impaired liver function with elevated blood concentration of liver transaminases to twice the normal concentration • Pulmonary edema • Persistent cerebral or visual symptoms
Severe features of preeclampsia (any of these findings)	• Systolic blood pressure of ≥160 mm Hg or diastolic blood pressure of ≥110 mm Hg on two occasions at least 4 hours apart while a patient is on bed rest (unless antihypertensive therapy is initiated before this time) • Thrombocytopenia (platelet count <100,000/μL) • Impaired liver function as indicated by abnormally elevated blood concentrations of liver enzymes (to twice the normal concentration), severe persistent right upper quadrant or epigastric pain unresponsive to medication and not accounted for by alternative diagnoses, or both • Progressive renal insufficiency (serum creatinine concentration of >1.1 mg/dL or a doubling of the serum creatinine concentration in the absence of other renal disease) • Pulmonary edema • Persistent cerebral or visual disturbances
Eclampsia	• Generalized seizures that occur in a preeclamptic woman that cannot be attributed to other causes
Superimposed preeclampsia (likely when any of these are present)	• A sudden increase in blood pressure that was previously well-controlled or an escalation of antihypertensive therapy to control blood pressure • New onset of proteinuria or sudden increase in proteinuria in a woman with known proteinuria before or early in pregnancy Severe features: • Severe range blood pressure despite escalation of antihypertensive therapy • Thrombocytopenia (platelet count <100,000/μL) • Impaired liver function as indicated by abnormally elevated blood concentrations of liver enzymes (to twice the normal concentration), severe persistent right upper quadrant or epigastric pain unresponsive to medication and not accounted for by alternative diagnoses, or both • New onset or worsening renal insufficiency • Pulmonary edema • Persistent cerebral or visual disturbances
HELLP syndrome	• Presence of *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets; may or may not occur in the presence of hypertension and is often considered a variant of preeclampsia
Gestational hypertension	• New onset of sustained elevated blood pressure after 20 weeks' gestation in a previously normotensive woman (≥140 mm Hg systolic or ≥90 mm Hg diastolic on at least two occasions 6 hours apart) • No proteinuria

*Precise diagnosis is often challenging, and high clinical suspicion is warranted given the increase in maternal and fetal-neonatal risks associated with superimposed preeclampsia.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

as well as the progressive and systemic nature of this syndrome. Severe features of preeclampsia include:

- Systolic blood pressure of 160 mm Hg or higher, or diastolic blood pressure of 110 mm Hg or higher on two occasions at least 4 hours apart while a patient is on bed rest (unless antihypertensive therapy is initiated before this time)
- Thrombocytopenia (platelet count <100,000/μL)
- Impaired liver function as indicated by abnormally elevated blood concentrations of liver enzymes (to twice the normal concentration), severe persistent right upper quadrant or epigastric pain unresponsive to medication and not accounted for by alternative diagnoses, or both
- Progressive renal insufficiency (serum creatinine concentration of >1.1 mg/dL or a doubling of the serum creatinine concentration in the absence of other renal disease)
- Pulmonary edema
- Persistent cerebral or visual disturbances

Eliminating the dependence on proteinuria from the diagnosis of preeclampsia is a major revision from the previous diagnostic criteria, with the intent to recognize the systemic and progressive nature of preeclampsia. This is more consistent with other diagnostic criteria used internationally. Fetal growth restriction was also removed from the diagnosis but remains an important aspect in the evaluation and management of women with preeclampsia. As in the 2000 Working Group Recommendations, an increase of 30 mm Hg systolic or 15 mm Hg diastolic blood pressure from baseline in early pregnancy measurements is not included in the diagnostic criteria, because women with these changes alone are not at increased risk for adverse outcomes. Although edema may raise clinical suspicion for preeclampsia, it is not a diagnostic criterion for preeclampsia, because nondependent edema occurs in 10%-15% of women who remain normotensive throughout pregnancy and is neither a sensitive nor specific sign of preeclampsia.

Eclampsia

Eclampsia refers to generalized seizures occurring in a woman with preeclampsia that cannot be attributed to other causes.

Chronic Hypertension

Chronic hypertension is defined as hypertension present prior to pregnancy or that is newly diagnosed before 20 weeks of gestation. Persistent blood pressure of greater than 140/90 mm Hg is considered hypertension. High blood pressure that persists 6-12 weeks postpartum is also classified as chronic hypertension.

Superimposed Preeclampsia

Preeclampsia superimposed on chronic hypertension is characterized by a sudden and sustained increase in blood pressure with or without substantial increase in proteinuria. Diagnosis is often challenging because both blood pressure and urinary protein excretion increase toward the end of pregnancy. High clinical suspicion is warranted given the increase in maternal and fetal-neonatal risks. End-organ involvement such as thrombocytopenia, elevated liver transaminase enzymes, or a rapid decline of renal function are also diagnostic of superimposed preeclampsia.

HELLP Syndrome

HELLP syndrome is defined by the presence of *h*emolysis, *e*levated *l*iver transaminases, and *l*ow *p*latelets. This may or may not occur in the presence of hypertension or proteinuria. It is generally considered a variant of preeclampsia.

A major criticism of the various classification systems is that none have been independently evaluated for the ability to identify the subgroup of women who are at increased risk of adverse pregnancy outcomes. Furthermore, there is disagreement regarding the degree of hypertension, presence or absence of proteinuria, and criteria for disease severity among the different classification systems used internationally.[70] These inconsistencies have led to challenges in comparing and generalizing epidemiologic and other research findings. Studies have sought to develop clinically relevant definitions guided by the evidence and based on predictors of adverse outcomes.[71] The most recent ACOG Task Force recommendations address many of these issues.

Epidemiology of Preeclampsia

The incidence of preeclampsia is increasing in the United States and is likely related to the higher prevalence of predisposing disorders, such as hypertension, diabetes, and obesity, and to delay in child-bearing, as well as to the use of assisted reproductive technologies with their associated increase in multifetal gestation.[22,74] The global impact of preeclampsia is profound, with short- and long-term effects on both mother and baby.

Maternal Effects

Short Term

In a systematic review by the World Health Organization, hypertensive disorders of pregnancy account for 16% of all maternal deaths in developed countries and as high as 26% in Latin America and the Caribbean.[40] In areas in which maternal deaths are high, mortality is largely attributable to eclampsia rather than preeclampsia.[26] Based on data from the United States National Hospital Discharge Survey, the rate of preeclampsia increased by 25% between 1987 and 2004; however, there was a trend toward a decrease in eclampsia by 22%.[74] Although maternal mortality owing to hypertensive disorders is less common in high-income countries, rates of severe morbidity—including renal failure, stroke and permanent neurologic impairment, cardiac dysfunction or arrest, respiratory compromise, coagulopathy, and liver failure—are high. In a study of hospitals managed

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

by the Health Care America Corporation, preeclampsia was the second leading cause of pregnancy-related admission to intensive care units after obstetric hemorrhage.[54]

Recurrence in Subsequent Pregnancies

Recurrence of preeclampsia varies between 7% and 20%. This wide variation in the estimates is based on the quality of the diagnostic criteria used. The risk of recurrent preeclampsia is even higher with two prior preeclamptic pregnancies or with earlier gestational age of preeclampsia onset.[33,47]

Long-Term Cardiovascular Risks

A landmark study published in 1976 demonstrated that women who had eclampsia in any pregnancy after their first had a mortality risk that was two- to fivefold higher over the next 35 years compared with controls.[13] Since that time, several large epidemiologic studies have confirmed that women with preeclampsia in any pregnancy have an increased risk of cardiovascular diseases later in life and related mortality.[48] This risk is higher among women with preeclampsia that was recurrent, that necessitated a preterm delivery, or that was associated with fetal growth restriction. Hypertension, dyslipidemia, insulin resistance, endothelial dysfunction, and vascular impairment have all been observed months to years after the preeclamptic pregnancy, further supporting the link between preeclampsia and cardiovascular disease.[48] In 2011, the American Heart Association added preeclampsia to its list of recognized risk factors for cardiovascular disease. Based on these data, women with a history of preeclampsia should have ongoing, close surveillance to prevent or detect cardiovascular disease. Further investigation is needed to resolve whether common risk factors lead to the development of both preeclampsia and subsequent cardiovascular disease or whether preeclampsia itself contributes to this future risk.

Fetal and Neonatal Effects

Fetal and neonatal outcomes related to hypertensive disorders vary widely around the world and are associated with resource availability, presence of neonatal intensive care facilities, and limits of viability as defined by gestational age and birth weight. In developing countries, one-quarter of stillbirths and neonatal deaths are associated with preeclampsia-eclampsia. Infant mortality is three times higher in low-resource settings compared to high-income countries, largely due to the lack of neonatal intensive care facilities.[26]

It is estimated that 12%-25% of fetal growth restriction and small-for-gestational-age (SGA) infants, as well as 15%-20% of all preterm births, are attributable to preeclampsia.[4] These preterm births are generally indicated, because the only known cure for preeclampsia is delivery of the fetus and placenta. The associated complications of prematurity are substantial, including neonatal deaths and serious long-term morbidity. The risk of complications is inversely associated with gestational age at delivery. Extremely premature infants (<25 weeks) have the highest mortality rate, and if they survive, they are at substantial risk for long-term issues. These include neurodevelopmental impairment such as impaired cognitive skills, motor deficits with fine and/or gross motor delay, cerebral palsy, vision problems, hearing loss, and behavioral and psychological problems, as well as recurrent hospitalization and chronic lung problems and other health problems.[35]

Prematurity also impacts adult health and has been associated with increased insulin resistance, hypertension, and cardiovascular disease.[17,39] There is growing evidence suggesting that the in utero environment affects later life health and disease (termed the *Barker hypothesis*) with particular focus on fetal growth restriction and later life cardiovascular disease (see also Chapter 16). A systematic review of 18 studies that included 45,249 individuals demonstrated that cardiovascular risk factors, specifically blood pressure and body mass index (BMI), were increased in children and young adults born to preeclamptic pregnancies.[17] Thus, preeclampsia and related complications may be associated with long-term sequelae in both the mother and infant.

Risk Factors

Risk factors for preeclampsia reflect the heterogeneous nature of the syndrome and can be broadly classified into pregnancy-specific characteristics and maternal pre-existing features (Box 17.1).

Pregnancy-Specific Characteristics

Nulliparity is a strong risk factor, almost tripling the risk of preeclampsia.[22] It is estimated that two-thirds of cases occur in first pregnancies. New paternity also increases the risk of preeclampsia in a subsequent pregnancy. Excess placental volume, as with multifetal gestations and hydatidiform moles, is also associated with the development of

• BOX 17.1 Risk Factors for Preeclampsia

Pregnancy-Specific Factors

- Nulliparity
- Partner-related factors: new paternity, limited sperm exposure (e.g., barrier contraception)
- Multifetal gestation
- Hydatidiform mole

Maternal Pre-Existing Conditions

- Older age
- Higher body mass index
- Pregestational diabetes
- Chronic hypertension
- Renal disease
- Antiphospholipid antibody syndrome
- Connective tissue disorder (e.g., systemic lupus erythematosus)
- Family history of preeclampsia
- Prior preeclampsia
- Lack of smoking

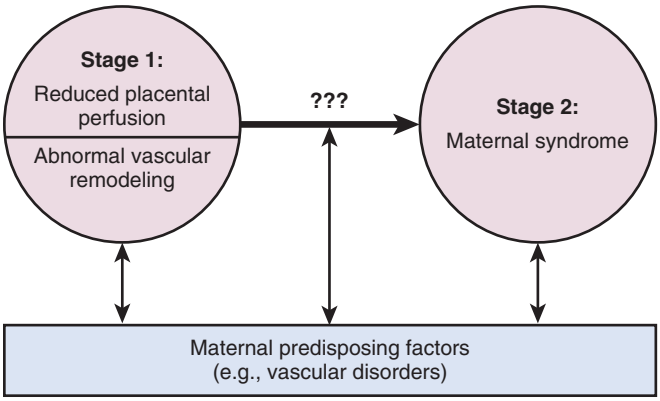
preeclampsia.[18,22] The disease process may occur earlier and have more severe manifestations in these cases. The risk progressively increases with each additional fetus.



Maternal Characteristics

Extremes of childbearing age have been associated with preeclampsia.[74] However, when adjustments for parity are made in the younger age group (because most first pregnancies occur at a younger age), the association between younger age and preeclampsia is lost.[22] Women who were 40 years of age or older had almost twice the risk of developing preeclampsia after controlling for baseline differences such as chronic medical conditions.[22] The association between race and preeclampsia has been confounded by the higher prevalence of chronic hypertension among African-American women, which is often undiagnosed. Whereas some studies demonstrate a higher risk of preeclampsia among African-American women,[29,42] larger prospective studies that controlled for other risk factors and rigorously defined preeclampsia did not find a significant association between preeclampsia and African-American race.[64,65] More severe forms of preeclampsia may be associated with maternal nonwhite race.

A family history of preeclampsia nearly triples the risk of preeclampsia, whereas a personal history of preeclampsia in a previous pregnancy increases the risk of recurrence by sevenfold.[22,33,47] Cardiovascular risk factors such as pre-existing hypertension, diabetes, obesity, and vascular disorders (renal disease, systemic lupus erythematosus, antiphospholipid antibody syndrome) also increase the risk of preeclampsia.[22] This risk correlates with the severity of the underlying disorder. Obesity increases the overall risk of preeclampsia by approximately two- to threefold.[11] The risk of preeclampsia progressively increases with increasing body mass index (BMI), even within the normal range. Importantly, it is not only the late or mild forms that are increased but also early-onset and severe preeclampsia, which are associated with greater perinatal morbidity and mortality.[10] Given the obesity epidemic in the United States and around the world, this is one of the largest attributable and potentially modifiable risk factors for preeclampsia. Paradoxically, cigarette smoking during pregnancy is associated with a reduced risk of preeclampsia.[28]

Pathophysiology

Although research in this area is extensive and ongoing, the precise pathophysiology remains incompletely understood. Preeclampsia has been described as occurring in two stages.[58] The first stage consists of inadequate remodeling of the maternal spiral arteries by the invasive placental trophoblasts, which results in reduced placental perfusion. The second stage describes the maternal systemic vascular dysfunction, which leads to clinical features, including multiorgan involvement (Fig. 17.1). Some women enter pregnancy with vascular disease (e.g., chronic hypertension, diabetes, renal disease, lupus), which may result in poor placental implantation (stage I) and/or a susceptibility to the vascular damage associated with preeclampsia (stage II), thereby increasing the risk of developing preeclampsia.

• **Fig. 17.1** Two-stage concept describing the pathophysiology of preeclampsia.

The placenta plays a critical role in the pathophysiology of preeclampsia. The placenta, but not necessarily the fetus (as with hydatidiform moles), is requisite for the development of preeclampsia. Greater placental volume, as with multifetal gestation, hydatidiform moles, and hydropic placentas, is associated with a higher risk of preeclampsia.[22] Importantly, delivery of the placenta is the cure for preeclampsia. In normal pregnancy, the cytotrophoblast cells of the developing placenta invade the uterine spiral arteries within the decidua and myometrium of the uterus and remodel the small-caliber, high-resistance arteries into large-caliber, low-resistance vessels. Persistence of the uterine artery smooth muscle renders these vessels susceptible to local and circulating vasoconstrictors as well as poor perfusion, which can result in placental ischemia-hypoxia and generation of potentially harmful reactive oxygen species.[69]

The precise factor(s) linking stage I and stage II has been the focus of numerous studies in this field. There is evidence to support the role of angiogenic factors, inflammatory cytokines, circulating placental microparticles, and oxidative stress, to name a few.[69] Preeclampsia has been called the "disease of theories"—and it is likely that this syndrome is heterogeneous with multiple different pathways, either individually or in combination, that converge to result in vascular dysfunction and clinical features of the syndrome. Classifying preeclampsia into subtypes may facilitate research and a better understanding of pathophysiology. For example, experts have proposed a "placental preeclampsia" in which placental dysfunction and fetal growth restriction are major features.[68]

Angiogenic Factors

Pro-angiogenic factors, placental growth factor (PlGF), and vascular endothelial growth factor (VEGF), as well as the anti-angiogenic factors, soluble VEGF receptor 1 (soluble fms-like tyrosine kinase-1 [sFlt-1]), and soluble endoglin (coreceptor for transforming growth factor [TGF-β]) have

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

gained increasing attention for their role in the pathogenesis of preeclampsia. It is proposed that circulating sFlt-1 from the placenta binds and inactivates VEGF and PlGF, thus competing with receptors located on the endothelium and resulting in impaired vascular function.[46] Soluble endoglin inhibits TGF-β1 signaling in endothelial cells, disrupting nitric oxide–induced vasodilation. Compared with normotensive women, circulating sFlt-1 and soluble endoglin levels are higher and PlGF levels lower in preeclampsia, even weeks prior to the recognition of the clinical condition, and also correlate with disease severity.[44,45] Soluble Flt-1 administered to pregnant rats induces preeclampsia-like features (hypertension, proteinuria, glomerular endotheliosis).[46] Soluble endoglin potentiates these effects in pregnant rats, resulting in features of severe preeclampsia, HELLP syndrome, and fetal growth restriction.[72] Placental ischemia and hypoxia is hypothesized to trigger sFlt-1 release from the placenta.[31]

Immunologic/Inflammatory Factors

Prior exposure to paternal antigens appears to be protective against preeclampsia, whereas less exposure to paternal antigens is associated with a higher risk of preeclampsia, such as with nulliparous women, new paternity, longer interpregnancy interval, barrier contraceptive use, and pregnancies achieved by intracytoplasmic sperm injection.[60] These epidemiologic observations support the role of immunologic factors in stage I of preeclampsia. The immunologic abnormalities observed with preeclampsia have been compared to transplant organ rejection.[49] The only known polymorphic histocompatibility antigens on the fetal trophoblast are HLA-C molecules. Maternal decidual natural killer (NK) cells express killer immunoglobulin receptors (KIRs) that recognize specific HLA-C molecules and interact with the invasive trophoblast cells to regulate placental implantation. The conflict between maternal and paternal genes observed in preeclampsia may lead to increased NK activity and abnormal placental implantation. Some HLA-C and KIR isoforms predispose to preeclampsia.[49] Placental bed biopsies from women with preeclampsia also demonstrate increased numbers of dendritic cells (antigen-presenting cells) in the decidua, which may also affect placental implantation and/or maternal immunologic responses.[56] Compared with the nonpregnant state, normal pregnancy is an inflammatory state; this is even more exaggerated in women with preeclampsia, which likely contributes to stage II and generalized endothelial dysfunction. Circulating inflammatory markers, C-reactive protein, tumor necrosis factor-α, and interleukin-6 are all elevated in preeclampsia compared with uncomplicated, normotensive pregnancy.[56] Placenta hypoxia and reperfusion can result in oxidative stress, with subsequent apoptosis and necrosis of the syncytiotrophoblast with release of these materials into the maternal circulation, which can stimulate inflammation.[56] These circulating placental microparticles and trophoblastic debris have been shown to be bioactive and even contain antiangiogenic factors.[55,56]

Renin Angiotensin System

Normal pregnancy is characterized by vasodilation and resistance to vasopressors. Despite the decrease in systemic vascular resistance, levels of renin, angiotensin, and aldosterone are increased with normal pregnancy. With preeclampsia, there is increased sensitivity to angiotensin II and other vasoconstrictors. Circulating autoantibodies to the angiotensin II type 1 receptor have been demonstrated in women with preeclampsia.[19] This autoantibody is an agonistic antibody similar to angiotensin II that is able to activate the receptor and result in hypertension and vascular injury, which are characteristic of preeclampsia. In a rodent model, injection of these antibodies results in some of the clinical features of preeclampsia, further supporting the pathogenic nature of these autoantibodies.[19]

Genetics

Epidemiologic associations of preeclampsia with positive family history, preeclampsia in a prior pregnancy (see "Risk Factors"), or a male partner who has fathered a preeclamptic pregnancy indicate a genetic basis for preeclampsia. A number of candidate genes have been studied with positive findings in small cohorts, but subsequent larger studies have not confirmed their association with preeclampsia. Genome-wide association studies have been performed and have shown modest associations, but the findings are not consistent across different populations.[75] Genetic studies are likely confounded by the heterogeneity of preeclampsia, inconsistent definitions, and population variation. Recent investigations are turning toward evaluating environmental influences such as hypoxia and epigenetic modifications that may be associated with preeclampsia.[75]

Endothelial Dysfunction

The endothelium, an important modulator of vascular tone, is dysfunctional in preeclampsia and contributes to the increased peripheral vascular resistance.[16] Endothelial dysfunction is central to the systemic maternal manifestations of preeclampsia, including increased blood pressure, increased response to vasoconstrictors, vasospasm/ischemia, activation of the coagulation cascade, proteinuria, and reduced perfusion leading to multiorgan damage, including renal, hepatic, cerebral, and placental injury.[16] In vivo assessments in women have demonstrated reduced vasodilatory responses during and even prior to the onset of clinically evident preeclampsia. Ex vivo investigations using subcutaneous resistance arteries have demonstrated reduced to absent flow-mediated and endothelium-dependent vasodilatory responses in women with preeclampsia relative to normal pregnancy. Markers of endothelial dysfunction such as cellular fibronectin, von Willebrand factor, and thrombomodulin are also increased in blood or urine of women with preeclampsia, with some of these changes manifested weeks before the clinically recognized syndrome. In addition, there appears to be increased production of vasoconstrictors such as endothelin-1 and thromboxane, as

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

well as a decrease in vasodilators such as prostacyclin and nitric oxide.[16] Markers of oxidative stress are also increased in preeclampsia; the imbalance of potentially damaging reactive oxygen species and the ability to scavenge these harmful products are postulated to be a point of convergence leading to endothelial damage. Immunologic, inflammatory, and angiogenic components are also important contributors.

Pathophysiology by Organ System

Cardiovascular

Preeclampsia is characterized by high systemic vascular resistance, which manifests clinically as hypertension. This is in contrast to marked lowering of vascular resistance during normal pregnancy. Preeclampsia does not appear to directly affect the myocardium. However, the heart responds to the hemodynamic changes. In an untreated group of preeclamptic women, the systemic hemodynamics were characterized as a low output–high resistance state.[73] Others have suggested that a high output–low resistance state precedes the clinical onset of preeclampsia, with subsequent crossover to a low output–high resistance state.[12,27] Many of the studies are confounded by the treatments used for preeclampsia, such as antihypertensive medications and intravenous magnesium sulfate.

Renal

Marked renal alterations occur with preeclampsia.[36] Glomerular filtration rate and renal plasma are reduced, on average, by 32% and 24%, respectively, from normal late-pregnancy levels. Handling of proteins and other substances such as uric acid and calcium are altered. Urinary protein excretion is increased owing to the impaired integrity of the glomerular barrier as well as altered tubular handling of filtered proteins. Both size and charge selectivity of the glomerular barrier are affected. Glomerular endotheliosis is considered a renal pathologic lesion characteristic of preeclampsia. Features include endothelial swelling, loss of fenestrations, and occlusion of the capillary lumina. This is believed to resolve after delivery.

Brain

Headaches, visual symptoms, and seizures are thought to be related to pathophysiologic changes in the brain.[14] Histopathologic findings based on autopsy specimens include hemorrhage, petechiae, cerebral edema, vasculopathy, ischemic brain damage, microinfarcts, and fibrinoid necrosis. Retinal arteriolar narrowing has been noted on funduscopic examination. Cerebral edema and ischemia with or without hemorrhagic changes in the posterior hemispheres are often observed on computed tomography and magnetic resonance imaging.[14] These findings are posited to be related to vasospasm associated with severe hypertension or the loss of cerebrovascular autoregulation leading to areas of vasoconstriction and forced vasodilation, which has been termed *posterior reversible leukoencephalopathy syndrome*.

Hepatic

Periportal hemorrhage and intraparenchymal hepatic infarction associated with intense vasospasm are the major hepatic histopathologic lesions associated with preeclampsia.[38] Pain in the epigastrium and/or right upper quadrant associated with preeclampsia is thought to be secondary to stretching of the Glisson capsule owing to liver swelling and/or subcapsular hemorrhage.

Placenta

A common finding in the preeclamptic placenta is acute atherosis, which refers to fibrinoid necrosis of the vessel wall and accumulation of lipid-laden macrophages, and a mononuclear perivascular infiltrate.[41] This can also occur in the maternal decidual vessels. The syncytiotrophoblast contains areas of apoptosis and necrosis, whereas the cytotrophoblast cells are increased in number and have higher mitotic activity; these changes are thought to be associated with hypoxia.[37] Chronic underperfusion of the placenta may also lead to small placenta (weight less than the tenth percentile) and areas of ischemia and infarction.

Clinical Presentation of Preeclampsia

The clinical presentation and course of disease progression can be quite variable. In most cases, the diagnosis of preeclampsia with hypertension and proteinuria is made after 34 weeks' gestation. Approximately 10% of preeclamptic women develop early-onset preeclampsia prior to 34 weeks. Approximately 25% of women will present with, or develop features of, severe preeclampsia; however, the degree of hypertension and proteinuria and presence/absence of severe features are highly variable (see Table 17.1).[4] *Importantly, the progression of preeclampsia to severe disease and/or worsening clinical status is unpredictable and potentially rapid within hours to days, highlighting the critical need for close surveillance even if there are no severe features of preeclampsia at the time of presentation.* Preeclampsia may also be first recognized postpartum in 5% of women, usually within the first 48 hours after delivery.[2]

Initial Evaluation

A high degree of clinical suspicion for preeclampsia is warranted, given its unpredictable nature and serious consequences. Frequent visits in the third trimester, a routine part of prenatal care, are intended to facilitate timely detection and avoid adverse pregnancy outcomes. Each visit should include assessment of blood pressure and urine dipstick for proteinuria, as well as a careful history regarding symptoms and signs of maternal end-organ involvement (see Table 17.1). Women should be questioned about neurologic symptoms (headache, visual changes, scotomata), epigastric or right upper quadrant abdominal pain, nausea and/or vomiting, difficulty breathing, decreased urine output, decrease in fetal movement, and vaginal bleeding. Initial

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

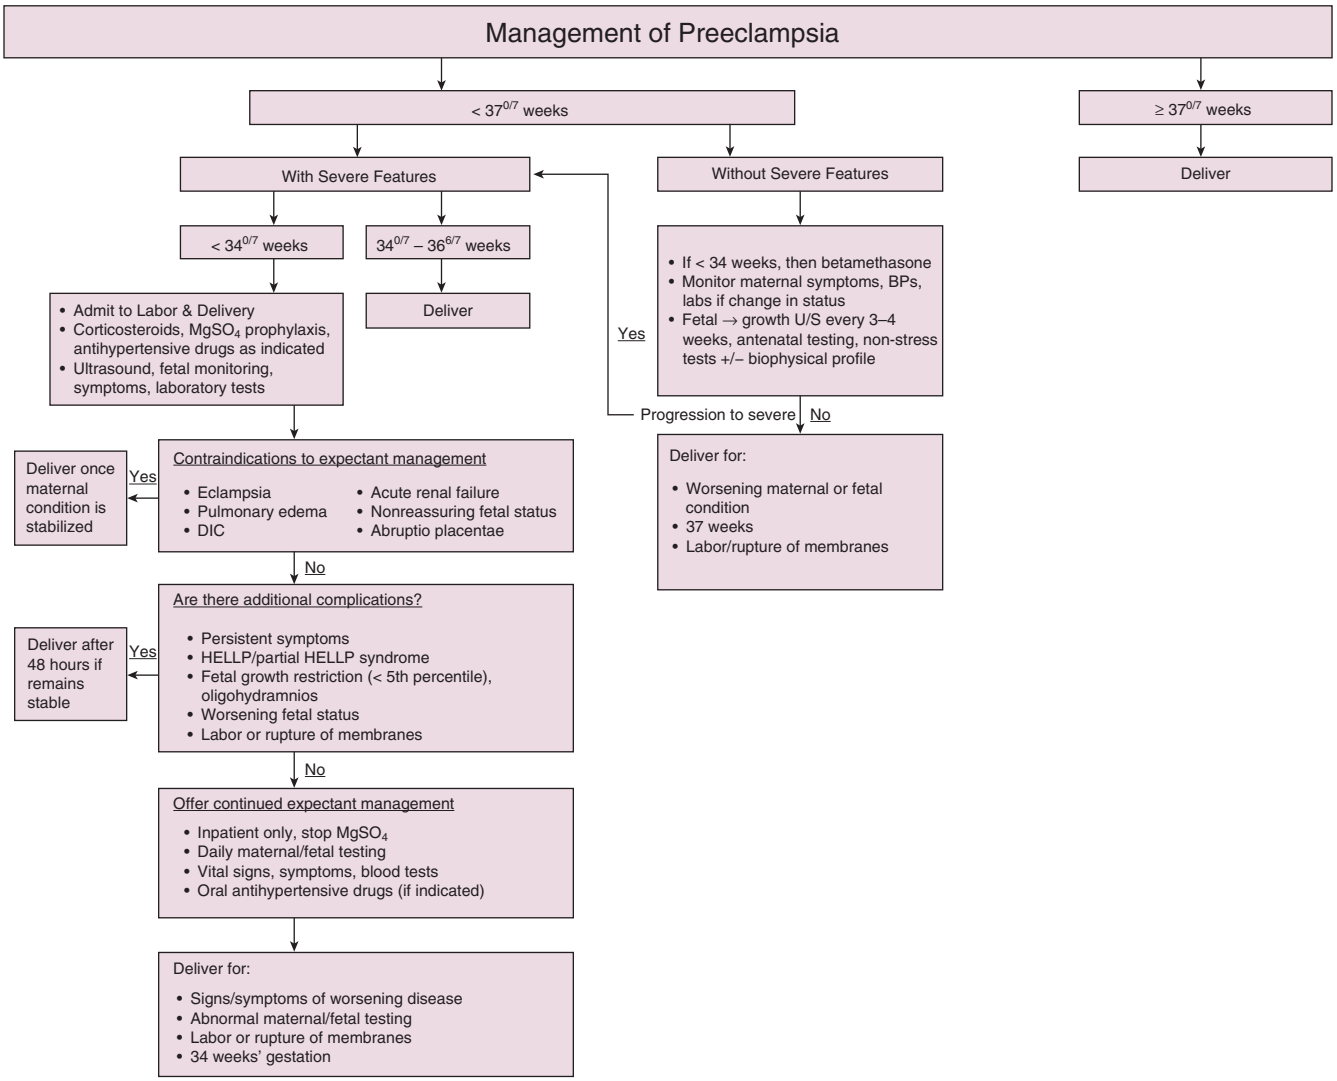
evaluation of preeclampsia should generally occur in a triage or hospital setting. Serial blood pressures should be measured to confirm sustained elevations. Physical examination should be performed with attention to signs of preeclampsia and associated complications. Proteinuria should be assessed by urine dipstick, protein-to-creatinine ratio, or a 24-hour urine collection. Although the urine protein-to-creatinine ratio has the advantage of being convenient, rapid, and not subject to the errors of 24-hour urine collection, the 24-hour urine total protein excretion remains the standard for preeclampsia diagnosis. Laboratory evaluation should include a complete blood count with platelets, liver transaminases, and serum creatinine to evaluate for possible end-organ involvement. Uric acid may be useful in identifying a subgroup of hypertensive women who are at increased risk for premature delivery and infants small for gestational age.[59] Peripheral blood smear, lactate dehydrogenase, haptoglobin, and/or indirect bilirubin may be ordered if there is concern for hemolysis and possible HELLP syndrome. Fetal well-being should be assessed with ultrasound to evaluate estimated fetal weight, growth, and amniotic fluid index. Nonstress testing and/or fetal biophysical profiles should also be performed. In the setting of fetal growth restriction, umbilical artery Doppler measurement is a useful tool to assess resistance within the placental and umbilical vasculature. Use of these assessments has been shown to reduce perinatal death as well as unnecessary delivery of the preterm growth-restricted fetuses.[9]

Principles of Management

Definitive treatment for preeclampsia is delivery. Delivery is always beneficial for the mother to prevent disease progression and organ damage; however, preterm delivery may be hazardous to the fetus/neonate. Thus, the decision to deliver is based on gestational age, severity of the disease, and maternal and fetal well-being. Other management considerations include administration of antenatal glucocorticoids, magnesium sulfate for seizure prophylaxis, antihypertensive therapy, and fetal surveillance (Fig. 17.2).

Administration of Corticosteroids

Women with preeclampsia diagnosed prior to 37 weeks' gestation are at risk of preterm delivery. Antenatal glucocorticoids have been demonstrated to decrease the risk of neonatal respiratory distress syndrome, intraventricular hemorrhage, and necrotizing enterocolitis, as well as mortality. As per the National Institutes of Health consensus guidelines, antenatal glucocorticoids should be administered to women at less than 34 weeks' gestation who are at risk for preterm delivery to decrease neonatal morbidity and mortality.[5] The dosing regimen consists of two doses of betamethasone 12 mg intramuscular injection 24 hours apart. Intravenous dexamethasone may be considered if there is concern for a coagulopathy and complications associated with a deep muscular injection. More recent data indicate potential benefit of betamethasone administration between 34 0/7 weeks and 36 6/7 weeks if late preterm delivery is anticipated.[32]



Seizure Prophylaxis

Eclampsia is associated with maternal mortality in the range of 0.3%-1% and is associated with serious morbidity, including renal failure, pulmonary edema, aspiration pneumonia, stroke, and cardiopulmonary arrest.[4] Most women recover without permanent neurologic injury; however, there is evidence of long-term maternal sequelae such as persistence of white matter lesions and impaired cognitive function.[7,8] Most eclamptic seizures occur during the intrapartum and postpartum period (within 48 hours of delivery) or with the initial presentation of severe preeclampsia. A Cochrane systematic review included six trials with 11,444 women comparing magnesium sulfate to placebo for seizure prophylaxis with a risk reduction of 0.41 (95% confidence interval 0.29-0.58).[23] Magnesium sulfate is also superior to a number of other agents (phenytoin, diazepam, lytic cocktail) for the prevention of seizures in women with preeclampsia. Intrapartum and postpartum magnesium sulfate is recommended for women with severe preeclampsia. There remains disagreement about its routine use in mild preeclampsia. Signs and symptoms that are traditionally considered premonitory to eclampsia (e.g., neurologic symptoms, clonus, right upper quadrant pain) as well as worsening clinical course should be included in the decision to initiate magnesium sulfate during labor and delivery. The usual dose is a 4-gram intravenous loading dose followed by constant infusion of 1-2 g/hour. The infusion dose may need to be reduced in the setting of renal failure. Duration of therapy is generally during labor and then 24-48 hours postpartum. Patients should be monitored closely for evidence of toxicity, including loss of reflexes and respiratory depression. Magnesium crosses the placenta with cord blood concentrations approximating maternal serum levels. Neonatology presence should be considered if there are concerns for neonatal effects, including respiratory depression related to magnesium toxicity. Results from numerous large studies indicate that magnesium sulfate given before an anticipated early preterm birth has neuroprotective effects and reduces the risk of cerebral palsy in surviving infants.[21]

Antihypertensive Therapy

Antihypertensive medications are not routinely given to women with preeclampsia. The primary reason for using antihypertensive drugs is for the treatment of severe maternal blood pressure elevations with the goal of reducing cerebrovascular accidents such as strokes and intracranial hemorrhage as well as acute coronary events. This is in contrast to the principles of blood pressure control in nonpregnant adults whereby tight control is advocated to decrease the risk of end-organ damage. There is no evidence that lowering blood pressure reduces fetal morbidity or prevents maternal seizures. Acute therapy is reserved for systolic blood pressures of greater than 160 mm Hg and/

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• **Fig. 17.2** Management scheme for preeclampsia.

or diastolic blood pressures of greater than 105 mm Hg.[1,24] Treatment should occur in a hospital setting. Rapid and marked lowering of blood pressure may compromise uterine perfusion and lead to iatrogenic fetal distress. Intravenous labetalol and hydralazine are considered first-line agents for acute lowering of blood pressure in pregnant women.[24] Table 17.2 summarizes the mechanism of action, dosing, and frequency of commonly used medications for the acute lowering of blood pressure. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are contraindicated in pregnancy. These medications have teratogenic potential and are associated with central nervous system and cardiac anomalies with first-trimester use.[15,51] Second- and third-trimester use is associated with fetal renal failure and oligohydramnios, which can lead to pulmonary hypoplasia. Fetal skull ossification defects have also been reported.

Ongoing Maternal and Fetal Surveillance

Timing of Delivery

Delivery is recommended for preeclampsia diagnosed at term (≥37 0/7 weeks). Neonatal outcomes are favorable, and continuation of pregnancy incurs risks to both the mother and fetus.[67] Preeclampsia without severe features diagnosed prior to term (<37 0/7 weeks) should be managed expectantly, with delivery if there is progression to severe disease or nonreassuring maternal or fetal status. Preeclampsia is generally managed as an inpatient, at least initially, to ensure that the disease is not rapidly progressing. Outpatient management may be considered in a subset of preeclamptic women without severe features who have remained stable, are able to comply with frequent maternal and fetal monitoring, and have ready access to medical facilities (e.g., distance to the hospital, transportation). No major differences in clinical outcomes were observed with outpatient management with monitoring in antenatal day facilities compared to hospital admission.[20] Recommendations include close monitoring of symptoms, home blood pressures, strict fetal kick counts, at least twice weekly nonstress tests and/or biophysical profile, and monthly growth ultrasounds, as well as weekly laboratory evaluation and physician office visits. As previously noted, umbilical artery Doppler velocimetry is useful in the setting of fetal growth

TABLE 17.2 Drugs for the Acute Management of Hypertension†

Drug	Mechanism of Action	Dose	Onset of Action	Comments†
Labetalol	α- and β-Adrenergic antagonist	10-20 mg IV, then 20-80 mg every 20-30 minutes to a maximum dose of 300 mg OR continuous infusion 1-2 mg/min IV*	5-10 min	Considered a first-line agent. Less tachycardia and fewer side effects. Avoid in patients with asthma or congestive heart failure.
Hydralazine	Arteriolar vasodilator, smooth muscle relaxant	5 mg IV or IM, then 5-10 mg IV every 20-40 minutes OR continuous infusion 0.5-10 mg/hour	10-20 min	Higher or frequent dosing associated with maternal hypotension, headaches and fetal distress—may be more common than other agents.
Nifedipine	Calcium channel blocker	10-20 mg orally, repeat in 30 minutes if needed, then 10-20 mg every 2-6 hours	10-20 min	May observe reflex tachycardia, headaches.
Sodium nitroprusside		0.25-20 mcg/kg/min IV*	Within seconds	Relatively contraindicated and agent of last resort; longer use associated with cyanide toxicity.

*Continuous IV infusions should be used only in an ICU setting.
†All agents are associated with headache, flushing, nausea, and tachycardia (likely due to hypotension and reflex sympathetic activation); these side effects are less with labetalol.

restriction. This management strategy should be modified if there is any change in maternal and/or fetal status. In addition to the above, inpatient surveillance includes frequent monitoring of maternal symptoms and blood pressure as well as daily fetal assessment.

For women with preeclampsia with severe features diagnosed at or after 34 0/7 weeks, delivery is recommended. With severe preeclampsia prior to 34 0/7 weeks, timing of delivery is based on maternal and fetal status as well as the risk-benefit balance of expectant management. Options include: (1) immediate delivery after maternal stabilization, (2) short-term pregnancy prolongation to achieve steroid benefit for the fetus, and (3) pregnancy prolongation for greater than 48 hours (expectant management) with the goal of improving gestational age and neonatal outcomes. Because of the significant maternal and fetal/neonatal morbidity, immediate delivery after maternal stabilization is recommended if any of the following are present: uncontrollable severe hypertension, eclampsia, pulmonary edema, disseminated intravascular coagulation, new and/or worsening renal dysfunction, placental abruption, or nonreassuring fetal status. Unfortunately, many studies do not clearly differentiate between immediate delivery and an attempt to achieve some degree of steroid benefit.[62,63] Women with neurologic or epigastric pain symptoms, HELLP syndrome or partial HELLP syndrome, thrombocytopenia, elevated liver transaminases, or fetal growth restriction are potential candidates for short-term (48-hour) pregnancy prolongation to achieve steroid benefit with close inpatient monitoring and with readily available tertiary obstetric, intensive care unit, and neonatal and anesthesia services.[62,63] Delivery is recommended for worsening of maternal or fetal status. Multidisciplinary care is essential with close communication between maternal-fetal medicine, neonatology, critical care medicine, and obstetric anesthesiology teams.

In two randomized trials comparing expectant management of severe preeclampsia at less than 34 0/7 weeks of gestation with planned delivery at 48 hours after steroid administration, expectant management was associated with significant prolongation of pregnancy, reduction in neonatal respiratory distress syndrome, fewer days in the neonatal intensive care unit, and higher birth weight with reasonable maternal safety in the expectantly managed group.[50,63,66] Women with severe preeclampsia were candidates for expectant management if blood pressures were controlled, there was no evidence of severe end-organ involvement, and fetal status was reassuring without growth restriction. Based on these and other supporting data from observational studies, expectant management of severe preeclampsia is acceptable in a well-selected population with close inpatient management in a tertiary center until 34 weeks or worsening disease, whichever comes first.

Mode of Delivery

Vaginal delivery is generally recommended for women with preeclampsia; cesarean section is reserved for the usual obstetric indications. The rate of vaginal delivery decreases to approximately 33% at less than 28-32 weeks owing to the higher rate of nonreassuring fetal tracing and failure of

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

induction, which may influence counseling on mode of delivery at these early gestational ages.[3]

Other Hypertensive Disorders of Pregnancy

Gestational Hypertension

The risk of gestational hypertension progressing to preeclampsia is estimated to be 15%-25%. Pregnancy outcomes with nonsevere gestational hypertension are generally favorable. Initial evaluation is similar to that of women with preeclampsia. Close monitoring for worsening blood pressure, progression to preeclampsia, and fetal status is recommended. Severe gestational hypertension is associated with higher rates of preterm delivery, small for gestational age infants, and placental abruption comparable to rates reported with severe preeclampsia.[4] Therefore, management approach is similar to that described for severe preeclampsia. Timing of delivery is recommended between 37 and 39 weeks.[4,43,67] In most cases, blood pressures normalize within the first few weeks postpartum. Approximately 15% of women with gestational hypertension will have persistent hypertension 12 weeks postdelivery, which represents either previously undiagnosed or a new diagnosis of chronic hypertension.

HELLP Syndrome

HELLP syndrome develops in approximately 10%-20% of women with severe preeclampsia-eclampsia. Although HELLP is considered a variant of preeclampsia, as many as 15%-20% of women with HELLP do not have antecedent hypertension or proteinuria.[62] This syndrome is often characterized by sudden and progressive deterioration in maternal and fetal status as well as increased rates of morbidity and mortality. Clinical presentation is variable, with common symptoms including abdominal pain in the epigastric area and/or right upper quadrant. In addition to symptoms of preeclampsia, nausea, vomiting, and malaise may be presenting complaints. Diagnosis is based on symptoms and laboratory abnormalities indicating hemolysis, elevated liver transaminases, and low platelets. HELLP syndrome may be associated with serious hepatic manifestations including liver infarction, hemorrhage, and rupture. Prompt delivery is recommended. Delaying delivery to achieve steroid benefit may be reasonable in select cases with close monitoring in a tertiary setting with experienced personnel.[4] Several observational and retrospective studies have suggested that corticosteroid use for HELLP syndrome improves maternal morbidity. A recent Cochrane meta-analysis demonstrated improved maternal platelet count but no evidence of improvement in maternal mortality or severe morbidities.[4] Additional well-conducted studies are needed to clarify whether steroids or other therapies improve maternal morbidity with HELLP syndrome.

Differentiating HELLP syndrome from acute fatty liver of pregnancy, thrombotic thrombocytopenic purpura (TTP), or hemolytic uremic syndrome (HUS) may be challenging.[36] Acute fatty liver is characterized by progressive hepatic failure in pregnancy and is associated with nausea, vomiting, malaise, abdominal pain, jaundice, and (less commonly) mental status changes. Laboratory abnormalities include elevated liver transaminase enzymes, hyperbilirubinemia, elevated ammonia levels, clotting abnormalities, and hypoglycemia. Treatment is delivery and supportive care. Thrombocytopenic purpura is associated with a pentad of findings, including thrombocytopenia, hemolytic anemia, fever, neurologic abnormalities, and renal dysfunction. There are similar features with HUS except that renal involvement is more profound, and neurologic involvement is less frequent. As previously mentioned, it is often difficult to differentiate these conditions from the preeclampsia spectrum of disorders (Table 17.3). Proper diagnosis is important because the treatments are different. Delivery is the primary treatment for preeclampsia, HELLP, and acute fatty liver, whereas plasmapheresis is the mainstay of therapy with TTP/HUS. Often the diagnosis can only be made by following the disease progression after delivery. Supportive therapy and a multidisciplinary medical team are critical in the acute phase, particularly until the diagnosis is clear.

Chronic Hypertension

Chronic hypertension complicates approximately 0.5%-5% of all pregnancies. The prevalence of chronic hypertension increases with age and is higher in African-American women. Perinatal complications are increased with chronic hypertension, primarily related to superimposed preeclampsia, fetal growth restriction, and perinatal death. In a large cohort study the perinatal death frequency was 29/1000, and fetal growth restriction was 10.5% among uncomplicated chronic hypertensive women, which was significantly higher than among normotensive pregnant women.[57] Superimposed preeclampsia has a prevalence of 20%-25% in women with mild chronic hypertension but can be as high as 50% in women with severe pre-pregnancy hypertension.[4] Rey and colleagues also reported a relative risk for perinatal death of 3.6 in women with superimposed preeclampsia compared with uncomplicated chronic hypertensive controls. The incidence of fetal growth restriction was 35% among superimposed preeclamptic women.[57]

Clinical care for pregnant women with chronic hypertension is focused on blood pressure management, close monitoring for superimposed preeclampsia, and careful fetal surveillance. In contrast to the guidelines for tight blood pressure control and associated benefits for nonpregnant hypertensive individuals, the guidelines for pregnant women with chronic hypertension are less clear. As discussed previously, the goal of antihypertensive therapy during pregnancy is to prevent maternal cerebrovascular and coronary events associated with severe blood pressure elevation. The controversy surrounding "tight control"

TABLE 17.3 Other Conditions That Can Mimic Preeclampsia and HELLP Syndrome*

	Preeclampsia/ HELLP	Acute Fatty Liver of Pregnancy	Thrombotic Thrombocytopenic Purpura	Hemolytic Uremic Syndrome
Onset	Usually 3rd trimester	Close to term	Median 23 weeks	Often postpartum
Primary/unique clinical manifestation	Hypertension and proteinuria	Nausea, vomiting, malaise	Neurologic symptoms	Renal involvement
Purpura	Absent	Absent	Present	Absent
Fever	Absent	Absent	Present	Absent
Hemolysis	Mild	Mild	Severe	Severe
Coagulation studies	Variable	Prolonged abnormal	Normal	Normal
Hypoglycemia	Absent	Present	Absent	Absent
Other possible lab abnormalities	Absent	Absent	ADAMTS 13 deficiency and increase in von Willebrand factor multimers	May be complement-mediated or associated with Shiga toxin
Primary treatment	Delivery	Delivery	Plasmapheresis	Plasmapheresis

*Precise diagnosis can often be made only after delivery. Preeclampsia, HELLP syndrome, and acute fatty liver of pregnancy resolve soon after delivery.

versus "less tight control" during pregnancy in this subgroup is not yet resolved. Issues include: (1) the concern for higher fetal exposure to antihypertensive drugs that have not been studied well in terms of long-term growth and development; (2) the theoretical concern that marked lowering of blood pressure could chronically reduce uterine blood flow resulting in reduced delivery of oxygen and nutrients to the fetoplacental unit, which may lead to fetal compromise; and (3) the lack of evidence to support the lowering of blood pressure to prevent superimposed preeclampsia.[4] Given these concerns, the focus in pregnancy has been on short-term outcomes and avoiding fetal harm rather than long-term prevention of cardiovascular risk and end-organ damage. Oral medication therapy is generally initiated when systolic pressures exceed 150 mm Hg and diastolic pressures exceed 95-100 mm Hg.[4] Exceptions include pre-existing renal disease or other evidence of end-organ compromise that may benefit from tighter blood pressure control, such as retinopathy and cardiac disease. Additional research is needed to determine the optimal level of blood pressure control in the chronic hypertensive woman during pregnancy.

Frequent outpatient visits and home blood pressure monitoring are helpful in detecting progressive blood pressure elevations, which may be the first sign of superimposed preeclampsia. Regular assessment of urinary protein excretion and educating the patient regarding symptoms of preeclampsia are helpful in early diagnosis of superimposed preeclampsia (see previous discussion on clinical management of preeclampsia). Baseline urine protein excretion, renal function, and laboratory testing obtained in early pregnancy can be helpful for comparison. Serial growth ultrasounds, approximately every 3-4 weeks, in the third trimester are recommended with nonstress tests and/or biophysical profiles after 32 weeks' gestation, particularly if there is any evidence of fetal growth restriction. Given the overall increased perinatal morbidity, delivery is recommended at 39 weeks or sooner if indicated.

Pharmacologic therapy is guided by safety and efficacy. Medications used for the treatment of chronic hypertension are outlined in Table 17.4. Oral labetalol, nifedipine, and methyldopa are most commonly used. These medications are considered safe in pregnancy and with breastfeeding.[4]

Superimposed Preeclampsia

Distinguishing superimposed preeclampsia from benign and expected third-trimester increases in blood pressure and proteinuria in women with underlying chronic hypertension can be quite challenging (see Table 17.1). Given the substantial risk of adverse pregnancy outcomes with superimposed preeclampsia, high clinical suspicion and overdiagnosis of preeclampsia may be preferable, with the goal of increasing vigilance and preventing catastrophic maternal and fetal outcomes. End-organ involvement such as thrombocytopenia, elevated liver transaminases, or a rapid decline of renal function are also diagnostic of superimposed preeclampsia. Initial evaluation should occur in a hospital setting to confirm the diagnosis, evaluate maternal and fetal status, and monitor for progressive worsening of the disease.

TABLE 17.4 Oral Antihypertensive Drugs Used for the Management of Chronic Hypertension

Drug (FDA Category)	Mechanism of Action	Dose	Maximum Dose	Comments
Labetalol (C)	α- and β-Adrenergic antagonist	200-2400 mg/day orally in 2-3 divided doses	2400 mg/day	Well-tolerated. Potential bronchoconstrictive effects.
Nifedipine (C)	Calcium channel blocker	30-120 mg/day orally of a slow-release preparation	120 mg/day	Do not use sublingual form. Side effects include headache, flushing, tachycardia; once a day dosing may improve compliance.
Methyldopa (B)	Centrally acting α2-receptor agonist	0.5-3 g/day orally in 2-3 divided doses	3 g/day	Childhood safety data up to 7 years. May not be as effective in control of severe hypertension. Side effect profile includes lethargy.
Hydrochlorothiazide (C)	Thiazide diuretic	12.5-50 mg/day orally	50 mg/day	Not used as a primary agent in pregnancy and considered an adjunctive agent; theoretical concerns of reduced intravascular volume and decreased uterine blood flow in pregnancy; electrolytes should be monitored.
Hydralazine (C)	Vasodilation, smooth muscle relaxant	50-300 mg per day orally in 2-4 divided doses	300 mg/day	Not used as a primary agent in pregnancy and considered an adjunctive agent; may be used in combination with a sympatholytic agent (e.g., methyldopa or labetalol) to prevent tachycardia.
Angiotensin-converting enzyme inhibitors/ angiotensin receptor blockers		Associated with anomalies		CONTRAINDICATED IN PREGNANCY AND PRECONCEPTION PERIOD

Principles of management are generally extrapolated from preeclampsia, including administration of antenatal glucocorticoids if less than 37 weeks' gestation, antihypertensive therapy for acute lowering of severely elevated blood pressures, and magnesium sulfate for seizure prophylaxis. Delivery is recommended if there is any evidence of end-organ involvement or concern for fetal well-being. In the absence of severe features and with reassuring fetal status, expectant management with ongoing close maternal and fetal surveillance is reasonable. Optimal timing of delivery between 34 and 37 weeks with superimposed preeclampsia without any evidence of severe features or worsening disease is unclear.

Prediction

The utility of any predictive test depends on the overall prevalence of the disease. Because the incidence of preeclampsia in the general obstetric population is low (3%-8%), screening tests with a positive test result require high likelihood ratios to predict the probability of disease in an individual patient. Likewise, tests with a negative result would require low likelihood ratios to confidently exclude the disorder. Importantly, for any predictive test for preeclampsia to be clinically useful, there needs to be evidence that interventions (e.g., instituting preventive care, specific treatments, more intensive surveillance) improve maternal and/or fetal outcomes.[4] As of 2017, there is no single predictive test for preeclampsia that is recommended for general obstetric use.

Using clinical risk factors to predict preeclampsia during early pregnancy, the detection rate was 37% for early-onset preeclampsia and 29% for late-onset preeclampsia, with a false positive rate of 5%.[52] Many different biomarkers and combinations of biomarkers have been proposed for the prediction of preeclampsia, including uterine artery Doppler, angiogenic factors, placental protein-13, and uric acid, to name a few.[4] When placental growth factor was combined with uterine artery pulsatility index, mean arterial pressure, pregnancy-associated plasma protein-A, BMI, parity, and previous preeclampsia, Poon and colleagues demonstrated a 93% detection rate for early-onset preeclampsia with a false positive rate of 5%.[53] While these biomarkers are promising, future studies are needed to validate these results in other populations and demonstrate clinical utility of preeclampsia prediction in improving maternal and fetal outcomes.

Prevention

Numerous strategies have been tested for the prevention of preeclampsia, including protein or salt restriction, zinc, magnesium, fish oil, diuretics, antihypertensive medications, heparin, aspirin, calcium, and vitamins. Results from most of these trials showed little to no benefit for preeclampsia prevention.[4] Calcium, aspirin, and antioxidant vitamin therapy have been evaluated more recently. A common theme has been promising results from small, single-center studies followed by larger, appropriately powered, randomized trials that failed to show a significant benefit in preventing preeclampsia or other adverse pregnancy outcomes.

Aspirin, an antiplatelet agent with anti-inflammatory properties, has been tested extensively for the prevention of preeclampsia in both low- and high-risk women. Initial studies indicated a substantial benefit of aspirin therapy; however, subsequent large, randomized trials of high-risk and low-risk women failed to demonstrate a statistically significant benefit. A systematic review of aspirin therapy to prevent preeclampsia in high-risk women demonstrated a modest reduction of preeclampsia, perinatal death, and preterm birth.[25] A subsequent meta-analysis using individual patient data from 32,217 women in 31 randomized trials of antiplatelet therapy for the primary prevention of preeclampsia demonstrated a lower risk of preeclampsia (RR 0.90, 95% CI 0.84-0.97), delivery before 34 weeks (RR 0.90, 95% CI 0.83-0.98), and overall serious adverse pregnancy outcome (0.90, 95% CI 0.85-0.96).[6] No single identifiable subgroup preferentially benefitted from this prophylaxis. Importantly, there were no substantial risks of aspirin therapy. Although there is no consensus, low-dose aspirin may be considered in women at high risk for developing preeclampsia.

Oxidative stress has been posited as a pathogenic factor in preeclampsia; thus, antioxidant vitamins have been proposed for the primary prevention of preeclampsia. Despite initial, promising results from a small study in high-risk women, large, randomized, placebo-controlled trials of vitamins C and E did not reduce the risk of preeclampsia or improve maternal or fetal outcomes in various low- and high-risk populations. A Cochrane systematic review of vitamins C and E for the prevention of preeclampsia that included over 20,000 women enrolled in 15 randomized clinical trials found no benefit (relative risk 0.94, 95% CI 0.82-1.07).[61] Therefore, antioxidant therapies are not currently recommended for preeclampsia prevention.

Calcium supplementation for the prevention of preeclampsia has also been studied extensively.[4] In a multicenter, randomized, placebo-controlled trial of healthy, nulliparous women conducted in the United States, calcium supplementation of 2 g per day did not reduce the incidence or severity of preeclampsia or delay its onset. However, a Cochrane meta-analysis of 13 trials, which included 15,730 women, demonstrated a significant reduction in preeclampsia risk with calcium supplementation (RR 0.45, 95% CI 0.31-0.65), with the greatest effect among women with low calcium intake at baseline (RR 0.36, 95% CI 0.20-0.65).[34] In aggregate, the evidence suggests a beneficial effect of calcium supplementation of 1.5-2 g per day for preeclampsia prevention in populations with low calcium intake at baseline.

Lifestyle modifications such as activity level have also been considered in the prevention of preeclampsia. Evidence to support bed rest is limited to small studies that have not adequately addressed other important adverse pregnancy outcomes and side effects of bed rest such as venous thromboembolism.[4] Physical activity has been hypothesized to reduce the risk of preeclampsia by improving vascular function as well as promoting placental angiogenesis. Although several small studies have evaluated modest exercise in the prevention of preeclampsia, results are inconclusive, and larger, well-controlled studies are needed to fully evaluate the effect of exercise on adverse pregnancy outcomes.[4]

Further research is warranted to identify pathophysiologic subtypes of preeclampsia that may benefit from targeted preventive therapies.

Key Points

- Hypertensive disorders of pregnancy, including preeclampsia, affect up to 10% of all pregnancies and are associated with substantial maternal and fetal/neonatal morbidity and mortality.
- Appropriate diagnosis and classification are important for management.
- Preeclampsia is a multi-organ syndrome that can rapidly progress within hours to days. Proper recognition of maternal and fetal status with escalation of care may be indicated.
- Key principles of management include anti-hypertensive therapy, magnesium sulfate for seizure prophylaxis, antenatal glucocorticoids for fetal benefit, and appropriate timing of delivery.
- Ideal care for women with hypertensive disorders of pregnancy requires a multidisciplinary team approach often including specialists in maternal-fetal medicine, critical care medicine, obstetric anesthesia, and neonatologists.
- Low-dose aspirin therapy may have modest benefit in preeclampsia prevention in high-risk women.
- To date, there is no single test that accurately predicts preeclampsia.

Pregnancy Complicated by Diabetes Mellitus

ISAAC BLICKSTEIN, SHARON PERLMAN, YENON HAZAN, AND ERIC S. SHINWELL

In the United States, depending on the applied diagnostic criteria, 135,000-200,000 women develop gestational diabetes mellitus (GDM) annually, adding to the number of pregnant women diagnosed with either type 1 or type 2 diabetes.[17] Of greater concern may be the fact that approximately 80% of these mothers will develop type 2 diabetes and metabolic syndrome, both of which are associated with high mortality and morbidity. Furthermore, not only the diabetic mothers are at risk for development of metabolic syndrome but also their neonates (see Chapter 16).

Diabetes mellitus (DM) that results from relative or absolute lack of insulin is encountered during pregnancy in two situations: pregestational (pre-GDM) and gestational diabetes mellitus (GDM). The former refers to women who had diabetes mellitus prior to conception, with the well-known microvascular diabetes-associated complications (renal, retinal, cardiac, and nervous system), and the latter refers to otherwise healthy women who developed glucose intolerance during pregnancy.

These two entities are entirely distinct from both obstetric and neonatal perspectives: Pre-GDM and its associated small vessel injury may affect placental function and fetal growth, while GDM is a transient pregnancy problem that affects the fetus in the opposite way (i.e., macrosomia and its obstetrical consequences—dystocia and increased incidence of operative delivery).

This chapter focuses mainly on GDM and its neonatal consequences.

Gestational Diabetes Mellitus

GDM is defined as glucose intolerance presenting or diagnosed for the first time during pregnancy.[2] GDM complicates approximately 7% of all pregnancies in the United States. Despite the great variations that exist between populations and ethnicities, the prevalence of GDM is increasing in the United States, probably secondary to increasing rates of maternal overweight and overt obesity.

Screening and Diagnosis

Screening and diagnosing GDM have a long history of controversy, related mainly to significant implications on health care costs, the effect on obstetric interventions, and whether diagnosis and treatment of GDM will improve maternal and perinatal outcomes. In 2001, the American College of Obstetricians and Gynecologists (ACOG) recommended that all pregnant women should be screened for GDM, whether by patient history, clinical risk factors, or a glucose challenge test.[2] The latter is comprised of a "two step" method consisting of a 50-g, 1-hour glucose challenge test (GCT) and a 100-g, 3-hour oral glucose tolerance test (OGTT) for a definitive diagnosis. However, in 2003, the US Preventive Services Task Force (USPSTF) and the Cochrane Collaboration found insufficient evidence to recommend for or against screening for GDM, similar to the conclusions reached in 2008; namely, that insufficient evidence exists to balance between the benefits and harms of screening for gestational diabetes.[26] In the same year, the Hyperglycemia and Adverse Pregnancy Outcome (HAPO) Study Cooperative Group published the results of a large, multicenter observational study designed to examine the relationship between maternal hyperglycemia less severe than overt GDM and adverse pregnancy outcome.[14,20] This study clearly demonstrated a relationship between increased maternal blood glucose and birth weight, cord blood C-peptide (a measure for intrauterine fetal hyperinsulinemia), neonatal hypoglycemia, and delivery by cesarean section.

The International Association of Diabetes in Pregnancy Study Group recommended in 2007 a simplified "one step" approach to the screening and diagnosis of GDM with a 75-g, 2-hour glucose tolerance test.[18] Although implementation of these guidelines would presumably double the number of patients diagnosed with GDM, no evidence exists that this will lead to clinically significant improvement in maternal and neonatal outcomes. Regardless of these reservations, universal screening for GDM was adopted by more than 90% of practices.[2]

Abstract

Gestational diabetes mellitus (GDM) is defined as glucose intolerance beginning or diagnosed for the first time during pregnancy. The prevalence of GDM varies according to ethnicity, method of diagnosis, and incidence of overweight and obesity in a specific population. At present, two screening methods are available: the two-step approach (50 g glucose challenge test followed by 100 g oral glucose tolerance test) and the single oral 75 g test. Normoglycemia may be achieved with diet alone (GDMA1) or with insulin therapy (GDMA2).

GDM is mainly implicated in fetal macrosomia hence the risk of difficult birth, brachial plexus injury, and obstetrical interventions. GDM, as opposed to pregestational DM, is not associated with increased risk of malformations. It follows that management is aimed to control fetal growth. In addition, theory suggests that intrauterine exposure of the fetus to the diabetic environment may increase the risk of metabolic syndrome in the offspring. Pregestational DM is a disease state that might affect many target organs before pregnancy. Also, placental insufficiency may be present with consequential fetal growth restriction and potential fetal distress. The approach and management of these two types of diabetes during pregnancy are different.

In the sequential "two step" testing, a 50-g GCT is performed in pregnant women between 24 and 28 weeks' gestation unless a high risk for developing GDM exists (glycosuria, diabetes in first-degree relative, history of glucose intolerance, previous GDM, marked obesity, and previous infant with macrosomia). At-risk women should be screened by the 50-g GCT at their first prenatal visit. Screening cutoff values are 130 mg/dL (7.20 mmol/L; 90% sensitivity) or 140 mg/dL (7.75 mmol/L; 80% sensitivity). Random or fasting glucose measurement is not recommended for screening because of poor specificity.

In women who screen positive, a 100-g, 3-hour OGTT is used to diagnose GDM. Gestational diabetes is diagnosed if two or more plasma glucose measurements are abnormal. The World Health Organization and the American Diabetes Association recommend simultaneous screening and diagnosis using a 75-g OGTT (Table 18.1).

The interested reader will find more information about the controversial diagnosis of GDM elsewhere.[19]

Antenatal Management

Despite uncertainty regarding the clinical value of treating GDM, data strongly suggest that treatment may reduce adverse maternal and neonatal outcomes. The Australian Carbohydrate Intolerance Study in Pregnant Women randomized patients to receive either routine care or treatment for GDM.[7] Primary fetal outcomes included death, shoulder dystocia and its consequences such as bone fracture, and nerve palsy. Primary maternal outcomes were induction of labor and cesarean delivery. Infants of women in the treatment group had significantly fewer perinatal complications (RR 0.33; 95% CI 0.14, 0.75). There were more labor inductions in the treatment group (RR 1.36; 95% CI 1.15, 1.62), but the number of cesarean deliveries was similar in both groups. Further evidence of possible adverse effects associated with even mild maternal hyperglycemia comes from the HAPO trial.[14,18] The results of this trial point to a linear correlation between increasing maternal glucose levels and increasing birth weight, primary cesarean delivery, fetal C-peptide levels, and neonatal hypoglycemia. Most clinicians use glucose targets as defined by the Fifth International Workshop-Conference on Gestational Diabetes Mellitus (Table 18.2).

Diabesity is a relatively new term denoting the combination of diabetes and obesity. In a recent large population based study, Blickstein et al. found that the ill-effect of pregravid obesity is greater than that of GDM.[4] Obesity, with and without GDM, increased the odds of having chronic hypertension, whereas preeclampsia appears to be influenced by obesity only, as were the risk of births at <33 weeks' gestation, of birth weight >4000 g, low 5-minute Apgar scores, and neonatal intensive care unit (NICU) admissions. They concluded that obesity (without diabetes) is more frequently associated with adverse perinatal outcomes than GDM in nonobese mothers. They argued that a campaign to decrease pregravid obesity should have at least the same priority as any campaign to control GDM.

TABLE 18.1 Diagnostic Glucose Values for Gestational Diabetes

Diagnostic Test	Fasting mg/L (mmol/L)	First Hour mg/L (mmol/L)	Second Hour mg/L (mmol/L)	Third Hour mg/L (mmol/L)

Interestingly, this effect of diabesity was not found in twin pregnancies.[25]

Treatment

First-line therapy for women with gestational diabetes (the so-called GDM-A1) is nutritional and lifestyle modification; however, the impact on patient outcome has not been conclusively demonstrated in large randomized controlled trials. Pharmacotherapy is indicated when nutritional control is inadequate (the so-called GDM-A2), especially in patients with elevated fasting glucose levels, since diet is largely ineffective in this metabolic presentation. The ACOG and the American Diabetes Association recommends insulin therapy for women in whom the fasting glucose level exceeds 95 mg/dL, 1-hour postprandial glucose level is greater than 130-140 mg/dL, or 2-hour postprandial glucose level is greater than 120 mg/dL (6.65 mmol/L). Intermediate- and short-acting insulins served as the first-line therapy for GDM for many years; however, long-acting insulin was approved for use during pregnancy with its clear advantages in measures of patient compliance.

A safe and effective oral agent for the treatment of gestational diabetes is highly desired. Research efforts have focused on the effectiveness, safety, and placental metabolism of sulfonylurea glyburide. Despite a large number of studies, the absolute number of patients is relatively small and currently glyburide is classified as FDA class C (i.e., animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks). Nevertheless, glyburide therapy is a viable alternative for women who are unable or unwilling to take insulin, and it is used in many practices as first-line therapy.

Metformin (Glucophage) may be another option for women with GDM. Although metformin clearly crosses the placenta, it is classified as FDA class B (i.e., animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women).

Further research is needed to establish the role of oral hypoglycemic medications in the treatment of GDM either as a first-line therapy or in addition to insulin.

Fetal Surveillance

Gestational diabetes mellitus is associated with increased perinatal morbidity and mortality. In an attempt to reduce the risk of adverse outcome, prenatal surveillance, including assessment of fetal well-being and growth as well as screening for congenital anomalies, is recommended.

Screening for Congenital Anomalies

The time frame for risk of congenital malformations is during organogenesis, which takes place between 5 and 8 weeks of gestation (3-6 weeks after conception). Therefore, prevention of anomalies via improvement of the glycemic profile requires prenatal counseling and adequate compliance during the preconception period, since in the well-controlled population, the anomaly rate is similar to that in the general population. However, in poorly controlled pregestational diabetic mothers, the risk is three to five times higher (4%-11%). Jensen compared adverse pregnancy outcome and glycosylated hemoglobin (HbA1C) levels and found a good correlation between levels of HbA1C and the risk for congenital anomalies[16] (Fig. 18.1).

• **Fig. 18.1** Three-dimensional ultrasound of a 36-week macrosomic fetus of a mother with poorly controlled gestational diabetes mellitus. The characteristic "chubby" face is apparent. (Courtesy of Dr. Y. Hazan.)

It is believed that GDM does not carry an increased risk of congenital anomalies, because the hyperglycemia develops after embryonic organogenesis and the fetus is not exposed to high levels of glucose, ketones, and other metabolites involved in the pathophysiology of malformations in pre-GDM. Nevertheless, women with a history of GDM in previous pregnancies, obesity, or those with a presumable diagnosis of pre-GDM (HbA1C levels greater than 9%, fasting glucose levels greater than 120 mg/dL, GDM diagnosis during the first trimester) may have an increased risk for congenital anomalies and should be offered a detailed sonographic anatomical scan for detection of fetal anatomical malformations.[29] Special attention should be focused on the cardiovascular, neural tube, gastrointestinal, urinary, and skeletal systems (Box 18.1) with the possibility of malformation sequences such as VATER or VACTERL (*v*ertebral defects, *a*nal atresia, *c*ardiac defects, *t*racheo-*e*sophageal fistula, *r*enal anomalies, and *l*imb abnormalities).

Although the detection rate of fetal malformations has its own limitations, the benefits of ultrasonography should be discussed with all patients with GDM, and appropriate multidisciplinary prenatal counseling should be given accordingly to the future parents.

The most common malformations in the fetus of the diabetic mother are cardiac. In addition to developmental

• BOX 18.1 Major Congenital Malformations in Infants of Diabetic Mothers

Cardiac

Septal defect	Ventricular septal defect (VSD), atrial septal defect
Conotruncal anomalies	Transposition of the great arteries, truncus arteriosus, single ventricle, coarctation of aorta
Situs anomalies	Dextrocardia

Central Nervous System

Neural tube defects
Holoprosencephaly
Caudal regression syndrome
Sirenomelia

Gastrointestinal

Duodenal atresia
Imperforate anus
Small left colon syndrome
Esophageal atresia/tracheoesophageal fistula
Intestinal malrotation/atresia
Situs anomalies
Urorectal septum malformation sequence

Renal Anomalies

Renal agenesis
Hydronephrosis
Double collecting system
Horseshoe kidneys

Genitalia

Hypospadias
Megalourethra
Urogenital malformation sequence

Skeletal

Polydactyly
Syndactyly
Focal femoral hypoplasia
Rib defects
Spine defects—abnormal vertebral segmentation
Sacral defects
Limb deficiency

Others

Single umbilical artery

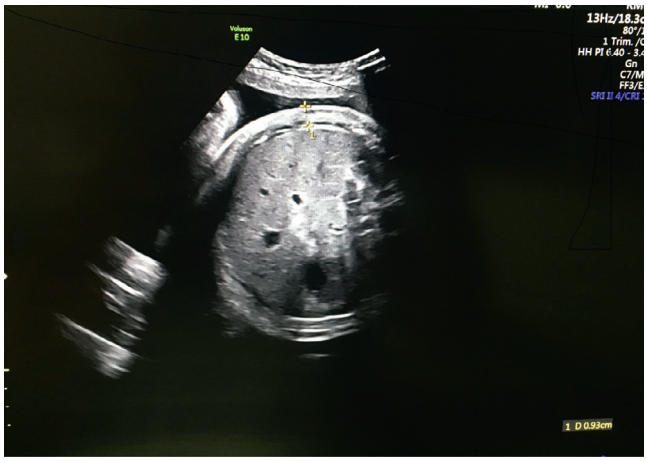
malformations, it should be noted that cardiomegaly, septal hypertrophy, and hypertrophic cardiomyopathy with left ventricle outflow tract obstruction may develop and, therefore, in cases of poor glycemic control, sequential fetal echocardiograms should be considered.

Caudal agenesis, seen predominantly (300- to 400-fold greater) in insulin-dependent diabetic pregnancies, is a specific malformation to the fetus of the diabetic mother. The exact etiology of this malformation or the correlation with abnormal glycemic control remains unknown.

Monitoring Fetal Well-Being

Frequency and timing of fetal well-being monitoring is based on the degree of metabolic control, pharmacological intervention, and co-existence of other complications such as hypertension. Generally, antenatal monitoring of women with GDM-A2, as well as those with poor glucose control, should be the same as for women with pre-GDM. A nonstress test and sonographic biophysical profile should be conducted at least weekly, beginning early in the third trimester.

Assessment of Fetal Weight



Virtually all fetuses of GDM mothers are growth promoted. Fetal macrosomia, which is frequently confused with large for gestational age (weight above the 90th percentile for gestational age), is defined as a birth weight greater than 4000-4500 grams. The incidence of macrosomia increases significantly when the mean maternal blood glucose values are greater than 130 mg/dL.

The accuracy of sonographic-estimated weight and characteristics of the fetus of the diabetic mother were studied quite extensively in the literature because of the increasing incidence of gestational and pregestational diabetes, wide implementation of prenatal diagnosis, and increased awareness to medicolegal issues. Several studies indicated that clinical estimation of fetal weight is as reliable as or even superior to those made by sonographic measurements.[24] A reliable, accurate, and predictive formula based on sonographic data is still lacking; therefore, routine sonographic fetal weight assessment to identify fetal macrosomia should be used cautiously in clinical management.

Since the estimated fetal weight is used for risk assessment for labor complications such as obstructed labor and shoulder dystocia, various studies assessed the predictive value of sonographic measures such as the difference between abdominal diameter and biparietal diameter and evaluation of fetal fat layer with quite disappointing results. None of the previously mentioned measures became a tool in the decision-making process regarding mode of delivery[5,9] (Fig. 18.2).

Polyhydramnios (i.e., increased amniotic fluid volume) is a frequent sonographic finding defined either by a single vertical pocket of 80 mm or according to nomograms of amniotic fluid index per gestational age. The etiologies for polyhydramnios in the context of the fetus of the diabetic mother are the large-for-gestational-age fetus and osmotic diuresis secondary to high glucose level. However, in cases of severe polyhydramnios and poor glycemic control, the presence of malformations such as tracheo-esophageal fistula, which are more common in the fetus of the diabetic mother, should be considered and investigated appropriately. It

• **Fig. 18.2** Increased subcutaneous fat at the fetal abdominal level (0.93 cm) is an important sign of infants of diabetic mothers (IDMs).

should be noted that polyhydramnios itself serves as an adjunct sign for fetal macrosomia.

Timing and Mode of Delivery

Definite data to support the optimal timing or and mode of delivery in women with GDM is lacking. Although earlier deliveries reduce the risk for macrosomia, this policy did not reduce the rate of brachial plexus injuries, clavicular fractures, or neonatal hypoglycemia. Although the common belief is that brachial plexus injury is solely the result of vaginal delivery, the risk for such injury in the fetus of the diabetic mother is 4% in cesarean deliveries. Shoulder dystocia may indeed cause debilitating results, and its high frequency in macrosomic fetuses of diabetic mothers lead many clinicians to recommend cesarean upon vaginal delivery in such cases.

Since hundreds of elective cesarean deliveries will be performed to prevent one case of brachial plexus injury, and since the exact cut-off (either 4000 or 4500 g) is controversial, additional data combining maternal and fetal demographic and sonographic parameters are needed for better prediction and risk assessment of shoulder dystocia in the population of macrosomic fetuses of diabetic mothers.

Intrapartum Management

While patients with GDM-A1 (dietary control) do not require glucose monitoring during labor, women with GDM-A2 require frequent glucose measuring. Most patients are euglycemic during labor and do not require insulin. In case of hyperglycemia, dextrose solution with intravenous insulin should be administered. The patient should discontinue long-acting insulin treatment during labor and delivery, and regular insulin should be used to meet most or all of the insulin needs of the mother at this time.

Postpartum Maternal Management

Insulin requirements typically drop markedly after delivery, and most GDM patients do not require insulin postpartum. Women with gestational diabetes have an approximately 50% risk to develop type 2 diabetes within 5-10 years after birth in addition to being at risk of recurrent GDM in subsequent pregnancies. Therefore, an oral glucose tolerance test at 3-year intervals is a cost-effective strategy for screening these women. Continuous nutritional modifications to encourage prompt postpartum weight loss, breastfeeding, and moderate exercise are all recommended.

Pregestational Diabetes Mellitus

In the past, most patients presenting with pregestational diabetes were those affected by juvenile diabetes; however, during recent years, the proportion of maturity onset diabetes of the young (MODY) has increased in parallel to the increase in maternal age.

Pre-GDM is much more difficult to control, and insulin treatment with frequent dosing or by insulin pump is required. Potential risks are the development of life-threatening diabetic ketoacidosis (DKA) on one hand and profound hypoglycemia on the other. It is recommended that patients and their families should know how to respond quickly and appropriately to hypoglycemia.[1]

In contrast to GDM, uncontrolled pre-GDM carries increased risk for fetal malformations. However, the risk of malformations appears to be significantly reduced (to background levels) if the patient conceives when glucose levels are controlled. This can be estimated by the HbA1C. Adequate glucose control near physiologic levels before conception and during pregnancy may decrease the risk of abortion, macrosomia, fetal death, and neonatal morbidity.

Target organ diabetic effects (renal, retinal, cardiac, and nervous system) should be evaluated prior to conception and during pregnancy. The effect of DM on the microvasculature and placenta may cause growth restriction rather than growth promotion, which is the hallmark of GDM.

Pre-GDM pregnancies are at increased risk for fetal death, therefore, fetal movement counting, nonstress testing, and sonographic biophysical profiles performed at appropriate intervals might prove valuable to monitor these pregnancies. Timing and mode of delivery are usually tailored to the patient's condition, degree of vasculopathy, and fetal thriving, among other factors.

Implications for the Neonate

Infants of diabetic mothers are at risk for increased morbidity and even mortality in the neonatal period. Mortality is mostly secondary to malformations and the complications of prematurity. The recognition that there is a clear relationship between degree of control of maternal hyperglycemia and the risk for congenital anomalies and the

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

occurrence and severity of birth trauma and neonatal morbidity and mortality has led to improved outcomes in recent years.[3] Long-term effects have been recognized in recent years. Interestingly, recent data indicate that in high-resource settings, maternal diabetes is not associated with an increased risk of in-hospital mortality or severe morbidity in very preterm infants with a birth weight <1500 g.[21a]

Maternal hyperglycemia causes intermittent and prolonged fetal hyperglycemia, leading to upregulation of insulin production by the fetal pancreas. Because fetal insulin mostly does not cross the placenta, a state of chronic hyperinsulinemia ensues, leading to increased fetal growth that results in macrosomia and visceromegaly, particularly in the liver, kidneys, skeletal muscle, and heart. Secondarily, insulin raises the metabolic rate, increasing oxygen demand leading to chronic mild hypoxemia that stimulates erythropoietin production. After birth, this will express itself as polycythemia and hyperviscosity and secondary hyperbilirubinemia. The hyperviscosity, together with low cardiac output secondary to cardiomyopathy and low maternal levels of protein C, protein S, and antithrombin, contribute to increased risk for thrombotic events, in particular renal vein thrombosis.

Hyperinsulinemia also retards the production and secretion of pulmonary surfactant, both phospholipids and surfactant-associated proteins, leading to significant increase in the risk for respiratory distress syndrome (RDS) up to 38 weeks' gestation.[8,10,22] Additional mechanisms have been identified that include reduced pulmonary vascular function and inhibition of angiogenesis that appear to be mediated via downregulation of hypoxia-inducible factor (HIF) and vascular endothelial growth factor (VEGF) secondary to changes in the insulin signal transduction pathway.[15] In addition, the tendency to deliver diabetic women by elective cesarean section without labor contributes to an increased risk for transient tachypnea of the newborn (TTN). Fortunately, tighter control of glucose levels in pregnancy has significantly reduced both of these respiratory risks for infants of diabetic mothers (IDMs).

After birth, the infant is suddenly removed from the source of excess glucose and other nutrients, namely, the mother, but continues to have upregulated insulin production, and despite increased glycogen stores, appears incapable of secreting glucagon and catecholamines to prevent the resultant hypoglycemia. Both the incidence and the severity of hypoglycemia are increased when the mother has received insulin and also when glycemic control has been inadequate. All IDMs require close monitoring of blood glucose, particularly during the hours and days shortly after birth. Hypoglycemic infants may be asymptomatic or may show clinical signs such as tremor, seizures, poor feeding, respiratory distress, and hypotonia. Debate continues around the definition of hypoglycemia, which is based mostly on statistical calculations and not on the relationship between specific values over specific periods of time and neurodevelopmental outcomes. Unfortunately, medical uncertainty over a condition that may have long-term adverse effects opens the door to litigation in which a judge or jury are left to decide on how low is too low.[13] Continuous subcutaneous monitoring of blood glucose is a technique that may help clarify this uncertainty.[11]

Congenital malformations in a number of organ systems are increased two- to threefold in IDMs whose mothers require insulin, but not so in patients with gestational diabetes that developed after the stage of embryogenesis (see Box 18.1). Poor diabetic control with raised HbA1C in the periconceptual period exposes the fetus to hyperglycemia during early embryogenesis and organogenesis, thereby exerting a significant teratogenic effect. Hyperinsulinemia does not develop until later in pregnancy and, therefore, does *not* play a role in this mechanism.

Later exposure to hyperinsulinemia contributes to the development of cardiac manifestations, including cardiomyopathy characterized by generalized cardiomegaly together with asymmetric septal hypertrophy, leading to functional left ventricular outflow tract obstruction. Cardiac dysfunction has a wide range of possible clinical presentations, ranging from an asymptomatic infant to a critically ill infant with either cardiac failure or severe respiratory distress that may be difficult to distinguish from respiratory distress syndrome. The cardiac hypertrophy resolves spontaneously within a few months of birth. Beta blockers are useful therapeutic agents, whereas cardiotonic agents may worsen the condition. The cardiomyopathy may be recognized in the second trimester by evidence of septal hypertrophy.

Hypocalcemia is seen in IDMs, often after 2-3 days of life, and is related to the severity of the maternal diabetes. The mechanisms are related to inadequate parathyroid hormone (PTH), excess calcitonin, and altered vitamin D metabolism. The most common physical sign is tremor, which usually resolves spontaneously, although occasional infants may require calcium supplementation.

Infants of diabetic mothers are at significantly increased risk for asphyxia for a number of reasons. Macrosomia results mainly from excess body fat in a distribution that increases the risk for shoulder dystocia, which may lead to asphyxia, brachial plexus injury, diaphragmatic paralysis, and recurrent laryngeal nerve injury.[27] In addition, in uncontrolled diabetics, increased HbA1C together with increased maternal 2,3-diphosphoglycerate (2,3-DPG) can lead to increased affinity of hemoglobin for oxygen, thereby reducing oxygen delivery to the fetal tissues.[12,21]

Although the vast majority of IDMs recover rapidly and appear to have no residual effects, type 1 diabetes is transmitted to the child in 2% of cases if the mother was insulin dependent and in 6% if the father was insulin dependent.[23] Additional long-term effects may include increased childhood and adolescent obesity, impaired glucose tolerance, and subtle neuropsychological effects.[28] Box 18.2 summarizes the major morbidity in infants of diabetic mothers.

• BOX 18.2 Major Morbidity in Infants of Diabetic Mothers

- Macrosomia and visceromegaly
  - Birth trauma—shoulder dystocia, brachial plexus injury, diaphragmatic paralysis, recurrent laryngeal nerve injury
  - Premature birth
- Congenital malformations
  - Cardiac, central nervous system, gastrointestinal, musculoskeletal, renal
- Metabolic disturbance
  - Hypoglycemia
  - Hypocalcemia
- Hematologic
  - Polycythemia
  - Hyperbilirubinemia
- Respiratory
  - Respiratory distress syndrome
  - Transient tachypnea of the newborn
- Skeletal
  - Caudal regression syndrome

Breastfeeding in Women With Gestational Diabetes Mellitus

Breastfeeding should be strongly recommended for its multiple health benefits for the neonate and mother. It reduces the long-term risk for obesity, diabetes, hypertension, and cardiovascular disease. The inverse association between breastfeeding and obesity is dose-dependent (approximately 4% reduction in risk of being overweight per month of breastfeeding) and is seen across all age groups and ethnicities. Children who had been breastfed for at least 2 months also had lower rates of type 2 diabetes. Because of the increased risk of hypoglycemia in IDMs and the low substrate of breast milk after delivery, hypoglycemia should be aggressively monitored and treated with supplements (see Chapter 86). Among postpartum women with recent gestational diabetes mellitus, breastfeeding the infant during the 2-hour, 75-g OGTT may modestly lower plasma 2-hour glucose (5% lower on average) as well as insulin concentrations in response to ingestion of glucose.

Key Points

- Gestational diabetes (GDM) is defined as glucose intolerance beginning or first diagnosed during pregnancy.
- Pregestational diabetes refers to women with DM prior to conception.
- Women with pregestational diabetes may exhibit vascular complications, placental insufficiency, and growth restriction.
- The main perinatal risk in GDM is macrosomia, whereas pre-GDM can be associated with a variety of malformations.

Obstetric Management of Prematurity

MAGED M. COSTANTINE, ANTONIO SAAD, AND GEORGE SAADE

Preterm birth is defined as a delivery that occurs at 20 weeks' gestation or later but prior to 37 weeks' gestation (from the first day of the last menstrual period). Although advancements in neonatology and obstetrical interventions have dramatically improved outcomes and reduced the burden associated with prematurity, the rate of preterm birth itself has not changed substantially over the past 40 years. From 1990-2006, the preterm birth rate *increased* to a peak of 12.6%, probably because of the increase in indicated preterm deliveries and early deliveries related to multiple gestations conceived with assisted reproductive techniques.[109] This was followed by an encouraging drop in preterm birth rate to 9.57% in 2014. However, since then there has been a reverse trend with the 2016 preliminary birth data showing a preterm birth rate of 9.85%.[109] On the other hand, the low birth weight rate declined slightly to 8.1% in 2015,[109] and the infant mortality rate remained stagnant and was reported as 5.96 infant deaths per 1000 live births in 2013, compared with 6.15 deaths in 2010.[111]

Prematurity remains a leading cause of neonatal morbidity and mortality worldwide, accounting for 60%-80% of deaths of infants without congenital anomalies. In 2013, 36.1% of all infant deaths in the United States were preterm related, second only to congenital malformations and chromosomal abnormalities among the leading causes of infant mortality.[111] Maternal race and ethnicity have a particularly strong effect on preterm-related infant mortality, with 44% of non-Hispanic black infant deaths attributed to preterm-related causes, a 3 times higher rate compared with non-Hispanic white infants.[111] However, although the preterm-related infant mortality rate was highest for non-Hispanic black women, they also experienced the largest declines since 2005, with the preterm-related infant mortality rates having declined by 22% for non-Hispanic black women, compared with a 14% decline for non-Hispanic white women.[111]

There are few obstetric interventions that successfully delay or prevent spontaneous preterm birth. Interventions to reduce the morbidity and mortality of preterm birth can be primary (directed to all women), secondary (aimed at eliminating or reducing existing risk), or tertiary (intended to improve outcomes for preterm infants). Most efforts so far have been tertiary, including regionalized care and treatment with antenatal corticosteroids, tocolytic agents, magnesium sulfate for neuroprotection, and antibiotics. These measures have reduced perinatal morbidity and mortality but essentially have no effect on the incidence of preterm birth itself. Advances in primary and secondary care, following strategies used for other complex health problems such as cervical cancer, are necessary to truly move toward eradicating prematurity-related illness in infants and children.[87]

Promising interventions such as progestin supplementation, cerclage placement, and cervical pessary insertion appear to be useful in the prevention of preterm birth in certain populations. The most pressing need is to better define the populations of pregnant women for whom these and other interventions are beneficial, and continued work to understand the complex pathophysiology of prematurity in an effort to design future interventions effective in reducing preterm birth.[125]

Prematurity

Preterm birth prior to 37 weeks' gestation may be divided into two major categories: (1) indicated preterm births and (2) spontaneous preterm births. Indicated preterm births include deliveries prompted by concerns regarding maternal or fetal well-being, processes that account for approximately 25% of all preterm births together.[56] Common reasons for these indicated early deliveries include preeclampsia/eclampsia (see Chapter 17) and nonreassuring fetal status secondary to abnormal fetal heart rate, intrauterine growth restriction (see Chapter 15), or oligohydramnios (see Chapter 24).

Spontaneous preterm births include deliveries that follow either spontaneous labor or preterm premature rupture of membranes (PPROM). Spontaneous preterm births account for approximately 70% of all preterm deliveries, with 40%-50% of these early deliveries owing to preterm labor and 25% to PPROM.[56]

The risk of neonatal mortality and morbidity is inversely related to the gestational age at the time of delivery.[6,49] A recent review of studies from the United States and other developed countries showed survival to discharge of 23%-27% for births at 23 weeks, 42%-59% for births at

Abstract

Preterm labor and delivery remains a significant clinical problem globally, accounting for a substantial component of all neonatal morbidity and mortality. Despite important insights into the pathophysiology of preterm labor over the past several decades, effective therapeutic interventions to decrease spontaneous preterm delivery remain limited. Clearly, the development of effective screening tools to identify patients at greatest risk for spontaneous preterm delivery, primary and secondary prevention strategies, and interventions to improve neonatal outcomes are urgently needed. With the advances in neonatal care, coupled with various obstetric interventions including the use of progesterone, cervical cerclage, and pessary to prevent preterm birth in select populations, and the use of antenatal corticosteroids, magnesium sulfate, and intrapartum antibiotics all contributed to decrease in neonatal mortality and morbidities associated with preterm birth. This chapter aims to review the epidemiology and pathophysiology of preterm labor, as well as the current therapeutic strategies that may be employed in this setting.

24 weeks, and 67%-76% for births at 25 weeks of gestation.[6] Gestational-age-specific neonatal mortality rates are listed in Table 19.1 (see also Fig. 19.1).[6,35,155,171,177] Survival by gender is presented in Fig. 19.2. Attention has primarily been focused on prevention of early preterm births (23-32 weeks' gestation), which represent less than 2% of all deliveries but contribute to 60% of perinatal mortality and nearly 50% of long-term neurologic morbidity. Perhaps the greatest benefit of this focus has been reaped by the extremely premature neonates. Although once considered to be nonviable, survival rates of 20%-40% have recently been noted in neonates delivered at 22-23 weeks' gestation.

Stoll et al.[172] reported that survival increased between 2009 and 2012 for infants at 23 weeks' gestation (27%-33%; adjusted RR 1.09 [95% CI, 1.05-1.14]) and 24 weeks (63%-65%; adjusted RR 1.05; 95% CI, 1.03-1.07), with smaller relative increases for infants at 25 and 27 weeks' gestation and no change for infants at 22, 26, and 28 weeks' gestation. Survival without major morbidity increased approximately 2% per year for infants at 25-28 weeks' gestation, with no change for infants at 22-24 weeks' gestation.

These babies are at risk for a wide array of complications, though, including long-term neurologic impairment.[6] Moore noted from the EPICure studies that looked at extremely preterm infants that survival of babies admitted

for neonatal care increased from 39% (35%-43%) in 1995 to 52% (49%-55%) in 2006, an increase of 13% (8%-18%), and that survival without disability increased from 23% (20%-26%) in 1995 to 34% (31%-37%) in 2006, an increase of 11% (6%-16%).[123] A recent cohort from the Neonatal Research Network of non-anomalous infants born between 2006 and 2011 before 27 weeks showed similar patterns with overall rates of survival and intact survival (without severe impairment) of 5.1% (IQR 0-10.6) and 3.4% (IQR 0-6.9) respectively among children born at 22 weeks to 81.4% (IQR 78.2-84) and 75.6% (IQR 69.5-80) respectively among those born at 26 weeks' gestation.[155]

While extremely premature neonates contribute the bulk of perinatal mortality and morbidity, those born as late preterm (between 34 weeks 0 days and 36 weeks 6 days; 6.87% in 2015) make up the majority of preterm infants,[28] and recent evidence has emerged showing that they have increased mortality and various morbidities, including transient tachypnea of the newborn, respiratory distress syndrome (RDS), persistent pulmonary hypertension, respiratory failure, temperature instability, jaundice, hypoglycemia, feeding difficulties, and prolonged neonatal intensive care unit (NICU) stay compared with their term counterparts (Table 19.2).[28,174] These late preterm infants may also manifest long-term neurodevelopmental consequences. It is, therefore, important to remember that although morbidity is inversely related to gestational age, there is no gestational age, including term, that is wholly exempt from adverse outcomes.[157] The best outcomes remain for babies delivered at 39 weeks.

While gestational age remains the major determinant of morbidity and mortality, other factors affect these rates. For example, female infants demonstrate better survival rates than male infants at any gestational age, and black neonates tend to do better than white neonates.[177] Neonatal survival rates also increase as infant birth weight increases, with 55% survival at 501-750 g, 88% at 751-1000 g, 94% at 1001-1250 g, and 96% at 1251-1500 g.[49] In addition, differences in hospital practices regarding the initiation of active treatment in infants born between 22 and 24 weeks' gestation may affect overall and intact survival among these patients.[155] The best outcomes at the limits of viability continue to be reported from Japan.

Neonatal morbidities related to prematurity also remain a significant clinical problem, including RDS, intraventricular hemorrhage, periventricular leukomalacia, necrotizing enterocolitis, bronchopulmonary dysplasia, sepsis, patent ductus arteriosus, jaundice, growth failure, cerebral palsy, disorders of cognition, and retinopathy of prematurity. The risk for these morbidities is inversely related to both gestational age at delivery and birth weight, with Table 19.3 depicting the morbidity rates according to gestational age. Use of antenatal corticosteroids (betamethasone or dexamethasone) has been shown to reduce the incidence or severity of RDS, intraventricular hemorrhage, and necrotizing enterocolitis, but rates of other adverse outcomes remain unchanged.

Cerebral palsy is an umbrella term encompassing disorders of movement and posture, attributed to non-progressive disturbances occurring in the developing fetal or infant brain. Cerebral palsy complicates approximately 2 per 1000 live births. Although the majority of cases are associated with term deliveries, the relative risk for an early preterm infant developing cerebral palsy is nearly 40 times that of a term infant. The risk of cerebral palsy is particularly high in children with extremely low birth weight (less than 1000 g), a population that also has substantially higher rates of cognitive disorders, hearing and visual disabilities, neurobehavioral dysfunction, and poor school performance (see Chapter 60).[26] The high risk of cerebral palsy in this population may be associated with the increased rate of intrauterine infection and inflammation in extreme preterm patients. Intrauterine infection and postnatal sepsis appear to play an important role in the pathophysiology of this condition. Intrauterine infection and inflammatory cytokines appear to substantially increase the risk of cell death, resulting in periventricular leukomalacia and intraventricular hemorrhage, and ultimately contributing to development of cerebral palsy.[26,186] Recently, obstetric professional societies have advocated for the use of magnesium sulfate for fetal neuroprotection. Research has shown that administration of this therapy to women at risk for imminent delivery of a fetus less than 32 weeks' gestation may reduce the risk of moderate or severe cerebral palsy by up to 45%.[7,164]

Pathogenesis

Despite exhaustive research attempts, a complete understanding of the pathogenesis of preterm labor remains elusive. It is becoming increasingly clear that the factors that lead to the development of preterm labor are distinct from those that occur with term labor and thus represent a pathologic rather than a physiologic process. To add to the complexity, preterm labor appears to involve a number of

*An infant was determined to have respiratory distress syndrome if each of the following was true: required oxygen at 6 hours of life, continuing to age 24 hours; demonstrated clinical features up to age 24 hours; needed respiratory support to age 24 hours; had an abnormal chest radiograph up to age 24 hours.
Modified from data obtained between 1/1/04 and 12/31/07 from the National Institute of Child Health and Human Development (NICHD), Stoll BJ, Hansen NI, Bell EF, et al., Eunice Kennedy Shriver National Institute of Child Health and Human Development Neonatal Research Network. Neonatal outcomes of extremely preterm infants from the NICHD Neonatal Research Network. *Pediatrics*. 2010;126(3):443-456.

processes that all lead to the common pathway of spontaneous preterm birth.

To understand the pathophysiologic processes of preterm labor, one must be familiar with the pathway leading to normal term labor. Three main biologic events appear to be involved with the onset of spontaneous labor: cervical ripening, formation and expression of myometrial oxytocin receptors, and myometrial gap junction formation. Prostaglandins E_2 and $F_{2\alpha}$ (PGE_2 and $PGF_{2\alpha}$) are believed to be important factors involved in these events. Levels of these specific prostaglandins increase in amniotic fluid, maternal plasma, and urine during labor, wherein they have been shown to facilitate cervical ripening and to promote myometrial gap junction formation. To that end, exogenous administration of prostaglandins facilitates cervical ripening and induction of labor at any point in gestation, while administration of prostaglandin synthetase inhibitors arrests preterm labor. Although prostaglandins are clearly an important component of the parturition process, the mechanism by which this cascade of events begins is not fully understood. Several theories exist regarding the initiation of parturition, including (1) progesterone withdrawal, (2) oxytocin initiation, and (3) decidual activation.

The progesterone withdrawal theory stems primarily from studies of sheep. Endogenous progesterone is known to inhibit decidual prostaglandin formation and release. As parturition nears, the fetal adrenal axis becomes more sensitive to adrenocorticotropic hormone, which incites an increased secretion of cortisol. Fetal cortisol then stimulates trophoblast 17α-hydroxylase activity, which decreases progesterone secretion and leads to a subsequent increase in estrogen production. This reverse in the estrogen-to-progesterone ratio then results in increased prostaglandin formation, thus leading to parturition. However, although this mechanism is well established in sheep, it does not appear to be the primary initiator of parturition in humans. Despite this, it is thought that premature activation of this axis can lead to preterm birth, primarily as triggered by increased maternal physical or psychological stress or fetal uteroplacental vasculopathy (i.e., as seen with preeclampsia or intrauterine growth restriction). Supporting this theory are the increased fetal adrenal zone size and elevated corticotropic hormone levels associated with preterm delivery, particularly late preterm births.

The second parturition theory involves oxytocin, a substance known to cause uterine contractions and to promote prostaglandin release, as an initiator of labor. The number of myometrial oxytocin receptors increases substantially as women near term. Despite this, oxytocin levels themselves do not rise before labor, and the involvement of this hormone in parturition likely represents a final common pathway instead of an inciting event.

The final and most likely theory regarding preterm parturition involves premature decidual activation through processes such as inflammation and/or hemorrhage. There is a large body of evidence establishing a strong link between inflammation, such as seen in the presence of genitourinary pathogens or even with systemic infections, and spontaneous preterm delivery. Colonization or infection of the upper genital tract results in inflammation and disruption of the choriodecidual interface, initiating a cascade of events ultimately resulting in spontaneous labor. Pathogens may have

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

a direct role in this process, as evidenced by the finding of bacteria (usually organisms that are hard to culture using standard techniques) within the amniotic fluid of up to two-thirds of women with preterm birth. More importantly, however, pathogens lead to inflammation that then drives the process of preterm parturition. The evidence for these events is well supported by the biochemical changes that have been observed within the amniotic fluid, trophoblast, and decidua of patients with spontaneous preterm labor. Further support for this hypothesis comes from studies of mid-trimester amniotic fluid, obtained at the time of genetic amniocentesis, which demonstrate that elevated interleukin (IL)-6 levels are often associated with subsequent spontaneous abortion, fetal death, or preterm labor. In addition, amniotic fluid levels of the proinflammatory cytokines IL-1β and tumor necrosis factor-α increase in association with preterm labor. These specific cytokines appear to enhance prostaglandin production in the amnion and decidua while also triggering expression of matrix metalloproteinases that subsequently cause the breakdown of the cervical-chorionic-decidual extracellular matrix. These processes then lead to cervical ripening, separation of the chorion from the decidua, and possible membrane rupture.

Hemorrhage, as with overt placental abruption or even more subtle bleeding, can also lead to decidual activation. Multiple studies have linked the occurrence of vaginal bleeding to an approximately fourfold increase in the risk of spontaneous preterm birth. It is likely that inflammatory and coagulation pathways converge to result in this association. Not only can inflammation or infection lead to hemorrhage secondarily, but vaginal bleeding may also be the inciting event itself, triggering thrombin production that then generates pro-inflammatory cytokines.

The strong association between inflammation and preterm birth represents a series of complex, interconnected pathways. Recognition of this association is an important advance in our understanding of the mechanisms involved in spontaneous preterm delivery and represents a potential target for therapeutic intervention.[56,87,125]

Risk Factors

The identification and management of preterm labor have been directed at defining various epidemiologic, clinical, and environmental risk factors that are related to spontaneous preterm birth. Early recognition of these risk factors (Box 19.1) may allow modification of the traditional approaches to prenatal care and ultimately may reduce the rate of preterm deliveries.

Demographics

In the United States, race is one of the most significant risk factors for preterm delivery. In 2015 birth data, black women have a prematurity rate of about 13.4%, in comparison with 8.9% for white women. The rate of preterm birth less than 32 weeks was more than double in non-Hispanic black women (3.09%) compared with non-Hispanic white women (1.27%).[109] Similarly, the rate of very low birth weight neonates (less than 1500 g), which are associated with the greatest risk of neonatal morbidity and death, is more than doubled in non-Hispanic black women (2.89%) compared with non-Hispanic whites (1.09%).[109] Other risk factors including extremes of maternal age, less education, and lower socioeconomic status, are associated with increased risk of preterm delivery.[29] However, even when these factors are controlled for, black women still have higher rates of preterm delivery.[29]

In addition to race, various behavioral factors increase the risk of preterm birth. Nutritional status, low maternal prepregnancy weight and BMI, and poor gestational weight gain are associated with increased risk. Smoking is associated with several poor pregnancy outcomes including placental abruption, intrauterine growth restriction, and preterm birth, with 10% to 20% of all preterm births attributed to maternal smoking. Substance use in pregnancy, especially cocaine, opiates, and alcohol, are other behavioral factors. Whether the pathophysiology of substance use is direct or through concurrent exposure to other lifestyle-related risks is to be determined.

Yet another behavioral factor related to preterm birth rates is the degree of physical activity and stress during

• BOX 19.1 Risk Factors Associated With Preterm Delivery

Demographic Factors

- Age
- Race
- Socioeconomic status

Behavioral Factors

- Smoking
- Substance abuse
- Poor nutrition
- Absent or inadequate prenatal care

Maternal Medical Conditions

- Poor obstetric history
- Uterine or cervical malformations (short cervix)
- Myomas
- Exposure to diethylstilbestrol
- Hypertension
- Diabetes
- Other medical conditions

Current Pregnancy Complications

- Multiple gestation
- Excess or decreased amniotic fluid
- Vaginal bleeding
- Low body mass index (<19.8 kg/m^2)
- Fetal anomalies
- Abdominal surgery
- Infection (systemic or local)

pregnancy. Several studies have evaluated the effects of employment on preterm delivery, with disparate results ranging from an increase to an actual decrease in the risk of preterm birth in the working group. These variable results are likely related to the fact that physical activity levels probably impact the rate of preterm birth more than simple employment statistics. For example, activity in the standing position has been shown to increase uterine irritability, likely owing to uterine compression of pelvic vessels resulting in a decreased venous blood return to the heart, a phenomenon that may be temporarily relieved via contractive activity. Maternal stress also plays a role in the association between work activity and preterm birth.[33] It seems, therefore, reasonably clear that women who engage in hard, physical work for long hours under increased stress are at a greater risk of preterm birth than inactive women or those with less physically demanding jobs.

Obstetric History

A history of a prior preterm delivery is one of the most significant risk factors. The recurrence risk of preterm birth ranges from 12%-57%, depending on the number of prior preterm deliveries and the gestational age at which those deliveries occurred. For example, whereas women with one prior preterm birth have a threefold increased risk for preterm delivery in comparison with women with no such history, a six- to tenfold increased risk is seen in women with two previous preterm births.[115] Furthermore, the risk of recurrent preterm birth is increased in women with prior second-trimester losses, induced abortions, prior twin preterm birth, and prior indicated preterm birth.

Cervical and Uterine Factors

Patients with congenital Müllerian anomalies have an increased risk of preterm delivery. Approximately 3%-16% of all preterm births are associated with a uterine malformation. The incidence of preterm labor varies greatly depending on the type of uterine anomaly with unicornuate, didelphic, and bicornuate abnormalities having higher preterm labor rates (approximately 35%) compared with septate uterus (approximately 15%). In addition, these patients are at increased risk of placental abruption and PPROM.

Uterine leiomyomata have also been associated with an increased risk of preterm delivery, primarily owing to an increased incidence of antepartum bleeding and PPROM. Of the various types of myomata, submucosal and subplacental myomata appear to be most strongly associated with preterm delivery.

Cervical incompetence is another important risk factor for preterm delivery. The classic clinical description of cervical incompetence involves a history of painless cervical dilation between 12 and 20 weeks. A history of a second-trimester pregnancy loss has been the cornerstone of the diagnosis, but distinguishing between cervical incompetence and preterm labor can at times be difficult, and many times may not help in the clinical management of these patients.

Intrauterine exposure to diethylstilbestrol (DES) is a significant factor associated with congenital causes of cervical incompetence and both upper and lower genital tract structural abnormalities. An estimated 1-1.5 million women were exposed in utero to DES between the late 1940s and 1971. These women have an increased risk of preterm delivery ranging from 15% to 28%, with an increased risk of spontaneous abortion of 20%-40%. Women exposed to DES who have associated anomalies, such as T-shaped uterus, cervical incompetence, or vaginal structural anomalies, have a greater risk of preterm delivery than those who do not demonstrate these structural abnormalities. Because most women exposed to DES in utero are now older than 40, this risk factor is becoming less and less of an issue.

In addition, cervical procedures performed for the diagnosis and treatment of cervical intraepithelial neoplasia, including cold knife conization, or loop electrosurgical excision, have been associated with increased risk of preterm birth in subsequent pregnancies. A greater depth of excision was suggested to lead to greater risk of PPROM and preterm birth. However, a recent meta-analysis showed that the risk of preterm birth was only increased when these patients were compared to women without any history of cervical dysplasia and not when compared to those with history of abnormal cytology. This suggests other factors like high-risk HPV virus infection as the link toward increased preterm birth risk rather than the procedure itself.[22]

Multifetal Gestations

Multiple gestations carry a sixfold increased risk of preterm delivery compared with singleton pregnancies. In the United States, 15%-20% of all preterm births are in multifetal pregnancies (only 3% of all pregnancies). Approximately 50% of twin and nearly all of higher-multiple gestations deliver prior to 37 completed weeks, with an average length of gestation of 35.2 weeks for twins, 32.1 weeks for triplets, and 29.7 weeks for quadruplets. Owing to artificial reproductive techniques, the prevalence of multiple gestations has increased in the United States. Multiple gestations are discussed further in Chapter 21.

Bleeding

Vaginal bleeding is also associated with an elevated risk of preterm delivery. This is particularly true in the setting of placenta previa and placental abruption, but first- or second-trimester vaginal bleeding in the absence of these conditions is also associated with an increased risk of preterm delivery. The mechanism responsible for the development of preterm labor in the setting of vaginal bleeding appears to be related to thrombin deposition with subsequent production of prostaglandins and plasminogen activators that stimulate an array of degradative enzymes leading to destruction of the extracellular matrix.

Infection

Infections of the decidua, fetal membranes, and amniotic fluid have been associated with preterm delivery (see Chapter 25).[16,23] For example, although intra-amniotic infection or chorioamnionitis complicates 1%-5% of term pregnancies, the contribution of infections to preterm birth has been estimated to be at least 25%-40% (see also Chapter 25).

There are data suggesting a link between occult upper genital tract infection and spontaneous preterm delivery even in the absence of clinical features of intra-amniotic infection. Moreover, the likelihood of a positive amniotic fluid culture or colonization of the chorioamnion in women with spontaneous preterm labor is inversely proportional to the gestational age at delivery.[16] Typical organisms associated with histologic chorioamnionitis include *Ureaplasma*, *Mycoplasma*, *Gardnerella*, *Bacteroides*, and *Mobiluncus* species.

Numerous theories exist regarding the underlying pathogenesis of intra-amniotic infection: (1) ascending infection from the vagina and cervix, (2) transplacental passage through hematogenous dissemination, (3) retrograde seeding from the peritoneal cavity through the fallopian tubes, and (4) iatrogenic means as a result of intrauterine procedures such as amniocentesis and chorionic villus sampling. There is some evidence to support each of these theories, but ascending infection is the most well-accepted theory.

The mechanism of ascending infection appears to start with excessive overgrowth of certain organisms within the vagina and cervical canal. These microorganisms then gain access to the intrauterine cavity by infecting the decidua, the chorion, the amnion, and then finally the amniotic cavity itself. In this manner, pathogens are able to cross intact membranes. The fetus then becomes infected by aspirating or swallowing infected amniotic fluid or by direct contact with the organism within the fluid, leading to localized infections such as pneumonitis, otitis, or conjunctivitis. Seeding of these areas can lead, in turn, to fetal inflammatory response syndrome and sepsis. Alternatively, sepsis may result from maternal bacteremia, leading to placental infection with subsequent spread of organisms through the umbilical cord to the fetus.

Intra-amniotic infection can also lead to preterm labor through less direct methods, namely stimulation of prostaglandin. Microorganisms, probably through the release of endotoxins (in gram-negative organisms) such as phospholipase A_2 and C or lipopolysaccharide, activate pattern-recognition receptors such as Toll-like receptors that lead to release of inflammatory cytokines such as IL-8, IL-1β, and TNF-α, which in turn stimulate the production of prostaglandins and matrix-degrading enzymes by the amnion and decidua. The amniotic fluid concentrations of prostaglandins $PGF_{2\alpha}$ and PGE_2, as well as their metabolites, are increased in patients with preterm labor, preterm premature rupture of membranes, and intra-amniotic infection.

Group B streptococcus (GBS) has been associated with an increased risk of preterm delivery, but more importantly, GBS colonization plays a major role in neonatal morbidity and death. Between 10% and 30% of pregnant women are colonized with GBS. Pregnant women colonized with GBS have higher incidence of preterm birth, PPROM, and low birth weight. Patients with urinary colonization also have positive results on cervical and vaginal cultures, possibly indicating that the presence of GBS in the urine may be a marker of more severe forms of genital tract colonization. Unfortunately, treatment of GBS genital tract colonization has never been shown to decrease the risk of preterm delivery or PPROM.[8,181]

In 2010, the Centers for Disease Control and Prevention (CDC), in conjunction with the American College of Obstetricians and Gynecologists and the American Academy of Pediatrics, revised their guidelines for the prevention of perinatal GBS disease to confirm universal screening at 35-37 weeks of gestation and intrapartum antibiotic prophylaxis for culture-positive and high-risk women. The revised guidelines also included new recommendations for laboratory methods for identification of GBS colonization during pregnancy, algorithms for screening, and intrapartum prophylaxis for women with preterm labor and premature rupture of membranes, as well as clarification of the colony count threshold required for reporting GBS detected in urine of pregnant women, updated prophylaxis recommendations for women with a penicillin allergy, and a revised algorithm for the care of newborn infants.[8,27,181]

Intrapartum GBS prophylaxis is indicated in women with: (1) prior infant with invasive GBS disease, (2) GBS bacteriuria any time during pregnancy, (3) GBS carriers through prenatal screening cultures collected at 35-37 weeks' gestation, and (4) unknown GBS culture at the onset of labor in women with any of the following: (i) preterm labor at less than 37 weeks' gestation, (ii) membranes ruptured for 18 hours or longer, (iii) intrapartum maternal fever of 38°C or higher, and (iv) intrapartum nucleic acid amplification test (NAAT) GBS positive.[8]

For women who are culture positive for GBS, intrapartum chemoprophylaxis with intravenous penicillin G (5 million units initially and then 2.5 million units every 4 hours) is recommended until delivery. Intravenous ampicillin (2 g initially, and then 1 g every 4 hours) is an acceptable alternative to penicillin G. Because of emerging resistance of GBS to macrolides, guidelines have recently been modified for women who are allergic to penicillins.[8,181] In penicillin-allergic women who are not at high risk for anaphylaxis, intravenous cefazolin (2 g initially, and then 1 g every 8 hours until delivery) is recommended. In penicillin-allergic women who are at high risk for anaphylaxis, clindamycin and erythromycin susceptibility testing of the GBS isolate is recommended. If the isolate is sensitive to both clindamycin and erythromycin, intravenous treatment with clindamycin 900 mg every 8 hours is recommended.[8] If the GBS isolate is resistant to either agent or susceptibility is unknown, treatment with intravenous vancomycin (1 g every 12 hours) is recommended. Currently, 70%-80% of cases of neonatal GBS infection in the United States occur in term

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

infants; however, the case fatality rate and the burden of disease is much higher in those born preterm. In addition, half the cases are usually early in onset (within the first week of life). In addition, 10%-15% of neonatal infection cases were attributed to missed screening among mothers, and many were born to women who had tested negative for GBS before delivery. Further improvement toward eradication of GBS colonization and disease may involve universal screening in conjunction with rapid diagnostic technologies or other novel approaches, including DNA techniques for the identification of GBS. Given the complications and potential limitations associated with maternal intrapartum prophylaxis, however, vaccines are being considered to prevent neonatal GBS disease. Developing a universal vaccine has proved to be a daunting task, though, because of the variability of serotypes in diverse populations and geographic locations.

Bacterial vaginosis (BV) is yet another infection associated with an increased risk for preterm labor and delivery. It is a common lower genital tract infection found in approximately 20%-40% of African-American women and 10%-15% of white women. This condition is a clinical syndrome characterized by a decrease in the normal vaginal lactobacilli-dominant microflora and a compensatory predominance of bacteria such as *Gardnerella vaginalis*, *Prevotella*, *Bacteroides*, *Peptostreptococcus*, *Mobiluncus*, *Mycoplasma hominis*, and *Ureaplasma urealyticum*. Characteristically, patients with symptomatic BV complain of a watery, homogeneous grayish discharge with a fishy amine odor.

As above, BV has been associated with increased risk for preterm birth, especially among African-American women in whom up to 40% of early spontaneous preterm births may be associated with BV. While some randomized clinical trials demonstrated that treating BV in high-risk patients resulted in reductions in preterm birth rates, other trials did not confirm these findings.[24,77] The majority of women with BV never manifest any signs or adverse outcomes related to the infection, and it is likely that BV is only a surrogate marker for a more important, presently unrecognized condition that may be the cause of the preterm birth.[16,23]

Many other maternal infections or colonizations have been reportedly associated with preterm birth. One of the difficult questions to address is whether these relationships are causal or associative. Gonorrhea, chlamydia, trichomonas, syphilis, and other genital pathogens are more frequently found in women who have a spontaneous preterm birth. For example, gonorrhea, chlamydia, and syphilis have all been associated with a twofold increased risk for preterm delivery, and trichomonas has been associated with a 1.3-fold increased risk. Furthermore, many other sexually transmitted infections (e.g., human immunodeficiency virus, human papilloma virus, hepatitis B, and genital herpes simplex virus) have been associated with an increased risk for spontaneous preterm birth in some, but not most, studies. Importantly, the women affected by these infections often have other risk factors for preterm birth (e.g., low socioeconomic status, malnutrition, smoking, substance abuse, bacterial vaginosis). These confounding variables make it difficult to establish causality.

Genetic Factors

Despite evidence that genetic factors contribute to the duration of gestation and the risk of preterm birth, robust associations with genetic variants have not until recently been identified. Zhange used large data sets that included the gestational duration to determine possible genetic associations.[188] They performed a genome-wide association study in a discovery set of samples obtained from 43,568 women of European ancestry using gestational duration as a continuous trait and term or preterm (<37 weeks) birth as a dichotomous outcome. In the discovery and replication data sets, four loci (EBF1, EEFSEC, AGTR2, and WNT4) were significantly associated with gestational duration. Functional analysis showed that an implicated variant in WNT4 alters the binding of the estrogen receptor. Common variants in EBF1, EEFSEC, and AGTR2 showed association with preterm birth with genome-wide significance. An analysis of mother-infant dyads suggested that these variants act at the level of the maternal genome. Previously established roles of these genes in uterine development, maternal nutrition, and vascular control support their mechanistic involvement.

Other Risk Factors

A variety of other factors have been associated with an increased risk for preterm labor (see Box 19.1), including the following:

- Extremes in the volume of amniotic fluid, including polyhydramnios or oligohydramnios
- Fetal anomalies, especially those involving multiple organ systems and central nervous system abnormalities
- Maternal abdominal surgery in the late second and third trimester
- Maternal medical conditions, such as gestational or pre-existing diabetes and hypertension (although these preterm births are often induced, not spontaneous)
- Asymptomatic bacteriuria
- Systemic infections including bacterial pneumonia, pyelonephritis, and acute appendicitis

Predicting Preterm Labor

The multifactorial nature of preterm delivery has thus far impeded efforts to decrease or even eliminate preterm birth. Indicated deliveries account for 20%-25% of all preterm births while PPROM is associated with another 25%-40% of these early deliveries. In these cases, tocolysis is usually not applicable or contraindicated. Of the remaining 40%-50% of early deliveries owing to spontaneous preterm labor, more than half occur beyond 34 weeks' gestation when the use of tocolysis is also not recommended. Consequently, only about 15%-20% of patients at risk for preterm

birth are true candidates for treatment. A significant volume of research has focused on predicting preterm birth in this cohort of patients. Classical clinical predictors including cervical change; uterine activity; socioeconomic, demographic, and other clinical variables; and various combinations of risk scoring systems were not shown to be useful predictors of preterm birth. The use of home uterine monitoring is also not recommended. Other categories of risk factors are explored in the following paragraphs: biochemical predictors and ultrasound predictors.[29,168]

Biochemical Predictors

The biochemical processes leading to the initiation of either term or preterm labor are complicated, such that these pathways have not been fully established in humans. Despite this limitation, important insights into the pathophysiology of spontaneous preterm labor have helped to identify various biochemical markers that may predict preterm delivery.[57]

Perhaps one of the most important biochemical markers identified to date is fetal fibronectin.[145] This glycoprotein is found within the extracellular matrix that surrounds the extravillous trophoblast at the uteroplacental junction. Clinically, it serves as a prototypic example of a marker of choriodecidual disruption. Fetal fibronectin is usually absent from cervicovaginal secretions starting from the 20th week of gestation until near term. Detection of elevated cervicovaginal levels of fetal fibronectin has, therefore, been strongly associated with an increased risk for preterm delivery in high-risk patients.[59,142,168] Sensitivities in the 80%-90% range with positive predictive values of 30%-60% have been reported. For example, Goldenberg and associates demonstrated that, in asymptomatic women at 24 weeks' gestation, elevated cervicovaginal fetal fibronectin levels (greater than 50 ng/mL) were strongly associated with subsequent spontaneous preterm delivery, with ORs of 59.2 (95% CI, 35.9-97.8) for delivery before 28 weeks' gestation, 39.9 (95% CI, 25.6-62.1) for delivery less than 30 weeks' gestation, and 21.2 (95% CI, 14.3-62.1) for delivery less than 32 weeks' gestation.[59] Further supportive data comes from Tanir and associates, who prospectively confirmed the clinical value of cervicovaginal fetal fibronectin, showing that a positive fetal fibronectin test was associated with an increased likelihood of preterm delivery in women with signs and symptoms of preterm labor.[173] Quantitative fetal fibronectin testing was also evaluated in women with preterm labor symptoms, demonstrating an increasing positive predictive value for preterm birth of 19%, 32%, 61%, and 75%, with increasing fetal fibronectin thresholds of 10 ng/mL, 50 ng/mL, 200 ng/mL, and 500 ng/mL respectively.[1] While these data suggest that fetal fibronectin is a marker for spontaneous preterm delivery, trials using antibiotics in women with positive fetal fibronectin were not supportive, and no other studies showed any benefit in predicting or preventing preterm birth. While many clinicians rely on the test (usually alone or in combination with cervical length) in symptomatic women at less than 32 weeks' gestation, to justify their management in an ambulatory fashion due to the test's high negative predictive value, recent meta-analysis and review showed that testing of fetal fibronectin in singleton gestations with threatened preterm labor is not associated with prevention of preterm birth or improvement in other perinatal outcomes but is associated with other costs.[21] Therefore, screening of low-risk women with fetal fibronectin test to predict preterm birth is not recommended.[29,81,168]

Estriol is another biochemical marker that was suggested to be of use in predicting preterm delivery.[145] Estriol is a unique hormone of pregnancy that is produced almost entirely by the trophoblast using precursors derived from the fetal adrenal gland and liver. Levels of this hormone rise throughout pregnancy, with a characteristic exponential increase 2-4 weeks before the spontaneous onset of labor at term. Interestingly, patients undergoing induction of labor at term fail to demonstrate this increase in estriol, indicating that it plays a role in the onset of spontaneous labor. This finding has led to the theory that salivary estriol levels may be used to identify patients at risk for preterm delivery.[145] However, studies did not show any reduction in the preterm birth rate with the use of these assays. A variety of other serologic, salivary, cervical, and amniotic fluid markers have been evaluated as predictors for preterm delivery, including corticotropin-releasing hormone, alpha-fetoprotein, human chorionic gonadotropin, human placental lactogen, corticotropin-releasing factor, C-reactive protein, alkaline phosphatase, ferritin, placental isoferritin, progesterone, estradiol, matrix metalloproteinase, IL-6, TNFα, and granulocyte colony-stimulating factor. Each of these markers has been shown to have a modest correlation with spontaneous preterm delivery, and none is currently useful clinically.[81]

A variety of enzymes including collagenases and metalloproteinases have been studied with regard to their ability to predict preterm birth. IL-1 stimulates cervical, decidual, and other cells to produce various collagenases, which then act to break down the collagen matrix of the cervix. Serum levels of these collagenases remain relatively constant until the onset of labor, when a marked increase occurs. This increase appears to be exaggerated in women who deliver prematurely, with an up-to-eightfold greater elevation in preterm births. In addition to the collagenases, the metalloproteinases and their inhibitors have received increasing interest in regard to their role in predicting preterm birth. In particular, elevated metalloproteinase-2 (MMP-2) and MMP-8 levels have been associated with preterm labor, especially PPROM, likely owing to their role in membrane weakening through degradation of the chorioamnion basement membrane.[14,125] Granulocyte elastase is another granulocyte degradative enzyme that may play a role in parturition. Granulocytes are stimulated by IL-8 (an inflammatory marker that is elevated in amniotic fluid in labor) and then degraded by granulocyte elastase. The activity of granulocyte elastase has been shown to be increased in the cervix in both term and preterm labor, suggesting that it

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

may be involved in cervical ripening and degradation of fetal membranes. Similar to the previous markers, none of these have been shown to either predict or help prevent preterm birth, therefore, they are not used clinically.[29,81,168]

Given the association of occult upper genital tract infection with early spontaneous preterm birth, a variety of serum, amniotic fluid, and cervicovaginal inflammatory markers have also been evaluated as potential markers for the prediction of spontaneous preterm delivery. Both serum and cervical IL-6 levels are significantly elevated at 24 weeks' gestation in women with subsequent spontaneous preterm birth at less than 35 weeks' gestation.[16,23] Rizzo and colleagues further characterized the inflammatory milieu of the cervix and amniotic fluid, showing that levels of several cytokines (IL-1, IL-6, TNFα) were elevated in a series of patients with preterm labor and intact membranes, a finding that was significantly associated with the presence of intra-amniotic infection.[148] In that study, cervical IL-6 was the most potent marker for infection, with an RR of 7.7 (95% CI, 3.5-17.8) in the presence of elevated levels (greater than 410 pg/mL) of this protein.[148] Serum granulocyte colony-stimulating hormone, ferritin, and lactoferrin are examples of other inflammatory markers that may be elevated in asymptomatic women who subsequently deliver prematurely. However, none of these tests is used clinically in low- or high-risk women to predict preterm birth.[16,29,81,168]

Ultrasound Predictors

Regardless of the gestational age at delivery, cervical changes occur before the onset of clinical symptoms associated with preterm labor. Detection of these changes previously involved digital examination only, a test that is problematic because of such possible factors as the introduction of infection, interobserver differences, underestimation of cervical length, and an inability to evaluate the internal cervical os when the external os is closed. In fact, detection of these changes digitally may be possible only late in the process, limiting the clinician's ability to initiate potential treatments. Ultrasonography, therefore, has several potential benefits, allowing for a more objective approach to examination of the cervix with visualization of changes earlier in the process of parturition.[137] Cervical changes visible via ultrasonography include cervical length, dilation of the internal cervical os, dynamic changes that occur in the cervix with time, the presence of intra-amniotic debris, and cervical funneling or wedging.

Transvaginal ultrasound is far superior to transabdominal ultrasound. Transabdominal ultrasound is technically more difficult because the distance between the transducer and the cervix is relatively long, particularly in obese patients. Transabdominal assessment of cervical length and internal os dilation may also be affected by bladder filling and emptying. Finally, fetal parts can cause acoustic shadowing of the cervix when looking abdominally. Transperineal ultrasonography is also effective in the assessment of cervical length, revealing findings that correlate well to those obtained via digital cervical examination and/or transvaginal imaging.[18,79,167]

In a study by Smith and colleagues, low-risk patients were observed serially via transvaginal ultrasonography, showing that the average cervical length of 37 mm remained stable between 10 and 30 weeks of gestation and then began to decrease slightly after week 32. In general, most additional studies reported lengths of more than 30 mm as normal, although this estimate depends upon the population studies and the gestational age at which the length is measured.

Iams and colleagues, in a large multicenter trial, provided the clearest insights into the relationship between cervical length and spontaneous preterm delivery.[86] In this prospective study of 2915 women with a singleton pregnancy, transvaginal sonographic determination of cervical length was obtained at 24 weeks' and again at 28 weeks' gestation. A cervical length less than the 10th percentile (26 cm) at 24 weeks was significantly associated with an increased risk for spontaneous preterm birth at less than 35 weeks' gestation (RR 6.19; 95% CI, 3.84-9.97). An inverse relationship between cervical length and the rate of preterm delivery was noted in this study. The investigators concluded that the risk of spontaneous preterm birth is increased in women who are found to have a short cervix by transvaginal ultrasonography during pregnancy.

Owen and colleagues further evaluated the use of cervical length assessment in a cohort of high-risk women screened between 16 and 18 weeks' gestation.[138] In this study, a cervical length of 25 mm or less was significantly associated with increased risk for spontaneous preterm delivery prior to 35 weeks (RR 3.4; 95% CI, 2.1-5.0). It should also be noted that, in contrast to singleton pregnancies, cervical lengths differ significantly in higher-order gestations, probably reflecting a greater risk for subsequent preterm delivery.[18,167]

Dilation of the internal cervical os and the dynamic nature of the cervix may also be assessed via transvaginal ultrasonography. While increased dilation and the presence of dynamic changes appear to correlate with an increased risk for preterm birth, studies did not show either one to improve the ability of cervical length to predict preterm birth.[29]

Ultrasound assessment of the cervix represents a relatively easy way to identify patients who may be at higher risk for spontaneous preterm delivery, but the positive predictive value of this test is relatively low, and universal screening of all pregnant women remains controversial.[29,167] Cervical length measurements have, therefore, been combined with biochemical parameters in an attempt to improve the specificity and sensitivity of these individual screening tests. However, this combined screening approach does not appear to be superior in identifying women at risk for preterm birth and guiding acute management in such situations.[130]

Prevention

Optimal management of women with a history of spontaneous preterm birth includes a thorough review of the

patient's obstetric, medical, and social history, with particular attention paid to potentially reversible causes of preterm birth (e.g., smoking, acute infections, strenuous activities). Care for these women should also involve accurate ultrasound dating, consideration of progesterone therapy, cerclage, or pessary (depending on clinical history), and close surveillance during the pregnancy for evolving findings.

Programs attempting to decrease the rate of preterm delivery now use three main approaches: (1) education and surveillance programs, (2) cervical assessment, and (3) supplementation with progestins. Education and surveillance programs train women to recognize the symptoms of preterm labor and educate them about lifestyle changes, nutrition, and smoking cessation.

One of the largest intervention studies was conducted by Papiernik and coworkers in France from 1971-1982.[141] These investigators employed the use of a proactive educational program for the prevention of preterm delivery. The preterm birth rate in the region studied apparently fell from 5.4% to 3.7%. These findings are hard to interpret because the investigation was not a controlled trial, such that changes in antenatal care during that decade make it difficult to assume that the improvement was due solely to the educational program. In subsequent studies modeled after the Papiernik design, no statistically significant differences were identified.

Several theories may explain why these studies have failed to demonstrate significant improvements in the rates of preterm birth. First of all, the level of education and supervision may not have been adequate for the patient population under evaluation. The highest incidence of preterm delivery tends to consist of a population of lower socioeconomic status, in which education and surveillance may be more difficult to achieve. More importantly, early symptoms of premature labor are often subtle and varied, with diagnostic sensitivity less than 50%. For example, women often do not perceive contractions until labor is relatively advanced.

Home uterine activity monitoring was, therefore, proposed as a potential solution to this problem. Although some of these earlier and smaller trials of home uterine activity monitoring demonstrated a significant decrease in preterm births among enrolled subjects, trials were not convincing and were criticized due to overdiagnosis of preterm labor and the potentially biased nursing support; in addition subsequent studies have not shown a benefit. Moreover, the use of home uterine activity monitoring may be harmful in that monitoring may lead to unnecessary hospital admissions and/or intervention such as tocolysis or cerclage placement. Experts have, therefore, concluded that home uterine activity monitoring has no clinical value at this time and should not be used to manage patients outside of a randomized, controlled clinical trial.[29]

Although home uterine monitoring is no longer routinely employed, one study demonstrated more promising results in regard to the beneficial effects of preterm birth prevention clinics. Manuck and colleagues evaluated the rates of recurrent spontaneous preterm births in women assigned either to receive care in a consultative preterm birth prevention clinic (70 patients) or a routine prenatal care clinic (153 patients).[105] Women who were seen in the specialized clinic had lower rates of recurrent spontaneous preterm birth (48.6% vs. 63.4%, $p = 0.04$), delivered at a later mean gestational age (36.1 vs. 34.9 weeks, $p = 0.02$), and had lower rates of composite major neonatal morbidity (5.7% vs. 16.3%, $p = 0.03$). These findings suggest that preterm birth prevention clinics may play a role in the care of high-risk women.

Treatment

One of the primary obstacles encountered when deciding on the optimal therapeutic intervention to prevent preterm delivery is the difficulty in accurately distinguishing between preterm labor and preterm contractions. Traditionally, this distinction is made by the combination of persistent uterine contractions with change in the dilation or effacement of the cervix by digital examination. Another issue that must be addressed is how aggressively one should pursue treatment. Gestational age clearly plays an important role in this decision. Before 32 weeks' gestation, an aggressive approach seems reasonable because of the neonatal consequences of early preterm birth. However, beyond this gestational age, when neonatal morbidity and mortality rates begin to approach those of term infants, maternal treatment becomes more controversial. Many of the interventions discussed in this section have the potential for significant maternal and fetal side effects, and the risks of these adverse events must be weighed against the benefits of treatment in each individual patient.

Therapeutic interventions employed in the setting of preterm labor have the following purposes: (1) to prevent premature birth, (2) to control contractions when they do occur and delay the time from onset of contractions to the actual time of delivery, and (3) to optimize fetal status and maturation before preterm delivery. Most efforts to prevent preterm labor have not proven to be effective and, equally frustrating, most efforts at arresting preterm labor once started have also failed. Management has, therefore, focused more on preventing neonatal complications, including antenatal administration of corticosteroids for enhancement of fetal lung maturity, magnesium sulfate for fetal neuroprotection, and intrapartum antibiotics for prevention of group B streptococcal neonatal sepsis. Ensuring delivery in a medical center with an experienced resuscitation team and the availability of a high-quality newborn intensive care unit also helps to optimize neonatal outcomes.

Bed Rest

Bed rest is one of the most common interventions implemented for the prevention or treatment of threatened preterm labor, but limited data exist to demonstrate significant benefit with this recommendation. Although bed

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

rest is prescribed for up to 20% of pregnancies and a wide range of conditions, there is little evidence of effectiveness. Unfortunately, no conclusive, well-performed, prospective, randomized studies exist that have independently evaluated the potential effects for the treatment or the prevention of preterm labor in singletons. Despite a lack of evidence proving that bed rest is beneficial, many obstetricians recommend bed rest for arrested preterm labor and PPROM. In Canada, although care providers have been discouraged from routinely recommending bed rest for women at risk of preterm birth because of potential adverse side effects (i.e., venous thromboembolism, muscle weakness, bone loss, and maternal depression), most providers have not incorporated these recommendations into clinical practice.[169]

McCall et al. reviewed the evidence for bed rest and concluded that "therapeutic" bed rest continues to be used widely despite evidence of no benefit and known harms. Cochrane systematic reviews do not support "therapeutic" bed rest for threatened abortion, hypertension, preeclampsia, preterm birth, multiple gestations, or impaired fetal growth. This assessment has been echoed in other comprehensive reviews. Prescribing bed rest is inconsistent with the ethical principles of autonomy, beneficence, and justice. Hence, if bed rest is used, it should be only within a formal clinical trial.[112]

Hydration or Sedation

One of the mainstays in the initial treatment of preterm labor is the use of oral or intravenous hydration. At least two theories exist in regard to the mechanism of action behind hydration as a potentially effective treatment for preterm contractions. The first theory holds that hydration inhibits the release of antidiuretic hormone through the Gauer-Henry reflex. This reflex, however, has been demonstrated only in animals. The second theory is based on the suggestion that patients with preterm labor are hypovolemic, a theory supported by the delay in delivery that may be seen when women with preterm contractions are treated with albumin in an effort to expand plasma volume. Despite these theories, few studies have prospectively evaluated the use of hydration in women with preterm contractions, and those that do exist actually suggest no benefit to this intervention. For example, in one trial, the combination of bed rest and aggressive hydration was found to be no more effective than bed rest alone in stopping contractions. When the contractions actually did stop, patients in both groups remained at equally high risk for subsequent preterm birth. Another study by Guinn and colleagues reported similar findings in a prospective, randomized trial of 179 women with preterm contractions.[67] Patients were randomized to one of three arms: observation alone, intravenous hydration, or a single dose of subcutaneous terbutaline. No significant differences were noted among the three groups in regard to the interval between intervention and delivery or the incidence of preterm birth, suggesting that intravenous hydration offers no clinical benefit.

Sedation is another strategy that has been used to differentiate between preterm contractions and true preterm labor. As with hydration, limited data document the efficacy of sedation in this clinical setting. Helfgott and associates performed a prospective comparative study of 119 women with preterm labor who were randomly assigned to treatment with hydration and sedation or to the control treatment of bed rest alone. Women in the treatment arm received a combination of 8-12 mg of intramuscular morphine sulfate and 500 mL of intravenous lactated Ringer's solution. No significant differences in contraction cessation or preterm labor rates were seen between the patients assigned to receive hydration and sedation and those assigned to bed rest alone.

Overall, current research does not support the use of hydration or sedation in the initial treatment of preterm labor. Clinically, in many cases, initial hydration with intravenous infusion of fluid occurs before initiating treatment with a tocolytic agent. In addition to being ineffective, aggressive hydration may increase the risk of fluid overload and subsequent development of pulmonary edema when used in the setting of tocolytic therapy, especially with β-sympathomimetic agents.

Progesterone

Based on the progesterone withdrawal theory of parturition initiation, use of progesterone or similar other progestins has been proposed for the prevention of preterm labor and delivery.[167]

Several randomized controlled trials have confirmed the efficacy of progesterone therapy for the prevention of preterm birth.[167] Da Fonseca and colleagues performed a double-blinded, placebo-controlled trial of 142 high-risk pregnancies in which they showed a significant reduction in preterm birth rates prior to 37 weeks' gestation in women assigned to receive weekly progesterone vaginal suppositories (13.8% compared with 28.5% in the control group, $p < 0.05$).[40] Preterm birth prior to 34 weeks was also significantly lower in the progesterone group when compared with the placebo group (2.7% vs. 18.5%, respectively, $p < 0.05$). Meis and colleagues from the National Institute of Child Health and Human Development (NICHD) Maternal-Fetal Medicine Units (MFMU) Network reported similar results from a large randomized clinical trial designed to evaluate the efficacy of 17α-hydroxyprogesterone caproate for the prevention of preterm birth in high-risk women.[116] Among women receiving weekly intramuscular progesterone therapy from 16-36 weeks' gestation, the incidence of preterm birth prior to 37 weeks' gestation was 36.3%, compared with an incidence of 54.9% in the placebo group (RR 0.66; 95% CI, 0.54-0.81). The incidence of preterm birth at less than 35 weeks (RR 0.67; 95% CI, 0.48-0.93) and at less than 32 weeks (RR 0.58; 95% CI, 0.37-0.91) was also significantly decreased in women treated with progesterone when compared with placebo. Fonseca et al. screened more than 24,000 women and enrolled 1.7% of them whose

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

cervical length was less than 15 mm (less than third percentile). Women randomized to 200 mg vaginal progesterone suppositories had a lower preterm birth rate (19% vs. 44%; RR 0.56; 95% CI, 0.36-0.86) compared with those randomized to placebo.[50] Hassan and colleagues screened more than 32,000 women worldwide and enrolled those with cervical length of 10-20 mm. Four hundred sixty-five women were randomized to 90 mg vaginal progesterone gel (daily until 36 weeks) and had lower rates of preterm birth before 28, 33, and 35 weeks compared with placebo. Neonatal morbidity and mortality were also lower in treated women (7.7% vs. 13.5%; RR 0.57; 95% CI, 0.33-0.99).[75]

However, as the number and size of such trials have increased, the role of progesterone in preventing prematurity has become less clear. O'Brien and colleagues conducted a randomized, double-blind, placebo-controlled, multinational trial evaluating whether prophylactic administration of vaginal progesterone would reduce the risk of preterm birth in high-risk women with a history of spontaneous preterm birth.[135] Therapy with either progesterone vaginal gel or placebo was initiated between 18 weeks and 0 days and 22 weeks and 6 days of gestation, and patients were asked to continue once-daily treatment until delivery, 37 weeks' gestation, or development of preterm rupture of the membranes. In this trial, progesterone did not decrease the frequency of preterm birth at less than or equal to 32 weeks, and there was no difference between the groups with respect to the mean gestational age at delivery, infant morbidity or mortality, or other maternal or neonatal outcome measures.[135] However, examination of a subset of this cohort in a planned secondary analysis revealed that vaginal progesterone may reduce the rate of early preterm birth and improve neonatal outcome in women with a short sonographic cervical length in addition to a history of a prior spontaneous preterm birth.[42] Moreover, the use of vaginal progesterone in high-risk women was investigated recently in the OPPTIMUM study, published in 2016. This was a large (1228 subjects), multicenter, double-masked randomized trial comparing 200 mg of vaginal progesterone per day to placebo in women at high risk for preterm birth, including those with previous spontaneous birth at less than or equal to 34 weeks' gestation, or a cervical length less than or equal to 25 mm, or those with positive fetal fibronectin test combined with other clinical risk factors for preterm birth. Progesterone supplementation did not reduce the risk of preterm birth or composite neonatal outcomes and had no long-term benefit on outcomes of children at 2 years of age. In addition, in a subgroup of women with a history of a prior spontaneous preterm birth (n = 903), there were no significant differences in the rate of preterm birth less than 34 weeks of gestation between those receiving vaginal progesterone and placebo (15.9% vs. 18.8%).[133]

Use of progesterone has also been investigated in other populations, with varying results. For example, progesterone use has been investigated in women following arrest of acute preterm labor. Rozenberg and colleagues performed an open-label, multicenter, randomized controlled trial enrolling women presenting with preterm labor symptoms and a cervical length measurement less than 25 mm.[154] After successful tocolysis, women were assigned to either receive intramuscular progesterone injections or placebo until 36 weeks' gestation, with no benefit seen in the prevention of preterm birth in the group assigned to the progesterone arm of the trial.[154]

Progesterone has also been evaluated in the setting of multiple gestations, with most studies showing no reduction in rates of preterm birth in women with twin and triplet gestations.[152,167] Progesterone use has been examined in otherwise low-risk patients with cervical shortening. In a large, multicenter, randomized controlled trial enrolling nulliparous women with cervical shortening (<30 mm), Grobman and associates within the MFMU Network showed no benefit in regard to prevention of spontaneous preterm birth in women assigned to weekly 17 α-hydroxyprogesterone caproate as compared with placebo.[62]

In addition to the controversies with the use of progesterone, these studies lead to another one regarding the use of transvaginal ultrasonography, with some experts espousing universal screening of all patients and others recommending a risk-based screening approach. Currently, the Society for Maternal Fetal Medicine and the American College of Obstetricians and Gynecologists recommend the use of intramuscular 17 hydroxyprogesterone caproate to singleton women with a history of prior spontaneous preterm birth and vaginal progesterone to women with a cervical length of 20 mm or less before 25 weeks' gestation.[29,165,167]

Cerclage

Cerclage is a procedure in which a nonresorbable suture is placed in simple purse-string fashion at the level of the internal os. It can be placed either transvaginally or transabdominally. The transvaginal approach consists mainly of two techniques: McDonald (suture placed at the cervicovaginal junction) and the Shirodkar (the suture is placed as close to the internal cervical os by dissecting the vesicocervical mucosa). The transabdominal approach is usually performed due to anatomic limitations (prior trachelectomy) or history of prior failed transvaginal approach. Indications for cervical cerclage include: history of second trimester painless cervical dilation 1 or more times that resulted in pregnancy loss in the absence of abruption or labor; second trimester findings on physical exam consistent with painless dilated cervix; history of preterm less than 34 weeks and with cervical length less than 25 mm before 24 weeks' gestation.

Cerclage is most beneficial in women with prior cervical insufficiency when placed electively before any cervical change. This case scenario leads to low rates of complication and high cerclage success rates.

The optimal time for cerclage placement is early second trimester (12-14 weeks), since miscarriage rates are more likely to occur before this interval and major anatomic anomalies (e.g., anencephaly) can be detected by this period.

In addition, this period allows obstetricians to perform early aneuploidy testing by chorionic villus sampling. The upper limit of gestational age, by which cerclage placement is contraindicated, remains controversial. It is generally accepted that after fetal viability (23-24 weeks' gestation), complication risks outweigh the potential benefits of the intervention, and cerclage should not be attempted. Moreover, interventional trials that elucidated the efficacy of cerclage limited gestational age at 24 weeks for screening and initiation of therapies. It is not recommended to place a cerclage after 24 weeks; above this gestational age, there should be extensive counseling about benefits and risks of the procedure when the patient desires cerclage placement.

Contraindications to cerclage placement include rupture of membranes, evidence of intrauterine infection, major fetal anomalies, active vaginal bleeding of unknown cause, and active labor. Potential morbidities associated with cerclage placement include bleeding, infection, rupture of membranes, maternal soft tissue injury, spontaneous suture displacement, and the risks of anesthesia. Additional complications may be seen in association with delivery, including cervical laceration in up to 13% of cases. Rare reports of uterine rupture have also been reported in patients in whom labor occurred before suture removal. Scarring of the cervix from the procedure may also contribute to an increased incidence of cesarean delivery.

Cerclage success rates were first reported to be greater than 75%. These initial findings may have been misleading. Since pregnancy outcomes in the intervention group were compared to outcomes of prior pregnancies, the trials did not account for patients that may have a successful pregnancy even after repeated mid-trimester losses.

Several trials that followed evaluated the efficacy of cerclage in women with a history of preterm birth rather than with classical history of cervical insufficiency. The majority of these studies showed no advantage of cerclage in reducing the rates of preterm birth, PPROM, or perinatal mortality, despite being associated with higher administration rates of tocolytic agents and of hospitalization. In a large study conducted by the Royal College of Obstetricians and Gynaecologists, 1292 patients with a history of either an early delivery or a prior cervical surgery were randomly assigned to cerclage placement or expectant management.[144] Significantly fewer deliveries occurred prior to 33 weeks in the cerclage group (13% versus 17%), but a higher incidence of puerperal pyrexia was also demonstrated in this treatment group.[144] Limitations of all of these studies included the ill-defined subjective enrollment criteria and the lack of statistical power to adequately address neonatal morbidity outcomes.

As discussed, the use of transvaginal cervical sonography has greatly altered current recommendations regarding cerclage placement for singleton gestations. Cerclage placement has been shown beneficial in women with history of preterm birth and a short cervix. Several prospective studies have been conducted using cervical length shortening as a marker to determine the patient population who may best benefit from cerclage placement for the prevention of recurrent preterm birth.[4,17,19,63,176] Althuisius and colleagues reported findings from a small randomized trial comparing the efficacy of therapeutic cerclage plus bed rest with bed rest alone for the prevention of subsequent preterm birth in women with an ultrasonographically determined short cervix (less than 25 mm) before 27 weeks' gestation.[4] Use of cerclage in this study was associated with a significant reduction in the incidence of preterm birth prior to 34 weeks when compared with women treated with bed rest alone (0% vs. 44%; $p < .002$).[4] In contrast, To and colleagues, in a large multicenter randomized trial of cervical cerclage for women with an ultrasound-detected short cervix (less than 15 mm) between 22 and 24 weeks' gestation, reported that the use of prophylactic Shirodkar cerclage did not significantly reduce the incidence of preterm birth at less than 33 weeks' gestation when compared with expectant management (22% vs. 26%; $p < .44$).[176] A meta-analysis by Belej-Rak and colleagues evaluated the literature relating to the effectiveness of cervical cerclage in women with a sonographically detected shortened cervix.[17] Based on this systematic analysis of six pertinent trials, the authors reported that there was no statistically significant effect of cerclage on the rates of preterm birth (less than 37, less than 34, less than 32, and less than 28 weeks).[17] Singleton pregnancies with history of prior preterm birth have shown to have a greater than 30% risk of developing a short cervix (<25 mm) before 24 weeks.[19,136] Owen et al. randomized 302 women with a history of preterm birth and cervix length of <25 mm to either have or not have cerclage placed. In this large multicenter trial, women with cerclage had reduced perinatal death by almost 50% (8% vs. 16%), and reduced births before 24 weeks (6.1% vs. 14%) and before 37 weeks (45% vs. 60%).[136] In the same high-risk population, Berghella et al. performed a meta-analysis review that showed a 30% reduction in preterm birth rate at less than 35 weeks' gestation[20] (28% vs. 41%; RR 0.70; 95% CI, 0.55-0.89). The composite perinatal morbidity and mortality was also reduced by 36% (16 vs. 25%; RR 0.64; 95% CI, 0.45-0.95) in the cerclage group.

Cerclage placement in women with multiple gestations and short cervix (CL < 25 mm) has been associated with a twofold increase in preterm birth (RR 2.15; 95% CI, 1.15-4.01).[20] In light of these results, cerclage placement is not recommended in the setting of multiple gestation.

Removal of the cerclage is normally performed at about 36-37 weeks' gestation unless active preterm labor begins before that time. There are no prospective studies to guide management of women with cerclage in the setting of PPROM. Retrospective studies report conflicting results but have generally concluded that retaining the cerclage for 24 hours after PPROM was associated with pregnancy prolongation.[55] Due to their retrospective nature, the studies' results may have been biased due to other confounders such as preterm labor or infection. Other studies reported that cerclage retention after PPROM was associated with increased neonatal deaths due to infection, sepsis, chorioamnionitis,

and respiratory distress syndrome.[55,101] While cerclage retention may certainly be reasonable to permit completion of a course of antenatal corticosteroids, prolonged retention should be undertaken only with extreme caution. ACOG does not recommend antibiotic prophylaxis beyond 7 days if the cerclage remains in place.

Current ACOG and SMFM guidelines recommend progesterone supplementation to all pregnant women with history of prior preterm birth.[29,167] Cerclage placement has been shown to best benefit this patient group if short cervix is noted by transvaginal ultrasound (cervical length [CL] <25 mm).[19,136] In a meta-analysis review that included 169 pregnant women with history of preterm birth and CL less than 25 mm occurring at less than 25 weeks' gestation, vaginal progesterone was shown to decrease preterm birth rates at less than 33 weeks (RR 0.54; 95% CI, 0.30-0.98).[150]

Currently, it is recommended that women with a singleton gestation and a history of prior preterm birth receive progesterone prophylaxis until term, and undergo transvaginal serial cervical surveillance early in the second trimester to determine which patients are candidates for cerclage placement.[19,85,167]

Pessaries

Use of pessaries for the prevention of preterm birth in women at risk for preterm birth has been evaluated and was first proposed in the 1950s. While several different pessary types have been used, the Arabin pessary, a flexible ringlike silicone device, has been most effective in published trials. This pessary is designed such that the smaller inner diameter should fit around the cervix snugly, thereby mechanically holding the cervix closed in an effort to prevent exposure of fetal membranes to the vaginal flora.[13] Placement of the pessary changes the inclination of the cervical canal, directing it posteriorly so that the weight of the pregnancy centers on the anterior lower segment.[13]

The PECEP trial, the largest trial to date, was a randomized controlled trial that enrolled women with cervical shortening (cervical length ≤25 mm), 192 of whom were assigned to receive an Arabin pessary with 193 assigned to expectant management.[61] Twelve women (6%) delivered before 34 weeks' gestation in the pessary arm compared with 51 women (27%) in the expectant management arm, an 82% reduction.[61] Despite these encouraging positive results, evidence from two recent RCTs did not show such benefit.[83,131] Data from two large clinical trials showed no benefit in women with asymptomatic twins with no other risk factors (not screened for short CL) that received pessaries.[103,132]

Recently, three prospective studies elaborated the role of pessaries in preventing preterm birth in women with multiple gestations and with a short cervix (CL ≤25 mm before 25 weeks' gestation).[60,103,132] The Arabin pessary was used in all the trials. Only two out of the three RCTs supported the use of pessaries in this population by significantly reducing rates of preterm birth.[60,103] A recent review pooled the above-referenced RCTs and reported no significant differences in preterm birth rates or neonatal outcomes among the group that received pessary versus no pessary group.[156]

The role of pessaries in preventing preterm birth remains unanswered. We are still awaiting several RCTs to be completed. We recommend not to use pessaries for prevention of preterm birth, and their use should be only reserved for research purposes.

Tocolytics

In the United States, up to one in eight children are born before 37 weeks.[109] Despite being poorly understood, preterm birth's impact on neonatal morbidity and mortality is detrimental, with skyrocketing health care costs,[111] emphasizing the importance in identifying an efficacious treatment for this burden. The optimal tocolytic agent remains to be determined, and RCTs evaluating their efficacy have been hindered by various obstacles. Designing clinical trials to test tocolytics is complicated in that the health of two patients must be considered. These trials also face problems related to the fact that the nature of preterm birth and its outcomes are different in the setting of early preterm labor (less than 28 weeks) as compared with late preterm labor (34-36 weeks). Maintenance tocolysis has not been shown to be effective in improving neonatal outcomes nor preventing preterm birth,[43,73] whereas short-term tocolysis has been shown to be superior to placebo.[70] Given the difficulty in predicting and preventing preterm birth, management has been focused on patients admitted for preterm labor. In the latter case, the most important intervention to date is the administration of antenatal corticosteroids.[5] Hence, the primary objective of tocolytic administration has been shifted to preserve pregnancy for at least 48 hours to allow steroid administration, magnesium for neuroprotection, or transportation to a higher level of care facility.

β-Sympathomimetic Agents

In general, β-sympathomimetic tocolytic agents are β2 selective agents. β2 receptors are located in the uterus, blood vessels, bronchioles, and liver. These agents bind to β2 receptors as agonists and activate the cyclic AMP pathway, leading to intracellular depletion of calcium. The latter decreases myometrial contractility and ultimately leads to smooth muscle relaxation. Despite being β2 selective, when administered in vivo at the dosages used pharmacologically, these agents stimulate nonselective β-receptors throughout the body, leading to many adverse effects, thus limiting their clinical use. In the United States, terbutaline is the most common β2-adrenergic agonist used in obstetrics. Ritodrine is no longer available in the US market despite being the most studied and the only FDA-approved tocolytic agent.

Ritodrine

Initial studies supported its use as an efficient tocolytic agent with minimal side effects.[119] In addition, these studies

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

showed a statistically significant effect on pregnancy prolongation, with a reduction in neonatal morbidity and mortality.

Subsequent reports have not been as positive with respect to neonatal morbidity and mortality. Ritodrine treatment has still been shown to significantly delay delivery but not to significantly modify perinatal outcomes. King and associates conducted a meta-analysis involving 16 clinical trials with a total of 890 women, demonstrating that women treated with ritodrine had significantly fewer deliveries within 24 and 48 hours of the start of therapy[96]; however, no statistically significant decrease in the incidence of RDS, birth weight less than 2500 g, or perinatal death was demonstrated. Of note, these studies were completed before the use of antenatal steroid therapy had become widespread.

Ritodrine can be administered either intravenously or orally. Treatment usually begins with intravenous infusion. The patient should be closely monitored for fluid balance, cardiac status, electrolytes (including potassium and glucose), and fetal well-being. The initial infusion rate of 100 μg/min described by Barden and colleagues[15] may be too high. A study by Caritis and coworkers suggested that there is an adequate response using an initial infusion of 50 μg/min with a maximum rate of 350 μg/min.[25] With cessation of uterine activity, the rate should be reduced at hourly intervals. Due to its half-life of 1-2 hours, oral ritodrine has a rigorous dosing scheme of either 10 mg every 2 hours or 20 mg every 4 hours. Plasma levels with oral dosing are only 27% of those obtained with intravenous infusion, suggesting that a higher dose may be needed to maintain adequate plasma levels. Relative contraindications to ritodrine use include diabetes mellitus, underlying cardiac disease, use of digitalis, hyperthyroidism, severe anemia, and hypertension.

Many of the maternal side effects result from stimulation of beta receptors throughout the body. These side effects include tachycardia, hypotension, tremulousness, headache, fever, apprehension, chest tightness or pain, and shortness of breath. Serious maternal cardiopulmonary side effects reported with the use of ritodrine include pulmonary edema, myocardial ischemia, arrhythmia, and even maternal death.[15] Pulmonary edema may occur in up to 4% of patients receiving parenteral ritodrine. Predisposing factors associated with this serious complication include multiple gestations, positive fluid balance, blood transfusion, anemia, infection, polyhydramnios, and underlying cardiac disease. Pulmonary edema probably results from overhydration and activation of the renin-angiotensin system, resulting in an increase in aldosterone, and thus subsequent salt and water retention. If untreated, the pulmonary edema can progress to adult RDS. The concurrent use of corticosteroids has been associated with an increased risk for development of pulmonary edema. The two most commonly used antepartum steroids, betamethasone and dexamethasone, have minimal mineralocorticoid activity and are thus unlikely to contribute greatly to this complication. Another serious complication, peripartum heart failure, has also been reported with long-term use of β-sympathomimetics. A baseline electrocardiogram should be obtained before the start of therapy, and therapy should be discontinued when patients develop a heart rate greater than 130 beats per minute or systolic blood pressure less than 90 mm Hg.

Metabolic effects of ritodrine include hypokalemia. Hypokalemia results from increases in insulin and glucose concentrations, which drive potassium intracellularly. This imbalance is transient, resolving within 24 hours of discontinuing therapy. Total body potassium remains unchanged. Elevated serum glucose levels are the result of an increase in cyclic adenosine monophosphate, with peak levels achieved 3 hours after initiation of treatment. Serum insulin levels increase both in response to the serum glucose elevation and also because of a direct effect of β2 stimulation of the pancreas. Furthermore, β1 stimulation results in lipolysis and mobilization of free fatty acids, acetoacetate, and β-hydroxybutyrate. In patients with diabetes mellitus, diabetic ketoacidosis may occur if blood sugar concentrations are not adequately controlled.

Initial studies evaluating long-term exposure to β-sympathomimetics demonstrated no differences in Apgar scores, head circumference, or neurologic status (i.e., development of developmental delay and behavioral differences), but fetal cardiac complications have been reported. These medications readily cross the placental barrier, achieving concentrations in the fetus similar to those in maternal serum. Elevation in the baseline fetal heart rate is seen, as is a questionable increase in heart rate variability. A wide range of complications has been described, including rhythm disturbances such as supraventricular tachycardia and atrial flutter. These usually resolve within 2 weeks after cessation of therapy. Septal hypertrophy in the fetus and neonate has also been described with maternal ritodrine treatment. The degree of hypertrophy correlates with the duration of therapy, and this finding usually resolves within 3 months of age.

Other, more serious fetal complications have been described as well, including hydrops fetalis, pulmonary edema, extrauterine cardiac failure, intrauterine fetal demise, neonatal death, and myocardial ischemia. Neonatal hypoglycemia is another potential complication with β-sympathomimetics. This usually develops when delivery occurs within 2 days of treatment, and the hypoglycemia is transient, resulting from medication-induced hyperinsulinemia. Finally, neonatal periventricular-intraventricular hemorrhage may be increased with β-sympathomimetic therapy. In a retrospective study of 2827 women delivering preterm, there was a twofold increase in hemorrhage in fetuses that received beta-mimetics.[64] Ritodrine has thus fallen out of favor as a primary tocolytic agent, largely as a result of these potential complications.

Terbutaline

Terbutaline was initially studied by Ingemarsson, who randomly assigned 30 patients with preterm labor to either

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

intravenous terbutaline therapy or placebo. Ingemarsson demonstrated an 80% success rate in comparison to only 20% for the placebo.[88] Unfortunately, as with other tocolytic agents, subsequent studies did not show such positive results.

Terbutaline can be administered via oral, subcutaneous, and intravenous routes. When administered intravenously, clinicians must carefully monitor the fetus, fluid balance, cardiac status, and electrolytes. The initial infusion rate is 5-10 μg/min, and the rate is gradually increased every 10-15 minutes to a maximum of 80 μg/min. Orally administered terbutaline undergoes significant first-pass metabolism in the intestinal tract, resulting in a bioavailability ranging from only 10%-15%. The mean half-life of oral terbutaline is 3.7 hours, with increased clearance noted in pregnant patients. The usual oral dosages range from 2.5-5 mg every 4-6 hours, adjusted by patient response and maternal pulse. Subcutaneous regimen is the most common route of administration, and it usually involves 250-μg doses every 20-30 minutes (four to six doses). Although subcutaneous terbutaline administration is one of the first-line tocolytic agents for preterm labor, it has no effect on actual preterm birth rates.

One possible explanation for the failure of long-term treatment with β-sympathomimetics is a phenomenon involving desensitization or downregulation of responsiveness to these agents. The use of a low-dose subcutaneous infusion pump attempts to overcome this problem. Lam and colleagues compared the use of the terbutaline pump with oral terbutaline therapy.[100] The average duration of therapy before breakthrough of preterm labor was 9 weeks with the pump and 2 weeks with oral administration of terbutaline. Total daily drug dosage was also considerably lower (3 mg versus 30 mg/day) with the pump.[100] Guinn and associates conducted a prospective, double-blind, randomized clinical trial comparing terbutaline pump maintenance therapy with placebo, demonstrating no significant differences in either the preterm delivery rate or neonatal outcomes.[68] A Cochrane review of 11 RCTs (1322 women) showed that β2 agonists were associated with decreased risk of delivery within 48 hours (RR 0.63; 95% CI, 0.53-0.75) despite having no significant effect in perinatal morbidity or mortality.[12] Another review of 95 RCTs demonstrated similar results; the probability to delay delivery within 48 hours was higher in the group of women that received β2 agonists (OR 2.41; 95% CI, 1.27-4.55). β2 agonists had higher rates of adverse effects that required physicians to opt for another alternative agent (OR 22.68; 95% CI, 7.51-73.67).[70]

Maternal side effects and complications are similar to those stated for ritodrine. Terbutaline seems to affect the maternal heart rate less than ritodrine when administered intravenously. However, both oral and intravenous forms of terbutaline are more diabetogenic than ritodrine. Interestingly, subcutaneous administration of terbutaline via pump does not appear to increase the risk of gestational diabetes but does cause elevations in blood glucose levels in patients with diabetes. Neonatal effects of maternally administered terbutaline are similar to those of ritodrine.

In 2011, a warning was released by the US Food and Drug Administration (FDA) concerning terbutaline administration to treat preterm labor secondary to serious maternal side effects.[179] Another study reported an association between antenatal exposure of the drug and offspring adverse behavioral effects.[184] Based on the above evidence, it is recommended to limit the use of terbutaline only for inpatient short-term tocolysis or for the acute management of uterine tachysystole.

Magnesium Sulfate

Magnesium sulfate has been one of the most commonly used tocolytic agents, especially since it has been shown to have fetal neuroprotective effects. Magnesium appears to have similar efficacy with fewer side effects than terbutaline.

Magnesium has tocolytic properties by acting as a calcium competitor in the sarcoplasmic reticulum, diminishing the interaction of calcium with the actin-myosin complex and interfering with myometrial repolarization.[72,98] Magnesium may also block influx of extracellular calcium and disrupt intracellular release of calcium via inositol triphosphate pathways. Ultimately, the release of acetylcholine at the neuromuscular junction is decreased, leading to decreased amplitude of motor endplate potential and leading to decreased sensitivity.

Magnesium sulfate is administered intravenously and is normally given as an initial bolus of 4-6 g over 30 minutes, followed by a maintenance infusion of 1-4 g/hr. In contrast to intravenous magnesium sulfate for tocolysis, oral magnesium therapy is not effective for the treatment of preterm labor.

Magnesium is a bivalent cation, and it is the second-most common intracellular cation.[48] Less than 1% is found extracellularly. It is most commonly found in bone (53%), followed by myocytes (27%).[185] Most extracellular magnesium is in ionized form and its serum level drops in pregnancy secondary to hemodilution of pregnancy.[99,183] It is transported across the cell membrane through a sodium-ATP-dependent transporter.

Magnesium is almost exclusively excreted by the kidneys. Approximately 75% of the infused dose of magnesium is excreted during the actual infusion, with 90% excretion by 24 hours. Magnesium is reabsorbed at the renal level by a transport-limited mechanism; therefore, the glomerular filtration rate significantly affects excretion. Serum magnesium levels of 5-8 mg/dL are considered therapeutic for inhibiting myometrial activity on the basis of in vitro studies. Once cessation of uterine activity is achieved, the patient is maintained at the lowest possible rate for 12-24 hours and then weaned off as tolerated.

Maternal side effects caused by magnesium sulfate are typically dose related. Common side effects include flushing, heat intolerance, nausea, headache, drowsiness, and blurry vision. Constant monitoring of deep tendon reflexes is mandatory to avoid toxicity. Diminished deep tendon

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

reflexes occur when serum magnesium levels reach or exceed 12 mg/dL (10 mEq/L). Significant respiratory depression can occur as serum levels reach 14-18 mg/dL (12-14 mEq/L), and cardiac arrest may occur with levels greater than 18 mg/dL (15 mEq/L). In general, respiratory depression does not occur before loss of deep tendon reflexes. The toxic effects of high magnesium levels can be rapidly reversed with the infusion of 1 g of calcium gluconate.

Magnesium sulfate is absolutely contraindicated in patients with myasthenia gravis or heart block. It is relatively contraindicated in patients with underlying renal disease or a history of a recent myocardial infarction. It is also relatively contraindicated in women who are receiving calcium channel blockers.

Pulmonary edema has been reported to have an incidence of approximately 1%. The risk for pulmonary edema is increased in patients with multifetal gestations and in those receiving combined tocolytic therapy. Because of the potential risk of fluid overload and the subsequent development of pulmonary edema, periodic assessment of fluid balance is essential.

Magnesium readily crosses the placenta, achieving fetal steady-state levels within hours after the start of treatment. No significant alterations in neurologic status or Apgar scores have been reported with mean umbilical cord concentrations of 3.6 mg/dL. At a cord concentration between 4 and 11 mg/dL, though, apnea, hypotension, refractory bradycardia, respiratory depression, hypotonia, and motor depression have been reported. Long-term use of magnesium (greater than 7 days) has been shown to cause fetal bone loss in the proximal humerus, a finding of unclear significance since these cases were based on unsolicited reports to the FDA's Adverse Event Reporting System (18 cases) and epidemiologic analysis with design concerns.[80,110,114,127,161,187]

Consequently, the FDA released a warning against using magnesium sulfate for more than 5-7 days for the sole purpose of preventing or treating preterm labor. As a result, the safety drug classification for magnesium was changed from class A-D.[51] ACOG and SMFM followed with a statement advising obstetricians to continue using magnesium for the following indications[30]:

- seizure prophylaxis in preeclampsia or treatment of eclampsia,
- fetal neuroprotection before anticipated early preterm (less than 32 weeks of gestation) delivery,
- short-term prolongation of pregnancy (up to 48 hours) to allow for the administration of antenatal corticosteroids in pregnant women who are at risk of preterm delivery within 7 days.

Mercer et al. reviewed the role of magnesium sulfate as a tocolytic agent.[117] Only three out of the four RCTs comparing magnesium sulfate as control or placebo evaluated its effect on delivery within 48 hours or within 7 days.[36,37,52,82] Magnesium did not affect preterm delivery within 48 hours (RR 0.75; 95% CI, 0.54-1.03). The same results were noted for delivery before 37 weeks or within 7 days. There was also no improvement in neonatal morbidities. Compared to magnesium, alternate tocolytic agents (total of 16 RCTs: beta mimetics, calcium channel blocker, and cyclooxygenase inhibitors) did not show any additional improvements in delivery at 48 hours, 7 days, preterm delivery, or low birth weight. In summary, there is no evidence supporting the use of magnesium as a tocolytic agent, even when used short term. In the meantime, no other tocolytic agent has been shown to be superior to magnesium.

Initial observational studies suggesting the beneficial role of magnesium in decreasing neonatal neurologic morbidities occurred in the early 1990s.[129,139,162] Since then, several RCTs were performed to elucidate this role.[38,107,108,120,121,153] Mittendorf et al. included women in preterm labor before 34 weeks and cervical dilation greater than 4 cm ($N = 57$) that were randomized to either magnesium or placebo.[120,121] Infant death was not increased in the neuroprotection group, but when performing a secondary analysis of magnesium sulfate versus other tocolytic agents, infant death was significantly increased in the former group. This led to early termination of the trial. This was followed by a multicenter placebo-controlled trial that included women with planned or expected delivery within 24 hours at less than 30 weeks' gestation. Infant death or cerebral palsy or both by 2 years of age was not different in the women who received magnesium.[38] Secondary analysis showed that infants exposed to magnesium had less frequent inability to walk without assistance. Another placebo-controlled trial included 564 gravid women less than 33 weeks' gestation, with planned or expected delivery within 24 hours.[108] There was no significant difference in infant death or severe white matter injury or both before discharge or in a 2-year follow-up among groups. Although there was no decrease in cerebral palsy in the long-term follow-up, the authors reported reduction in "gross motor dysfunction" or "motor" or "cognitive dysfunction" in the magnesium group. This was followed by a large multicenter trial that included 2241 gravid women at less than 32 weeks' gestation with imminent risk of delivery before 32 weeks' gestation.[153] Subjects were randomized to receive either magnesium or placebo. The magnesium treatment group had a significant reduction in moderate to severe cerebral palsy. When performing a prespecified secondary analysis, magnesium reduced cerebral palsy by greater than 30% (4.2 vs. 7.3%, $p = 0.004$). Pooling the results from the above RCTs, Doyle et al. suggested that antenatal administration of magnesium sulfate for neuroprotection decreased the incidence of cerebral palsy[44] (RR 0.71; 95% CI, 0.74-0.98). These results were confirmed in two other metanalyses.[31,34] Based on the above evidence, magnesium sulfate, when given before early preterm delivery, reduces the risk of cerebral palsy in surviving infants.

Prostaglandin Synthetase Inhibitors

Because prostaglandins appear to play a pivotal role in the pathway leading to preterm labor and delivery, attempts to interrupt this cascade of events are of utmost importance.

Prostaglandins are 20-carbon cyclopentane carboxylic acids derived from membrane phospholipids (primarily arachidonic acid) via the enzymatic action of phospholipase A and cyclooxygenase (prostaglandin synthetase). Because a number of drugs are available that inhibit the action of prostaglandin synthetase (e.g., aspirin, ibuprofen, indomethacin, sulindac), this pathway represents a key target for pharmacologic intervention. Of these drugs, indomethacin has been the most extensively studied. It reversibly binds to cyclooxygenase.

Indomethacin

A 2005 Cochrane review that was updated in 2010 identified three trials comparing prostaglandin inhibitors to placebo in the treatment of preterm labor.[94] One RCT, despite its small sample size, showed a significantly lower rate of preterm deliveries earlier than 37 weeks' gestation (RR 0.21; 95% CI, 0.07-0.62) in women who received prostaglandin inhibitors. The authors also reported a nonsignificant trend toward lower risk of delivery before 37 weeks' within 48 hours (RR 0.20; 95% CI, 0.03-1.28) or within 7 days of receiving the tocolytic agent (RR 0.41; CI, 0.1-1.66) when receiving this class of agent. The authors concluded that these results should be taken with caution due to the small sample size involved in the review.

Another meta-analysis showed that out of 1000 gravid women receiving prostaglandin inhibitors, only 80 would deliver within 48 hours, versus 182 (for the next best treatment). The authors conclude that prostaglandin inhibitors should be considered first-line for preterm labor prior to 37 weeks' gestation.[71] In a network meta-analysis, prostaglandin inhibitors were shown to be more efficacious than placebo in delaying delivery by 48 hours (OR 5.94; 95% CI, 2.14-12.34).[70] In this analysis, the authors suggested that this class of tocolytics was more efficient than any other agent and ranked prostaglandin inhibitors in the top three most efficacious tocolytics (96% probability).

Indomethacin is usually administered orally or rectally in divided doses. A loading dose of 50 is followed by 25-50 mg orally every 6 hours for up to 48 hours. Indomethacin blood concentrations usually peak 1-2 hours after oral administration, whereas rectal administration is associated with levels that peak slightly earlier. Approximately 90% of the drug is protein bound, undergoing excretion by the kidneys unchanged. Indomethacin readily crosses the placenta, equilibrating with maternal concentrations 5 hours after administration. The half-life is approximately 15 hours in term neonates and somewhat shorter in preterm neonates.

Most studies have limited the use of indomethacin to 24-48 hours' duration because of concerns regarding the development of oligohydramnios and constriction of the ductus arteriosus. The latter of these effects may lead to fetal pulmonary hypertension and neonatal persistent pulmonary hypertension.[122] If longer therapy is required, close fetal monitoring is indicated, including weekly amniotic fluid indexes to evaluate for oligohydramnios and ductal velocity assessment to examine for ductal constriction or closure. If the amniotic fluid volume (measured as the fluid depth in the four quadrants of the uterus) falls below 5 cm or if the pulsatility index of the ductus arteriosus decreases to less than 2 cm/sec, discontinuation of therapy should be considered. Several long-term studies have evaluated the efficacy and safety of this drug.

Maternal contraindications to indomethacin use include peptic ulcer disease, allergies to indomethacin or related compounds, significant hematologic disease, hepatic or renal dysfunction, and drug-induced asthma. Major maternal side effects are minimal and infrequent. Gastrointestinal upset may occur but can be relieved by either taking the medication with meals or using an antacid.

Fetal contraindications include pre-existing oligohydramnios, gestational age greater than 32 weeks, and congenital fetal heart disease in which the fetus is dependent on the ductus arteriosus for circulation. Several fetal side effects have been reported with the use of indomethacin. It has been associated with oligohydramnios. Although indomethacin has been shown to reduce fetal urine output, these levels return to baseline within 24 hours after discontinuation. Examining the effect on renal artery blood flow, Mari and colleagues found no change in the pulsatility index in 17 fetuses during the first 24 hours of indomethacin therapy, suggesting that renal artery constriction and a decrease in renal blood flow are responsible for the reduction in urine output.[106] Regardless, oligohydramnios is usually seen with long-term therapy of more than 7 days, although this onset seems to vary from one patient to another and is somewhat unpredictable. Therefore, the amniotic fluid index should be followed while the patient is receiving therapy. Resolution of oligohydramnios usually occurs within 48 hours of discontinuation of treatment. Although persistent anuria, neonatal death, and renal microcystic lesions have been reported with prenatal indomethacin exposure, most of these infants were exposed to doses greater than 200 mg/day for up to 36 weeks of gestation with inadequate amniotic fluid volume assessment.

Another important potential complication of prenatal indomethacin exposure is the development of ductus arteriosus constriction or closure. It is theorized that ductal constriction or closure leads to the diversion of right ventricular blood flow into the pulmonary vasculature. With time, this causes pulmonary arterial hypertrophy. After birth, relative pulmonary hypertension can then cause right-to-left shunting of blood through the foramen ovale and away from the lungs, resulting in persistent pulmonary hypertension. This complication has been described with long-term indomethacin therapy but not in fetuses exposed to the drug for less than 48 hours.[54] Development of ductus arteriosus constriction can be identified by Doppler echocardiography. Moise and colleagues detected ductal constriction in 7 of 14 fetuses exposed to indomethacin in utero, with these changes seen up to 72 hours after initiation of treatment.[122] There was no correlation with maternal drug levels, and the constriction resolved within 24 hours after treatment

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

was stopped. No cases of persistent pulmonary hypertension were reported in this case series. The observed effects on ductal constriction have been shown to increase with advancing gestational age, with 50% of fetuses demonstrating constriction when exposed at 32 weeks' gestation. Based on this data, indomethacin therapy should be discontinued by 32 weeks at the latest.

Yet another reported complication is an increased risk of necrotizing enterocolitis in infants exposed to indomethacin prenatally. This complication is specifically seen in neonates who are born at less than 30 weeks' gestation. Norton and coworkers performed a retrospective case-control study of 57 neonates that delivered at less than 30 weeks' gestation after recent antenatal exposure to indomethacin, comparing them to 57 matched control fetuses.[134] In this study, the incidence of necrotizing enterocolitis was 29% in the indomethacin group versus 8% in the control group. Additionally, a statistically higher incidence of grade II-IV intraventricular hemorrhage and patent ductus arteriosus was noted in the indomethacin treatment group.[134] No correlations were made in regard to duration of treatment or the time frame between exposure and delivery. Although these results are of concern, indomethacin appears to be a relatively safe and effective tocolytic agent when used with the appropriate caution (less than 48 hours duration of therapy in pregnancies only at less than 32 weeks' gestation).

Sulindac

Sulindac is another prostaglandin synthetase inhibitor that is closely related to indomethacin in structure. Although this agent has been reported to have fewer side effects than indomethacin when used for tocolysis, preliminary experiences also indicate that oral sulindac therapy may not be very useful in the prevention of preterm birth.

Kramer and colleagues conducted a randomized, double-blind study to evaluate the comparative effects of sulindac and terbutaline on fetal urine production and amniotic fluid volume.[97] Sulindac administration also resulted in a significant decrease in fetal urine flow and amniotic fluid volume. Additionally, two fetuses developed severe ductus arteriosus constriction. These data suggest that sulindac shares many of the fetal side effects associated with indomethacin.

Haas and coworkers sought to determine the optimal first-line tocolytic agent for treatment of premature labor.[71] These investigators performed a quantitative analysis that included 58 randomized controlled trials of tocolysis. They extracted data regarding delay of delivery for 48 hours and 7 days, term deliveries, adverse effects causing discontinuation of therapy, absence of RDS, and neonatal survival. A random-effects meta-analysis showed that all tocolytic agents were superior to placebo or control groups in delaying delivery both for at least 48 hours (53% for placebo compared with 75%-93% for the tocolytics) and 7 days (39% for placebo compared with 61%78% for the tocolytics). No statistically significant differences were found for the other outcomes, including the incidence of respiratory distress and rates of neonatal survival. Importantly, this decision model demonstrated that prostaglandin inhibitors provided the best combination of tolerance and delay of delivery, indicating that these agents may be considered the optimal first-line agent for tocolysis prior to 32 weeks of gestation.

Cyclooxygenase-2 Inhibitors

Both indomethacin and sulindac are nonselective cyclooxygenase (COX) inhibitors. In the setting of inflammation, cyclooxygenase-2 (COX-2) is preferentially upregulated. Given that many early cases of preterm labor and delivery are likely related to underlying occult infection or inflammation of the upper genital tract, specific targeting of COX-2 represents a logical target for tocolytic therapy. In addition, by specifically targeting COX-2, there is a theoretical potential for reduction of some of the untoward renal, gastrointestinal, and cardiac side effects that are relatively common with the nonselective COX inhibitors.

The emergence of several selective COX-2 inhibitors (e.g., celecoxib, nimesulide) led to several investigations designed to evaluate the efficacy of these agents for the treatment of preterm labor.[159,160,170] For example, Stika and colleagues reported findings from a randomized, double-blind, placebo-controlled trial of celecoxib versus indomethacin for the treatment of preterm labor.[159] In this small study of 24 women, no difference between the two agents was noted with respect to length of prolongation of pregnancy. Although a transient decrease in amniotic fluid volume was noted with both agents, mean maximal ductus arteriosus blood flow velocity, which was increased with indomethacin, was not significantly altered in women receiving celecoxib.[159] Sawdy and colleagues conducted a similar randomized double-blind, placebo-controlled study of nimesulide versus indomethacin versus sulindac for the treatment of preterm labor.[160] Similar reductions were noted among the three treatment groups with respect to amniotic fluid volume, fetal urine production, and ductus arteriosus Doppler pulsatility index over the initial 48-hour treatment period.[160] To date, no large trials have been reported that have critically evaluated the therapeutic efficacy of the COX-2 inhibitors to prevent preterm birth or reduce neonatal morbidity in women presenting with preterm labor.

Calcium Channel Blockers

Dihydropyridine calcium channel blockers (nifedipine and nicardipine) act on L-type calcium channels blocking transmembrane calcium influx into myometrial cells. Low intracellular calcium levels counteract myosin light chain kinase activation preventing myometrial contraction. The majority of clinical investigations evaluating the use of calcium channel blockers for the treatment of preterm labor have used nifedipine. Ulmsten and associates first reported the use of nifedipine as treatment of preterm labor in a study involving 10 patients, with resultant cessation of uterine activity for 3 days in all patients receiving treatment.[178] In

a subsequent three-armed randomized control study, Read and colleagues reported that the nifedipine group had a significantly longer time interval from presentation to delivery than either ritodrine or placebo.[147] These results suggest that nifedipine is as effective as ritodrine in prolonging pregnancy, with far fewer side effects causing discontinuation of therapy.

Nifedipine can be administered orally or in a sublingual form. It is rapidly absorbed by the gastrointestinal tract with detectable blood levels attained within 5 minutes of sublingual administration. Nifedipine readily crosses the placenta, and serum concentrations of the fetus and the mother are comparable. Most studies used an initial loading dose of 10-30 mg orally, repeated every 15-20 mins for the first hour, followed by 10-20 mg every 4-8 hours.[32] Up to 30 mg can be administered per dose, but such high doses may result in more side effects. The sublingual form is usually not used for treatment of preterm labor because it acts more rapidly than the oral form, resulting in an increased risk of acute hypotension.

Contraindications to the use of nifedipine, or any of the calcium channel blockers, include hypotension, congestive heart failure, aortic stenosis, and pre-existing peripheral edema. Concurrent use of calcium channel blockers and magnesium sulfate can result in profound hypotension and hence should be avoided. Maternal side effects, including dizziness, lightheadedness, flushing, headache, and peripheral edema, result from the potent vasodilatory effects of these agents. These side effects occur in approximately 17% of patients, although they are severe enough to warrant discontinuation of therapy in only 2%-5% of women.

Studies evaluating the fetal effects of calcium channel blocker therapy have been limited to date. One obstacle that limits the performance of large trials is the potentially adverse effects that calcium channel blockers may have on uteroplacental blood flow. Although uteroplacental blood flow appears to be reduced in animal models, studies examining blood flow in humans have yet to demonstrate any significant adverse effects on fetal or uteroplacental blood flow during treatment with nifedipine. Additional studies are needed to more completely evaluate the potential fetal effects of calcium channel blocker therapy.

Several meta-analyses support the use of nifedipine as an effective acute tocolytic agent. A Cochrane review elaborating the role of calcium channel blockers in acute tocolysis included 12 RCTs ($N = 1029$ patients). The authors concluded that these agents were effective in delaying delivery for 7 days and past 34 weeks' gestation.[95] A subsequent review included 26 RCTs ($N = 2179$ patients); nifedipine was not superior to other tocolytic agents in preventing birth within 48 hours. However, when compared to β2-adrenergic agonist, it was found to delay delivery within 7 days and to prolong gestation past 37 weeks.[32] Minimal adverse effects were noted in the nifedipine group. Network meta-analysis and decision analysis suggested that nifedipine be considered as first-line tocolytic with regard to various important outcome.[70,71]

Other investigators regard nifedipine as a cost-effective option, with cost taking into account drug price together with the costs of treating adverse events.[78] Hayes and associates determined the optimal tocolytic based on a cost decision analysis.[78] A PubMed search of commonly used tocolytics was performed to determine the probability of adverse events. Cost for an agent was determined by acquisition cost together with the probability and cost of adverse events. Nineteen clinical trials yielded a cohort of 1073 patients (indomethacin 176, magnesium sulfate 451, nifedipine 176, and terbutaline 270). The probability of adverse events was 58% for terbutaline, 22% for magnesium sulfate, 27% for nifedipine, and 11% for indomethacin. Nifedipine and indomethacin were found to be the least expensive treatment options at less than $20 each, compared with $200 for magnesium sulfate and $400 for terbutaline, largely related to the cost of monitoring and treating adverse events. They concluded that if one elects to proceed with tocolysis, either nifedipine or indomethacin should be the agent of choice based on this cost decision analysis. These findings essentially agree with the recommendations by Haas and coworkers, who recommended prostaglandin inhibitors as the top three most efficacious tocolytic agents.[71]

Oxytocin Antagonists

Oxytocin antagonists have been set forth as a novel category of agents that may be useful for the treatment of preterm labor. Based on the theory that preterm labor may result from early gap junction formation coupled with a rise in oxytocin receptor concentration, oxytocin may be a pivotal hormone in the evolution of parturition. Oxytocin has been shown to be intimately involved in the physiologic pathways leading to both term and preterm labor. Whereas the role of oxytocin may represent the terminal event for a variety of pathophysiology pathways leading to preterm delivery, it represents an important central pathway that may be amenable to therapeutic intervention. Because the primary cellular targets for oxytocin are the myometrium and decidua, oxytocin antagonists have the theoretical benefit of being highly organ specific with minimal potential for adverse side effects.

Oxytocin antagonists have been shown to effectively inhibit oxytocin-induced uterine contractions in both in vitro and in vivo animal models. The initial human experience with oxytocin antagonist therapy came from several small uncontrolled studies performed in the late 1980s.[2,9] Akerlund and colleagues reported on a series of 13 patients who received a short-term infusion of an oxytocin antagonist. This therapy resulted in inhibition of premature labor in all patients, but 10 of these patients subsequently required treatment with β-agonists.[2]

Similarly, Anderson and associates reported their experience with 12 patients between 27 and 33 weeks of gestation who were treated with a competitive oxytocin receptor antagonist for 1.5-13 hours.[9] Of these 12 patients, 9 had arrest of contractions, and the remaining 3 had no change in contraction frequency.

The most studied oxytocin antagonist is atosiban. Atosiban is a nonapeptide oxytocin analogue that competitively antagonizes the oxytocin-vasopressin receptor and is thus capable of inhibiting oxytocin-induced uterine contractions. Atosiban is typically administered intravenously. Standard dosing recommendations are for a single initial intravenous bolus of 6.75 mg of atosiban, followed by an intravenous infusion of 300 μg/min for the first 3 hours and then 100 μg/min for up to 18 hours. Maintenance therapy can be implemented at a rate of 30 μg/min via continuous infusion. It appears to have a good maternal safety profile, with rare and non-life-threatening side effects (hypersensitivity and injection site–related reactions).

Several prospective, randomized, masked clinical trials have demonstrated that atosiban is effective in diminishing uterine contractions in women with threatened preterm birth without causing significant maternal, fetal, or neonatal adverse effects.

Romero and coworkers, in a prospective, randomized, double-blind, placebo-controlled, multicenter investigation of 501 women with documented preterm labor, demonstrated that atosiban was significantly more effective than placebo in delaying delivery for 24 hours, 48 hours, and 7 days.[151] Importantly, however, the median from start of therapy to delivery or treatment failure was not significantly different between the study groups, nor were perinatal outcomes. In this trial, rates of extremely premature fetal death were higher in the atosiban group, despite not reaching statistical significance. These concerns may be explained by lack of stratification by gestation in the trial's randomization method (atosiban group had significant higher numbers of women less than 26 weeks' gestation) and the presence of other significant confounders. Moutquin and colleagues compared atosiban to ritodrine for the treatment of preterm labor.[124] In this multicenter, double-blind, randomized, controlled trial of 212 women, the investigators demonstrated that the tocolytic efficacy of atosiban was comparable to that of conventional ritodrine therapy in terms of cessation of preterm labor and neonatal outcomes, with fewer adverse side effects reported with atosiban. The potential use of atosiban for maintenance therapy in patients with arrested preterm labor has also been evaluated. Valenzuela and associates reported experience from a multicenter, double-blind, placebo-controlled trial of 513 women with arrested preterm labor.[180] Median time from start of maintenance therapy to first recurrence of labor was significantly longer for women treated with atosiban (32.6 days) than for those treated with placebo (27.6 days). Another trial by Salim and colleagues compared atosiban to nifedipine, showing that more women undergoing tocolysis with atosiban remained pregnant after 48 hours, but nifedipine had longer-lasting effects (i.e., patients more likely to remain pregnant after 7 days).[158] These data suggest that atosiban may be useful in delaying delivery 24-48 hours in the setting of preterm labor, but this delay appears to have minimal impact on neonatal outcomes.

Atosiban was not superior to β2-agonists or placebo in neonatal outcomes nor tocolytic efficacy in a Cochrane review (N = 1695 patients).[140] Lower infant birth weight and higher drug adverse effects were noted in the atosiban group (weighted mean difference, 138.31 g; 95% CI, −248.76 - −27.86; RR 4.02; 95% CI, 2.05-7.85 respectively). In the same review, compared to β2-agonists, the rates of infants born under 1500 g were higher in the oxytocin antagonist group (RR 1.96; 95% CI, 1.15-3.35). In the Haas' network meta-analysis, atosiban was superior to placebo in postponing delivery within 48 hours (OR 2.02; 95% CI, 1.1-3.8), but the same observation was noted when it was compared to other tocolytics.[70]

Further well-designed, randomized, placebo-controlled trials are needed to more clearly elucidate the role, if any, of the oxytocin antagonists in the therapeutic armamentarium for preterm labor.

Nitric Oxide Donors

Nitric oxide is a potent endogenous hormone that facilitates smooth muscle relaxation in the vasculature, gastrointestinal tract, and uterus. Interest has arisen about the potential use of nitric oxide donors (e.g., nitroglycerin and glycerol trinitrate) as tocolytic agents. Lees and colleagues compared transdermal glycerol trinitrate to ritodrine for tocolysis in a randomized investigation of 245 women with documented preterm labor between 24 and 36 weeks' gestation.[102] These investigators found no significant differences in either tocolytic effect or neonatal outcomes, but glycerol trinitrate was associated with fewer maternal side effects.

El-Sayed and colleagues evaluated 31 women with documented preterm labor before 35 weeks' gestation in a randomized comparison of intravenous nitroglycerin and magnesium sulfate.[46] Tocolytic failure (continued need for tocolysis after 12 hours of treatment) was significantly more common in patients treated with nitroglycerin than in women treated with magnesium sulfate. Importantly, 25% of the patients treated with nitroglycerin experienced significant hypotension, requiring discontinuation of treatment.

A Cochrane review in this topic included eight RCTs (N = 466 women).[45] Only one trial compared this class of drugs to placebo. Delaying delivery for 48 hours was not different among groups (RR 3.06; 95% CI, 0.74-12.63). The same observation was noted when comparison to other tocolytic agents was performed (RR 1.43; 95% CI, 0.47-4.37). Despite these results, nitrates were superior to other tocolytics in decreasing preterm delivery before 37 weeks (RR 0.69; 95% CI, 0.53-0.88) with fewer drug side effects (RR 0.47, 95% CI, 0.37-0.61).

The network meta-analysis by Haas et al. suggested that these agents will have at best 4% probability to delay delivery for 48 hours and 10% of being the best agent based on maternal side effects.[70]

Given the small number of trials available, there is insufficient data to determine whether nitric oxide donors are effective tocolytics. Therefore, clinical use of these agents for the treatment of preterm labor should only be investigational.

Antibiotics

Before 37 weeks of gestation, PPROM complicates approximately 3% of pregnancies and accounts for one-third of all preterm births. Also, PPROM is associated with significant maternal and neonatal morbidity and mortality related to infection, umbilical cord compression, placental abruption, and preterm birth. As previously discussed, preterm labor, especially at less than 30 weeks' gestation, has been associated with occult upper genital tract infection. Many of the bacterial species involved in this occult infection are capable of inciting an inflammatory response, which ultimately may culminate in preterm labor and delivery. It is on this basis that antibiotics have been suggested as a potential therapy for the treatment or prevention of spontaneous preterm birth.

Elder and associates provided the first insights into the potential use of antibiotics to prevent preterm birth, demonstrating that treatment of asymptomatic pregnant patients with daily tetracycline therapy resulted in fewer preterm deliveries.[47] Despite these promising results, subsequent prospective trials using antibiotics in women colonized with *Chlamydia*, *Ureaplasma*, and group B streptococci have shown no significant decrease in preterm birth. The association of bacterial vaginosis with preterm birth, though, prompted renewed interest in the potential use of antibiotics to prevent preterm birth in asymptomatic women. Several prospective trials have demonstrated that antenatal treatment of bacterial vaginosis in asymptomatic women at high risk for spontaneous preterm delivery may reduce the subsequent spontaneous preterm delivery rate.[76,77] For example, Hauth and colleagues conducted a prospective, randomized, double-blind, placebo-controlled study of 624 women who were identified as being at risk for preterm delivery (e.g., history of previous preterm birth or prepregnancy weight of less than 50 kg).[76,77] These women were randomized to metronidazole (250 mg three times a day for 7 days) and erythromycin (333 mg three times a day for 14 days) therapy or to placebo. The investigators observed a significant reduction in the rate of preterm birth (49% vs. 31%) in women with bacterial vaginosis who received antibiotic treatment. In women without bacterial vaginosis, antibacterial treatment was associated with a significant *increase* in the rate of preterm birth (13.4% vs. 4.8%, $p < .02$).[76,77] Carey and coworkers further evaluated the use of metronidazole for prevention of preterm birth.[24] In a prospective, randomized, placebo-controlled study of 1704 low-risk asymptomatic women with bacterial vaginosis, treatment with metronidazole was not found to reduce the risk for preterm delivery or adverse perinatal outcomes. Based on these data, it appears that screening and treatment of bacterial vaginosis in women at high risk for preterm delivery may be an effective treatment to prevent preterm birth, but nondiscriminative screening and treatment of asymptomatic low-risk women does not appear to offer any clear benefit.

Several investigations have explored the use of targeted antibiotic therapy using fetal fibronectin as a screening tool to identify asymptomatic women at the greatest risk for early preterm birth induced by infection or inflammation.[11,58,76] Goldenberg and colleagues first explored this interesting theory.[58] In a subgroup analysis of women enrolled in a trial of antibiotic therapy for the prevention of preterm birth, 70 women with bacterial vaginosis and a positive fetal fibronectin test were randomized to receive either two courses of metronidazole treatment or placebo.[58] Patients who received metronidazole treatment had a lower incidence of preterm birth (8%) than the placebo group (16%), but this difference did not reach statistical significance ($p = .311$).[58] Despite the lack of statistical significance, this trend was compelling enough to lead to several randomized clinical trials designed to further evaluate the efficacy of antibiotic therapy in women with a positive fetal fibronectin test.[11,58,76]

In the largest of these trials, Andrews and colleagues screened 16,317 women between 21 and 25 gestational weeks with cervical or vaginal swabs for fetal fibronectin. Of the screened women, 1079 (6.6%) had a positive fetal fibronectin test (50 ng/mL or greater), 759 of whom consented to randomization to receive a 10-day course of metronidazole (250 mg orally three times per day) and erythromycin (250 mg orally four times per day) or identical placebo pills.[11] The primary outcome for this investigation was defined as spontaneous delivery prior to 37 weeks' gestation. No difference was observed in the incidence of spontaneous preterm birth prior to 37 weeks' (14.4% vs. 12.4%, $p = .43$), 35 weeks' (6.9% vs. 7.5%, $p = .76$), or 32 weeks' (4.3% vs. 2.2%, $p = .12$) gestation between the antibiotic-treated women and the placebo-treated women. Interestingly, among women with a prior spontaneous preterm delivery, the rate of recurrent spontaneous preterm birth prior to 37 weeks was significantly higher in the metronidazole plus erythromycin group than in the placebo group (46.7% vs. 23.9%, RR 1.95; 95% CI, 1.03-3.71; $p = .04$).[10]

The findings of the MFMU Network trial were consistent with those of two similar studies.[76] It is clear from these investigations that the use of antibiotic therapy in asymptomatic women with a positive cervical or vaginal fetal fibronectin test in the late mid-trimester does not decrease the incidence of spontaneous preterm delivery.

In contrast, the use of antibiotics for the treatment of acute preterm labor has had mixed results.[97,146] More than 15 investigations have been reported that evaluate the efficacy of different antibiotic regimens (i.e., ampicillin, erythromycin, clindamycin, ceftizoxime, amoxicillin-clavulanate, ampicillin plus erythromycin, ampicillin plus sulbactam, ampicillin plus metronidazole, amoxicillin-clavulanate plus erythromycin, and mezlocillin plus erythromycin) for the prevention of spontaneous preterm birth in women presenting with preterm labor and intact membranes.[97,175] These studies have yielded inconsistent results with regard to the benefits of antibiotics in prolonging pregnancy or improving short- and long-term neonatal outcomes.[97,146] The ORACLE II trial, the largest such study to date, was

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

a multicenter, prospective, randomized study of antibiotics (erythromycin alone, amoxicillin-clavulanate alone, or combination of both agents) versus placebo in 6295 women with preterm labor and intact membranes.[91] This study failed to demonstrate significant prolongation of pregnancy or an improvement in a predefined composite neonatal outcome among women receiving any of the antibiotic regimens. A Cochrane review further evaluated the use of antibiotics in this population of women.[93] The reviewers concluded as follows: (1) antibiotic use is associated with a significant prolongation of pregnancy (5.4 days; 95% CI, 0.9-9.8), (2) maternal infection is decreased in women receiving antibiotic treatment (OR 0.59; 95% CI, 0.36-0.97), (3) the incidence of neonatal necrotizing enterocolitis is significantly reduced with maternal treatment using antibiotics (OR 0.33; 95% CI, 0.13-0.88), and (4) there is a trend toward a decreased risk of neonatal sepsis in the setting of maternal treatment with antibiotics (OR 0.67; 95% CI, 0.42-1.07). Surprisingly, the meta-analysis also demonstrated an increased perinatal mortality rate associated with maternal antibiotic treatment (OR 3.36; 95% CI, 1.21-9.32).[93] The authors, therefore, concluded that despite the prolongation in time to delivery, a clear overall benefit of antibiotic treatment for preterm labor has not yet been proven.[97] Antibiotics do play a clear role in prevention of neonatal sepsis caused by group B streptococci. In women perceived to be at an acute risk for preterm delivery, antibiotic therapy with appropriate agents against group B streptococci should be continued until either negative cultures are obtained or imminent delivery is no longer anticipated.

In the setting of preterm delivery caused by PPROM, antibiotic therapy remains a mainstay of treatment. Numerous investigations have shown that the use of a variety of antibiotics in this setting can result in an increased latency period from the time of membrane rupture to the time of delivery. A large, prospective, randomized clinical investigation by Mercer and coworkers conducted through the NICHD MFMU Network was designed to more clearly address the neonatal benefits of antenatal antibiotic use in women with PPROM.[118] In this trial, 614 women with PPROM were randomized to treatment with either intravenous ampicillin (2 g every 6 hours) plus erythromycin (250 mg every 6 hours) for 48 hours followed by oral amoxicillin (250 mg every 8 hours) and erythromycin base (333 mg every 8 hours) for 5 days or to a matched placebo treatment regimen. In addition to significantly increasing the latency period, the use of antibiotics in this investigation resulted in significant reductions in the incidences of RDS, necrotizing enterocolitis, and composite neonatal morbidity (defined as any of the following: fetal or infant death, respiratory distress, severe intraventricular hemorrhage, stage 2 or 3 necrotizing enterocolitis, or sepsis within 72 hours of birth).[118] In contrast, Kenyon and colleagues reported that antibiotic use in the setting of PPROM did not result in a reduction in neonatal morbidity.[90] These investigators conducted a large, multicenter, multinational investigation of 4809 women with PPROM at less than 37 weeks' gestation. Women were randomized to one of four treatment regimens for 10 days: placebo, amoxicillin-clavulanate, erythromycin, or a combination of amoxicillin-clavulanate plus erythromycin. Significant prolongation of pregnancy was noted among all antibiotic treatment groups when compared with placebo therapy. The investigators, however, noted no significant differences between the four treatment groups with regard to composite neonatal morbidity (defined as neonatal death, chronic lung disease, or major cerebral abnormality on ultrasound): placebo 15%, amoxicillin-clavulanate 14%, erythromycin 13%, and amoxicillin-clavulanate plus erythromycin 14%.[90]

Altogether, the use of antibiotics in the setting of PPROM appears to result in significant prolongation of pregnancy, with a potential reduction of neonatal short-term morbidity in certain subsets of patients (i.e., early PPROM at less than 32 weeks' gestation). On the basis of a meta-analysis, Hutzal and colleagues confirmed these conclusions, showing that antibiotics prolong pregnancy and reduce neonatal morbidity in women with PPROM at a gestation of 34 weeks or less, an effect that is not seen in women in preterm labor.[84]

Care must, therefore, be taken with the administration of antenatal and intrapartum antibiotics. Although they prolong pregnancy in the setting of PPROM, eradicate group B streptococci, and are effective in reducing the incidence of early-onset neonatal sepsis, this benefit may come at the cost of favoring the emergence of ampicillin-resistant organisms that may cause severe neonatal infections.

Corticosteroids

The use of antenatal corticosteroids for the prevention of neonatal RDS stems from original animal work performed by Liggins and Howie in the late 1960s. They initially observed that in gravid sheep given glucocorticoids to induce preterm labor, lambs demonstrated accelerated fetal lung maturity and decreased respiratory problems at birth. The investigators followed up on these interesting findings by conducting the first trial of antenatal glucocorticoid therapy in humans, showing that antenatal glucocorticoid administration (two doses of 12 mg of betamethasone given 24 hours apart) resulted in significant decreases in RDS and perinatal mortality in newborns born before 34 weeks.[104]

Since that landmark study, more than 15 additional prospective, randomized, controlled trials have confirmed this decrease in neonatal RDS related to antenatal administration of glucocorticoids (either betamethasone or dexamethasone). Roberts conducted a meta-analysis including 30 randomized controlled trials (7774 women and 8158 infants), reiterating the finding that antenatal glucocorticoid therapy significantly decreases the incidence and severity of neonatal RDS.[149] Neonatal mortality was also significantly reduced in this meta-analysis, as was the incidence of intraventricular hemorrhage and necrotizing enterocolitis. Maximal benefits were achieved when delivery

occurred more than 24 hours but within 7 days of treatment initiation.

Despite this body of evidence, antenatal corticosteroids remained underused throughout the 1980s and early 1990s until the National Institutes of Health (NIH) convened a Consensus Development Conference on Antenatal Steroids in 1994 to review the potential risks and benefits of antenatal corticosteroid therapy. The panel concluded that sufficient data exist, demonstrating that antenatally administered corticosteroids (betamethasone or dexamethasone) significantly reduce the incidence or severity of RDS, intraventricular hemorrhage, and potentially necrotizing enterocolitis. The panel recommended that all fetuses between 24 and 34 weeks' gestation at risk for preterm delivery should be considered candidates for antenatal corticosteroid treatment. Additionally, given that treatment for less than 24 hours was also significantly associated with a decreased risk for RDS, intraventricular hemorrhage, and mortality, the panel concluded that steroids should be administered unless delivery is imminent. For patients with PPROM, treatment was recommended at less than 30-32 weeks because of the high risk of intraventricular hemorrhage.

Long-term follow-up of children at 3 and 6 years of age who were exposed in utero to antenatal corticosteroid therapy has not demonstrated any adverse effect on growth, physical development, motor or cognitive skills, or school progress. However, antenatal steroid therapy appears to be an independent risk factor for the development of asthma between 36 and 72 months of age.[143] All together, a single course of corticosteroids appears to be an efficacious and safe treatment modality to improve neonatal outcomes in patients at risk for preterm delivery.

One unresolved issue is related to the safety and efficacy of repeated steroid dosing. In animal studies, repeat courses of antenatal corticosteroids have been shown to have a deleterious effect on lung growth and organization, cerebral myelination, function of the hypothalamic-pituitary-adrenal axis, fetal growth, and retinal development. Several randomized trials have, therefore, evaluated the efficacy of repeated steroid courses in women at risk for preterm delivery.[66,182] Guinn and associates reported results from a randomized, double-blind, placebo-controlled clinical trial comparing repeated weekly betamethasone administration with a single course of betamethasone administered to pregnant women at the onset of threatened preterm delivery.[66] In this study of 502 women, no overall benefit was noted from repeated steroid courses with regard to composite neonatal morbidity (defined as any of the following: fetal or neonatal death, bronchopulmonary dysplasia, intraventricular hemorrhage, sepsis, necrotizing enterocolitis, and periventricular leukomalacia) when compared with single-course steroid administration (22.5% vs. 28.0%, respectively; $p < .16$).[66] Whereas the incidence of severe RDS was significantly lower among those infants in the repeated steroid course group (15.3%) when compared with those in the single-dose group (24.1%, $p < .01$), the incidence of severe intraventricular hemorrhage was higher in the repeated steroid course group (7.6% vs. 2.0%, $p < .06$).[66] Wapner and colleagues from the NICHD MFMU Network subsequently conducted a randomized trial of single versus weekly courses of corticosteroids for women at less than 32 weeks' gestation who were at increased risk for spontaneous preterm birth.[182] The primary study outcome was the occurrence of intrauterine fetal demise or neonatal death (scored together), severe RDS, grades III and IV intraventricular hemorrhage, periventricular leukomalacia, or chronic lung disease. No difference was noted between the study groups with respect to the primary study outcome. An important finding of this investigation, however, was a significant reduction in birth weight among infants exposed to four or more courses of steroids.[182]

Murphy and colleagues further evaluated this issue, randomly assigning 1858 women at 25-32 weeks' gestation who remained undelivered 14-21 days after an initial course of antenatal corticosteroids and continued to be at high risk of preterm birth. These patients were assigned to either receive multiple courses of antenatal corticosteroids ($n = 937$) or placebo ($n = 921$) every 14 days until week 33 or delivery, whichever came first. Multiple courses of antenatal corticosteroids did not improve mortality (around 12.5%) or neonatal morbidity, but there was a significant decrease in weight, length, and head circumference at birth in this group.[126] These results prompted the investigators to recommend against this treatment regimen.

In response to these concerns, the NIH reconvened a Consensus Development Conference in 2000 to review the available data on potential risks and benefits of courses steroid use when compared with single-dose administration.[128] It concluded that available evidence supporting the use of repeat courses of antenatal corticosteroids is limited due to study design and "methodologic inconsistencies." The panel also stated that despite possible benefit from repeated courses (especially in the reduction and severity of respiratory distress), several animal and human data suggest deleterious effects on cerebral myelination, lung growth, and function of the hypothalamic-pituitary-adrenal axis of the fetus. The panel stated that repeat courses should not be used outside of the context of a randomized trial.[128] Garite and coworkers subsequently randomized 437 patients with either singleton or twin gestations prior to 33 weeks' gestation who were judged to have a recurring threat of preterm delivery in the coming week. Women were eligible if they had completed a single course of antenatal corticosteroids prior to 30 weeks' gestation and at least 14 days before inclusion in this trial. Patients were randomized to receive either a single rescue course of betamethasone ($n = 223$) or placebo ($n = 214$).[53] Fifty-five percent of the patients in each group delivered before 34 weeks, but there was a significant reduction in the primary outcome of composite neonatal morbidity in the rescue steroid group. Neonates who received rescue-course steroids in utero also displayed significantly decreased RDS, ventilator support, and surfactant use, but perinatal mortality and other morbidities were similar in each group. These investigators concluded that

administration of a single rescue course of antenatal corticosteroids before 33 weeks improves neonatal outcome without an associated increase in short-term risk. In 2015, Crowther performed a Cochrane meta-analysis of 10 trials (4733 women and 5700 infants).[39] The authors included trials with a repeat course of corticosteroids as early as 7 days from the initial course. The pooled results showed a significant reduction in RDS with no significant adverse outcomes. The authors noted an association with a small reduction in birth weight. We recommend that gravid women less than 34 weeks who are at risk of preterm delivery within 7 days, and whose prior course of antenatal corticosteroids was previously administered more than 14 days, should be offered a single repeat course of antenatal corticosteroids.

Recent attention has turned toward the use of antenatal corticosteroids in the late preterm period (34 0/7 weeks to 36 6/7 weeks). Recent data from the Maternal Fetal Medicine Units (MFMU) Network Antenatal Late Preterm Steroids trial supports the use of betamethasone in gravid women at high risk of late preterm birth (between 34 0/7 weeks and 36 6/7 weeks of gestation) that did not receive a prior course of antenatal corticosteroids.[69] This was a double-blind, placebo-controlled, randomized clinical trial that included women who were in preterm labor, or had preterm PROM, or had a planned delivery in the late preterm period. Administration of betamethasone led to a significant decrease in the need for respiratory support. Severe respiratory complications were significantly decreased (12.1% in the placebo group versus 8.1% in the betamethasone group; RR 0.67; 95% CI, 0.53-0.84; $P < .001$). The rates of transient tachypnea of the newborn; bronchopulmonary dysplasia; a composite of respiratory distress syndrome (RDS), transient tachypnea of the newborn and RDS; and the need for postnatal surfactant were all decreased in the intervention group. Neonatal sepsis, chorioamnionitis, or endometritis were not increased with late preterm betamethasone. Infants exposed to betamethasone had a higher rate of hypoglycemia (24.0% vs. 14.9% (RR 1.61; 95% CI, 1.38-1.88) but this did not lead to adverse events. As a result of this trial, SMFM supported the administration of a single course of betamethasone for pregnant women between 34 0/7 weeks and 36 6/7 weeks of gestation at risk of preterm birth within 7 days and who have not received a previous course of antenatal corticosteroids.[166] When planning to administer antenatal corticosteroids in the late preterm birth period, obstetricians should be aware of the following considerations based on the methodology used in the trial. First, late preterm gravid women with clinical chorioamnionitis should not receive antenatal corticosteroids. Second, tocolysis should not be administered to delay delivery for the sole purpose of administering antenatal corticosteroids in the late preterm period. Third, no delays should occur in medically indicated late preterm delivery (e.g., preeclampsia with severe features) for the only purpose to administer antenatal corticosteroids. Since women with multiple gestations, pregestational diabetes, or who previously had received a course of corticosteroids or gave birth by cesarean at term were excluded from the trial, no recommendations can be made for this specific population group regarding benefits from late preterm antenatal corticosteroid administration.

The Global Network's Antenatal Corticosteroids Trial (ACT) was a multicountry (Argentina, Guatemala, India, Kenya, Pakistan, and Zambia), cluster-randomized trial to improve appropriate use of antenatal corticosteroids (ACS) in low-resource settings in low-middle income countries (LMIC).[3] ACT substantially increased ACS use in the intervention clusters, but the intervention failed to show benefit in the targeted less than fifth percentile birth weight infants and was associated with increased neonatal mortality and stillbirth in the overall population. Maternal and neonatal infections were increased in the intervention clusters across all sites and increased infections are a possible partial explanation for the increase in neonatal mortality and stillbirth in the intervention clusters, especially in the African sites. The African sites appeared to have increased neonatal mortality in the intervention clusters, while the Guatemalan site had a significant reduction in neonatal mortality, perhaps related to a combination of ACS and improving obstetric care in the intervention clusters.[113] An expert group convened by WHO has concluded that there is a clear need for more efficacy trials of ACS in these settings to inform clinical practice.

The commonly used steroids for the enhancement of fetal maturation are betamethasone (two doses of 12 mg administered intramuscularly every 24 hours) and dexamethasone (four doses of 6 mg administered intravenously every 6 hours). At least one small trial suggested that betamethasone administered at 12-hour intervals is as effective as 24-hour dosing, a regimen that may be particularly useful in women who are at risk for imminent delivery.[92] Regardless of dosing, these two glucocorticoids have been identified as the most efficacious, because they readily cross the placental barrier to reach the fetal compartment. They also display the benefits of having long half-lives and limited mineralocorticoid activity.

Unresolved issues related to the use of corticosteroids include whether betamethasone is superior to dexamethasone, the efficacy and the appropriate dosing and efficacy in multifetal pregnancies. Despite these holes in knowledge, administration of antenatal corticosteroids remains one of the most important therapeutic advances and interventions in women at risk for preterm delivery.

Additional Interventions

Initial reports suggested that antenatal maternal treatment with phenobarbital or vitamin K reduced the incidence of intraventricular hemorrhage. However, these reports failed to control for the use of corticosteroids, a therapy that is known itself to significantly decrease the incidence of

intraventricular hemorrhage. At this time, neither phenobarbital nor vitamin K appear to offer a significant advantage for the prevention of intraventricular hemorrhage beyond that observed with antenatal corticosteroids alone.[163]

Omega-3 fatty acid supplementation has also been proposed as possible intervention to prevent preterm birth. In a large, multicenter, randomized, double-masked, placebo-controlled trial, Harper and colleagues enrolled 852 women with a prior history of spontaneous preterm birth.[74] These women were assigned either to receive a daily omega-3 supplement or matching placebo, with no benefit noted in reducing preterm birth prior to 37 weeks' gestation in the treatment arm of the trial.

Summary

The epidemiology and pathophysiology of preterm labor are reviewed in this chapter, as are the current therapeutic strategies that may be employed in this setting. Despite all efforts thus far, preterm labor and delivery remains a significant clinical problem globally, accounting for a substantial component of all neonatal morbidity and mortality. Despite important insights into the pathophysiology of preterm labor over the past several decades, effective therapeutic interventions to decrease spontaneous preterm delivery remain limited. Clearly, the development of effective screening tools to identify patients at greatest risk for spontaneous preterm delivery is important to further the discovery of novel therapeutic strategies. As insights into the diverse etiologies of spontaneous preterm labor evolve, these strategies may lead to a significant reduction in the incidence of spontaneous preterm delivery, with concomitant improvement in perinatal morbidity and mortality rates. Because many of the preterm births are late preterm (≥70%), there is hope that major progress will be made in the near future.

The answer to prevention of prematurity is complex. This issue has been well summarized by Damus: "Despite the complex changing environment of perinatal care, shrinking resources and higher risk pregnancies, innovative strategies, expanded interdisciplinary partnerships, a focus on perinatal quality initiatives, more evidence-based interventions, tools to better predict preterm labor/birth, dissemination of effective community-based programs, a commitment to enhance equity, promoting preconception health, translation of research findings from the bench to bedside to curbside, effective continuing education for busy clinicians and culturally sensitive, health literacy appropriate patient education materials can collectively help to reverse the increasing rates of preterm births."[41] Measures that show demonstrable benefits in improving neonatal outcomes in preterm infants include antenatal corticosteroid therapy, administration of antibiotics to women with PPROM, and regionalization of care with a policy of prenatally transferring women to high-quality maternal-fetal units with experienced caregivers for mother and baby.

Preterm labor is a complex problem. The current treatment options are symptomatic, rather than causally directed, and the primary objective is to delay delivery long enough for a full course of antenatal corticosteroids to be administered. This has been accomplished with a variety of tocolytic drugs with different mechanisms of action (beta-mimetics, oxytocin antagonists, calcium-channel blockers). Preventive treatment with progesterone can lower the rate of preterm birth in selected high-risk groups by more than 30%. Premature rupture of the membranes is an indication for antibiotics. It has become fashionable to treat a short cervix with rest and progesterone, but the results have been inconsistent. It is time to try new approaches, and the application of the human genome is the logical step. Data are now accumulating on the important role for genetics in the timing of the onset of human labor. The use of modern genomic approaches, such as genome-wide association studies, rare variant analyses using whole-exome or genome sequencing, and family-based designs, holds enormous potential. Some progress has been made in the search for causative genes and variants associated with preterm birth, but the major genetic determinants remain to be identified. Further advances will depend on the identification of biomarkers for earlier detection of preterm labor as well as the development of effective therapeutic agents to inhibit labor when fetal compromise is not an issue.

Acknowledgments

The author and editors acknowledge the contribution of Kara Beth Markham and Avroy Fanaroff to previous editions of this chapter, portions of which remain unchanged.

Key Points

- Preterm labor and delivery remains a significant problem globally, accounting for a substantial component of all neonatal morbidity and mortality.
- Effective maternal therapeutic interventions to decrease the burden of disease remain limited.
- The use of antenatal corticosteroid, magnesium sulfate therapy, and intrapartum antibiotics in women at risk of preterm delivery and administration of antibiotics to prolong latency in women with PPROM lead to improvement in neonatal outcomes in preterm infants.
- Obstetric interventions including the use of progesterone, cervical cerclage, and pessary to prevent preterm birth in select populations have contributed to a decrease in neonatal mortality and morbidities associated with preterm birth.

Fetal Effects of Autoimmune Disease

ISAAC BLICKSTEIN AND CALANIT HERSHKOVICH-SHPOREN

Placental Transfer: General Remarks

The maternal-fetal interface is quite efficient in its selective exclusion of substances during the transport process from the maternal to the fetal circulation. At the same time, the placenta selectively transfers other substances, a process that is facilitated by the proximity of the respective maternal-fetal vascular systems within the placental cotyledons. Although there is no mixing of the maternal and fetal blood, the placental barrier is not impermeable, and small amounts of fetal blood, including fetal cells, gain access to the maternal circulation in most pregnancies through breaks in the fetal-maternal interface. When fetal blood cells are recognized as antigens by the maternal immunologic system, they may provoke an immune response and the production of immunoglobulins. This mechanism occurs in only a few pregnancies and is the basis of incompatibility disorders (see Chapter 23), whereby exogenous antigens such as fetal cells or incompatible blood sensitize the maternal immune system. The maternal antibodies, which are produced as a response to sensitization, cross the placenta and may destroy fetal cells. Generally, the mother is disease free, and the diagnosis is reached after the delivery of an affected infant or by screening tests.

A second type of maternal antibody that crosses the placenta and affects the fetus may arise from sensitization of the mother's immune system by her endogenous antigens, with the resultant production of autoantibodies. The mother with autoantibodies has an autoimmune disorder, and the diagnosis of the maternal disease usually precedes the diagnosis of the fetal or neonatal complication.

These generalizations describe immune processes that may affect the fetus or neonate. Although the maternal immune system may produce a wide range of immunoglobulins, only maternal antibodies of the IgG class (but not IgM or IgA) can cross the placental barrier. The common denominators of such disorders are the production of IgG in the maternal compartment, the transfer of IgG through the placenta, and the effects of these antibodies in the fetal compartment or neonate. This chapter discusses examples of such disorders.

Fetal Thrombocytopenia

Box 20.1 lists the immunologic etiologies of fetal, and consequently neonatal, thrombocytopenia. The most significant pathologies are neonatal alloimmune thrombocytopenia and immune (idiopathic) thrombocytopenic purpura (ITP). Although the two conditions have some similarities, they are distinct diseases, each with a different underlying pathogenesis (Table 20.1) (see Chapter 79).

Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura in adults is often a chronic disease mediated by autoantibodies directed against cell surface components (glycoproteins) of platelets (IIb/IIIa or Ib/IX). Thrombocytopenia occurs when the platelet-antibody complexes are destroyed by the reticuloendothelial system. A low platelet count raises suspicion for ITP, but the diagnosis is reached after exclusion of other causes of thrombocytopenia by history, physical examination, blood count, peripheral blood smear, and autoimmune profile.[9] A spuriously low platelet count should be evaluated by examining a blood smear to exclude pseudothrombocytopenia caused by ethylene diaminetetra-acetic-acid–dependent platelet agglutination. The normal range of platelet counts in nonpregnant women and neonates is 150,000-400,000/μL; however, the mean counts tend to be lower during pregnancy. The prevalence of maternal ITP is one to two cases per 1000 deliveries. The potential risk of a low platelet count for the mother is bleeding; however, the risk becomes significant only when the platelet count becomes less than 20,000/μL. A maternal platelet count of greater than 50,000/μL is considered to be hemostatic during vaginal or cesarean birth.

Thrombocytopenia of the fetus or newborn is caused by active transplacental transport of the antiplatelet antibodies; however, no significant correlation has been observed between neonatal thrombocytopenia and maternal autoimmune antibodies. A low platelet count increases the risk for hemorrhage, but this seems to be more theoretical than real because intrauterine fetal hemorrhage has not

Abstract

Two mechanisms may provoke the maternal immune system during pregnancy. First, fetal blood cells that enter the maternal circulation are recognized as antigens and may provoke an immune response and the production of immunoglobulins. Maternal antibodies cross the placenta and may destroy fetal cells. Second, autoantibodies from the mother's immune system provoked by an autoimmune disorder may cause fetal or neonatal complications. The common denominators of such disorders are the production of IgG in the maternal compartment, the transfer of IgG through the placenta, and the effects of these antibodies in the fetal compartment or neonate. This chapter discusses immune thrombocytopenic purpura (ITP), neonatal alloimmune thrombocytopenia, fetal-neonatal consequences of maternal antinuclear and antiphospholipid antibodies, myasthenia gravis, and herpes gestationis. Although the last decade has witnessed great progress in better understanding the underlying pathogenesis of most of these conditions, in many instances, however, therapy before birth and in the neonatal period remains controversial. Generally, steroids and intravenous immunoglobulins are the mainstay of these therapies. The obstetrical approach should consider the potential risk for the fetus during childbirth, and hence, tailor the best mode of delivery.

TABLE 20.1 Characteristics of Neonatal Thrombocytopenia Based on Etiology

	Alloimmune Thrombocytopenia	Maternal Immune Thrombocytopenic Purpura
Cause of sensitization	Antigen on fetal platelets	Autoantibodies
Maternal platelet count	Normal	Low
Fetal platelet count	Low	Variable
Fetal risk (pregnancy)	High	Low
Fetal risk (delivery)	High	Depends on platelet count
Maternal risk	None	Depends on platelet count

• BOX 20.1 Immunologic Etiology of Fetal or Neonatal Thrombocytopenia

- Maternal production of autoantibodies
  - Immune thrombocytopenic purpura
  - Systemic lupus erythematosus
  - Drug-induced thrombocytopenia
- Neonatal alloimmune (isoimmune) thrombocytopenia
- ABO incompatibility

been reported in patients with ITP. The concern is for the potential trauma at birth and the potential risk for cerebral hemorrhage in the neonate. This serious complication is rare because the prevalence of fetal or neonatal ITP is about 10% that of maternal ITP, and less than half of these infants have platelet counts less than 20,000/μL. In the past, obstetricians performed antepartum cordocentesis (percutaneous umbilical vein blood sampling [PUBS]) or fetal scalp blood sampling to identify a fetus with a platelet count less than 50,000/μL and to deliver the fetus by the abdominal route. The current view holds that PUBS and fetal scalp sampling are unnecessary in pregnant women with known ITP even with platelet counts of 40,000/μL. Generally, when the maternal platelet count is greater than 50,000/μL, and the fetal platelet count (or the platelet count of previous offspring) is unknown, cesarean section is not indicated; a vaginal delivery is allowed, and the cesarean option is reserved for obstetric indications. If the fetal platelet count is known to be less than 20,000/μL, cesarean section is appropriate.

Treatment of ITP during pregnancy follows the guidelines published in 1996[9,20] and mainly reaffirmed later.[31] Pregnant patients with ITP and platelet counts greater than 50,000/μL throughout gestation and patients with platelet counts of 30,000-50,000/μL in the first or second trimester do not routinely require treatment.[20] Treatment in the form of glucocorticoids or intravenous immune globulin (IVIG) is indicated in patients with platelet counts less than 10,000/μL and patients with platelet counts of 10,000-30,000/μL who are in their second or third trimester or are bleeding. Intravenous immune globulin is an appropriate initial treatment for patients with platelet counts less than 10,000/μL in the third trimester and for patients with platelet counts of 10,000-30,000/μL who are bleeding. When glucocorticoid and IVIG therapy have failed, splenectomy is appropriate in the second trimester in women with platelet counts less than 10,000/μL who are bleeding. Splenectomy should not be performed in asymptomatic pregnant women with platelet counts greater than 10,000/μL.[20] Platelet transfusion is indicated for patients with counts less than 10,000/μL before a planned cesarean section and for those who are bleeding and expected to deliver vaginally. Prophylactic transfusions are unnecessary when the platelet count is greater than 30,000/μL and there is no bleeding.

Immune thrombocytopenic purpura does not preclude breastfeeding. The use of IVIG during pregnancy may improve platelet counts in the mother, but the treatment may not prevent fetal thrombocytopenia because the placental transfer of IVIG is inconsistent and mostly insufficient to reach fetal therapeutic levels.[3] A retrospective study examined the morbidity of 92 obstetric patients with ITP during 119 pregnancies over an 11-year period.[35] The authors found that most of these patients had thrombocytopenia during pregnancy. At delivery, 89% had platelet counts less than 150,000/μL. For many patients, the pregnancy was uneventful; however, 21.5% of the women had moderate to severe bleeding. In 31.1% of the pregnancies, treatment was required to increase the platelet counts. Most deliveries (82.4%) were vaginal. Platelet counts of less than 150,000/μL were found in 25.2% of the infants, including 9% with platelet counts less than 50,000/μL. Treatment for hemostatic impairment was necessary in 14.6% of the infants. During the study period, two fetal deaths occurred, including one caused by hemorrhage.[35]

After birth, the platelet count of newborns whose mothers have ITP-mediated thrombocytopenia may continue to decrease, and careful follow-up of the thrombocytopenia should be performed during the first week of life. Ultrasound imaging of the brain seems to be indicated if the count is less than 50,000/μL, even in the absence of neurologic findings. Neonates who exhibit severe thrombocytopenia (<20,000/μL) should be treated with platelet transfusion or IVIG or both. Neonates with platelet counts of 20,000-50,000/μL do not require IVIG treatment;

however, careful platelet count monitoring is needed. Neonates with intracranial hemorrhage or any other bleeding manifestation should be treated with combined platelet transfusion and IVIG or glucocorticoid therapy, especially if the platelet count is less than 20,000/μL. Neonatal thrombocytopenia usually resolves within 4-6 weeks.

Neonatal Alloimmune Thrombocytopenia

The pathogenesis of neonatal alloimmune (also known as isoimmune) thrombocytopenia is similar to Rh disease. A mother with antigen-negative platelets is sensitized by antigen-positive fetal platelets gaining access to the maternal circulation via breaches in the placental barrier. As a result, the mother produces antiplatelet antibodies, and these IgG antibodies cross the placenta and destroy the fetal platelets. In contrast to Rh disease, 50% of neonatal alloimmune thrombocytopenia cases occur during the first pregnancy of an at-risk couple. This difference is explained by the higher immunogenicity of the platelet antigen and the smaller size of the platelets, which may facilitate their fetomaternal transfusion.

Of the several types of platelet antigens, the human platelet antigen 1a (HPA-1a) is involved in 80%-90% of neonatal alloimmune thrombocytopenia cases in whites, and HPA-5b is responsible for a further 5%-15% of the cases.[19] Among people of color (e.g., Asians), HPA-1a incompatibility is a rare cause of neonatal alloimmune thrombocytopenia, and other alloantigens (e.g., HPA-4b) are implicated.[5] The fetus acquires the antigen from the father. When the father is heterozygous, 50% of the fetuses would be affected, whereas all fetuses of a homozygous father would be HPA positive.

The prevalence of neonatal alloimmune thrombocytopenia is 0.5-2 cases per 1000 deliveries. Fetomaternal platelet incompatibility is much more frequent. The discrepancy is explained by the facilitating role of certain human leukocyte antigen (HLA) types that are associated with the development of neonatal alloimmune thrombocytopenia. HLA-DR3 is associated with a 10- to 30-fold risk for HPA-1a antibody production.

In the usual scenario, an asymptomatic woman delivers an otherwise normal infant in an otherwise uncomplicated birth. Most neonates are asymptomatic, and the thrombocytopenia is detected by a blood count performed for other perinatal causes. In some cases, neonates present with generalized petechiae, hemorrhage into abdominal viscera, excessive bleeding after venipuncture or circumcision, or, in extreme cases, abnormal neurologic manifestations secondary to intracranial hemorrhage. The platelet count commonly decreases further during the first week after birth.

The diagnosis of neonatal alloimmune thrombocytopenia involves typing platelet antigens in the newborn and in the parents to show that the mother lacks a platelet antigen that is present on the platelets of the father and the neonate. A more sophisticated test is to establish the existence of the antiplatelet antibody in the mother's serum that is directed against a platelet antigen in the father. Testing the infant is generally unnecessary if the father is available for testing.

Human platelet antigen genotyping is now available as a routine laboratory technique and can be used to identify HPA incompatibilities between mother and child. Several techniques are known, and the polymerase chain reaction with sequence-specific primers is used. New microarray technologies are expected to support routine genotyping of all known HPAs, which allows detection of incompatibilities for low-frequency antigens, increasing the sensitivity for the detection of antibodies against low-frequency antigens.

Older methods that measure the antibody associated with platelets lack adequate specificity, but newer enzyme-linked immunosorbent assays specifically detect the antiplatelet antibody. In antigen capture immunoassays, monoclonal antibodies directed against platelet antigens are used to identify various known platelet antigens individually, although these may be negative in maternal blood 2-4 weeks after delivery in 30% of the cases. Flow cytometry and polymerase chain reaction assays can also be used to identify the patient's platelet antigens. Establishing the diagnosis of neonatal alloimmune thrombocytopenia has immediate importance and implications for future pregnancies.

Management of the Neonate

In suspected cases of neonatal alloimmune thrombocytopenia, treatment should be started on the basis of the clinical diagnosis without waiting for the results of the immunologic workup. Management depends on the gestational age of the infant, the severity of the thrombocytopenia, the presence of bleeding, and the presence of additional risk factors for bleeding. Treatment is based on transfusion of random-donor, ABO-compatible and Rh-compatible, and HPA-1a-negative platelets (preferably with HPA-5b–negative platelets as well) in neonates with severe thrombocytopenia. This transfusion is compatible in approximately 90% of cases of neonatal alloimmune thrombocytopenia.[5,16,36] When random-donor platelets are unavailable, washed maternal platelets can be administered. Human platelet antigen–incompatible platelets should be used only if compatible ones are unavailable; they can be combined with IVIG treatment to achieve a transient increase in the platelet count until IVIG becomes effective.[5]

High-dose IVIG, 1 g/kg per day for 2 days or 0.5 g/kg per day for 4 days, is also effective in increasing the platelet count in most cases,[5] although the increase may be delayed for 1 or 2 days.[11] Corticosteroids were used in the past but have become less popular since the availability of IVIG. In any case, the neonatal platelet count should be closely monitored during the first days of life.

Management of a Subsequent Pregnancy

When the diagnosis of alloimmune thrombocytopenia is established, parents need to be counseled regarding risks and management of future pregnancies. The recurrence rate of neonatal alloimmune thrombocytopenia in a subsequent

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

pregnancy is greater than 90%, and the risk for intracranial hemorrhage is the same or greater than in the previous pregnancy. The difference is, however, that in a subsequent pregnancy the patient and her caregivers are aware of the neonatal alloimmune thrombocytopenia affecting the first child. In the absence of screening (which has very low cost-effectiveness) for the presence of antiplatelet antibodies in maternal blood, the diagnosis is almost impossible without a history of neonatal alloimmune thrombocytopenia in a previous gestation. One exception is an incidental finding of intracranial hemorrhage during an ultrasound scan.

The risk for antenatal intracranial hemorrhage in the fetus with alloimmune thrombocytopenia is substantial enough to warrant intervention either by giving the mother weekly infusions of high-dose IVIG with or without corticosteroids (the preferred approach in North American centers) or by repeated in utero fetal platelet transfusions (the preferred approach in some European centers).[5] There is no way to predict which infant is going to have intracranial hemorrhage.[33] Antenatal therapy is aimed at increasing the number of fetal platelets regardless of the presence of a risk factor.

Although screening procedures are not indicated to detect neonatal alloimmune thrombocytopenia, a high index of suspicion is needed in certain cases (Box 20.2). Typically, a woman presents in early pregnancy with a history of delivering an infant with neonatal alloimmune thrombocytopenia or presents with some clues to the diagnosis.[27] The first step should be assessment of the father. In the heterozygous case, the status of the fetus is unknown, and direct assessment of fetal platelets is via PUBS or via genotyping cells in the amniotic fluid. The timing of the procedure and the risk involved are matters of debate. Failure to treat carries the risk for intrauterine intracranial hemorrhage, which is expected to occur in 30% of cases, with 10% of affected newborns dying and 20% experiencing neurologic sequelae secondary to intracranial hemorrhage. Percutaneous umbilical vein blood sampling has a high risk for miscarriage or fetal death. The operator must be prepared to transfuse platelets if the results show a dangerously low platelet count. If the infant is found to be HPA positive or the father is homozygous for the allele, there is a choice between serial platelet transfusions and IVIG administered to the mother.[32] Amniocentesis is performed mainly to exclude the presence of platelet antigens and thus to avoid unnecessary interventions.

• BOX 20.2 Maternal History That Merits Assessment of Alloimmune Thrombocytopenia

- Previous infant with proven alloimmune thrombocytopenia
- Fetal hydrocephalus
- Delivery of an infant with petechiae, bruising, or hemorrhage in an otherwise atraumatic delivery
- Unexplained fetal thrombocytopenia with or without anemia
- Recurrent miscarriages

Serial intrauterine platelet transfusions carry the risk of a single PUBS multiplied by the number of procedures. Because the survival of transfused thrombocytes is short, performing serial intrauterine transfusions requires repeating the procedure every week or 10 days.[32] In a study of the fetal loss rate in neonatal alloimmune thrombocytopenia managed by serial platelet transfusions, the authors found two perinatal losses in 12 pregnancies managed by a total of 84 platelet transfusions.[32] One loss was procedure related and resulted from exsanguination despite platelet transfusion. The procedure-related fetal loss rate was 1.2% per procedure but 8.3% per pregnancy. The authors calculated a cumulative risk for serial weekly transfusions of approximately 6% per pregnancy, indicating the need to develop less invasive approaches.[32]

The invasive procedure is used less often now than previously; this may be the result of favorable outcomes related to maternal treatment with high-dose IVIG (1 g/kg per week). The beneficial effect of megadose IVIG is presumably mediated by masking the antigenic effect of fetal platelets, reducing the production of antiplatelet antibodies. Intravenous immune globulin also stabilizes endothelial cells and reduces the incidence of intracranial hemorrhage even when the fetal platelet count remains low. It is debatable whether corticosteroids should be added to the IVIG management protocol.[26]

A European collaborative study of the antenatal management of neonatal alloimmune thrombocytopenia attempted to determine whether the severity of the disease in the current pregnancy could be predicted from the history of neonatal alloimmune thrombocytopenia in previous pregnancies and to assess the effects of different types of antenatal intervention.[4] The study enrolled 56 women who had had a prior infant affected by neonatal alloimmune thrombocytopenia owing to HPA-1a alloimmunization. The authors found that fetuses with a sibling history of antenatal intracranial hemorrhage or severe thrombocytopenia (a platelet count of <20,000/μL) had significantly lower pretreatment platelet counts than fetuses whose siblings had less severe thrombocytopenia or postnatal intracranial hemorrhage. Maternal therapy resulted in a platelet count exceeding 50,000/μL in 67% of cases. None of the fetuses managed by serial platelet intrauterine transfusions had intracranial hemorrhage after treatment. Several serious complications of PUBS arose, however. The results of this study suggest that the start of therapy can be stratified on the basis of the sibling history of neonatal alloimmune thrombocytopenia and support the use of maternal therapy as first-line treatment.[4]

Some patients who receive IVIG do not respond. Nonresponders cannot be recognized without PUBS, however.[10] When PUBS is planned to assess the effectiveness of therapy, the preparation for intrauterine platelet transfusion should be similar to the procedure used when PUBS is performed to diagnose neonatal alloimmune thrombocytopenia in a case with a heterozygous father (i.e., when the risk of an affected fetus is 50%). Nonresponders may be treated with either serial intrauterine platelet transfusions or steroids

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

added to IVIG. It has been suggested that such assessment of treatment is unnecessary in patients who previously responded to IVIG therapy.

Alloimmune thrombocytopenia may also result from fetomaternal HLA mismatch. The meaning and treatment of this rare situation are controversial.

Fetal-Neonatal Consequences of Maternal Antinuclear Antibodies

Antinuclear antibodies (ANAs) are produced in various diseases with an immune component (Box 20.3). Antinuclear antibodies of the IgG and IgM types bind to nuclei or to nuclear components. Their presence is detected in the patient's serum, and they may be classified according to their subunits, each of which is related to the diagnosis of a disease. Anti-double-stranded DNA (anti-dsDNA) antibodies are specific for systemic lupus erythematosus. In this chapter, the maternal manifestations of these autoimmune diseases are not discussed; the focus is on neonatal lupus—a model of passively acquired autoimmunity—and the effects of the ANAs anti-Ro and anti-La.

Neonatal lupus is caused by transplacental passage of maternal autoantibodies. It is rare: Only about 1% of infants with maternal ANAs develop neonatal lupus. The infant may present with cardiac, dermatologic, hepatic, and hematologic manifestations. In children with neonatal lupus, there is commonly involvement of only one or two organ systems. The skin lesions on the face and scalp, often in a distinctive periorbital distribution, may be present at birth but usually develop within the first few weeks of life and tend to resolve in a few weeks or months without scarring.[29] Fetal heart block typically begins during the second or third trimester of pregnancy. In some instances, this begins as first- or second-degree heart block and progresses to third-degree heart block.[29] Complete heart block seems to be irreversible and may be combined with cardiomyopathy (see Chapter 77).[29] Hepatobiliary complications (10% of cases) may be manifested as liver failure occurring at birth or in utero, transient conjugated hyperbilirubinemia, or transient transaminase elevations occurring in infancy.[29] Thrombocytopenia, neutropenia, or anemia occurs in about 10% of affected infants. The noncardiac manifestations are transient and tend to resolve within months after birth. A case of neonatal lupus affecting both twins has been described.[34]

Mothers of children with neonatal lupus may have ANA-related connective tissue disease (e.g., systemic lupus erythematosus, Sjögren syndrome, undifferentiated autoimmune syndrome, or rheumatoid arthritis). The recurrence rate of neonatal lupus for a mother with anti-Ro autoantibodies, which are present in almost 95% of patients, is approximately 25%. Immunoglobulin G (IgG) autoantibodies are found alone or in combination and are directed against Ro (SSA), La (SSB), or U1-RNA (U1-RNP) antigens, and their presence increases the risk for neonatal lupus erythematosus.

Anti-Ro and anti-La autoantibodies recognize cardiac adrenoceptors and muscarinic receptors, and this recognition may explain the cardiac arrhythmia associated with these ANAs. Maternal anti-Ro and anti-La antibodies and complement components are deposited in fetal heart tissues, leading to inflammation, calcification, necrosis, and fibrosis of the conducting tissue (and, in some cases, of the surrounding myocardium).[12] The postinflammation fibrotic response to injury is quite rapid and, in most cases, irreversible. The process by which maternal anti-Ro or anti-La antibodies begin and propagate inflammation that leads to scarring of the atrioventricular node is not entirely clear. It has been proposed that the process begins with apoptosis of cardiocytes, resulting in translocation of Ro or La antigens and subsequent surface binding by maternal ANAs. This leads to a phagocytosis-mediated scarring process.[12] In addition, the anti-Ro antibodies have been shown to have arrhythmogenic activity through inhibition of calcium flux across cell membranes.[7] Animal models suggest that reactivity to the p200 region of the Ro52 protein and antibody targeting of L-type calcium channels may be associated in the developing cardiac neonatal lupus.[25] In vitro, the β-2 glycoprotein 1 seems to prevent anti-Ro binding to apoptotic cells, the urokinase-plasminogen activator/receptor system seems to activate TGF-β, and endothelin-1 secretion by macrophages seems to mediate tissue injury.[25] It also appears that fetal major histocompatibility complex is involved in the pathogenesis.[25] Interestingly, it was demonstrated that mothers of children with neonatal lupus accumulate genetic risk factors preferentially from the neonatal lupus child's grandparents.[25]

• BOX 20.3 Conditions Associated With Antinuclear Antibodies

Rheumatologic Conditions

- Systemic lupus erythematosus
- Rheumatoid arthritis
- Mixed connective tissue disease
- Sjögren syndrome
- Necrotizing vasculitis

Infections

- Chronic active hepatitis
- Subacute bacterial endocarditis
- Infection with human immunodeficiency virus
- Tuberculosis

Miscellaneous Conditions

- Type I diabetes mellitus
- Multiple sclerosis
- Pulmonary fibrosis
- Silicone gel implants
- Pregnancy
- Age: older adult

Medications

- Drug-induced lupus erythematosus

The cardiac rhythm disorders increase the risk for fetal congestive heart failure and point to the most important intervention during pregnancy, close follow-up with echocardiography and ultrasonography. Echocardiography can show the conduction defect and estimate the cardiac function.

About 10% of fetuses with congenital heart block are born with hydrops fetalis and congestive heart failure, and their prognosis is poor (see Chapter 23). Retrospective studies addressed the role of fluorinated steroids, IVIG, and hydroxychloroquine for prevention and treatment.[25] Intrauterine treatment with maternal corticosteroids may decrease the pericardial effusion or improve the symptoms of heart failure, but the heart block remains. Prophylactic treatment with IVIG awaits larger clinical trials.[13] It is possible to place an intrauterine pacemaker, but success is not ensured. Neonatal mortality rate in infants born with a congenital heart block ranges from 20%-30%; however, death may occur from late pacemaker failure later in childhood. Most neonates born with a heart block secondary to neonatal lupus require pacemaker placement in the neonatal period or later in life. Most children with neonatal lupus do not seem to develop rheumatic diseases, but follow-up has been limited to late adolescence.[13]

Fetal-Neonatal Consequences of Maternal Antiphospholipid Antibodies

Phospholipids are involved in facilitating the coagulation cascade. Antiphospholipid antibodies (APLAs) are autoantibodies against phospholipids or against plasma proteins bound to phospholipids. The most common subgroups involved in disease states are anticardiolipin antibodies, lupus anticoagulant antibodies, and anti–β_2-glycoprotein I antibodies. The hypercoagulability function of these antibodies is epitomized by the fact that they cause "bleeding in the test tube but clotting in the body," referring to their involvement in pathologic clotting. Antiphospholipid antibodies promote clotting in arteries and veins (i.e., thrombophilia) by activation of endothelial cells, via oxidant-mediated injury to endothelium, and by modulating the regulatory function of coagulation proteins.

It is common practice to use clinical and laboratory criteria for the diagnosis of APLA syndrome. According to the Sapporo criteria, patients are required to have either vascular thrombosis (venous or arterial, including neurologic disease) or fetal loss, and to show evidence of APLA either by the detection of anticardiolipin antibodies or by a positive test for lupus anticoagulant antibodies.[22] At present, one should look for the lupus anticoagulant (LAC), antiphospholipid antibody (APLA), and anti–β-2-glycoprotein I. To differentiate between persistent autoantibody response and transient responses from other causes, APLA must be detected on at least two occasions 12 weeks apart. These classification criteria are reported to have a sensitivity of greater than 75% and a specificity of nearly 100%. Patients with APLA and one major clinical criterion are considered to have APLA syndrome. Primary APLA syndrome refers to the syndrome occurring outside the setting of systemic lupus erythematosus.[30]

In women with APLA, there is a high incidence of pregnancy complications. Among women with a history of recurrent miscarriage (three or more consecutive losses of pregnancy), 15% have persistently positive test results for APLA and a rate of fetal loss of 90% when no specific treatment is given during pregnancy[22]; 25% of successful pregnancies were delivered prematurely.[22] Other potential complications of pregnancy include preeclampsia, placental insufficiency, fetal growth impairment, preterm birth, maternal thrombosis (including stroke), and complications of treatment.[8]

The pathogenesis underlying thrombosis and fetal loss in APLA syndrome remains to be established. The potential mechanisms that have been proposed include interference with the function of the coagulation cascade leading to a procoagulant state, cellular immune mechanisms, and the presence of predisposing factors. A "second hit" may be necessary for the clinical manifestation of the syndrome to occur.[22] The adverse effect of APLA syndrome on pregnancy is most likely associated with abnormal placental function.[8] Studies have shown abnormalities in the decidual spiral arteries, narrowing of the spiral arterioles, intimal thickening, acute atherosis, and fibrinoid necrosis in cases of fetal loss associated with APLA syndrome.[8] Other studies have found extensive placental necrosis, infarction, and thrombosis related to the procoagulant activity of APLAs in inducing adhesion molecules, platelet activation, and aggregation factors and the inhibition of key anticoagulant factors (see Chapter 27). The possibility of APLA-related neurologic morbidity (in the form of cerebral palsy) in the fetus or neonate is of major medicolegal importance and under investigation. At present, except from case reports, the association between fetal-neonatal thrombophilia from APLA and neurologic damage is yet to be established.

Treatment options include corticosteroids, low-dose aspirin, heparin (either fractionated or unfractionated),[6] and IVIG. These were administered either as single agents or in combination to increase the live birth rates in women with APLA syndrome. Although the available studies are flawed by small sample size, varying entry criteria and treatment protocols, and lack of standardized laboratory assays, many clinicians would treat patients with APLA syndrome with a combination of aspirin and heparin (fractionated or unfractionated).

There are few trials evaluating treatment of refractory APLA syndrome (recurrent pregnancy losses occur in 20%-30% of cases in most studies). A woman whose pregnancy fails on a prophylactic regimen should receive full anticoagulation therapy in a subsequent pregnancy.[8] If the treated pregnancy with full anticoagulation fails, some physicians advise adding glucocorticoids, IVIG, or hydroxychloroquine to the anticoagulation regimen.[8] The interested

reader is referred to the review discussing the pathogenesis of the antiphospholipid syndrome.[21]

Myasthenia Gravis

Myasthenia gravis is an autoimmune neuromuscular disease affecting twice as many women as men, and it usually affects women in their third decade of life. The symptoms include weakness and fatigue of the skeletal muscles of the face and extremities. The diagnosis, which is beyond the scope of this chapter, involves a comprehensive neurologic workup based on clinical history and signs, improvement with anticholinesterase injection (edrophonium), determination of serum anti–acetylcholine receptor (AChR) antibody titers by radioimmunoassay, and electromyography.

In 90% of patients with myasthenia gravis, autoantibodies (usually IgG) against human AChRs are detected. The antibodies interfere with impulse conduction across neuromuscular junctions by decreasing the number of available AChRs there. Because myasthenia gravis typically affects women during reproductive years, the potential for exacerbation, respiratory failure, adverse drug response, crisis, and death during pregnancy is of great concern. Myasthenia gravis has a variable and unpredictable course during pregnancy, including exacerbation, crisis, and remission. In one study, 17% of asymptomatic patients with myasthenia gravis who were not receiving therapy before conception had a relapse; among patients receiving therapy, myasthenia gravis symptoms improved in 39%, remained unchanged in 42%, and deteriorated in 19% of the pregnancies. Myasthenia gravis symptoms worsened after delivery in 28% of the pregnancies.[1] In another study, myasthenia gravis symptoms deteriorated in 15% of the pregnancies, and a further 16% deteriorated during the puerperium.[17]

Therapy is based on anticholinesterase medications and plasmapheresis during a myasthenia gravis crisis. Other medications often have adverse effects on the disease, resulting in a long list of drugs that should be avoided in these patients. Plasmapheresis can be performed during pregnancy but may be associated with preterm birth. Of special concern are cesarean delivery and the hazards of anesthesia, which might prove very stressful for these patients. Some complications of myasthenia gravis in the form of exacerbation should be anticipated during pregnancy, including anxiety and physiologic stress of pregnancy (mainly present as hypoventilation), infection, a prolonged second stage at delivery (because the patient may become exhausted and be unable to push), and the contraindication to using magnesium sulfate in patients with preeclampsia.

Neonatal risks of myasthenia gravis include neonatal myasthenia gravis, prematurity, malformation, and death. Neonatal myasthenia gravis occurs in 10%-20% of infants born to mothers with myasthenia gravis and is caused by the transplacental transport of immunoglobulins from mother to infant. There is no correlation between myasthenia gravis severity and neonatal myasthenia gravis, and there is no correlation between maternal anti-AChR antibody titers and the occurrence of neonatal myasthenia gravis. This discrepancy is partially explained in neonatal myasthenia gravis by the protective role of α-fetoprotein, which inhibits the binding of myasthenia gravis antibody to its receptor.

The infant's symptoms are generally manifested by the third day of life in the form of respiratory distress and inadequate suck, which may gradually subside over 1-4 weeks. Rarely the disease becomes permanent when there is irreversible destruction of AChR by the maternal antibodies, or when there is production of antibodies by the infant. Analysis of data collected from the Medical Birth Registry of Norway, comparing 127 births by women with myasthenia gravis with 1.9 million births by women without myasthenia gravis, showed that women with myasthenia gravis had a higher rate of complications at delivery. In particular, the risk for preterm rupture of membranes was threefold higher in the myasthenia gravis group. Interventions during birth were also significantly increased, and the rate of cesarean section was twice that of the general population. Five children (3.9%) born to mothers with myasthenia gravis had severe anomalies, and three of them died.[23]

Herpes Gestationis

Herpes gestationis, also known as pemphigoid gestationis, is a rare autoimmune skin disease of pregnancy, occurring in less than 1 in about 50,000 pregnancies. Despite its name, herpes gestationis has no association with the herpesvirus infection. During pregnancy, IgG autoantibodies are produced against an important element in epidermal-dermal adhesion—the bullous pemphigoid antigen 2 (BPAg2, also known as BP180). It is assumed that these autoantibodies bind complement to the basement membrane of the epidermis and activate an immunodermatologic reaction that is responsible for the development of subepidermal vesiculae and bullae.[28]

Herpes gestationis is sometimes associated with other autoimmune diseases, and it seems that all these conditions have in common a relationship to HLA-B8 and HLA-DR3. Although herpes gestationis most commonly manifests during the second and third trimesters, in 25% of the cases it develops during the puerperium. There are reported cases of persistent herpes gestationis, but usually the disease spontaneously regresses after birth.[2]

Affected women usually present with inexorable pruritus associated with erythematous urticarial patches and plaques, which are typically located around the navel. The skin lesions may progress to tense vesicles and blisters, which spread peripherally. The face, palms, soles, and mucous membranes are usually unaffected. Although the symptoms usually wane toward the end of pregnancy, peripartum exacerbations do exist. Herpes gestationis may recur in subsequent pregnancies, and it may recur with menses and oral contraception.

The diagnosis is usually reached by collaboration between the attending obstetrician and an immunodermatologist.

Treatment is directed toward alleviation of itching and suppression of blistering. Lukewarm baths or compresses may reduce the irritation, but corticosteroids (local, intralesional, or systemic) remain the primary therapeutic means. New treatment modalities including cyclosporine, IVIG, and tetracyclines postpartum have shown promising results.[28]

Herpes gestationis is associated with a greater incidence of premature birth and neonates who are small for gestational age. The infants of affected mothers may rarely have transient cutaneous manifestations, which disappear along with the clearance of maternal autoantibodies.[15,18] Blistering may increase the risk, however, for superimposed infection, thermoregulatory problems, and fluid and electrolyte imbalance. The attending neonatologist should also be aware of the medications received by the mother. The interested reader is referred to two reviews.[14,24]

Summary

This chapter discusses several examples of maternal immune-mediated conditions that may directly affect the fetus or neonate. Some of these conditions are quite rare, but some may be encountered in daily practice. From the neonatal point of view, the main mechanism of disease is transplacental transfer of antibodies from the mother to the fetus and the effect of these antibodies on fetal components. The last decade has witnessed great progress in better understanding the underlying pathogenesis of most of these conditions. In many instances, therapy remains controversial, however.

Key Points

- Maternal IgG antibodies are able to cross the placenta and affect the fetus-neonate.
- Better understanding the underlying pathogenesis of most immune conditions has not resulted in clearcut therapy before birth and in the neonatal period.

Obstetric Management of Multiple Gestation and Birth

ISAAC BLICKSTEIN AND ERIC S. SHINWELL

The human female is programmed by nature to mono-ovulate, to nurture one fetus, and to take care of one neonate at a time. This natural pattern results in the relatively rare birth of twins (about 1 per 80 to 100 births) and in the extremely rare occurrence of high-order multiple gestations. The rarity of high-order multiple gestations can be appreciated by the quasi-mathematical Hellin-Zellany rule for twins, triplets, and quadruplets.[11] According to this rule, if the frequency of twins in a population is $1/N$, the frequency of triplets would be $1/N^2$, and that of quadruplets would be $1/N^3$.

The Hellin-Zellany relationship was found to be accurate as long as the population remained homogeneous and natural procreation occurred. In the middle of the twentieth century, however, it became apparent that deviations from the rule occur mainly because of racial differences in the frequency of dizygotic twinning.

This ordinary circumstance did not change until the emergence of effective treatment of infertility. Thereafter, it became clear that within an infinitely small fraction in human history, all we knew about natural multiples has been profoundly changed. Physician-made (iatrogenic) multiple gestations are now seen in most developed countries, with frequencies approaching 50% of twins and more than 75% of high-order multiple gestations. The contribution of infertility treatment can be appreciated from data of the 2015 Israel Neonatal Network. The data indicate that among infants weighing less than 1500 g, 13% of singletons were conceived by assisted reproduction compared with 51% of twins and 79% of triplets.[48] The reduced incidence of multiples among these very low birth infants is presumably a result of the new policies of embryo transfer in assisted reproduction.

Biology

Most human conceptions (>99.2%) emerge from a single zygote (i.e., monozygotic [MZ]), resulting from the fertilization of a single egg by a single spermatozoon. In the remaining cases, more than one egg is ovulated and fertilized, resulting in polyzygotic conceptions (i.e., dizygotic [DZ], trizygotic). This phenomenon occurs more often in taller, older, parous, heavier, and black women. Although direct and indirect evidence points to a genetic predisposition, the exact mechanism whereby the ovary is naturally stimulated to release more than one egg per cycle is unknown. All infertility treatments are associated, however, with ovarian stimulation and polyovulation. The contribution of infertility treatments to polyzygotic gestations has become extremely significant since the 1970s.

Most MZ conceptions result in singleton births. In a small fraction of cases (0.4% of all natural conceptions), the zygote splits to form an MZ twin gestation. The mechanism of zygotic splitting is unclear. It has been postulated (but never completely established) that all forms of assisted reproduction produce a breach in the integrity of the zona pellucida—the acellular layer of the egg—resulting in herniation of the part of the early embryo through that gap and splitting of the embryo.

The frequency of MZ splitting is also increased with all methods of assisted reproduction.[24] The true incidence of zygotic splitting after assisted reproduction is unknown. In a large study of single-embryo transfers, a sixfold increase in zygotic splitting was found. The frequency was not influenced by using fresh versus frozen-thawed embryos or by performing embryo transfers during a spontaneous versus an induced cycle.[24] A later hypothesis suggests that the potential to undergo splitting might be an inherent characteristic of the oocyte.[15]

Two points related to the issue of DZ and MZ twinning warrant further discussion. The first is the change of overall frequency of MZ conceptions. In a population comprising mainly of spontaneous gestations, the usual quoted frequency of MZ twinning is about one-third of the twin population, whereas in a population comprising a sizable proportion of iatrogenic pregnancies, one should expect one MZ pregnancy in 15-20 twin gestations.

The second point to consider is the placental arrangement (see Chapter 26). Dizygotic twins have two placentas (separate or fused), each with chorion and amnion, forming

Abstract

The incidence of twins is continuously increasing worldwide. This is mainly a result of iatrogenic multiples following assisted reproduction. At the same time, the incidence of triplets seems to be, at present, high but steady. Since the most important disadvantage of multiples is preterm and very preterm births, the net effect is a continuing rise of prematurity. Most twins are dizygotic and, hence, have a dichorionic placenta. Less common, the very early embryo might split to create monozygotic twins. The subset of monochorionic twins is of particular interest because of the associated peculiar morbidity. It follows that chorionicity assessment by ultrasound is a critical step in the management of multiples.

Monozygotic twins have also an increased risk of malformations, some of which are among the most extraordinary anomalies (such as twin reverse arterial perfusion [TRAP] sequence and conjoined twins). It appears that all multiple pregnancies need special attention during pregnancy by experienced personnel. During pregnancy, the role of ultrasound in establishing the wellbeing of the set is indispensable. In some situations in monochorionic twins (such twin–twin transfusion syndrome, selective anomaly, selective growth restriction), intrauterine surgery may be indicated.

The risk of prematurity is plurality dependent. This has resulted in multifetal pregnancy reduction offered to expected mothers of triples and more. The risk of prematurity has direct effect on perinatal morbidity and mortality.

Most twins are born by cesarean section as are practically all higher-order multiples.

the so-called dichorionic (DC) placenta. Placentation of the MZ twins is postulated to depend, however, on the stage of embryonic development at which the split occurs. It is believed that early splits (about one-third) result in DC placentas, whereas later splits result in monochorionic (MC) placentas. If the amnion has not yet differentiated, the MC placenta includes two amniotic sacs: the MC-diamniotic placenta (about two-thirds of the cases). If the split occurs later than 8 days after fertilization, an MC-monoamniotic placenta develops. Finally even later splits result in all varieties of conjoined twins. However, one should remember that this well-known theory has never been proved.

When describing a multiple gestation, one must differentiate between zygosity and chorionicity. Because MZ conceptions with a DC placenta cannot be differentiated clinically from same-sex DZ twins (half of DZ conceptions) who also have a DC placenta, zygosity can be determined with certainty only in the DC—unlike sex twins (all must be DZ conceptions) and in twins with an MC placenta (all must be MZ conceptions). Simple calculation reveals that we are blind to zygosity in about 45% of the cases, and zygosity determination must be performed by DNA testing. Thus nothing should be said about zygosity to parents of same-sex twins with a DC placenta.

Maternal Consequences

When discussing maternal complications during multiple gestation, two important issues should be considered. The first issue involves the significant changes in the roles of women in Western societies witnessed after World War II. The new roles in society were facilitated by effective contraception, allowing ample time to achieve education and a career. This change resulted in increased maternal age at first delivery. Because age and fecundity are inversely related, however, infertility treatment to achieve a pregnancy often becomes inevitable. Because all infertility treatments carry an increased risk of multiple gestations, the end result of these sociomedical trends is an increased age of the cohort of mothers of multiples. US data clearly show that the increase in maternal age is more striking in high-order multiple gestations than in twins and in twins than in singletons, with a net result of multiples being more often delivered to older mothers in whom chronic disease conditions have already accumulated.[6]

The second issue involves the overwhelmed maternal homeostasis. Consider the fact that the average singleton, twin, and triplet have a similar birth weight until 28 weeks (≈1000 g). By 28 weeks, the mother of twins and the mother of triplets have accumulated twice and three times the fetal mass of singletons. This excess of fetal mass must come from either existing maternal resources or from supplemental energy. During the third trimester, all maternal systems are overwhelmed, and some may be only a step away from clinical insufficiency.

Two examples vividly demonstrate the situation. The first is the increased frequency of clinically significant anemia as a result of depleted maternal iron stores or inadequate iron supplementation.[18] The incidence of anemia is significantly increased among mothers of multiples. A second example relates to the increased cardiac output. It has been estimated that in the worst-case scenario (i.e., preterm labor because of infection in a multiple gestation), the cardiac output may exceed 10 L/min (two to three times the normal value). It is understandable why cardiac function so easily turns into dysfunction when additional load—in the form of β-sympathomimetic tocolysis—is administered to a patient with multiples who experience premature contractions.[54]

Regardless of the inherent changes in maternal physiology resulting from the multiple gestation, there are some maternal disease conditions that are more frequent in these gestations. Hypertensive disorders are two to three times more frequent,[50] and their most dangerous complication—eclampsia—is six times more frequent among mothers of multiple gestations.[31] Preeclamptic toxemia occurs earlier in multiples than in singletons and often occurs in a more severe form.[17] Because triplets and other high-order multiples were rare in the past, there were scant data related to hypertensive disorders in high-order multiple gestations. With the current epidemic dimensions of multiple gestations, it has been shown that the risk of hypertensive disorders depends on plurality: The risk in triplets is higher than that in twins, and the risk in twins is higher than that in singletons.[55]

Although the data are still conflicting, the frequency of gestational diabetes also seems to be increased among mothers of multiples. Critical reading of the literature suggests that most stimulation tests to detect glucose intolerance of various degrees showed a diabetogenic effect of multiple gestations, whereas demographic analyses failed to show increased rates of gestational diabetes.[33] The latter analyses were conducted in the era before the epidemic of iatrogenic multiples, however, and before the effect of older maternal age could be documented.[33] Sivan and colleagues showed that the risk of gestational diabetes depends on plurality, as is the case for hypertensive disorders.[53] The correlation of multiple gestation with hypertensive disorders and gestational diabetes seems to point, at least in a teleologic way, to the increased placental size—hyperplacentosis—as a potential common denominator. Simões and coworkers showed that pregravid obesity appears to predispose women to gestational diabetes during twin pregnancy and that there is no advantage in terms of birth weight in twins born to diabetic mothers.[51]

All mothers of multiples are at considerably greater risk of preterm labor and delivery. Preterm contractions with or without cervical changes quite often necessitate tocolytic treatment. Many prophylactic measures, including progestogens, cervical suture (cerclage), β-sympathomimetics, bed rest, and hospitalization, were proposed to reduce preterm birth rates (see Chapter 19). All prophylactic measures failed to reduce significantly this common complication of multiple gestation. A cervical pessary has been proposed to help in cases of preterm birth in twins.[34] Expecting mothers of

TABLE 21.1 Categories of Structural Defects in Twins

Category	Defect
Malformations more common in twins than in singletons	Neural tube defects Hydrocephaly Congenital heart disease Esophageal and anorectal atresia Intersex Genitourinary tract anomalies
Malformations unique to monozygotic twins	Amniotic band syndrome TRAP sequence Conjoined twins Twin embolization syndrome
Placental malformations	Single umbilical artery Twin–twin transfusion syndrome Velamentous cord insertion
Deformations owing to intrauterine crowding	Skeletal (postural) abnormalities

TRAP, Twin reverse arterial perfusion.

multiples are frequently asked to leave work and to conduct a more sedentary lifestyle. Box 21.1 lists the most common maternal complications during multiple gestations.[13]

Fetal and Neonatal Consequences

Animal models, similar to humans, show an inverse relationship between litter size and gestational age and birth weight. In humans, the average gestational age at birth is around 40 weeks for singletons, 36 weeks for twins, 32 weeks for triplets, and 29 weeks for quadruplets. Although multiple gestations exhibit many specific complications, the consequences of prematurity are the most common.

Malformations

Most texts cite a two- to threefold increased risk of malformations among multiples. It seems that the increased risk is primarily related to MZ twinning, however, and that the malformation rate of DZ twins is similar to that of singletons.[16] The higher malformation rate among MZ twins is explained by the hypothesis of a common teratogen; that is, the one that causes the split of the zygote is also responsible for the malformation.

Malformations among multiples are grouped into four types (Table 21.1).[16] The first type includes malformations that are more frequent among multiples, notably malformations affecting the central nervous and cardiovascular systems. The second type involves malformations related to MZ twinning, such as twin reverse arterial perfusion sequence and the various forms of conjoined twins. The third type relates to consequences of placental malformations, in particular the MC placenta, resulting in the twin–twin transfusion syndrome (TTTS). Finally, the fourth type involves skeletal (postural) deformities (e.g., clubfoot, dolichocephaly, brachycephaly) that are caused by intrauterine fetal crowding.

Some malformations can have a major impact on the properly formed twin. In the twin reverse arterial perfusion sequence, the circulation of the severely anomalous acardiac-acephalic twin is entirely supported by the normal (pump) twin. Sooner or later this cardiac overload leads to cardiac insufficiency of the apparently normal twin. Another example is the case in TTTS whereby both twins might be completely normal, but the anomalous transplacental shunt of blood can cause serious morbidity in both twins. The most striking example is the case of single fetal demise in MC twins, whereby the surviving fetus might die in utero soon after the death of the first twin. Alternatively, the surviving twin can be seriously damaged (see Embryonic and Fetal Demise).

In contrast to structural malformations, chromosomal anomalies are not more frequent among multiples. Each member of the multiple gestation has the same maternal age–dependent risk for trisomy 21. By probability calculations, the risk for a mother that one of her twins will have trisomy 21 is greater, however, than that of a mother of a singleton who is at the same age. A 32-year-old mother of twins has approximately the same risk of one infant with trisomy 21 as a 35-year-old mother of a singleton.[41]

Because multiples are commonly seen in older mothers, and invasive cytogenetic procedures (amniocentesis or chorionic villus sampling) carry a much higher risk of pregnancy loss when performed in multiples, there is a genuine

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

utility to maternal screening of aneuploidy to minimize the need for invasive procedures in these premium pregnancies. Screening tests such as the triple or quadruple test (second-trimester maternal serum human chorionic gonadotropin or free β-human chorionic gonadotropin, α-fetoprotein, and unconjugated estriol, with or without PAPP-A or inhibin) have a significantly lower prediction for trisomy 21 in multiples compared with singletons.[13] Thus at present, the basic screening for aneuploidy is the nuchal translucency thickness measurement.

Most structural anomalies can be detected by a comprehensive ultrasound scan. In addition, echocardiography and Doppler velocimetry can detect structural and functional cardiovascular anomalies. This ability raises the question of reduction of the anomalous twin. In multichorionic multiples, reduction is accomplished by ultrasound-guided intracardiac injection of potassium chloride. Because of the risk to the survivor in MC sets, however, highly invasive procedures are used to interrupt the umbilical circulation of the anomalous twin.

All invasive procedures (amniocentesis, chorionic villus sampling, and reduction methods) are associated with the risk of 5%-10% of membrane rupture and loss of the entire pregnancy. When an invasive procedure is considered during the second trimester, the risk of extremely preterm birth of the normal twin is apparent. This situation is exemplified in discordant lethal malformations. When one twin is anencephalic, the risk of reducing this twin should be weighed against the risk of endangering the normal fetus by preterm birth.

Embryonic and Fetal Demise

From the early days of sonography, it was clear that there are more twin gestations than twin deliveries. The early loss of one twin was eventually designated "vanishing" twin syndrome to denote the disappearance of an embryonic structure during the first trimester.[36] Many authorities consider this spontaneous reduction the natural equivalent of intentional multifetal gestation (numerical) reduction. The true frequency of vanishing twin syndrome is unknown, because many twin gestations remain unnoticed unless sonography is performed at an early stage. One estimate of frequency of vanishing twin syndrome comes from iatrogenic conceptions: Spontaneous reduction of one or more gestational sacs or embryos occurred before the 12th week of gestation in 36% of twin, 53% of triplet, and 65% of quadruplet gestations.[29] Pinborg and coworkers found that 1 in 10 singletons after IVF started as a twin pregnancy.[46] Interestingly, case-control studies on plurality-dependent spontaneous embryonic loss rates after assisted reproduction found that twin pregnancies have a two to five times lower miscarriage rate of the entire pregnancy compared with singletons.[40]

Single fetal death occurring beyond the first trimester is also more common in multiples. In DC twins, it is believed that the risk to the surviving twin is extremely low, and present only if there is an external insult such as maternal disease. Fetal death in MC twins is a totally different story.

Historically, it was believed that some ill-defined thromboplastin-like material is transfused from the dead to the live fetus—the twin embolization syndrome. The theory was that these emboli might cause fetal death or result in end-organ damage, such as brain and kidney lesions. In the early 1990s, after meticulous postmortem examinations, the embolic theory was replaced by the ischemic theory, which postulates that blood is acutely shunted from the live twin to the low-resistance circulation of the deceased fetus, causing acute hypovolemia, ischemia, and end-organ damage in the survivor. The chance of serious damage in the survivor is significant and estimated to be 20%-30%, although later estimations suggest lower figures.[45]

The diagnosis often is made some time after single fetal death, however, and the question arises whether prompt delivery is indicated to reduce the risk for the survivor. Data suggest that acute blood loss occurs just before the time of death of the surviving twin, and it is unlikely that immediate delivery of the surviving twin could decrease the associated high mortality and morbidity rates.[44] It is prudent to suggest conservative management in such cases, especially remote from term, and to use ultrasound and magnetic resonance imaging (MRI) to exclude brain lesions. MRI should be performed at 32 weeks' gestation, when white matter lesions can be better visualized.

Complications of the Monochorionic Placenta

The monochorionic (MC) placenta, by itself an anomalous structure, has three distinct pathologic structures. First, it is possible that the twins share unequal placental territories that inevitably lead to discordant growth. If the placental share of one twin is too small, selective intrauterine growth restriction (sIUGR) develops. Second, the MC placenta invariably contains interfetal anastomoses, and when there is significant unbalanced shunting, the twin–twin transfusion syndrome (TTTS) develops. Finally, most MC placentas have one umbilical cord attached to the membrane and to the side of the placenta—the so-called velamentous cord insertion. This placental anomaly is associated with growth restriction and TTTS.

TTTS is a consequence of MC twinning (see Chapter 26). TTTS is seen mainly (or only) in the diamniotic variety.[2] The extensive literature on TTTS may lead to the erroneous impression that the syndrome is frequently seen. TTTS occurs in about 10% of MC twins, and about half are of mild severity. Nonetheless, early-onset (before 20 weeks' gestation), severe TTTS, unless intensively treated, is associated with 100% mortality of both twins.

The pathology of TTTS is transplacental arteriovenous anastomoses that lead to shunting of blood from one twin (the donor) to the other (the recipient). Because all MC placentas have intertwin anastomoses, the syndrome probably occurs because of fewer compensating venovenous and arterioarterial connections. The hypovolemia of the

donor is manifested by poor micturition (absent bladder and oligohydramnios on ultrasound scan) and signs of growth restriction. Conversely the hypervolemic recipient is surrounded by polyhydramnios and manifests signs of cardiac overload ranging from tricuspid regurgitation to cardiac insufficiency and hydrops fetalis.[58] Thus, the first stage (Quintero's) of TTTS is the twin oligohydramnios-polyhydramnios sequence (TOPS), followed by (stage II) absent urinary bladder on sonography of the donor, then pathologic Doppler values, and finally hydrops before fetal death. Intervention is at present indicated in all cases of stage II or higher. Treatment of stage I is currently controversial.

Many treatment modalities have been suggested to treat TTTS (Box 21.2).[47,58] Generally, TTTS means serious morbidity, but the specific outcome is related to the gestational age when TTTS occurred and to the severity of the syndrome. No single therapy has emerged as a treatment of choice with significantly better short-term results, which puts the clinician in a difficult position vis-à-vis the patient. Other data suggest, however, that long-term outcomes are better with laser occlusion than with amnioreduction (see Chapter 13). Nonetheless, in some instances, intervention can be used to buy time (i.e., increasing gestational age to the point of viability) rather than a true solution to the intertwin shunt. Laser treatment is technically possible from 17 weeks onward. However, most authorities maintain that laser treatment after 27-28 weeks is too risky and advocate elective preterm delivery thereafter.

Because we are unable to predict accurately which case is going to deteriorate over time, waiting may mean delivery of more mature twins who are in a worse or worsening condition. In addition, discordant fetal conditions remote from term pose difficult ethical questions: Waiting increases the risk for fetal death and long-term morbidity for the ailing twin, whereas pregnancy termination by cesarean section exposes both twins to the risk of preterm delivery.[58] Despite these difficulties, innovations in the treatment of TTTS may lead to an expected breakthrough in the future. The neonates may present with some of the problems that the twins acquired in utero, such as cardiac decompensation and renal problems. Also twins may manifest diseases that once were thought to be part of the TTTS. For example, significant differences in hemoglobin levels (at least 5 g/dL), now called twin anemia polycythemia sequence (TAPS), is found in 5% of MC twins but is more common after laser treatment (when a tiny A-V anastomosis was left behind). At present, fetal anemia is easily recognized by Doppler studies of the middle cerebral artery pick systolic velocity (MCA-PSV).[56] At birth, the donor is usually pale and anemic, whereas the recipient is polycythemic.[2] One may consider re-entry and performing laser photocoagulation of the remaining anastomosis, or at times, even blood transfusion to the anemic twin. The donor twin might be acutely distressed, with severe anemia and hypovolemic shock necessitating transfusion or exchange of blood products, or both. The recipient occasionally requires partial dilution exchange and support for cardiac failure (see Chapter 80). The long-term outcomes of TAPS are not clearly established.

• BOX 21.2 Treatment Modes of Twin-to-Twin Transfusion Syndrome

- Conservative management with careful monitoring

Fetal Growth

As noted earlier, multiples grow in utero to the same extent as singletons until about 28 weeks. Thereafter, during the third trimester, growth curves of multiples show a clear decelerating trend compared with the growth curve of singletons. The limited uterine capacity to nurture multiples leads to growth aberrations (see Chapter 15).[5]

The higher risk of delivering infants with low birth weight in a multiple birth is well known, as is the advantage for the multiparous patient. Analysis of population-based data related to 12,567 live-born twin pairs found that overall the risk of having at least one infant with very low birth weight (VLBW) (<1500 g) was 1:5 among nulliparous women and 1:12 among multiparous women. The risk of having both twins with VLBW among nulliparas (1:11) was double that of multiparas (1:22).[22] A similar trend and similar frequencies, but for infants with extremely low birth weight (<1000 g), were found in the analysis of triplets.[23]

The most common growth aberration in multiples is birth weight discordance.[9] Birth weight discordance occurs whenever there is difference in birth weights between the larger and the smaller infant of a multiple gestation set. When one analyzes a large series of multiples, one rarely finds that all members of the set have the same birth weight. Some variation is expected between siblings, and the magnitude of the difference—the degree of discordance—must be incorporated in the definition. The most common definition of discordance is the percent definition, whereby the birth weight disparity is calculated as a percentage of the larger infant. The definition does not refer to the actual size of the twins, however, and it can assign the same

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

degree of discordance (e.g., 20%) to a twin pair weighing 1500 g and 1200 g and to a pair weighing 3000 g and 2400 g. The cumulative frequency shows that about 75% of twins exhibit less than 15% discordance, about 20% are 15%-25% discordant, and about 5% are more than 25% discordant.[9]

The definition of birth weight discordance is even more complex in triplets. Clinicians usually employ the same percent definition used for twins and calculate the difference between the largest and smallest triplet of each set, although this scheme ignores the middle-sized triplet and the true intertriplet relationship. A new description was developed in which the relative birth weight of the middle triplet was defined.[25] The middle triplet was defined as symmetric when the birth weight was within 25% of the average birth weight of the largest and smallest triplets, as low-skew when a set comprised one large and two small triplets, and as high-skew when the set comprised one small and two large triplets. The frequencies of different types of triplet discordance did not change with gestational age, suggesting three distinct types of discordant growth in triplets that are independent of gestational age (average values—symmetric 57%, high-skew 30%, low-skew 13%).[25]

An important related issue is the birth order of the smaller twin in a discordant set; it was commonly believed that the smaller twin is usually the second-born twin. It has been determined, however, that at lower levels of discordance either twin can be the smaller, but the likelihood of the second-born twin being the smaller increases with increasing discordance levels.[29] At discordance levels greater than 25%, the smaller twin was three to six times more often the second born.[20]

Data From Multiple Birth Data Sets

Population-based studies using the Israeli and the US Matched Multiple Birth Data Set have reached the following conclusions.

Levels of Discordance

Data suggest that there are three levels of discordance.[20,21] In the lowest levels (probably <25%), discordance seems to be related to the normal variation expected from the natural dissimilarities between siblings. In the highest level (probably >35%), discordance seems to be related to the exhausted uterine environment and reflects growth restriction.

The clinical approach to both levels is generally accepted: observation for the lowest degrees of discordance and intervention for the highest degrees of discordance. Between these levels are twins, constituting 10% of the entire twin population, who are of special interest, however, because of the controversies involved in their clinical management (aggressive versus conservative). The benefit of discordance would be an adaptive measure to promote maturity (i.e., delivery at a more advanced gestational age) by reducing the inevitable uterine overdistention, as has been shown in the group of twins within a total birth weight range of 3000-5000 g.[8]

Mortality

Mortality was 11 times higher among highly discordant smaller twins (>30%) compared with nondiscordant smaller twins. Risk estimates ranged from 1.1 among 15%-19% discordant twins to 2 among highly discordant twins. After accounting for the association between fetal growth and discordance, mortality risk was substantially higher among smaller and larger twins who were highly discordant (≥30%). The authors concluded that after controlling for fetal growth, smaller and larger twins affected by higher levels of birth weight discordance (>25%) remain at disproportionate risk for neonatal mortality.[26] Increasing birth weight discordance has been associated with increased risk of intrauterine death and malformation-related neonatal deaths.[28]

When it became clear that not all discordant twins have the same outcome, discordance was classified further according to the birth weight of the smaller twin. When neonatal mortality rates were compared among three groups of discordant twins (>25%), distinguished by the birth weight of the smaller twin being in the lowest 10th percentile (62.4%), in the 10th-50th percentile (32.9%), or greater than the 50th percentile (4.7%), the rate was significantly higher among pairs in which the smaller twin's birth weight was in the lowest 10th percentile (29% versus 11.1% and 11 per 1000).[14] This difference results from the higher mortality rates among the smaller, but not among the larger, twins. The authors concluded that even in severely discordant twin pairs, about 40% do not constitute a growth-restricted fetus. Identification of this group is an imperative step in the management of birth weight discordance in twin gestations and in avoiding unnecessary interventions that may lead to iatrogenic prematurity.[27,35]

An important practical issue in the assessment of growth in a multiple gestation is whether to use singleton or twin growth curves. Because so many twins and, logically, almost all infants in high-order multiple gestations weigh less than singletons of the same gestational age, it seems that multiples grow differently than singletons do and are frequently and erroneously defined as small for gestational age by singleton standards.[5] Before birth, ultrasound assessment of individual fetal growth cannot establish a pattern of growth restriction unless repeated scans are performed and deceleration or arrest of the growth pattern is established. Despite the relative accuracy achieved by ultrasound estimations of the individual fetal weight, the "plus or minus" situation that exists for each estimation can cause quite significant underestimation and overestimation of the weight difference between fetuses and lead to low positive predictive values of discordance.[19]

As is the case with singletons, growth restriction—genuine or relative—is usually managed conservatively unless signs of fetal distress are seen. Discordant growth and discordant fetal well-being sometimes go hand in hand, however. When the risk for the unaffected neonate is lower than the expected risk for the affected fetus, delivery is a clear option, as would be the case at greater than 32 weeks. Clinical dilemmas may arise, however, remote from term,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

when a decision to save the ailing fetus may endanger the healthy fetus with potential risks of extreme preterm birth.

Fetal assessment in multiples is no different from assessment in singletons, although it is more complicated. With the availability of modern equipment, fetal heart rate is currently traced for both twins at the same time. Intrapartum dual tracing is as important as during pregnancy, and when the membranes are ruptured, the presenting twin is usually traced with a scalp electrode, and the nonpresenting twin is followed with an external Doppler transducer. The fetal biophysical profile is similarly assessed individually.

Birth Weight Discordance in Monochorionic Twins

As noted previously, birth weight discordance is no longer part of the diagnostic criteria of TTTS. Twins may have a very unequal placental territory,[37] which may lead to severe discordance and growth restriction of one MC twin (selective IUGR, sIUGR). In the subset of MC twins, this may lead to death of the smaller twin with subsequent damage or death to the appropriately growing co-twin.[37,45] Selective intrauterine growth restriction in MC twins is associated with increased perinatal mortality and morbidity for both twins.[57] Selective intrauterine growth restriction is classified according to the umbilical artery diastolic flow, whereby sIUGR type I has normal diastolic flow and relatively good outcome, type II has persistent absent/reverse end-diastolic flow and is associated with a high risk of intrauterine demise of the IUGR twin and/or very preterm delivery, and type III has intermittent absent/reverse end-diastolic flow and is associated with 10%-20% risk of unexpected fetal demise of the smaller twin and 10%-20% risk of neurologic injury in the larger twin.[57] Management for types II and III is still controversial, suboptimal, and may include selective (preventive) feticide (to avoid sudden fetal death of one twin and death or damage to its co-twin).

Delivery Considerations

Almost 80%-90% of twins and practically all high-order multiple gestations initiate spontaneous labor at less than 38 weeks' gestation. Data have suggested that at least for twins, "term" by singleton standards (i.e., 40 weeks) might be inappropriate and could carry a risk similar to post-term singletons. This concept emerged from data suggesting that neonatal mortality[42] and morbidity[39] are increased after 37 completed weeks compared with singletons, and the concept that twins should be delivered by 37 or 38 weeks comes from evidence that the fetal systems of the multiple gestation are mature by this date.[1,38] This has been supported by Dodd and coworkers, who found that elective birth at 37 weeks of gestation was associated with a significant reduction in risk of serious adverse outcome for the infant in uncomplicated twin pregnancies.[30]

At present, great controversy exists regarding elective preterm (at 34-35 weeks) delivery of MC twins.[52] This initiative derived from the finding of increased prospective risk of intrauterine death in uncomplicated MC twins. The initially reported high risk was not universally confirmed,[52] however, and extensive research is currently trying to quantify this prospective risk accurately. Current Royal College of Obstetricians and Gynaecologists (RCOG) guidelines recognize this disadvantage of MC twins and recommend delivery at 36 weeks' gestation.

There are many reasons why cesarean section could be indicated in most twins and all high-order multiple gestations.[3] Because twin gestations often involve maternal and fetal complications and are often considered "premium" pregnancies, many clinicians follow the principle "no high-risk pregnancy should end with a high-risk delivery" and deliver twins by cesarean section for many subtle reasons other than clear, evidence-based indications. The decision for an abdominal birth in twins, intentionally or not, is based on qualitative variables that were not quantified by randomized trials and on quantitative variables that suggest no advantage for a cesarean delivery in most cases.[3]

Vaginal birth is permitted in twins whenever the first twin is in vertex presentation. Breech delivery of the second twin or internal podalic version of a transverse-lying second twin is still permitted.[7] Otherwise, all pairs with a nonvertex presenting twin are likely to undergo a cesarean section. Nuances on this construct consider fetal size, discordance, prior uterine surgery, and, mainly, the experience and dexterity of the obstetrician.

When a multiple birth is expected, the main neonatal problem is logistic rather than medical, because immediate neonatal treatment of an infant of a multiple gestation is not significantly different from treating a singleton except that twins come in pairs and triplets come in sets. In practical terms, this means more staff in the delivery suite, more cribs available in the nursery, and more stations ready in the neonatal intensive care unit (NICU). Delivery of several very preterm sets in a short period sometimes may occupy the entire NICU for a long period. If the availability of NICU beds lags behind the increased production of multiples, a serious public health situation may be created.

Outcome

Given the greatly increased risk of maternal and fetal complications during a multiple gestation, the overall outcome for multiples is worse compared with the outcome for singletons. The increased risk of cerebral palsy among multiples is clear: 28-45 for triplets, 7.3-12.6 for twins, and 1.6-2.3 for singletons per 1000 survivors, indicating that the greater the number of fetuses, the greater the prevalence of cerebral palsy. The increase in cerebral palsy with the number of fetuses seems to be exponential.[4]

The as-yet-unanswered question is: Are the outcomes of multiples poorer than the outcomes of singletons matched for birth weight or gestational age? Consider, for example, that the usual prophylactic dose of corticosteroids given to singletons may not be enough for twins to enhance lung maturity and reduce the risk of neonatal respiratory distress.[43]

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

One way to estimate neonatal morbidity is to examine the influence of plurality on a cohort of infants with similar initial characteristics. Multivariate logistic regression analysis using all significant perinatal covariates of prospectively collected data from the Israeli national VLBW infant database ($N = 5594$: 3717 singletons, 1394 twins, and 483 triplets) has shown that respiratory distress syndrome was significantly more common in twins and triplets despite increased exposure to antenatal steroids.[48] In addition, VLBW triplets were at increased risk of death. Very low birth weight twins and triplets had no increased risk of chronic lung disease or adverse neurologic findings.[48]

Another way is to examine the influence of birth order on these variables.[49] Comparisons of outcome variables by birth order of VLBW twins, after stratification by mode of delivery and gestational age, revealed that second-born twins had increased risk of respiratory distress syndrome, chronic lung disease, and death, but not adverse neurologic findings. Mode of delivery did not significantly influence outcome.

Summary: Prevention Versus Cure

The epidemic dimensions of multiple births, and especially of high-order multiple gestations, became clear toward the end of the 1980s as an aftershock resulting from effective infertility treatment.[10] To amend this untoward consequence of infertility treatment, clinicians proposed to reduce the number of embryos during pregnancy.[32] Multifetal gestation reduction, albeit considered by many to be the ultimate paradox of medicine,[11] soon became a popular "cure" of the side effects of infertility treatment. This procedure, performed during the early second trimester via the transvaginal or transabdominal route, carries a risk of about 5% total loss and a risk for significant maternal psychological morbidity.

Multifetal gestation reduction is associated with better outcomes, however, because fewer fetuses expectedly do better than more fetuses. When clinicians refined and mastered the technique, the debate about the final number became pertinent, and the current controversy is about multifetal gestation reduction of triplets.[12]

As always in medicine, prevention is better than cure. In terms of infertility treatment, this means transferring only one embryo in in vitro fertilization programs and canceling ovulation induction cycles when more than one ripe follicle is visualized. Such preventive measures would reduce the overall success rates, although it is debatable if a multiple gestation with three or four severely premature infants constitutes success.

It is evident that multiple gestations and births are a true challenge for all medical disciplines involved in caring for the mother and fetuses and infants. At the same time, the increase in iatrogenic multiple births may have an antievolution effect with as-yet-unknown consequences.

Key Points

- Multiples are at higher risk of prematurity and fetal anomalies. Special risks are related to monochorionicity.
- All multiple pregnancies need special attention during pregnancy by experienced personnel.
- Most twins are born by cesarean section as are practically all higher-order multiples.
- The risk of prematurity has direct effect on perinatal morbidity and mortality.

Post-Term Pregnancy

ISAAC BLICKSTEIN AND ORNA FLIDEL RIMON

The human gestation is said to last 266 days from fertilization or 280 days from the last menstrual period (LMP). This amounts to 40 weeks of gestation—10 lunar months, or about 9.5 calendar months. Because no one knows exactly how long any particular pregnancy should last, clinicians use statistical distributions of gestational ages to conclude that a given pregnancy should last between 37 and 42 completed weeks (called *term*). Using such a distribution, about 80% of infants are delivered at term, 10% are delivered before 37 completed weeks, and about 10% are delivered post-term (>42 completed weeks). The American College of Obstetricians and Gynecologists is strict in defining *post-term*—that is, pregnancies carried beyond what is considered to be term—as any time after 42 completed weeks from the LMP.[3]

The problem in defining the end of pregnancy is that the beginning of a pregnancy is seldom known. In contrast to conceptions that follow in vitro fertilization, in which the day of transferring the embryo is known, spontaneous pregnancy is associated with educated guessing, resulting in accuracies of about plus or minus 2-3 weeks. Ultrasound assessment, especially with earlier measurements, has increased the accuracy of pregnancy dating. Sonographic dating is now available using the crown-rump length, the biparietal diameter, and the femur length. Of these, the crown-rump length is the most accurate, because it is measured in the second half of the first trimester. The biparietal diameter is the most popular biometric value and is most accurate during the first half of the second trimester. The femur length is the most consistent marker for gestational age and is used from the beginning of the second trimester onward.

The addition of sonographic measurement has improved our educated guess of the gestational age and narrowed the margin of error to about plus or minus 1 week (especially when an early scan is performed). It is customary to use the known (but inaccurate) LMP whenever the calculations are within 1 week of the estimated age by early ultrasonography. If the first scan is done late in the second trimester, however, sonographic accuracy is much reduced. Because ultrasound assessment is not available everywhere, dating may be inferred from a series of clinical estimations (Box 22.1).

Accurate dating is important, because inaccurate dating is the most common reason for a pregnancy appearing to be post-term. Inaccurate dating may be a result of late ovulation, especially in cases of infrequent menstruation, or simply because the patient cannot accurately remember the LMP. Genuine post-term gestations may rarely be associated with anencephaly or with placental sulfatase deficiency. Both of these mechanisms point to the concept of the fetal placental clock, which involves the role of corticosteroid-releasing hormone and estriol in normal parturition and delivery.[22] Meanwhile, as prematurity rates have significantly declined in developed countries, current investigation is focused on the role of maternal-fetal adaptive immunity in triggering the onset of labor.[6]

Risks of Post-Term Pregnancy

Generally the risks of post-term pregnancy are of two types. In one type, the placenta continues to function, more or less as in the previous months, and the fetus continues to grow. This continued growth results in a large—so-called macrosomic—infant. McLean and colleagues studied 7000 infants with confirmed expected date of confinement (±7 days) and showed a gradual shift toward greater birth weight between 39 and 43 weeks' gestation.[21] These authors voiced their concern for fetal macrosomia rather than for intrauterine growth restriction (IUGR) in post-term pregnancy (see Chapter 15).

The other type, which seems to be more common, occurs when the placenta's function is reduced. When this situation is prolonged, some form of placental insufficiency results. Typically placental insufficiency is associated with a reduction in the nutrients and oxygen transferred to the fetus, leading not only to a wide range of perinatal morbidities but also to increased rates of perinatal mortality. In an attempt to quantify this rate, Divon and coworkers[12] evaluated the National Swedish Medical Birth Registry. In 181,524 singleton pregnancies with reliable dates delivered at greater than 40 weeks, the authors found a significant increase in the odds ratio for fetal death at greater than 41 weeks' gestation, but the odds ratios for neonatal mortality did not show a significant gestational age dependency. Intrauterine growth restriction was associated with significantly higher

Abstract

Post-term refers to pregnancies carried beyond what is considered to be term—as any time after 42 completed weeks from the last menstrual period (LMP). At this point of gestation, fetal complications depend on placental function: If the placenta continues to function, fetal growth continues, and the main risk is related to macrosomia. However, in case of placental dysfunction, the risk of fetal growth restriction and hypoxygenation may increase ante- and intrapartum death. These cases are also more likely to exhibit signs of distress during labor and, hence, are associated with more instrumental and cesarean birth. Management of fetal macrosomia is complicated by inaccurate diagnosis, leading to many unnecessary cesarean deliveries to prevent one permanent brachial plexus injury in fetuses with antenatal estimated weights of 4000 and 4500 g.

Dysmaturity (postmaturity) is associated with fetal growth restriction attributable to placental insufficiency. The neonate may exhibit low weight, relative absence of subcutaneous fat, wrinkling of the skin, prominent fingernails and toenails, absence of the vernix caseosa, skin desquamation, and meconium stains. Dysmaturity is associated with increased perinatal mortality rate, antepartum and intrapartum fetal distress, increased neonatal morbidity, meconium aspiration, peripartum asphyxia, neonatal hypoglycemia, hypothermia, hyperviscosity, and polycythemia. To avoid these complications, it is customary to closely follow pregnancies after 41 weeks and to induce labor at 41-42 weeks' gestation.

• BOX 22.1 Clinical Methods to Estimate Gestational Age

- Promote early prenatal care. The earlier the patient is seen, the more accurate is the estimation.
- Take a very careful menstrual history.
- If unknown, try to track the last menstrual period.
- Find out when the symptoms of pregnancy began.
- Perform a pelvic examination; dating by uterine size is better than nothing and often quite accurate. This is also true for dating by fundal height.
- Positive or negative pregnancy test results can help exclude unlikely dates.
- Look for heart tones with a simple Doppler. They can appear by 9-11 weeks.

odds ratios for fetal and neonatal mortality rates at every gestational age examined. This extensive study of accurately dated pregnancies documented a significant increase in fetal mortality beyond 41 weeks' gestation—an observation corroborated by many others[8]—and a significant contribution of IUGR to the perinatal mortality in these pregnancies.[12] A French review suggests that perinatal mortality increases regularly, from 0.7-5.8/1000 from 37-43 weeks' gestation.[30]

Another assessment of the Swedish population found that perinatal mortality depended on parity.[15] The stillbirth rate was highest for primiparas at 38 completed weeks (2.3%) and lowest at 40 weeks (1.2%), and then it increased to 2.36% in the post-term period, but the difference compared with multiparas was significant only from 41 weeks onward.[15] Neonatal mortality was increased at 41 completed weeks for primiparas, but for multiparas it changed significantly only after 42 completed weeks. Except for the parity effect on stillbirth, this study documented the parity-independent risk of neonatal deaths after 42 completed weeks.

The most recent Practice Bulletin of the American College of Obstetricians and Gynecologists added a relatively new definition of late term (41 0/7 to 41 6/7 weeks) and reaffirmed the definition of post-term gestations and its association to neonatal morbidity and mortality.[2]

Macrosomia

The well-known risks of macrosomic fetuses include dystocia (i.e., difficult delivery), borderline cephalopelvic disproportion necessitating instrumental or abdominal delivery, frank cephalopelvic disproportion ending in abdominal birth, traumatic delivery (shoulder dystocia) with or without birth trauma (brachial plexus injury, fracture of the clavicle), neurologic damage, and infant death. The risk of each of these complications is related to the degree of macrosomia; that is, the larger the infant, the greater the risk. It is unclear, however, what the relative contributions are of prolonged pregnancy, maternal diabetes, and obesity in producing macrosomia. In cases of gestational diabetes, it is logical to assume that if there is no placental insufficiency, the fetus would be continuously influenced by the growth-promoting effect of the maternal disease (see Chapter 18).

Management of fetal macrosomia is complicated by two factors. First, the diagnosis (clinical or sonographic) is often inaccurate; prediction and prevention of these risks are not always possible. Second, these risks are primarily, but not exclusively, associated with vaginal birth. When the diagnosis is uncertain, preventing most of the potential complications means performing many unnecessary cesarean deliveries. Rouse and colleagues[26] calculated that in nondiabetic pregnancies, 2345 and 3695 cesarean deliveries are necessary to prevent one permanent brachial plexus injury in fetuses with antenatal estimated weights of 4000 and 4500 g.

Because the medicolegal environment often fuels decision making in cases of potential macrosomia, clinicians may choose to induce labor in a diabetic patient before 40 completed weeks to avoid the development of macrosomia and its sequelae.[19] Alternatively, cesarean section is offered when the estimated fetal weight is greater than 4500 g and to diabetic mothers when the estimated fetal weight is greater than 4000-4200 g. Recently reaffirmed ACOG guidelines regarding macrosomia suggest that vaginal delivery is not contraindicated when the estimated fetal weight is less than 5000 g in the absence of maternal gestational diabetes.[4]

Dysmaturity

The dysmaturity (postmaturity) syndrome was described almost 50 years ago.[10] It affects about 20% of post-term pregnancies.[11] It is associated with arrest of fetal growth, IUGR, and is attributed to placental insufficiency. The neonate may exhibit many of the following signs: low weight; relative absence of subcutaneous fat; wrinkling of the skin; prominent fingernails and toenails (nails appear to be long, as if the infant was 8 days old); absence of the vernix caseosa; desquamation of the skin; and yellow-green discoloration of the umbilical cord, nails, and skin (Fig. 22.1). Dysmaturity was historically associated with increased perinatal mortality rate (3%-15%), antepartum and intrapartum fetal distress, increased neonatal morbidity, meconium aspiration, peripartum asphyxia, neonatal hypoglycemia, hypothermia, hyperviscosity, and polycythemia. These complications may result in developmental sequelae.

Meconium passed *in utero* may be aspirated either *in utero* or with the initial respiratory efforts of the infant, and it is uncertain which occurs in infants with meconium aspiration syndrome. The current International Consensus of the Neonatal Resuscitation Chapter Collaborators is that if the infant is not vigorous (does not have strong respiratory efforts, good muscle tone, and a heart rate >100 beats/min), the infant should first be resuscitated, and then the decision of suctioning of the mouth and nose to clear secretions is made.[25]

Obstetric management of dysmaturity and its related complications is primarily preventive. It requires close

• **Fig. 22.1** Infant of 42 weeks' gestation. Note the prominent nails; absence of the vernix caseosa; desquamation of the skin; and discoloration of the umbilical cord, nails, and skin.

follow-up of patients approaching post-term and the consideration of avoiding a post-term situation by inducing labor during the 40th week or during late-term gestation.

During labor, oligohydramnios and meconium-stained amniotic fluid are associated with increased incidence of variable fetal heart rate decelerations. This particular type of tracing is more likely when the cord is compressed between the fetal body and the uterine wall. Some clinicians perform amnioinfusion (i.e., intra-amniotic instillation of saline) to increase the amniotic fluid volume and to dilute the meconium.

Assessment of Fetal Well-Being

All methods of assessing fetal well-being are associated with good negative predictive value and relatively poor positive predictive value; most of the tests adequately exclude signs of fetal distress. The reverse is not true because the tests are not sensitive enough to detect all truly distressed fetuses. As a result, many fetuses with suspected fetal distress are not distressed at all (see Chapter 12). Methods to assess fetal well-being include fetal heart rate monitoring without contractions (nonstress test); fetal heart rate reaction to contractions (oxytocin challenge test or contraction stress test); ultrasound assessment of fetal movements, tone, breathing movements, and amniotic fluid volume (together called the biophysical profile); and the more sophisticated Doppler velocimetry of various maternal or fetal vessels (Table 22.1).

In the past, visualization of the color of membranes via a transcervical amnioscope was used to exclude the possibility of meconium in the amniotic fluid. This procedure is no longer performed because meconium staining is no longer considered to be a reliable sign of acute fetal distress. Even the current method of assessing the nonreassuring fetal state—the amount of amniotic fluid as indicated by the amniotic fluid index (AFI)—yields equivocal results. It was found that neither the AFI nor the reduction in AFI was related to meconium staining and fetal distress.[28] In contrast, Morris and coworkers found in a large prospective study that an AFI of less than 5 cm was significantly associated with birth asphyxia, meconium aspiration, cesarean section for fetal distress in labor, cord arterial pH less than 7 at delivery, and low Apgar scores.[23] Despite the significant association with adverse outcomes, the sensitivities of AFI were only 28.6%, 12%, and 11.5% for major adverse outcome, fetal distress in labor, and admission to the neonatal unit.[23] Deciding the optimal management on the basis of fetal heart rate monitoring is also difficult because of the high frequency of nonreassuring patterns on electronic monitoring of normal pregnancies with normal fetal outcomes.[20]

All of these factors point to the need for a more holistic approach to the evaluation of the prolonged pregnancy. The first question is whether to avoid the potential complication by inducing delivery before 42 weeks. If the answer is yes, when should it be done? Finally, does such intervention reduce neonatal complications?

Should Labor Be Induced Before 42 Weeks?

The benefit of reducing potential fetal risks with induction of labor must be balanced against the morbidity associated with this procedure. Management of an otherwise uncomplicated pregnancy prolonged beyond the estimated date of confinement, when the woman presents with unfavorable cervical conditions, has been the subject of extensive research. One of the earliest studies compared two strategies for managing post-term pregnancy: immediate induction and expectant management.[24] Patients with uncomplicated pregnancies at 41 weeks' gestation were randomly assigned to either immediate induction of labor (within 24 hours of randomization) or expectant management (nonstress test and AFI assessment twice a week). Adverse perinatal outcome (neonatal seizures, intracranial hemorrhage, need for mechanical ventilation, or nerve injury) was similar in both groups (1.5% in the induction group vs. 1% in the expectant management group). There were no fetal deaths in either group, and there were no differences in mean birth weight or the frequency of macrosomia. The cesarean delivery rate was not significantly different between the groups.[24]

Systematic review with meta-analysis of 16 randomized controlled trials compared induction and expectant management for uncomplicated, singleton, live pregnancies of at least 41 weeks' gestation.[27] Patients who underwent labor induction had lower cesarean delivery rates (odds ratio 0.88; 95% confidence intervals 0.78, 0.99). No significant differences were found in perinatal mortality rates, rates of admission to neonatal intensive care units, meconium aspiration, meconium below the cords, or abnormal Apgar scores.[27] These results lead to the conclusion that labor induction at 41 weeks' gestation for otherwise uncomplicated singleton pregnancies reduces cesarean delivery rates without compromising perinatal outcomes.[26] The ACOG

TABLE 22.1 Methods of Assessing Fetal Well-Being

Test	Method	Description	Interpretation
Nonstress test (NST)	Cardiotocography	FHR tracing in the absence of uterine contractions showing FHR accelerations (≥15 beats/min above baseline for >15 s)	Reactive (normal) NST: ≥2 FHR accelerations within 20 min, regardless of fetal movement Nonreactive NST: <2 FHR accelerations over a 40-min period
Contraction stress test (CST)	Cardiotocography	Response of FHR to uterine contractions (3 per 10 min), assuming that fetal oxygenation deteriorates transiently during contractions Contractions may be spontaneous or induced by oxytocin (OCT) or nipple stimulation	Negative (normal): no late or severe variable decelerations Positive: late decelerations after ≥50% of contractions Suspect: intermittent late decelerations or severe variable decelerations
Fetal movement	Kick counts	Perception of decreased fetal movement sometimes precedes fetal death	>5 fetal movements per 30 min is considered reassuring
Biophysical profile (BPP)	Cardiotocography and ultrasound	NST Fetal breathing movements Fetal movement Fetal tone Amniotic fluid volume	Normal: Reactive Normal: ≥1 episode of rhythmic fetal breathing of ≥30 s per 30 min ≥3 discrete body or limb movements per 30 min ≥1 episode of extension or flexion of a fetal limb per 30 min Vertical pocket of amniotic fluid >2 cm *Scoring*: 0 = abnormal, absent, or insufficient; 2 = normal *Score results*: ≥8 = normal; 6 = equivocal; ≤4 = abnormal
Umbilical artery Doppler velocimetry (systolic to end-diastolic [S/D] ratio)	Doppler ultrasound	Normally growing fetuses have low S/D ratios. In patients with intrauterine growth restriction, the ratio is high. Absent end-diastolic or reversed flow is an ominous sign	S/D ratio >4 is considered high
Amniotic fluid index (AFI)	Ultrasound	Sum of 4 vertical pockets of amniotic fluid	AFI decreases with gestational age. AFI <8 cm is considered oligohydramnios

FHR, Fetal heart rate; OCT, oxytocin challenge test.

Practice Bulletin suggests that induction of labor between 41 0/7 weeks and 42 0/7 weeks of gestation can be considered (level B conclusion) and induction of labor after 42 0/7 weeks and by 42 6/7 weeks of gestation is recommended (level A conclusion).[2] Implementation of such a policy is expected to influence neonatal morbidity. The new policy influenced the frequency of meconium aspiration syndrome, which decreased nearly fourfold from 1990 to 1992 to 1997 to 1998. The only change in neonatal characteristics was a 33% decrease in births at more than 41 weeks, with a reciprocal 33% increase in births at 38-39 weeks during 1997-1998.[31]

An equally important question is whether to induce post-term pregnancies when the woman has a favorable cervix. One study found that the cesarean section rate was not different between expectant management and immediate induction, and that 95% of the expectant group delivered within 1 week after enrollment. Maternal and fetal complications in both groups were similar, as were the mean birth weight and the frequency of macrosomia. Expectant management and immediate induction are acceptable.[9]

How Should Labor Be Induced?

When labor induction was shown to be an acceptable choice in the management of prolonged pregnancies, the question of how labor should be induced became equally pertinent. Generally, methods of labor induction include mechanical, surgical, pharmacologic, and nonpharmacologic methods (Box 22.2). All mechanical methods share a similar mode of action: local pressure, which stimulates the release of natural prostaglandins. One of the most popular

• BOX 22.2 Methods of Labor Induction

Mechanical
- Intracervical balloon
- Stripping of the membranes

Surgical
- Artificial rupture of the membranes

Nonpharmacologic
- Nipple stimulation

Pharmacologic
- Oxytocin stimulation
- Prostaglandins (in various forms)
- Misoprostol
- Mifepristone

mechanical methods is to use a saline-filled balloon (Foley catheter or a special balloon), which exerts mechanical pressure directly on the cervix. In some designs it is possible to infuse extra-amniotic saline or prostaglandins. Ripening of the cervix after balloon insertion is not equivalent to the natural ripening, and the procedure often involves augmentation of labor with oxytocin.[18] Another popular mechanical means is stripping of the membranes. Stripping results in increased phospholipase A_2 activity and prostaglandin $F_{2\alpha}$ concentrations, and it causes mechanical dilation of the cervix, which releases prostaglandins. Nulliparas and multiparas who received weekly stripping starting at 38 weeks had significantly earlier deliveries and significantly fewer deliveries at 41 weeks or greater.[5] The combination of membrane stripping and intravaginal prostaglandin E_2 gel has been claimed to reduce post-term pregnancies and antenatal visits.[13] Recently, it was also found that antepartum membrane stripping in GBS carriers appears to be a safe obstetrical procedure that does not adversely affect maternal or neonatal outcomes.[16]

The most popular surgical method is amniotomy (artificial rupture of the membranes). It is postulated that the resultant amniorrhexis (leak of amniotic fluid) is involved in increased levels of prostaglandins. Amniotomy is more frequently successful when performed in women with a favorable cervix, however. Often oxytocin is given for augmentation of labor.

A nonpharmacologic method is nipple stimulation, which increases the level of oxytocin via the nipple–posterior pituitary neurohormonal axis. Evidence is lacking to support this method as a practical mode of labor induction. Nipple stimulation is frequently used, however, when there is a relative contraindication to oxytocin stimulation, such as cases of grand multiparity or trial of labor after a previous uterine surgery.

The simplest pharmacologic method of labor induction is oxytocin infusion. Myometrial receptors to oxytocin are scant during the first half of gestation but increase thereafter to 100-300 times the initial number. Oxytocin increases intracellular calcium levels and stimulates the contractions of myometrial smooth muscle cells. The number of receptors increases with contractions, leading to a positive feedback cycle that increases the efficiency of the uterine muscle. Two regimens of oxytocin stimulation—low dose (physiologic levels) and high dose (pharmacologic levels)—have been proposed. Both regimens are equally potent for labor induction.

Vaginal or cervical prostaglandins (prostaglandin E_2) change the composition of the extracellular cervical matrix and facilitate the process of dilation. There is, however, also some effect on the myometrium, which causes uterine stimulation as well. In a Cochrane review of 52 studies comparing prostaglandins for cervical ripening or labor induction with placebo or no treatment, it was found that vaginal prostaglandins increase the odds for a vaginal birth within 24 hours of application.[17] The oral and vaginal use of a synthetic prostaglandin E_1 analogue (misoprostol) was also reviewed.[1] The authors concluded that oral misoprostol seems to be more effective than placebo and at least as effective as vaginal dinoprostone. Safety data and appropriate dose-ranging studies are still required. It seems that in countries where misoprostol remains unlicensed for the induction of labor, many caregivers prefer the legal protection of using a licensed product. In a very recent multicenter trial, 3062 and 3044 low risk nulliparous women were assigned to either labor induction at 39 weeks or to expectant management, respectively. Adverse neonatal outcomes were similar in both groups but the frequency of abdominal births was lower in the induction group.[14a]

Post-Term Twin Pregnancies

In the usual setting, the major problem associated with twins is preterm birth (see Chapter 21). Although term is defined by the period during pregnancy after which most pregnancies end in spontaneous labor, this period is not defined for twins. Twins are delivered about 3 weeks earlier than singletons, which has raised the question of whether term occurs earlier in twins. If this is the case, many of the complications attributed to post-term singleton pregnancies are expected in twins at 38 weeks' gestation. Several arguments support this view.[7]

First, the distribution of twin births by gestational age is almost identical to that of singletons but shifted toward a lower gestational age. Second, comparison between growth patterns of twins and of singletons suggests that incremental growth reaches the near-term plateau earlier in twin pregnancies, indicating that birth weight does not significantly increase beyond 37-38 weeks' gestation. Third, morbidity increases beyond 37 weeks. The risk of cerebral palsy in singletons and twins decreases steadily until 36-37 weeks, and thereafter the risk of cerebral palsy in singletons continues to decrease, but the risk for twins increases again after 37 weeks' gestation. Fourth, perinatal death rates in twins gradually decline until 37-38 weeks' gestation and then

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

increase again, in a manner similar to that observed after 40 weeks' gestation in singletons. The incidence of perinatal death seen at 38 weeks' gestation in twins was similar to that seen at 43 weeks in singletons.

These lines of circumstantial evidence seem to indicate that term occurs earlier in twins. Limiting the estimated date of delivery to 37-38 weeks may be appropriate. If 38 weeks or more for twins represents post-term, however, it does not follow that 36-37 weeks is equivalent to term in singletons. Twin deliveries around 36 weeks are still associated with increased morbidity compared with births at 38 weeks.[29] These lines of thinking were supported by Dodd and coworkers, who found that elective birth at 37 weeks of gestation was associated with a significant reduction in risk of serious adverse outcome for the infant in uncomplicated twin pregnancies.[14]

Summary

Improvement in management and outcomes of post-term pregnancies has been observed over the past two decades, which seems to be a direct result of better understanding of the associated pathology, implementation of new technologies, careful assessments of risk versus benefit of various strategies, and new methods of assessing fetal well-being and avoiding unwarranted complications.

Key Points

- Accurate dating is imperative. First-trimester ultrasound confirmation of the LMP is essential for an accurate diagnosis of post-term pregnancies.
- A plan of management is necessary for cases presenting during the 42nd week of gestation (i.e., after 41 completed weeks). This plan should be discussed with the patient and should include the pros and cons for each management option (e.g., expectant follow-up vs. labor induction).
- If a favorable cervix is found on pelvic examination during the 42nd week, induction seems to be a logical option.
- If the cervix is unfavorable, the option of labor induction should be considered. Because induction of labor may take some time, some clinicians start the induction procedure 1-2 days before 42 weeks.
- If induction is unacceptable to the patient, proactive and frequent fetal assessment should be offered. Fetal size and well-being should be carefully assessed. Nonreassuring fetal conditions must be promptly treated.
- Close intrapartum surveillance is recommended. The potential need for a neonatologist during the immediate postpartum period should be anticipated.

Immune and Nonimmune Hydrops Fetalis

PAMELA M. SIMMONS AND EVERETT F. MAGANN

Hydrops fetalis (HF) is defined as the presence of excessive fetal fluid in two or more of the following spaces: abdominal ascites, pleural effusion, pericardial effusion, skin edema, polyhydramnios, or placentomegaly. The diagnosis is made by ultrasound imaging evaluating body cavities, the placenta, and the amniotic fluid volume. Classically, HF has been classified into two categories based on etiology: Immune HF accounts for an estimated 10%-24%, with nonimmune HF accounting for 76%-90% of cases and becoming increasingly the main cause of HF (Table 23.1).

Immune Hydrops Fetalis

Immune hydrops fetalis (IHF) was initially recognized as the combination of neonatal hydrops, anemia, and jaundice along with erythroblastosis and red blood cell hemolysis by Diamond and coinvestigators in 1932.[16] The pathophysiology of the IHF was explained by the work of Landsteiner and associates, who discovered the rhesus (Rh) antigen in 1940.[31] In 1941, Levine and coworkers observed that if an Rh-negative woman is exposed to red blood cells that are Rh positive, she will form antibodies that may result in transplacental passage of the antibodies to fetal red blood cells and may result in fetal hemolysis. The resultant maternal alloimmunization was initially documented by Chown and coworkers.[10]

Anti-D antibodies were proposed as a method to prevent the nonimmunized Rh-negative mother from becoming sensitized after birth. Freda and coworkers studied the efficacy of specific anti-D IgG in Rh-negative male prison volunteers who were given Rh-D-positive blood and observed that sensitization could be prevented.[21] A subsequent investigation confirmed that if prisoners were given Rh-D-positive blood and received anti-D IgG within 72 hours that alloimmunization did not occur.[20]

Genetics of the Rh System

Blood group antigens were among the first discoveries of genetic polymorphisms in human proteins.[12] Of these, the Rhesus factor (the largest of all of the blood groups) has more than 50 different described antigens, with additional discoveries likely to continue. Most of these are quantitative antigens (affecting the amounts of Rh factors expressed), although some are qualitative in nature. Not all antigens have clinical significance in pregnancy.

Three of the most concerning antigens in pregnancy, the Rh(D) and Rh(CcEe) antigens, are encoded at two human loci, found on chromosome #1 (1p36.1).[29] They can cause antibody formation in pregnancy and lead to significant hemolytic disease of the newborn (HDN) in future pregnancies. Although there are multiple nomenclature systems for maternal rhesus (DCE) status, the Fisher and Race method has clinical advantages, such as ease of use and remembrance, and was also proved genetically correct.[43] In this system, each parent contributes an allele from the Rh(D), Rh(C), and Rh(E) gene loci. In broad terms, these alleles are called D or d, C or c, and E or e. A person can be homozygous or heterozygous for each of these alleles. The genes are so closely linked on chromosome #1 that crossover between the alleles is not thought to occur.

The D antigen is a transmembrane protein with several extracellular loops located on erythrocytes and their immediate progenitors. Most alleles of the Rh(D) gene (≈170 identified) are caused by nonsense or missense mutations, although frameshift and splice-site mutations have also been reported.[57] Alleles that cause strongly reduced or complete absence of the Rh-D antigen are often called DEL or negative alleles, respectively. These include the most common European d (Rh-negative phenotype). The Rh-negative phenotype is most common in individuals of European and North American descent (15%-17%), then followed by African and Indian (3%-8%), with the rarest in Asia (0.1%-0.3%).[23,61] Thirty percent of Rh-negative Asians actually carry a DEL allele, whereas this phenotype is rare in Europeans. Other alleles may result in "partial D" antigens (qualitative). There are also alleles that produce a "weak" Rh(D) antigen. DEL, negative, partial D, and weak D alleles can be clinically significant in pregnancy and increase the risk for HDN.

Abstract

Hydrops fetalis is the presence of excessive fetal fluid in two or more spaces. The diagnosis is made by ultrasound imaging evaluating the fetal body cavities, the placenta, and the amniotic fluid volume. Hydrops fetalis has been divided into two categories, including immune and nonimmune. Nonimmune hydrops fetalis has dominated as the main cause of hydrops fetalis since the routine implementation of anti-D immune globulin. Nonimmune hydrops fetalis has multiple etiologies, and often the diagnosis is made incidentally after a mother undergoes an ultrasound for other indications. Hydrops fetalis is the result of fetal anemia. Prediction of anemia can be assessed with ultrasound using Doppler flow studies. The objective of Doppler flow studies is to detect physiologic compensatory changes in the fetal circulation that would be associated with mild to moderate anemia. This is done by measuring the peak systolic velocity of the middle cerebral artery. Intervention with fetal blood sampling to confirm anemia and fetal blood transfusion may be done between 18-35 weeks' gestational age. This has been shown to improve overall survival and is associated with a low procedure-related fetal loss rate. Repeat ultrasound evaluation and antenatal testing is important for surveillance and timing of delivery.

TABLE 23.1 Definition and Diagnostic Criteria for Immune and Nonimmune Hydrops Fetalis

Diagnostic Criteria	Definition
Presence or absence of red blood cell alloimmunization (immune vs. nonimmune HF)	Rh-D status Antibody screen
Plus Two or More Abnormal Fluid Collections	
Ascites	Echolucent rim encompassing entire fetal abdomen in the transverse view[4]
Pleural effusions	Unilateral or bilateral visualization of lung border[7]
Pericardial effusion	Nonphysiologic fluid ≥2 mm[17]
Skin edema	Subcutaneous edema ≥5 mm[48]
Polyhydramnios	Single deepest fluid pocket ≥8 mm AFI ≥25 cm[33]
Placentomegaly	Placenta ≥6 cm thickness[45]

AFI, Amniotic fluid index; HF, hydrops fetalis.

The D alleles are dominant over the d alleles. It is important to note that d is simply the absence of D antigen; there has been no identification of an actual d antigen. Thus, it is the presence or absence (and the extent) of the D antigen that will determine if an individual is Rh positive or Rh negative. There are significantly fewer alleles identified at the Rh(CcEe) gene. Unlike the Rh(D) alleles, the Cc and Ee alleles are codominant; both are expressed in a heterozygote state. The mutations/changes between the alleles are limited and result in amino acid changes at only five locations.[19] Partial C, c, E, and e antigens can be present, but the clinical significance of these in pregnancy is undetermined.

The Kell blood group gene, located on chromosome #7 (7q33),[29] has many polymorphisms, and its alleles encode for approximately 20-25 antigens. Behind the Rh and ABO blood group antigens, Kell antigens carry the most risk for HDN in human pregnancy. The two most common alleles are K and k. The Kell protein transverses the red blood cell (RBC) membrane only once, unlike D and CcEe. Kell antibodies work differently in the lysing of fetal RBCs than Rh and CcEe antibodies; Kell antibodies actually destroy early precursors of erythrocytes in the fetal liver and effect early proliferation of RBCs, instead of only attacking mature RBCs in fetal circulation.[13]

Because each of these antigens can lead to hemolytic disease of the newborn, knowing ethnicity may be helpful in predicting risks for fetal status in a broad sense or if the father of a fetus is unavailable. Of course, when possible, it is advisable to obtain paternal DCE antigen and/or Kell antigen genotyping in at-risk pregnancies. Certainly other antigens have been linked to HDN, but genotyping is not available for all of these blood groups. These results are of great importance in delineating the best courses of action during gestation for monitoring an at-risk fetus.

Typical methods of monitoring at-risk fetuses have included monitoring of maternal antibody titers; targeted ultrasounds to obtain serial middle cerebral artery peak systolic velocity (MCA-PSV) values and exclude the presence of hydrops, amniocentesis, or chorionic villus sampling (CVS) for fetal antigen genotyping; and/or amniocentesis to determine ΔOD450, whereas the latter is rarely used clinically anymore. Traditionally, fetal genotyping has been performed using polymerase chain reaction (PCR) on amniocytes or chorionic villi. New technology now allows for noninvasive determination of fetal Rh-D antigen status through the use of cell-free fetal DNA collection from a maternal blood sample. Although this technology is relatively new, this method of testing has proved to be very accurate (94%-97%), with high sensitivity and specificity.[5,24] Because fetal DNA is directly tested from maternal serum, it reduces the need for invasive testing, Rh-D prophylaxis, and paternal antigen genotyping in most cases.

Pathophysiology of Rh-D Isoimmunization

Alloimmunization, which was formerly known as isoimmunization, occurs when a mother develops antibodies to a paternally derived red blood cell antigen that is inherited by the fetus or from a transfusion of unmatched or mismatched blood. If this occurs, hemolytic disease of the fetus or neonate in subsequent pregnancies can occur.

In Rh alloimmunization, an Rh-D-negative mother is exposed to Rh-D-positive blood. A quantifiable amount of hemorrhage occurs between the fetus and the mother in up to 75% of all pregnancies. This may range from less than 0.1 mL of blood in 60% of pregnancies to an excess of 5 mL in less than 1% of pregnancies. In an analysis of maternal fetal hemorrhage, 0.01 mL of fetal blood was detected in the maternal circulation in 3%, 12%, and 46% in the first, second, and third trimesters of pregnancy, respectively.[6] The risk of sensitization is related to the amount of blood that passes between the fetus and mother. For 0.1 mL of blood, the risk of sensitization is 3% and for 0.4 mL, the risk rises to 22%. Rh sensitization has been reported as early as 38 days, and fetal maternal hemorrhage has been demonstrated as early as 5-6 weeks (mean maternal fetal transfusion at 8 weeks is 0.3 mL). The minimal amount of fetal blood needed to cause alloimmunization is estimated to be 0.25 mL. The greatest risk occurs at the time of delivery when that risk is approximately 17%. ABO incompatibility of the mother and fetus in pregnancy with Rh sensitization (mother O; father A, B, or AB) will reduce the sensitization risk to 2%. Additionally, 30% of Rh-negative individuals are nonresponders and will not become sensitized. Box 23.1 summarizes the numerous risk factors for maternal fetal hemorrhage during pregnancy.

Immune hydrops fetalis (IHF) is the end result of progressive red blood cell destruction, in which even with the

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

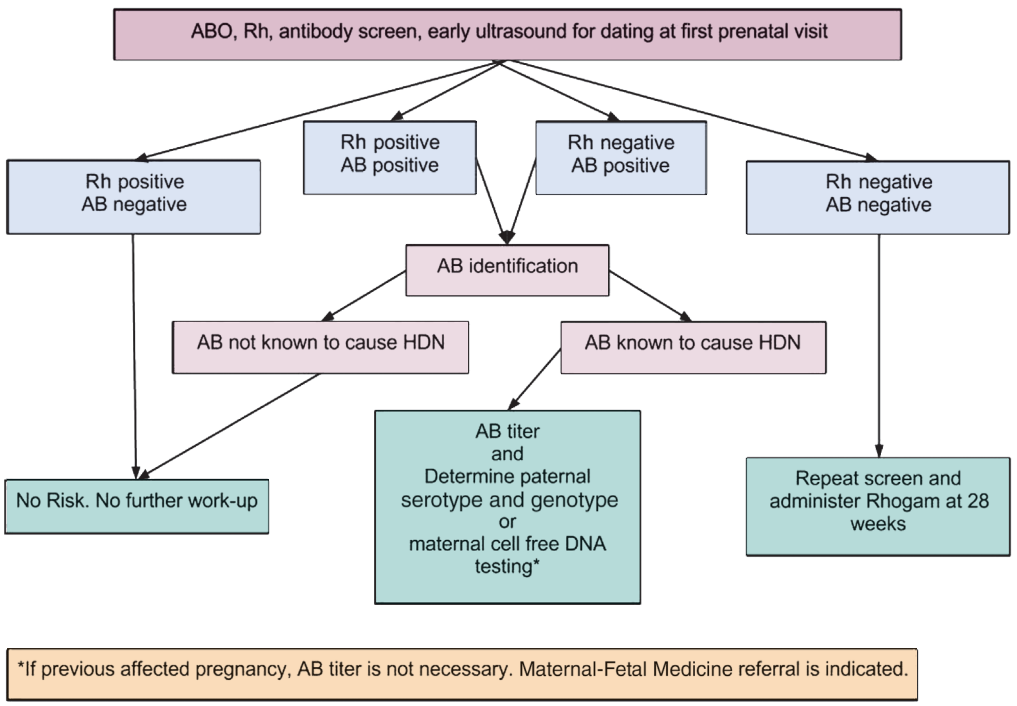
recruitment of extramedullary tissue (liver and spleen), the severity of the hemolysis results in severe fetal anemia, HF, and often fetal death. Although the fetus is able to compensate for progressive anemia, one study determined that once the hemoglobin deficit has exceeded 7 g/dL, this compensatory ability of the fetus may become exhausted and IHF will ensue.[39] The concept of a fixed hemoglobin level for IHF likely needs to be adjusted for gestational age, because with advancing gestational age the mean hemoglobin value increases, going from 10.6 g/dL at 18 weeks to 13.8 g/dL at 40 weeks. It has been suggested that a hemoglobin value of less than 0.5 times the median for gestational age might be a more appropriate predictor for fetuses at significant risk for HF.

• BOX 23.1 Risk Factors for Maternal Fetal Hemorrhage During Pregnancy

- Spontaneous abortion
- Elective abortion
- Amniocentesis
- Chorionic villus sampling
- Antepartum hemorrhage
- Fetal blood sampling
- Ectopic pregnancy
- Blunt abdominal trauma
- Fetal death in utero
- Abruption
- Placenta previa with bleeding
- Cesarean delivery
- Manual removal of the placenta



Progressive ultrasound findings of IHF include the early findings of polyhydramnios and placentomegaly, followed by hepatomegaly and pericardial effusions and late findings of ascites, scalp edema, pleural effusions, and finally, oligohydramnios.[60] Severe fetal anemia (fetal hemoglobin of ≤5 g/dL) associated with the development of HF[8] has implications on fetal survival. In a study with intravascular transfusions, the survival rate for nonhydropic fetuses was 94% compared with 74% in fetuses with hydrops.[49]

The exact mechanism that causes IHF is unknown. Proposed mechanisms include high output cardiac failure, liver dysfunction, and fetal hypoxemia from fetal anemia. It is likely that a combination of all three is responsible for fetal hydrops.

Management

Prevention

Prevention of Rh alloimmunization begins at the first prenatal visit. A careful history should be taken of any problems associated with previous pregnancies or deliveries, prior blood transfusions, or blood disorders. Initial laboratory work should include ABO typing, Rh-D status, and an antibody screen. If the mother is Rh-D negative, this should be carefully documented in the chart. If the antibody screen is positive, the antibody test and a titer of the antibody should be repeated and a determination should be made for antibodies, Rh-D, and others that are not Rh-D, to ascertain if the antibody is known to cause hemolytic disease of the newborn (Fig. 23.1). If the antibody is positive Rh-D,

• Fig. 23.1 Initial management of blood type and screen. AB, antibody; HDN, hemolytic disease of the newborn.

then the patient should be questioned about a prior injection of anti-D immune globulin, as this could be the reason for the positive antibody titer.

Rh-Immunoglobulin Prophylaxis

Anti-D immune globulin is a passive immunoglobulin that when given to Rh-D-negative women will prevent the vast majority of cases of alloimmunization. Unfortunately, there are no other immune globulins specific for the other red blood cell antigens. After the initial screen at the first prenatal visit, a repeat Rh-D antibody screen is done at 24-28 weeks. If the antibody screen is negative, 300 μg of anti-D immune globulin is administered at that gestational age and then again within 72 hours of delivery if the neonate is Rh-D positive. Other accepted regimens are 100 μg at 28 and 34 weeks and following delivery if the neonate is Rh-D positive. Suggested doses of anti-D immune globulin for a first-trimester induced or spontaneous abortion, amniocentesis, or chorionic villus sampling, and first-trimester ectopic pregnancy, are 50–120 μg of anti-D immune globulin up to 12 weeks' gestation. After 12 weeks' gestation it is recommended to use 300 μg of anti-D immune globulin.[22,42,46] Three hundred micrograms of anti-D immune globulin will suppress the immune response of 30 mL of fetal blood or 15 mL of packed D-positive red blood cells. Women should be screened at delivery and when maternal fetal hemorrhage is suspected, to prevent an inadequate dose of anti-D immune globulin being administered and subsequent alloimmunization (Table 23.2).

Preimplantation Diagnosis

Newer techniques using molecular genetics have permitted the preimplantation diagnosis of the Rh-D status.[1] This technology has the potential to prevent Rh isoimmunization through selective transfer of Rh-D-negative embryos. In the case of severe maternal alloimmunization, the approach can prevent fetal hemolytic disease with its associated morbidity and mortality. In the first use of this technology in 2005, an unaffected Rh-negative neonate was born to an Rh-D alloimmunized mother.[50] Following intracytoplasmic sperm injection, 12 embryos were obtained, and on day 3, biopsies were performed followed by PCR. Two Rh-D-negative embryos that were subsequently transferred resulted in the delivery of a healthy Rh-D-negative infant at 39 weeks of gestation. Notwithstanding the emotional, psychological, and financial burdens of in vitro fertilization, this represents a potentially lifesaving approach for selected couples with maternal Rh alloimmunization.

Rh Alloimmunization

Detection of Rh alloimmunization begins with the initial laboratory work. Pregnant women who are Rh negative are screened for antibodies by the indirect Coombs test. This allows detection of Rh-D antibodies as well as antibodies to other atypical antigens known to cause alloimmunization. If Rh-negative women are alloimmunized to Rh-D, they need to have their anti-D titer determined, because that

TABLE 23.2 Indications for Rh Immunoglobulin Prophylaxis

Indication	Justification	Dosage (μg)	
		First Trimester	Second or Third Trimester
Spontaneous abortion/IUFD	2%-3% sensitization	50	300

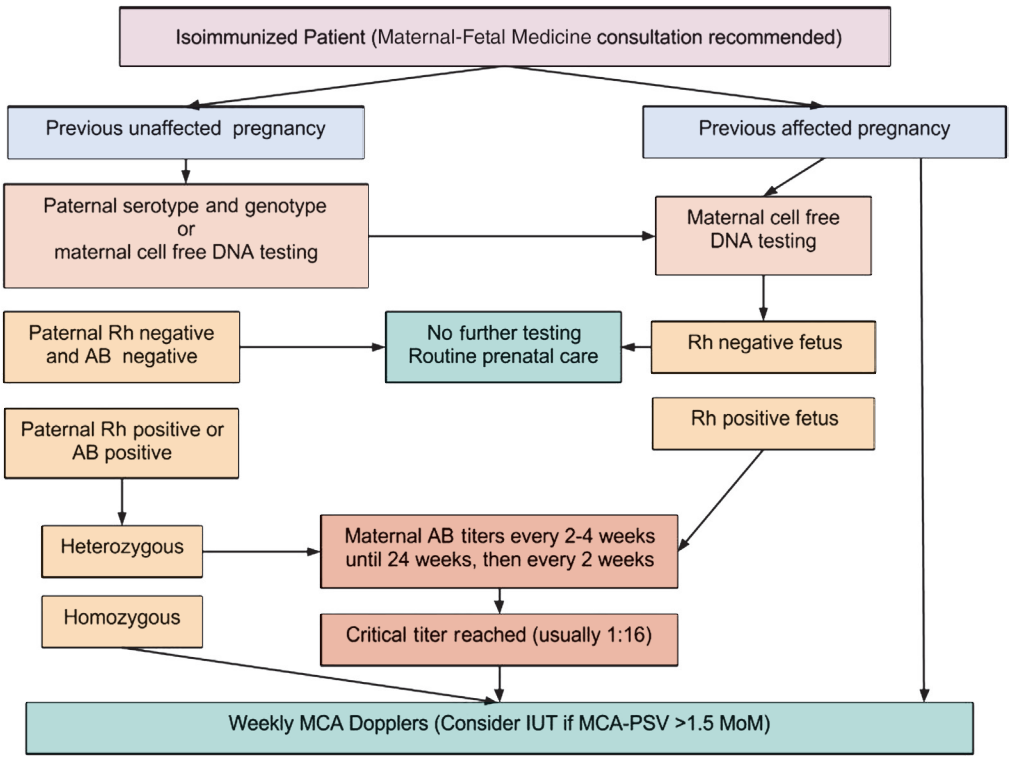
titer is known to roughly correlate with the severity of the disease and the need for Doppler flow studies. Although each lab sets its own standards based on experience, anti-D titers of 1:16 or greater require further assessment. If the titer is less than 1:16, the patient can be followed with monthly titers.



In sensitized Rh-D–negative women where the father is Rh-D positive, paternal genotyping may help clarify the fetal risk. PCR determination of paternal Rh-D status can facilitate counseling and dictate the need for intervention, because paternal heterozygosity is associated with a 50% risk of fetal Rh-D negativity, whereas homozygosity always produces an Rh-D-positive fetus, assuming correct paternity. Fetal Rh-D typing can also be done with amniocytes in the second trimester or with villi in the first trimester (Fig. 23.2). More recently, fetal Rh-D genotyping has been achieved through isolation of cell-free fetal DNA from the maternal circulation and provides a noninvasive way to directly assess fetal blood type and antibody status.

Prediction of Anemia

Cordocentesis and sampling of fetal blood is the most accurate method to determine if fetal anemia is present. However, this technique is invasive and carries a fetal loss risk of up to 3%. This has led to the use of other techniques to evaluate when the risk for fetal anemia is present so that fetal blood sampling can be undertaken. Fetal anemia had been determined previously by amniocentesis and determination of risk for fetal anemia using optical density of amniotic fluid (ΔOD450). This method used an assessment of the bilirubin content of amniotic fluid to determine the estimated level of fetal anemia. Often, a series of amniocenteses was necessary to monitor the pregnancy and determine when a more invasive cordocentesis was undertaken. With improvements in ultrasound technology, this method has been replaced by serial assessments of the peak systolic velocity (PSV) of the middle cerebral artery (MCA) in the detection of fetal anemia.[37]

The objective of Doppler flow studies is to detect physiologic compensatory changes in the fetal circulation that would be associated with mild to moderate anemia. As anemia progresses, both right and left ventricular outputs increase up to 45% with the heart rate remaining unchanged. This increases stroke volume. Progressive anemia leads to decreased blood viscosity. If the given fetal blood vessel cross-sectional area also remains unchanged, and applying Poiseuille's law (blood velocity is directly proportional to flow), increased stroke volume results in increased flow (flow being the product of velocity and the cross-sectional area).

A number of fetal vessels were evaluated by Doppler flow studies to determine which vessel would be the most predictive of fetal anemia. The MCA was selected because it is well known that the cerebral arteries respond rapidly to hypoxemia by increasing blood flow velocity to maintain cerebral perfusion. Additionally, the MCA is easy to identify with low interobserver and intraobserver variability. Mari and the Collaborative Group for Doppler Assessment of the Blood Velocity in Anemic Fetuses measured the hemoglobin concentrations in blood obtained by cordocentesis and correlated those concentrations with MCA-PSV in 111

fetuses at risk for anemia secondary to red blood cell alloimmunization.[34] The group used a hemoglobin concentration of 5 g/dL as a threshold to calculate degrees of anemia, because fetal hydrops is rare with a hemoglobin concentration greater than 5 g/dL.[38] Strict cutoffs using receiver-operating–characteristic curves were determined to detect 100% of those fetuses with moderate to severe anemia. They found the optimal threshold was 1.29 times the median for mild anemia, 1.5 times the median for moderate anemia, and 1.55 times the median for severe anemia, with a false-positive rate of 12%. These thresholds were chosen so as to not miss any fetus with moderate or severe anemia that might result in either fetal hydrops or death (Table 23.3). Measurements of the MCA-PSV can be started as early as 16-18 weeks and should be repeated at 1- to 2-week intervals.

TABLE 23.3 Reference Values for Peak Systolic Velocity of Middle Cerebral Artery

Peak Systolic Velocity of Middle Cerebral Artery					
Gestational Age (weeks)	Multiples of the Median				
	1	1.3	1.5	1.7	2
15	20	26	30	34	40

Suppressive Therapy

Intravenous Immunoglobulin

Although most fetuses with severe Rh alloimmunization can be treated with in utero intravascular transfusions, some cannot because of gestational age (<18 weeks); they may be difficult to transfuse because of small vessels or other technical issues that may make the intravascular transfusion impractical or impossible. Maternal administration of intravenous immunoglobulin (IVIG) has been proposed as an alternative therapy until an intravascular transfusion is possible. The proposed mechanism of action is feedback inhibition of maternal antibody synthesis, blockade of reticuloendothelial Fc receptors, or blockade of placental antibody transport. There is some literature that suggests in pregnancies with severe Rh alloimmunization before 20 weeks that treatment with high-dose IVIG followed by an intrauterine transfusion after 20 weeks compared with pregnancies treated only with an intrauterine transfusion after 20 weeks had improved fetal survival.[56] In another series of four pregnancies with severe Rh alloimmunization treated with high-dose IVIG, there appeared to be no effect on the total number of transfusions or the amount of blood transfused or progression to fetal hydrops.[9] In one study of Rh-sensitized pregnancies with mild anemia treated with high-dose IVIG, benefit was observed only if treatment was started before the development of severe anemia.[25] In another, a combination of plasmapheresis and IVIG had been reported to be successful in the treatment of severe maternal red blood cell alloimmunization.[47]

Despite the high cost of treatment with IVIG, there may be a role in pregnancies less than 18-20 weeks with severe fetal anemia caused by Rh alloimmunization, either with IVIG alone or in combination with other therapies, to prolong the pregnancy so that an intrauterine transfusion can be done at a later gestational age. Unfortunately, the cost of treatment with IVIG is a limiting factor in the treatment of Rh alloimmunization.

Fetal Transfusion

Intravascular Transfusion

The first direct intravascular fetal blood transfusion for Rh alloimmunization was done by fetoscopy and described in 1984.[44] Since that time, fetoscopy is no longer used, and needle placement is by ultrasound. When screening Rh alloimmunized pregnancies, once the MCA-PSV exceeds 1.5 multiples of the median (MOM), then sampling of the fetal blood is necessary to determine if fetal anemia is present. Fetal transfusions are typically done between 18 and 35 weeks. If fetal anemia is confirmed, then an intrauterine fetal transfusion will be necessary. The blood transfused is type O, Rh(D) negative, cytomegalovirus negative, irradiated packed red blood cells, cross-matched against maternal

blood. The usual hematocrit of the blood is around 75%, which allows for minimal blood volume to be transfused.

The procedure is done in an operating room or in close proximity to an operating room, in case there is a complication that would require an urgent delivery. For this reason, an anesthetist should see the patient before the procedure and be immediately available if there is an urgent need for an abdominal delivery. The administration of corticosteroids to accelerate fetal lung maturity should also be considered in those pregnancies starting at viability. Depending on the institution, this can be between 22 5/7 weeks and up to 34 weeks of gestation. The administration of antibiotics and/or tocolytics before the procedure is not supported by any randomized trials. The tubing and syringes used in the procedure are heparinized. The maternal abdomen is prepped, and sterile towels and sheets are used to create a sterile field. A 20- to 22-gauge echogenic tip needle is used to puncture the umbilical vein with the most desirable site being near the cord insertion site into the placenta. A free loop of cord, the intrahepatic portion of the hepatic vein, or the umbilical artery may be considered as alternatives but are less desirable sites because of fetal bradycardia and procedure-related complications that may accompany cord puncture at those sites.[44,52,55,59] Some surgeons prefer a fetal paralytic agent (vecuronium 0.1 mg/kg), which may then be injected intramuscularly or intravascularly at time of cordocentesis to prevent fetal movements. A system should be in place to report the fetal hematocrit as soon as possible. The blood sample can be confirmed using the mean corpuscular volume (MCV), which is greater than 110 μm^3 in fetal blood. The volume of blood to be transfused depends on the estimated weight of the fetus, the fetal hematocrit, and the hematocrit of the red blood cells to be transfused and the gestational age. This can be calculated using a variety of techniques, with a common calculator available online.[18] Following the blood transfusion, hematocrit assessment should be obtained. A post-transfusion hematocrit should be approximately 40% unless the gestational age is less than 24 weeks. If the gestational age is less than 24 weeks, the post-transfusion hematocrit should be 25% with repeat procedure in 48 hours.

The overall procedure-related fetal loss rate is approximately 1%, and the emergency delivery rate within 24 hours for procedure-related complications and subsequent perinatal demise is 1.8%.[30] Following the procedure, the fetus is continuously monitored for up to 4-6 hours, but that time may be extended if there are complications during the procedure or if uterine contractions develop following the procedure. Typically, the fetal hematocrit will fall approximately 1 percentage point per day, and a follow-up transfusion is likely to be necessary in approximately 2 weeks. Ultrasound evaluation of the MCA-PSV after the procedure may need to use a higher MoM cutoff of 1.69.[15]

Intraperitoneal Transfusion

Intraperitoneal transfusions are rarely performed in modern practice except when the caliber of the umbilical vessels does not permit placement of the needle for the transfusion (generally <18 weeks) or when an intravascular transfusion is technically impossible because of fetal position or the location of the umbilical cord. The infused red blood cells are absorbed into the circulation via the subdiaphragmatic lymphatic lacunae and the right lymphatic duct, making fetal respiration important for absorption to occur. Early work in sheep suggests that the time to complete absorption is about 150 hours and that the absorption rate is directly related to the transfusion volume. The higher the volume, the faster the absorption.[28] Generally, fetal intraperitoneal transfusions are less effective when fetal hydrops is present. In an assessment of intraperitoneal transfusions covering 154 fetuses treated by 270 intraperitoneal transfusions, the survival rate in the nonhydropic group increased from 35%-83% over 22 years of the study compared with the hydropic group, in whom the survival increased from 24%-42% over those same 22 years.[3]

In the literature, the size of the needle used for the transfusion has varied from a 16- to 20-gauge Tuohy needle, with the smaller needle being more commonly used when the rarely needed intraperitoneal transfusion is undertaken. The fetal abdomen is usually entered between the umbilicus and the fetal bladder to avoid the liver. The catheter tip should be free in the abdominal cavity, which can be confirmed with injected saline. Calculation of the amount of blood to transfuse is important, because if the intraperitoneal pressure exceeds the pressure of blood in the umbilical vein, there will be no blood flow and fetal demise will result.[11] This should not occur using the formula of Bowman for infused blood volume [volume = (weeks' gestation − 20) × 10 mL]. Generally, not enough blood can be given with the first transfusion, and a second transfusion may be necessary 9-10 days later. Before fetal intravascular transfusions, the transfusions were repeated every 4 weeks with delivery at 34-35 weeks. In modern practice, intraperitoneal transfusion often can be abandoned as soon as vascular access can be achieved.

Timing of Delivery

The overall timing of the delivery is somewhat controversial but is generally calculated based on severity of alloimmunization and degree of HF. If antenatal testing suggests that the fetal hemolysis is determined to be mild, then a reasonable approach would be to induce labor between 37 and 38 weeks or sooner if the fetal lung studies document lung maturity at an earlier gestational age. If the studies suggest severe alloimmunization, with fetal/neonatal survival greater than 95% in most tertiary neonatal intensive care units, the last transfusion should be given around 30-32 weeks, with delivery between 32 and 34 weeks with corticosteroids given to accelerate fetal lung maturity and to decrease the morbidity linked with preterm deliveries. Other experts have advocated that intrauterine transfusions continue up through the 35th week when there is a reasonable chance of fetal lung maturity with delivery at 37 weeks. The fetus should have continuous electronic fetal monitoring during

labor, and a cord blood sample should be sent immediately to the laboratory following delivery for neonatal blood group, Rh typing, direct Coombs, bilirubin, hemoglobin, and hematocrit. Delivery should occur at a tertiary care facility that has adequate neonatal intensive care, blood banking, and laboratory services.

Outcome

Short Term

With improvements in ultrasound technology, improved echogenic tip needles, and level of care offered in tertiary neonatal intensive care units, perinatal survival following an intrauterine fetal transfusion has increased dramatically. These improvements are well demonstrated in two large retrospective studies from the Netherlands and Scotland.[36,54]

A retrospective review of survival in fetuses treated for anemia caused by Rh alloimmunization with intrauterine transfusions between 1988 and 1999 in the Netherlands was performed in 208 pregnant women treated with 593 blood transfusions.[54] The overall survival rate was 86%. Survival of the hydropic fetuses (78%) was significantly less than the survival of those pregnancies without hydrops (92%). Low survival rates were also observed if the first transfusion took place at less than 20 weeks and the fetus was hydropic (55%). Survival was much greater in Rh alloimmunized pregnancies (89%) compared with Kell alloimmunized pregnancies (58%). Overall fetal loss rate linked to the procedure was 4.8%.
