Immediate neonatal period	Glucose-galactose malabsorption Congenital lactase deficiency
Weaning age	Glucoamylase deficiency Congenital sucrase-isomaltase deficiency

• BOX 83.1 Causes of Infantile Chronic and Protracted Diarrheal Illness

Osmotic Diarrhea

- Carbohydrate Malabsorption
  - Glucose-galactose malabsorption
  - Sucrase-isomaltase deficiency
  - Congenital lactase deficiency
  - Maltase-glucoamylase deficiency
- Fat Malabsorption
  - Pancreatic insufficiency
  - Defective handling of bile acids—primary bile acid malabsorption, cholestasis
  - Defective mucosal lipid handling—intestinal lymphangiectasia, abetalipoproteinemia, chylomicron retention disease
- Protein Malabsorption
  - Primary enterokinase deficiency
  - Hartnup disease

Secretory Diarrhea

- Normal Villous Architecture
  - Chloride-losing diarrhea (Cl^--HCO_3^- exchanger defect)
  - Sodium-losing diarrhea (Na^+-H^+ exchanger defect)
  - Neurogenin-3 mutation
- Villous Atrophy
  - Microvillous inclusion disease
  - Tufting enteropathy
  - Acrodermatitis enteropathica
  - Trichohepatoenteric syndrome (phenotypic or syndromic diarrhea)
  - Congenital disorders of glycosylation defects (CDG1b)

Combined Secretory and Osmotic Diarrhea (Partial Response to Fasting With Some Decrease in Diarrhea)

- Autoimmune Enteropathy and Infantile Onset Inflammatory Bowel Disease
  - IL10/IL10R defects
  - Hyperimmunoglobulin D from mevalonate kinase deficiency presenting as severe neonatal colitis
  - IPEX/IPEX-like syndrome
- Infectious Enteropathies
- Postinfectious Enteropathies
- Allergic Enteropathy
- Idiopathic

recessive form.[149] However, some heterozygotes can be symptomatic.[160] Several theories have been proposed for the pathogenesis of this enzyme deficiency, and there are at least seven known phenotypes.[91]

Clinical Features

Patients present with diarrhea, abdominal pain, and bloating upon ingestion of sucrose, maltose, and starch, typically noticed around the age of 3-6 months when the infant is weaned from breast milk to baby foods that contain sucrose. If the baby has been switched to a sucrose-containing formula, the diarrhea will develop earlier, around the time of the dietary change. Affected infants present with severe, chronic, or intermittent watery diarrhea; abdominal distention; cramping; metabolic acidosis; and failure to thrive.[11] Severity of symptoms is influenced by residual enzymatic activity, levels of carbohydrate intake, gut motility, and colonic fermentation. The stool pH is less than 7 as a result of fermentation of unabsorbed carbohydrates by colonic bacteria, but because sucrose is a nonreducing sugar, Clinitest or a test for stool-reducing substances is negative.[112]

Diagnosis and Treatment

A detailed history will provide the correlation of the onset of diarrhea and the dietary changes. Stools are acidotic but test negative for reducing substances. Stool osmolality reveals an elevated osmolar gap (>50 mOsm), indicating the presence of malabsorbed sugars. Sucrose hydrogen breath testing is a noninvasive test to evaluate for sucrase-isomaltase deficiency,[66] but it is not specific for a congenital deficiency and will be abnormal also if there is mucosal injury and secondary disaccharidase deficiency, for example, from bacterial overgrowth.[150] The gold standard for diagnosis is endoscopy with biopsies analyzing the actual enzyme level.[91] Treatment consists of strict lifelong avoidance of sucrose-containing fruits and beverages.[150] Affected patients can try a supplemental sacrosidase when ingesting sucrose-containing foods.[110,184] One study has documented a poor response to diet restriction and a good response to enzyme replacement therapy with supplemental sacrosidase at 8500 U at meal times.[146]

Congenital Lactase Deficiency

Congenital lactase deficiency is a very rare autosomal recessive disorder. Patients usually present very soon after birth with watery diarrhea, vomiting, poor weight gain, lactosuria, aminoaciduria, and changes in the nervous system.[79,111] Most of the cases reported are from Finland, where more than 42 cases have been described since the first documented diagnosis in 1959.[72] More recently, mutations have been reported in a Japanese infant[185] and patients from Italy and Turkey.[44,72]

Etiology

Congenital lactase deficiency is caused by the deficiency of lactase in the small intestine and has been linked to chromosome 2q21.[79] Villous architecture of the intestinal mucosa is preserved, as seen on biopsy specimens of the small intestine.[194] Congenital lactase deficiency is different from the adult-type hypolactasia, which is very common. Usually, congenital lactase deficiency is an isolated deficiency, but Nichols and coworkers have reported it in association with other disaccharidase deficiencies such as maltase-glucoamylase.[125]

Clinical Features

The symptoms appear when lactose-containing milk is introduced to the diet. Breast milk and other commercial formulas have lactose; therefore, the onset is usually within the first 10 days of life.[79] As with other disaccharidase deficiencies, the stool is acidic and the diarrhea resolves after switching to a lactose-free formula,[91] which confirms the diagnosis. Apart from diarrhea, these babies are lively and have a good appetite; they exhibit poor weight gain but no vomiting.[91,158] Occasionally, they can have hypercalcemia and nephrocalcinosis.[158] The hypercalcemia is probably secondary to the metabolic acidosis or to enhanced absorption of calcium in the ileum, facilitated by the nonabsorbed lactose. The hypercalcemia resolves after starting a lactose-free diet.[158] As a result of metabolic acidosis, the urinary excretion of citrate decreases, producing hypocitruria, which, associated with the hypercalcemia, facilitates the development of nephrocalcinosis.[134]

Diagnosis and Treatment

Congenital lactase deficiency can be diagnosed by obtaining a good dietary history and can be demonstrated by a lack of increase in blood sugar after a load of lactose.[106] The blood sugar does increase after the intake of individual monosaccharides and other disaccharides.[106] The diagnostic gold standard is quantification of the enzyme levels from duodenal biopsy specimens,[194] but this may not be possible in all cases.[106]

The treatment consists of avoiding lactose-containing formula and breast milk. When treated appropriately, patients have good catch-up growth with normal psychomotor development. Some patients may even tolerate supplementation with lactase as they age.[194]

Maltase-Glucoamylase Deficiency

Maltase-glucoamylase is a brush border hydrolase[125] that serves as an alternate pathway for starch digestion. It compensates partially for the lack of sucrase-isomaltase and vice versa.[194] Congenital maltase-glucoamylase deficiency, first described in 1994, is very rare,[124] with an estimated incidence of 1.8% among children with congenital diarrhea.[91] Maltase-glucoamylase is very similar to sucrase-isomaltase (59% homology) and has two catalytic sites that are identical to those of sucrase-isomaltase.[125] Therefore, patients may have a deficiency of both enzymes.

Clinical Features

The clinical symptoms are very similar to other disaccharidase deficiencies with diarrhea, abdominal distention, and

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

bloating. In this disorder, the symptoms start with the introduction of starch into the infant's diet, usually at the time of weaning.[194]

Diagnosis and Treatment

Endoscopy with biopsies will show decreased levels of the enzyme when symptomatic treatment requires starch elimination from the diet.[194]

Transport Defects

Glucose–Galactose Malabsorption

Glucose–galactose malabsorption is a rare disorder. Infants present in the neonatal period with hypernatremia and severe watery diarrhea, which can lead to rapid dehydration and death.[194] Clinically, it cannot be differentiated from congenital lactase deficiency.[134] It was first reported in 1962 in Sweden by Lindquist and Meeuwisse[107] and is transmitted in an autosomal recessive manner.[181]

Etiology

Glucose–galactose malabsorption derives from a defect in the intestinal glucose–galactose transport protein, SGLT1,[194] located on the brush border membrane. SGLT1 transports glucose and galactose intracellularly coupled with Na^+, using an electrical gradient to transport against the concentration gradient.[134,194] The transporter has been mapped to chromosome 22q13.1, which is the site of the gene *SLC5A1*.[186] Multiple mutations have been identified in the *SLC5A1* gene, but not all mutations produce glucose–galactose malabsorption; therefore, the results of mutation analysis must be used in combination with dietary changes and intestinal biopsy when trying to establish the diagnosis.

Clinical Features

The predominant sugar of breast milk is lactose, which is hydrolyzed to glucose and galactose before being absorbed. Therefore, these infants present at the start of breastfeeding or with ingestion of glucose-containing formula. This severe watery diarrhea is often confused with urine. This diarrhea can lead to rapid dehydration and electrolyte imbalance.[181] The diarrhea is osmotic and acidotic, caused by fermentation of the nonabsorbed sugars (glucose and galactose) by the bacteria.[194] If undiagnosed, this diarrhea can rapidly progress to death. A stool test is positive for reducing substances.[134] An oral glucose tolerance test demonstrates a flat glucose tolerance curve with the presence of glucose in stools. The histology is normal on endoscopy and colonoscopy. Because SGLT1 is also expressed in renal tubular cells, patients may also have glucosuria.[134] Case reports of nephrocalcinosis and urinary calculus formation in patients with glucose–galactose malabsorption have been described in the literature.[134,178,181] Mechanisms responsible for renal stone formation, as explained earlier for congenital lactase deficiency, may also exist in glucose–galactose malabsorption. As with congenital lactase deficiency, hypercalcemia resolves after initiation of a glucose-free diet and control of diarrhea.[134,178]

Diagnosis and Treatment

The diagnosis is made by the onset of diarrhea after the introduction of glucose, the presence of glucose in stools, hypoglycemia, hypernatremic dehydration, and normal intestinal morphology. The diarrhea improves on elimination of glucose, galactose, and lactose from the diet.[194] The diagnosis can be further established by an abnormal glucose breath hydrogen test and SGLT1 sequencing, although these are not needed to confirm the diagnosis.[194] The treatment consists of avoiding the "offending" sugars by using a fructose-containing formula.[134] Parents should be counseled on looking at labels to be sure no glucose and galactose are added in foods and medications.

Fat Malabsorption

The absorption of lipids from the gastrointestinal tract occurs in five steps:

1. Pancreatic enzyme lipolysis with lipase and colipase. Infants produce limited amounts of pancreatic lipase and only reach adult levels by 2 years of age[103]; therefore, infants rely on gastric lipase for fat digestion.[65]
2. Bile salt stabilization of fatty acids and monoglycerides to form micelles, which in turn stabilize cholesterols, diglycerides, and fat-soluble vitamins.
3. Flow of micelles, fatty acids, and monoglycerides across luminal brush and transport of cholesterol across the brush border via ABC transporter protein. In the terminal ileum, the transport of bile salts is through the ASBT transport protein.
4. Formation of the chylomicron and VLDL, which takes place in the enterocyte with triglycerides, phospholipids, and cholesterol. In the terminal ileum, the bile salts are bound with ileal bile acid-binding protein.
5. Uptake of chylomicrons into the lymphatic system through pinocytosis.

When any of these steps is disrupted, it will result in fat malabsorption and, consequently, diarrhea.

Pancreatic Insufficiency

Pancreatic insufficiency results in the absence of pancreatic enzymes needed for nutrient digestion. Stool fecal elastase is highly sensitive and specific for pancreatic insufficiency.[177] For an infant older than 2 weeks, elastase greater than 200 μg/g of feces is sufficient, and less than 100 μg/g of stool is considered a marker of pancreatic insufficiency.[127] Fecal elastase may miss cases of mild pancreatic insufficiency.[195] Some of the most common causes of pancreatic insufficiency include cystic fibrosis, Shwachman-Diamond syndrome, and Johanson-Blizzard syndrome.

Cystic Fibrosis

Cystic fibrosis (CF) is one of the most common fatal genetic disorders.[32] It is also the most common cause of exocrine pancreatic insufficiency and lung disease in childhood.[60] Although in the past, the prognosis was very

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

poor in childhood, currently the estimated survival is 43 years.[48]

Cystic fibrosis affects between 1 in 1900 and 1 in 3700 live births in the white population[170] and is much less common among African Americans (1 in 17,000)[170] and Asian populations (1 in 90,000).[32] Despite these racial differences, CF should be considered in the differential for any child who presents with poor weight gain and chronic lung disease.[152]

Etiology

Cystic fibrosis is transmitted in an autosomal recessive manner.[60] In whites, about 1 in 20 individuals have the recessive form of the allele.[43] In 1989, the gene responsible for CF was cloned.[87] The cystic fibrosis transmembrane conductance regulator (*CFTR*) gene is located on chromosome 7q31.2.[28] Currently, more than 1600 mutations in the *CFTR* gene have been described and about 1300 are thought to be pathogenic.[28] The ΔF508 mutation accounts for two-thirds of mutations in patients with CF.[28]

Clinical Features

This disorder can present very early in life with meconium ileus, which is an obstruction of the ileum as a result of thick meconium plugs.[170] On abdominal x-rays, the small bowel loops may have a ground-glass appearance resulting from dilated loops of bowel with bubbles of gas and meconium without air-fluid levels.[152] The infants may also present with microcolon.[194] About half of the infants presenting with meconium ileus develop complications, including peritonitis, volvulus, atresia, and necrosis, which may show up as calcifications on abdominal x-ray.[152] The presence of meconium plug syndrome, which is a temporary obstruction of the distal colon, should also raise concerns for the possibility of CF.[152]

Another common presentation of CF is chronic diarrhea secondary to pancreatic fat malabsorption.[91] Some CF mutations (class I-III) present earlier in life, usually within the first month with pancreatic insufficiency.[196]

Infants can present less commonly with extrahepatic biliary duct obstruction as a result of thick inspissated bile.[152] Therefore CF should be included in the differential diagnosis of any neonate with prolonged conjugated hyperbilirubinemia.[76,170] If not supplemented with pancreatic enzymes, infants and children with pancreatic insufficiency have poor weight gain and worse pulmonary outcomes.[152]

Diagnosis and Treatment

Since 2010, every state in the United States plus the District of Columbia includes screening for CF as part of the newborn screen.[192] The screening program is less accurate in children with less common alleles; therefore, a normal newborn screen does not rule out the presence of CF.[26] The diagnosis is confirmed by a sweat chloride test showing a chloride greater than 60 mEq/L,[170] which is present in 99% of patients with CF.[170] However, certain conditions may give falsely positive and negative values.[32,170] When confirming the diagnosis of CF, the sweat test should be done in centers certified by the Cystic Fibrosis Foundation.[32] Genetic testing can also be performed.[172] Nevertheless, even with the most comprehensive testing, 1%-5% of the mutation will be missed.[28]

The prenatal diagnosis of CF can be done based on the carrier status of the parents by mutational analysis of fetal cells obtained by chorionic villus sampling or amniocentesis. The diagnosis should be confirmed by sweat testing after birth.[152]

Management

The management of infants and children with CF is a multidisciplinary team effort that includes a gastroenterologist, a pulmonologist, a nutritionist, and a social worker,[194] and it focuses on caloric intake, the replacement of fat-soluble vitamins, meticulous pulmonary toilet and chest physiotherapy, pancreatic enzyme replacement, and the provision of supportive care.[152] Any infant with a fecal elastase level less than 200 μg/g or with a mutation associated with pancreatic insufficiency should be treated with pancreatic enzyme supplementation.[131,163]

Shwachman-Diamond Syndrome

The Shwachman-Diamond syndrome complex includes exocrine pancreatic insufficiency, bone marrow failure, and skeletal changes. It was described by many groups, including Nezelof and Watchi (1961),[123] Bodian and colleagues in the United Kingdom (1964),[17] Burke and coworkers in Australia (1967),[21] and Shwachman in the United States (1964).[173] Although it is a rare cause of pancreatic insufficiency, it is the second most common cause of bone marrow failure.[35] It has been reported in the North American population (1 in 50,000), Europe, Asia, and Africa.[194]

Etiology

This disorder is probably transmitted in an autosomal recessive mode. A majority of patients have compound, heterozygous, loss-of-function mutations in the Shwachman-Bodian-Diamond syndrome (*SBDS*) gene.[18] Recently, patients who are negative for the *SBDS*-gene mutations have been detected to carry a de novo missense variant in *SRP54* (encoding signal recognition particle 54 kDa).[25] The gene affected in Shwachman-Diamond syndrome has been mapped to chromosome 7.[36]

Clinical Features

Patients present with failure to thrive in infancy secondary to exocrine pancreatic insufficiency and variable degrees of bone marrow failure.[153] The most common hematologic abnormality is neutropenia with defective neutrophil chemotaxis, resulting in frequent bacterial infections.[34] The neutropenia is cyclic, ranging from low values to normal white cell counts.[35] These patients may also have anemia or thrombocytopenia.[194] The bone marrow is hypocellular and is replaced with fatty infiltration.[36]

Diagnosis and Treatment

Diagnosis of Shwachman-Diamond syndrome requires fulfillment of two criteria. The first criterion is demonstration of a hematologic cytopenia, which includes any of the three cell lines. The neutropenia is usually cyclic; therefore, neutrophils of less than 1.5×10^9/L must be demonstrated on two separate occasions over at least a 3-month period. The second criterion is documentation of exocrine pancreatic insufficiency.[122] Other findings support the diagnosis of Shwachman-Diamond syndrome, such as persistent elevation of hemoglobin F, persistent macrocytosis, abnormal 72-hour fecal fat, reduced levels of at least two fat-soluble vitamins, evidence of pancreatic lipomatosis, bone abnormalities, behavioral problems, or the presence of other family members with Shwachman-Diamond syndrome. Genetic testing is available, but up to 10% of patients are negative for mutations in the *SBDS* gene.[37]

The management of children with Shwachman-Diamond syndrome includes pancreatic enzyme replacement and supportive care. When the cytopenia is severe, these patients may require G-CSF therapy and blood and platelet transfusion.[37] Children should be monitored by measuring CBC, levels of fat-soluble vitamins, growth, bone density, and neuropsychological functioning.[37]

Johanson-Blizzard Syndrome

Johanson-Blizzard syndrome (JBS) is a very rare autosomal recessive disorder that was first described in 1971 by Johanson and Blizzard,[72] and there are still fewer than 100 patients reported worldwide.[147]

Etiology

Johanson-Blizzard syndrome results from mutations in the *UBRI* gene on the long arm of chromosome 15.[7]

Clinical Features

Affected infants have characteristic phenotypic features with varied penetration,[38] including aplastic alae nasi (which gives the appearance of a beaklike nose with large nostrils),[8] extension of the hairline to the forehead with upswept frontal hair,[62] low-set ears, large anterior fontanelle, micrognathia, thin lips, microcephaly,[46] aplasia cutis (patchy distribution of hair with areas of alopecia), dental anomalies, poor growth, pancreatic exocrine insufficiency, and anorectal anomalies (mainly imperforate anus).[8,180] Other findings include mental retardation, deafness, genitourinary abnormalities, hypothyroidism, cardiac malformations,[8] cholestatic liver disease,[3] growth hormone deficiency,[180] and transfusion-dependent anemia.[4]

Diagnosis

Patients present with exocrine pancreatic insufficiency with poor weight gain, failure to thrive, hypoalbuminemia, edema, and anemia.[8] Sometimes, prenatal ultrasound can show a beaklike nose and dilation of the sigmoid colon as a result of an imperforate anus.[8] These infants have normal karyotype.[8]

Miscellaneous Causes of Pancreatic Insufficiency

Many other syndromes and diagnoses can be associated with pancreatic insufficiency. Donlan syndrome is similar to JBS, but with normal alae nasi and cleft palate.[62] Pearson syndrome is characterized by pancreatic insufficiency, sideroblastic anemia,[62] variable neutropenia, thrombocytopenia, and vacuolization of bone marrow precursors.[194] Jeune syndrome is a rare autosomal recessive disorder of pancreatic insufficiency and asphyxiating thoracic dystrophy.[194] Isolated deficiencies of amylase, lipase, colipase, and trypsinogen have also been described. Familial pancreatitis with mutations in the trypsinogen gene can cause chronic pancreatitis, pancreatic insufficiency, and chronic diarrhea although infants are rarely symptomatic.

Defective Handling of Bile Acids

Chronic diarrhea can also stem from alterations in bile acid metabolism and enterohepatic circulation. These disorders should be considered when the more common causes of chronic diarrhea have been ruled out. Bile acid diarrhea happens when there is disease or resection of the terminal ileum as well as congenital conditions affecting the terminal ileum, which disrupt the enterohepatic circulation.[130] The enterohepatic circulation of bile is the primary mechanism by which the body reabsorbs 98% of the bile that then is reused as bile salts.[119] When the bile is not reabsorbed, it reaches the colonic mucosa with subsequent secretion of fluid and electrolytes, leading to diarrhea, steatorrhea, and decreased blood cholesterol levels.[130]

Primary Bile Acid Malabsorption

Etiology

Primary bile acid malabsorption is linked to a missense mutation in the sodium–bile acid cotransporter gene, *SCL10A2*.[120,130] The pathophysiology is not clear but may be related to a reduced secretion of the hormone fibroblast growth factor 19, which prevents bile acid secretion through a negative feedback mechanism. When this factor is decreased, then the excessive bile acid leads to diarrheal fat malabsorption and secretion of fluids from the colonocytes secondary to bile acid stimulation.[83,137]

Clinical Features

The symptoms develop in infancy with diarrhea and failure to thrive. Patients may also have low levels of low-density lipoprotein (LDL). The diarrhea is exacerbated when dietary fats are added and often persists during fasting.

Diagnosis and Treatment

The measurement of bile acids in stool is done mainly for research.[83] Clinically, it can be done by ingesting a capsule with a gamma emitter selenium 75-homocholic acid taurine (SeHCAT), which is a selenium-labeled bile acid. The results are expressed as a percent retention, with retention of less than 10% after 7 days having a sensitivity

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

of up to 100% and specificity of up to 94% for primary bile acid malabsorption.[83,137] Treatment of primary bile acid malabsorption is the use of bile acid resins such as cholestyramine, which prevents the secretory action of bile acids.[83,137]

Defective Mucosal Lipid Handling

Primary Intestinal Lymphangiectasia (Waldmann Disease)

In 1961, Waldmann and coworkers described the first 18 cases of idiopathic hypercatabolic hypoproteinemia.[193] These patients had edema associated with hypoproteinemia and low serum albumin and gammaglobulin levels. Microscopic examination of small intestine biopsies showed variable degrees of dilation of the lymph vessels in the mucosa and submucosa. The authors also proposed the term *intestinal lymphangiectasia*.[193]

Primary intestinal lymphangiectasia is a rare disorder generally diagnosed before 3 years of age but may be diagnosed in older patients with unknown prevalence.

Etiology

Largely, the etiology of isolated primary intestinal lymphangiectasia is unknown. However, primary intestinal lymphangiectasia can be a component of multisystemic genetic syndromes, including Hennekam syndrome (caused by biallelic loss-of-function variants in *CCBE1* or *FAT4*). There is also a recent report of 11 patients associated with CD55 deficiency with hyperactivation of complement, angiopathic thrombosis, and protein-losing enteropathy (CHAPLE syndrome), caused by abnormal complement activation due to biallelic loss-of-function mutations in *CD55*.[133] Intestinal lymphangiectasia is responsible for lymph leakage into the bowel lumen, which leads to hypoalbuminemia, hypogammaglobulinemia, and lymphopenia. The edema that accompanies the disease is the consequence of hypoproteinemia with decreased oncotic pressure.

Clinical Findings

Primary intestinal lymphangiectasia most often presents with mild to moderate peripheral edema.[102] Patients may develop anasarca, which includes pleural effusion, pericardial effusion, and chylous ascites. Other signs and symptoms include fatigue, abdominal pain, weight loss or inability to gain weight, diarrhea, fat-soluble vitamin deficiencies caused by malabsorption, and lymphopenia. The lymphopenia is secondary to leakage of lymph into the gastrointestinal tract.[190] In some patients, limb lymphedema is associated with primary intestinal lymphangiectasia, and it is difficult to distinguish lymphedema from edema. These patients also have diarrhea.[104]

Five syndromes are associated with intestinal lymphangiectasia: von Recklinghausen, Turner (X0), Noonan, Klippel-Trenaunay, and Hennekam.[68] Primary intestinal lymphangiectasia may be suspected during pregnancy based on ultrasonography images, which can identify fetal ascites or lower limb lymphedema.[164]

Diagnosis and Treatment

The diagnosis of primary intestinal lymphangiectasia is made by the combination of elevated fecal alpha-1 antitrypsin levels and endoscopic evidence of intestinal lymphangiectasia.[189] A high-fat meal prior to endoscopy can increase the sensitivity of endoscopic evaluation.

Children are treated with a low-fat diet supplemented with medium-chain triglycerides.[81] The lack of fat in the diet prevents the engorgement of the intestinal lymphatics with chyle, therefore preventing their rupture with the subsequent loss of protein and T cells. Medium-chain triglycerides can be added to the diet, because they are absorbed directly into the portal venous circulation, avoiding lacteal engorgement and improving nutrition and caloric intake. Other treatments such as antiplasmin, octreotide, corticosteroid administration, and everoliums have been tried with inconsistent results.[102,132] Patients with primary intestinal lymphangiectasia and *CD55* mutation could benefit from eculizumab (terminal complement inhibitor).[98] Occasionally, when the lymphangiectasia is segmental and localized, intestinal surgical resection of the small bowel may be an option.[89,190]

DGAT1-Associated Congenital Diarrhea

DGAT1-associated congenital diarrhea was first described in 2012 in one family with two of three children affected by a congenital diarrhea and protein-losing enteropathy.[63]

Etiology

The *DGAT1* gene encodes acyl-CoA:diacylglycerol acyl transferase, which converts diacylglycerides to triglycerides. Several homozygous mutations in this gene have been linked to a congenital diarrhea with protein-losing eneropathy.[51,63,179]

Clinical Manifestations, Diagnosis, and Treatment

Symptoms of DGAT1-associated congenital diarrhea vary in severity and include diarrhea, malnutrition, and edema. Signs related to the associated protein-losing enteropathy include fat-soluble vitamin deficiency, hypoalbuminemia, elevated fecal alpha-1-antitrypsin, hypogammaglobulinemia, and lymphopenia.[51,63,179] Hypertriglycemia is also seen in some patients.[51] Clinical diagnosis is made based on improvement in hypoalbuminemia and lymphopenia with elimination of enteral lipid provision through administration of parenteral nutrition and intravenous lipids and elimination of other etiologies of protein-losing enteropathy. Exome sequencing can be used to confirm the diagnosis.[51,63,179]

Other Causes of Protein-Losing Enteropathy

Congenital disorders of glycosylation and Fontan surgery to correct single-ventricular hearts can cause a protein-losing enteropathy. Congenital disorders of glycosylation are caused by defects in protein N-glycosylation and are associated with mental and psychomotor retardation, sometimes

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

with coagulopathy, hypoglycemia, and liver fibrosis without neurologic involvement.[77] Westphal reported protein-losing enteropathy in a patient with a congenital disorder of glycosylation who showed reduced heparan sulfate accumulation in the enterocytes.[199] Protein-losing enteropathy in these children develops secondary to a combination of genetic and environmental factors, with loss of heparan sulfate proteoglycans from the basolateral surface of the intestinal epithelial cells, suggesting a link to protein leak.[16]

Hypobetalipoproteinemia and Abetalipoproteinemia

Etiology

Abetalipoproteinemia (ABL) is a rare autosomal recessive disorder resulting from mutations in the gene encoding the large subunit of microsomal triglyceride transfer protein (MTP) located on chromosome 4. In ABL, fatty acids can be converted to triglycerides, but because of the lack of apoprotein B, they are not converted to chylomicrons and, therefore, fat accumulates in the intestinal absorptive cell. To date, more than 33 MTP mutations have been identified in patients with ABL.[203]

Hypobetalipoproteinemia is an autosomal dominant disorder characterized by decreased or absent plasma concentrations of apolipoprotein (apo)-B–containing lipoproteins and low-density lipoprotein (LDL) cholesterol.[165] In heterozygous individuals, the disorder is usually clinically silent, because the concentrations of apo-B and LDL cholesterol are 25%-50% of normal, whereas homozygous individuals have extremely low levels and are indistinguishable from patients with abetalipoproteinemia.[91]

Clinical Presentation

Abetalipoproteinemia (ABL) is characterized by fat malabsorption, acanthocytosis, and hypocholesterolemia in infancy. Later in life, many of the symptoms are secondary to the deficiency of fat-soluble vitamins such as development of atypical retinitis pigmentosa, coagulopathy, posterior column neuropathy, and myopathy. Sometimes these patients have associated adrenal insufficiency and hypogonadism.[96]

In patients with the severe form of homozygous hypobetalipoproteinemia, there is complete absence of betalipoproteins, so they present clinically in a similar fashion to the subjects with ABL.[108] In contrast, patients with heterozygous hypobetalipoproteinemia may be asymptomatic or may have subtle neurologic findings.[91]

Diagnosis and Treatment

Diagnosis of abetalipoproteinemia and homozygous hypobetalipoproteinemia is made through low triglyceride and cholesterol levels. Endoscopic evaluation may reveal a yellow appearance of the small bowel, and pathology is significant for fat-laden enterocytes.[91] The management includes a low-fat diet and supplementation with fat-soluble vitamins.[194]

Chylomicron Retention Disease

Etiology

Chylomicron retention disease, also known as Anderson disease,[194] is a rare autosomal recessive disorder of lipoprotein assembly.[12,139] The mutations are in the *SAR1B* gene encoding the Sar1b protein. As a result of these mutations in the polypeptide subunit of microsomal triglyceride transfer protein, the enterocytes are unable to secrete chylomicrons across the basolateral membrane.[12]

Clinical Manifestations

The disease is characterized by hypocholesterolemia, fat malabsorption, and failure to thrive, with onset of diarrhea shortly after birth. These children may have vomiting, abdominal distention, and less often, hepatomegaly.[139] As with hypobetalipoproteinemia and abetalipoproteinemia, they may develop neurologic manifestations such as areflexia, proprioceptive abnormalities, ataxia, myopathy, and sensory neuropathy presenting in the early second decade of life,[139] but retinitis pigmentosa and neuromuscular manifestations are less severe.[194] It is not unusual to diagnose chylomicron retention disease in neonates who present with diarrhea, but it may get delayed until adolescence and present with vitamin E deficiency.

Diagnosis and Treatment

Patients with chylomicron retention disease have normal triglycerides with decreased total cholesterol, LDL, and high-density lipoprotein (HDL). On endoscopy, the duodenal mucosa may have a white coloration.[139] Pathology shows vacuolated enterocytes that stain strongly with oil red, indicating the presence of fat within the enterocytes.[12] On electron microscopy, lipid-laden enterocytes are seen.[12] The diagnosis is confirmed with the identification of the mutation in *SAR1B*.[139]

The treatment of chylomicron retention disease is with a low-fat diet with added essential fatty acids and medium-chain triglycerides to aid in fat absorption and supplementation with high doses of the fat-soluble vitamins A, D, E, and K. In severe cases, intralipid infusion may be required.[139]

Disorders of Protein Absorption

Primary Intestinal Enteropeptidase Deficiency

Enteropeptidase, formerly known as enterokinase, is located in the proximal small intestine and belongs to the group of serine proteases.[73] This enzyme initiates the digestion of protein in the small intestine by facilitating the conversion of trypsinogen to active trypsin, which in turn activates other pancreatic zymogens.[58]

Etiology

Congenital enteropeptidase deficiency is a rare recessively inherited disorder of the pro-enteropeptidase gene.[73]

Clinical Features

Affected infants present with symptoms and findings of a protein-losing enteropathy, including diarrhea, failure to thrive, edema, and hypoproteinemia.[11] These children also have fat malabsorption, because trypsin is required for activation of colipase and phospholipase.

Diagnosis and Treatment

Infants present with watery diarrhea with normal osmolality and absent osmolar gap. These children have significant hypoalbuminemia and hypoproteinemia. The diagnosis can be made by quantifying the enteropeptidase on small intestinal biopsies or by assaying the enzyme levels in the duodenal fluid.[58] The diagnosis can also be confirmed by switching the diet from an intact-protein-based formula to a protein-hydrolysate formula.[194] Treatment consists of pancreatic enzyme supplementation.[194]

Hartnup Disease

Hartnup disease was first described in 1956.[10] It is an autosomal recessive disorder with an incidence between 2.5 and 5.5 per 100,000 births.[166,201] In Hartnup disease, patients have increased urinary and intestinal neutral amino acid secretion. The symptoms result from deficiency of tryptophan.[161]

Etiology

The genetic abnormality responsible for the loss of the amino acids is in the neutral amino acid transporter SLC6A19 located on the brush border of renal and intestinal epithelia.[92,169]

Clinical Features

The clinical presentation can range from no symptoms[161,166] to a pellagra-like rash with cerebellar ataxia, psychiatric disturbances, and emotional lability.[95]

Diagnosis and Treatment

The diagnosis is established by the patterns of urine aminoaciduria, which includes increased alanine, asparagine, glutamine, histidine, isoleucine, leucine, phenylalanine, serine, threonine, tryptophan, tyrosine, and valine.[161] Patients with symptomatic Hartnup disease are treated with lifelong oral nicotinamide supplementation.[161]

Lysinuric Protein Intolerance

Lysinuric protein intolerance, also known as hyperdibasic aminoaciduria type 2 or familial protein intolerance,[135] is a disorder of amino acid transport characterized by subnormal plasma levels of dibasic amino acids, such as ornithine, arginine, and lysine, and their enhanced urinary excretion. This disorder is transmitted in an autosomal recessive manner and is found mainly in Finland, Italy, and Japan.[135] There is varied phenotypic presentation with signs and symptoms, including failure to thrive, lung disease, renal disease, protein intolerance, developmental delay, autoimmunity, and hemophagocytic-lymphohistiocytosis.[113] The infants usually develop symptoms around the time of weaning when they are switched from breastfeeding to high-protein foods.[135] These subjects are treated with supplementation with citrulline and a protein-restricted diet (1.5 g/kg per day).[167,194]

Disorders of Electrolyte Absorption

Congenital chloride diarrhea and congenital sodium diarrhea present in a similar fashion in the prenatal and newborn period. Both entities can present with polyhydramnios, suggesting that both conditions may start before delivery.[2] The fetus may have a distended abdomen and hypoechoic loops of bowel.[39] Newborns usually fail to pass meconium, probably secondary to severe secretory diarrhea in utero.[118] Diarrhea starts soon after birth, but because of the watery aspect, the diarrhea is often confused with urine and the diarrhea is initially missed. Because of the degree of stool output and dehydration, both entities can cause renal disease.[2,39,71] Infants can occasionally present with a picture mimicking bowel obstruction[101] or present with meconium ileus.[171] In both conditions, there is history of consanguinity,[39] and both congenital diarrheas are transmitted in an autosomal recessive manner.[69,117] Congenital chloride diarrhea is more common than congenital sodium diarrhea. Both are secretory diarrheas with severe electrolyte imbalance, although the electrolyte losses and serum electrolyte disturbances are different.

Congenital Chloride Diarrhea

Congenital chloride diarrhea is the most common cause of congenital secretory diarrhea with intact mucosal histopathology. This disorder occurs more frequently in Finland (1 in 20,000), Poland, and the Middle East.[69] Congenital chloride diarrhea is caused by mutations in the intestinal Cl^- $HCO3^-$ exchange transporter (SLC26A3), which results in sodium, chloride, and fluid depletion.[194]

Patients with congenital chloride diarrhea have a decrease in serum potassium, serum chloride, and urine chloride and high stool chloride. Evaluation should include measurement of fecal chloride concentration that is greater than 90 mmol/L.[39,70]

Because the abnormality cannot be corrected, treatment is aimed at replacing the decreased serum electrolytes. This is a lifelong treatment, and the concept is based on the presence of normal electrolyte absorption in the jejunum. Initially, patients may need intravenous replacement but then can be transitioned to oral supplementation. In the study of Elrefas and coworkers in 12 Arabic children, eight did well on long-term follow-up.[39] Other treatments have been tried, including proton pump inhibitors that decrease the chloride load to the gut[142] and oral butyrate. Butyrate stimulates intestinal water and ion absorption through

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

different mechanisms, including the activation of a parallel Cl^-/butyrate. A 12-month trial in one case did not produce any side effects, and stools were more formed, allowing the child to perform normal activities.[24]

Congenital Sodium Diarrhea

Congenital sodium diarrhea is a very rare secretory diarrhea that presents soon after birth. Congenital sodium diarrhea is related to a defect in the sodium-hydrogen exchanger in the proximal intestine[19,86] that is responsible for the absorption of Na^+ in exchange for H^+. Mutations in the *SPINT2* gene, *SLC9A2* gene, and *GUCY2C* gene are associated with syndromic congenital sodium diarrhea.[42,78] There may be an increased risk of inflammatory bowel disease in patients with mutations in either the *SLC9A2* or *GUCY2C* gene.[78]

This disorder has been diagnosed in premature infants.[2] The diarrhea is very high in sodium (>100-150 mmol/L), and the pH is greater than 7. Urine sodium concentrations are low-normal.[117]

As with congenital chloride diarrhea, biopsies of the small intestine are usually normal.[45,198] However, Muller and colleagues did report cryptic hyperplasia with jejunal villous atrophy on light microscopy in three patients, which on transmission electron microscopy had vacuolation of the surface epithelium.[117] The evaluation of an infant with severe watery diarrhea should include fecal electrolytes, stool osmolality, and pH. Stool osmolality of less than 50 mOsm, high fecal sodium losses, and alkaline stool pH are characteristic of congenital sodium diarrhea. Serum hyponatremia, metabolic acidosis, and hypokalemia are noted, which is in contrast to patients with congenital chloride diarrhea (Table 83.4). However, because of the rarity of the condition, it is not often entertained in the differential diagnosis, and affected infants may be diagnosed very late in the course of the disorder. Treatment is aimed at aggressive fluid and electrolyte replacement, either orally or intravenously.

TABLE 83.4 Characteristics of Congenital Chloride Diarrhea and Congenital Sodium Diarrhea

	Congenital Chloride Diarrhea	Congenital Sodium Diarrhea
Serum pH	Metabolic alkalosis	Metabolic acidosis
Serum chloride	Low	Normal to high
Serum potassium	Low	High
Serum sodium	Low	Low or normal
Stool bicarbonate	Low	High
Stool pH	Acidic	Alkaline
Stool sodium	—	High
Stool chloride	High	—

—, Not established.

Disordered Villous Architecture

Microvillus Inclusion Disease

Microvillus inclusion disease (MVI), also known as *microvillus atrophy*, is a secretory diarrhea that presents in two different forms: (1) congenital, which is rare and has a poor prognosis, and (2) late-onset, which usually starts at 6-12 weeks of life.[27,138,141] These infants have a prenatal history of polyhydramnios, although this is not as prevalent as in congenital chloride diarrhea.[141,156] In the congenital form, a secretory diarrhea starts soon after birth, and when untreated, progresses soon to dehydration and death.[138] In a study of 23 infants conducted by Phillips and coworkers,[141] 15 were girls, with 16 white, 6 Arabic, and 1 Asian. The gender predominance is not clear in this disorder, with a slight male predominance in a study done in the Navajo population.[143] In Phillips' study, more than half of the infants were born preterm, and 75% died before 9 months of age.

The diagnosis is made by histology. The histologic findings are present in the small intestine and also to a lesser degree in the colon. Under hematoxylin and eosin (H&E) staining, the mucosa shows some degree of villous atrophy without significant crypt hyperplasia. The diagnosis is made mainly by periodic acid-Schiff (PAS) staining, which shows accumulation of the PAS-positive granules in the apical side of the enterocytes. Also, the brush border looks atypical with an intracytoplasmic band along the apical border. Immunostaining with techniques directed against CD10 can also show the abnormal linear band on the brush border. In congenital microvillous inclusion disease, abnormal PAS staining is present in upper crypt cells, whereas in the late-onset form, abnormal PAS staining is present in the lower part of the crypt. Electron microscopy is also helpful in the diagnosis of this disease, showing decreased or absent microvilli in the apical membranes as well as an increased number of vacuoles.[156]

Treatment consists of nutritional support with parenteral nutrition, frequently for life. In the late-onset form, some children may start tolerating some enteral feeds and could have decreased need for parenteral nutrition. In the congenital form, there is no improvement in the intestinal structure over time. Many children die before the age of 3 years from central line infections and complications from liver failure.[156] Intestinal transplantation alone or with liver transplant is also an option. Ruemmele and coworkers[157] described 12 patients with early-onset microvillous inclusion disease who were evaluated for transplant. Seven underwent transplantation; four had combined intestinal and liver transplantation. At 3 years' follow-up, 100% survived in the group that underwent intestinal transplant alone and 75% in the other group. All were weaned from parenteral nutrition.[157]

This disorder may be caused by mutations in myosin 5B (MYO5B). The microvillus inclusions are a consequence of the MYO5B loss in the neonatal period.[74] MVID patients are also at risk of developing a progressive familial intrahepatic cholestasis (PFIC)-like liver disease manifesting as cholestasis with normal gamma-gluatmyl transferase (GGT), which may hamper outcomes of intestinal transplant.[50,52] A second mutation in STX3 has also been identified.[200] Both of these genes are involved in apical membrane trafficking.[191] It has an autosomal recessive inheritance.

Tufting Enteropathy

Tufting enteropathy is also called intestinal epithelial dysplasia. It is a congenital secretory diarrhea that presents very early in life and is very rare but perhaps more common than microvillous inclusion disease. It is more common in countries where consanguinity is common, suggesting an autosomal recessive inheritance.

Usually, there is no history of polyhydramnios, and infants pass large volumes of very liquid stool in the range of 100-200 mL/kg. This congenital diarrhea can be associated with choanal atresia, esophageal atresia, and imperforate anus.[14,53] This disorder can be associated with other malformations, such as dysmorphic facial features and abnormal hair.[14]

The diagnosis is made by biopsy of the intestine. Tufting enteropathy affects not only the small intestine but also the colon. All subjects have some degree of villous atrophy. The epithelium shows crowding and disorganization, which look like tufts. These tufts are localized close to the tips of the villi, but crowding also occurs at the crypt level. Sometimes biopsies can be near normal and make the diagnosis more difficult. Therefore, in these cases, it is important to repeat the endoscopy with biopsy at a later time.[53] Sivagnanam and coworkers identified an epithelial cell adhesion molecule (EpCAM) as the gene for congenital tufting enteropathy in a family with two children affected with tufting enteropathy.[176] These mutations have been reported in other cases as well.[29,93,159] This mutation produces abnormalities in the epithelial tight junction proteins, leading to decreased transport of ions in the intestine and increased intestinal permeability.[94] These infants require parenteral nutrition for life. The diarrhea continues to a lesser degree even when nothing is given enterally. Some infants have a milder form of the disease that allows them to tolerate some enteral feeds.[23] Some of these infants have undergone bowel transplantation.[100,136] Recently, siblings of ages 17 and 19 were diagnosed with tufting enteropathy after many years of diarrhea requiring parenteral nutrition supplementation. The diagnosis was done by whole exome sequencing, showing mutations in the EpCAM gene.[64]

Acrodermatitis Enteropathica

Acrodermatitis enteropathica (see Chapter 94) is a rare autosomal recessive disorder resulting from the inability to absorb zinc from the diet. This disorder usually starts with diarrhea after the infants are weaned from breast milk, suggesting perhaps that breast milk may have some factors that improve the absorption of zinc. The diarrhea has been reported to start between 15 days and 9 months of age. These infants also develop a perioral rash that can be very severe,[6,88] such as in perioral or perianal areas. These infants may also develop alopecia, irritability, apathy, and sometimes growth failure.

The serum zinc level is usually low, but there is no good correlation between the zinc level and the clinical picture.[88] This disorder is caused by a genetic defect in chromosome 8q24.3 in the intestinal zinc-specific transporter gene *SLC39A4*.[99] Treatment is supplementation with zinc gluconate or zinc sulfate with significant improvement in the rash within 3 weeks.[88]

Trichohepatoenteric Syndrome (Phenotypic or Syndromic Diarrhea)

Trichohepatoenteric syndrome (THE-S), previously referred to as syndromic diarrhea or phenotypic diarrhea, presents in most infants with chronic secretory diarrhea, polyhydramnios, premature birth, and intrauterine growth restriction. Most of these infants develop diarrhea between 2 weeks and 7 months of age, although a report shows a 12-year-old with the genetic mutation and all the phenotypic characteristics without diarrhea.[148] Affected infants frequently have a history of consanguinity in their ancestors. Many of the subjects have shown two types of mutations with the same phenotype. These mutations were found in TTC37 and in SKIV2L.[41,67]

Most patients also have dysmorphic features (wide forehead, broad nasal root, and hypertelorism) and immune disorders, and some develop early onset of severe liver cirrhosis. Other features include hypopigmentation or café-au-lait spots, hair changes with trichorrhexis nodosa, and cardiac anomalies such as ventricular septal defect, tetralogy of Fallot, aortic insufficiency, and pulmonic stenosis. Some children are developmentally delayed. There is a case series of six patients with THE-S presenting with pancolitis and variable degree of enteritis with some responding to immunosuppressive therapy.[22]

Blood work shows low immunoglobulins and thrombocytosis, sometimes with large platelets. On intestinal biopsies, majority show villous atrophy with a variable degree of mononuclear infiltration.[54,67] Immunologic defects commonly seen in this population include hypogammaglobulinemia, defect in antibody production after vaccinations, and low lymphocyte counts.[40] Management includes long-term use of parenteral nutrition. Periodically, enteral feeds with either a semi-elemental or an elemental formula should be tried, because some infants will progressively tolerate enteral feeds and be able to wean from parenteral nutrition. Mortality is very high with up to 40% by 15 years of age.

Autoimmune Enteropathy

Autoimmune enteropathy (AIE) is a clinic–pathologic diagnosis that is characterized by severe intractable inflammatory diarrhea with intestinal biopsies showing villous atrophy, increased epithelial apoptosis, and mononuclear cell infiltration with or without the presence of anti-enterocyte antibodies.[55] Patients with autoimmune enteropathy commonly present before 6 months of age but can manifest at any age. These patients typically need prolonged immunosuppressive therapy. With recent technologic advances in genetic diagnostics, some patients presenting with AIE were identified to have specific diagnoses such as IPEX syndrome (immune dysregulation, polyendocrinopathy, enteropathy, and X-linked), IL-10 and IL-10R defects, and APCED (autoimmune polyendocrinopathy, candidiasis, and ectodermal dysplasia).[15,49]

Children with AIE can have intestinal and extraintestinal manifestations.[115] These infants have refractory diarrhea, with malabsorption, and anorexia, with severe weight loss, that requires treatment with total parenteral nutrition. The extraintestinal manifestations may include endocrine, renal, pulmonary, hepatic, hematologic, and musculoskeletal system involvement. The diagnostic criteria for AIE include chronic diarrhea for greater than 6 weeks with malabsorption, partial or complete blunting of the small bowel villi, deep crypt lymphocytosis, increased crypt apoptotic bodies, minimal intraepithelial lymphocytosis, and no other causes that may explain the villous atrophy. The diagnosis could also be supported by detecting anti-enterocyte (AE) or anti-goblet (AG) cell antibodies.

Management includes total parenteral nutrition. In addition, medical therapy is commonly used, usually with corticosteroids (budesonide and prednisone). However, some patients are refractory to corticosteroids and may require immunosuppressive therapy with azathioprine, 6-mercaptopurine, cyclosporine, tacrolimus, mycophenolate mofetil, sirolimus, infliximab, and rituximab.[49]

IPEX Syndrome

This is a rare syndrome inherited in an X-linked recessive pattern with expression only in males.[30] Patients usually present with a watery diarrhea, eczematous dermatitis, and endocrinopathy. It is caused by germ-line mutations in the *FOXP3* gene, which is a transcriptional regulator for the development of CD4 regulatory T (Treg) cells.[1] These children have decreased and/or dysfunctional regulatory T cells, which then lead to loss of peripheral immune tolerance.

Male infants present usually at less than 3 months of life with severe watery diarrhea that may have mucus and blood, malabsorption, and failure to thrive, and they eventually develop cachexia. Severe cases require total parenteral nutrition (TPN).[155] Some children can present at older ages, but most do not survive past the third decade of life. The most common endocrinopathy is type 1 diabetes mellitus with onset in the first months of life. Hypothyroidism is also common. The skin manifestation is usually eczematous dermatitis, but some develop erythroderma, psoriasiform dermatitis, and pemphigus nodularis.[126] Some of the affected children have other autoimmune disorders, including autoimmune thrombocytopenia, autoimmune neutropenia, Coombs-positive anemia, and tubular nephropathy.

Evaluation shows normal B cells, $CD8^+$ T cells, and NK cells. These children have increased IgE and sometimes eosinophilia. The other immunoglobulins are usually normal, but if the protein-losing enteropathy is severe, they may be decreased. Small intestine biopsy shows villous atrophy with a mononuclear cell infiltrate (activated T cells) in the lamina propria. Colon biopsy shows mucosal lymphoplasmacytic infiltration.[155]

The diagnosis is suspected primarily by the presenting clinical features and then by flow cytometry, showing decreased FOXP3- and CD25-expressing regulatory T cells. The definitive diagnosis is done by sequence analysis of the *FOXP3* gene.[30] It should be recognized that up to 25% of patients with IPEX syndrome could have normal FOXP3 expression despite having mutations in *FOXP3* gene.[168]

Treatment requires aggressive immunosuppression either with steroids alone or in combination with azathioprine, cyclosporin A, or tacrolimus, sirolimus, or bone marrow transplantation.[155]

Infectious Enteropathy

Intestinal infections should always be considered as a potential etiology of chronic diarrhea in infants.[59,61] Stool studies for bacterial cultures and viral antigen detection should be a part of the work-up for infantile diarrhea (see Chapters 48 and 50).

In developing countries, entero-adherent *Escherichia coli* and *Cryptosporidium parvum* can produce severe chronic diarrhea. In developed countries, viral infections such as rotavirus and norovirus are more common causes of chronic infectious diarrhea. After certain infections, infants and children can develop a postenteritis syndrome. In these cases, small intestinal mucosal damage persists after the acute gastroenteritis. Some of these children have a secondary disaccharidase deficiency or may develop food sensitization.[140]

Small bowel bacterial overgrowth is produced by an increased number of bacteria in the duodenal fluid or the presence of anaerobic bacteria. It induces chronic diarrhea through villous damage with loss of absorptive surface and/or fermentation of ingested nutrients producing an osmotic overload. Many times, the diagnosis is made by empiric treatment with antibiotics and evaluation of the response.

Allergic Colitis or Eosinophilic Proctocolitis

Allergic colitis or eosinophilic proctocolitis usually develops in the first few months of life.[116] Cow milk protein and soy proteins are the most common offending antigens.[20,129] Breastfeeding is not protective for this disorder, and up to

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

50% of cases of allergic colitis occur in breastfed infants who become sensitized to dietary cow milk in the mother's milk. This disorder is a non-IgE, cell-mediated, delayed-onset hypersensitivity reaction limited to the GI tract.[116]

These infants present with vomiting, diarrhea, abdominal pain, rectal bleeding, and sometimes anemia. They often have irritability and straining with stools. Rarely, infants may present with failure to thrive. The mean age of diagnosis is 60 days, but infants as young as 2 days could present with allergic colitis,[97] suggesting in utero sensitization. Furthermore, 30%-40% of infants with cow milk protein intolerance are intolerant of soy protein.[129]

The diagnosis is made based on the clinical history and is confirmed by a response to elimination of cow milk protein and soy protein. These infants may have eosinophilia and sometimes increased serum IgE.

Although colonoscopy is not routinely done anymore, when performed, it may show mucosal erythema and in severe cases, ulceration. Biopsies demonstrate intense eosinophilic infiltration of the lamina propria and muscularis mucosa, without features of chronicity.[202]

The treatment consists of changing the infant's formula to a protein hydrolysate[188](close to 95% response rate) or an amino acid–based formula (almost 100% response rate) when bottle-fed. There is some evidence for benefit of supplementing extensively hydrolyzed formulae with probiotics, especially *Lactobacillus* GG.[9] In breastfed infants, elimination of milk- and soy-containing products in the mother's diet may be beneficial; however, care should be taken to ensure that the maternal diet remains balanced and includes calcium and vitamin D intake from other sources. In breast fed babies who do not improve with soy and milk elimination of the maternal diet, atopy patch test could be helpful in determining which foods should be avoided.[109] The improvement is drastic after elimination of the offending protein.[31] The prognosis is excellent, and the majority of patients are able to reintroduce milk protein by 1-3 years of age.[116]

Food Protein-Induced Enterocolitis Syndrome

Food protein-induced enterocolitis syndrome (FPIES) is an uncommon pediatric non-immunoglobulin E (IgE)-mediated disorder triggered by the ingestion of certain food proteins. The incidence is between 0.0% and 0.34% of newborns.[84] The pathophysiologic features are still poorly understood, although they are probably produced by stimulation of the T cells in the gastrointestinal tract by some food protein.[57,116,187] The diagnosis is clinical. Children present about 2 hours after ingestion of a food protein with profuse vomiting and/or diarrhea, often with pallor, lethargy, cyanosis, metabolic acidosis, and neutrophilia.[121,144,174,175] They usually recover within a few hours, although up to 20% of children may present in hypovolemic shock, requiring fluid resuscitation.[47,128]

Often, these infants are thought to have sepsis, a metabolic disorder, or a surgical abdominal emergency.[5,80,116] The mean age at initial presentation is around 5 months. Children frequently experience multiple episodes before a correct diagnosis is made. Most of the children react to only one food product, but some may react to two. The most common problem foods are cow milk, soy, and rice, although other food products such as vegetables and fruits, legumes, meats, and seafood are also reported.[84] These infants usually present with vomiting followed by lethargy, pallor, diarrhea, and hypothermia (<36°C).

Diagnosis is suspected based on the clinical presentation and three of the five criteria described below, and it has to be confirmed by an oral food challenge (OFC) performed by an allergist.[105] Although an OFC is the most conclusive diagnostic method, it has been associated with risk of systemic reactions; therefore, the risks and benefits of the challenge need to be evaluated. Because of the potential severity of the response, an allergist should handle reintroduction of foods when clinically indicated. The five criteria include: (1) vomiting and/or diarrhea, (2) blood in the stool, (3) leukocytes in the stool, (4) eosinophils in the stool, and (5) a change in the blood polymorphonuclear neutrophil count.[145]

Treatment is elimination of the offending food or the use of a hypoallergenic infant formula (protein hydrolysate and elemental formulae). Most individuals tolerate reintroduction of foods by 2-3 years of age.[114] In a study of Korean infants with cow milk FPIES, 64% tolerated cow milk at 10 months and 92% tolerated soy at 10 months.[75] Sometimes patients with FPIES develop an IgE-mediated allergy to the same food products.[84]

Other Causes of Infantile Diarrhea

Motility Disorders and Small Intestinal Bacterial Overgrowth

Severe and extensive motility disorders such as total or subtotal intestinal aganglionosis (long-segment Hirschsprung disease) or chronic intestinal pseudo-obstruction syndrome[140] may also cause permanent intestinal failure. Small intestine bacterial overgrowth is a common problem in motility disorders and contributes to diarrhea and malabsorption. Children undergoing bowel surgery in the neonatal period and those having more than one procedure are at greater risk of developing small intestine bacterial overgrowth postoperatively. Patients with bacterial overgrowth could have carbohydrate, fat, and protein malabsorption leading to diarrhea. They frequently have vitamin B_{12} deficiency. Empiric response to a trial of metronidazole may be diagnostic and therapeutic.

Neurogenin-3 Mutation in Malabsorptive Diarrhea

This is a newly described entity with just a few case reports. Patients present during the first several weeks of life with

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

vomiting, diarrhea, and dehydration, and develop hyperchloremic metabolic acidosis. The diarrhea stops when there is no enteral intake except water. Even when water is mixed with amino acids or medium-chain triglycerides, the diarrhea relapses. Small bowel biopsies are grossly normal, with normal villi and no increase in inflammatory cells. Special staining for chromogranin A of the small and large intestine shows very decreased to absent entero-endocrine cells. These infants show homozygous missense mutation in the neurogenin-3 gene (*NEUROG3*).[197] In Wang's report of three cases, the children developed diabetes at around age 8 years. Diabetes can also present at birth. The association with diabetes is related to the need of the transcription factor neurogenin-3 in the early specification of the endocrine portion of the pancreas, as well as in the developmental pathway of gut epithelial stem cells destined to become endocrine cells.[82] Neurogenin-3 is differentially required for endocrine cell fate specification in the intestinal and gastric epithelium.[56,154]

There is no treatment for the diarrhea except parenteral nutrition. In the three cases reported by Wang and coworkers, one underwent transplantation but died of sepsis.

Mevalonate Kinase Deficiency Manifesting as Severe Colitis in Neonates

Mevalonate kinase deficiency (MVD) presents in most patients in the first 12 months of life and in some in the neonatal period with attacks of severe diarrhea, often bloody, with fever, vomiting, abdominal pain, stomatitis, and in some with arthralgia and myalgia. These patients could have up to 10 attacks per year that last for variable duration. Some may continue to manifest symptoms in between attacks. Up to 75% of patients could have elevated IgD levels. The best screening test currently available is urinary mevalonic acid levels with a sensitivity of 93% in a large cohort.[182] Treatment is mainly immunosuppressive therapy with corticosteroids and biologic agents directed against IL-1 and TNF.

Intestinal Failure

Intestinal failure is a condition in which there is insufficient functional bowel to allow for adequate nutrient and fluid absorption to sustain adequate growth in children, necessitating parenteral nutrition. There can be medical and surgical causes for intestinal failure. Surgical causes include patients with necrotizing enterocolitis, intestinal atresias, and midgut volvulus, among others. Many of these conditions do not intrinsically cause intestinal failure, but their natural histories often lead to surgical resection of bowel, resulting in short bowel syndrome and its complications. Medical causes of intestinal failure include infants with dysmotility disorders[33] or patients with severe intractable diarrheas described above. Children with surgical causes of intestinal failure have greater potential for bowel adaptation than children with medical causes of intestinal failure.[33] Patients with intestinal failure need intestinal rehabilitation, which is done by improving nutrition as well as using pharmacologic and surgical methodologies to improve enteral nutrition. Commonly used surgical modalities include the STEP (serial transverse enteroplasty) and Bianchi procedures. A systematic review did not find superiority of one procedure over another.[90] Intestinal transplantation is indicated in patients in whom long-term parenteral nutrition cannot be performed safely. Common reasons for intestinal transplantation include short bowel syndrome, congenital mucosal diseases, and motility disorders.[162] In children with intestinal failure, transplantation must be discussed early and should evolve from being a rescue procedure to becoming a true therapeutic option.[162]

Key Points

- There are many causes of diarrhea presenting in newborns or early infancy.
- Be aware of these conditions in the presence of polyhydramnios, failure to pass meconium, and profound diarrhea.
- Examination of serum electrolytes, complete blood count, immunoglobulin levels, and the contents of the stool are essential to determine the diagnosis.
- Biopsies may be necessary to distinguish the etiology of the many disorders, and genomic analysis has also resolved the underlying causes.
- Supportive care includes enteral and parenteral nutrition, elimination of offending agents, and the use of special formulae.
- Bowel and liver transplantation may be necessary for certain rare but complex conditions.

Selected Gastrointestinal Anomalies in the Neonate

MICHAEL DINGELDEIN

Thoracic Anomalies

Esophageal Atresia and Tracheoesophageal Fistula

Combined anomalies of the esophagus and trachea are regular occurrences in most tertiary neonatal units caring for high-risk infants. The spectrum of recognized deformities comprises a variety of combinations involving esophageal atresia (EA) and tracheoesophageal fistula (TEF). These malformations are well-recognized entities, yet they continue to stimulate a great deal of interest for a variety of reasons, and almost all are lethal unless surgically corrected. Many have concurrent pulmonary complications, and most are associated with other congenital anomalies that require careful coordination of interdisciplinary care. There are few conditions, if any, that require a greater degree of cooperation between neonatologist and surgeon.

The reported incidence of EA/TEF is roughly 1-2 per 3500 live births.[105] The incidence of EA/TEF is higher in white populations than in nonwhite. There is also a slight preponderance of males and a disproportionate rate of twinning among affected infants. Although the majority of cases are sporadic, there are numerous well-recognized genetic associations. Approximately 7% of affected infants have a chromosomal abnormality such as trisomy 13, 18, or 21. Additionally, EA/TEF has been reported in infants with the Pierre-Robin, DiGeorge, Fanconi, and polysplenia syndromes.

Although usually sporadic, most cases of EA/TEF are not isolated. Most affected infants, up to 70% in some series, have at least one other anomaly.[37] The likelihood of coexisting anomalies is considered to be greatest with pure EA and least with pure TEF. The most widely recognized relationship between EA/TEF and other congenital anomalies is within the constellation of defects referred to as the VACTERL association—abnormalities involving *v*ertebral, *a*norectal, *c*ardiac, *t*racheal, *e*sophageal, *r*enal/genitourinary, and *l*imb structures. There is a lesser association with CHARGE *s*yndrome (*c*oloboma, *h*eart defects, *a*tresia choanae, *r*etarded development, *g*enital hypoplasia, *e*ar defects/deafness). Gastrointestinal anomalies (other than anorectal defects) associated with EA/TEF include duodenal atresia, annular pancreas, jejunoileal atresia, and intestinal malrotation. Neurologic defects, especially hydrocephalus, may be associated with EA/TEF, as may diaphragmatic hernia and abdominal wall defects. In order of approximate frequency, the affected organ systems most commonly associated with EA/TEF are cardiovascular (35%-45%), gastrointestinal (25%), genitourinary (25%), skeletal (15%), and neurologic (10%).

The anatomy of EA/TEF includes five well-recognized variants. A number of anatomic classifications have been devised but have been largely discarded in favor of simple descriptive nomenclature. The most common variant is the combination of a proximal esophageal atresia and a distal tracheoesophageal fistula. The proximal atresia/distal fistula variant occurs in about 85% of affected patients. It manifests classically as a dilated, blind-ending proximal pouch that extends to the lower neck or upper mediastinum, and a distal esophageal segment that originates from the posterior membranous wall of the trachea, carina, or main stem bronchus and connects to the stomach in a normal fashion. The next two most common variants are isolated EA and isolated TEF, both of which occur in approximately 5%-10% of patients. An isolated TEF is often referred to as an H-type fistula; the fistula itself is usually angled downward, with the esophageal end inferior to the tracheal end. The rarest variants include the proximal fistula/distal atresia, and the double fistula, both occurring in no more than 1% or 2% of patients.

No single unified model of pathogenesis has been developed to explain a variety of anomalies seen with esophageal atresia. Normal development of the esophagus and trachea includes the formation of a primordial lung bud as a diverticulum of the ventral foregut during the 4th week of gestation. The appearance of this diverticulum is associated with a pair of lateral infoldings of the foregut—the laryngotracheal folds—which begin at the caudal end of the lung bud and fuse to form the tracheoesophageal septum.

Abstract

This chapter discusses the commonly seen congenital anomalies of the GI tract and their management.

Keywords

tracheoesophageal fistula
esophageal atresia
duodenal atresia
intestinal atresia
GI duplication cysts
Hirschsprung disease

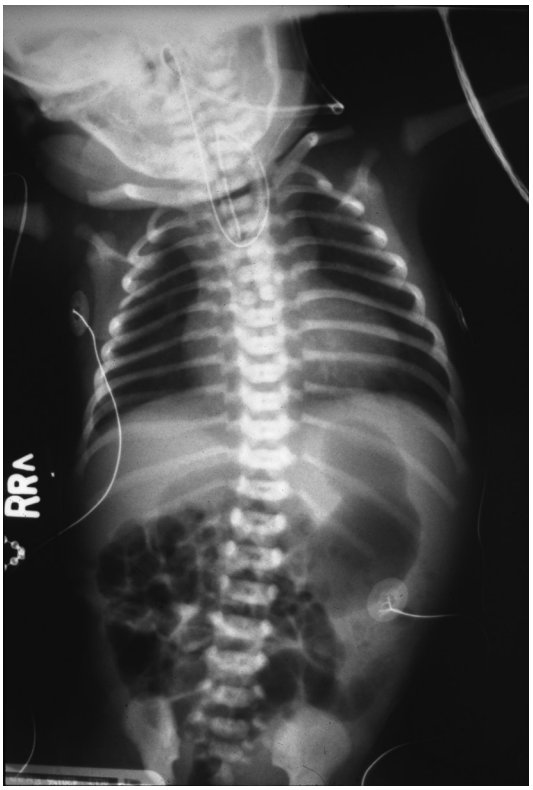
This process of lateral invagination and fusion was historically believed to proceed cranially, displacing the orifice of the lung bud in a cephalad direction and separating the developing trachea from the esophagus as the tracheal bifurcation moved caudally in a relative sense. Therefore, in the traditional model for the cause of tracheoesophageal malformations, the esophagus and trachea shared a common foregut precursor over a significant distance, becoming separated by the cephalad movement of the tracheoesophageal septum. Perturbations of this process would account for the observed variety of abnormal connections between these two adjacent structures. This theory of cephalad migration of a tracheoesophageal septum is now controversial. Evidence suggests that the position of the laryngeal orifice remains constant relative to the developing notochord and that the tracheal bifurcation descends simply as a result of linear tracheal growth without any cephalad movement of a tracheoesophageal septum.[36,73]



Given this alternative scheme of tracheoesophageal development, a different etiologic theory is required to explain tracheoesophageal anomalies. One such theory has arisen from observations in the Adriamycin-treated rat model of VACTERL deformities. In this model, pregnant rats are exposed to Adriamycin during early gestation and give birth to offspring that express VACTERL phenotypes, including EA/TEF. Investigations have demonstrated that the distal "esophageal" segment in EA/TEF arises from a respiratory precursor, descends from the carina along with the two main stem bronchi, and elongates caudally to merge with the stomach. A respiratory origin for this third structure is supported by the finding of pseudostratified respiratory epithelium and respiratory-specific thyroid transcription factor-1 (TTF-1) in distal fistulas from Adriamycin-treated rat model sources, and of TTF-1 expression in distal fistula specimens from human sources.[16,17,95] This structure does not branch as the developing bronchi do, because of abnormal epithelial-mesenchymal interactions caused by deficiencies of mesenchymal fibroblast growth factor and epithelial FGF receptors.[18] In support of this hypothesis, findings document a brief stage in the Adriamycin-treated rat model during which the stomach is anatomically disconnected from the rest of the developing foregut.[94]

If current proposals of a respiratory-derived distal fistula are accurate, the proximal atresia must, therefore, have a separate etiology. One proposed explanation is an abnormal concentration gradient of the early embryonic morphogen known as *sonic hedgehog* (Shh), which is elaborated by the developing notochord and is believed to participate in early foregut differentiation. Notochord abnormalities have been documented in the Adriamycin-treated rat model and in specimens of human distal fistulas that had been shown to be specifically deficient in Shh.[27,96] A unifying theory that links these newer models and provides a comprehensive explanation for tracheoesophageal maldevelopment is still lacking.

The clinical presentation of infants with EA/TEF depends on the specific anatomic variant encountered. Many cases of EA/TEF are not diagnosed prenatally, but current prenatal imaging techniques may raise a suspicion of EA/TEF in a significant number of infants. The combination of maternal polyhydramnios and a small or absent stomach has both sensitivity and a positive predictive value for EA/TEF of approximately 40%-60% in most series.[43,92] The finding of a dilated upper pouch in the neck by high-resolution ultrasonography or magnetic resonance imaging can increase the diagnostic accuracy in this selected group of patients to nearly 100%.[54,88]

In most affected infants, the diagnosis is made in the immediate postnatal period. The infant cannot swallow secretions and appears to drool excessively. As the upper pouch fills, antegrade aspiration may occur, leading to significant coughing, respiratory distress, and cyanosis. In patients with a distal fistula, the stomach may dilate with air, leading to the reflux of gastric secretions back into the lungs, resulting in significant and progressive respiratory distress caused by reactive bronchoconstriction and chemical pneumonitis.

Attempted passage of a gastric tube is usually diagnostic. The tube fails to pass distally and extrudes back through the mouth. A simple chest radiograph usually establishes the diagnosis by demonstrating the radiopaque catheter curled in the upper pouch (Fig. 84.1). If the diagnosis is still in question, the upper pouch should be cautiously evaluated with water-soluble contrast by an experienced imager, because aspiration can cause parenchymal lung injury. Air itself makes an excellent contrast agent, and the catheter can

• **Fig. 84.1** Typical chest radiograph of a patient with a tracheoesophageal fistula, with proximal atresia and a distal fistula.

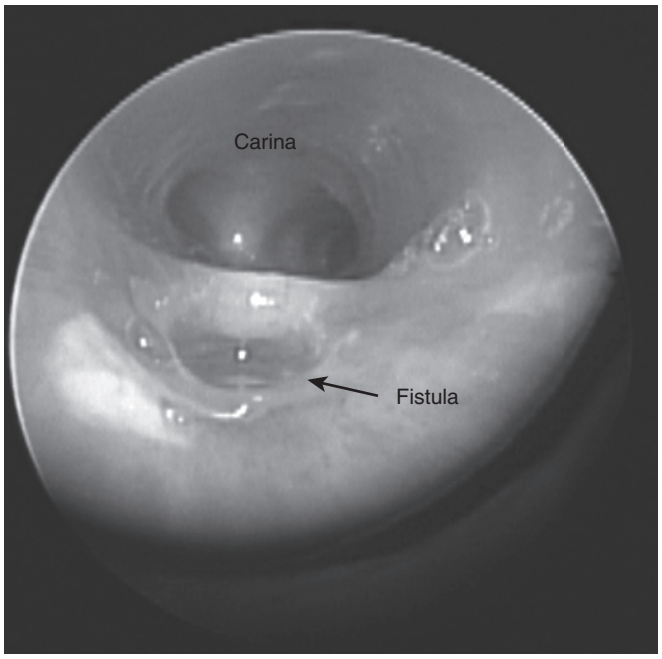
• **Fig. 84.2** Chest radiograph of patient with pure esophageal atresia.

be pulled back under fluoroscopic guidance until the tip is positioned in the proximal esophagus, and then 5-10 mL of air is injected slowly. A radiolucent dilated pouch is then easily documented. If there is no luminal gas below the diaphragm, the anomaly can be further defined as a pure or distal atresia (Fig. 84.2). The clinical presentation of an H-type TEF is typically much more subtle and delayed. It usually includes a history of coughing during feedings and occasionally the development of pneumonia owing to aspiration through the fistula. An H-type TEF may be very difficult to confirm radiographically. Contrast must be injected through a tube positioned in the thoracic esophagus, with the patient prone and in the Trendelenburg position, allowing the contrast to flow back up the angled fistula. Often, an H-type fistula is documented only on rigid bronchoscopy during evaluation for respiratory distress.

Once the diagnosis is established, efforts are made to prevent aspiration-induced lung injury, to provide respiratory support if necessary, and to define associated anomalies while preparing the patient for surgical correction. Gastric acid blockade should be instituted while the infant is maintained in a slightly head-up position to reduce reflux of gastric secretions into the airway. A small-caliber sump tube is kept in the upper pouch and suctioned intermittently. The use of preoperative broad-spectrum antibiotics during the first several days should be considered. Spontaneous ventilation is preferred to minimize the introduction of air into the stomach, as gastric decompression is possible only by percutaneous needle aspiration. This is particularly important in the presence of distal intestinal obstruction. The use of continuous positive airway pressure is discouraged. If parenchymal lung disease mandates the use of positive-pressure ventilation, mean airway pressures are minimized to avoid shunting of tidal volume through the fistula. This may be difficult in patients with lung disease and poor compliance. Under these circumstances, the use of high-frequency oscillatory ventilation (HFOV) may allow adequate gas exchange to occur at lower peak airway pressures, preventing the loss of ventilation through the fistula. The failure or unavailability of HFOV in a patient requiring aggressive ventilatory support may be an indication for urgent surgical intervention to ligate the fistula, ligate the gastroesophageal junction, or occlude the fistula with a balloon catheter.



A thorough evaluation for other VACTERL-associated defects is mandatory. A preoperative radiograph provides much information regarding cardiopulmonary status, diaphragmatic integrity, and the presence of vertebral abnormalities. The only other studies necessary before surgical management of the EA/TEF are an echocardiogram in all patients and a renal ultrasound. Echocardiography not only identifies significant cardiac anomalies that may influence anesthetic management but also establishes the presence of aortic arch anomalies that may alter the surgical approach.

Patients with respiratory compromise and EA/TEF can present a particular challenge to the care team. Endotracheal intubation and the conversion to positive pressure ventilation can often lead to worsening respiratory status, because frequently the path of least resistance is through the fistula and into the GI tract. This leads to inadequate pulmonary ventilation. At the same time, the stomach becomes grossly distended, increasing intrathoracic pressure and further decreasing bronchial airflow. These children may require emergent bedside gastric decompression or fistula ligation to stabilize the pulmonary status. Any decision to place EA/TEF patients on positive pressure ventilation must be discussed among all team members.

The nature and timing of surgical intervention depend on the specific anatomic variant being treated. Surgical strategies include immediate primary repair, delayed primary repair, staged repair, and esophageal replacement. Immediate primary repair is appropriate for the majority of infants with EA/TEF. Rigid bronchoscopy immediately before surgical repair is often a useful adjunct to confirm the diagnosis before thoracotomy and to obtain useful information; the location of the fistula can be determined, the presence of a second upper pouch fistula can be detected, and the structural status of the trachea can be assessed (Fig. 84.3).

An open repair is approached through a right extrapleural thoracotomy, or through the left side if preoperative echocardiography documents a right-sided aortic arch. An extrapleural approach is preferred to avoid a pleural empyema if an anastomotic leak subsequently develops, but this is more of a historic and not evidence-based decision. The division of the fistula is the key step of the procedure.

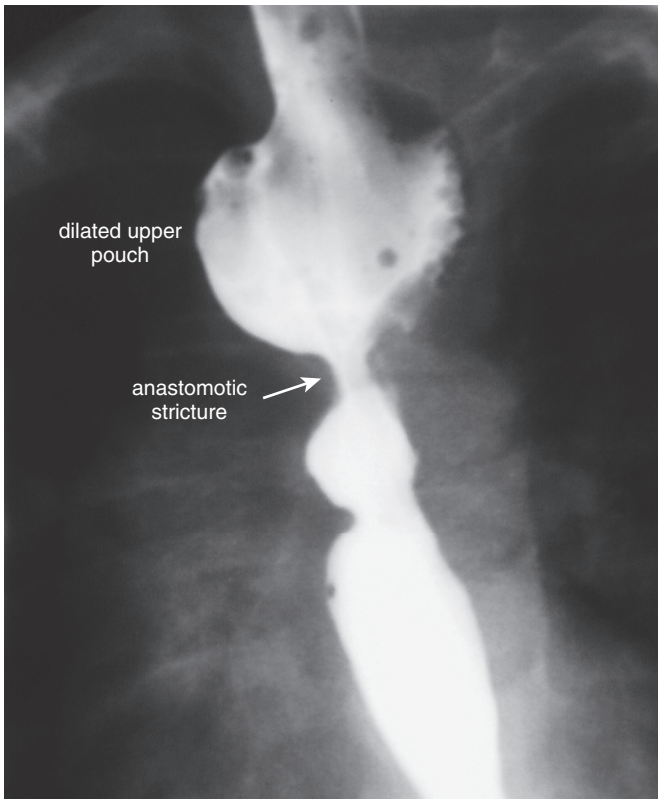
• **Fig. 84.3** Bronchoscopic view of tracheoesophageal fistula.

Fistula division allows stabilization of the pulmonary mechanics. The fistula is divided and the tracheal side closed transversely to prevent narrowing of the trachea. A primary anastomosis between the proximal esophageal pouch and the distal esophageal segment is then performed.[51]

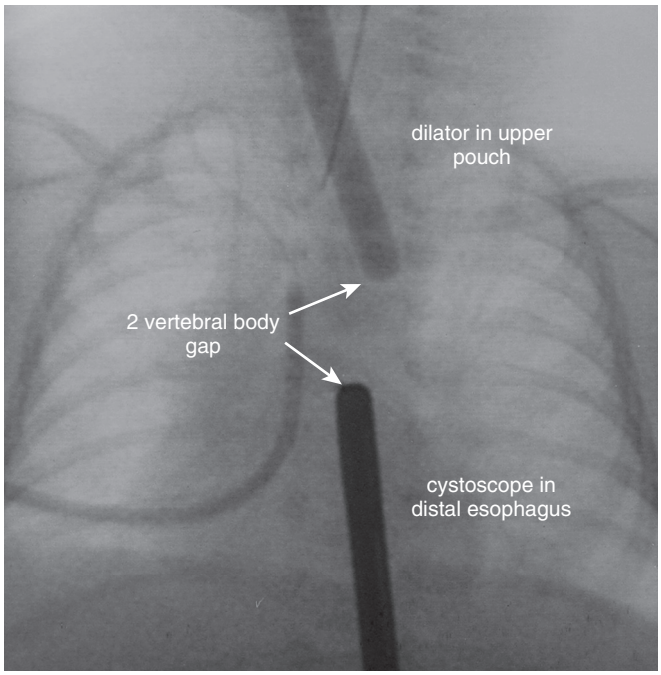
Thorascopic repair of EA/TEF, although technically challenging, has become a standard mode of repair especially in full-term infants with relatively normal respiration. Thorascopic technique typically uses two 3-mm ports and one 5-mm port. Advocates of thorascopic repair have been able to demonstrate improved cosmoses, improved pain control, improved postoperative respiration, chest wall maldevelopment, and scoliosis, all known complications of neonatal thoracotomy. Leak and stricture rates are similar to open repair.[9]

Compared with open repair (OR), a longer operative time has been associated with a thoracoscopic approach (TR), although the TR procedure could possibly reduce the length of hospital stay, time to extubation, and first oral feeding time. Meanwhile, the occurrence rates for leaks, strictures, and pulmonary complications; the fundoplication rate of GERD; and blood loss were similar between the OR and TR groups.[114,115]



In most patients, a gap of some degree exists between the proximal and distal esophagus, requiring mobilization of both ends and still resulting in some degree of tension at the anastomosis. Anastomotic ischemia caused by overaggressive mobilization or excessive tension leads to fibrosis and stricture formation. The blood supply to the cervical esophagus originates proximally and extends distally through the submucosal plexus, allowing extensive mobilization of the upper pouch without causing ischemia at the distal tip. The blood supply to the normal thoracic esophagus derives from the intercostal vessels and is, therefore, more segmental. Whether or not this limits the ability to mobilize the distal fistula without causing ischemia is debated. If careful mobilization does not sufficiently reduce tension at the anastomosis, two options are available. One option is to lengthen the upper pouch by performing a circular or spiral myotomy. A second option is to employ a technique first described by Foker that obtains length by placing the two ends under tension for a prolonged period—up to 3 weeks in some patients—prior to primary anastamosis.[67] Although met with great resistance when first described,[24] it is now an accepted option and considered the first choice for repair of long-gap atresia by many surgeons.

The postoperative care of patients with primary esophageal repairs must be meticulous and conservative. Removal of the endotracheal tube should occur only after respiratory mechanics have been optimized, as failure of extubation may lead to aggressive bag-mask ventilation and reintubation—events that place the tracheal and esophageal repair at risk for disruption. The head of the bed is elevated and gastric acidity neutralized to minimize reflux injury to the healing anastomosis. After 5-7 days, a contrast esophagram is carefully performed with a water-soluble agent followed by barium. If no leak is demonstrated, oral feedings are initiated and the chest tube is removed. Small, asymptomatic leaks that are adequately controlled by the existing extrapleural chest tube may be managed nonoperatively and repeat studies performed until healing is documented. Large leaks and intrapleural leaks often mandate exploration for repair or diversion.



In many clinical situations, the described primary approach is neither feasible nor appropriate. In the premature infant with very low birth weight, or in any infant with a significant cardiac defect, respiratory compromise, or sepsis, primary anastomosis should be postponed until the patient is a better surgical candidate. If the anticipated surgical delay is brief, careful upper pouch suctioning and parenteral nutrition may be used until the delayed primary repair can be carried out. If a lengthy or indeterminate delay is expected, a staged approach may be required. This strategy provides temporizing measures that allow later esophageal repair to be undertaken electively. Typically, a gastrostomy tube is placed for decompression and feeding, and the fistula is divided via an extrapleural approach to protect the lungs from further injury. Later, a transpleural approach may be taken to restore esophageal continuity.

The list of postoperative complications that occur in this complex group of patients is long and varied. Beyond the immediate postsurgical period, when anastomotic leak is the most feared problem, anastomotic strictures represent the most common complications of surgical treatment, occurring in up to 40% of patients in some series.[45] Strictures result from fibrosis during healing, which in turn results from ischemia, excessive tension, leakage, or acid-peptic injury. An anastomotic stricture should be suspected whenever dysphagia or respiratory symptoms occur in a patient who had previously tolerated oral feedings. A contrast esophagram reliably demonstrates the stricture and

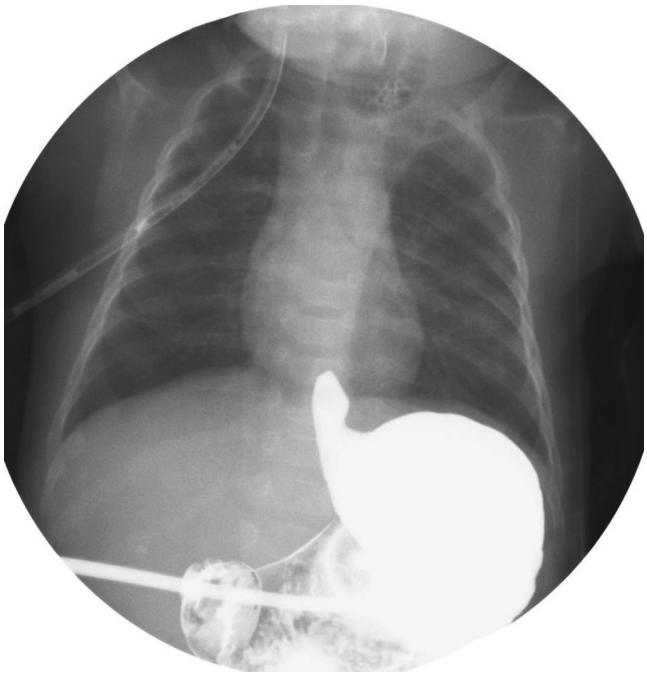
• **Fig. 84.4** Barium esophagram demonstrating anastomotic stricture and upper pouch dilation.

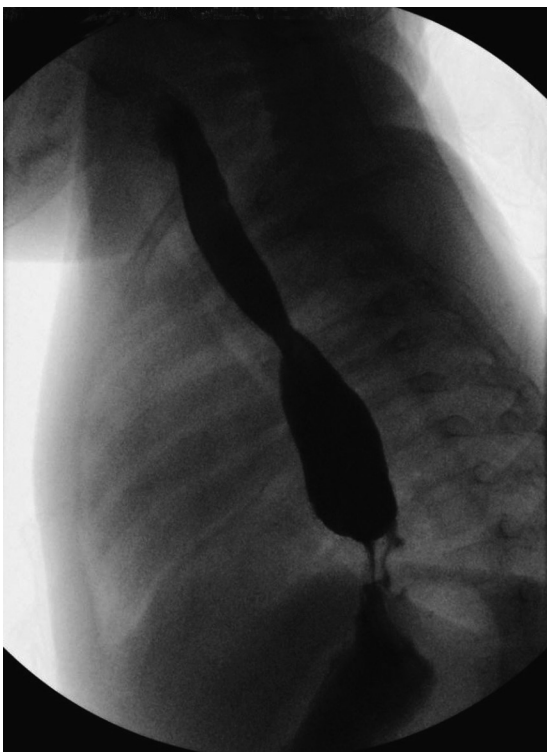
• **Fig. 84.5** Measuring gap length in pure esophageal atresia.

often demonstrates distention of the upper pouch with posterior compression of the trachea—the so-called upper pouch syndrome (Fig. 84.4). Strictures are best treated by tangential dilation under fluoroscopic guidance and control of acid reflux. Near-occlusive strictures require placement of an indwelling transanastomotic guide line that can be used to pull sequential dilators safely through the stricture on a frequent basis. If pharmacologic suppression of gastric acid secretion fails to prevent recurrent strictures, an antireflux procedure may be required. Finally, a stricture refractory to aggressive management may require segmental resection.



Recurrent fistulas occur in 5%-10% of cases and usually present with respiratory distress during feeding or with recurrent aspiration pneumonia.[22] Diagnosis is made with a dilute barium esophagram in the prone position. Most recurrent fistulas result from small, contained anastomotic leaks that cause chronic inflammatory changes and gradually erode back through the tracheal repair. Surgical options range from primary closure to segmental esophageal resection, and they must include interposition of healthy, well-vascularized soft tissue such as a pleural or strap muscle rotation flap. Some repairs can be approached from a cervical incision, which limits the complications associated with secondary leaks.

Functional disturbances of the esophagus are nearly universal after repair of EA/TEF. Occasionally, dysphagia is associated with severe esophageal dysmotility in the absence of a stricture. Solid-phase esophagography demonstrates that solid foods have great difficulty traversing the anastomosis and lower esophagus because of a lack of peristaltic force. In these situations, dietary modification and adjustment of feeding behavior may be all that can be offered. Gastroesophageal reflux (GER) disease is present to some degree in most of these patients and may be clinically significant in up to 50% of patients with tracheoesophageal malformations.[107] Some advocate lifelong follow-up care.[59] Deficient autonomic and enteric innervation, intrinsic developmental abnormalities of the lower esophageal muscle, shortening of the intra-abdominal esophagus, and distortion of the angle of His may all contribute to lower esophageal sphincter dysfunction in varying degrees. Lower esophageal sphincter incompetence is exacerbated by esophageal dysmotility, reducing clearance of gastric acid from the esophagus. Some degree of tracheomalacia is also expected in all patients with EA/TEF. Most patients exhibit the typical raspy cough caused by vibration of the weak and flattened tracheal wall, and they outgrow these minor symptoms with age.



In patients with isolated EA, a long gap is anticipated, and primary repair, immediate or delayed, is not feasible. Historically, long-gap EA had been an absolute indication for esophageal substitution without attempts at staged primary repair. Over the past two decades, however, the proportion of patients with pure atresia who eventually undergo successful esophageal repair has increased dramatically, obviating esophageal substitution in a large number of children.[10,24] There is no universal agreement regarding the maximal gap that will permit esophageal repair.[76,97] However, a fluoroscopically measured gap of greater than four vertebral bodies with the segments in neutral position, or greater than two vertebral bodies (Fig. 84.5) with the segments stretched toward each other, portends a low

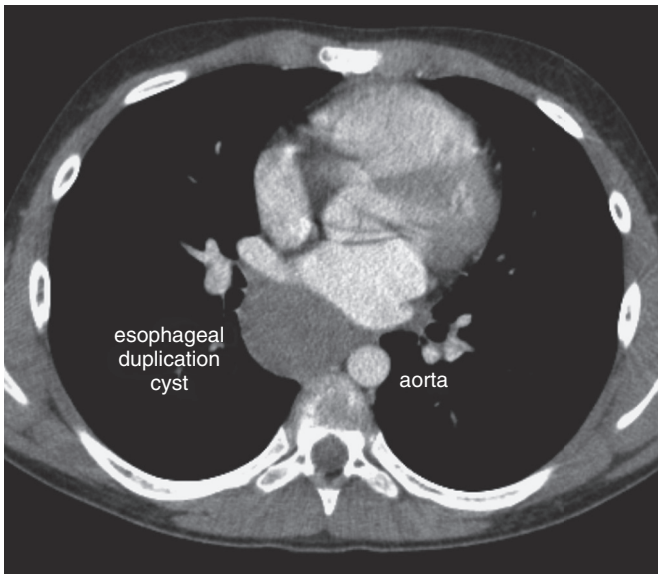
likelihood of successful primary anastomosis. Elongating the upper and lower pouches over a 1- to 3-week period, followed by primary anastomosis, has been very successful at keeping the native esophagus and avoiding esophageal replacement.[24] Fig. 84.6 and Fig. 84.7 show preoperative and postoperative contrast images of a patient with a long-gap atresia of nearly seven vertebral bodies treated by elongation and primary repair. Reflux requiring fundoplication is common in these patients, as are dilations to relieve strictures. However, when compared with the multiple, significant complications associated with esophageal replacement using either small or large bowel, the Foker procedure requires strong consideration in all patients with long-gap esophageal atresia.[67,100] Esophageal replacement is reserved for those cases of long-gap atresia unsuitable for immediate or delayed primary repair, and when attempted primary repair has failed irretrievably because of leakage or stricture.

• **Fig. 84.6** Long-gap esophageal atresia. Note proximal air-filled upper pouch and small distal esophagus. Gap is approximately seven vertebral bodies in length.

• **Fig. 84.7** Same patient as in Fig. 84.6 after Foker repair and Nissen fundoplication. Patient is able to eat all foods without difficulty.

Long-term outcomes for all variants of EA/TEF have improved steadily over the last three to four decades.[11,36] Waterston and colleagues were the first to stratify patients on the basis of risk factors shown to affect prognosis and to recommend treatment strategy based on this stratification.[113] In this analysis, prognosis was dependent on birth weight, associated anomalies, and the presence of pneumonia. Many stratification schemes subsequently evolved, and Spitz and associates refined this prognostic model to include only birth weight and the presence of significant congenital heart disease (Table 84.1).[98] In the current era, most infants born with tracheoesophageal anomalies ultimately experience a positive outcome owing equally to refinements in surgical technique and to neonatal support over the past several decades.

Esophageal Duplications



Esophageal duplication cysts are uncommon causes of esophageal obstruction during infancy. These structures result either from abnormalities in the vacuolization process that re-establishes the esophageal lumen after obliterative epithelial proliferation during early embryonic development, or from the "budding" and separation of a portion of the developing foregut. These structures are usually cystic, but they may be tubular and may be located within the muscular wall of the esophagus or exist separately in the posterior mediastinum. They contain an epithelial lining derived from any foregut structure: squamous, columnar, or pseudostratified ciliated respiratory epithelium. They may also contain gastric epithelium and pancreatic or adrenal rests.

TABLE 84.1 Determinants of Survival in Cases of Tracheoesophageal Malformation

Group	Characteristics	Survival
I	Birth weight >1500 g without CHD	97%
II	Birth weight <1500 g or CHD	59%
III	Birth weight <1500 g and CHD	22%

CHD, Congenital heart disease (major).

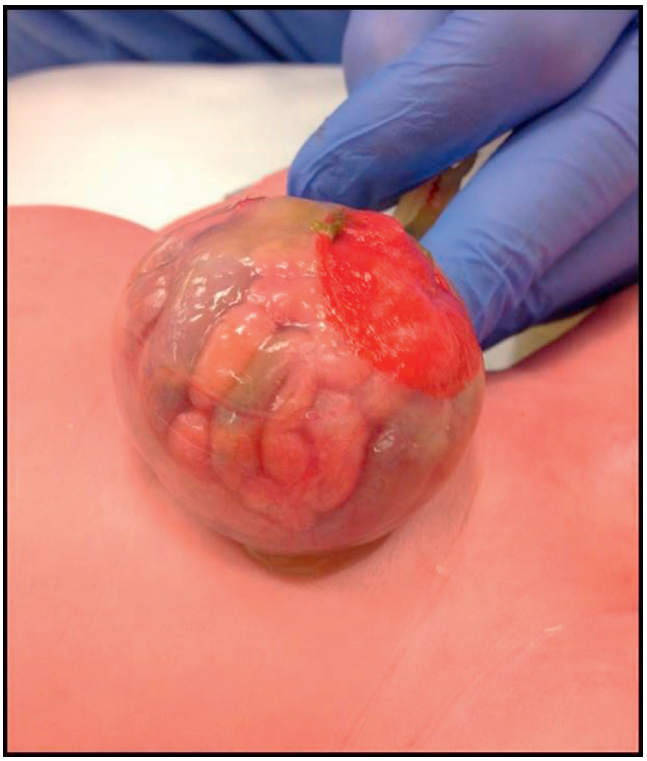
• **Fig. 84.8** Esophageal duplication cyst demonstrated by computed tomography.



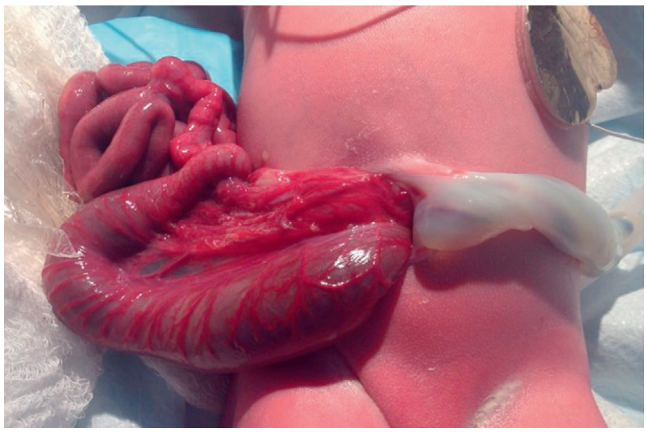
Infants with esophageal duplication cysts are usually asymptomatic, and the diagnosis is made when chest radiography unexpectedly demonstrates a mediastinal mass. Some infants, however, experience feeding difficulties or respiratory compromise if the cystic structure compresses the adjacent esophagus or trachea. Cysts containing gastric mucosa may present with complications of acid-induced injury: upper gastrointestinal hemorrhage, ulceration, perforation, or erosion into the bronchial tree.

Although the diagnosis may be suggested by a plain chest radiograph or by contrast esophagram, computed tomography is definitive and helpful in planning the operative approach (Fig. 84.8). Magnetic resonance imaging provides additional information about the status of the spinal cord, which may be abnormal; this information should be obtained in all patients with a vertebral abnormality or a cystic structure in close proximity to the spine. Esophagoscopy is unnecessary and potentially harmful.

Surgical treatment involves resection of the cyst and repair of any esophageal defect. This may require a thoracotomy, but many lesions lend themselves to thoracoscopic resection. Cysts complicated by infection with abscess formation or by internal hemorrhage may expand rapidly and may require urgent drainage before resection. Duplications that are deemed unresectable because of their extensive nature, which may include extension into the abdomen, should be treated by stripping the mucosa from the duplication and leaving the muscular remnant to heal to the existing esophageal wall. Excellent results can be expected in most patients.

Congenital Diaphragmatic Hernia

See Chapter 66.



• **Fig. 84.9** Small omphalocele with open Meckel diverticulum.

Abdominal Wall Defects

The most common abdominal wall defects seen in neonates are omphalocele and gastroschisis, occurring in approximately 4 per 10,000 live births. These conditions result from different developmental miscues and manifest as distinct clinical entities. In the case of omphalocele, a central abdominal wall defect of variable size is covered by a domelike mesenchymal membrane composed of amnion. The umbilical cord connects to the central portion of this membrane (Fig. 84.9). The underlying abdominal organs are protected from exposure to amniotic fluid. In gastroschisis, the defect is usually smaller and located to the right of the umbilical attachment. There is no protective membranous covering. The abdominal contents, therefore, are eviscerated and suspended in amniotic fluid during gestation (Fig. 84.10).

Omphalocele results from a failure in the folding mechanism that converts the flat trilaminar germ disc into a complex "tubular" structure starting at about 5 weeks' gestation. The lateral body folds and craniocaudal folds converge at the umbilical ring, which contracts, closing the ventral abdominal wall. In patients with omphalocele, this ring fails to contract and leaves a round defect of variable size and a corresponding sac composed of amnion. The liver and small intestine usually occupy a portion of the sac, along with a variable amount of other abdominal contents. The underlying failure of umbilical ring closure may be related to aberrant development and migration of abdominal wall muscular components, or to failure of the developing midgut to

• **Fig. 84.10** Typical gastroschisis defect with mild "peel."

• **Fig. 84.11** Pentalogy of Cantrell.

return to the abdominal cavity after a period of herniation into the umbilical stalk. Rarely, the defect is cephalad to the umbilicus, producing a complex deformity referred to as the pentalogy of Cantrell: sternal, diaphragmatic, and pericardial defects; upper abdominal omphalocele; and ectopia cordis (Fig. 84.11). When centered below the umbilicus, bladder or cloacal exstrophy may occur. The cause of gastroschisis is equally unclear, but it may involve a rupture of the umbilical stalk during the period of midgut herniation. Gastroschisis is usually described as an abdominal wall defect, to the right of a normally inserted umbilical cord, without membranous covering of the extruded organs. Etiologically it has been suggested that gastroschisis represents a failure in the normal attachment between umbilical cord and umbilical ring.[83] Competing theories involving thromboembolic infarction of the developing abdominal wall or a failure of mesenchymal migration are less convincing.

• **Fig. 84.12** Giant omphalocele with predominant liver component.

The factors influencing morbidity and survival in these two distinct conditions are very different. Omphalocele, with a stable incidence of about 2-2.5 per 10,000 live births, is associated with other structural or genetic defects in 50%-75% of affected infants.[15] These associated anomalies, which may involve the cardiovascular, gastrointestinal, genitourinary, or central nervous systems, account for most of the morbidity in these patients. Because the abdominal contents are protected throughout gestation, little morbidity accrues from injury to the intestinal tract. The discrepancy between the volume of eviscerated abdominal organs and the size of the abdominal cavity—the "loss of domain"—accounts for the other major source of morbidity in these patients. In a giant omphalocele (Fig. 84.12), eventual closure of the abdominal wall by any means may be challenging, leading to a variety of problems related to structural integrity of the torso, chronic ventral hernias, and posture and gait development. Additionally, infants with giant omphaloceles may have a high incidence of pulmonary hypoplasia, resulting in respiratory compromise and pulmonary hypertension.[4]

The syndromes most often associated with omphalocele include the VACTERL association, Beckwith-Wiedemann syndrome (macrosomia, macroglossia, visceromegaly, hemihypertrophy, hypoglycemia, renal pathology), EEC syndrome (ectodermal dysplasia, ectrodactyly, cleft palate), and OEIS complex (omphalocele, exstrophy, imperforate anus, spinal defects). An oft-reported association of omphalocele with cryptorchidism is unsubstantiated. Chromosomal abnormalities, including trisomies 13, 18, and 21, occur in 25%-50% of affected patients. The presence of a small sac, the absence of liver in the sac, and the presence of other malformations strongly predict an abnormal karyotype.[20,26]

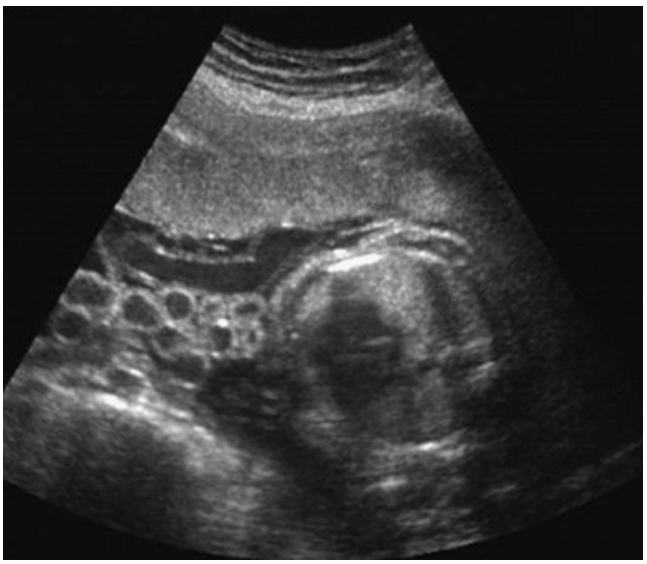
Gastroschisis, in contrast, is sporadic in the vast majority of cases. The incidence of gastroschisis is approximately 1.5 per 10,000 live births and increasing. Risk factors for gastroschisis include young maternal age, lower socioeconomic status, and exposure to external agents, such as vasoconstricting decongestants, nonsteroidal anti-inflammatory agents, cocaine, and possibly pesticides/herbicides.[29,106] The 5%-20% incidence of associated defects is lower than for omphalocele, and it represents mostly intestinal atresias directly associated with ischemic or mechanical injury to the eviscerated bowel during gestation. Abnormalities not directly related to the abdominal wall defect are uncommon.

Morbidity in infants with gastroschisis, as opposed to those with omphalocele, is almost entirely related to intestinal dysfunction caused by in utero injury to the eviscerated bowel. The spectrum of injury displayed by the eviscerated bowel in gastroschisis ranges from mild to catastrophic. Morphologically, the bowel appears edematous, matted, and foreshortened. Often, the mass appears to be contained within an inflammatory rind—the "peel" of gastroschisis (Fig. 84.13). Histologically, the intestine is characterized by villous atrophy and blunting, submucosal fibrosis, muscular hypertrophy and hyperplasia, and serosal inflammation.[52,99] The cause of injury is unclear, but it is probably related to a combination of two separate insults. Exposure to amniotic fluid appears to be a major contributing factor, as amniotic fluid exchange can prevent peel formation.[2] The second cause of injury may be the partial closure of the defect around the base of the eviscerated intestinal mass. This causes progressive constriction around the intestinal mesentery, resulting in the obstruction of luminal, lymphatic, and venous outflow. Intra-abdominal bowel distension is associated with increased postnatal complications, including delay to full feeds and increased duration of hospital stay in infants with prenatally diagnosed gastroschisis; however, this association seems to be limited to those with multiple loops of dilated intra-abdominal bowel.[42]

The functional consequences of these structural changes include impaired absorption, reduced brush border enzyme synthesis, and a prolonged motility disorder related to rigidity of the bowel wall and possible derangements in the production of enteric neurotransmitters such as nitric oxide.[5] These changes concur with the clinical observation that infants with a dense peel suffer prolonged gastrointestinal dysfunction that requires precise nutritional management. This nutritional failure and the complications arising from prolonged enteral and parenteral nutritional therapy constitute a significant proportion of the adverse clinical outcomes in these patients.



The prenatal diagnosis of abdominal wall defects by fetal ultrasonography is well established (Fig. 84.14). Any uncertainty in distinguishing omphalocele from gastroschisis may be eliminated by measuring amniotic fluid α-fetoprotein levels, which should be elevated in gastroschisis only. A prenatal diagnosis of omphalocele should prompt a thorough sonographic survey of the entire fetus to evaluate for associated anomalies. Chromosomal analysis may also be helpful in determining postnatal management and prognosis.

The obstetric decisions related to timing and route of delivery continue to engender considerable debate. In the case of omphalocele, if the membrane is intact, the pregnancy should be carried to term if possible, because early delivery has no theoretical benefit for the fetus. Cesarean delivery has historically been recommended to prevent rupture of the omphalocele membrane (Fig. 84.15), which would necessitate emergent surgical intervention without the benefit of preoperative evaluation and stabilization. Studies, however, have suggested that the route of delivery has no effect on morbidity or prognosis in abdominal wall defects in general.[3,40,87] Recommendations regarding the route of delivery for a fetus with a giant omphalocele or associated anomalies should be individualized.

Early delivery after lung maturation has been enthusiastically endorsed by some, but definitive evidence that this strategy confers any statistically verifiable benefit is lacking. A more selective approach in which early delivery

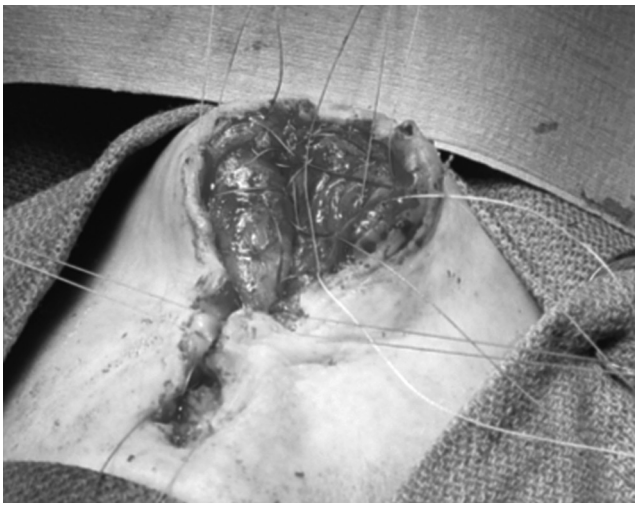
• **Fig. 84.15** Ruptured omphalocele.

is undertaken when sonographic surveillance suggests progressive bowel injury, as defined by bowel dilation and wall thickening, has yielded numerous conflicting reports.[41,64] Until the efficacy of selective early delivery for gastroschisis has been studied in a prospective, randomized fashion, support for this strategy will remain anecdotal.[31] Regardless of the timing of delivery, almost all infants with gastroschisis may be delivered vaginally without increased injury to the bowel.

The surgical goal of establishing complete fascial and skin closure without causing further injury to the underlying bowel is common to patients with both omphalocele and those with gastroschisis. The surgical strategies applied to these two conditions are, however, quite different. In patients with gastroschisis, urgent closure or coverage of the defect is of the highest priority to limit intestinal injury and reduce morbidity. The eviscerated intestine should be completely covered in the delivery room to prevent water and heat loss through evaporation, conduction, and convection. Temporary coverage can be provided by wrapping the torso with transparent plastic film or by placing the baby in a transparent surgical "bowel bag" and cinching the drawstring closed gently under the axillae. This arrangement effectively limits heat and water loss, and it allows the intestine to be visualized at all times so that inadvertent volvulus and ischemia can be detected and reversed. A lateral decubitus position is often better tolerated than supine. A gastric decompression tube is placed immediately to prevent intestinal dilation. Great care must be taken to keep the bowel directly above the belly and not draped to one side or the other while waiting for surgical repair. This keeps the vessels supplying the exposed bowel—the superior mesenteric artery and vein—from kinking and further compromising the bowel.

Many infants with gastroschisis are born prematurely, and aggressive respiratory care, including supplemental oxygen, endotracheal intubation, and intratracheal surfactant, may be necessary. Intravenous access is established for fluid resuscitation and administration of broad-spectrum



• **Fig. 84.16** Gastroschisis in silo bag for delayed primary closure of abdominal wall defects.

antibiotics. As soon as the baby is physiologically stable, surgical management is advisable. Unnecessary delay only compounds the problems of further bowel swelling and possible ischemia.

Gastroschisis can be managed by either primary or staged closure, depending on the size discrepancy and the infant's physiologic status. Although 60% to 70% of gastroschisis cases can be closed primarily, the decision to do so is individualized in each circumstance. As the intestine is returned to the abdominal cavity and the abdominal fascia approximated, increased abdominal pressure may prevent safe, complete closure. In infants with preexisting pulmonary compromise, the restriction of diaphragmatic excursion may decrease extrinsic compliance and cause ventilatory pressures to rise to unacceptable levels. Increased abdominal pressures may also impair mesenteric, hepatic, and renal perfusion. Trials of a "plastic closure" for gastroschisis have reported good success.[85] In this technique, the bowel is returned to the abdomen in the NICU, and the umbilicus is placed over the defect with a dressing. The defect closes on its own without the need for sutures. A number of these patients have a resulting umbilical hernia, most of which close spontaneously with time.

When respiratory problems or abdominal pressures prevent safe primary closure, placement of a temporary prosthetic "silo" allows for more gradual reduction of the eviscerated intestine into the abdominal cavity and delayed primary closure at a later time (Fig. 84.16). Previous retrospective studies had documented improved survival with primary closure, prompting an era marked by an aggressive approach to immediate closure. Appreciation of the fact that this survival advantage simply represented a selection bias, along with recognition of the deleterious effects of high

• **Fig. 84.17** Final reduction and closure of abdominal wall defect after silo reduction.

intra-abdominal pressures, has led to a more liberal use of temporary silo coverage. Current commercially available presized silos are now available that can be placed in the NICU, obviating the need for a trip to the operating room. Some have suggested that prolonged silo placement leads to increased wound infection rates and fascial dehiscence, but these are small retrospective studies.

When a silo has been constructed, the intestinal contents are squeezed back into the abdominal cavity in daily increments. Abdominal wall cellulitis related to the open wound and presence of the prosthetic material limits the use of a silo to a period of approximately 1 week. When reduction of the silo contents is complete, the patient is returned to the operating room for final closure (Fig. 84.17). Broad-spectrum antibiotics are given until the silo is removed. Placement of a silo does not preclude postoperative extubation, and spontaneous ventilation during staged closure is preferable to positive-pressure ventilation. Infants should be maintained on a ventilator to allow for neuromuscular paralysis in only the most severe cases of abdominovisceral disproportion requiring aggressive closure. When postoperative mechanical ventilation is required, increased levels of positive end-expiratory pressure may be necessary to maintain functional residual capacity and optimize compliance.

During staged closure, parenteral nutrition is administered through a peripherally inserted central venous catheter, or one placed at the time of silo placement. Complete bowel rest and gastric decompression are maintained during reduction of the silo. After abdominal wall closure, whether primary or delayed, enteral feedings should be initiated only after clinical resolution of the ileus is apparent—cessation of bilious gastric aspirates, presence of bowel sounds, and passage of meconium. Advancement of enteral feedings should be conservative, as infants with gastroschisis, especially those with a dense peel requiring silo closure, are extremely sensitive to changes in nutritional substrate load. Delayed enteral feedings and prolonged parenteral infusions are a principal source of morbidity in this group. Development of cholestatic jaundice is common, and hepatic dysfunction and fibrosis may occur in a small number of refractory patients. Early administration of partial enteral mini-feedings, meticulous avoidance of infection, and reduction of copper and manganese have all been advocated to reduce the incidence of cholestatic liver disease.[61]

The coexistence of intestinal atresias with gastroschisis deserves special mention. Intestinal atresias occur in 5%-25% of patients with gastroschisis, and they are one of several independent variables that have a negative impact on prognosis in gastroschisis. In a patient who fails to exhibit intestinal patency within 1 month of abdominal wall closure, a water-soluble lower gastrointestinal contrast study should be obtained to exclude the presence of an unrecognized atresia. Introduction of exclusive human milk feedings after gastric repair has been shown to decrease the time to achieve full enteral feeds and time to discharge.[48]

The mortality of infants with complex gastroschisis (gastroschisis with atresia, necrosis, perforation, or volvulus) present in 17% of cases with gastroschisis was more than double that of simple gastroschisis. Significantly different outcome was found for the following parameters: Infants with complex gastroschisis are started on enteral feedings later, and they take longer to full enteral feedings with a subsequent longer duration of parenteral nutrition. Their risk of sepsis, short bowel syndrome, and necrotizing enterocolitis is higher. They stay longer in hospital and are more likely to be sent home with enteral tube feedings and parenteral nutrition.[6]

The surgical options for abdominal wall closure for omphalocele are similar to those for gastroschisis. The main difference relates to the preoperative management of these patients. A careful assessment of physiologic status and a thorough search for syndromic and chromosomal anomalies are imperative to guide anesthetic management and to identify prognostic factors. The presence of a protective membrane allows a careful and unhurried preoperative evaluation.

As defined previously, the factors affecting prognosis for gastroschisis and omphalocele are quite distinct. Prematurity, degree of peel formation, and associated atresias account for most of the morbidity in gastroschisis, which has an overall survival rate of 90%-95%.[34,69] Most of the deaths attributed to gastroschisis are related to perioperative complications, such as sepsis, necrotizing enterocolitis, and abdominal visceral ischemia, or to late hepatic failure caused by parenteral nutrition-related cholestatic disease. Surprisingly, midgut volvulus related to obligatory intestinal malrotation in these patients is virtually nonexistent, possibly because of the development of peritoneal adhesions that limit mobility of the intestine. The reported survival rate for infants with omphalocele ranges from 30%-80%.[68,116] When mortality caused by associated malformations is excluded, the survival rates approach those for gastroschisis. Long-term tolerance of enteral feedings, as well as physical

growth and development, are usually normal after 1 or 2 years, even in severe cases. With thoughtful management and attention to the prevention of parenteral nutrition–related hepatic complications, most infants born with abdominal wall defects should survive with an acceptable quality of life.

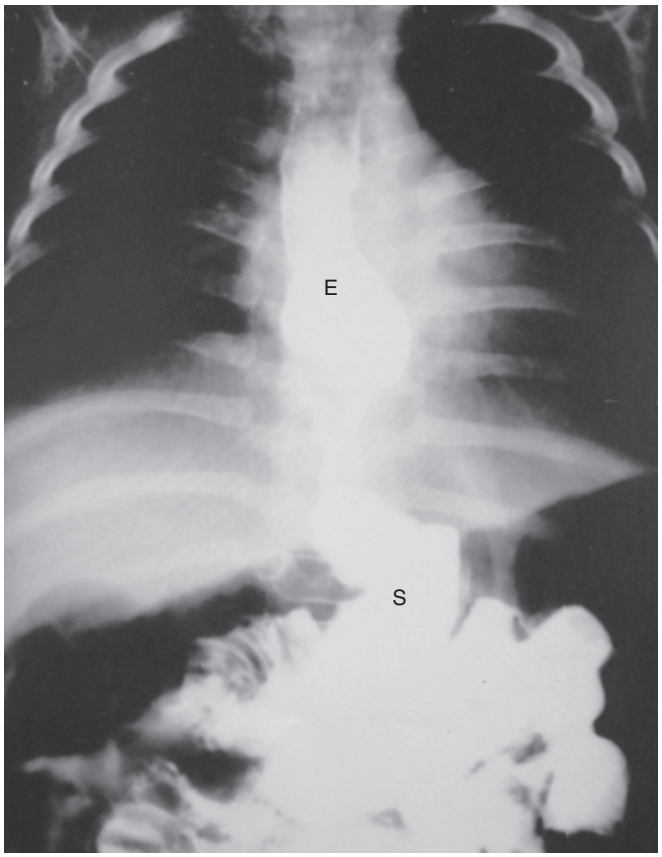
Gastric Volvulus

Congenital deficiencies of mesenteric fixation of the stomach to the surrounding structures predispose to gastric volvulus and can take two distinct forms. Absence or laxity of the gastrohepatic and gastrosplenic ligaments allows the stomach to rotate around its longitudinal axis, producing an organoaxial volvulus. Similar abnormalities of the gastrophrenic ligament and duodenal attachments allow rotation around the stomach's transverse axis, referred to as a *mesentericoaxial volvulus*. Organoaxial volvulus is the more common of the two types in infants and children. A strong association has been found between gastric volvulus and malrotation, asplenia, and congenital abnormalities of the diaphragm.[60] Gastric volvulus may also be associated with conditions that result in gastric distention, such as aerophagia and hypertrophic pyloric stenosis. Because these entities all result in absence or stretching of stabilizing attachments, a causative role is assumed.

Although gastric volvulus can occur as either an acute or a chronic problem, the acute form is more common in children. The classic presentation of sudden epigastric pain, retching without emesis, and inability to advance a nasogastric tube into the stomach is rarely encountered in the actual clinical setting. Children may experience emesis, which can be bilious or nonbilious, and may not have abdominal distention. Intermittent gastric volvulus may be considered in the workup of infants presenting with apparent life-threatening events.[72] Any combination of symptoms suggesting a partial or complete proximal mechanical obstruction may be present. Profound physiologic decompensation, hemodynamic instability, or unrelenting metabolic acidosis suggests strangulation, ischemic necrosis, and possibly perforation.

Radiologic assessment can reveal several characteristic findings. On plain abdominal radiographs, massive gastric dilation can usually be seen, often with a distinct incisura pointing toward the right upper quadrant. The spleen and small intestine may be displaced inferiorly. If a contrast study has been attempted, the contrast column may be confined to the esophagus, with a long, gradual tapering at the bottom. Occasionally, a paraesophageal hiatal hernia is detected. Classic findings on barium upper gastrointestinal study include transverse lie of the stomach and inversion of the greater curvature and pylorus (Fig. 84.18). Operative treatment of acute gastric volvulus includes gastric decompression by nasogastric suction or needle aspiration and reduction of the volvulus. Coexisting anomalies, such as malrotation and diaphragmatic defects, should be corrected, and recurrence is rare.

• **Fig. 84.18** Upper gastrointestinal contrast study demonstrating gastric volvulus with rotation of the greater curve and antrum of the stomach above the duodenal bulb.



Microgastria

Congenital microgastria is a rare anomaly (only 43 cases have been reported) in which the stomach is characterized by very small volume, a tubular shape, and abnormal fixation. Gastric volume does not undergo complete compensatory growth and remains relatively small as the child ages.[8] Associated abnormalities include megaesophagus, GER, intrinsic duodenal obstruction, malrotation, biliary anomalies, situs inversus, asplenia, and skeletal defects.[86]

Microgastria presents with vomiting and failure to thrive in the infant, often associated with persistent diarrhea. Vomiting may be caused by gastric insufficiency, GER, or duodenal obstruction. Diarrhea is presumed to be due to rapid gastric transit and dumping. The diagnosis is established by contrast upper gastrointestinal tract study, which reveals a small stomach with a transverse lie and frequently a large, patulous esophagus (Fig. 84.19). Particular attention should be given to the anatomy of the duodenum and the ligament of Treitz.

The initial management of microgastria includes continuous drip enteral feeding and supplemental parenteral nutrition. When continuous feedings can be maintained for several weeks, the stomach may undergo some enlargement, allowing for a gradual transition to bolus and ad libitum feedings. Antireflux precautions, including small, frequent meals, may be required indefinitely. Although case reports of successful management by gastrojejunostomy exist, the favored surgical approach involves gastric augmentation with a Roux-en-Y jejunal reservoir.[110]

• **Fig. 84.19** Upper gastrointestinal contrast study of patient with microgastria (*S*) and megaesophagus (*E*).

Gastric Perforation

The causes of gastric perforation in neonates can be categorized as traumatic, ischemic, or spontaneous. In addition, the use of postnatal steroids for bronchopulmonary dysplasia (possibly in combination with cyclooxygenase inhibitors for ductal closure) has been implicated. Traumatic perforations are generally caused by puncture of the stomach during placement of a gastric tube, or by gastric distention from bag-mask ventilation or positive-pressure ventilation in an infant with a tracheoesophageal fistula. Usually these appear as short lacerations or discrete puncture wounds. Ischemic perforations occur in the setting of severe physiologic stress, such as extreme prematurity, perinatal asphyxia, or necrotizing enterocolitis. The pathophysiology of these lesions is presumed to be associated with a reduction in submucosal blood flow resulting in impaired mucosal defense and/or focal infarction of the gastric wall. It is possible that some of these lesions represent perforated stress ulcers. Rarely, a healthy neonate presents with a spontaneous gastric perforation of unknown cause. The most common location is high on the greater curvature near the gastroesophageal junction.

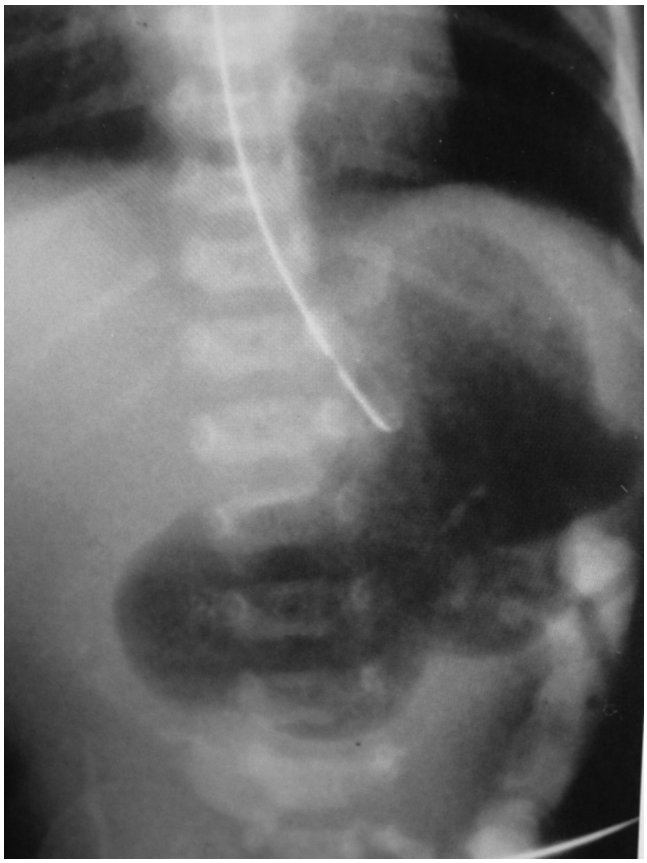
The most constant diagnostic feature of gastric perforation in the neonate is massive pneumoperitoneum, unless the perforation is posterior and contained within the lesser sac. Surgical management is individualized to either simple debridement and closure or closure around a temporary gastrostomy tube. Extensive gastric resections have not been necessary. Outcomes depend on the cause of the perforation and any associated disease, such as respiratory failure and complex congenital malformations.

Lactobezoars

Lactobezoars are compact aggregations of undigested milk constituents that develop within the gastric lumen in infants. Little is known about their underlying cause, although a single etiology is unlikely. Historically, they were believed to result from commercial formulas of high caloric density, particularly those rich in casein protein, which precipitated in the stomachs of premature neonates. Lactobezoars, however, have been reported in term neonates and older infants on diets of human milk and homogenized cow milk.[89,108]

The majority of infants with lactobezoars present with abdominal distention, nonbilious emesis, and diarrhea. A palpable mass may be detectable on physical examination. Plain radiographs often display a frothy appearance in the gastric lumen. An upper gastrointestinal tract contrast series is diagnostic. Ultrasonography, which can detect a hyperechoic intraluminal gastric mass, may also be used to establish the diagnosis.[65] Treatment is nonsurgical in the great majority of patients who do not present with perforation. Simple withholding of enteral feedings and administration of parenteral nutrition usually results in spontaneous resolution of the bezoar; gastric lavage may hasten this process.[21] After follow-up imaging studies document resolution, enteral feedings can be reinstituted using the same formula. Recurrence has not been reported.

Pyloric Atresia



Congenital partial or complete gastric outlet obstructions are rare causes of feeding intolerance in infants. The obstruction may involve either the antrum or the pylorus and may take the form of a segmental defect (gap), which is sometimes bridged by a fibrous cord, or a membrane (web), which can have one or more apertures through which gastric contents pass. Histologically, such membranes consist of mucosa and submucosa without a muscularis. Prepyloric membranes become redundant after exposure to antegrade propulsive pressures, creating a "windsock" web that can prolapse through the pyloric channel. Pyloric webs account for two-thirds of these obstructions, pyloric atresia accounts for about a quarter, and most of the remainder are antral webs and atresias. Another rare cause for the obstruction is the presence of ectopic pancreatic tissue within the submucosa of the pyloric channel that bulges into the lumen and causes a partial obstruction.

The etiology of antral and pyloric atresia is not understood. An in utero vascular accident, such as results in jejunoileal atresias, is unlikely because of the stomach's redundant blood supply. As the stomach (unlike the duodenum) does

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

not undergo a solid embryonic phase, failure of recanalization cannot account for these anomalies. Instead, some form of foregut segmentation mechanism is proposed but unproved. A genetic cause has been identified for some cases of pyloric atresia that occur in association with epidermolysis bullosa lethalis (Herlitz and Carmi syndromes), which is inherited in an autosomal recessive manner. A hemidesmosome defect has been identified in the gastric mucosal epithelium in this syndrome, and genetic studies have documented a variety of mutations in the genes coding for cell-surface beta 4 integrins.[66] This condition is marked by extreme mucocutaneous fragility and is usually lethal in the first year of life.

Complete membranes or atresias appear in the first few days of life as acute gastric outlet obstruction with nonbilious vomiting. There is often a history of maternal polyhydramnios. Gastric distention leading to respiratory compromise can occur, and frank gastric perforation has been reported as early as 12 hours of life. Incomplete gastric outlet obstruction caused by perforated membranes or heterotopic pancreatic tissue can present early in the neonatal period or later in childhood. Radiologic evaluation reveals a large gastric air bubble, with little or no gas in the distal intestine (Fig. 84.20). Because neonatal gastric hypotonia can reproduce these radiographic findings, upper gastrointestinal tract contrast studies are mandatory. These studies either show nonfilling of the duodenum or delineate the membrane when viewed laterally. Ectopic pancreatic tissue can cause an eccentric protrusion into the pyloric channel.

• **Fig. 84.20** Plain radiograph of gastric bubble in patient with pyloric atresia.

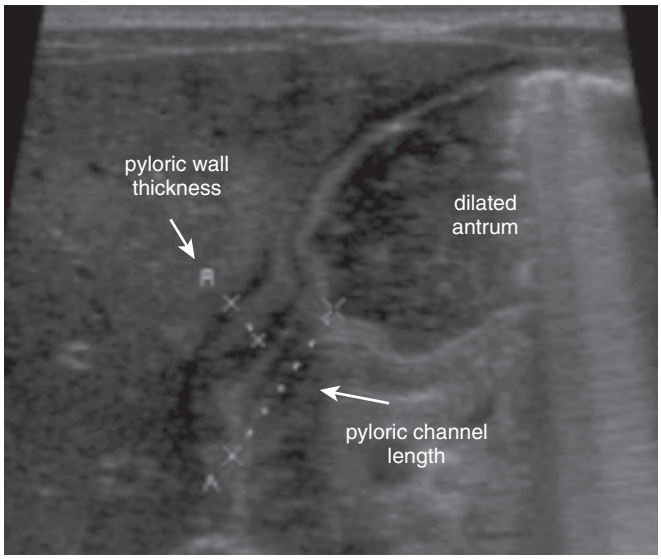
Preoperative resuscitation and gastric decompression are necessary in infants with complete gastric outlet obstruction. A chloride-responsive contraction alkalosis is often seen and requires specific measures to restore fluid volume and correct chloride and potassium deficits. Prolonged vomiting in the neonate can also lead to profound hypoglycemia, which must be anticipated and corrected. In general, webs can be excised and closed transversely to avoid stenosis. Complete atresias with anatomic disconnection can usually be corrected by primary anastomosis, such as gastroduodenostomy. Gastrojejunostomy is poorly tolerated in the neonate and should be avoided whenever possible. Recognition of windsock deformities and distal atresias by passage of a balloon catheter proximally and distally can be helpful in defining the exact anatomy and in detecting additional distal obstructions. Ectopic pancreatic tissue in the pylorus requires excision of the mass and reconstruction of the pylorus.

Hypertrophic Pyloric Stenosis

Hypertrophic pyloric stenosis (HPS) is an acquired condition in which the circumferential muscle layer of the pyloric sphincter becomes thickened, resulting in narrowing and elongation of the pyloric channel. This produces a high-grade gastric outlet obstruction with compensatory dilation, hypertrophy, and hyperperistalsis of the stomach. The incidence of HPS ranges between 0.1% and 1% in the general population and appears to be rising. A longitudinal study using ultrasound in 1400 randomly selected term neonates documented that all nine infants (0.65%) in whom HPS later developed had normal pyloric dimensions at birth.[84] There is a significant male predominance of about 4:1, although the long-held belief that HPS primarily afflicts first-born males is unproven. The incidence in whites exceeds that in blacks by several-fold; the incidence in Asian infants is low. The transmission of HPS appears to involve multifactorial threshold inheritance or the effects of multiple interacting loci. Transmission from mothers is more common than from fathers: HPS develops in 19% of boys and 7% of girls whose mothers had HPS as infants, and in 5% of boys and 2.5% of girls whose fathers were previously affected.[63]

The pathophysiology underlying pyloric dysfunction in HPS is undetermined. Observations of decreased ganglion cell density and elevated levels of prostaglandins E_2 and F_2 have not been causally linked to the development of HPS. Gastric outlet obstruction owing to pylorospasm has been reported in neonates receiving prostaglandin infusions, but pyloric dysfunction in these infants does not lead to muscular hypertrophy.[62]

Perhaps a more promising hypothesis for the pathophysiology of HPS is a primary abnormality of the enteric nervous system (ENS). Axonal degeneration in both the myenteric plexus and the intramuscular nerves has been



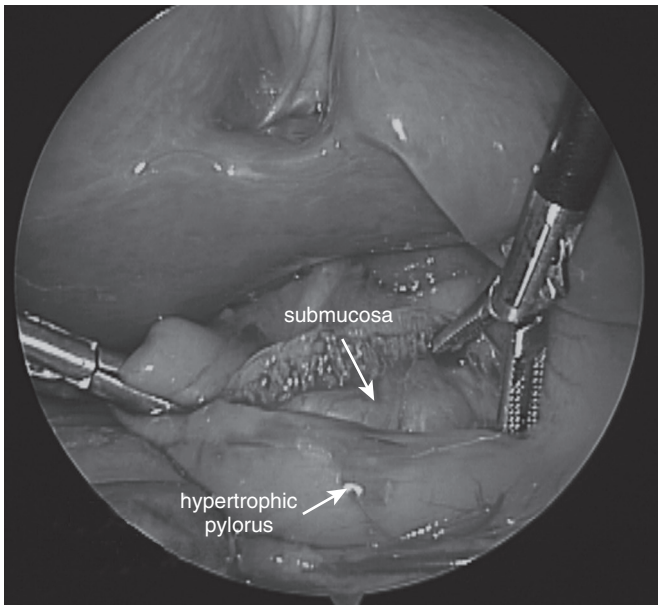
Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

observed in patients with HPS. Studies have documented decreased and disordered innervation of the circumferential muscle layer in specimens of pyloric muscle taken at the time of pyloromyotomy.[47,53] Furthermore, the muscle layer in HPS appears to be nearly devoid of neurotrophins—peptides that govern differentiation and survival of ENS neurons.[33] Circumstantial evidence exists to suggest that such neural immaturity is transient, consistent with the observation that HPS does not recur after reconstitution of the pyloric sphincter after pyloromyotomy.[46] Immunohistochemical staining for neuropeptides has revealed a marked reduction in a variety of neuropeptides, such as gastrin-releasing peptide, vasoactive intestinal peptide, somatostatin, and substance P, in patients with HPS.[1] Nitric oxide synthase, which can be identified in significant concentrations in the circular and longitudinal pyloric muscle layers and the myenteric plexus in normal controls, has been shown to be selectively absent in the circular muscle layer in patients with HPS.[109] This has also been documented for nitric oxide synthase mRNA.[49] A deficiency of nitric oxide, a ubiquitous paracrine and neurocrine mediator of smooth muscle relaxation, might be a final common pathway in the dysregulation of pyloric function in HPS.

The typical patient is a term male infant between 3 and 6 weeks of age who has progressive, nonbilious, projectile vomiting. Many infants with HPS are significantly dehydrated at the time of presentation, and chemistry analyses may reflect a hypochloremic, hypokalemic, contraction metabolic alkalosis with paradoxical aciduria. Significant hypoglycemia can also be present and may precipitate seizures. Unconjugated hyperbilirubinemia is common and correlates with a decrease in hepatic glucuronyl transferase activity. This jaundice is transient and resolves as soon as the gastric outlet obstruction is corrected, making it attractive to speculate that the hepatic defect is secondary to abnormal enteroendocrine feedback between the stomach and the hepatocyte.

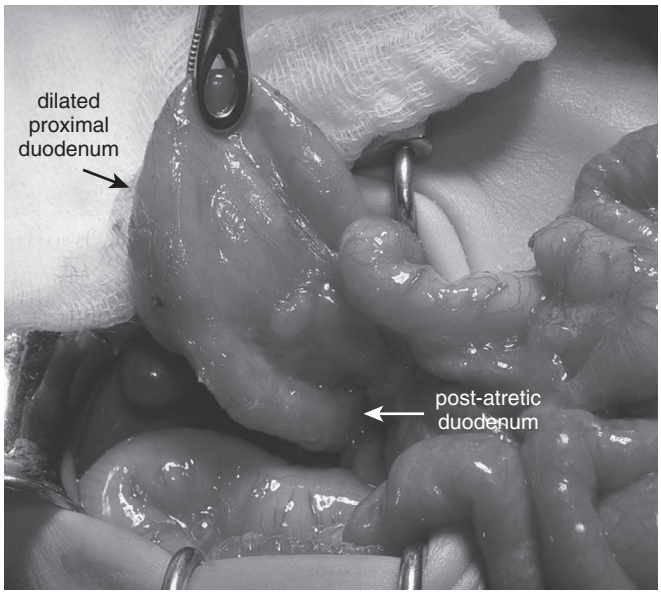
The hallmark of the diagnosis is the finding of a small, mobile, ovoid mass in the epigastrium. The process of detecting this mass, the "olive," on examination may be quite difficult. A positive examination is very accurate, with a selectivity value of more than 97%.[28] If the pylorus is unequivocally felt, the diagnosis is established, and no further diagnostic maneuvers are necessary.

If the pylorus is not detected and the clinical presentation is sufficiently suggestive to warrant further evaluation, radiologic evaluation can be definitive. Real-time ultrasonography has supplanted barium upper gastrointestinal tract study as the procedure of choice. The hypertrophied pylorus appears to have a characteristic appearance on B-mode ultrasound, and measurement of pyloric dimensions accurately establishes the diagnosis of HPS. Parameters measured include overall diameter, single wall thickness, and pyloric channel length, with the latter two being the most commonly used (Fig. 84.21). Measurements found to have greater than 90% positive predictive value include overall diameter of 17 mm or more, muscular wall thickness of 4 mm or greater, and



• **Fig. 84.21** Abdominal ultrasound of patient with hypertrophic pyloric stenosis.

channel length of 17 mm or greater. In infants 30 days of age or younger, it has been suggested that diagnostic criteria for wall thickness be reduced to 3 mm. Real-time lack of movement of gastric contents across the pylorus is also an important observation when assessing for hypertrophic pyloric stenosis. When parameters are equivocal, an upper gastrointestinal tract study can be diagnostic by demonstrating an elongated and narrowed pyloric channel, with the characteristic shoulders of the hypertrophied pylorus bulging into the gastric lumen. Although an accurate diagnosis based on physical examination should be possible in most cases, and should be attempted in all, it is evident that an increasing reliance on ultrasonography will continue to erode the skills of examiners. A review comparing diagnostic accuracy between two eras in a single pediatric institution found that the sensitivity of physical examination declined by half during a period of increasing reliance on ultrasound.[57]



Preoperative preparation is critical once the diagnosis is made. Hypertrophic pyloric stenosis is not a surgical emergency, so careful correction of fluid and electrolyte losses should be accomplished before operative intervention. The infant who presents early in the course of the disease with no clinical dehydration, normal serum electrolytes and glucose, and a normal urine output can be operated on at the earliest convenience. Many patients, however, present with dehydration, hypoglycemia, or a contraction alkalosis of sufficient severity to require preoperative resuscitation for 24-48 hours. Once volume status and urine output have improved, serum chloride, potassium, and bicarbonate have normalized, and paradoxical aciduria has resolved, surgery can be conducted safely.

The treatment of HPS is pyloromyotomy, which is never emergent. Historically, the operation is performed through a transverse right upper quadrant incision. Laparoscopic repair has become common and is standard at most US

• **Fig. 84.22** Laparoscopic pyloromyotomy.

• **Fig. 84.23** Type I duodenal atresia with continuity of muscular wall.

medical centers (Fig. 84.22).[25] It is common for occasional emesis to occur after pyloromyotomy; this should not delay the progression of the feeding schedule in most cases. In general, most infants so managed can be discharged within 24-48 hours of surgery. Persistent postoperative vomiting beyond 48 hours is uncommon. In this circumstance, the possibilities of an incomplete myotomy or unrecognized perforation should be considered.

Most children treated for HPS can expect excellent short- and long-term outcomes. With appropriate resuscitation, expert anesthesia, and a standard surgical approach, mortality has been virtually eliminated. Wound infection and dehiscence, which were significant problems in previous eras, are relatively uncommon today. Postoperative ultrasound studies have documented a return to normal muscle thickness within 4 weeks, associated with healing of the pyloric muscle and return of function. A study addressing gastric emptying and abdominal symptoms after pyloromyotomy found no differences between treatment and control groups several decades after surgery.[56]

Duodenal Atresia and Stenosis

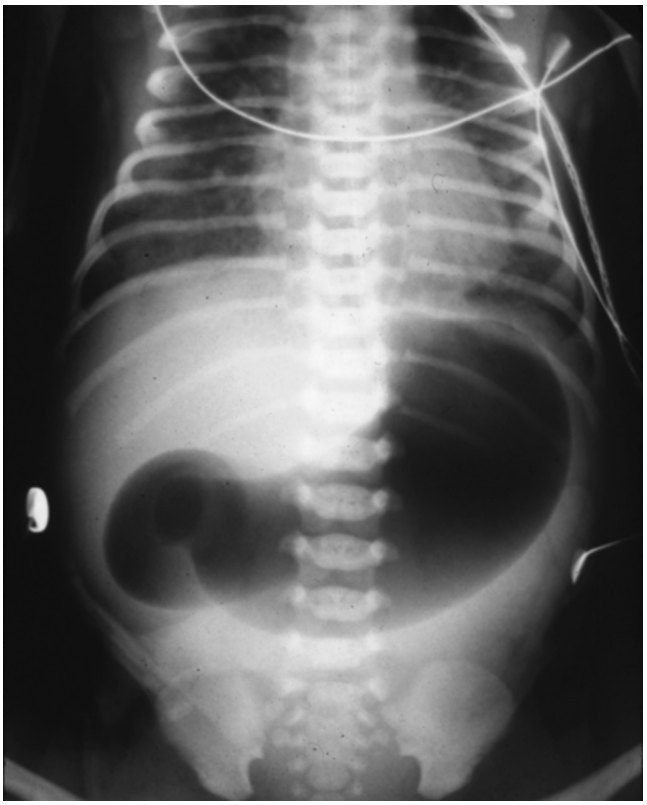
Congenital duodenal obstruction may be complete or partial, intrinsic or extrinsic. Intrinsic atresias or stenoses have an incidence of about 1 in 7000 live births and account for about half of all small intestinal atresias. Extrinsic obstruction has many causes, including malrotation with Ladd bands, preduodenal portal vein, gastroduodenal duplications, cysts or pseudocysts of the pancreas and biliary tree, and annular pancreas. Annular pancreas is commonly associated with an intrinsic cause of duodenal obstruction.

Intrinsic duodenal obstructions and annular pancreas result from events that occur during early development of the foregut. Duodenal atresia and stenosis are believed to result from a failure of recanalization of the embryonic duodenum, which becomes solid as a result of early epithelial proliferation. Annular pancreas occurs when the ventral pancreatic bud fails to rotate behind the duodenum, leaving a nondistensible ring of pancreatic tissue fully encircling the second portion of the duodenum.[102] Annular pancreas frequently coexists with intrinsic duodenal anomalies and anomalies of the pancreaticobiliary ductal system, suggesting closely linked mechanisms of pancreatic, duodenal, and biliary development during this stage.

Atresias of the duodenum have several basic morphologies. Type I atresias constitute luminal webs or membranes, some of which contain a central defect or fenestration of variable size and result in a marked size discrepancy with mural continuity (Fig. 84.23). Type II atresias have dilated proximal and diminutive distal segments connected by a fibrous cord. Type III atresias are characterized by a complete discontinuity between the segments. The relationship between the point of obstruction and the ampulla of Vater is important. Most series document a predominance of postampullary obstructions, although some have described a preampullary predominance. Obstructions caused by type I membranes are frequently associated with anomalies of the common bile duct in which the common bile duct may terminate within the membrane itself.

Congenital duodenal obstructions are often associated with other congenital anomalies, which account for most of the morbidity and mortality in these patients. Various reports put the incidence of associated conditions between 50% and 80%. Congenital heart disease and trisomy 21 are the most common associated conditions, each occurring in about 30% of cases.[32] Not infrequently, all three conditions coexist in the same patient.[23] Among patients with trisomy 21 who underwent prenatal ultrasonography, about 4% were found to have prenatal evidence of duodenal atresia.[71]

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.



Other associated anomalies include intestinal malrotation (20%), esophageal atresia, imperforate anus (10%-20%), thoracoabdominal heterotaxia, and gallbladder agenesis. The outcome for patients with duodenal atresia depends more on the severity of these associated anomalies and the ease with which they can be corrected than on the surgical management of the obstruction itself.

Many patients with duodenal atresia have the diagnosis suggested by prenatal ultrasonography. A maternal history of polyhydramnios is common in congenital duodenal obstruction, approaching 75% in one series.[93] Prenatal sonographic evaluation of the fetus at 22-23 weeks of gestation can reliably detect two dilated, fluid-filled structures consistent with a double bubble. The unavailability of a sonographic diagnosis until relatively late in gestation frequently results in an ethical dilemma for prospective parents, who may consider elective termination based on the association of duodenal atresia with trisomy 21.

The clinical presentation of the infant with congenital duodenal obstruction depends on the presence or absence of a membranous aperture, its size, and the location of the obstruction relative to the ampulla. The classic presentation of a complete postampullary obstruction includes bilious vomiting within 24 hours of birth in an otherwise stable infant with a nondistended abdomen. Plain radiographs of the abdomen typically show the classic double-bubble sign—two distinct gas collections or air-fluid levels in the upper abdomen resulting from the markedly dilated stomach and proximal duodenal bulb (Fig. 84.24). Air makes an excellent contrast agent and may obviate a barium or water-soluble contrast study in routine cases. The distal intestinal tract may be gasless or may contain a small amount of intraluminal air owing to a membranous aperture or perforation or an anomalous bile duct with openings on both sides of the obstructing diaphragm.[75]

The importance of differentiating intrinsic duodenal obstruction from intestinal malrotation with a midgut volvulus in the infant who presents with bilious vomiting cannot be overstated. A clue may be derived from the appearance of the duodenum on the plain radiograph. In the classic double-bubble sign, the duodenum appears distended and round because of chronic intrauterine obstruction. When a distended stomach is associated with a normal-caliber duodenum, the diagnosis of malrotation with duodenal obstruction secondary to Ladd bands or volvulus must be entertained. In an unstable patient, echocardiography and contrast studies may be required to distinguish hemodynamic compromise caused by volvulus from that caused by cardiac disease. Even when the diagnosis of duodenal atresia is established in the stable patient, cardiac anatomy and function should be evaluated before surgical correction.

Preoperative preparation includes nasogastric decompression, fluid and electrolyte replacement, and a thorough evaluation for associated anomalies. If malrotation is ruled out, surgical correction of duodenal atresia can be temporarily postponed and more urgent conditions evaluated and treated. Prophylactic perioperative antibiotics are begun preoperatively.

• **Fig. 84.24** Plain abdominal radiograph in patient with duodenal atresia.

The surgical management of an intrinsic duodenal web is usually limited to excision of a portion of the web and an enteroplasty to widen the duodenal lumen at that point. *As the membrane occasionally contains the terminal common bile duct, great caution must be taken in excising or incising the membrane to avoid biliary injury and stricture formation.* The most widely accepted surgical management of both true atresia and annular pancreas involves constructing an anastomosis between the dilated proximal duodenum and the diminutive distal duodenum. Open and laparoscopic repair are acceptable. Laparoscopic repair can be technically challenging because of the high rate of other congenital anomalies seen in duodenal atresia patients.

A feeding gastrostomy should not be necessary for postoperative management of an uncomplicated duodenal repair. Gastroduodenal function usually returns within 5-7 days, at which time enteral feeding can be initiated with small boluses and the volume progressively advanced as tolerated. One of the most problematic issues following repair of duodenal atresia is delayed transit, usually associated with a persistently dilated and dyskinetic proximal duodenum. A significant number of infants with corrected duodenal atresia also experience GER, which may be exacerbated by an impairment in gastric emptying. Survival rates of 95% are reported in those who are deemed satisfactory surgical candidates. As mentioned earlier, morbidity and mortality are usually related to associated anomalies.

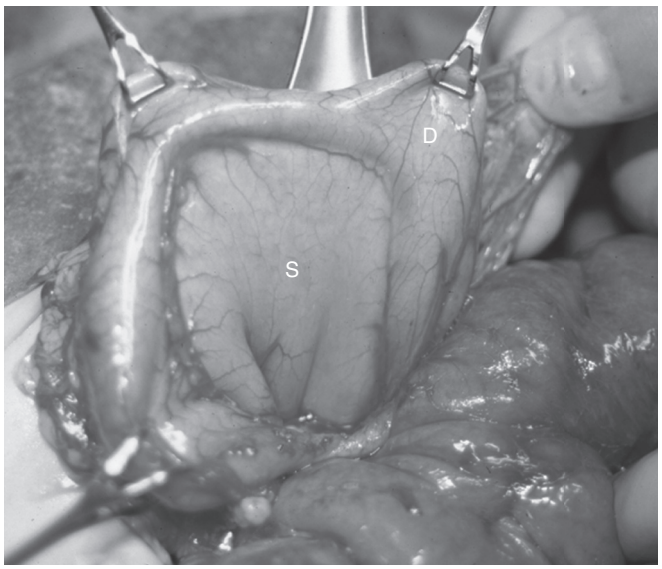
Gastrointestinal Duplications

The stomach and duodenum are the least common regions of the gastrointestinal tract in which duplications occur. For most congenital lesions of the stomach and duodenum included in this category, the term *duplication* may be a misnomer. The actual embryologic cause of these lesions is unknown, but the designation of *enterogenous cyst* or *congenital diverticulum* may be more accurate. Nevertheless, it is important to recognize that gastric and duodenal duplications are occasionally associated with other gastrointestinal duplications or with vertebral anomalies. Communications with or attachments to an abnormal vertebral column suggest they may be caused by aberrant splitting of the primitive notochord during early embryonic development.



Classically, four pathologic criteria are considered necessary to establish the diagnosis of gastric duplication: (1) contiguity with the stomach, (2) an outer smooth muscle layer, (3) a shared blood supply with the stomach, and (4) a gastric epithelial lining (which may also contain pancreatic tissue). Most gastric duplications are cystic, do not communicate with the gastric lumen, and are located along the greater curvature of the stomach. When a luminal communication is present, it may result from peptic ulceration of the common wall between the two structures. Tubular duplications are less common, frequently communicate with the gastric lumen, and are also most commonly found on the greater curvature (Fig. 84.25). Extragastric cystic structures lined by gastric epithelium and exhibiting a muscular wall, however, are usually referred to as gastric duplications regardless of their proximity to the stomach.

In the neonatal period, duplications often present with symptoms and signs of proximal gastrointestinal obstruction. Vomiting is common and can be bilious or nonbilious, depending on the location of the extrinsic compression relative to the ampulla of Vater. Case reports of gastric duplications, both adjacent to the stomach and in the retroperitoneum, have described connections to the pancreatic ductal system and have resulted in chronic pancreatitis and pseudocyst formation. Connections to the biliary system and to extrapulmonary sequestrations have also been reported. Duodenal duplications most commonly occur in the first or second portion, usually on the posterior surface, and may be lined with gastric mucosa. These may also cause pancreatitis by compression of the pancreatic duct within the duodenal wall. Gastroduodenal hemorrhage or perforation secondary to peptic ulceration is the usual emergency indication for surgery. Gastrointestinal hemorrhage secondary to ulcer penetration from a noncommunicating duplication cyst into an adherent loop of intestine or colon has been reported.

Gastroduodenal duplications are being detected by antenatal ultrasound with increasing frequency and should be considered along with choledochal cysts and omental cysts in the differential diagnosis of a fetal right upper quadrant cystic mass. Postnatally, an upper gastrointestinal tract contrast study may demonstrate an extrinsic compression of the stomach or duodenum, but ultrasound and computed tomography can definitively reveal the mass itself. Technetium-99m scans may identify duplications distant from the stomach if they contain ectopic gastric mucosa but are not specific for duplications per se.

Resection of the entire duplication, either by enucleation or by limited gastric resection, is the treatment of choice. Successful laparoscopic resection has been reported and may be advisable for smaller, uncomplicated lesions. Extensive duplications, however, require removal of the entire mucosal cyst lining to avoid potential malignant degeneration.

Duplications of the small or large intestine are more common than those of the stomach and duodenum. They are usually cystic but may be tubular and extend for a variable distance (Fig. 84.26). Cystic duplications may cause obstruction or volvulus, and they may present with a palpable mass. Either type may present with hemorrhage. Simple cystic duplications of the small or large intestine are most easily managed by resection and primary anastomosis.

• **Fig. 84.25** Gastric duplication of greater curvature. D, Duplication; S, stomach.

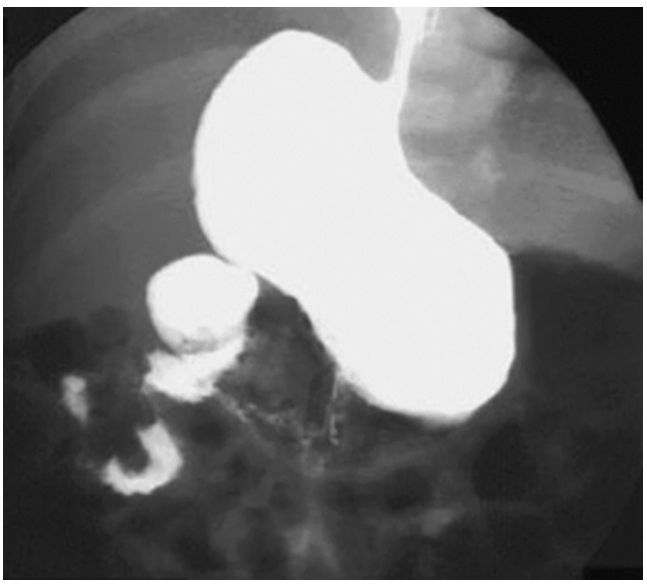
Long tubular duplications may be managed by mucosal stripping to prevent future peptic complications and remove potentially dysplastic epithelium. Long colonic duplications may result in anal duplication. If the second anus is within the muscular sphincter, division of the septum to establish a common lumen may be sufficient. Cystic rectal duplications must be distinguished from sacrococcygeal teratomas and meningoceles before trans-sacral or posterior sagittal resection is undertaken.

Malrotation and Midgut Volvulus

Malrotation of the intestine is a widely varied group of anomalies. As described in the development chapter, the bowel undergoes two independent 270-degree counterclockwise rotations during the 6th-12th weeks of gestation. One involves the duodenojejunal junction around the axis of the superior mesenteric artery, and the other involves the ileocolic junction around the same axis. Although this is difficult to grasp spatially, the concept is simple. When the bowel rotates appropriately during development, it fixes itself in the abdomen in such a way that it absolutely cannot twist and obstruct itself or, as occurs in volvulus, compromise its own blood supply (Fig. 84.27). This is remarkable, considering the length of bowel involved. However, if the bowel does not rotate and fix itself in the abdomen properly, the stage is set for later obstruction or volvulus. Yet malrotation, more comprehensively described as an anomaly of intestinal fixation and rotation, is not a problem in itself. It is estimated that nearly 1 in 100 people have some form of improper rotation or fixation, yet 1% of the population do not have the related clinical symptoms. Rather, 1 in 6000 live births leads to a clinical discovery.[14,112]

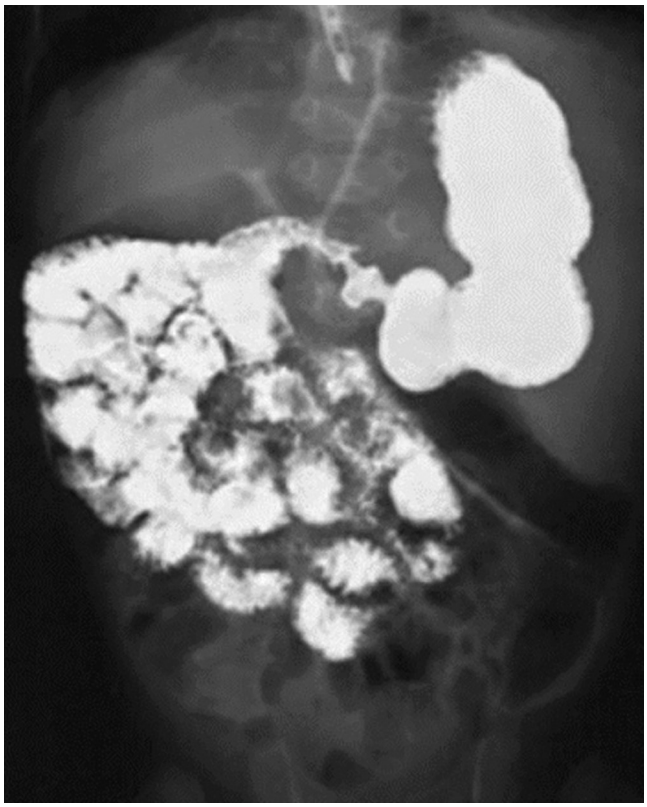
Because so many variations of malrotation can exist, there are many possible clinical presentations. Any case of unexplained abdominal pain or emesis should have malrotation somewhere in the differential diagnosis. However, the main symptom complexes can be grouped together as those related to acute volvulus, to duodenal obstruction, to evidence of intermittent or chronic abdominal pain, or as an incidental finding in an otherwise asymptomatic patient. More than half of patients present in the first month of life, with half of the rest in the first year. However, 25% can still present at any other time in life.[101] Bilious emesis in any child younger than 1 year of age should be assumed to be caused by malrotation until proved otherwise.



The preoperative evaluation of the malrotation or midgut volvulus is the radiologic determination of the position of the ligament of Treitz, and secondarily, its distance and relation to the ileocecal junction.[111] The initial film is typically a plain radiograph. Although alone it is not sufficient for a diagnosis, obvious obstruction of the stomach with little or no distal air in an acutely ill newborn or infant can be enough to warrant taking the child immediately to the operating room. Midgut volvulus is one of the few pediatric emergencies in which operating takes precedence over resuscitation. More typically, plain radiographs are nonspecific and further urgent evaluation is warranted.

The upper gastrointestinal series is the gold standard for making the diagnosis of malrotation. The procedure must be performed in the radiology suite by a trained radiologist using fluoroscopy. In cases of volvulus, the site of obstruction is in the second or third portion of the duodenum and has the appearance of a bird's beak. If the duodenum is partially obstructed, a spiral or corkscrew configuration may be seen (Fig. 84.28). In diagnosing malrotation alone, the position of the duodenojejunal junction must be documented. Normally, it is to the left of midline, rising to approximately the level of the pylorus and fixed well posteriorly. In a patient with malrotation, it is anterior, low, and often midline or to the right of midline (Fig. 84.29). The diagnosis requires judgment and, therefore, an experienced and confident radiologist.

Barium enema was historically the procedure of choice, but it has several limitations. Most importantly, the cecum can be in the proper position in the patient with duodenojejunal malrotation, and the latter can, therefore, be missed. As the risk for midgut volvulus is related to duodenojejunal



• **Fig. 84.27** Malrotation with midgut volvulus.

• **Fig. 84.28** Upper gastrointestinal contrast study in patient with malrotation and midgut volvulus.

• **Fig. 84.29** Upper gastrointestinal contrast study in patient with malrotation without volvulus. Note location of duodenojejunal junction and small intestine to right of midline.

malrotation and not jejunoileal, the barium enema cannot be depended on. A contrast enema can, however, help determine the potential width of the mesenteric base, and therefore the risk of volvulus, in a child when the location of the duodenojejunal junction on upper gastrointestinal investigation is unclear.

Ultrasonography can be used to determine the orientation of the superior mesenteric vessels and thus may be helpful in the diagnosis of malrotation. Normally, the superior mesenteric vein lies to the right of the superior mesenteric artery. If the superior mesenteric vein lies either anterior or to the left of the superior mesenteric artery, malrotation may be present. However, this is inconsistent and does not lead to a definitive diagnosis. Currently, ultrasound should not be considered the definitive imaging of choice.

An acutely ill child with the presumed diagnosis of volvulus requires urgent operative intervention even at the expense of full resuscitation. Imaging is not required and not appropriate. As the operation gets under way, intravenous fluids continue, bladder and stomach catheters can be placed, blood is drawn for type and crossmatch, and broad-spectrum antibiotics are administered. *Time is critical*. In patients with malrotation without volvulus or obstruction, urgency is somewhat less. As long as all caregivers are vigilant for the development of volvulus, early operation (within a day or two of diagnosis) would appear to be justified. Older individuals with intermittent symptoms can be treated more electively.

The surgical treatment of these emergent patients involves seven aspects: evisceration of the bowel, detorsion of a volvulus, division of Ladd bands, widening the mesenteric base, relieving duodenal obstruction, incidental appendectomy, and nonrotational return of the bowel to the abdomen. Ladd bands extend from the ascending colon (on the medial aspect of the duodenum in patients with malrotation) across the duodenum and attach to the posterior aspect of the right upper quadrant. They presumably represent the attempt of the ascending colon to become retroperitoneal, as it is in the normally rotated individual. They must be completely divided. Techniques to widen the mesenteric base and relieve duodenal obstruction are then used. Incidental appendectomy and nonrotational return of the bowel to the abdomen may seem unusual. It would seem logical to try to rotate the bowel properly or to try to fix it in place. However, this does not work in practice. Experience has shown that returning the bowel with the small bowel on the right and the large bowel on the left (total nonrotation) is effective. Thus once a patient has malrotation, they have abnormal intestinal rotation for the rest of their lives. It is a chronic condition and families must be educated to that point.

Laparoscopic Ladd's procedure is effective for nonurgent malrotation patients. It is not appropriate for critical midgut volvulus patients. While laparoscopic Ladd's procedure has become common at many medical centers, long-term prospective randomized trails comparing it to traditional Ladd's procedure are lacking.

Recurrent volvulus is relatively infrequent (less than 10%) but must always be considered. Gastrointestinal motility disturbances are not uncommon after operative correction of malrotation. Other complications can occur as a result of compromised bowel from ischemia caused by volvulus, such as reperfusion injury with hemodynamic instability and delayed stricture formation. Adhesive bowel obstruction is possible in any patient after abdominal exploration. Finally, midgut volvulus accounts for nearly 20% of the cases of short gut syndrome in the pediatric population.

Meconium Syndromes

Meconium syndromes are associated with intestinal obstruction resulting from thick, inspissated meconium. These syndromes are broadly characterized by several patterns of clinical presentation, including meconium ileus, meconium plug syndrome, meconium peritonitis, and meconium ileus equivalent. In meconium ileus, which is almost always associated with cystic fibrosis, the inspissated meconium typically obstructs the small bowel, usually at the level of the distal jejunum or the proximal ileum. Meconium plug syndrome is observed more frequently in preterm infants and involves obstruction at the level of the colon. It is thought to occur as a result of poor intestinal motility, but it can be associated with cystic fibrosis in a minority of infants. Meconium peritonitis results from bowel perforation, usually intrauterine, which is secondary to

meconium-related obstruction. Meconium ileus equivalent is a condition associated with stool-related bowel obstruction in older children with cystic fibrosis.

Meconium Ileus

Meconium ileus occurs in approximately 10%-20% of newborns with cystic fibrosis. Cystic fibrosis is caused by mutations in the gene that codes for a protein called *cystic fibrosis transmembrane conductance regulator* (CFTR), which regulates chloride transport across epithelia.[19,82] Luminal epithelial cells of patients with cystic fibrosis either lack or have defective CFTR and are relatively impermeable to chloride and excessively reabsorb sodium. This leads to dehydration and hyperviscosity of secretions with secondary obstruction of the lumina that these cells line, including the mucus-secreting glands of the bowel wall and the ductal cells of the exocrine pancreas.

The hyperviscosity of mucosal cell secretion leads to the formation of thick, tarlike meconium, which becomes increasingly inspissated farther along the small bowel lumen, eventually resulting distally in the formation of small, dense meconium pellets and a microcolon. Resultant small bowel obstruction is usually present at birth and can even be diagnosed antenatally on ultrasonic examination of the maternal abdomen. Postnatal clinical signs of bowel obstruction usually evolve within 24-48 hours, including increased abdominal distention associated with failure to defecate and eventual bilious vomiting. Bowel loops, which have a pliant, doughlike quality, can often be palpated on abdominal examination. Abdominal radiographs may have a granular, soap-bubble appearance as a result of air bubbles in the meconium. This clinical picture is classically used to characterize *simple meconium ileus.* However, luminal bowel obstruction of this sort can progress to volvulus, necrosis, and perforation, and these clinical situations constitute *complicated meconium ileus*. If bowel necrosis and perforation have occurred in utero, a pseudocyst may form and present as a palpable mass on abdominal examination at birth. Volvulus can also present as a palpable abdominal mass. In addition to the classic features of intestinal obstruction (i.e., multiple distended bowel loops), abdominal radiography may reveal a large mass containing calcified material (pseudocyst) or calcifications distributed throughout the peritoneal cavity (meconium peritonitis) in association with this process. Ascites, free air, or a granular, soap-bubble appearance caused by air bubbles in the meconium may also be present. The absence of any or all of these radiographic findings does not necessarily rule out meconium ileus. However, a contrast enema almost always demonstrates a microcolon, usually associated with small, "rabbit-pellet" meconium concretions seen proximally. The differential diagnosis includes meconium plug syndrome, small bowel and proximal colonic atresia, total colonic Hirschsprung disease, and congenital hypothyroidism.

Management options to treat meconium ileus depend on the type of presentation. General management principles always include prompt rehydration with adequate fluid and electrolyte support, gastric decompression with a dual-lumen sump nasogastric tube, and appropriate antibiotic coverage.

Simple meconium ileus can be treated either nonoperatively or operatively. Nonoperative intervention requires that other causes of distal bowel obstruction be ruled out and that complicated meconium ileus (volvulus, necrosis, perforation, pseudocyst, or peritonitis) does not exist. A hyperosmolar solution (typically Gastrografin®) is administered as an enema and allowed to reflux into the ileum. The hypertonic solution (1900 mOsm/L) establishes a concentration gradient across the bowel wall that draws fluid into the lumen and promotes passage of the meconium. It is extremely important that the infant receive adequate intravenous fluid therapy before and during this procedure to compensate for the rapid fluid shift out of the plasma compartment as a result of the intestinal osmotic load. This procedure should be performed by an appropriately trained and experienced pediatric radiologist, with a pediatric surgeon available. Although the technique is successful a little over 50% of the time, there is also an 11% perforation rate.[80] Furthermore, necrotizing enterocolitis can result from the exposure of the bowel to the hyperosmolar solution. Surgical treatment involves evacuation of the meconium from the intestine. This can be accomplished by creating an enterotomy and irrigating the bowel with 2%-4% N-acetyl-L-cysteine, which helps to partially dissolve the inspissated meconium, making it easier to flush through the lumen. In addition, the bowel can be partially diverted using a variety of techniques (Bishop-Koop, Santulli-Blanc, or Mikulicz procedures), which allow for evacuation of the meconium over a longer term with gradual resumption of distal bowel utilization.

Complicated meconium ileus requires an exploratory laparotomy. Volvulus can be relieved by untwisting the bowel. Bowel resection is usually required to treat atresia, necrotic, and perforated bowel, and in some instances, remarkably dilated bowel. Partial or complete temporary intestinal diversion is usually required along with the irrigation techniques previously mentioned. Initial postoperative care involves adequate fluid and electrolyte support, continued nasogastric sump tube decompression of the stomach, and appropriate antibiotic therapy. Careful ostomy irrigation by the pediatric surgeon can be continued postoperatively to facilitate further meconium evacuation if needed. Bowel function usually returns within 3-5 days, at which time oral nutritional support can be initiated, first with elemental formulations if the inflammation encountered at exploration was extensive or if surgery was complicated by intra-abdominal infection. Pancreatic enzyme supplementation should also be considered. If bowel function does not return within this period, parenteral nutritional support should be initiated. Early postoperative recovery is usually good. Proper ostomy care is essential, and surgical closure is usually carried out 4-6 weeks after the initial surgery. Because long-term mortality in patients with cystic fibrosis is most frequently associated with respiratory complications,

aggressive pulmonary toilet during the initial postoperative period is mandatory.

Meconium Peritonitis

Intestinal obstruction from a variety of causes, including, but not limited to, meconium ileus, volvulus, atresia, peritoneal bands, and internal hernia, can result in bowel necrosis and perforation during the fetal period. Meconium escaping into the peritoneal cavity combined with intestinal necrosis can cause an inflammatory reaction, leading to calcification and extensive scarring (fibroadhesive peritonitis), which seals the perforation; cystic meconium peritonitis (if a seal does not form and meconium continues to leak into the peritoneal cavity); or meconium pseudocyst (when loops of bowel and necrotic tissue are encased in scar tissue and surround the extramural meconium). Meconium ascites present as a large amount of liquid meconium, presumably resulting from a recent perforation just before birth, which fills the peritoneal cavity.

Asymptomatic patients with radiographic evidence of intraperitoneal calcification can be managed conservatively; however, babies with meconium peritonitis who present with bowel obstruction usually require surgical intervention. Surgical management is based on the findings at laparotomy and may include resection of necrotic bowel or temporary intestinal diversion or both. Every attempt should be made to preserve as much bowel length as possible to decrease the risk of developing short gut syndrome. The principles of postoperative care are similar to those for meconium ileus.

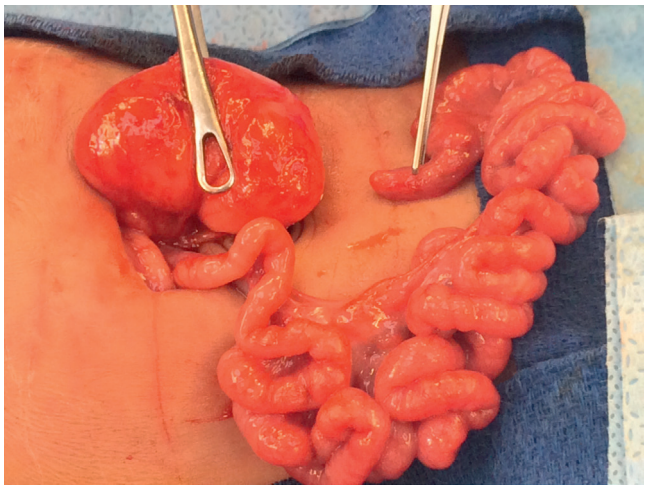
Meconium Plug Syndrome

Meconium plug syndrome is believed to relate to colonic hypomotility. It is more frequently observed in preterm infants and in infants of diabetic mothers and is termed *neonatal small left colon syndrome*. Several factors known to affect bowel motility have been implicated. These include hypermagnesemia and hypoglycemia. A hypermagnesemia-associated decrease in the release of acetylcholine can result in myoneural depression. This mechanism has been used to explain meconium plug syndrome observed in preterm neonates whose mothers received magnesium to treat eclampsia. Furthermore, immature development of the myenteric plexus of preterm infants may impair intestinal motility, accounting for the increased observation of meconium plug syndrome in this patient population. Hypoglycemia, frequently observed in infants of diabetic mothers, is thought to induce increased glucagon secretion and may be associated with intestinal hypomotility.

This disorder is seen in preterm infants who present with abdominal distention associated with minimal passage of meconium. Multiple dilated bowel loops are present on abdominal radiography. Although a digital rectal examination can sometimes result in the passage of the obstructing meconium, a water-soluble contrast enema is valuable both for diagnostic purposes (usually demonstrating a microcolon distal to the obstruction) and for therapy (to induce passage of the obstructing meconium plug). Surgical therapy is infrequently required to relieve the blockage. Because of the association of meconium plug syndrome with cystic fibrosis and Hirschsprung disease, patients with this disorder may need to be evaluated for cystic fibrosis and undergo a rectal biopsy.

Jejunoileal Atresia and Stenosis

The potential pathogenesis of small bowel atresia is varied and includes events during the second and third trimester of intrauterine life, such as intussusception, internal herniation of bowel, volvulus, bowel perforation, vascular constriction in association with gastroschisis (and, less frequently, omphalocele), mesenteric thrombosis, and possibly excessive resorption of the intestinal attachment of the omphalomesenteric remnant. The suggestion of in utero vascular compromise as an etiologic factor was first demonstrated in beagle puppies by Christian Barnard and colleagues, who observed that the late-gestational ligation of mesenteric vessels resulted in a classic V-shaped mesenteric defect in association with a noncontiguous gap atresia (most likely caused by resorption of the ischemic bowel supplied by the ligated vessels).[55]



These observations have subsequently been confirmed in a number of different animal models. The notion that the etiologic events occur after the 12th week of embryonic life is supported by the frequent clinical finding of bile pigments and lanugo hairs in the postatretic bowel segment, because secretion of bile into the bowel lumen and fetal swallowing of amniotic fluid begin during the 11th-12th weeks of gestation. Another potential etiologic factor is linked to the concept of epithelial plugging. From the 5th-8th weeks of gestation, the intestine undergoes a period of epithelial growth so rapid that it can completely obliterate the intestinal lumen (solid-cord stage). After the 8th week, the intestinal lumen is re-established through a process termed *revacuolization*. Lack of complete revacuolization has been postulated to account for the development of intestinal stenoses and webs (membranous atresias).

The classification of jejunoileal atresia is as follows. Operative management of intestinal atresia and stenosis is based on pathologic findings.

Type I: Mucosal (membranous) web
Type II: Blind ends connected by a fibrous cord
Type IIIa: Blind ends separated by a V-shaped mesenteric defect
Type IIIb: Apple-peel or Christmas-tree deformity (blind ends; distal small bowel segment forms corkscrew around ileocecal artery terminus) (Fig. 84.30)
Type IV: Multiple atresias (string of sausages)

The anatomic distribution is approximately 50% in the jejunum (proximal 30%, distal 20%) and 50% in the ileum

• **Fig. 84.30** Type IIIb intestinal atresia.

• **Fig. 84.31** Operative photograph of a type II ileal atresia.

(proximal 15%, distal 35%). Approximately 90% of all small bowel atresias are single. Type IV atresias more often involve the proximal jejunum.

The initial diagnosis is often entertained when pregnant mothers present with polyhydramnios, resulting from the inability of the fetus to absorb amniotic fluid via the obstructed bowel. Prenatal ultrasonography shows distended loops of fetal bowel consistent with obstruction. Newborn infants typically present with the abdominal distention and bilious vomiting often associated with failure to pass meconium. A more proximal (higher) location of the obstruction is characterized by an earlier onset of bilious vomiting and less abdominal distention in comparison with a more distal (lower) obstruction. On plain abdominal radiography, distended air-filled bowel loops are usually observed. The lower the obstruction, the greater the number of distended loops and air-fluid levels. Often, a markedly distended loop (relative to other bowel loops) is visualized, which may help to identify the location of the blind end of the obstructed bowel. A contrast enema typically reveals a microcolon, which results from the fact that little or no gastrointestinal contents have passed distal to the obstruction.

The differential diagnosis includes malrotation (with or without volvulus), meconium syndromes, duodenal or colonic atresia, internal hernia, intestinal duplication, and total colonic Hirschsprung disease. The particular distinguishing features of these conditions are discussed elsewhere in this chapter; however, jejunoileal atresia may coexist with malrotation (10%-18%), meconium peritonitis (12%), meconium ileus (10%), and, less frequently, with other comorbid obstructive conditions. Intestinal ileus secondary to sepsis can also present with abdominal distention and bilious vomiting. When the level and pattern of obstruction suggest the possibility of malrotation, a limited upper gastrointestinal contrast study should be performed to demonstrate a normally positioned ligament of Treitz (located to the left of the vertebral column at the level of the pylorus).

Initial treatment should include prompt adequate intravenous hydration and orogastric decompression of the stomach with a sump tube placed at intermittent suction with frequent regular irrigation of the tube to ensure patency. The operative management of the child should not be undertaken until the fluid and electrolyte status is within normal range. Bilious drainage from the stomach should be replaced and good urine output maintained.

Operative intervention is based on the type of atresia, the presence of associated surgical co-morbidities, and the condition of the bowel at the time of surgical exploration. Abdominal exploration is usually carried out through a transverse incision above the level of the umbilicus. In considering the most appropriate operation, a general strategy is to preserve as much viable bowel as possible. Although dilation of the bowel proximal to the obstructing blind end is always present, a marked and relatively abrupt increase in the caliber of dilation is often found at the terminus itself, creating a large, bulbous pouch (Fig. 84.31). Because peristalsis of massively dilated bowel is thought to be ineffective, a primary anastomosis between such a pouch and the small-caliber, unused distal bowel should not be attempted. Instead, the pouch should be surgically tapered (or resected, if the involved segment is appropriately limited to avoid creating short gut syndrome) to allow for better postoperative peristalsis.

Before creation of the anastomosis, the distal lumen of the bowel is gently irrigated (inflated) to ensure that no further atretic segments or webs are present. Multiple atresias can be managed either by multiple resections and anastomoses or by intramural stenting.[12] This latter method may help to preserve intestinal length. Particular care is required in handling the distal bowel involved in the fragile apple-peel deformity, as the entire length of the segment is based on a delicate, easily injured ileocecal artery terminus. If the bowel is compromised by inflammation or ischemia, a primary anastomosis is postponed and the bowel is diverted.

Postoperative care involves adequate nutritional support, often administered parenterally until adequate bowel function is present. In a large series spanning 10 years, 80% of patients weaned off parenteral nutrition; 20% required

prolonged home TPN. All patients survived.[70] The most serious postoperative complications usually involve anastomotic leakage and sepsis. Over the longer term, anastomotic stricture can be problematic.

Hirschsprung Disease

Congenital intestinal aganglionosis (Hirschsprung disease) is the result of arrested fetal development of the myenteric nervous system (see Chapter 81). Hirschsprung disease is the most common cause of intestinal obstruction in the neonate. It occurs in about 1 in 5000 live births with a male-to-female ratio of 3.4:1. Total-colon Hirschsprung disease, noted in up to 8% of cases, favors females at a ratio of 1.6:1. More than 75% of the time, the transition zone from normal to involved colon is located in the rectosigmoid region. Down syndrome is the most commonly associated anomaly, occurring in 8%-16% of patients. Approximately 5% of patients with Down syndrome have Hirschsprung disease. Family history is important because the risk of a sibling having Hirschsprung disease is 1%-5% for short-segment disease and 9%-33% with long-segment disease. Familial Hirschsprung disease occurs in 4%-8% of patients.[39,79,81,103] Hirschsprung disease or tumors of neural crest origin (neuroblastoma, ganglioneuroblastoma, and ganglioneuroma) occur in association with congenital central hypoventilation syndrome in approximately 20% and 6% of cases, respectively.[7] Advances in the genetics of Hirschsprung disease have increased understanding of the molecular pathology of neural crest cell migration.

Approximately 80%-90% of patients present in the neonatal period with complete intestinal obstruction characterized by abdominal distention, emesis, and failure to pass meconium. Approximately 95% of normal, full-term infants pass meconium in the first 24 hours, whereas an equal number of patients with Hirschsprung disease do not. Physical examination shows a distended, soft abdomen, but rectal examination can produce an explosive stool. A contrast examination can be diagnostic in 80% of newborns. Findings may include a rectum with a smaller diameter than the sigmoid colon, a transition zone, normal caliber in the majority of the colon, and failure to completely evacuate on a 24-hour delayed film. Contrast enemas in all age groups are performed on unprepared bowel if the diagnosis of Hirschsprung disease is being considered. The definitive diagnosis of Hirschsprung disease, however, rests on demonstration of aganglionosis and hypertrophy of the nerve trunks on biopsy. In newborns, adequate biopsy specimens can often be obtained by the suction technique in the nursery.

Hirschsprung-associated enterocolitis occurs in 10% of patients overall and is more common beyond the neonatal period. This can be fatal and can happen even after treatment for Hirschsprung disease has been completed. All practitioners should be aware of this complication and treat for it whenever it is suspected. Enterocolitis is associated with abdominal distention, fever, emesis, and spontaneous diarrhea or an explosive diarrheal stool with gas during and after rectal examination. Enterocolitis is treated with decompression of the rectum with a large catheter and with warm saline irrigations using 20 mL/kg three or four times per day, volume resuscitation, and administration of broad-spectrum antibiotics.

The initial goal of treatment is decompression. Traditionally, this was performed with a leveling ostomy. Leveling here refers to the intraoperative determination of where on the bowel the ganglion cells make an appearance. This is done by taking seromuscular biopsies and having the pathologist review the frozen sections. The ostomy is then placed proximal to this to ensure its adequate function. Primary pull-through procedures are being performed with much greater frequency and would now be considered the standard of care. Here, instead of the traditional three stages (ostomy, definitive repair, ostomy takedown), the operation is done in one stage and without a protective stoma. Occasionally, a primary repair with a protective ostomy is performed—a two-stage operation in that ostomy takedown is still required.

The three traditional open abdominal surgical methods used to treat Hirschsprung disease are (1) Swenson, (2) Soave, and (3) Duhamel. No statistically significant difference has been shown among the outcomes of any of these procedures if they are performed properly. Over the last decade, experience with laparoscopic/transanal approaches has increased. Systematic reviews show that more children achieved continence with the laparoscopic/transanal approach.[30] Another meta-analysis concentrated on short-term outcomes and showed shorter intraoperative time and hospital stay, less incontinence, and less constipation.[13] The laparoscopic/transanal approach is considered the preferred approach at many specialty children's hospitals at this time.

Regardless of the procedure performed, these patients must be followed for years postoperatively. Postoperative care and long-term issues are similar to those for patients with anorectal malformations. Mandatory dilations are not necessary in Hirschsprung disease, because a neorectum is not created. However, strictures are not uncommon, and these patients need to be diligently followed during the first year. If any narrowing is noted, a full dilation program is started. Because there appears to be no detriment to dilations, some surgeons start a dilator program in all patients, including home dilation by the parents. There is debate over the necessity of this.[104] Also, enterocolitis is not typically seen in patients with anorectal malformations but can absolutely occur after repair in a patient with Hirschsprung disease. All patients with Hirschsprung disease, at any time in their lives, should have enterocolitis included in their differential diagnosis whenever they have abdominal pain, distention, or diarrhea. Also, unique to patients with Hirschsprung disease is the possibility of a retained aganglionic segment contributing to ongoing, postoperative constipation. This occurs when poorly vascularized, poorly ganglionated, or frankly aganglionic bowel is brought down in the pull-through. Repeat biopsy is necessary. Anal sphincter achalasia can also occur, and injection with botulinum toxin can help make this diagnosis. If suspected, an anal myomectomy can

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

provide a permanent solution. All the potential complications, however, must be balanced by the long-term results, which indicate that approximately 90% of these patients ultimately achieve normal or near-normal bowel function.

Anorectal Anomalies

Anorectal malformations, or imperforate anus, are a class of congenital malformations that covers a wide spectrum of defects.[38,74,77] They can be quite minor in appearance—for example, a mildly anteriorly displaced anus—or quite severe. Overall, most patients do reasonably well, with more than 75% attaining a good degree of bowel control when they have adequate treatment.[77] The most severe forms of pelvic malformations, such as cloacal exstrophy, are not discussed here; this discussion is limited to malformations of the anus and rectum alone.

Imperforate anus occurs in 1 of every 4000-5000 newborns. The estimated risk for a couple having a second child with an anorectal malformation is approximately 1%. The frequency of this defect is slightly higher in male than in female patients.

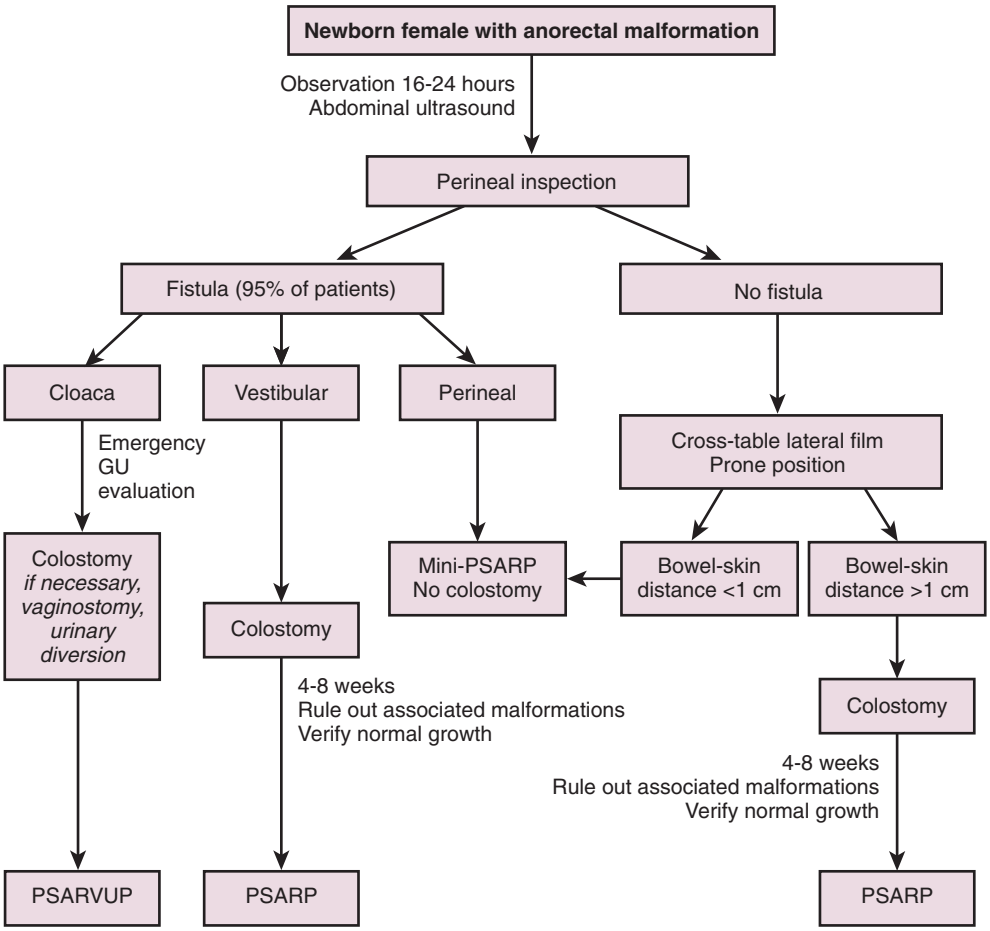
Traditionally, the terms high, intermediate, and low were used to describe various degrees of imperforate anus. However, terminology should relate to the location of the rectal fistula for both prognostic and therapeutic implications.

More than 80% of male patients with imperforate anus have a fistulous connection between the rectum and the urinary tract. This can go from the rectum to the bladder (rectovesical), to the prostatic urethra (rectoprostatic), and to the bulbar urethra (rectobulbar). When the rectal fistula opens onto the perineal skin, it is called a *perineal fistula*. An unusual form of imperforate anus occurs when the rectum ends blindly in the pelvis. More than 50% of these patients have Down syndrome and almost all patients with Down syndrome and imperforate anus have this variant.

In female patients, there are three main types of malformations: perineal fistulas, vestibular fistulas, and complex malformations called *cloacae*. In the perineal fistula, the rectum opens on the perineal skin anterior to the anal dimple. A vestibular fistula opens in the posterior aspect of the introitus but outside the hymen. A cloaca is a malformation in which the rectum, vagina, and urethra all open into a common channel of variable length, which then opens onto the perineum. A rectovaginal fistula is extremely uncommon; these are usually rectovestibular fistulas.

Anorectal malformations may be associated with malformations of the sacrum and spine. One missing vertebra does not appear to have prognostic significance; however, two or more missing sacral vertebrae is a poor prognostic sign in terms of bowel continence and, sometimes, urinary control. Hemivertebrae in the thoracic and lumbar spine are also associated with imperforate anus.

Tethered cord is a defect frequently associated with imperforate anus, seen in up to 25% of cases. The actual repercussions of tethered cord are more difficult to determine. It usually coincides with very high anal defects, a very abnormal sacrum, or spina bifida. Cause and effect is unclear, as is the benefit of surgical treatment of the tethered cord, but the current standard of care is to look for tethered cord in all patients with imperforate anus and surgically treat if discovered.



The frequency of associated genitourinary defects varies from 20%-50%. The width of the range is most likely related to how diligently the defects are sought. The higher the malformation, the more frequent are the associated urologic abnormalities. Patients with a persistent cloaca or rectovesical fistula have a 90% chance of an associated genitourinary abnormality. Conversely, children with perineal fistulas have less than a 10% chance of an associated urologic defect. Hydronephrosis, urosepsis, and metabolic acidosis from poor renal function are the main sources of mortality and morbidity in newborns with anorectal malformation. In fact, a thorough urologic evaluation should take precedence over the colostomy itself in patients with high lesions. In patients with lower lesions such as perineal fistulas, the urologic evaluation can be performed on an elective basis. This evaluation must include an ultrasonographic study of the kidneys and the entire abdomen to rule out the presence of hydronephrosis or any other obstructive process.

Approximately 5% of patients with imperforate anus have associated esophageal atresia, and up to 10% have significant cardiac malformations such as tetralogy of Fallot, ventricular septal defect, or patent ductus arteriosus.

The initial diagnosis of imperforate anus is almost always made during the first newborn physical examination. Occasionally, a mild perineal fistula is missed. Two important questions need to be answered within the first 24 hours. The first is whether a colostomy will be needed, deferring definitive repair until later in life, or whether to proceed with definitive repair. The second is to determine whether associated defects, such as urologic abnormalities, require more urgent treatment. It should be stressed that imperforate anus is not a surgical emergency and rarely needs to be operated on within the first 24 hours of life. This time should be used to complete the workup and discuss options with the family. On the other hand, some associated abnormalities can carry morbidity and mortality risks in the first 24 hours, and these must be addressed. Intravenous fluids, antibiotic coverage, an abdominal ultrasound, a radiograph of the spine, anteroposterior and lateral radiographs of the sacrum, a cardiac evaluation, and a nasogastric tube are indicated.

The decision to perform a colostomy or to proceed with the definitive repair can be answered within the first 24 hours by physical examination alone in more than 80% of male patients and 95% of female patients (Fig. 84.32 and Fig. 84.33). In the male, the presence of a well-developed midline groove between the buttocks, a prominent anal dimple, and meconium exiting through a small orifice located anterior to the sphincter in the midline of the perineum are evidence of a perineal fistula. Occasionally, there is a prominent skin bridge that an instrument can be passed beneath (known as a "bucket handle") or a midline

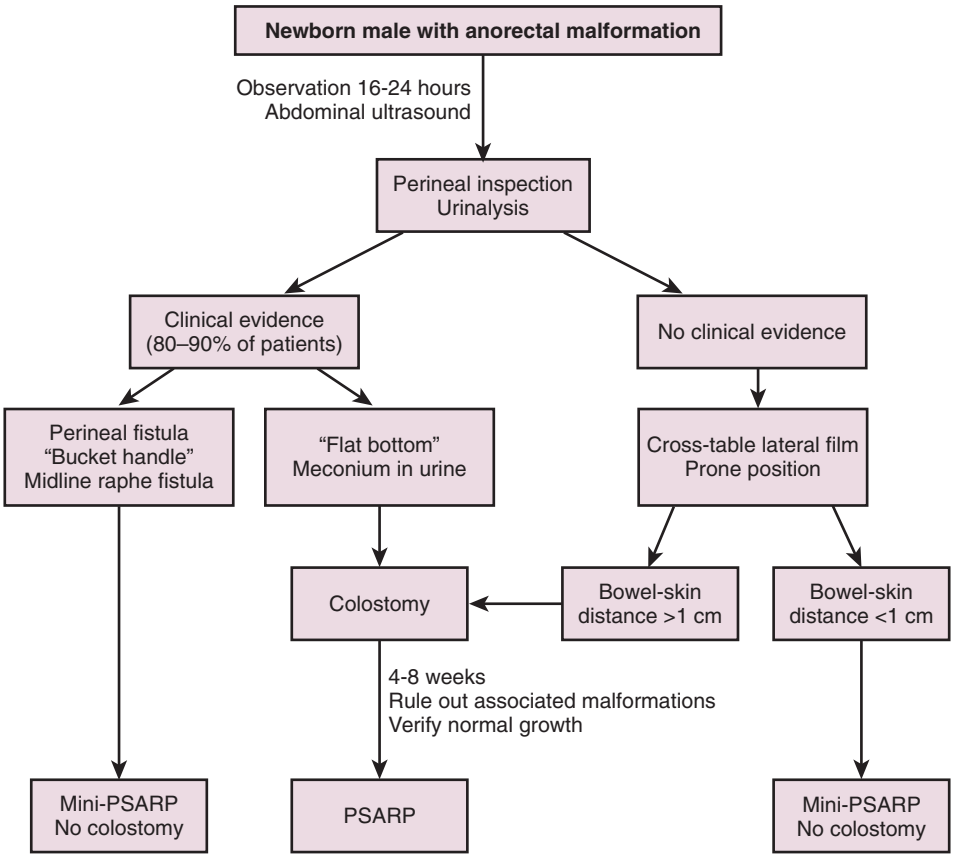
raphe "black ribbon" of subepithelial meconium. These malformations can be repaired via a perineal approach during the newborn period without a colostomy. However, flat buttocks with no evidence of a perineal opening and the presence of meconium in the urine are indications of a rectourethral fistula. A small gauze pad over the tip of the penis can be helpful in spotting meconium in the urine. Most surgeons place a colostomy in these patients.



It can take up to 24 hours for enough pressure to build up in the colon to push meconium out of a perineal fistula. So, unless meconium is definitely seen in the urine, waiting is appropriate. If the diagnosis is still in doubt after 24 hours, a cross-table lateral radiograph of the abdomen and pelvis with the infant in the prone position is indicated. By identifying the anal dimple with a lead marker, the distance between the end of the dilated bowel and the skin can be estimated. If this distance is less than 1 cm, a primary repair can be attempted. It is important to wait 24 hours before obtaining this radiograph, because pressure within the colon is necessary for its prognostic value. Fewer than 20% of male patients need this radiograph.

In the female patient, physical examination alone can lead to the proper initial surgical treatment in more than 95% of cases. If a single perineal opening is observed where the urethra is normally located, the diagnosis of cloaca is established and a colostomy is indicated. A normal urethra and an opening within the vestibule of the female genitalia but outside of the hymen confirms the diagnosis of rectovestibular fistula. Initial treatment of this defect is the most variable. Pediatric surgeons experienced in its repair often either temporarily dilate the fistula and perform a definitive repair in a few weeks or proceed directly to definitive repair. The most conservative option is to place a colostomy and perform the repair at a later date. This is by far the most common defect seen in girls.

A fistula tract located anterior to the center of the sphincter but posterior to the vestibule of the genitalia establishes the diagnosis of perineal fistula. These babies undergo primary anoplasty without a protective colostomy. In the absence of any fistulous tract in the female patient, imperforate anus without fistula is the diagnosis, particularly in patients with Down syndrome. The cross-table film is needed for fewer than 5% of female patients.

The surgical care of patients with anorectal malformations often involves a complex interplay between clinical judgment and technical expertise. Surgical strategies include the creation of a temporizing or palliative colostomy and various types of corrective repairs.

• **Fig. 84.33** Algorithm for neonatal management of anorectal malformation in male patients. GU, Genitourinary; PSARP, posterior sagittal anorectoplasty.

The main purpose of a colostomy is to provide immediate relief of bowel obstruction related to imperforate anus. It also allows the medical and surgical team time to plan the definitive repair, and it permits other medical and surgical issues, some of which may be more pressing, to be properly addressed. A colostomy is nearly always a temporary measure, as patients with imperforate anus very rarely require permanent diversion.

It is extremely important that the surgeon know the exact location of the fistula before undertaking the definitive repair. A distal colostogram must be obtained for all male patients who undergo a colostomy and all female patients with a cloaca. This study accurately shows the location of the fistula between the rectum and the genitourinary tract, the length of available colon from the colostomy to the fistula site, the distance from the rectum to the anal dimple, its relationship with the sacrum, the characteristics of the urethra in the male patient, the characteristics of the vagina in a female patient, and the presence or absence of vesicoureteral reflux.

The goal of the definitive repair is to place a neoanus in the appropriate location, allowing control by the patient. For the vast majority of patients with imperforate anus, surgery can be approached via the posterior sagittal route by a posterior sagittal anorectoplasty. Male patients with a bladder neck fistula and female patients with a long common channel (greater than 2.5 cm) require combined abdominal and posterior sagittal approaches. Laparoscopic/transanal approaches are also possible.[35]

After colostomy, broad-spectrum antibiotics are continued for 3 days. A stoma appliance is fitted, and the mucous fistula is typically left exposed. Once the colostomy is productive, feedings are begun.

Two to three weeks after surgery, dilations are begun using Hagar dilators. That this procedure is critical for success must be impressed on the patient's caregivers. Dilations continue for 6-12 months postoperatively. If this process is interrupted, there is a high likelihood that a stricture will develop. If a colostomy is present, it can be closed once the desired anal size is reached, typically a 14 Hegar dilator in a 6-month-old child. The importance of dilation cannot be overstated.

After colostomy closure or primary definitive repair, the usual multiple bowel movements frequently produce severe perianal excoriations. These may take time to heal, and caregivers should be forewarned. Every attempt to prevent prolonged contact of stool and skin should be made. Barrier products are frequently used, but it is most helpful to avoid using a diaper on the patient as much as possible.

These patients need lifelong follow-up. Constipation is the most common sequela in patients with anorectal malformations, and it can be most severe in the benign group of malformations. The more complex malformations have a poorer prognosis in terms of bowel control but

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

less chance for constipation. Constipation must be treated aggressively, and prolonged use of laxatives in this population is indicated.

Twenty-five percent of patients with anorectal malformations suffer from some level of fecal incontinence and require some form of bowel management.[74,77,78] Urinary incontinence is not common in boys; 99% enjoy control. In females with cloacae, 50%-60% have control, 20% require a continent diversion, and the rest remain dry with intermittent catheterization.

Acknowledgments

The author and editors acknowledge the prior contribution of Edward M. Barksdale, Jr., Walter J. Chwals, David K. Magnuson, and Robert L. Parry to previous editions of this chapter, segments of which remain largely unchanged.

Key Points

- In infants with esophageal atresia/tracheoesophageal fistula, look for associated anomalies, VATER, and VACTRL syndromes.
- Omphalocele and gastroschisis are distinct entities. The former is associated with other structural or genetic defects in more than 50% of cases; in contrast, the latter is typically sporadic and only accompanied by gastrointestinal morbidity.
- In the face of projectile emesis, ultrasonography has high sensitivity for diagnosing hypertrophic pyloric stenosis.
- A "double bubble" on either pre- or postnatal imaging is almost diagnostic of duodenal obstruction and other structural anomalies and/or trisomy 21 should be excluded.
- Bilious emesis requires the urgent exclusion of malrotation with midgut volvulus by imaging the position of the duodenojejunal junction.
- Hirschsprung disease is the most common cause of neonatal intestinal obstruction, definitively diagnosed by rectal biopsy, often at bedside.

Neonatal Necrotizing Enterocolitis

OLEKSANDR KUDIN AND JOSEF NEU

Summary

Necrotizing enterocolitis (NEC) is a devastating disease of the gastrointestinal tract that affects mostly premature infants. It is the most significant contributor of gastrointestinal morbidity and mortality in preterm infants. NEC was first described over 60 years ago but despite significant research efforts, its pathogenesis remains poorly understood. A general lack of reliable and specific early clinical or laboratory signs affects the ability to promptly and accurately diagnose this disease and initiate treatment. The absence of a clear definition for NEC impedes the ability to study its epidemiology, pathogenesis, and preventive and treatment modalities. Decades have passed without any significant and meaningful additions to treatment options. Currently, a heterogeneous group of pathologic processes is lumped into one diagnosis termed "NEC." Those entities are similar in that they can lead to the same outcome—intestinal necrosis. The inciting factors and initial changes in these entities, however, are different. This chapter will describe some of these pathologic processes while focusing on a "classic" form of NEC.

Definition of NEC

A clear definition of any given disease provides a common foundation to study its epidemiology, pathogenesis, outcomes, and effectiveness of treatments. The lack of a clear definition for NEC has complicated efforts directed at studying this disease. A primary cause for the inability to clearly define NEC is the fact that it is not simply one disease entity, but rather a spectrum of conditions.[29,63] These conditions have a similar outcome—necrosis of the intestine. However, the pathophysiology of these conditions is very different. The chain of events that leads to intestinal necrosis in a term infant with intestinal ischemia caused by a congenital heart lesion is very different when compared to a 6-week-old infant who was born at 24 weeks of gestation. Grouping multiple conditions under one umbrella of NEC affects the reliability of statistical data collected for this disease and stalls efforts to develop effective preventive and treatment strategies (Table 85.1).

Another important issue is developing strict, well-defined diagnostic criteria of the disease. Criteria should be specific, sensitive, and accurate and allow clinicians to differentiate between subsets of NEC and other entities such as spontaneous intestinal perforation (SIP).[63]

This chapter will focus on the "classic" form of NEC. This form of NEC peaks in preterm infants at a similar corrected gestational age and is most often accompanied by clinical deterioration and clear signs of intestinal inflammation, including abdominal distension, periumbilical erythema, bloody stools, elevation of nonspecific inflammatory markers, and distinctive radiologic changes such as pneumatosis intestinalis and portal venous gas.

Epidemiology

Incidence of NEC inversely correlates with gestational age at birth with a higher incidence in babies born at lower gestational ages. About 90% of NEC cases occurred in preterm infants. There is also a correlation between gestational age at birth and length of interval between birth and onset of disease: the earlier an infant is born, the more time will pass between birth and onset of NEC. This results in the highest NEC incidence between 28 and 33 weeks of corrected gestational age.[28,96] In infants whose gestational age ranges from 22-28 weeks, the incidence of NEC in the United States declined from 13% in 2008 to 9% in 2012.[87] However, the Canadian Neonatal Network reported an average NEC prevalence of 5.9% and in the Japanese Neonatal Research Network it was 1.6%.[36] Infants born at a gestational age of up to 32 weeks were included in this review, which could in part explain lower NEC rates reported in Canada and Japan.[36]

About 10% of cases of NEC occur in term infants, but when compared with premature infants, these cases have a strong association with such risk factors as congenital heart disease, gastroschisis, and/or hypoxic-ischemic events. In addition to gestational age, other risk factors for the development of NEC are being investigated. Race seems to affect the risk for development of NEC, with African-American infants being at higher risk compared to Caucasian.[79] Genetic predisposition is evolving as a risk factor for NEC as well.[77,78]

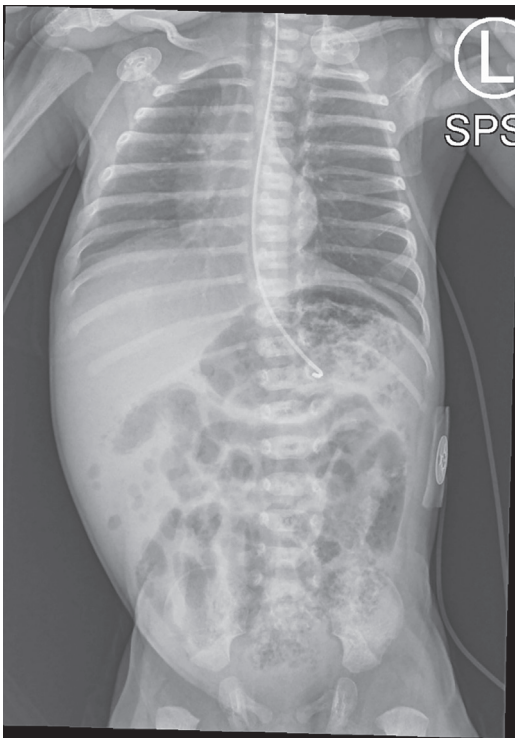
TABLE 85.1 Clinical Scenarios That Are Often Misdiagnosed as Necrotizing Enterocolitis (NEC)

Spontaneous intestinal perforation
Food protein–induced enterocolitis syndrome (FPIES)
Bowel ischemia due to congenital heart disease
Congenital bowel anomalies (Meckel diverticulum, Hirschsprung disease, etc.)
Misinterpretation of stool gas as pneumatosis intestinalis

Adapted from: Neu J. Necrotizing enterocolitis: the mystery goes on. *Neonatology*. 2014;106(4):289-95.



Clinical Features

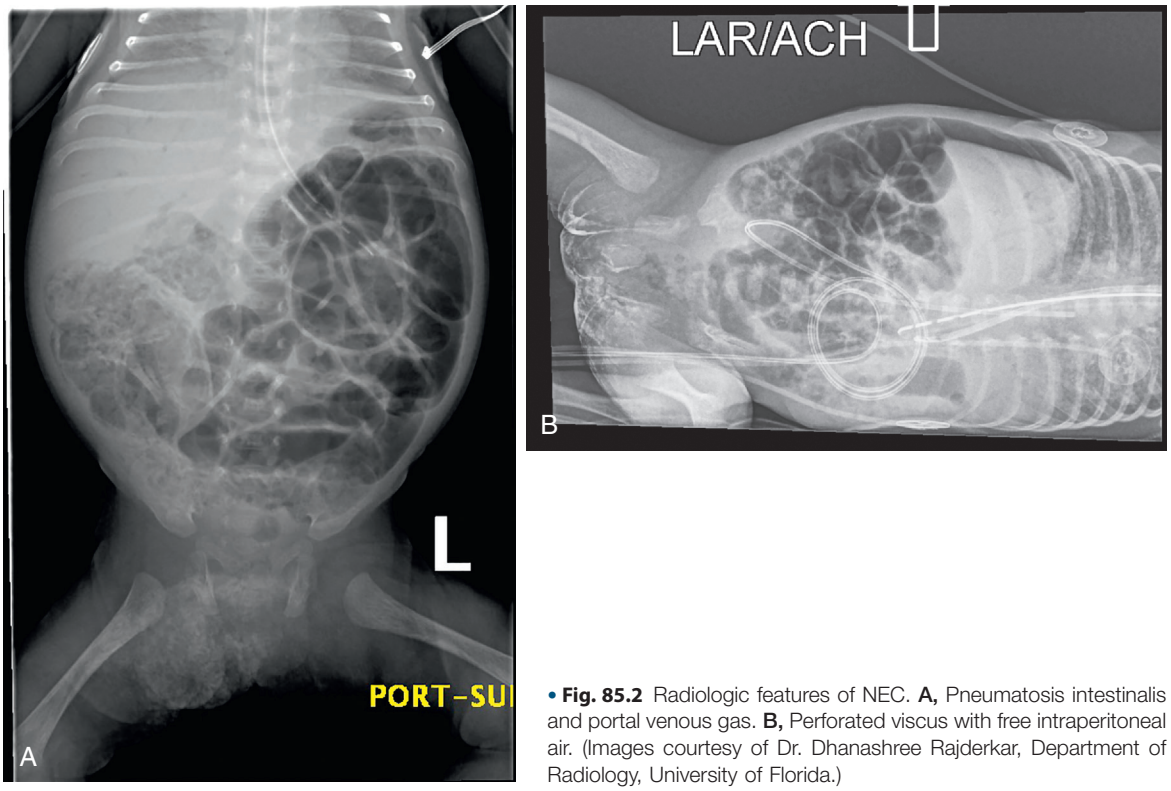
Presentation

Early clinical signs of NEC are usually vague and nonspecific and may include slight changes in vital signs (tachy- or bradycardia), new onset or increased apneic episodes, feeding intolerance or increased gastric residuals, and emesis. As the disease progresses, deterioration becomes obvious on physical examination. The signs of disease progression are also nonspecific: hypotonia, respiratory distress, and cardiovascular instability. The abdominal exam reveals distention, tenderness, discoloration of the abdominal wall, and lack of bowel sounds. Laboratory changes are notable for neutropenia, thrombocytopenia, and metabolic acidosis. Blood may be noticed in gastric contents and or stool.

Diagnosis

Diagnosis is made using a combination of clinical, laboratory, and radiologic findings with the latter being more important for determining severity of the disease process. NEC was systematically described and staging criteria proposed by Bell et al. in 1978 with modifications of staging made by Kliegman et al. in 1987. Modified Bell's criteria are widely used for data collection and in research. However, there are limitations to this classification. Stage I consists of a combination of highly nonspecific findings. It significantly distorts the incidence of NEC. Pneumatosis intestinalis, a hallmark of Stage II disease, may be hard to find on radiographs. Additionally, presence of heterogeneously appearing intestinal stool content may be misinterpreted as pneumatosis intestinalis (Fig. 85.1). A hallmark of stage III is perforated viscus with free intraperitoneal air, which could be due to spontaneous intestinal perforation or NEC. True diagnosis remains unknown when a primary peritoneal drain is placed and no direct bowel visualization and histologic evaluation is performed. This classification also falls short when NEC progresses without exhibiting pneumatosis intestinalis or portal venous gas. Even with free intraperitoneal air, if only a drain is placed without direct observation by the surgeon, the definitive diagnosis of NEC cannot be made.

• **Fig. 85.1** Radiograph showing heterogeneous stool that may easily be confused with pneumatosis intestinalis.



It is important to note that available modes of diagnostics for NEC are able to recognize only changes that occur in the late stages of the disease when the intestinal epithelial barrier has already been compromised and the signs of systemic response and deterioration are obvious.

Decreasing platelet counts, elevated I/T ratio, and elevated or decreased neutrophil counts have been used as laboratory signs of NEC with none of them being specific for this disease. Multiple inflammatory and immunologic markers have been studied as potential predictive biomarkers of NEC. Among them are C-reactive protein (CRP), procalcitonin, an array of cytokines and chemokines, platelet activating factor (PAF), and inter alpha inhibitory protein (IaIp) to name a few. So far, none of them has shown significant ability to do so.[26] Markers of intestinal inflammation and injury such as fatty acid binding protein (FABP), fecal calprotectin (FC), and claudins are being investigated as well. Their usefulness as early screening markers for NEC is questionable.[26] The absence of a clear definition of NEC and limited understanding of its initial pathophysiologic changes impede the ability to develop reliable biomarkers of early disease.

Radiologic signs used to diagnose NEC include pneumatosis intestinalis and portal venous gas (Fig. 85.2), free intraperitoneal air, distended and fixed loops of bowel, and a gasless abdomen. However, studies have shown significant variability in interpretation of abdominal radiographs of infants with suspected NEC.[22,51]

Abdominal ultrasound (US) may be emerging as an important imaging modality in evaluating infants with suspected NEC. Its advantages over x-ray are real-time imaging

• **Fig. 85.2** Radiologic features of NEC. **A,** Pneumatosis intestinalis and portal venous gas. **B,** Perforated viscus with free intraperitoneal air. (Images courtesy of Dr. Dhanashree Rajderkar, Department of Radiology, University of Florida.)

(ability to assess for presence of peristalsis), detection of even minimal ascites, accurate detection of intestinal wall thickness, and perfusion.[8,23]

The above factors lead to uncertainty in diagnosing early stages of the disease and unnecessary exposure of significant numbers of ELBW infants to interruptions of enteral feedings, courses of broad-spectrum antibiotics, and prolonged need for central access. These interventions are associated with an increased incidence of late onset sepsis, prolongation of parenteral nutrition, and hospitalization.

Treatment

Medical Management

Because of incomplete understanding of the etiology of NEC, treatment modalities have focused mostly on supportive measures such as stopping enteral feedings, decompressing the GI tract, broad spectrum antibiotics, and correction of metabolic (acidosis) and hematologic (thrombocytopenia, anemia) derangements. Careful attention must be paid to maintenance of normal cardiovascular and respiratory functions. This may include utilization of mechanical ventilation, vasopressors, and fluid resuscitation.

Choice of antibiotics usually depends on practice in each individual unit, but in general consists of two broad-spectrum agents that cover intestinal microorganisms. Anaerobic coverage may be added as well. The effect of addition of anaerobic coverage to the antimicrobial regiment was evaluated in a large propensity matched study.[10] Overall, the infants in the anaerobic coverage group developed more strictures (OR 1.73; 95% CI, 1.11-2.72 [p = 0.02]). In infants with surgical NEC, death was significantly less common (OR 0.70; 95% CI, 0.52-0.95 [p = 0.02]).[10] Antimicrobial therapy may be tailored to a specific microorganism in case of a positive blood culture. The length of the antibiotic course usually ranges from 7-10 days. The decision to stop or prolong antimicrobial therapy is usually guided by clinical status and nonspecific laboratory markers of inflammation such as C-reactive protein (CRP). There is, however, little evidence-based data to help clinicians determine the appropriate duration of antimicrobial therapy. It is also unclear how beneficial antibiotics are in NEC cases with negative blood cultures.

Serial abdominal x-rays are used to monitor progression of radiologic findings and are useful in determining the need for surgical intervention.

Surgical Management

Surgical intervention is required in about 30%-40% of NEC cases.[86,94] Two types of surgical approaches used in NEC are exploratory laparotomy and peritoneal drain placement. Historically, exploratory laparotomy (ExLap) with resection of nonviable intestine was a procedure of choice since the 1970s. Primary peritoneal drain (PPD) placement, however, started being utilized initially as a temporary measure in infants who were deemed to be too sick to tolerate exploratory laparotomy. PPD placement became more accepted as a definitive therapy after reports supporting this approach were published in the late 1990s and early 2000s. Two RCTs aiming to find a superior

surgical approach were published about 10 years ago.[59,72] Both studies showed no differences in survival, length of hospital stay, and need for parenteral nutrition in ExLap vs. PPD groups. A randomized trial of laparotomy vs. drainage for infants with necrotizing enterocolitis (NCT01029353) that assesses outcomes at two years of age was completed in 2018. Results from this trial, the largest study of patients with NEC, will yield insights into the optimal surgical NEC management.

Outcomes

A diagnosis of NEC has significant negative impact on neonatal survival and on other outcomes. Mortality depends on the gestational age, birth weight, extent of bowel involvement, and the need for surgical intervention. The overall mortality due to NEC ranges from 20%-30%.[35,64] In infants who underwent surgery, the mortality rate is higher (35%) compared to infants who required only medical treatment (21%).[35] Mortality in medically treated neonates decreases with increase in birth weight. Such correlation was weaker in infants with NEC who required surgical intervention. The mortality in that group plateaued around 30%.[35] Survivors of NEC have an increase in adverse neurologic outcomes, specifically elevated rates of IVH and PVL, and perform worse on neurodevelopmental assessment.[82,90] Gastrointestinal complications include development of bowel stricture, short bowel syndrome, and intestinal failure. However, it is noted that patients with intestinal failure due to NEC have higher potential for rehabilitation compared with other causes (volvulus, intestinal atresia, and gastroschisis).[85] NEC is also a significant contributor to health care costs. The annual economic burden of the disease is estimated to be between 500 million and 1 billion US dollars.[64] Longer hospitalization, increase in amount of required procedures, and other resources contribute to the cost of initial hospitalization. Cost of care for infants with NEC is significantly higher compared to infants of the same gestational age but without this disease.[39] Care for infants who had NEC remains more expensive after discharge as well. According to data from Texas Medicaid, cost of care for infants with medically treated NEC became similar to children who did not have NEC after 1 year of age.[25] Medical expenses in children who underwent surgical intervention for NEC continued to be higher for an additional 1-2 years.[25]

Outpatient follow-up of infants who had NEC is important because of significant long-term consequences of this disease. Standardized multidisciplinary approaches with special attention to nutrition and rehabilitation should be utilized.

Pathophysiology of Necrotizing Enterocolitis

A "classic" form of necrotizing enterocolitis is associated with prematurity. It occurs at 2-6 weeks of age with highest incidence of the disease at 28-32 weeks of corrected gestational age.[27] Although there are many factors that predispose preterm infants to NEC, prematurity along with formula feeding and intestinal dysbiosis are considered the major contributing factors for NEC development.[31,43] A concerted effort is directed at elucidating the factors associated with prematurity that predispose this already vulnerable population to NEC. Those factors are categorized and described below.

Altered Host Defense

The ability of premature infants to respond to and control infection is significantly different from full-term newborns. This complicated and interconnected system is comprised of:

- Physical barriers that prevent intrusion of infectious agents (skin, mucous membranes, epithelium of the intestine with the mucous layer, and biomedical factors)
- Innate and adaptive immune systems (including cellular and humoral components)

Both human and animal studies indicate that the above-mentioned barriers are deficient in premature infants when compared to term infants and adults.[12,17] This deficiency can be quantitative, qualitative, or both for different elements of the host defense. Ability of gastric parietal cells to secrete acid is diminished as well in premature infants. Coordination of contractile activity in the developing gut corresponds with gestational age. The mature pattern of peristalsis is not developed until around 36 weeks of gestational age.

There is lack of data on gestational development of tight junctional barrier, but this barrier is thought to be deficient in premature infants.[15] The defense mechanisms of intestinal epithelial layer itself are underdeveloped in preterm infants. This includes decreased numbers of Paneth cells.[53] Paneth cells produce a number of peptides (lysozyme, defensins, secretory phospholipase A2) that play important roles in protecting intestinal epithelium from bacterial invasion and shaping the microbiome. The ability of Goblet cells to secrete mucin is also increasing throughout gestation and achieves maturity at term.[14] The mucous layer protects intestinal epithelium from interacting with pathogenic microorganisms while creating an environment for growth of commensal microorganisms.[88]

Of particular interest is an excessive pro-inflammatory phenotype of macrophages observed in patients with NEC when compared to healthy term infants. Studies explain this phenomenon by upregulation of Smad7 in macrophages of patients with NEC, which in turn inhibits TGF-β.[56,61] The latter factor downregulates pro-inflammatory response of macrophages. Intraepithelial lymphocytes (IEL) can be viewed as an important way of communication between intestinal content and the adaptive immune system. The predominant type of IELs in the intestine of preterm infants is γδ cells.[93] They play an important role in mucosal defense and are significantly decreased in intestinal samples obtained from infants with NEC.[93]

Another disbalance in the cellular component of the immune system of infants with NEC is a shift in T-cell differentiation with an increase in $CD4^+$ TH17 lymphocytes and a decrease in counter-inflammatory Treg cells.[20] IL17, a product of $CD4^+$ TH17 lymphocytes, leads to increased apoptosis of enterocytes and negatively affects both intestinal epithelial tight junctions and proliferation of enterocytes.[20,34] The $CD4^+$ TH17/Treg disbalance was also shown to result in apoptosis of $LGR5^+$ intestinal stem cells in the mouse model.[65] The B-cell arm of the adaptive immune system serves as antigen-presenting cells and produces immunoglobulins. IgA is of particular significance as animal studies have shown that sIgA shapes intestinal microbiota and by this token regulates the maturation of intestinal epithelial cells (ILC) and development of intestinal barrier function.[54,74] Short- and long-term benefits of exposure to maternal sIgA were shown as well.[74] sIgA in human breast milk is considered to be one of the components that contributes to the protective effect of this mode of nutrition, especially in preterm infants. A review of studies that evaluated the potential benefit of Igs in preterm infants did not show a reduction in NEC incidence.[68] It is important to point out that only studies of intravenous Igs were reviewed.

Intestinal epithelium to some extent can be viewed as a teeter-totter, with the microbiome on one side and the hyper-activated immune system on the other. Pathogen-associated molecular patterns (PAMPs) of intestinal microbiota are binding and activate a series of pattern recognition receptors (PRRs). The roles of human toll-like receptors (TLRs) and intracellular nucleotide-binding oligomerization domains (NODs) in the pathogenesis of NEC have been under much scrutiny in last 10-15 years.

TLR-4 receptors and their activation is one of the cornerstones in NEC pathogenesis.[20] These receptors participate in normal gut development in humans and mice.[62] This explains a higher level of expression of these receptors in the developing gut.[62] In premature infants, TLR-4 expression remains elevated after birth.[66] The TLR-4 receptors located on IECs are activated by lipopolysaccharide (LPS), which is abundant in cell walls of gram-negative bacteria that colonize the gut.[4] This activation leads to a number of negative effects: increased apoptosis, impaired regeneration of IECs, and proinflammatory cytokine response.[47] Endoplasmic reticulum (ER) stress was also shown to be a result of TLR-4 activation in animal studies.[3] All of the above features are important elements of NEC. New data is emerging about other members of the TLR family.

NOD receptors are a family of intracellular receptors that are present in monocytes, Paneth cells, and IECs.[81] Peptidoglycan from the bacterial wall of Gram-positive and Gram-negative bacteria serves as a ligand for NOD receptors. NOD2 receptors mediate production of defensins by Paneth cells.[89] NOD2 activation was shown to inhibit TLR-4 in IECs and decrease apoptosis while improving mucosal intestinal injury repair.[73] NOD2 provides a way of communication between intestinal commensal bacteria and the innate immune system. One population-based study from Germany showed that VLBW infants with two or more NOD2 variant alleles were at higher risk of developing surgical NEC.[33]

Refer to Table 85.2 for the role of cytokines and chemokines in the pathogenesis of NEC. Vascular endothelial growth factor (VEGF) and development of intestinal microvasculature also appear to be involved in the pathogenesis of NEC. One study demonstrated that the level of VEGF is decreased in intestinal tissue obtained from infants with NEC.[75] An animal study also demonstrated the importance of VEGF and its receptor signaling for

TABLE 85.2 Selected Signaling Agents and Their Role in the Pathogenesis of Necrotizing Enterocolitis (NEC)

Signaling Agents	Role
Platelet activating factor (PAF)	Pro-inflammatory mediator. In animal models, causes ischemic necrosis in small intestine. Degrading enzyme PAF-acetylhydrolase (PAF-AH) remains low for weeks after birth. Breast milk contains PAF-AH.
Tumor necrosis factor (TNF)	Inflammatory cytokine that activates NF-κB pathway. Elevated in intestinal tissue of patients with NEC.
IL-1	Pro-inflammatory cytokine. Initiates production of other mediators of inflammation, leads to tissue damage.
IL-6	Acute phase immune mediator.
IL-8	Belongs to chemokine family. Helps with neutrophil recruitment to the site of inflammation.
IL-10	Important dampener of immune response in intestine. Thought to be an important protective factor in NEC.
IL-17A	Participates in chemokine induction and neutrophil activation. Leads to loss of intestinal intracellular tight junction, reduces enterocyte proliferation, increases enterocyte apoptosis.
TGF-β	Promotes Treg function but also activates Th17 cells. Downregulates inflammatory cytokine production. Reduced in preterm infants and in infants with NEC.

maintenance of integrity of intestinal microvasculature in the postnatal period.[95] Interestingly, the peak incidence of NEC occurs at the same corrected gestational age as retinopathy of prematurity. This coincidence is intriguing and whether this relates to the VEGF system requires additional research.

Dysbiosis

Until recently, sterility of the fetus in utero was a well-accepted notion. However, now we know that microorganisms colonize the fetal gut before birth.[60] Culture and non-culture-based studies revealed the presence of microorganisms in the amniotic fluid, placenta, and meconium. Known factors that affect gut colonization in infants are preterm birth, mode of delivery, and breastmilk vs. formula feeding. Resemblance between fetal and neonatal bacterial colonization on one side and bacterial flora of the maternal oral cavity and placenta on the other side strongly points to hematogenous transfer of bacteria during gestation.[1,49] The microbiome of a developing gut can modify health outcomes of both term and preterm infants for years to come. More studies are needed to elucidate the mechanisms of this influence. The study of gut colonization in preterm infants showed that shifts in predominant bacterial classes are well orchestrated and abrupt: from bacilli to Gammaproteobacteria and then to Clostridia.[46] The proportion of anaerobes approached that of older children by 33-36 weeks of postconceptual age (PCA). Factors like gestational age at sample collection, mode of delivery, and treatment with antibiotics affected the pace of colonization but not the actual sequence of bacterial classes.[46]

Studies comparing stool microbiome of preterm infants who developed NEC with matched controls found an increase in Gammaproteobacteria and decrease in Clostridia and Negativicutes in those infants who developed NEC.[92] Recent systematic review and meta-analysis of sequencing data from 14 studies showed that preterm infants that developed NEC had increased relative abundance of Gammaproteobacteria and decreased relative abundance of Firmicutes and Bacteroidetes.[69] Increased relative abundance of Gammaproteobacteria prior to development of NEC emerged as a key element of a dysbiotic shift observed in this pathology. This provides an abundance of LPS—a ligand of the TLR-4 receptor. TLR-4 activation, as discussed earlier, is a very important step in pathogenesis of NEC.

Enteral Feedings

The vast majority of NEC cases occur in infants who have received partial or full enteral nutrition. The disease usually develops days to weeks after initiation of enteral feedings. This form of alimentation, therefore, was regarded as an important risk factor for "classic" form of NEC for decades. Delaying initiation and slow advancement of enteral feedings were used to avoid this dreaded disease. Results from animal and adult human studies provide compelling evidence that these practices have a negative impact on the GI tract. This includes mucosal atrophy, bacterial translocation, sepsis, and dysregulation in the secretion of trophic hormones. Recent neonatal studies suggest that longer NPO status in preterm infants is associated with an increased risk for NEC and an increase in intestinal inflammation.[42,44] In 2014, a Cochrane review dedicated to this question found no evidence that delaying initiation of enteral feeds beyond 4 days of life affects the risk of NEC development.[58] This review included 1106 infants from 9 randomized controlled trials (RCTs). Once enteral nutrition is initiated, the controversy shifts toward determining the optimal rate of volume advancement. Another Cochrane database review was published in 2017 and included data from 10 RCTs with a total of 3753 infants. Slow advancement was defined as daily increment of 15-20 mL/kg of enteral feeding volume and faster advancement as a daily increment of 30-40 mL/kg. No difference in the risk of NEC, and all-cause mortality was found between the groups.[67]

Role of Breast Milk

Breast milk provided by the mother of an infant, mother's own milk (MOM), is considered the gold standard of nutrition for an infant of any gestational age. Breast milk contains multiple bioactive components that collectively confer protective benefits to the growing premature infant. These benefits include augmentation of the infant's immune system, anti-inflammatory effects, strengthening of the mucosal barrier, and enriching of beneficial bacterial flora of the gut. Breast milk components include epidermal growth factor (EGF), heparin-binding EGF-like growth factor, platelet activating factor acetyl hydrolase (PAF-AH), secretory IgA (sIgA), lactoferrin, human milk oligosaccharides (HMO), nitrates, glutamine, IL-10, etc. It is important to know that freezing/thawing and pasteurization of breast milk affects the content of these components and will likely decrease its protective effect.

In many cases, however, mothers of preterm infants do not produce sufficient amounts of breast milk, especially in the immediate postnatal period, and formula supplementation is required. Human donor breast milk (HDM) emerged as an alternative for nutrition of preterm infants when MOM is unavailable. A 2014 Cochrane database review that included nine trials (1070 infants) concluded that formula-fed infants had higher risk for NEC development—risk ratio of 2.77 when compared with infants who received HDM.[71] Meinzen-Derr et al. (2009) showed that human milk has a dose-dependent protective effect against NEC. In their study, likelihood of NEC or death after 2 weeks decreased by a factor of 0.83 for each 10% increase in proportion of human milk in the total intake. Another study showed that administration of exclusive breast milk for less than 7 days in the first month of life increased risk of NEC fourfold in VLBW infants.[40]

Fortification of human milk products (MOM and HDM) is necessary to meet nutritional needs of the preterm infant. Studies suggest that feeding only human milk and human milk-based fortifier provides better protection against NEC when compared to feeding bovine products.[2] The occurrence of NEC reportedly decreased from 17% to 5% and surgical NEC from 12% to 1%, but the studies used in this analysis were not powered to detect NEC occurrence as a primary outcome.[2] A recent multicenter retrospective cohort study found that exclusive human milk diet (MOM and/or HDM + human milk–based fortifier) significantly reduced the incidence of NEC, late-onset sepsis, retinopathy of prematurity, bronchopulmonary dysplasia, and mortality when compared with bovine-based diet.[32]

Role of Blood Transfusions

Premature infants are at higher risk of needing packed red blood cell (pRBC) transfusions, with some studies estimating that about 90% of infants with birth weight below 1500 g receive at least one.[11] This highly prevalent intervention has long been under scrutiny for its potential role in NEC pathogenesis. Distinguishing whether transfusions predispose preterm infants to NEC or whether NEC is related to a pretransfusion deteriorating status remains difficult. Transfusion guidelines are not uniform and changes in the clinical status of the infant frequently trigger laboratory evaluations with subsequent pRBC transfusions. This subset of NEC is called transfusion-associated NEC (TANEC).

Studies that found associations between pRBC transfusion and development of NEC prompted the development of the term transfusion-associated gut injury (TRAGI).[13,48] This association was reinforced by a systematic review of 12 retrospective studies, although only part of those studies were included in calculation of odds ratios.[55] Only 5 out of 12 included studies reported unadjusted estimates of infants' exposure to transfusion in the previous 48 hours, and NEC and only 4 studies reported adjusted estimates of such exposure.[55] Several mechanisms were proposed to explain the role of transfusions in the development of NEC: (1) reperfusion injury due to transfusion; (2) immunologic reactions and injury of intestinal mucosa triggered by cytokines, fragmented RBCs, and free hemoglobin; and (3) transient mesenteric ischemia after blood transfusion. A prospective observational study found significant elevation of proinflammatory cytokines (IL-1β, IL-8, IFN-γ, IL-17, MCP-1, IP-10, and ICAM-1) at different time points following blood transfusion in preterm infants less than 32 weeks of gestation.[18]

Alternatively, evidence has also accumulated about the lack of association between pRBC transfusions and NEC.[83,91] Moreover, some studies found that blood transfusions are associated with a lower risk for NEC.[7,84] In a recent prospective multicenter study, secondary analysis revealed that severe anemia (Hb <8 g/dL), but not blood transfusion, was associated with development of NEC.[70] In one meta-analysis, authors found that data from RCTs conflict with the results of observational studies. The RCTs show that blood transfusions are associated with lower risk for NEC, and the observational studies show that transfusions are associated with NEC.[41] A large ongoing randomized controlled trial, Transfusion of Prematures, should provide additional information about this controversial topic (ClinicalTrials.gov identifier: NCT01702805).

Administration of enteral feedings during blood transfusion is another daunting issue. A small case-control study found that implementation of a policy for withholding of enteral feedings during pRBC transfusion was associated with reduction of NEC incidence.[21] Another small study looked at trends of mesenteric tissue oxygenation during and after pRBC transfusions relative to feeding status.[50] This study found that infants who received enteral alimentation during pRBC transfusions had negative trends in postprandial mesenteric tissue oxygenation for up to 15 hours after the transfusion compared to infants who were not fed. There was no difference in mesenteric oxygenation during the transfusion between the groups. The authors suggested a relative postprandial ischemia after transfusion in infants who were fed. It is important to note that in this study the majority of infants who were fed during transfusion were getting formula feedings (6 out of 8) and the majority of infants whose feeds were held during transfusion were receiving breast milk feedings (7 out of 9).[50] This difference could have had significant impact on the difference in the NEC incidence by itself. A systematic review recently evaluated the evidence for withholding enteral feedings during pRBC transfusions.[38] This review showed that the practice of withholding enteral feedings during pRBC transfusions significantly reduced the incidence of transfusion-associated NEC with RR of 0.47; 95% CI: 0.28-0.80 ($P = 0.005$). No RCTs were included in this review since they were not found. Conclusions were drawn by comparing rates of transfusion-associated NEC before and after implementation of the practice to withhold feedings in the peri-transfusion period.[38] Authors stated that the quality of the generated evidence was moderate.[38] In summary, controlled and adequately powered studies are needed to generate better evidence to determine the association between withholding enteral feedings during pRBC transfusions and NEC.

Preventive Strategies

Developing preventive strategies to decrease the incidence of NEC is very important in view of the limited ability to diagnose early stages of the disease and to treat it. Below is a discussion of several of the most important aspects of NEC prevention. Readers should keep in mind that:

- Only evidence-based measures should be employed.
- A combination of measures, rather than any separate intervention, has the highest potential for decreasing incidence of NEC in the NICU setting.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Standardized evidence-based feeding protocols have been shown not only to decrease the incidence of NEC but also to improve other important outcomes like shortening the time to achieve full enteral feeds and decreasing the incidence of late onset sepsis and mortality.[52,80] The advantages of maternal breast milk and donor breast milk over formula products have been discussed earlier. This evidence should be incorporated into feeding guidelines for VLBW and ELBW infants.

Understanding of the role dysbiosis plays in the development of NEC leads to development of new strategies that aim to avoid alteration of the developing intestinal microbiome.

Antibiotics are among the most commonly used medications in the NICU. The vast majority of VLBW and ELBW infants receive broad-spectrum antibiotics in the NICU. These medications alter the intestinal microbiome in neonates.[9,30] Prolonged use of broad-spectrum antibiotics in culture-negative infants is associated with worse outcomes, including increased risk of NEC, late onset sepsis, and higher mortality.[45] One study found an almost threefold increase in risk of NEC when infants were exposed to antibiotics for more than 10 days.[5] Antibiotic stewardship is, therefore, a necessary part of the medical culture in the NICU.

Antireflux medications (both H2 blockers and proton pump inhibitors) have also been overused in the NICU. These medications are mostly prescribed not to treat the symptoms of gastroesophageal reflux (GER) per se but with a hope to decrease the amount of apneas and episodes of bradycardia and desaturation in preterm infants. A large study showed that only about 3% of these events follow an episode of GER.[19] Therefore, the prescription of antireflux medications is clinically unsubstantiated in the vast majority of infants. Additionally, it is shown that prescription of antireflux medications leads to undesired effects: alteration of microbiome, bacterial overgrowth, impaired bactericidal properties of gastric secretions, delayed gastric emptying, and impaired chemotactic response.[76] Indeed, a large systematic review has shown a strong association between the use of antireflux medications and NEC in preterm infants.[57] Routine use of these medications, therefore, should be avoided in premature infants.

Perhaps the most controversial topic in NEC prevention is use of probiotics. This seems to be a logical step given the importance of dysbiosis in the pathogenesis of NEC. Probiotics are live bacteria that confer health benefits on the host when administered in adequate amounts. Multiple studies and meta-analyses were performed to study whether probiotics reduce NEC in preterm infants. Results of the latest Cochrane review showed a statistically significant reduction in the incidence of NEC and mortality in infants who received enteral probiotics.[6] The trials included in the above-mentioned review, however, were highly variable in their inclusion criteria; baseline risk of NEC in control groups; and most importantly, timing, dose, formulation of probiotics, and feeding regimen.[6] This variability necessitates the caution with which the results may be interpreted.

The largest randomized adequately powered, double-blinded, placebo-controlled trial that showed a statistically significant reduction of NEC in VLBW infants was published in 2013.[37] This trial was conducted in 10 centers across Australia and New Zealand and used a combination of three bacteria in the intervention group: Bifidobacterium infantis, Streptococcus thermophilus, and Bifidobacterium lactis. There were no differences in primary outcomes between the groups (late-onset sepsis and all-cause mortality). NEC incidence was a secondary outcome. The incidence of NEC was reduced from 4.4% in the control group to 2% in the intervention group (RR 0.46 with 95% CI 0.23-0.93. $P = 0.03$). Babies with birth weights of less than 1000 grams did not show a benefit, a finding also seen in previous studies. The results of that trial were marred by the fact that in 2014 the manufacturer recalled the product used in the intervention group (ABC Dophilus; Solgar, Inc). The reason for the recall was a report by CDC that showed contamination of the product by a fungus Rhizopus oryzae, which caused a lethal infection in a premature infant.[24] This incident brings a safety concern for using live bacteria in preparations that are not considered pharmaceutical-grade quality in preterm infants whose immune systems are compromised.

Results of a large study that evaluated the effect of the probiotic bacterium Bifidibacterium breve BBG-001 on NEC and sepsis were published in 2016.[16] This study was randomized, double-blinded, and adequately powered to detect differences in primary outcomes: NEC (Bell stage 2 or 3), late-onset culture-positive sepsis, and death before discharge. There was no statistically significant reduction of NEC in the intervention group. No differences in other primary outcomes were observed between the groups either. This study also revealed that about half of the infants in the control group were colonized with the bacterium used for intervention by the end of the trial, raising a concern about potential cross-contamination of infants in the control groups of probiotic studies.[16]

In conclusion, although probiotics remain a promising preventative strategy for NEC, we should not recommend them for routine use in NICUs at this time. Strong evidence supporting the use of specific probiotics that are pharmaceutical grade for NEC prevention is lacking, especially in ELBW infants who are at the highest risk for developing this devastating disease. The following issues need to be addressed:

1. Probiotic formulations need to be manufactured under strict pharmaceutical regulations by country-specific agencies to ensure safety and quality of these agents.
2. Each probiotic strain or a combination of strains needs to be assessed separately by an adequately powered, randomized, blinded, and placebo-controlled trial before any recommendation for their widespread use can be made.

Key Points

- Different medical entities are currently grouped in one diagnosis of NEC.
- Development of a clear definition for NEC is needed for advancement of research as well as diagnostic, prevention, and treatment efforts.
- GI tract immaturity, intestinal inflammation, and dysbiosis are important pathophysiologic components of "classic" NEC.
- No reliable markers of early stages of this disease are available at this time and diagnosis is often delayed.
- Treatment options for NEC that are utilized at this time are only supportive.
- Standard feeding protocols using breast milk have been shown to decrease incidence of NEC.

Disorders of Carbohydrate Metabolism in the Neonate

MEENA GARG AND SHERIN U. DEVASKAR

The fetus depends entirely on the mother for its nutritional needs, of which glucose is the principal energy substrate that fuels fetal growth and metabolism. At birth, when the maternal supply is discontinued, the neonate must adjust to an independent existence. This transition to the extrauterine environment is often perturbed by alterations in the mother's metabolism or by intrinsic fetal and placental problems that result in changes in the neonate's glucose homeostasis. An understanding of the normal physiologic adaptation of the maternal–fetal nutritional relationship during pregnancy and of fetal glucose homeostasis and glucose metabolism during the transition to extrauterine life serves as a framework for evaluating disordered glucose metabolism in the neonate.

Placental Transport of Nutrients: Maternal–Fetal Relationship

The fetus is entirely dependent on the mother for nutrients supplied by the placenta. Yet the fetus is hormonally independent of the mother (Fig. 86.1), since no maternal peptide hormones are transported to the fetus in any significant amounts. The fetal endocrine and paracrine responses are mediated by the transport of nutrients such as glucose and amino acids.

Glucose

Glucose is the primary substrate for fetal energy metabolism for which the fetus depends entirely on maternal glucose because of minimal fetal gluconeogenesis.[26,63] Glucose is transported to the fetus along a downward concentration gradient via facilitated transport mediated by glucose transporters (GLUTs) encoded by the SCL2A genes.[64] A higher concentration of GLUT 1 is present on the maternal side of the syncytiotrophoblastic (SC) membrane compared to the fetal side of the SC basal membrane, suggesting a rate limiting step in glucose transport. In normal pregnancies, the plasma glucose concentration of the fetus is about 70%-80% of that of the mother. Because the range of glucose concentrations observed in human pregnancy does not saturate maternal–fetal glucose transfer, even when complicated by diabetes, fetal glucose uptake becomes excessive as the maternal glucose concentration increases. When fetal glucose uptake exceeds the requirements of energy production and growth, the excess glucose is stored as glycogen and triglycerides. Glucose transfer by placenta is also affected by the placental surface area, glucose metabolism, and blood flow.

Fatty Acids

A significant amount of fatty acids are transported to the fetus, as they are a critical source of energy and are an essential component of cell membranes, tissue development (white adipose tissue), and organogenesis (brain).[63] The transfer of nonesterified fatty acids (NEFA) from the mother to the fetus occurs by simple diffusion. A progressive shortening of chain length from C16-C8 is associated with an increased transfer rate. Protein binding appears to slow the rate of transfer. A number of fatty acid transport proteins (FATP 1-4, and 6) that are present in SC membranes in placenta are involved in the cellular uptake of long-chain fatty acids.[64] In addition, a significant amount of nonessential fatty acids appears to be synthesized de novo by the fetus in utero. Maternal adipose tissue and dietary intake are the primary sources of transplacental long chain polyunsaturated fatty acids (LCPUFA) to the fetus.[43]

Amino Acids

Amino acids are transported to the fetus against a concentration gradient by a carrier-mediated transport process. Amino acids may be transported through the placenta either unchanged or after placental metabolism and processing; for example, leucine can be transferred intact or as its keto analogue α-ketoisocaproic acid. The syncytiotrophoblast is usually considered the main transport epithelium of the term placenta (see Fig. 86.1). Amino acids are transported by means of energy-dependent processes through selective amino acid transport systems.

Abstract

Glucose, a six-carbon sugar, is the most important source of energy for all cells and is a universal currency for energy (ATP) production. It is also an essential source of energy for brain metabolism. The fasting blood glucose concentration in the adult is regulated within a rather narrow range (70-100 mg/dL), representing a balance between utilization of glucose to fuel cellular metabolic processes and availability of glucose to sustain the fetus via maternal–placental transport, transitioning in the newborn by glycogenolysis and gluconeogenesis while nutritional intake is established. After separation from the placenta, disturbances in the glucose homeostasis resulting in hypoglycemia are common occurrences in the preterm and term newborn infants. Yet uncertainty regarding the definition of hypoglycemia and long-term untoward effects of transient or recurrent hypoglycemia remain. The pancreatic beta cell maintains steady state blood glucose by a complex feedback mechanism involving the glucose sensing K_{ATP} channels toward regulating insulin secretion. Mutations in K_{ATP} channel genes can result in hyperinsulinemia due to loss of K_{ATP} function and continuous opening of Ca+ channels facilitating insulin release or neonatal diabetes due to gain of K_{ATP} channel function and closure of Ca+ channels that deters insulin release. Adequate storage of glucose and function of skeletal muscle, cardiac muscle, and white adipose tissue requires hormonal regulation by insulin and glucagon. Hepatic glycogen storage is essential for successful glycogenolysis, a process necessary for maintaining glucose homeostasis during the fasting state encountered between milk intake in the newborn. In this chapter we discuss various congenital and acquired conditions in the neonate that perturb glucose homeostasis.

Other Fetal Substrates

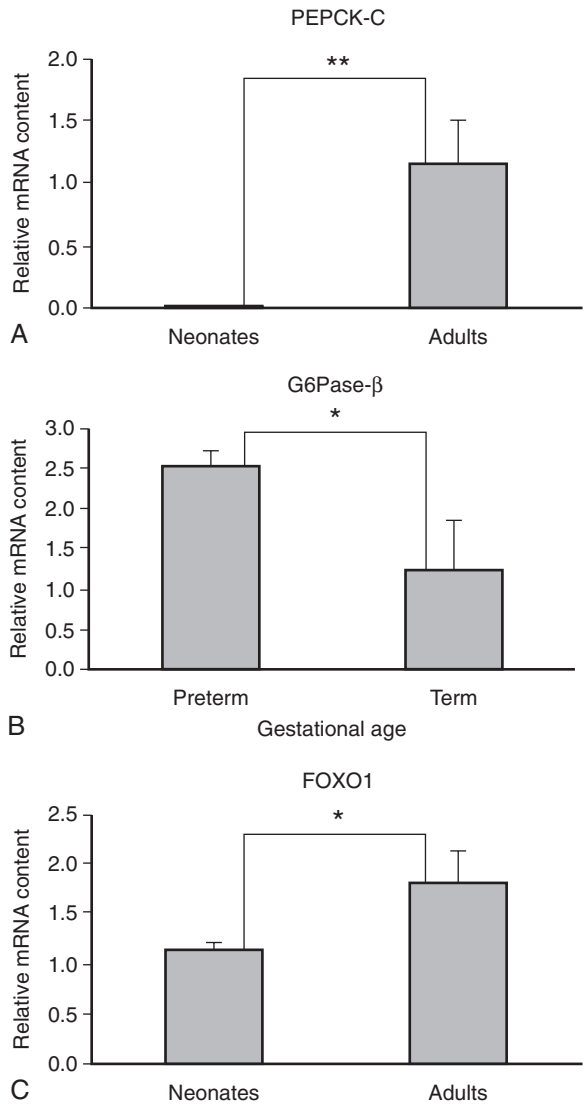
β-Hydroxybutyrate and possibly acetoacetate, the major ketone bodies, are transported along a concentration gradient.[22,34] The concentration of β-hydroxybutyrate in fetal blood is significantly less than that in maternal plasma (≈50%); however, a linear correlation between the maternal and fetal concentrations has been reported.

Glycerol

There is a linear correlation between maternal and fetal glycerol levels, with the fetal level in most instances being somewhat lower than the simultaneously determined maternal plasma level.[63]

Lactate

Data on the maternal–fetal lactate relationship in human studies are conflicting. Experimental data in sheep demonstrated placental production and fetal use of lactate, but data in human studies showed higher levels of lactate in fetal than in maternal blood. In the few studies in which umbilical artery and vein samples were obtained simultaneously, the data could be interpreted as net fetal production and placental clearance of lactate.



Fetal Hormones Mediating Growth

Insulin-like growth factors (IGF I and II) are highly expressed in all fetal tissues. IGF I in fetus is nutrient sensitive and corresponds with fetal growth independent of growth hormone. Immunoreactive insulin has been demonstrated in both plasma and pancreatic tissue as early as 8 weeks of gestation; the source appears to be the fetal pancreas, because the placenta is impermeable to insulin. At 13-18 weeks of gestation, the fetal insulin response to sustained maternal hyperglycemia is negligible. However, at term, the fetus is capable of a significant response to prolonged hyperglycemia, although to a lesser degree than adults. When the fetus receives appropriate glucose from the mother, the requirement for an insulin response is minimal. With repeated episodes of hyperglycemia, as in maternal diabetes, a greater insulin response is seen, indicating that B-cell sensitivity is being induced or enhanced. That insulin may modify the growth rate in utero has been shown by the positive correlation between the fetal plasma insulin concentration and fetal weight. Human growth hormone (GH) has been measured as early as 9 weeks of gestation and increases rapidly between the 11th and 16th weeks. Because the transplacental transfer of GH is negligible, the fetal pituitary appears to be its source in the fetus. At term, fetal plasma GH levels are higher than those of maternal plasma. Unlike those of adults, fetal GH levels are not suppressed during hyperglycemia and actually show a paradoxic rise. Several studies have demonstrated the role of insulin as the growth-promoting hormone of the fetus and that the fetus can sustain normal growth in the absence of GH.

Fetal Glucose Metabolism

Under normal circumstances (i.e., in an uncomplicated, normal pregnancy), the fetus is entirely dependent on the mother for a continuous supply of glucose for both energy metabolism and the synthesis of other metabolic substrates.[63] The fetal liver contains the full complement of enzymes required for the synthesis and breakdown of glycogen. Hepatic glycogen content is low early in gestation; a slow, continuous increase occurs between 15 and 20 weeks; and a rapid accumulation of glycogen in the liver is observed late. The fetus also has all the strategic hepatic enzymes involved in gluconeogenesis, although their levels are lower than those in adults.[38] The only exception is cytosolic phosphoenolpyruvate carboxykinase (PEPCK), which, at least in the rat, is not expressed in utero and appears immediately after birth (Fig. 86.2).[23] Data in humans in vivo are not available; however, in nonhuman primates, mitochondrial PEPCK and PEPCK-C gene expression increase with advancing gestational age, while glucose-6-phosphatase-alpha (G6Pase-a) and its target gene FOXO1 expression are higher at preterm compared to term gestation.[38] In the mammalian species studied, the gluconeogenic capacity is not expressed in utero under unperturbed circumstances, and the contribution of gluconeogenesis from lactate, pyruvate, or alanine to glucose is quantitatively negligible.[15,25] Studies in humans and animals have consistently demonstrated that the fetus does not produce glucose and that maternal glucose is the only source of fetal glucose.

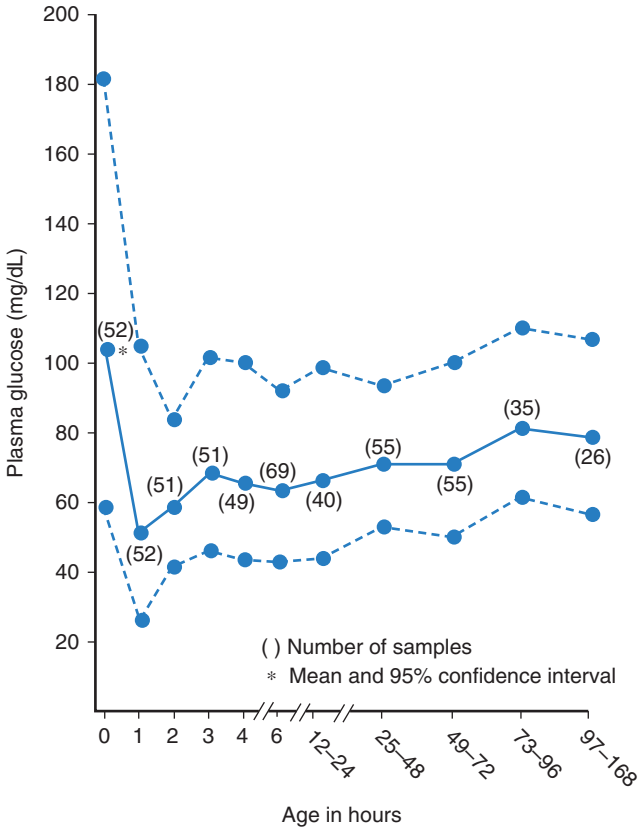
Fluctuations in maternal blood glucose are rapidly reflected in parallel changes in fetal glucose concentration. These variations occur even in response to acute hypoglycemia induced by insulin infusion in the mother during sheep pregnancy. However, if maternal hypoglycemia is prolonged, the fetus begins glucose production.[5] Whether such a response can occur in human pregnancy has not been examined and cannot be pursued without violating ethical standards. Glucose is the primary fuel for the fetus, accounting for about 80% of fetal energy consumption. The remaining 20% of fetal energy needs is provided by lactate, amino acids, and other means.

Glucose Metabolism After Birth



At birth, after separation from the umbilical circulation, the supply of glucose and other nutrients abruptly ceases, and the newborn infant has to mobilize its depots to meet energy requirements. This initial drop in glucose concentration may be an essential step in activating physiologic processes necessary for postnatal survival, such as promoting glucose production by gluconeogenesis, stimulation of appetite, adaptation to fast/feed cycles, and enhancement of oxidative fat metabolism. Acute surge in the levels of circulating epinephrine, norepinephrine, and glucagon and a fall in the levels of insulin coincides with clamping of the umbilical cord. These hormones concomitantly mobilize hepatic glycogen and stimulate gluconeogenesis, resulting in a steady rate of glucose production and maintenance of the plasma glucose concentration.

The plasma glucose concentration in umbilical vein blood is about 80% of the prevailing maternal blood glucose concentration. After birth, the plasma glucose concentration falls in all infants, reaching its lowest value between 30 and 90 minutes after birth. Thereafter, in full-term healthy neonates, the plasma glucose concentration rises and is maintained at a steady level of 40-80 mg/dL. Full-term newborn infants can tolerate fasting without a significant change in the blood glucose concentration. Fasting up to 9 hours after a meal did not cause a decrease in the plasma glucose concentration. After 4-6 hours post feeding state, steady state plasma glucose concentration is maintained with interactions between insulin and counter regulatory hormones (glucagon, cortisol, GH, epinephrine, and norepinephrine). Prolonged fasting state triggers increased utilization of FFA and ketone bodies with decrease in hepatic glycogenesis and increase in gluconeogenesis in response to increase in circulating glucagon and decrease in insulin concentrations.[25]

In full-term infants, the plasma glucose levels obtained at random intervals during the first week after birth have ranged from 40-100 mg/dL, with a mean of 80 mg/dL (Fig. 86.3).[25,34,64] These levels are higher than those previously reported in fasting infants and reflect changes in feeding practices and the random nature of measurements. The plasma glucose concentration in healthy, asymptomatic, breastfed babies has been reported to be lower with an average of 65 mg/dL (range 27-95 mg/dL) than that in formula-fed infants (mean 72 mg/dL, range 45-112 mg/dL) during the first 24 hours of life, but reveal higher blood ketone body concentration.[25] The plasma glucose values in infants who are small for gestational age (SGA) and in premature infants are somewhat lower.[28,32] Hypoglycemia in the neonatal period cannot be described by a single value. Most investigators consider a plasma glucose level lower than 45 mg/dL in the first 24 hours of life, and preprandial glucose less than 50 mg/dL up to 48 hours of age and less than 60 mg/dL after 48 hours of age[2] as meeting the criteria of hypoglycemia. Additionally, there are differences between arterial and venous sample values, venous being 10% lower and when comparing whole blood versus plasma, whole blood being 15% lower.

During hypoglycemia, endogenous hepatic glucose production (EHGP) is derived from gluconeogenesis and

• **Fig. 86.3** Plasma glucose levels in healthy term neonates delivered vaginally with birth weight between 2.5 and 4 kg. (From Srinivasan G, et al. Plasma glucose values in normal neonates: a new look. *J Pediatr.* 1986;109:114.)

glycogenolysis. The rates of endogenous glucose production in both full-term and preterm infants are significantly higher than in adults.[19] In preterm infants, gluconeogenesis is attributed to account for 72% of EHGP.[52,53] On average, the neonate produces glucose at rates between 4 and 6 mg/kg per minute. The higher rates of glucose production in the neonate reflect the higher ratio of brain to body weight, the brain being the major glucose-utilizing organ. In the first few days after birth, the rate of glucose production during fasting in full-term infants has been reported to decrease slightly. As the infant grows, the rate of glucose production expressed per unit of body weight decreases, so by adolescence, it approaches the rate seen in adults.

EHGP depends on (1) adequate glycogen stores, (2) sufficient supplies of endogenous gluconeogenic precursors, (3) normally functioning hepatic gluconeogenic and glycogenolytic systems, and (4) a normal endocrine system for modulating these processes. At birth, the neonate has glycogen stores that are greater than those in the adult. However, because of twofold greater basal glucose use, the stores begin to decline within 2-3 hours after birth. Muscle and cardiac carbohydrate levels fall more slowly. During asphyxia, the energy requirements are met by anaerobic glycolysis, an inefficient mechanism that results in a limited amount of energy and a decrease in glycogen stores. In premature infants, both total carbohydrate and fat content are reduced, and depletion of liver carbohydrates occurs. Endogenous *gluconeogenic* substrate availability is probably not a limiting factor, because the concentration of plasma amino acids is high at birth as a consequence of active placental transport. Similarly, other *gluconeogenic* precursors, such as lactate, pyruvate, and glycerol, are also increased. Nevertheless, active gluconeogenesis has been demonstrated in the human newborn soon after birth.[15] Finally, EHGP is normally regulated; that is, it decreases in response to glucose as well as insulin infusion in both full-term and preterm healthy neonates.[29] However, in extremely immature infants and in sick or stressed neonates, exogenous glucose infusion may not completely suppress endogenous glucose production.

The fall in blood glucose that normally occurs after birth is accompanied by an increased level of GH, a relatively low concentration of immunoreactive insulin, and an increase in plasma glucagon. The neonate shows an attenuated but significant insulin response to a variety of stimuli. After the oral administration of glucose, the insulin response in the normal neonate is similar to that in adults with chemical diabetes, that is, a lag in insulin response and a delayed peak. The premature infant has a minimal and variable insulin response, but the values are markedly increased by the intravenous administration of glucose plus amino acids. The physiologic role of increased GH levels has not been defined; GH values are high during the first 48-72 hours and gradually decline but are still elevated at 8 weeks of age. In addition, the newborn shows a paradoxic rise in GH after glucose infusion. Plasma glucagon values at birth are similar to or slightly higher than maternal levels. Glucagon and GH are not suppressed during hyperglycemia. In healthy newborns, intravenous and oral alanine feedings raise plasma glucagon and glucose levels.

Adaptation to prolonged starvation in adult humans is facilitated by the ability of the brain to derive much of its energy from the oxidation of ketone bodies, which decreases the need for gluconeogenesis and spares muscle protein. The enzymes involved in ketone body utilization pathways are present in the brain tissue of human fetuses and newborns. That ketone bodies can be used by the brain of infants and children has been shown by measurements of arteriovenous differences across the brain.

The transition from an intrauterine environment to independent extrauterine life is also characterized by intense lipid mobilization, as shown by a rapid increase in plasma glycerol and FFAs. In addition, there is a shift in the sources of energy for oxidative metabolism, as evidenced by a decline in the respiratory quotient. An increased contribution of fat to oxidative metabolism is reflected in a drop in the respiratory quotient from near 1.0 at birth to a level between 0.8 and 0.85 within a few hours after birth. Evidence of significant lipolysis in the neonate has been obtained by using isotopic tracers to measure glycerol kinetics.[44] These studies showed that lipolysis in the neonate occurs at rates almost threefold greater than those in adults and that the major metabolic fate of glycerol released as a result of lipolysis

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

is conversion to glucose. Free fatty acids are used by the heart and muscle in the absence of readily available glucose, producing ketone bodies that readily cross the blood–brain barrier to be used as fuel sources for the brain. Therefore, the hypoglycemic neonate may remain asymptomatic because of the ability in utilizing alternate nutrients (ketones and lactate). However, neonatal hypoglycemia caused by hyperinsulinism leads to reduced concentrations of free fatty acids and ketone bodies, depriving the brain of an alternative energy source of ketones for fueling cerebral metabolism. This results in neuroglycopenic symptoms with severe neurologic injury and dysfunction.[41]

Measurement of Glucose

Factors frequently overlooked in the interpretation of glucose concentration are the type of sample and the method of analysis. Whole blood includes red blood cells which, therefore, display a glucose concentration lower than that of plasma. Plasma glucose values are higher than those of whole blood by about 14%; the difference may be greater at very low glucose values (<30 mg/dL). Whole-blood glucose content also varies in accordance with the hematocrit. Neonatal red blood cells contain high concentrations of glycolytic intermediates; therefore, whole blood must be deproteinized before analysis. Capillary blood samples should be collected from a warm heel and kept on ice, because the rate of in vitro glycolysis is increased in red blood cells at room temperature; whole-blood glucose values may drop 15-20 mg/dL per hour if the sample is allowed to stand at room temperature. The most frequently used method for glucose determination in the laboratory is an automatic analysis technique with glucose oxidase or a commercial glucose oxidase immobilized electrode. Plasma or serum glucose concentrations are determined, and the results are very accurate.

In most newborn nurseries, the rapid point-of-care assessment of whole-blood glucose concentrations is accomplished by a glucose oxidase and peroxidase chromogen test strip method, either alone or with a reflectance colorimeter. However, all test strip methods show significant variations in glucose concentrations compared with laboratory methods, particularly in the low glucose range (<45 mg/dL).[12] Devices and operator techniques vary, with confounding influences of incubation time and the hematocrit values. There should not be sole reliance on test strip devices, and tests resulting in borderline values (<40-45 mg/dL) should be repeated by using standard laboratory methods.

Continuous glucose monitoring using a subcutaneously placed microdialysis sensor has been validated in adults and children with diabetes. The feasibility, safety, and usefulness of these techniques have been examined in babies with low birth weight.[12,39] However, similar to point-of-care devices, these methods cannot measure glucose levels less than 45 mg/dL with confidence. Thus far, continuous glucose monitoring has been used mostly for research studies, and its use in clinical setting is still limited.

Hypoglycemia

Perturbations in glucose metabolism after birth caused by failure to adapt to the extrauterine environment, as a result of either alterations in maternal metabolism or intrinsic metabolic problems in the neonate, often result in hypoglycemia. Despite many years of research, uncertainty remains regarding the concentration of glucose responsible for long-term untoward effects of transient or recurrent hypoglycemia.[1,2] The controversy arises partly because of the spontaneous decrease followed by recovery of the blood glucose concentration after birth and partly because many neonates have very low blood glucose concentrations without any clinical signs or symptoms (i.e., asymptomatic hypoglycemia).

Neuroglycopenia is known to cause seizures and permanent brain damage.[45] The critical glucose concentration at which there is an inadequate supply of glucose for the brain has been suggested to be less than 47 mg/dL because of altered somatosensory-evoked potentials and lower scores noted for mental and motor development. However, a subsequent study of 2-year-old and 15-year-old children, who were born at less than 32 weeks' gestation age with a blood glucose less than 47 mg/dL over at least 3 days when less than 10 days of postnatal age, found them to have no developmental or physical disability when compared to matched controls without hypoglycemia.[56]

Another recent study from University of Arkansas for Medical Sciences on 1400 10-year-old fourth graders with transient hypoglycemia (glucose <45 mg/dL) reported an association with decreased literacy and mathematics proficiency at fourth-grade achievement testing when compared to age and size-matched controls.[33]

McKinlay et al. reported no association between adverse neurodevelopmental outcome at 2 years and neonatal hypoglycemia (blood glucose <47 mg/dL) in 404 infants with birth weight less than 2500 g or greater than 4500 g and less than 37 weeks of gestational age.[39] The glucose was monitored continuously in this cohort, and abnormal neurodevelopmental outcomes showed a U-shaped relationship with adverse cognitive outcomes associated with time spent outside the range of 54-72 mg/dL in the first 48 hours of life.[39] In summary, inadequate blood supply to the brain or neuroglycopenia probably occurs at a range of glucose values. The harmful effect of blood glucose may be at a low, as well as unstable, high blood glucose values.

Clinical signs of hypoglycemia in the neonate are not specific to alterations in glucose concentration but rather reflect an immaturity of counter-regulatory hormonal stress response responsible for classical symptoms of hypoglycemia in older children and adults. Therefore, the presence or absence of such clinical signs cannot be used reliably to define neonatal hypoglycemia. The statistical definition of hypoglycemia is based on surveys of large numbers of infants. Abnormality is defined as a blood glucose concentration that falls outside a prescribed limit, for example, outside two standard deviations from the norm. AAP guidelines

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

also recommend screening in the first 24 hours of life of all asymptomatic at-risk infants for neonatal hypoglycemia (preterm infants 34-36 6/7 weeks and term infants who were born to mothers with diabetes, small for gestational age, or large for gestational age).[2] The AAP algorithm indicates lowest acceptable transitional glucose values of 25 mg/dL. Intervention is recommended between 25 and 40 mg/dL during the first 4 hours of life or during transition after birth in healthy neonates.[2] These levels approximate epidemiologic data at the 5th-10th percentile for glucose. From 4-24 hours after birth, the lowest level requiring action is 35 mg/dL (range is 35–45 mg/dL). Early feeding initiation is critical for establishing breastfeeding as well as in maintaining plasma glucose levels. This practice is different from the 1960s when newborns were generally fasted between 8 and 24 hours after birth.

A recent recommendation has emerged from the Pediatric Endocrine Society.[55] For high-risk neonates without a suspected congenital hypoglycemia disorder, they suggest the goal of treatment be to maintain a plasma glucose concentration greater than 50 mg/dL for those aged less than 48 hours and greater than 60 mg/dL for those aged greater than 48 hours. Higher treatment targets should be considered for those with a suspected genetic hypoglycemia disorder and for symptomatic neonates, because the risks of undertreatment outweigh those of overtreatment in these patients.

The definition of hypoglycemia for preterm infants should not be any different from that for full-term infants. Finally, hypoglycemia in the neonate should be described as transient or persistent, and in either or both of these cases, as symptomatic or asymptomatic. Such a description has implications for both clinical management and long-term consequences.

Transient hypoglycemia implies low glucose values that last only a short time if not corrected and that are confined to the newborn period. In contrast, persistent and recurrent hypoglycemia implies a form that requires prolonged management (glucose infusions for several days at high rates of infusion) and perhaps pharmacologic intervention. Several of these hypoglycemia syndromes may continue throughout infancy and childhood.

The clinical manifestations of hypoglycemia are nonspecific and similar to those of many disorders in newborn infants (Box 86.1). The clinical signs and symptoms of hypoglycemia should improve with correction of the low glucose concentration. In addition, careful attention should be given to ensure that other associated disorders (e.g., sepsis, asphyxia) are not missed.

Because of its implications for both long-term prognosis and clinical management, it is worthwhile to consider two types of neonatal hypoglycemia: those cases limited to the newborn period (transient hypoglycemia) and those cases continuing over an extended period of time or occurring more than once (persistent or recurrent hypoglycemia) (Box 86.2). Transient hypoglycemia is often a consequence of changes in the metabolic environment in utero or ex utero, whereas persistent or recurrent hypoglycemia arises from intrinsic metabolic problems in the infant. Either type of hypoglycemia may manifest asymptomatically or symptomatically.

• BOX 86.1 Clinical Symptoms and Signs of Hypoglycemia*

- Abnormal crying
- Irritability
- Apnea, cyanotic spells
- Jitteriness, tremors
- Feeding difficulty
- Lethargy or stupor
- Grunting, tachypnea
- Seizures
- Hypothermia
- Sweating
- Hypotonia, limpness
- Tachycardia

*Clinical signs should be alleviated with concomitant correction of plasma glucose levels.

Transient Hypoglycemia Caused by Changes in Maternal Metabolism

Intrapartum Glucose Administration

As discussed, the fetus is entirely dependent on the mother for the supply of glucose, and fetal glucose concentration closely mimics that of the mother.[63] An increase in maternal glucose concentration as a result of exogenous glucose infusion causes an increase in fetal glucose concentration, which in turn causes an increase in fetal insulin levels. Studies in animals have shown that fetal hyperinsulinism, caused by either direct infusion of insulin to the fetus or fetal hyperglycemia, results in an increased metabolic rate in the fetus, fetal hypoxemia, and metabolic acidosis. The acute administration of glucose during the intrapartum period—for example, to prevent hypotension during the conduction of anesthesia—has been shown to result in increased glucose, insulin, and lactate levels in the cord blood obtained at delivery. Fetal hyperinsulinism leads to hyperinsulinemia and hypoglycemia in the neonate. Similar observations have been reported in a diabetic pregnancy. Therefore, caution should be exercised in the administration of glucose to the mother during labor and delivery (see Chapter 27). Blood glucose concentrations in the mother should not be allowed to exceed those observed in the normal physiologic range.

Maternal Pharmacologic Treatment

Poor glycemic control during pregnancy has increased risk of diabetic embryopathy and congenital malformations. Insulin is the most common maternal therapy for gestational hyperglycemia; oral antihyperglycemic drugs are the other option. Among these agents, metformin alone or with insulin is used most commonly toward achieving timely glucose control and is associated with a decrease

• BOX 86.2 Causes of Neonatal Hypoglycemia

Transient Hypoglycemia

- Associated with changes in maternal metabolism
- Intrapartum administration of glucose
- Drug treatment
- Terbutaline, ritodrine, propranolol
- Oral hypoglycemic agents
- Diabetes in pregnancy: infant of diabetic mother
- Associated with neonatal problems
- Idiopathic condition or failure to adapt
- Intrauterine growth restriction
- Birth asphyxia
- Infection
- Hypothermia
- Hyperviscosity
- Erythroblastosis fetalis
- Other
- Iatrogenic causes
- Congenital cardiac malformations

Persistent or Recurrent Hypoglycemia

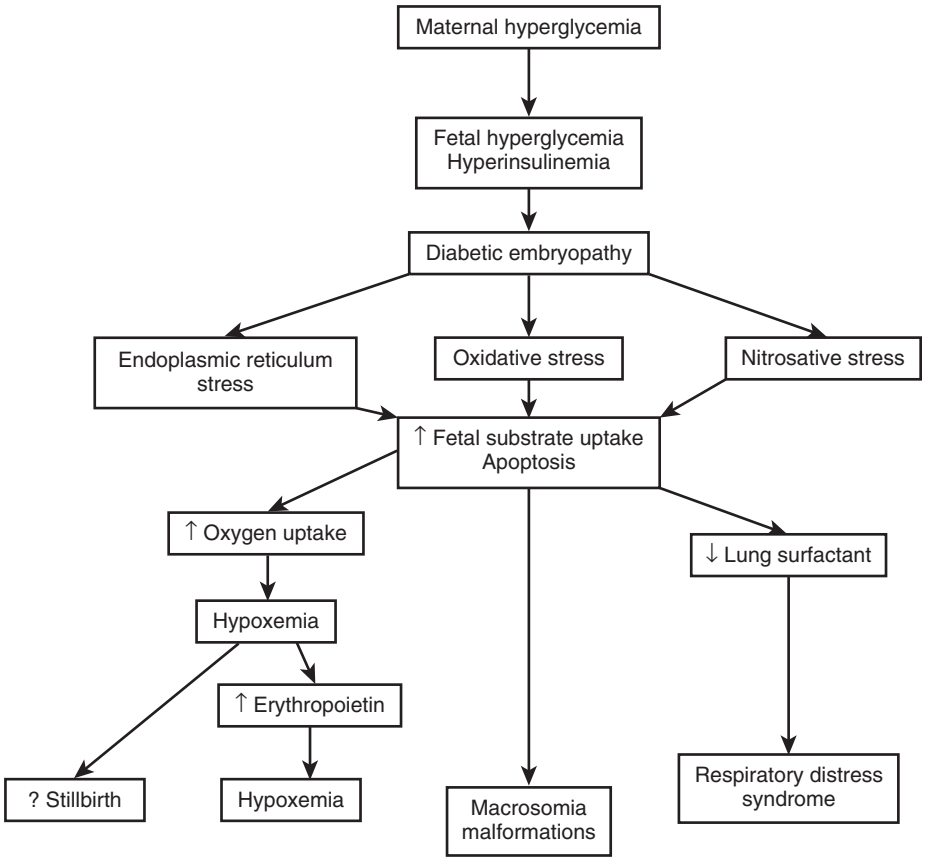
- Hyperinsulinism
- Congenital hyperinsulinism
- Beckwith-Wiedemann syndrome
- Endocrine disorders
- Pituitary insufficiency
- Cortisol deficiency
- Congenital glucagon deficiency
- Epinephrine deficiency
- Inborn errors of metabolism
- Carbohydrate metabolism
- Galactosemia
- Hepatic glycogen storage diseases
- Fructose intolerance
- Amino acid metabolism
- Maple syrup urine disease
- Propionic acidemia
- Methylmalonic acidemia
- Hereditary tyrosinemia
- 3-hydroxy, 3-methyl glutaric acidemia
- Ethylmalonic-adipic aciduria
- Glutaric acidemia type II
- Fatty acid metabolism
- Defects in carnitine metabolism
- Acyl-coenzyme dehydrogenase defects
- Neurohypoglycemia (hypoglycorrhachia) caused by defective glucose transport

in macrosomia, respiratory distress, and need for NICU admissions.[35] Glyburide is another oral antidiabetic drug with good efficacy, but it crosses the placenta and has a higher incidence of large-for-gestational-age (LGA) infants and neonatal hypoglycemia. Older antidiabetic drugs such as tolbutamide and chlorpropamide cross the placenta and produce pancreatic beta-cell hyperplasia and increased insulin release. Tolbutamide has a markedly prolonged half-life in the neonate and has been found in higher concentrations in the newborn after delivery than those found in maternal blood.

Benzothiadiazide diuretics may cause neonatal hypoglycemia by stimulation of fetal beta cells or secondary to an elevation in maternal glucose levels. Salicylates may cause hypoglycemia by uncoupling mitochondrial oxidative phosphorylation.

Oral beta-sympathomimetic tocolytic drugs such as terbutaline and ritodrine have caused sustained hypoglycemia and elevated cord blood insulin levels in infants delivered within 2 days after termination of tocolytic therapy (see Chapter 18). These agents may cause neonatal hypoglycemia through maternal hyperglycemia and fetal hyperglycemia and hyperinsulinemia.

Beta-adrenergic blocking agents such as propranolol cross the mammalian placenta, and their effects on the fetus are easily demonstrated. These drugs are used during pregnancy for the treatment of hypertension, hyperthyroidism, cardiac arrhythmia, and other conditions. They may interfere with the effects of the normal surge in catecholamine levels at birth. In animal studies, propranolol has been shown to impair fetal growth and may cause neonatal hypoglycemia and impair the thermogenic response to cold exposure.



• BOX 86.3 Morbidity in Infants of Diabetic Mothers

- Congenital anomalies
- Heart failure and septal hypertrophy of heart
- Surfactant deficiency respiratory distress syndrome, transient tachypnea of the newborn, persistent pulmonary hypertension
- Hyperbilirubinemia
- Hypoglycemia, hypocalcemia, hypomagnesemia
- Macrosomia, nerve injury related to birth trauma
- Renal vein thrombosis
- Small left colon
- Unexplained intrauterine demise
- Polycythemia
- Visceromegaly
- Predisposition to later-life obesity, insulin resistance, and diabetes

Diabetes in Pregnancy: The Infant of a Diabetic Mother

Despite advances in perinatal care, gestational and pregestational diabetes in the mother continues to result in neonatal morbidities involving major organ systems (Box 86.3). Many maternal and fetal–placental factors are implicated in the development of insulin resistance and gestational diabetes (GDM). The recent worldwide increase in obesity and diabetes at younger ages raises the concern for fetal programming. Small changes in the fetal metabolic environment can result in epigenetic modifications and gene expression lasting a lifetime and modifying the phenotype. The pathogenesis of the spectrum of fetal and neonatal morbidities in the IDM has now been described by a number of careful studies in human and animal models. Intermittent hyperglycemia in the mother results in hyperglycemia that causes hyperinsulinemia in the fetus because of hypertrophy

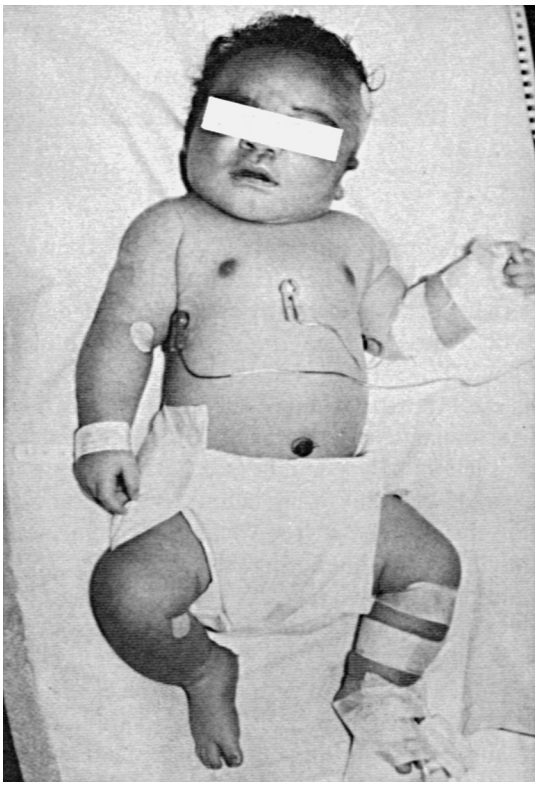
• **Fig. 86.4** Flow diagram of pathogenic events that result in fetal and neonatal morbidity in infants of diabetic mothers. (Modified from Schwartz R, et al. Infant of the diabetic mother. *J Pediatr Endocrinol.* 1992;5:197.)

of fetal pancreatic islets and beta cells and increased secretion of insulin. Because of the lack of significant transfer of insulin from the mother to the fetus in humans, the circulating insulin in the fetal compartment is mostly of fetal origin. Increased intracellular glucose concentration, by upregulated glucose transporters, enhances mitochondrial oxidative phosphorylation. The resulting increase in reactive oxygen species production plays an important role in diabetic embryopathy. Research studies and animal experiments show that aberrations in intracellular conditions result in oxidative stress, nitrosative stress, endoplasmic reticulum stress, and hexosamine stress.[20] These changes induce apoptosis and alterations in genetics and epigenetic systems, resulting in dysmorphogenesis.[20] Chronically higher fetal metabolic rate and oxygen consumption lead to relative hypoxemia, which in turn results in upregulation of proangiogenic factors, such as leptin, vascular endothelial growth factor (VEGF), or fibroblast growth factor 2 (FGF2), and matrix metalloproteinases (MMPs) as MMP14 and MMP15.[58] Fetal hypoxia caused by increased glycation of hemoglobin and reduced 2,3 DPG concentration, in addition to hyperglycemia and hyperinsulinemia, leads to increased erythropoietin and increased red blood cell mass resulting in polycythemia. In addition, hyperinsulinemia has been shown to suppress the production of surfactant in the lung and thus predisposes the infant to respiratory distress syndrome after birth (see Chapter 64). An excessive accumulation of glycogen in the liver, adipose tissue, and other tissues has also been observed in IDMs. The sequence of these metabolic events is outlined in Fig. 86.4.

Although the excessive transport of glucose from the mother to the fetus has been thought to be primarily responsible for fetal metabolic and physiologic perturbations in the IDM, nonglucose metabolites (fatty acids, amino acids, and micronutrients) play an important role as well. The increased concentration of these nutrients in the fetal circulation stimulates fetal insulin secretion, which in turn stimulates excessive fetal growth.



After birth, the newborn IDM whose mother's disease has not received rigorous antepartum management appears to be unable to produce sufficient circulating glucose and alternative fuels. Even infants of mothers with rigorous management (i.e., those who have maintained normoglycemia throughout gestation) develop significantly lower blood glucose concentrations than those of normal infants. In addition, they do not mobilize fatty acids from adipose tissue; as a result, their circulating levels of FFAs remain low, although a normal increase in plasma glycerol has been observed. Such a metabolic picture suggests persistent insulin action and the lack of a counter-regulatory hormonal response. The latter is confirmed by the lack of an increase in circulating glucagon and catecholamine levels in IDMs during hypoglycemia. The combination of hyperinsulinism and insufficient counter-regulation results in decreased hepatic glucose production, increased peripheral glucose uptake, and impaired lipolysis. When measured by

TABLE 86.1 Neonatal Outcome in Infants of Rigorously Managed Diabetic Mothers

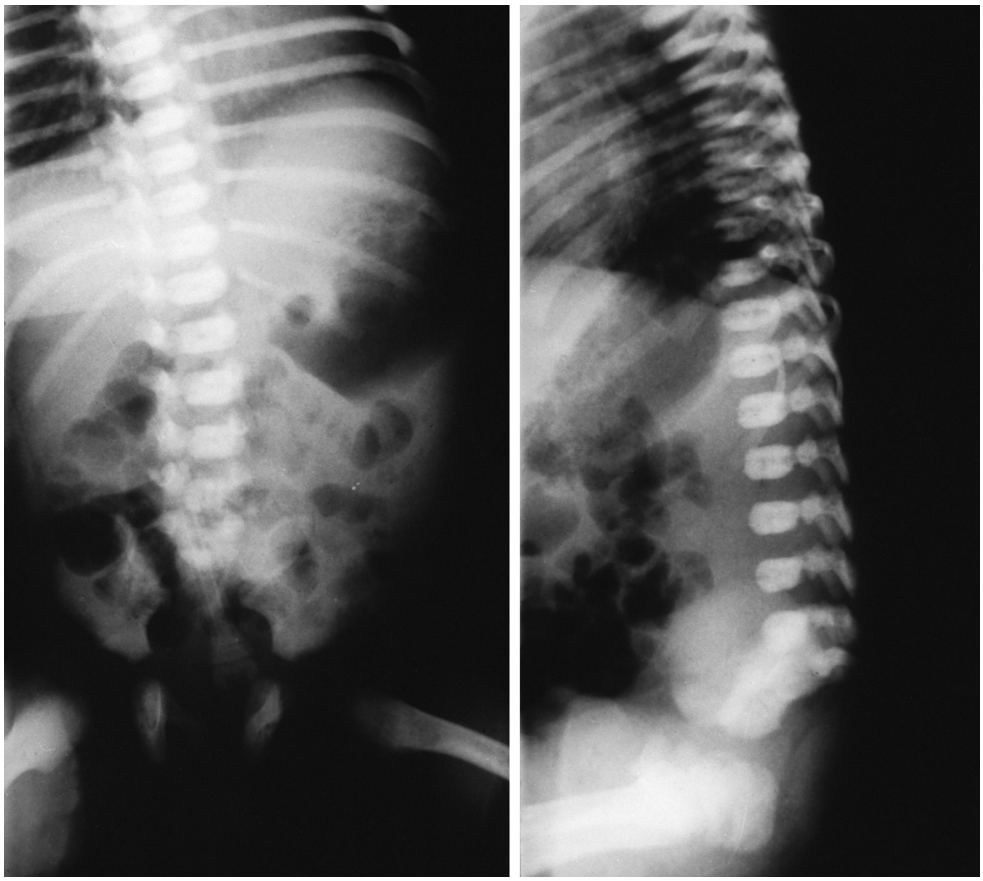
Parameter	Infants of Diabetic Mother (*N* = 78)	Controls (*N* = 78)	P
Birth weight (g)	3454 ± 817	3271 ± 621	—
Gestational age (wk)	37.9 ± 0.95	39.3 ± 1.7	.0001
K score*	0.77 ± 0.95	0.18 ± 0.91	.0001
Macrosomia (>4 kg)	19 (24%)	8 (10%)	.03
Large for gestational age	32 (41%)	12 (15%)	.0002
Hypoglycemia	11 (14%)	1 (1%)	0.0025
Hyperbilirubinemia	36 (46%)	18 (23%)	.002
Respiratory distress syndrome	9 (12%)	1 (1%)	.008
Admission to neonatal intensive care unit	21 (27%)	9 (12%)	.01

*The K score is a method of adjusting the birth weight in grams for the infant's gestational age. A K score of 1 represents the 90th percentile for weight; scores of 0 and –1 represent the 50th and 10th percentiles, respectively. Data from Aucott SW, et al. Rigorous management of insulin-dependent diabetes mellitus during pregnancy. *Acta Diabetol.* 1994;31:126.

• **Fig. 86.5** Infant of mother with gestational diabetes; the baby was born at 40 weeks of gestation with a birth weight of 4.6 kg. The infant developed hypoglycemia and was treated with intravenous glucose.

the isotope tracer dilution method, IDMs produce glucose at significantly lower rates than normal infants. In addition, their basal metabolic rates, or rates of oxygen consumption, have been reported to be lower than those of normal infants.

Several of these metabolic and morphologic abnormalities can be reversed with fastidious management of diabetes in the mother. Data from several studies showed that with rigorous management throughout pregnancy, IDMs do not become hypoglycemic and maintain normal rates of glucose production and basal metabolism.



Clinical Manifestations

It should be recognized that the clinical manifestations described here relate to diabetic mothers whose metabolism has not been well controlled. Data from a study in which maternal diabetes was rigorously managed by either an insulin infusion pump or split-dose insulin therapy are shown in Table 86.1. Despite rigorous management and reduced maternal hyperglycemia, significant morbidity may persist.

Macrosomia. At birth, these infants are obese, plethoric, and large for gestational age (LGA) and show evidence of excessive fat as well as visceromegaly in the form of a large liver, spleen, and heart (Fig. 86.5). Because the growth of the brain and possibly the kidney is not dependent on insulin, these two organs are normal in size. Careful management of maternal metabolism tends to reduce the incidence of macrosomia but does not prevent it entirely.

Congenital Anomalies. The incidence of congenital malformations is increased twofold to threefold in infants of insulin-dependent diabetic mothers compared with the normal population. The frequency of congenital anomalies is not increased in infants of gestationally diabetic mothers or in those of diabetic fathers. Chronic hyperglycemia in the diabetic embryo, causing accumulation of advanced glycosylation end-products (AGE) and glycated protein and oxidative stress, has been suggested to induce malformations.[20] A number of congenital anomalies, including facial, skeletal, and neural tube defects, were induced in the diabetic environment created in a RAGE (receptor for AGE) knock-out mouse model.[20] Dysmorphology of the cardiovascular system and genitourinary system has been reported. Caudal agenesis or dysplasia syndrome (Fig. 86.6) is seen with markedly increased frequency, especially in IDMs. This syndrome consists of agenesis or hypoplasia of the femora in conjunction with agenesis of the lower vertebrae and sacrum. Data from animal models show a complex process of genetic and epigenetic processes enhancing apoptosis and resulting in diabetic embryopathy with multiple structural defects. The frequency of congenital anomalies is significantly increased in mothers with poor metabolic control, as evidenced by increased hemoglobin A_{1c} levels early in

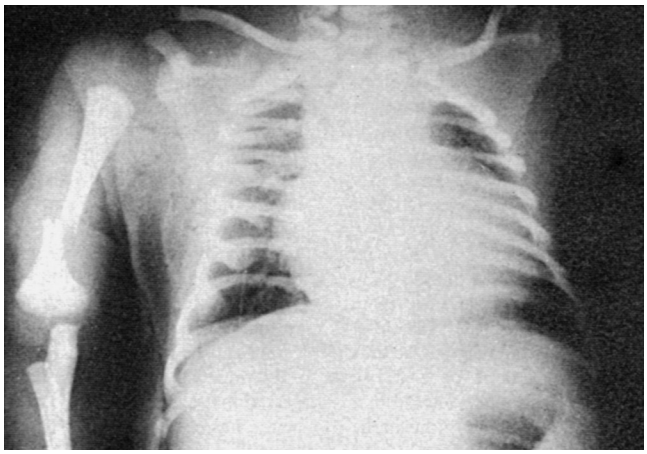
• **Fig. 86.6** Anteroposterior (*left*) and lateral (*right*) radiographs of sacral agenesis in an infant of a diabetic mother.

gestation, and a significant decrease in congenital malformations has been reported with rigorous metabolic regulation in the periconceptional period (see Chapter 18).

Hypoglycemia. The pathogenesis of hypoglycemia has been described already. Immediately after birth, there is a significant decrease in plasma glucose concentration, reaching a nadir between 30 and 90 minutes and followed by a spontaneous recovery in most infants. However, in some infants, the plasma glucose level remains persistently low (i.e., <45 mg/dL), necessitating intervention. Most of these infants are asymptomatic. Irrespective of symptoms, the current recommendation is to correct the hypoglycemia with an appropriate glucose infusion. It should be underscored that hypoglycemia in the newborn does not necessarily reflect the magnitude of antepartum metabolic control of the mother and may simply be the consequence of hyperglycemia during labor and delivery.

Hypocalcemia and Hypomagnesemia. See Chapter 87.



Alterations in calcium and magnesium homeostasis occur in about 50% of infants born to insulin-dependent diabetic mothers. Unlike hypoglycemia, hypocalcemia becomes apparent between 48 and 72 hours after birth. Plasma calcium concentrations of lower than 7 mg/dL are frequently observed. Hypocalcemia has been related to the severity and duration of maternal diabetes. In addition, it may be potentiated by prematurity and asphyxia. The mechanisms of hypocalcemia are probable failure of the IDM to mount an appropriate parathyroid hormone (PTH) response, persistently high levels of calcitonin, and possible alterations in vitamin D metabolism. Hypomagnesemia (≈1.5 mg/dL) has also been frequently observed. It is usually transient, and its pathophysiologic significance remains uncertain.

Both hypocalcemia and hypomagnesemia may be manifested with jitteriness and may require supplemental calcium therapy. However, in most infants, they are transient events that improve spontaneously.

The management strategies for other clinical problems, such as polycythemia (see Chapters 79 and 80), hyperbilirubinemia (see Chapter 91), and renal vein thrombosis (see Chapter 93), that occur with slightly higher frequency in IDMs are similar to those in otherwise normal infants.

Septal Hypertrophy of the Heart. Septal hypertrophy and cardiomegaly are specific phenotypic consequences of diabetes in pregnancy and may be manifested with heart failure in the neonate (Fig. 86.7). In addition, data in asymptomatic infants of gestationally diabetic mothers have shown alterations in diastolic function and decreased passive compliance of the ventricular myocardium. By serially evaluating cardiac growth in utero in the fetuses of diabetic mothers, it has been shown that despite good

• **Fig. 86.7** Chest radiograph of a vaginally delivered, full-term infant (4.7 kg) of a diabetic mother. The infant had cardiomegaly, hepatomegaly, congested lung fields, and fractures of the right humerus and left clavicle.

metabolic control, cardiac hypertrophy developed in late gestation (34-40 weeks). Although IDMs with septal hypertrophy may present with obstructive left heart failure, they may also be asymptomatic. Follow-up data show that cardiomyopathy in an IDM is a transient disease and usually disappears spontaneously within 6 months after birth. Otherwise minor functional changes, such as impaired diastolic filling, have been reported in infants of gestational diabetic mothers and are usually not clinically significant.

Management of the Diabetic Mother

See Chapter 18.

Strict metabolic control, improved fetal surveillance, early delivery, and neonatal intensive care have led to improved survival among IDMs. Preconceptional and early postconceptional metabolic control may decrease the incidence of congenital malformations. Improving maternal compliance, preventing ketoacidosis, and recognizing and treating pregnancy-induced hypertension and pyelonephritis are particularly important. Attempts should be made to maintain maternal fasting plasma glucose values at less than 80 mg/dL and 2-hour postprandial plasma glucose values at less than 120 mg/dL.

With appropriate ambulatory support, hospitalization is not required in most mothers. Indications for hospitalization include pregnancy-induced hypertension, acute or chronic polyhydramnios, infections, and poor metabolic control. Early screening for congenital malformations includes a determination of the maternal serum alpha-fetoprotein level for open neural tube defects and a level II ultrasound at 18-20 weeks of gestation (see Chapters 10 and 11). Follow-up ultrasonography is useful in the evaluation of amniotic fluid volume, fetal growth, and placental grading. Tests of fetal well-being begin in the second trimester (28-32 weeks of gestation). These tests usually include daily fetal movement counts and biweekly biophysical testing (nonstress testing, biophysical profile, or both) or nonstress testing combined with an amniotic fluid index (see Chapter 12).

With appropriate care and fetal surveillance, most patients are now monitored expectantly for the spontaneous onset of labor at term. Vaginal delivery is preferred, but obstetric factors may justify cesarean delivery. Caution should be exercised in the delivery of a macrosomic fetus at risk for traumatic complications. During labor, glucose and insulin therapy should be adjusted to maintain normoglycemia in the mother.

Delivery should take place in a hospital, where the newborn can be carefully monitored. Glucose values are checked during the first 3 hours after birth (typically between 30 and 60 minutes), sporadically before feedings, and any time symptoms are suspected. Feedings may be started as soon as the infant is stable, usually within 2-4 hours after birth, and continued at 3- to 4-hour intervals.

Even though physiologic and clinical data clearly demonstrate a marked reduction in fetal and neonatal morbidity and mortality in pregnancy with diabetes, studies from the United Kingdom failed to show that such a goal was achieved in clinical practice. Continuous rigorous surveillance of diabetes throughout the pregnancy and fastidious management of altered metabolism are required.

Prognosis

Improvements in antepartum care, fetal monitoring, rigorous control of maternal metabolism, and maternal education have all resulted in reduced perinatal mortality and morbidity. In addition, control of maternal metabolism during the periconceptional period has resulted in a decreased incidence of congenital malformations in IDMs. However, certain morbidities such as premature birth, cesarean section deliveries, hypoglycemia, macrosomia, and polycythemia, persist.[13] Additionally, as with birth weight less than 10th percentile body weight by gestational age, increased birth weight in IDM also increases the risk of type 2 diabetes mellitus and obesity phenotypes later in life because of fetal programming. Placental studies in preexisting diabetic pregnancies show higher birth weight/placental weight ratios compared to normal pregnancies, which may correlate with an increased risk for cardiovascular diseases in adult life.[24]

Even though macrosomic IDMs tend to revert to normal body composition during early childhood, they tend to be obese with increased adipose tissue mass during adolescence, followed by the development of later-life obesity and insulin resistance, as well as development of type 2 diabetes.[9,29] While these observations indicate that fetal hyperinsulinism and hyperglycemia, as well as hyperlipidemia, contribute toward an increase in the adult metabolic syndrome, the influence of genetics, environmental programming, and maternal weight cannot be entirely separated. The incidence of overweight and obesity in later childhood at ages 5–7 years varies depending on race and ethnicity.[60]

The evaluation of neurodevelopmental outcome of IDMs is confounded by the contribution of perinatal events such

as perinatal asphyxia and metabolic acidosis in addition to chronic metabolic insults and iron deficiency.[29] Increased red blood cell production can contribute to redistribution of iron from the developing neurons in the brain to the liver and bone marrow, producing neuronal iron deficiency, which has been correlated with limitations in cognitive development.[29] Electrophysiologic studies demonstrate a long-lasting impact on memory, indicating effect of prenatal iron deficiency on neural development.[29]

Several investigators have examined the impact of alterations in maternal metabolism, specifically changes in blood glucose and ketones, on neurodevelopment in the newborn period and early childhood in gestational diabetes as well as insulin-dependent diabetes. Intellectual delay at ages 3 and 5 years in infants born to women with acetonuria (a marker of poor metabolic control) has been observed.

Transient Hypoglycemia Associated With Neonatal Problems

Idiopathic Condition or Failure to Adapt

For apparently unknown reasons, a number of infants develop hypoglycemia, and the cases have been designated as idiopathic hypoglycemia or failure to adapt to the extrauterine environment. As maternal obstetric care continues to improve and more contributory factors are identified, the number of cases of idiopathic hypoglycemia continues to decrease. A careful maternal history should be obtained whenever an infant develops hypoglycemia for reasons that are not easily evident. Contributory factors may include maternal obesity and mild glucose intolerance in the mother.

Maternal Obesity

Many infants born to obese mothers without evidence of impaired glucose tolerance develop low blood glucose concentrations in the immediate newborn period. With the increasing incidence of obesity in the general population, the number of such babies continues to increase. Maternal obesity is associated with overweight offspring displaying abdominal obesity even in the absence of gestational hyperglycemia.[46] The exact mechanism of impaired glucose homeostasis in these infants is not clear yet but may pertain to maternal insulin resistance redirecting glucose from maternal tissues to the fetus.

Intrauterine Growth Restriction and Infants Who Are Small for Gestational Age

See Chapter 15.

Hypoglycemia has been frequently reported in infants who are SGA (<10th percentile in weight for gestational age) because of decrease in glycogen stores, adipose tissue, gluconeogenesis, decreased ability to oxidize free fatty acids, and increased sensitivity to insulin. Twenty-six percent of SGA infants were hypoglycemic (glucose <45 mg/dL) at greater than 2 hours of age in one study.[40] The incidence of hypoglycemia (blood glucose <45 mg/dL) in infants born SGA is 6%-26%, being higher in premature infants. Hypoglycemia, which may be either symptomatic or asymptomatic, is usually seen within the first 24 hours after birth. The incidence of hypoglycemia is variable, reflecting different causes of intrauterine growth restriction, such as maternal nutrition, uteroplacental insufficiency, fetal infection, or maternal metabolic perturbations. In addition, because polycythemia and fetal and neonatal hypoxemia are frequently seen in infants who are SGA, polycythemia and hypoxemia by themselves could contribute to the incidence of hypoglycemia.

The relation between neonatal hypoglycemia and so-called symmetric and asymmetric growth restriction has not been specifically addressed. In general, the consensus among investigators is that hypoglycemia is more common among infants with asymmetric growth restriction, because that group represents true intrauterine nutrient deprivation.

The pathogenesis of hypoglycemia has been the subject of numerous investigations and speculation in both humans and animal models. The IUGR fetus increases glucose uptake by increasing the transplacental glucose gradient as an adaptation to reduced placental size.[64] Clinical observations in infants who were SGA showed an early recruitment of fat for oxidative metabolism, as evidenced by a lower respiratory quotient and a higher rate of lipolysis, compared with infants who were appropriate sizes for gestational age. This finding led to the speculation of decreased glycogen stores and their early depletion in infants who are SGA. Early depletion of glycogen stores was also postulated based on the higher brain-to-body ratio of infants who are SGA and the dependence of the brain on glucose for oxidative metabolism. A decreased rate of gluconeogenesis has been proposed as a contributor to hypoglycemia in infants who are SGA based on high levels of gluconeogenic substrates and a lower glucose response to the administration of alanine, a strategic gluconeogenic amino acid. Infants who are SGA have been observed to mount a significant glucagon response to hypoglycemia. However, the response to exogenous glucagon administration has been variable, particularly in relation to plasma amino acids. Hypoglycemic infants who are SGA do not decrease plasma amino acids in response to an intravenous infusion of glucagon. The growth hormone response to hypoglycemia and glucose infusion is reported to be normal.

Studies of the IUGR placenta demonstrate a decrease in transplacental amino acid transfer (e.g., leucine and lysine) as well as an increase in FABP1-4, thereby increasing fat accumulation in response to a hypoxic IUGR fetus.[64]

When an infant born with a low birth weight exhibits a slow postnatal growth rate between 0 and 2 years of age, and an exponential growth rate thereafter, an increased propensity toward developing diabetes mellitus and cardiovascular disease as an adult in both men and women is seen.[6,18]

The management of these IUGR infants involves treatment of the associated clinical problems—hypoxia, hyperviscosity, careful monitoring for hypoglycemia, and the early establishment of adequate nutrition. The treatment of hypoglycemia is similar to the one outlined later.

Hepatic Glucose-6-Phosphatase and Prematurity

Glucose-6-phosphatase is a membrane-bound enzyme associated with the endoplasmic reticulum in the liver and the kidney—the two important glucogenic organs. It catalyzes the breakdown of glucose-6-phosphate into free glucose, the terminal step in both glycogenolysis and gluconeogenesis. Fetal glucose-6-phosphatase–alpha is decreased but increased in term gestation.[38] In a series of studies, a suggestion has been presented that the low activity of glucose-6-phosphatase, partly influenced by hormonal, nutrient, and other factors, including stress, may contribute to hypoglycemia in premature infants. However, the direct cause-and-effect relationship is difficult to discern from their studies. A severe deficiency of glucose-6-phosphatase certainly can lead to profound hypoglycemia, as in glycogen storage disease type I.

Neonatal Encephalopathy

The mechanism of low glucose after perinatal asphyxia remains unknown. Affected infants often require high rates of glucose infusion to maintain a normal glucose concentration, suggesting either an increased insulin concentration or increased sensitivity to insulin. Because asphyxia also results in an increase in plasma glucagon, interleukin-6, hydrocortisone, and other counter-regulatory hormones, with associated changes in insulin receptor binding, it can also induce an insulin-resistant state. Both hypoglycemia and hyperglycemia are associated with worse outcomes at 18 months of age in infants with neonatal encephalopathy.[10] Therefore, from a clinical perspective it is important to carefully monitor the plasma glucose concentration in infants with neonatal encephalopathy and adjust the parenteral glucose infusions accordingly.

Infection

See Chapters 48-50.

Hypoglycemia in association with overwhelming sepsis has been reported in newborn infants. Hyperglycemia is more common than hypoglycemia. The mechanism of hypoglycemia with sepsis is not well defined. Depleted glycogen stores, impaired gluconeogenesis, and increased peripheral glucose use may all be contributing factors. The usual response to sepsis in most animal models has been an increase in the rates of glucose production and gluconeogenesis as a result of counter-regulatory hormonal responses. A decrease in these processes is seen only during an agonal stage; therefore, hypoglycemia with sepsis should be considered an indicator of a fulminate infection.

Hypothermia

See Chapter 35.

The occurrence of hypothermia secondary to hypoglycemia has been well documented and is a useful clinical sign. Studies in which 2-deoxy-D-glucose was used in adults suggest that hypoglycemia, directly or secondarily, may affect a central thermoregulatory center in the hypothalamus that is sensitive to glucose. Hypoglycemia may also be secondary to hypothermia. The normal core temperature in the neonate is between 36.5° and 37.5°C (97.7°F-99.5°F). If the body temperature falls, heat production increases several times above that of the basal level, resulting in a more rapid depletion of energy stores. Hypoglycemia is also seen in neonates who had rectal temperatures lower than 32°C (89.6°F) after prolonged exposure to cold.

Hematologic Disorders

Glucose concentration is negatively correlated with plasma hematocrit. Association between erythroblastosis fetalis due to Rh incompatibility and neonatal hypoglycemia has also been observed for a long time. There are no correlations between the severity of anemia and hypoxemia and levels of plasma insulin and C peptide. Erythroblastosis at birth is associated with an increased number of nucleated red blood cells in the peripheral blood of newborns, again an indicator of fetal hypoxia. The prenatal management of Rh immunization has markedly reduced the severity of erythroblastosis fetalis and anemia in the fetus and the newborn infant. Nevertheless, the plasma glucose concentration should be carefully monitored in these infants after birth.

Iatrogenic Causes

Reactive hypoglycemia may occur after abrupt cessation of hypertonic glucose infusions, including those used for parenteral nutrition. Marked variability of blood glucose values may also occur as a result of changing rates of glucose infusion.

Refractory hypoglycemia has been associated with an umbilical artery catheter positioned near the origin of the vessels supplying the pancreas (T11 to L1). Direct glucose infusion into the vessels of the pancreas can lead to hyperinsulinemia and hypoglycemia. Hypoglycemia was also reported with a normally positioned catheter at T8-T9; it responded to catheter repositioning.

Congenital Cardiac Malformations

The mean blood glucose concentration in neonates and older children with congenital cyanotic heart disease or congestive heart failure may be lower than that in healthy controls. Glucose disappearance rates and fasting insulin and growth hormone values are normal, but glucose values after glucagon administration are lower than those in healthy children. Although the mechanism is unknown, chronic hypoxia, leading to decreased glycogen stores, may be a contributing factor. Hypoglycemia may also lead to cardiomegaly and congestive heart failure in the absence of congenital malformations. Therefore, the presence of either hypoglycemia or congestive heart failure should be considered when one or the other appears.

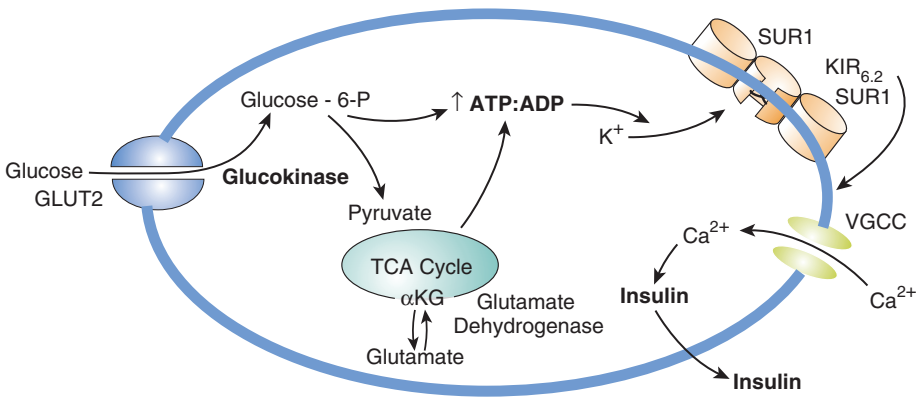
Persistent or Recurrent Hypoglycemia



Hyperinsulinism

Congenital Hyperinsulinism (CHI)

Congenital hyperinsulinism (CHI) is unregulated insulin secretion by the pancreatic β-cells, resulting from mutations of genes regulating insulin secretion. It is characterized by profound hypoglycemia in the newborn with hyperinsulinemia that inhibits glycogenolysis and prevents availability of alternate energy sources such as ketone bodies and lactate, causing brain and long-term neurodevelopmental impairments in some cases. It is the most common cause of persistent hypoglycemia in the newborn. The incidence is estimated at 1/50,000 live births, but it may be as high as 1/2500 live births with a higher incidence of consanguinity (Saudi Arabian and Ashkenazi Jewish populations).[7,23,41] Thus far, mutations in nine different genes (*ABCC8, KCNJ11*, *GLUD1*, *CGK*, *HADH*, *SLC16A1*, *HNF4A*, *HNF1A*, and *UCP2*) have been identified in patients with congenital forms of hyperinsulinism (CHI).[41] The most severe forms of CHI are caused by mutations in *ABCC8* and *KCJN11*, which encode the two components of pancreatic β-cell ATP-sensitive potassium channel (K_{ATP}). The sulfonylurea receptor is (SUR1) encoded by the *ABCC8* gene and the inward rectifying potassium channel ($Kir_{6.2}$) encoded by the *KCNJ11* gene.[7,41]

As shown in Fig. 86.8, insulin secretion by the beta cells requires an increase in the intracellular adenosine triphosphate (ATP) concentration as a result of glycolysis and the oxidation of glucose. After entry into the beta cell, which is facilitated by a specific glucose transporter protein (GLUT2), glucose is phosphorylated to form glucose-6-phosphate. The latter enters the glycolytic pathway to form pyruvate and is oxidized in the tricarboxylic acid (TCA) cycle. Glutamate is another substrate entering the TCA cycle to form alpha-ketoglutarate, a reaction catalyzed by glutamate dehydrogenase. The ultimate increase in ATP concentration and the consequent increase in the ATP to adenosine diphosphate (ADP) ratio affects the ATP-sensitive potassium (K^+) channel (K_{ATP}), resulting in depolarization of the beta-cell membrane. This process in turn results in activation of voltage-gated calcium channels and entry of Ca^{2+} into the cell. An increase in intracellular Ca^{2+} concentration results in the release of insulin into the circulation. When closed, the K_{ATP} channel depolarizes the plasma membrane, leading to insulin secretion.

The mutations in *ABCC8* or *KCNJ11* gene abolish the K_{ATP} channel function, so these neonates are unresponsive to the K_{ATP} channel agonist (diazoxide), requiring alternative therapies. Histologically, there are three major subgroups: (1) diffuse, (2) focal, and (3) atypical. The diffuse CHI is most commonly caused by recessive and dominant mutations in *ABCC8* and *KCNJ*.[7,41] The diffuse form of disease involves all β cells in the pancreas with a variable involvement and preservation of the islet pattern. The β cells are highly active with abundant cytoplasm and abnormal nuclei. Focal CHI is sporadic and associated with inheritance of a paternal mutation in *ABCC8* or *KCNJ11* and somatic loss of the maternal 11p allele (11p15.1-11p15.5).[41] The maternal allele loss unmasks the paternally inherited K_{ATP} channel mutation in addition to an imbalance of the imprinted genes in this region. This imprinting effect and paternal isodisomy are at the same locus. The lesion is usually restricted to a small area (<10 mm in diameter) and contains large endocrine cells with large cytoplasm and dispersed abnormally shaped nuclei. The focal lesion is multilobular and can have satellites that necessitate intraoperative margin analysis to

• **Fig. 86.8** Mechanism of glucose-induced insulin secretion by the beta cell of the pancreas. Glucose entry into the beta cell is facilitated by a specific glucose transporter protein (GLUT2). Intracellular metabolism of glucose through glycolysis and in the tricarboxylic acid (TCA) cycle increases the intracellular concentration of adenosine triphosphate (ATP). The increase in the ratio of ATP to adenosine diphosphate (ADP) affects the ATP-sensitive potassium (K^+) channel, causing an efflux of K^+ and depolarization of the beta-cell membrane that in turn activate the voltage-gated calcium (Ca^{2+}) channel (VGCC) and entry of Ca^{2+} into the cell. The increase in free intracellular Ca^{2+} initiates release of insulin. As discussed in the text, mutations of glucokinase, glutamate dehydrogenase, SUR1, and $KIR_{6.2}$ have thus far been associated with hyperinsulinemic hypoglycemia. αKG, α-ketoglutarate; glucose-6-P, glucose-6-phosphate; KIR, inward-rectifying potassium channel; SUR, sulfonylurea receptor.

ensure complete excision to avoid recurrence. The atypical disease shows diffuse histologic abnormalities with the coexistence of some normal and some abnormal islets. In this case, there is no clear genetic inheritance pattern established.[41]

Clinically, most infants present during the first 24-48 hours after birth with severe symptoms such as seizures, hypotonia, apnea, and cyanosis. The diagnosis is suspected when hypoglycemia appears soon after birth, requiring high rates of glucose infusion (12-13 mg/kg per min). Some neonates with CHI may be macrosomic because of hyperinsulinemia in fetal life, particularly those who carry mutations of the *HNF4* gene. Other CHI infants are normosomic, lacking positive physical findings. Sometimes facial dysmorphism may be reported later in infancy and childhood. Some patients have hypertrophic cardiomyopathy and hepatomegaly, probably reflecting fetal hyperinsulinemia. Maternal history is noncontributory, but a carefully taken history may reveal previous neonatal deaths or unexplained seizures or intellectual disability in other siblings. The diagnosis has been made at birth in asymptomatic infants and prenatally based on familial history. These infants typically have inappropriately high plasma insulin and C-peptide levels during hypoglycemia. Measurements of C peptide may be useful because of its nonpulsatile production with twice the half-life of insulin. Plasma glucose increases by glycogenolysis in response to exogenous glucagon administration, indicating absence of glycogen storage disease. Ketone body and free fatty acid content is low in both plasma and urine.

It is important to note that the mutation of glutamate dehydrogenase presents with hyperammonemia along with hyperinsulinemic hypoglycemia.[7,41] Other genetic disorders (e.g., short-chain 3-hydroxyacyl-coenzyme A dehydrogenase) have also been reported to present with hyperinsulinemic hypoglycemia. Testing of urine organic acids (high 3-OH-glutarate) and plasma acylcarnitine (high C4-OH-carnitine) is required to identify a short-chain-hydroxyacyl-CoA dehydrogenase (SCHAD) deficiency.[41]

Rapid diagnosis and prompt management of hypoglycemia is essential to prevent brain damage and improve the neurodevelopmental outcome. Clinical and biologic data can be used to differentiate the focal from the diffuse form of disease. K_{ATP} channel agonist, diazoxide, is the first line of therapy, and it acts by opening K_{ATP} channels and preventing glucose-mediated insulin release. Fig. 86.9 outlines the steps in management. Diazoxide is not effective when *ABCC8* or *KCNJ11* gene defects are present. Therefore, diazoxide-unresponsive patients should undergo rapid genetic mutation testing. Patients with genetically confirmed *ABCC8/KCNJ11* diffuse disease do not require further imaging. These patients will require near total pancreatectomy carrying an increased risk of developing diabetes mellitus and pancreatic exocrine insufficiency subsequently. Patients with paternally inherited mutation in

• **Fig. 86.9** A flow diagram of suggested management pathway of neonatal hypoglycemia caused by congenital hyperinsulinism (CHI). GIR, Glucose infusion rate.

ABCC8 or *KCNJ11* require [^{18}F]-DOPA positron emission tomography imaging.[61] Approximately 50% of diazoxide-unresponsive infants have focal disease and can experience a complete cure after surgical excision of the lesion.

Zinc protamine glucagon, as intramuscular injections or orally administered starch, has also been used postoperatively. However, in most instances, preoperative medical therapy consisting of various combinations of glucose infusion, diazoxide, glucagon, and octreotide fails to control hypoglycemia.[41] Continuous octreotide infusion with the addition of glucagon to correct octreotide-induced hypoglucagonemia has been used for temporary preoperative medical control. In a recent study, the use of sirolimus (rapamycin mTOR inhibitor) in four patients with diffuse hyperinsulinemic hypoglycemia that is unresponsive to diazoxide was successful in weaning intravenous infusions of dextrose and glucagon.[49] While this therapy may offer a potential alternative to subtotal pancreatectomy, long-term use and side effects from sirolimus are not well studied at this time.[49]

Conservative (nonsurgical) management has been successful in some asymptomatic hypoglycemic infants who were diagnosed at birth. Infants with the CHI spectrum have a high incidence of neurologic damage, which is probably a reflection of the severity of symptomatic hypoglycemia and the delay in diagnosis. It is imperative that neonatologists approach these neonates as a metabolic emergency and ensure against delaying diagnosis. Because *SUR1* genes are also expressed in neuronal cells, it has been suggested that the neurologic deficit in these infants may be related to a *SUR1* mutation in the brain. Long-term follow-up data in infants with total pancreatectomy demonstrate variable responses—some develop no pancreatic insufficiency, whereas others develop frank diabetes as well as exocrine pancreatic insufficiency.

Neurologic impairment associated with abnormal brain MRI was observed in 47% of CHI patients in a recent international study.[31] Neurologic impairment correlated with a delay of five or more days in initiating treatment. However there was no association with early vs. late disease onset, KATP-channel mutations, disease severity, or focal vs. diffuse disease.[31]

Beckwith-Wiedemann Syndrome

The characteristic features of Beckwith-Wiedemann syndrome (BWS) include macrosomia, macroglossia, omphalocele, hyperplastic visceromegaly, and hypoglycemia, often also called *congenital overgrowth syndrome*. Since the original description by Beckwith and Wiedemann, a number of other clinical findings of this syndrome have been described (Box 86.4).[62] BWS is a clinical spectrum, and the frequency of these clinical manifestations is variable. Macroglossia, a uniform enlargement of the tongue, is present in more than 80% of cases. Other craniofacial characteristics include midface hypoplasia, a prominent occiput, and nevus flammeus. Characteristic ear creases or pits are present in about 75% of individuals. Anterior abdominal wall defects, which are present in about 80% of cases, include omphalocele, umbilical hernia, and diastasis recti abdominis. Cardiac defects are reported in about 25% of cases; however, no specific cardiac abnormality is prominent.

• BOX 86.4 Major Findings in Beckwith-Wiedemann Syndrome

Clinical Findings

- Advanced bone age
- Ear anomalies
  - Pits and/or creases
- Facial nevus flammeus
- Hemihypertrophy
- Macroglossia
- Maxillary underdevelopment
- Muscular hypertrophy
- Neonatal hypoglycemia
- Neonatal polycythemia
- Prenatal and postnatal gigantism
- Prominent occiput
- Abdominal wall defects
  - Diastasis recti abdominis
  - Omphalocele
  - Umbilical hernia
- Cardiac defects
- Clitoromegaly
- Cryptorchidism
- Tumors (Wilms tumor)
- Visceromegaly: kidney, liver, spleen

Pathologic Findings

- Adrenal cortical cytomegaly and cysts
- Hypertrophy and hyperplasia of islets of Langerhans
- Medullary dysplasia and medullary sponge kidneys
- Nephromegaly with prominent lobulation
- Persistent nephrogenesis

Most (>75%) of BWS infants are above the 90th percentile in length and weight for gestational age and tend to remain at the 90th percentile during early infancy and childhood. No differences between male and female infants have been reported. Growth begins to slow down by about age 8 years, and adult height and life expectancy are usually normal.

Hypoglycemia is present in at least half the cases[62] and may be manifested soon after birth. Endocrine evaluation of the few reported cases has not been consistent. However, based on the clinical features of hypoglycemia with low free fatty acids and ketones and autopsy findings of islet cell hyperplasia, it is believed that hypoglycemia is caused by hyperinsulinism in this syndrome. Plasma growth hormone levels have been reported to be normal, and somatomedin levels were reported to be increased in one infant. These infants may require glucose infusion at high rates in the immediate neonatal period. Spontaneous regression of hypoglycemia is suggested in most infants. Hypocalcemia has also been reported in some instances.

About 10% of children with BWS are also predisposed to certain malignancies (adrenal carcinoma, nephroblastoma)

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

and appear to have an increased risk for malignancies associated with hemihypertrophy.

Genetic studies in patients with Beckwith-Wiedemann syndrome have identified three major subgroups of patients: familial, sporadic, and chromosomally abnormal. Molecular and cytogenetic testing in BWS patients display genetic and epigenetic aberrations in two domains of chromosome 11p15.5 (BWS critical region—imprinting center 1 [IC1] and imprinting center 2 [IC2]. These include loss of methylation on the maternal chromosome at IC2 in 50% of affected individuals, paternal uniparental disomy for chromosome 11p15 in 20%, and gain of methylation on the maternal chromosome at IC1 in 5%. Additionally, sequence analysis of CDKN1C (regulated by IC2) identifies a heterozygous maternally inherited pathogenic variant in approximately 40% of familial cases and 5%-10% of cases with no family history of BWS.[51,62]

Endocrine Disorders

Pituitary Insufficiency

Neonatal hypoglycemia associated with anterior pituitary hypofunction may represent a series of separate syndromes, with defects ranging from no structural abnormalities in the brain to septo-optic dysplasia, craniofacial defects, and anencephaly. Although this disorder is considered rare, the true incidence is unknown, because it usually goes unrecognized as a result of the absence of characteristic physical findings in the newborn.

Clinical and Laboratory Manifestations. Symptoms of hypoglycemia may begin during the first hours of postnatal life and are marked by their severity. They include sudden and profound limpness, convulsions, apnea, cardiovascular collapse, and cardiac arrest. The infants are of normal length and weight and born at or after term. Males predominate at a ratio of 2:1. The physical examination may be unrevealing; however, some male infants have a microphallus, poorly developed scrotum, small and undescended testes, or some combination of these features. Facial abnormalities consisting of a cleft lip and palate, a poorly developed nasal septum, hypotelorism or hypertelorism, abnormalities of antidiuretic hormone secretion, or widely spaced nipples have been described. Although the infants are of normal size at birth, growth restriction and delayed bone age may be found in children as young as 6-8 weeks of age.

Serum growth hormone (GH) values are not measurable or in the normal adult range, in contrast to the elevated values usually found in normal newborns. The paradoxic increase in GH during glucose infusion in normal newborns does not occur when hypoglycemia is associated with pituitary deficiency. The cortisol concentration may be low at the time of symptomatic hypoglycemia. Hypothyroidism is common. A deficiency in hypothalamic hormones has been shown by a rise in thyroid-stimulating hormone (TSH), or thyrotropin, after stimulation with thyrotropin-releasing hormone (TRH) and by increased prolactin levels with a poor luteinizing hormone (LH) response after stimulation with releasing hormone. The adrenals respond to adrenocorticotropic hormone (ACTH) stimulation, but a deficiency in ACTH may be demonstrated by the use of metyrapone.

Pathology. At postmortem examination, the pituitary gland may be hypoplastic or aplastic, the thyroid and adrenal glands small, and the cellular architecture of the adrenals disorganized, with atrophy or absence of the fetal cortex. Multiple congenital anomalies of the central nervous system (CNS), including holoprosencephaly and arrhinencephalia, may be found. Radiographic studies have demonstrated the absence of the septum pellucidum and massa intermedia. Hypoplasia or aplasia of the adenohypophysis without cerebral or facial anomalies may also occur. There may be different expressions of the same syndrome, depending on the extent of pituitary hypoplasia or other CNS anomalies, or both.

Pathogenesis. The underlying pathogenic mechanisms remain unclear, although aplasia of the anterior pituitary was found in siblings of three patients and in two patients with familial histories of consanguinity. This finding is consistent with a possible autosomal recessive inheritance. Whether the disorder is caused by failure of the pituitary to form or by degeneration of the pituitary is unknown. It is also possible that abnormalities of the hypothalamus with a deficiency in hypophysiotropic-releasing hormones are responsible for the multiple endocrinopathies observed in these infants. The pathophysiologic relationships among pituitary hypoplasia, CNS anomalies, and other pituitary hypofunctions are unknown. The exact mechanism of hypoglycemia in these disorders remains undefined.

Treatment. Therapy consists of replacement with synthetic GH. Cortisol is replaced cautiously, with maintenance doses of hydrocortisone for proven hypoadrenalism. Thyroxine (T_4) replacement is started when hypothyroidism is documented.

Cortisol Deficiency

Familial isolated glucocorticoid deficiency has been described in a family of five siblings; in two of the infants, glucocorticoid production was normal initially and deficient at a later age. This finding suggests that in some families there may be a degenerative process in the adrenal gland.

Maternal steroid therapy resulting in neonatal subclinical adrenal insufficiency was reported in an infant with cushingoid facies, transient hypoglycemia, and a poor response to intravenous corticotropin at 20 hours. However, maternal steroid therapy, such as that for chronic asthma, only rarely has been related to neonatal adrenal insufficiency and hypoglycemia.

Adrenocorticotropic hormone (ACTH) unresponsiveness is a hereditary disorder in which the adrenal glands fail to produce adequate cortisol but aldosterone secretion is normal and ACTH levels are increased. There are feeding problems, a failure to thrive, and regurgitation in the neonatal period; hypoglycemia, convulsions, and shock or even death may occur in infancy or early childhood.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

The syndrome is characterized by hyperpigmentation; normal serum electrolyte concentrations; and an unusually severe, untoward response to illness or stress. There is often a history of affected siblings, and an autosomal recessive mode of inheritance has been suggested. The pathogenesis of this syndrome is poorly understood. The differentiation of the zones of the adrenal cortex in utero requires ACTH except for the zona glomerulosa, which is primarily under renin-angiotensin control. The histologic examination of the adrenal glands of patients with ACTH unresponsiveness has revealed an intact zona glomerulosa and atrophy of the zona fasciculata and zona reticularis. An abnormality at the site (or sites) of ACTH action or cortisol biosynthesis has been postulated.

Adrenal hemorrhage is discussed in Chapter 29.

Congenital adrenal hyperplasia (see Chapter 89) may be diagnosed in the neonatal period because of the presence of hypoglycemia. The diagnosis is difficult in male infants when there are no positive physical findings. Family history may reveal previously unexplained neonatal deaths.

Congenital Glucagon Deficiency

Two male infants have been reported with glucagon deficiency; the disorder became evident on the second to third day of postnatal life, with repeated convulsive movements, hypotonia, weak crying, and poor sucking. In both infants, the diagnosis was based on a low basal glucagon concentration and a strong hyperglycemic response to glucagon. In one of the infants, the response to glucagon was lacking, and in the other, there was a lack of response to hypoglycemia and alanine infusion. The parents of this second infant were closely related and had partly deficient glucagon secretion; two siblings of this infant died before 5 months of age with probable hypoglycemia. Therefore an autosomal recessive inherited disorder is suggested.

Epinephrine Deficiency

This disorder is extremely rare. In infants who are SGA, it has been described secondary to adrenal hemorrhage. The diagnosis may be suspected in an infant who has been acutely ill (i.e., hypotensive) during the perinatal period and can be confirmed by measuring plasma or urine catecholamine levels. Some of these infants may develop adrenal calcification, which may be identified on follow-up.

Inborn Errors of Carbohydrate Metabolism

Galactosemia

See Chapter 90.

Hepatic Glycogen Storage Disease

See Chapter 90.

Fructose Intolerance

See Chapter 90. Fructose is the main sweetening agent in nature, occurring mostly in fruits, vegetables, and honey, and is often added as a sweetener to foods and beverages in the form of disaccharide sucrose. In humans, the liver is the main site of fructose metabolism, with significantly less important sites being the kidney, gut, and other tissues. Absorption of fructose in the gut does not appear to require an active transport system but relies on a facilitative transport system. Fructose is rapidly metabolized, disappearing from the circulation almost twice as fast as glucose. Fructose is metabolized by specific enzymes that convert it into intermediates of the glycolytic–gluconeogenic pathway. The strategic enzymes associated with disorders of fructose metabolism have been identified. Fructose is first phosphorylated to fructose-1-phosphate by fructokinase. Fructose-1-phosphate is split into dihydroxyacetone phosphate and glyceraldehyde by the action of aldolase. Glyceraldehyde is converted to glyceraldehyde-3-phosphate by the action of triokinase. Dihydroxyacetone phosphate and glyceraldehyde-3-phosphate are the intermediates in the glycolytic–gluconeogenic pathway. Additionally, fructose-1,6-bisphosphatase is a key gluconeogenic enzyme that catalyzes the conversion of fructose-1,6-biphosphate into fructose-6-phosphate.

It has been suggested that intravenous fructose be used for the treatment of hypoglycemia in both adults and newborn infants because of the lack of hyperglycemia associated with its administration and, therefore, the lack of reactive hypoglycemia. However, caution should be exercised because the metabolism of fructose in the liver causes increased lactate formation, high-energy phosphate depletion, increased uric acid formation, and inhibition of protein synthesis. The use of fructose in the treatment of hypoglycemia in the neonate, or for that matter in an adult, is not recommended.

Essential fructosemia is a rare and harmless disorder characterized by the appearance of fructose in the urine. This disorder is the consequence of a deficiency of fructokinase, which results in an inability to metabolize fructose.

Hereditary fructose intolerance, or aldolase-B deficiency, results in an inability to split fructose-1-phosphate into triose phosphates. The enzymatic activity contributing to the formation of fructose-1,6-biphosphate from triose phosphates is also reduced.

Affected babies can breastfeed without any ill effects, and symptoms do not appear until fructose or sucrose is introduced in the diet (e.g., cow milk formulas with added sucrose) or at weaning, when fruits and vegetables are introduced. Clinical manifestations after the ingestion of meals containing fructose include hypoglycemia; lethargy; nausea; vomiting; pallor; sweating; and evidence of liver dysfunction, such as jaundice, hepatomegaly, a bleeding tendency, and proximal renal tubular dysfunction. The symptoms are reported to be worse in younger infants than older children. Genetically, it is a heterogeneous disorder with wide variation in manifestations. Treatment consists of the complete elimination of all sources of fructose from the diet, including foods and medications.

Fructose-1,6-bisphosphatase deficiency should actually be called a defect in gluconeogenesis rather than a disorder of fructose metabolism, because these infants can

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

tolerate fructose in their diets. Fructose-1,6-bisphosphatase is the key regulatory enzyme in the gluconeogenic pathway involved in the formation of fructose-6-phosphate, the immediate precursor of glucose-6-phosphate, and finally glucose. A deficiency of this enzyme results in an inability to make glucose from all gluconeogenic precursors (i.e., pyruvate, amino acids, glycerol) and, therefore, results in hypoglycemia when gluconeogenesis is the major source of glucose, such as that occurring during fasting. These infants can present in the neonatal period with hypoglycemia and severe metabolic acidosis. The clinical manifestations are related to hypoglycemia and acidosis and include lethargy, tachycardia, apnea, hypotonia, and tachypnea. Laboratory findings include hypoglycemia during fasting (i.e., when glycogen stores are low), high plasma lactate, alanine, and ketones with metabolic acidosis. The defect is inherited as an autosomal recessive disorder and is seen more often in girls than boys.

Treatment is aimed at the maintenance of plasma glucose through frequent feedings and avoidance of prolonged periods of fasting. A therapeutic regimen consisting of the continuous nighttime administration of glucose by the nasogastric route, as in glycogen storage disease, should be successful.

Hereditary fructose intolerance may manifest in the neonatal period if the susceptible infant is fed a sucrose-containing formula or given table sugar, fruits, or fruit juices. Symptoms include vomiting, failure to thrive, excessive sweating, and unconsciousness or convulsions. Hypoglycemia is frequently seen, as are fructosemia and fructosuria, after the ingestion of fructose.

Glucose Transporter Type 1 Deficiency Syndrome (Glut1 DS)

Glucose is transported from the blood to the brain and cerebrospinal fluid by a carrier-facilitated diffusion transport protein Glut1 encoded by gene *SLC2A1*. Deficiency in Glut1 results in encephalopathy and intractable seizures. Glut1 also facilitates glucose transport into red blood cells, which allows RBC Glut1 to act as a surrogate marker for genetic abnormalities seen underlying brain glucose transport. Impaired transport of glucose to brain was originally described in 1991 by DeVivo and colleagues in two children with seizures unresponsive to antiepileptic drugs, delayed development with acquired microcephaly, and developmental delay.[45] In both infants, the seizures appeared at about 2 months of age. Repeated laboratory studies showed low glucose and lactate in the cerebrospinal fluid in the presence of normal blood glucose levels. A detailed evaluation revealed no other abnormalities such as meningitis or intracranial hemorrhage as a possible cause. The glucose levels in the cerebrospinal fluid ranged between 18 and 35 mg/dL when the blood glucose concentration ranged between 86 and 120 mg/dL.

The neurologic features of Glut1 deficiency syndrome (glut1DS) without low serum glucose (<60 mg/dL) are described as: (1) seizures (infantile or absence seizures), (2) movement disorders (spasticity, ataxia, dystonia, chorea), and (3) cognitive and behavioral disturbances (cognitive impairment, delayed adaptive behavior, variable attention). The syndrome may present with variations of combinations of milder to more severe forms.[45]

Diagnostic testing includes a fasting lumbar puncture documenting hypoglycorrhachia and genetic sequencing for the *GLUT1* gene at chromosome 1p34.2 (*SLC2A1* gene). EEG obtained in the fasting state shows mild to moderate slowing. Fluorodeoxyglucose positron emission (FDG-PET) imaging in Glut1DS demonstrates hypometabolism in thalamus and neocortical regions.[45]

Treatment with multiple antiseizure medications is unsatisfactory. Because the brain can use ketones for oxidative metabolism, and the transport of ketones across the blood-brain barrier is not mediated by GLUT1 proteins, a ketogenic diet is the essential treatment for controlling seizures as well as other clinical features of Glut1DS.[45] A fat-to-carbohydrate ratio of up to 4 : 1 is used to achieve a goal of blood beta-hydroxybutyrate concentration of 4-5 mM for seizure control. This is often challenging for families, particularly with older children in whom compliance is difficult.

Management of Neonatal Hypoglycemia

The clinical management of neonatal hypoglycemia should include: (1) anticipation of the group at high risk, (2) correction of hypoglycemia, and (3) investigation and treatment of the cause of hypoglycemia. Often, it is not possible to identify the cause of hypoglycemia, and the treatment remains limited to correction of the low blood glucose concentrations.

Because hypoglycemia is asymptomatic in a large number of neonates, it has become an accepted practice to monitor blood glucose in newborn infants who are at risk for hypoglycemia.[2] This monitoring practice includes: (1) preterm infants—34-36 6/7 weeks; (2) term infants who were born to mothers with diabetes, small for gestational age, intrauterine growth restricted infants, or large for gestational age; and (3) acutely ill infants in the intensive care unit with septicemia, asphyxia, respiratory distress, prematurity, and other illnesses. In the last category, the symptoms of hypoglycemia are overshadowed by those of the acute clinical problems. In addition, blood glucose should be routinely monitored in small preterm infants who are receiving total parenteral nutrition even if they appear clinically well and stable. Glucose monitoring in healthy infants born at term gestation is not recommended.

In asymptomatic infants at risk for hypoglycemia, blood glucose should be determined during the first 4 hours after birth until feeding is established; thereafter, blood glucose should be monitored before feeding. The blood glucose levels in all neonates decline, reaching a nadir between 30 and 60 minutes after birth, and then rise to reach a stable plateau between 90 and 180 minutes after birth with lowest

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

acceptable transitional glucose values of 25 mg/dL (range 25-40), requiring early feeding. Early feeding initiation is critical to establish breastfeeding as well as maintaining plasma glucose levels. Therefore, a blood glucose measurement obtained during these time periods necessitates a follow-up measurement to document whether the blood glucose level is decreasing or returning to normal, stable levels. These levels approximate epidemiologic data at the 5th-10th percentiles for glucose. From 4-24 hours after birth, the lowest level requiring action is 45 mg/dL (range 35-45 mg/dL) All bedside measurements of blood glucose concentration obtained by enzyme-strip methods should be considered only as screening results and confirmed by appropriate laboratory measurements. The enzyme-strip methods are not particularly accurate in the low blood glucose range, which is commonly observed in the newborn nursery or in the neonatal intensive care unit.

The treatment strategies for hypoglycemia depend on whether it is transient or persistent and asymptomatic or symptomatic. All infants with symptomatic hypoglycemia, regardless of cause or age, should be treated with parenteral glucose infusion.

Oral Dextrose Gel

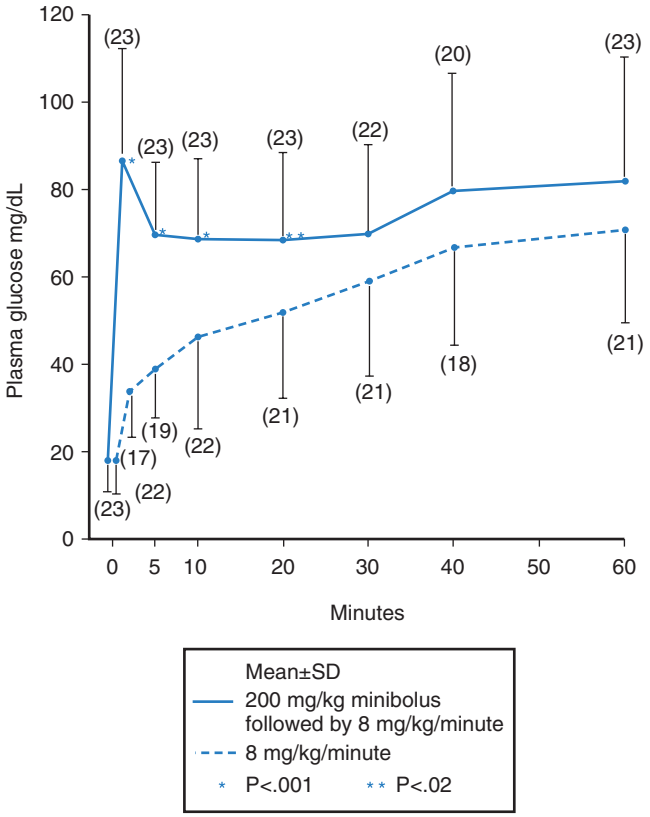
Oral dextrose gel containing 40 g of dextrose per 100 mL aqueous solution (40%) administered at doses of 200-400 mg per kg is recommended for early transitional hypoglycemia unresponsive to early feeding.[30,47] This is a change from previous recommendations. The estimated rise in blood glucose concentration following dextrose gel was 0.4 mmol/L (95% CI 0.14-0.94; one trial, 75 infants).[59] It can be applied directly to mucosal surfaces of the mouth, including buccal and lingual surfaces with rapid access to the circulation.[27] A Cochrane review of infants treated with dextrose gel found that they were less likely to be separated from their mothers for treatment of hypoglycemia (RR 0.54, 95% CI 0.31-0.93) and improved the rate of exclusive breastfeeding after discharge without altering the rate of developmental impairment at 2 years of age.[59] Buccal gel has been shown to be highly cost effective.[23a]

The greatest variance in the management of hypoglycemia is seen in the asymptomatic infant diagnosed soon after birth (i.e., during the first 2 hours). This type of hypoglycemia is often transient and recovers spontaneously. However, in clinical practice, it is often treated with early feedings. Early breastfeeding is recommended for all neonates, as it improves infant and maternal health outcomes all over the world. Controlled studies examining the benefits or impact of this early feeding on recovery from hypoglycemia have not been performed. It has been suggested that as many as 10% of healthy infants who are the appropriate size for gestational age develop transient asymptomatic hypoglycemia, which in most cases is managed by the initiation of early, normal feeding.

Persistent hypoglycemia is ascribed to the group of infants who continue to require high rates of intravenous glucose administration over several days to maintain normal glucose concentrations. Such persistent hypoglycemia is often related to hyperinsulinemia and may require pharmacologic interventions, as discussed later.

Intravenous Glucose Infusions

Parenteral glucose is administered at a rate of 6-8 mg/kg per minute, corresponding to 3.6-4.8 mL/kg per hour of a 10% dextrose solution. This infusion rate is based on the rate of endogenous glucose production in healthy newborn infants. The aim of therapy is to maintain the plasma glucose concentration at a level higher than 45 mg/dL. Plasma glucose levels are monitored frequently (every 1-2 hours) until they are stable and then less frequently (every 4-6 hours). If the glucose concentrations do not increase to normal levels, the rate of infusion should be increased by 1-2 mg/kg per minute every 3-4 hours while monitoring the glucose response. Infants with severe hypoglycemia and those who require high rates of glucose infusion may benefit from having a securely placed intravenous line such as a central line or an umbilical vein catheter placed above the liver. Caution should be exercised in administering glucose through the umbilical artery catheter; if the catheter is placed near the celiac axis, the administered glucose may preferentially perfuse the pancreas and thus inadvertently cause an increased insulin response and hypoglycemia.



In symptomatic infants and when there is a need to rapidly increase the plasma glucose level, a minibolus of 200 mg/kg (2 mL/kg of 10% dextrose in water) may be given over 1 minute (Fig. 86.10).[3] However, any glucose bolus must be administered through a secure intravenous line so that a constant-rate infusion of glucose may follow. In fact, in most instances, an attempt should be made to first start the intravenous infusion and then give the intravenous bolus infusion for the immediate correction of low plasma glucose.

Feedings may be initiated when the blood glucose level has been stable for several hours. Some investigators suggest that the feeding should be given only as a constant-rate nasogastric drip to avoid hormonal excursion. Although such a concept is theoretically logical, there are no observed data to support it. Nevertheless, infants with persistent hypoglycemia, those who are symptomatic, and those who require high rates of glucose infusion are best managed exclusively by parenteral glucose infusion and without oral feeding until their plasma glucose concentrations have stabilized.

The infant can be weaned from the parenteral glucose infusion after the plasma glucose concentration has been stable at about 50-70 mg/dL. Glucose infusions can be decreased every 3-4 hours as long as the blood glucose concentration remains stable. The concentration of glucose in the blood should be monitored with each change in the rate of intravenous glucose infusion. Such a regimen leads to the successful discontinuation of glucose infusion in almost all infants.

If the infant continues to require high rates of intravenous glucose infusion, a diagnosis of hyperinsulinism should

• **Fig. 86.10** A comparison of the results of two treatment regimens for hypoglycemic neonates. A group of 23 hypoglycemic infants was treated with 200 mg/kg of glucose given in a minibolus, followed by a constant glucose infusion of 8 mg/kg per minute; a separate group of 22 hypoglycemic neonates received only the constant glucose infusion (8 mg/kg per minute). (From Lilien LD, et al. Treatment of neonatal hypoglycemia with minibolus and intravenous glucose infusion. *J Pediatr.* 1980;97:25.)

be considered and pharmacologic intervention planned. The following pharmacologic agents are used for the treatment of hypoglycemia.

Glucagon

Except for the rare patient with a deficiency of this peptide, glucagon is seldom used to increase the plasma glucose concentration at an acute rate. It has been used most often for the diagnosis of hepatic glycogen storage disease, a condition in which no increase or a minimum increase in plasma glucose concentration is seen in response to glucagon. This single-chain peptide is secreted primarily by the alpha cells of the pancreas. Glucagon increases the blood glucose concentration by increasing both glycogenolysis and gluconeogenesis. An acute administration of glucagon, for example, 150-300 µg/kg given intravenously or intramuscularly, results in an increase in blood glucose by more than 50% in most normal infants. However, the effect is transient, and the administration of glucagon should be followed by intravenous glucose infusion to maintain blood glucose levels. Long-acting glucagon preparations (zinc protamine glucagon) have been used for glucagon deficiency states or in combination with somatostatin for the treatment of certain cases of CHI.

Epinephrine

Although the use of epinephrine to increase blood glucose concentration was recommended in the past, it is rarely used because of its other systemic effects. Its absolute indication would be in the rare infant with epinephrine deficiency. Epinephrine acts by increasing hepatic glucose output through glycogenolysis and decreasing peripheral glucose uptake, mostly in muscle. In addition, epinephrine suppresses insulin secretion and increases lipolysis so that the blood levels of FFAs and glycerol can increase after epinephrine administration.

Diazoxide and Chlorothiazide

Diazoxide is the first-line drug for managing hyperinsulinemic hypoglycemia and is used to evaluate the need for genetic testing and/or advanced imaging. It acts by opening the K_{ATP} channels via binding to the intact SUR1 component, thereby preventing glucose-stimulated insulin secretion (see Fig. 86.8). Diazoxide is a benzothiadiazine derivative that is structurally closely related to the thiazide diuretics, yet it has none of the diuretic effects of thiazides. Diazoxide has been shown to cause decreased insulin secretion, both in vivo and in vitro, and catecholamine release. The combined effect of decreased insulin secretion and increased epinephrine release results in an increase in hepatic glucose production and a decrease in the peripheral use of glucose. In addition, increased lipolysis results in an increase in plasma levels of FFAs and glycerol. The drug is eliminated for the most part by glomerular filtration, and hepatic transformation is quantitatively less important than renal excretion. Ninety percent of circulating diazoxide is bound to albumin. The estimated half-life in adults is 20-30 hours. Serum levels have not been related to the hypotensive effects of the drug. The usual effective dose for the management of hyperinsulinemic hypoglycemia in the newborn is 5-20 mg/kg per day, administered orally in an 8- to 12-hour dose. Significant side effects include hypotension, sodium and water retention leading to expansion of plasma volume and edema, hypertrichosis lanuginosa, thrombocytopenia, anorexia, diarrhea and vomiting, and sometimes extrapyramidal symptoms. However, these side effects are relatively uncommon except for hypertrichosis lanuginosa and fluid retention. Therefore, treatment with diazoxide is combined with chlorothiazide at a dose the same as diazoxide.

Somatostatin Analogue: Octreotide

In the neonate, octreotide is the second-line drug for hyperinsulinemic hypoglycemia, with variable success as an emergency measure. Somatostatin, a tetradecapeptide (a peptide containing 14 amino acids), was originally isolated from the rat hypothalamus and shown to inhibit the release of growth hormone. Subsequent work has shown the presence of a number of somatostatin-related peptides distributed widely in the body, including the hypothalamus, nervous

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

tissue, gut, and endocrine and exocrine glands (including the pancreas). When administered exogenously, somatostatin inhibits the secretion of glucagon, insulin, growth hormone, and thyrotropin. In addition, it has a number of physiologic effects on the gut, in particular the inhibition of exocrine secretion, changes in gut motility, and reduction of splanchnic blood flow. It has been used extensively in physiologic studies to examine the role of insulin and glucagon in the regulation of glucose metabolism. Infused into a normal human, it suppresses the secretion of both insulin and glucagon, causing a fall in plasma glucose owing to the suppression of glucagon secretion, followed by a transient increase. The ability of somatostatin to suppress hormone secretion has been used in the short-term treatment of a variety of hyperfunctioning endocrine tumors, such as insulinomas, glucagonomas, gastrinomas, and growth hormone-secreting adenomas. In the neonate, somatostatin has been used to treat hyperinsulinemic hypoglycemia as an emergency measure, with variable success, and to evaluate the usefulness of pancreatectomy.

Clinical use of somatostatin has been hampered by its short half-life of less than 3 minutes and a short duration of action. Therefore, attempts have been made to synthesize long-acting analogues. Octreotide, the first somatostatin analogue introduced for clinical use, is significantly more potent in its hormone-suppressive effect. It is given at 6-8 hourly intervals by subcutaneous injections. The starting dose is 5-10 μg/kg per day, and the dose can be increased up to 15-40 μg/kg per day. Tachyphylaxis leads to a rapid decrease in the response to octreotide 24-48 hours after treatment initiation. Hence, response can be assessed only 2 days after the initiation of a new dose.

Growth Hormone

Treatment with growth hormone should be used only when its deficiency or hypopituitarism has been confirmed.

Glucocorticoids

In the past, steroids were widely used in hypoglycemic infants. With the advent of diazoxide and octreotide, together with recognition of the side-effect profile of steroids, such therapy is used less frequently.

Pancreatectomy

The focal form of congenital hyperinsulinism confirmed by genetics (paternal *ABCC8/KCNJ11* mutation or none) and [^{18}F]-DOPA-PET/CT scan requires limited pancreatectomy.[4] However, diffuse form of congenital hyperinsulinism confirmed by genetic mutation analysis requires near total pancreatectomy (85%-90%) or total removal of the pancreas. Most of these infants develop insulin-dependent diabetes during puberty.

Prognosis of Neonatal Hypoglycemia

The long-term impact of hypoglycemia in the newborn has remained a subject of controversy and debate. Neonatal hypoglycemia can cause seizures, permanent neuronal injury, and death. Other neurologic problems include developmental delay, learning and behavior problems, hyperactivity and attention difficulties, autistic features, microcephaly, and cortical blindness.[56]

The brain is an obligatory consumer of glucose, which is transported to the brain, consuming 80% of total glucose produced. Glucose is transported across the blood–brain barrier into neurons and glia (astrocytes) by two major glucose transporter isoforms, GLUT1 found mainly in the blood–brain barrier and astrocytes and GLUT3 in neurons. In addition to glucose, ketones and lactate are transported across the blood–brain barrier and into astrocytes by the monocarboxylate transporter (MCT) isoforms 1 and into neurons by MCT2.[8] It has been speculated that the availability and use of alternative energy sources (i.e., ketones and lactate) may explain the apparent tolerance of lower plasma glucose concentrations by the neonate. Although the fetal and neonatal brain has been shown to have the ability to use ketones as alternative fuels, clinical data regarding the quantitative contribution of ketones to neonatal brain metabolism have not been secured. Another built-in protective mechanism is that cerebral glucose use is low at birth (18 mmol/minute per 100 g), increasing to 60 mmol/minute per 100 g only at 50 weeks' postconceptional age. Cerebral glucose metabolism, as measured by 18F-fluorodeoxyglucose positron emission tomography shows increasing uptake with advancing gestational age.[50] The neonatal brain, and especially the cerebral white matter, has relatively low oxygen consumption. Hypoglycemia is associated with gray and white matter injuries of the brain.

Until recently, brain injury patterns identified on early MRI scans and their relationship to the nature of the hypoglycemic insult and neurodevelopmental outcomes have been poorly defined. Burns studied 35 term infants with early brain MRI scans after symptomatic neonatal hypoglycemia (median glucose level: 1 mmol/L) without evidence of neonatal encephalopathy.[16] They reported that white matter abnormalities occurred in 94% of infants with hypoglycemia, being severe in 43%, with a predominantly posterior pattern in 29% of cases. Cortical abnormalities occurred in 51% of infants; 30% had white matter hemorrhage, 40% basal ganglia/thalamic lesions, and 11% an abnormal posterior limb of the internal capsule. Twenty-three infants (65%) demonstrated impairments at 18 months that were related to the severity of white matter injury and involvement of the posterior limb of the internal capsule. MRI studies in patients with severe hypoglycemia show a predominant involvement of occipital and parietal areas; however, there may be widespread involvement of cortex, or combined with white matter, or basal ganglia and thalamus.[37]

Transient asymptomatic hypoglycemia in an otherwise healthy neonate has been associated with a good prognosis. Brand and co-workers described neurodevelopmental outcome in 75 full-term, LGA infants with transient

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

hypoglycemia on the first day of life to be similar to healthy control children at the age of 4 years.

For the past 20 years, it has been thought that recurrent low blood glucose levels <2.5 mmol/L (45 mg/dL), even in the absence of any suggestive clinical signs, can harm a preterm infant's long-term development. Lucas and colleagues examined the neurodevelopmental outcome of 661 preterm infants weighing less than 1850 g at birth in a multicenter, randomized controlled trial of feeding. Moderate hypoglycemia (a plasma glucose concentration <46.8 mg/dL) occurred in 433 infants and was found in 104 infants on 3-30 separate days.[36] The number of days with moderate hypoglycemia was strongly related to reduced mental and motor developmental scores at a corrected age of 18 months, even after statistical adjustments for a wide range of factors known to influence development. Additionally, the number of days during which moderate hypoglycemia occurred was strongly related to reduced mental and motor development at 18 months corrected age.[36] However, the associated clinical problems of hypoxemia, birth trauma, respiratory distress, prematurity, and other conditions make it difficult to assess the independent long-term effects of hypoglycemia in the human neonate. The problem has been confounded by incomplete follow-up, the lack of adequate control groups, and the lack of a uniform definition of hypoglycemia.

In contrast to these observations, a prospective cohort study by Tin et al. evaluated premature infants born at <32 weeks' gestational age with hypoglycemia in the first 10 days of life. In this study, 47 premature hypoglycemic infants evaluated at 2 years, and 38 of these children evaluated again at 15 years, were not significantly different from that of matched controls.[56] Similarly, Caksen et al. studied 47 preterm and 40 full-term infants with hypoglycemia.[17] Abnormal MRI findings were found in 4% of preterm infants and 32.5% of term infants. The MRI findings were normal in 96% of preterm infants with hypoglycemia. Abnormal MRI findings were statistically significantly more common in symptomatic infants (35.7%) compared to asymptomatic infants (15%). In this cohort of neonatal hypoglycemia, 50% of symptomatic and 57.5% of asymptomatic infants were healthy. Cerebral palsy with or without seizures occurred in 50% of symptomatic and 42.5% of asymptomatic infants.

In summary, although neonatal hypoglycemia poses a risk for neurologic sequelae, the data on the long-term neurologic consequences of symptomatic hypoglycemia remain, for the most part, inconclusive because of co-morbidities identified with each study.

Hyperglycemia

A high blood glucose concentration is less frequently observed in newborn infants than hypoglycemia. This partially results from the ability of normal infants, both preterm and full-term, to adapt to exogenous glucose administration by (1) decreasing or suppressing endogenous glucose production, and (2) increasing glucose uptake in the periphery. The net effect of such an adaptive response is the maintenance of normal blood glucose concentrations, even during high rates of glucose infusion. The definition of hyperglycemia in the newborn remains unclear. Obviously, hyperglycemia should be defined in the context of its clinical implications. Similar to other situations in older infants and adults, hyperglycemia increases blood osmolarity and may cause electrolyte disturbances, osmotic diuresis, and the associated loss of electrolytes in the urine. Because renal function in the neonate is significantly different from that in adults, all of the effects of hyperglycemia may not be seen. Specifically, the plasma glucose level at which renal glycosuria may occur is highly variable, depending on the maturity of renal function, so that renal glycosuria may be seen in extremely immature infants at plasma glucose levels that would be considered within the normal range. In general, most clinicians consider a plasma glucose range of higher than 180-200 mg/dL to represent hyperglycemia. Whether such hyperglycemia requires treatment depends on the associated abnormalities. Studies have demonstrated that even in the presence of significant hyperglycemia (a blood glucose concentration of 197 ± 15 mg/dL, mean ± SEM), the amount of glucose excreted or lost in the urine was less than 1% of the infused glucose. In addition, there was no significant diuresis, suggesting that such hyperglycemia (and minimum glycosuria) does not require the adjustment of intravenous fluids or insulin therapy. It should be emphasized that a change in blood glucose concentration from 90-180 mg/dL results in a change in blood osmolarity of 5 mOsm/L, which is relatively small compared with the normal range of plasma osmolarity (280-300 mOsm/L). The clinical circumstances in which hyperglycemia is observed in the newborn are described here.

Hyperglycemia in the infant with low birth weight is probably the most commonly observed perturbation of glucose metabolism in neonatal intensive care units. In the past, it was often attributed to the "immaturity" of glucose homeostasis in the infant with low birth weight or to the inability of the neonate to tolerate exogenous glucose infusion. However, studies have demonstrated that glucose metabolism, even in an infant with extremely low birth weight, is comparable to that in the full-term infant. These studies showed that (1) infants with low birth weight produce glucose at rates similar to those in full-term infants; (2) hepatic glucose production is regulated both by glucose and insulin and is suppressed in response to exogenous glucose infusion, hyperglycemia, or increased insulin levels; (3) hepatic glucose production is completely suppressed when glucose and amino acids are infused simultaneously, as in parenteral nutrition; (4) intravenous lipids do not cause any change in glucose production; and (5) peripheral glucose uptake increases normally in response to an increase in circulating insulin levels. The reasons for the observed hyperglycemia in the infant with low birth weight appear to involve stress related to the clinical problems.

The circulating insulin levels in hyperglycemic infants were appropriately increased with a good linear correlation between plasma glucose and insulin levels in both normoglycemic and hyperglycemic infants.

In conclusion, hyperglycemia in the infant with low birth weight is most likely related to the secretion of glucose counter-regulatory hormones as a result of stress or to the release of cytokines in infected infants. In fact, the levels of circulating catecholamines were noted to be high in infants with low birth weight and were attributed to clinical manipulations such as ventilatory support. Therefore, a high glucose concentration in an infant with low birth weight should be considered an indicator of clinical problems such as sepsis not primarily related to glucose metabolism. In addition to having their blood glucose concentrations managed, these infants must be evaluated for the possible cause of hyperglycemia, which in most could be systemic septicemia.

Diabetes Mellitus in the Newborn

Neonatal diabetes mellitus (NDM) is a relatively rare condition caused by pancreatic beta-cell insufficiency or impaired insulin secretion/action, occurring between the second day after birth and 6 months of age. NDM does not show markers of autoimmune disease. Clinically, three subgroups are recognized: (1) transient NDM (TNDM) in approximately 50% of cases, (2) permanent NDM (PNDM) in approximately 50% of cases, and (3) syndromic NDM. Various genetic defects responsible for both permanent and transient neonatal diabetes have been identified. ATP-sensitive potassium (K_{ATP}) channels are strategic regulators of glucose-induced insulin secretion in pancreatic beta cells (see Fig. 86.8). Activating mutations of the K_{ATP} channel, which prevent closure of the channel and thus inhibit insulin secretion, are now known to be the predominant cause of permanent neonatal diabetes mellitus (PNDM). Transient neonatal diabetes (TND) has an incidence of 1:400,000-500,000.[54] It is defined as diabetes that starts within the first weeks of life and recovers by 18 months. Transient neonatal diabetes gets its name from the observation that remission occurs after a variable period, and the infants do not require insulin therapy. However, diabetes may manifest later, particularly around puberty. Three phases of TND are described: (1) neonatal diabetes, (2) apparent remission, and (3) relapse of diabetes. TND is usually owing to genetic or epigenetic aberrations at an imprinted locus on chromosome 6q24 and can be sporadic or inherited. Transient neonatal diabetes may also be associated with activating mutations of *KCNJ11* and *ABCC8* for the $Kir_{6.2}$ and SUR1 subunit of the K_{ATP} channel.

TNDM presents in a few days to weeks of life as hyperglycemia, glycosuria, dehydration, weight loss, and the presence or absence of ketonemia, ketonuria, or metabolic acidosis. The median age at diagnosis is 6 days (range, 1-81 days). Most of these infants are born SGA (Fig. 86.11). Plasma insulin levels during the basal state and in response to a glucose load have been reported to be low.

• **Fig. 86.11** Birth weight of 45 infants with neonatal diabetes mellitus. Closed symbols denote girls; open symbols denote boys; *circles*, transient diabetes; *triangles*, transient diabetes with later recurrence; *squares*, permanent diabetes. (From Von Muhlendahl KE, et al. Long-term course of neonatal diabetes. *N Engl J Med.* 1995;333:704.)

TNDM resolves in 12 weeks, but 50% of cases may relapse. Associated nondiabetic birth defects are also reported in some patients, including macroglossia, congenital heart defect, developmental delay, and hypothyroidism.[54]

Three genetic anomalies on chromosome 6 have been identified in 70% of cases of TNDM. They are paternal uniparental isodisomy of chromosome 6, unbalanced paternal duplications of 6q24, and methylation defects at 6q24, all implying a disorder of imprinting whereby the expression of a gene or genes is affected by parental origin.[54]

Patients with anomalies of chromosome 6 could be offered genetic counseling. With uniparental disomy, the risk for recurrence in a sibling or child of the index patient is small, whereas the risk for transmitting the disease to the children of a man with 6q trisomy would be high.

Mutations in the adenosine triphosphate (ATP) sensitive K^+ channel (KCNJ11 and ABCC8) account for the other 25% of cases of TNDM, but these are more commonly seen in PNDM.

Permanent neonatal diabetes presents a little later, usually within the first 3 months, and requires insulin treatment for life.[48] Mutations in about a dozen genes have been linked to the development of PNDM. The most frequent causes of PNDM are heterozygous mutations in the *KCNJ11*, *INS*, and *ABCC8* genes. Most cases of PNDM may be explained by a monogenic defect[48] (see Fig. 86.8). Patients with the molecular diagnosis of PNDM because of the *KCNJ11* and *ABCC8* gene mutations can be switched from insulin to oral sulfonylureas with an improvement in glycemic control. Patients with PNDM resulting from recessive *INS* mutations are characterized with even lower

birth weight and an earlier age of diagnosis (first week of life); about 60% of them are the product of consanguinity and most remain on insulin therapy.[21]

Because K_{ATP} channels and their $Kir_{6.2}$ pore-forming subunits are expressed in the skeletal muscle and neurons throughout the brain, it was speculated that the severe developmental delay observed in some patients may be related to the altered activity of these channels in the brain and skeletal muscle.

Syndromic NDM can be associated with immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome, Wolcott-Rallison syndrome, Wolfram syndrome and syndromes associated with mutations of *PDX/IPF1*, *PTF1A*, *GLIS3*, *NEUROD1*, and *HNF1B* genes.[42] IPEX presents with diabetes, thyroid disease, enteropathy, and exfoliative dermatitis in infancy due to autoimmune endocrinopathy. SNDM is considered when K-ATP channelopathies and other known mutations for NDM have been ruled out.

Diagnosis of monogenic NDM presenting in children less than 6 months of age requires molecular genetic analysis for K_{ATP} channel mutations. Treatment includes correction of fluid-electrolyte disturbances and hyperglycemia. These infants are often extremely sensitive to insulin and respond well to a daily insulin dose of 3-4 U/kg of body weight. Insulin dosage must be adjusted based on plasma glucose concentration, glycosuria, or both. Because of the risk for hypoglycemia, careful and frequent monitoring of plasma glucose levels should be performed. Sulfonylureas close the K_{ATP} channels and, therefore, most patients with these mutations (*KCNJ11* and *ABCC8*) are able to transition from insulin to oral sulfonylureas.

Diabetes mellitus owing to pancreatic lesions is extremely rare and is usually manifested soon after birth. The metabolic abnormalities are the result of either the absence of a pancreas (or pancreatic hypoplasia) or the congenital absence of insulin-secreting B cells. Both lesions result in a lack of insulin secretion. Because insulin is a primary growth-promoting hormone in utero, these infants are severely growth-restricted at birth. They rapidly become hyperglycemic soon after birth, often to extremely high levels, and require immediate insulin therapy. There may be other associated congenital abnormalities, such as congenital heart defects. In infants with pancreatic hypoplasia, insufficiency of the exocrine pancreas has also been reported. Very few infants have been reported to survive, primarily because of associated lethal congenital anomalies.

Insulin Therapy in the Baby With Low Birth Weight

Hyperglycemia is most commonly seen in extremely low birth weight infants at <26 weeks of gestation. Intravenous insulin in these infants has been used to (1) treat hyperglycemia and (2) enhance the delivery and assimilation of nutrients and consequently accelerate growth. When administering insulin to the neonate, frequent glucose monitoring and adjustment in the rate of glucose infusion are required to prevent hypoglycemia and its consequences. The rationale for such an approach is based on the observation that hyperglycemia and the inability to use glucose and other nutrients may be related to resistance to insulin action in those infants, resulting from either immaturity or a heightened counter-regulatory "stress" response.[11]

Insulin use increases glucose and total energy intake without affecting growth.[14] Use of insulin for hyperglycemia is not a widely utilized current practice because of suggested increase in mortality and adverse neurologic outcome in retrospective studies.[57]

Key Points

- Maternal glucose is the major substrate for fetal energy metabolism, facilitated by placental glucose transporters.
- Insulin is the major promoter of fetal growth.
- Hypoglycemia at levels of 25-40 mg/dL in the first 4 hours, and 35-45 mg/dL at 4-24 hours, requires intervention.
- Early feeding is critical to establish breastfeeding and maintain plasma glucose levels. Oral dextrose gel is recommended for early transitional hypoglycemia unresponsive to early feeds.
- Intravenous glucose infusions are begun at 6-8 mg/kg/minute and may need to be increased to maintain plasma glucose >50 mg/dL at <48 hours and >60 mg/dL at >48 hours of age.
- Hypoglycemia in IUGR infants results from multiple processes, including decreased glycogen stores and gluconeogenesis.
- Congenital hyperinsulinism (CHI) is an important cause of persistent and profound hypoglycemia. Diazoxide and octreotide are the first and second order drug treatments for hyperinsulinemic hypoglycemia.
- Transient asymptomatic hypoglycemia has a good prognosis. Severe symptomatic hypoglycemia may manifest brain injury, including occipital and parietal MRI lesions.

Disorders of Calcium, Phosphorus, and Magnesium Metabolism in the Neonate

STEVEN A. ABRAMS AND DOV TIOSANO

Approximately 98% of the calcium, 80% of the phosphorus, and 65% of the magnesium in the body are in the skeleton; these elements, often referred to as the "bone minerals," are also constituents of the intracellular and extracellular spaces. The metabolism of these bone minerals and mineralization of the skeleton are complex functions that require the interaction of various parameters. These include an adequate supply of nutrients, including proteins for collagen matrix synthesis, and an adequate intake and absorption of calcium and phosphorus for full bone mineralization. During prenatal development, nutrients are transferred mainly across the placenta. From the analysis of stillbirths and deceased neonates, it has been calculated that during the last trimester of gestation, the daily accretion per kilogram of body weight represents approximately 100-130 mg of calcium, 60-70 mg of phosphorus, and 3 mg of magnesium.[65] Therefore, at birth, the whole-body content of a term infant represents about 30 g of calcium, 16 g of phosphorus, and 0.75 g of magnesium. After birth, nutrient intake from most enteral sources, especially unfortified human milk, is below the amount needed to achieve this level of mineral retention.[63] This can promote the occurrence of relative osteopenia or clinical rickets in preterm infants and in some high-risk, full-term infants. This risk is greatest in infants with chronic illnesses such as bronchopulmonary dysplasia.[1,34] In addition to their role in bone formation, the bone minerals play important roles in many physiologic processes, such as transport across membranes, activation and inhibition of enzymes, intracellular regulation of metabolic pathways, secretion and action of hormones, blood coagulation, muscle contractility, and nerve conduction. The 20% of phosphorus that is not complexed within bone is present mainly as adenosine triphosphate, nucleic acids, and cell and organelle membranes. Magnesium, an essential intracellular cation, is critical in energy-requiring metabolic processes, protein synthesis, membrane integrity, nervous tissue conduction, neuromuscular excitability, muscle contractility, hormone secretion, and intermediary metabolism.

Calcium, Phosphorus, and Magnesium Physiology

Calcium Physiology

Serum Calcium

Serum calcium represents a very small fraction of total-body calcium. Less than 1% of whole body calcium is present in extracellular fluid and soft tissues. In the circulation, calcium is distributed among three interconvertible fractions. About 50% of total serum calcium is in the ionized form at the normal serum protein concentration and represents the biologically active component of the total serum calcium concentration. Another 8%-10% is complexed to organic and inorganic acids (e.g., citrate, lactate, bicarbonate, sulfate, and phosphate). Together, the ionized and complexed calcium fractions represent the diffusible portion of circulating calcium. About 40% of serum calcium is protein bound, primarily to albumin (80%) but also to globulins (20%).[30] Ionized calcium is the only physiologically active fraction. The protein-bound calcium is not biologically active but provides a rapidly available reserve of calcium. Under normal circumstances, the serum calcium concentration is tightly regulated by parathyroid hormone (PTH) and calcitriol (1,25-dihydroxy vitamin D_3; $1,25[OH]_2D_3$), which increase serum calcium (Fig. 87.1), and by calcitonin, which decreases serum calcium.

Serum total and ionized calcium concentrations are relatively high at birth but decrease sharply during the first hours of life to reach a nadir at 24 hours and increase progressively thereafter up to the end of the first week of life (Table 87.1). Sudden changes in the distribution of calcium between ionized and bound fractions may cause symptoms of hypocalcemia even in children with functioning hormonal

Abstract

The majority of the calcium, phosphorus, and magnesium in the body are in the skeleton. The metabolism of these bone minerals and mineralization of the skeleton are complex functions that require the interaction of various parameters. These include an adequate supply of nutrients, including proteins for collagen matrix synthesis, and an adequate intake and absorption of calcium and phosphorus for full bone mineralization. Key topics discussed in this chapter include intake recommendations, intestinal absorption, and excretion of these minerals, along with hormonal regulation of mineral metabolism in neonates.

• **Fig. 87.1** Regulation of calcium (Ca) and phosphate (PO_4) homeostasis. Parathyroid hormone (PTH) increases Ca release from bone, Ca resorption in the kidney, and $1,25(OH)_2D_3$ excretion from the kidney. PTH production is stimulated by low Ca and inhibited by low Mg and high $1,25(OH)_2D_3$. Vitamin D increases Ca release from bone and Ca and PO_4 absorption from the intestine. Vitamin D production is stimulated by high PTH and low PO_4. CaSR, Calcium-stimulating response; OH, hydroxylase; P, phosphorus; UV, ultraviolet light; Vit, vitamin.

TABLE 87.1 Early Life Changes in Serum Calcium, PTH, and Vitamin D Levels in Full-Term and Preterm Infants

	Cord Blood	24 Hr	48 Hr	96-120 Hr	30 Days
Calcium, nmol/L					
Full-term	2.42 ± 0.08	2.17 ± 0.10	2.16 ± 0.08	2.22 ± 0.12	2.52 ± 0.08
Preterm	2.28 ± 0.09	1.91 ± 0.06	1.86 ± 0.07	2.08 ± 0.11	2.43 ± 0.06
Intact PTH, pg/mL					
Full-term	5.1 ± 3	33 ± 8	30 ± 5	28 ± 16	
Preterm	4.5 ± 3	72 ± 17	56 ± 20	36 ± 14	
25(OH)D, ng/mL					
Full-term	13 ± 3	12 ± 2		12 ± 2	17 ± 1
Preterm	10 ± 3	8 ± 2		12 ± 2	17 ± 2
$1,25(OH)_2D$, pg/mL					
Full-term	38 ± 4	74 ± 9		100 ± 5	61 ± 4
Preterm	37 ± 6	62 ± 9		128 ± 29	108 ± 13

PTH, Parathyroid hormone.
Data from Hochberg Z, ed. *Vitamin D and rickets. Endocrine development* Vol 6. Basel, Switzerland: Karger; 2003:34-49.

mechanisms for the regulation of the ionized calcium concentration. Increases in the extracellular fluid concentration of anions such as phosphate, citrate, or bicarbonate increase the proportion of bound calcium and decrease ionized calcium. Alkalosis increases the affinity of albumin for calcium and thereby decreases the concentration of ionized calcium. In contrast, acidosis increases the ionized calcium concentration by decreasing the binding of calcium to albumin. Although it remains common to measure the total serum calcium concentration, more physiologically relevant information is obtained by direct measurement of the ionized calcium concentration. The total serum calcium

decreases about 0.8 mg/dL, or 0.25 mmol/L, for each 1 g/dL of decrease in serum albumin, without any change in the ionized calcium.

Placental Transport

During pregnancy, calcium is actively transferred from the mother to the fetus. The normal fetus accumulates about 25-30 g of calcium by the end of gestation. Approximately 80% of this calcium accumulates during the third trimester, when the fetal skeleton is rapidly mineralized. To meet the high demand for mineral requirements of the developing skeleton, the fetus maintains higher serum calcium and phosphorus levels than the maternal levels. This process is the result of the active transport of calcium across the placenta by a calcium pump in the basal membrane that maintains a gradient of maternal-to-fetal calcium of 1 : 1.4.

The main regulator of fetal ionized calcium appears to be parathyroid hormone related protein (PTHrP), which is produced by the placenta as well as by the fetal parathyroid glands. Animal data suggest that both PTH and PTHrP act in the regulation of fetal mineral metabolism. PTH-ablated mice showed significant abnormalities in fetal bone formation, including decreased mineralization of the cartilage matrix and decreased vascular invasion of the growth plate, suggesting a role of PTH beyond simply regulating serum mineral ion concentration.[49] In contrast to the relatively mild phenotype of PTH-ablated mice, animals that lack PTHrP show major developmental abnormalities, particularly a significant acceleration of chondrocyte differentiation in the growth plates leading to a lethal skeletal dysplasia characterized by the premature mineralization of all bones that are formed through an endochondral process.[41]

Although vitamin D is critical for mineral ion homeostasis and bone development during adult life, fetal mineral ion homeostasis appears to be mostly independent of this hormone. $1,25(OH)_2D_3$ is produced by the fetal kidney, and the vitamin D receptor is present in many fetal tissues, including the placenta.[55]

However, neonates deficient in 1-alpha-hydroxylase are grossly normal from birth until weaning.[19] Additionally, the absence of the vitamin D receptor (VDR) either in the mother or the fetus does not affect placental calcium transfer or fetal serum levels of calcium, phosphorus, or magnesium during the first days after delivery, indicating that the VDR in either side of the placenta, on the maternal or at the fetal side, is not critical for placental calcium, phosphorus, or magnesium transfer.[39,42,68] Cord concentrations of 25(OH)D and $1,25(OH)_2D_3$ correlate significantly with those found in the maternal circulation, suggesting that the vitamin D pool of the fetus depends entirely on that of the mother. $1,25(OH)_2D_3$ found in fetal plasma is a result of fetal kidney and placental hydroxylation activity. The placenta synthesizes and metabolizes $1,25(OH)_2D_3$ through the activity of 25-hydroxyvitamin D-1α hydroxylase and 1,25-dihydroxyvitamin D-24 hydroxylase, two key enzymes for vitamin D metabolism. Bone mass of neonates may be partially related to the vitamin D status of the mother, although this relationship is not consistently found in either the United States or in developing countries.[44,73]

After the umbilical cord has been cut, the neonate loses the transplacental supply of calcium and must adapt rapidly to ensure normal calcium homeostasis and skeletal growth and mineralization. The neonate is dependent on intestinal absorption to supply calcium and therefore must quickly stimulate the synthesis of PTH and $1,25(OH)_2D_3$, which had been suppressed in utero. Total and ionized calcium levels decrease significantly within 24-48 hours after birth. Calcium concentrations usually return to normal by 5-8 days after birth. Serum PTH levels, which are low at birth, increase within the first 24-48 hours, probably in response to the decrease in serum calcium. Subsequently, $1,25(OH)_2D_3$ levels rise to adult levels within a few days. Serum calcitonin rises two- to tenfold over cord blood levels within the first 48 hours. Hypocalcemic premature and asphyxiated newborns have the highest levels of postnatal calcitonin.[52]

Intestinal Absorption

Calcium absorption occurs primarily in the small intestine by both active and passive processes. Ionization of calcium compounds, which require an acidic pH, develops in the stomach and is a prerequisite for absorption. Vitamin D is essential for the active absorption of calcium, which involves carriers such as calcium-binding proteins. However, the role of vitamin D and active transport early in life is uncertain.

The absorption rate of calcium is higher than that during other periods of life except for during pregnancy in populations with low mineral intake. The average absorption of calcium from human milk in infants is approximately 50%-60% of its intake. The absorption of calcium added to human milk with commercially available fortifiers generally parallels that of the calcium endogenous to human milk.[27]

Studies in vitamin D receptor–knockout (VDR-KO) mice have underscored the importance of an intact VDR for intestinal calcium absorption. The VDR-KO mice exhibit decreased calcium absorption with a concomitant reduction in the expression of transcellular calcium transport proteins. Vitamin D–dependent transcellular calcium transport involves three major components: transient receptor potential vanilloid type 6 (TRPV6), calbindin D_{9k}, and Ca^{+2}ATPase. VDR-KO mice exhibit decreased calcium absorption with a concomitant reduction in the expression of transcellular calcium transport proteins. However, recent studies revealed that TRPV6/calbindin D_{9k} double KO mice do not demonstrate impaired intestinal calcium transport when they have usual dietary calcium intake, indicating that other compensatory factors are involved in intestinal calcium transport. Several studies underscored the importance of the paracellular route and suggested that $1,25(OH)_2D_3$ regulates tight junction proteins, such as Caludin-2,3, Caludin-12, and Cadherin-17, which lead to increased paracellular calcium transport.[16]

Passive calcium transport is driven by chemical gradients that represent movement of calcium among the cells (paracellular transport). It may account for most of the calcium

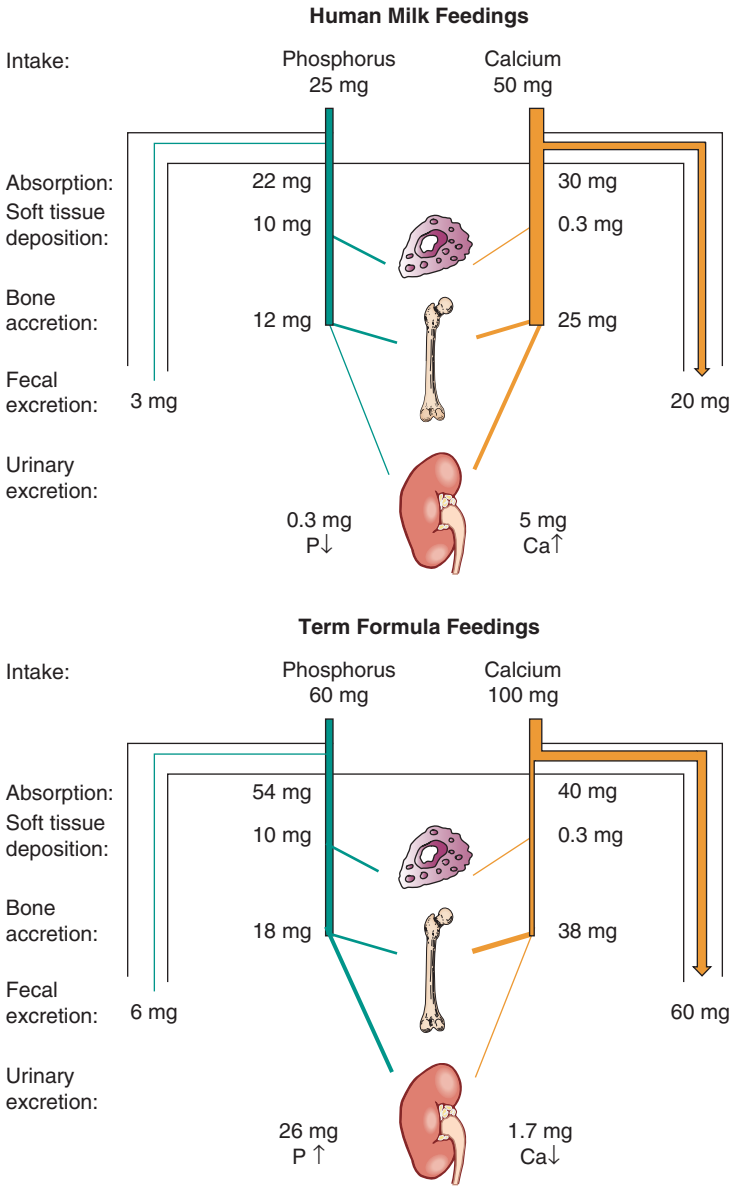
absorption very early in life, particularly in premature infants in whom the transport, which is transcellular and dependent on vitamin D, is not completely expressed.[13,39] In addition to vitamin D status, various other factors affect calcium absorption. Ionization of calcium compounds, which requires an acidic pH, occurs in the stomach and is a prerequisite for absorption. Therefore, low availability could be the result of an insoluble fraction of calcium intake or the precipitation of calcium in the gut. The quantity and quality of fat intake may influence calcium absorption through the formation of calcium soaps. Free palmitate content in the gastrointestinal tract after the hydrolysis of triglyceride may impair calcium absorption. Human milk contains a bile salt-stimulated lipase that is not specific to the Sn-1 and Sn-3 positions. The improvement of calcium absorption with the use of medium-chain triglycerides may be the result of the reduction of total saturated long-chain fatty acid content in formula. Relatively low gastrointestinal pH content or the lactose and casein content of the formula may also have an additional positive effect on calcium absorption.

Medications may also interfere with calcium absorption. For example, glucocorticoids inhibit intestinal absorption, and some anticonvulsants can also inhibit calcium absorption either directly (phenytoin) or indirectly through interference with vitamin D metabolism (phenobarbital and phenytoin). The clinical consequences of the use of these anticonvulsants in the neonatal period is not known but is unlikely to be a common major risk factor for low bone mineral accumulation in early life.

In infants, a significant amount of calcium is secreted in the intestinal lumen through digestive fluid. With the use of stable isotopes, endogenous fecal calcium excretion and true calcium absorption may be evaluated. Numerous metabolic balance studies have been performed in preterm infants fed human milk or a formula to evaluate apparent calcium absorption. In preterm infants fed human milk with or without fortification, calcium absorption ranges from 50%-70%. In formula-fed infants, the percentage of calcium absorption may be slightly less than that with human milk, although the difference does not appear to be large.[1]

Renal Excretion

Under normal circumstances, calcium status is maintained by a balance between its intestinal absorption and renal and endogenous fecal excretion with a small component of skin losses, especially with sweating. Although it is responsible for only 5%-10% of Ca^{2+} reabsorption, the major regulation of Ca^{2+} reabsorption occurs in the distal convoluted tubule by a mechanism independent of Na^{+} reabsorption but regulated by PTH and $1,25(OH)_2D_3$. Calcium reabsorption is increased by both PTH and $1,25(OH)_2D_3$. It is also regulated by ionized calcium concentration, phosphate concentration, and acid-base status. It increases with Ca^{2+} depletion and alkalosis but decreases with hypercalcemia, phosphate depletion, and acidosis. The effects of diuretics on renal calcium excretion vary considerably. Furosemide markedly increases renal calcium losses and is a risk factor for neonatal nephrocalcinosis.[24] Thiazides increase renal tubular calcium reabsorption, thereby reducing calciuria.



Nearly all filtered calcium (98%) is reabsorbed in the renal tubule. However, preterm and term infants differ from adults in three main aspects: (1) renal function is far from being completely developed; (2) mineral requirements for growth are very high; (3) renal calcium load results solely in the difference between net absorption and net bone and soft tissue retention. Considering that calcium soft tissue retention is negligible, renal calcium load is highly dependent on bone calcium deposition associated with phosphorus in the form of hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$ containing a molar calcium-to-phosphorus ratio of 1.67 (2.15 wt/wt). Therefore, the main determinant of the urinary loss of calcium in preterm and term neonates is phosphorus depletion and urinary excretion. When human milk is provided exclusively, there is an increase in the urinary excretion of calcium associated with very low urinary phosphate excretion. In contrast, when human milk is supplemented with phosphate, significant phosphaturia appears at the same time that calciuria decreases to a minimum level. Therefore, hypercalciuria can primarily be explained by a relative phosphate depletion that cannot meet the phosphate demand necessary for skeletal mineralization (Fig. 87.2).

Intake

Mature human milk contains approximately 260 mg of calcium per liter.[31] Considering the possibility of a lower efficiency (fraction) of calcium absorption from infant formulas compared with human milk, the guidelines of the Food and Drug Administration, the Life Sciences Research Office (LSRO),[36] and those of the Scientific Committee on Food of the European Commission for full-term infants during the first 6 months of life recommended a content of 50-140 mg of calcium per 100 kcal.[5] It should be noted that there are no comparisons of calcium absorption performed in the United States for infant formulas and human milk at the same calcium content, as the calcium content of human milk is uniformly less than the minimum mandated for infant formulas by the Infant Formula Act.[31] Typical 24-hour intake and retention values for human milk-fed infants are shown in Fig. 87.3.

The requirements for enteral calcium intake in preterm infants were reconsidered in an American Academy of Pediatrics (AAP) statement.[1] The AAP recommended a range of calcium intake of 150-220 mg/kg per day consistent with the LSRO recommendations for infants receiving 120 kcal/kg per day of feeding.[36] The AAP recommendations are slightly above those of the European authorities (Table 87.2).[5] In the United States, fortified human milk or preterm formula generally provides about 180-230 mg/kg per day of calcium at usual intakes (Table 87.3). There is no evidence that small variations among formulas within a class (e.g., different brands of preterm formulas marketed

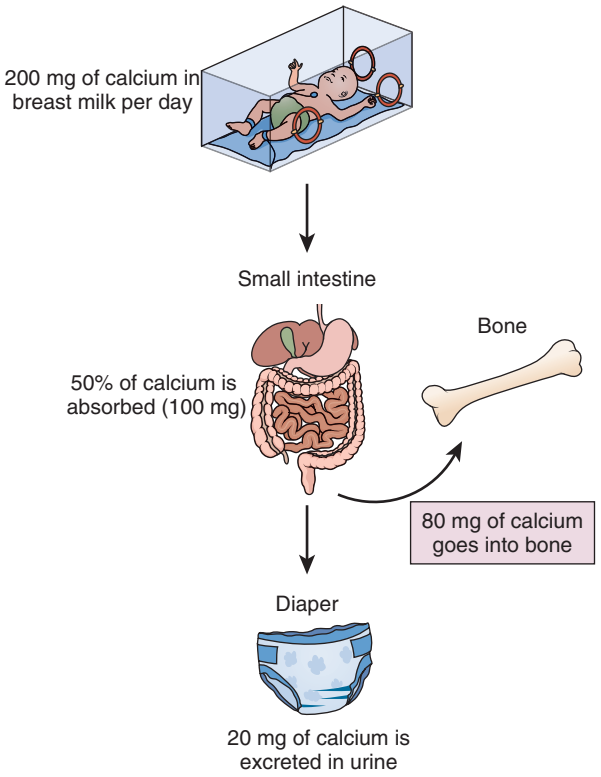
in the United States) in amount or source of calcium have a biologically meaningful impact on preterm infants.

Phosphorus Physiology



Unlike calcium, phosphorus is present in the soft tissues, mainly in the form of phosphate esters, and in extracellular fluid in the form of inorganic phosphate ions. This represents about 15% of the whole-body content. Given its widespread distribution, phosphorus plays a critical role in many biologic processes, including energy metabolism, membrane composition, nucleotide structure, cellular signaling, and bone mineralization. It is, therefore, not surprising that a deficiency of phosphorus results in clinical disease, including muscle weakness, impaired leukocyte function, and abnormal bone metabolism.

Serum Phosphorus

In serum, about two-thirds of phosphorus is organic (lipid phosphorus and phosphoric ester phosphorus) and one-third inorganic. In routine clinical practice, only inorganic phosphorus is measured. About 85% of the inorganic phosphorus is ionized, circulating as monohydrogen or dihydrogen phosphate; 5% is complexed with sodium, magnesium, or calcium; and 10% is protein bound. The serum concentration is conventionally expressed as the mass of the elemental phosphorus (mmol/L or mg/dL). In contrast to calcium, serum phosphorus concentration varies widely depending mainly on intake and renal excretion but is also influenced by age, gender, pH, and a variety of hormones. At birth, the mean serum phosphorus concentration is relatively low (2.6 mmol/L or 6.2 mg/dL) but thereafter rises rapidly to reach a typical value of 3.4 mmol/L, or

8.1 mg/dL, owing to both endogenous phosphorus release and low renal excretion.[43] The diet partially determines the serum phosphorus content, with higher values usually seen in infant formula compared to human milk–fed infants. Serum phosphorus is inversely related to serum calcium concentration and to age during childhood. Hypophosphatemia prevents apoptosis in the hypertrophic cells in the growth plate. In the absence of apoptosis, the hypertrophic cells accumulate in the growth plate and form the rachitic bone. It follows that the primary common denominator of rickets is hypophosphatemia, thus the diagnosis of rickets should be based substantially on the etiologies of hypophosphatemia, although in preterm infants with rickets it is clear that significant deficiencies of both calcium and phosphorus occur.[69]

• **Fig. 87.3** Typical values for calcium for breastfed infants at term for an entire 24-hour period.

Placental Transport

During pregnancy, there is transfer of phosphorus from the mother to the fetus that reaches a peak rate of 60-75 mg/kg per day during the third trimester; 75% is retained for bone mineralization, and 25% is retained in other tissues. The transplacental transport of phosphorus is an active process against a concentration gradient and is sodium dependent. Both $1,25(OH)_2D_3$ and fetal PTH may be involved in the regulation of placental phosphorus transfer.

Intestinal Absorption

Intestinal phosphorus absorption takes place primarily in the duodenum and jejunum. It occurs by two mechanisms: an active, sodium-dependent transcellular process localized to the mucosal surface by sodium phosphorous cotransporter 2B (NaPi 2B), and passive diffusion through the paracellular pathway. It depends on both the absolute amount of dietary

phosphorus and the relative concentrations of calcium and phosphorus (an excessive amount of either can decrease the absorption of the other). $1,25(OH)_2D_3$ stimulates NaPi 2B expression and active phosphorus absorption. In otherwise healthy intestines, the efficiency of this absorption is high (close to 90% of intake) regardless of the type of feedings provided to the infant.

Renal Excretion

The three major factors that control phosphorous reabsorption are high PTH activity, high FGF (fibroblast growth factor) 23, and renal defects that lead to inorganic phosphate (Pi) wasting. Hallmarks of high PTH activity are hypophosphatemia, phosphaturia, disturbance in vitamin D metabolism, and low calcium. The hallmarks of high FGF23 activity are hypophosphatemia and phosphaturia with inappropriately low $1,25\text{-}OH_2D$, and the hallmarks of renal rickets are hypophosphatemia and phosphaturia with high circulating $1,25\text{-}OH_2D$.

The kidney contributes to a positive phosphate balance during growth by the reabsorption of a relatively high fraction of filtered inorganic phosphate (99% in neonates, 95% in infants fed human milk, and 80% in adults). Preterm infants have an increased fractional excretion of phosphate and are at a greater risk for developing signs and symptoms of phosphate deficiency. The bulk of filtered phosphate is reabsorbed in the proximal tubule through sodium-dependent transporters, the Na-phosphate cotransporters 2A and 2C. A change from human milk with a low phosphate content to a formula with a higher content is associated with a rapid downregulation of Na-phosphate cotransporters mRNA and protein in the brush border membrane.

Because intestinal phosphorus absorption is very efficient and fairly unregulated, renal phosphorus excretion plays an important role in maintaining its balance. Filtered load depends on the plasma phosphorus level and glomerular filtration rate (GFR). Tubular reabsorption is an active and saturable process that gives rise to a maximal rate of tubular reabsorption (Tm). There is a plasma minimal threshold below which phosphorus reabsorption is almost complete and urinary excretion close to zero, and a maximal threshold above which all tubular reabsorptive systems are saturated, so each additional increment in filtered load is associated with a parallel increment in excretion.[43] In preterm infants, the minimal and maximal threshold levels are 1.75 mmol/L (5.4 mg/dL) and 2.45 mmol/L (7.6 mg/dL), respectively (Fig. 87.4). The three main factors responsible for Pi readsorption by the sodium/Pi cotransporter in the proximal tubule are urinary phosphorus, PTH, and FGF23. Renal handling of Pi is regulated by hormonal and nonhormonal factors. Changes in urinary excretion of Pi are almost invariably mirrored by changes in the apical expression of NaPi-IIa and NaPi-IIc in proximal tubules. Phosphate deprivation increases NaPi-IIa and NaPi-IIc expression in the proximal tubule. Both NaPi-IIa and NaPi-IIc, the main sodium/Pi cotransporters, are regulated in a similar fashion by PTH, FGF23, and dietary phosphate. Both PTH and FGF23 accelerate the cotransporter endocytosis, and FGF23 also accelerates cotransporters' degradation in the lysosome.

• **Fig. 87.4** Relationship between urinary excretion of phosphorus and serum phosphate level (N = 198) in preterm infants. Regression lines represent the minimal, mean, and maximal plasma phosphate concentration thresholds for tubular reabsorption of phosphate. Points to the left of the minimal threshold were considered hypophosphatemia associated with phosphorus depletion. Points to the right of the maximal threshold were considered hyperphosphatemia caused by low glomerular filtration rates and relative phosphorus overload.

During early postnatal life, the phosphate response to PTH is blunted, whereas PTH increases tubular calcium reabsorption. Together, these actions result in the retention of both calcium and phosphate in infants, which is favorable for growth and bone mineralization.

The level of FGF23 in cord blood is low, which might be caused by the low expression of FGF23 in fetal tissues. Measuring soluble α-Klotho and FGF23 levels in the cord blood reveals a negative correlation between the two.[54] The low FGF23 levels promote a relative hyperphosphatemia, and the relative increase in $1,25(OH)_2D_3$ promotes bone mineralization during early rapid growth in the neonatal period.

FGF23 functions principally as a phosphaturic factor. It is secreted by osteocytes and osteoblasts in response to high serum phosphate levels and $1,25(OH)_2D_3$. In the osteoblast, FGF23 post-translation undergoes O-glycosylation by GALNT 3. The glycosylation protects the molecule from degradation. Nonglycosylated FGF23 may be targeted

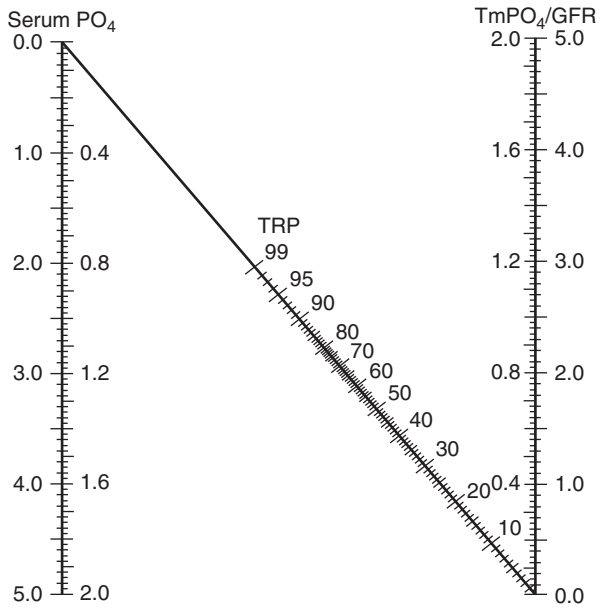
for degradation by subtilisin/furin-like endopeptidases. Impaired FGF23 synthesis or action, owing to *FGF23* gene mutations; mutations in GALNT 3; or mutations in Klotho, which is required for the conversion of FGFR1(IIIc) into the FGF23 receptor, leads to severe hyperphosphatemia and tumoral calcinosis.[67]

FGF23 accelerates NaPi-2a and NaPi-2c cotransporters' endocytosis to reduce renal phosphate reabsorption and thereby increases urinary phosphate excretion. Furthermore, FGF23 suppresses the expression of 1-α-hydroxylase to reduce the production of the active vitamin D metabolite $1,25(OH)_2D_3$. The hallmark of all clinical entities that share high FGF23 activity is rickets or osteomalacia with hypophosphatemia owing to renal phosphate wasting and inappropriately low serum $1,25(OH)_2D_3$ levels. Moreover, FGF23 can also induce 24-hydroxylase, which degrades $1,25(OH)_2D_3$.[10,21]

Absorbed phosphate enters the extracellular phosphate pool, which is in equilibrium with bone and soft tissue. In growing infants, the amount of phosphorus excreted is less than the net amount absorbed owing to the deposition of phosphorus in soft tissues and bone. In infants, phosphorus will preferentially go to soft tissue with a weight-to-weight nitrogen-to-phosphorus ratio of 15 : 1 and to bone with a weight-to-weight calcium-to-phosphorus ratio of 2.15 : 1. The residual phosphorus constitutes the renal phosphorus load influencing plasma concentration and urinary excretion. In the face of a limited total phosphorus supply, bone mineral accretion may be limited, leading to significant calcium excretion associated with very low urinary excretion of phosphorus. This particular situation is illustrated in Fig. 87.2, showing calcium and phosphorus metabolism in term infants fed human milk or formula.

Because the amount of Pi filtered through the glomeruli greatly exceeds intestinal absorption, it is the tubular reabsorption that determines Pi serum level. Bedside assessment of Pi renal handling is done by fasting spot urine and serum measurements of Pi and creatinine, calculating the tubular reabsorption of phosphate (TRP) or the renal threshold for Pi ($TmPO_4$/GFR). The first is based on the concept that:



$$\text{TRP}\,(\%) = (1 - \text{Pi clearance}/\text{creatinine clearance}) \times 100$$

By dividing clearance / clearance, the time and volume are redundant, and

$$\text{TRP}\,(\%) = (1 - \text{Up} \times \text{Scr}/\text{Sp} \times \text{Ucr}) \times 100.$$

(Up, Urinary phosphorus; Scr, serum creatinine; Sp, serum phosphorus; Ucr, urine creatinine; Pi, inorganic phosphate.)

The normal range for TRP is 80%-90%; low values indicate phosphaturia, such as in hyperparathyroidism or hypophosphatemic rickets; high values designate enhanced Pi reabsorption, such as in hypo- or pseudohypoparathyroidism. In the presence of abnormally high or low serum Pi, renal reabsorption decreases or increases, respectively. The TRP becomes, therefore, a lesser value in such conditions, and $TmPO_4$/GFR is calculated. $TmPO_4$, the tubular threshold for Pi reabsorption, reflects the highest serum Pi levels that will result in complete reabsorption of the filtrated Pi load. The nomogram developed for that purpose almost four decades ago is still a useful bedside tool (Fig. 87.5).[71]

• **Fig. 87.5** Nomogram reflecting the highest serum inorganic phosphate (Pi) levels that will result in complete reabsorption of the filtrated Pi load. GFR, Glomerular filtration rate; TRP, tubular reabsorption of phosphate; $TmPO_4$, maximal rate of tubular reabsorption of phosphate. (From Walton RJ, Bijvoet OL. Nomogram for derivation of renal threshold phosphate concentration. *Lancet*. 1975;2(7929):309-310.)

Intake

Mature human milk contains about 140 mg of phosphorus per liter. To avoid the occurrence of hypocalcemia or hypercalcemia resulting from an unbalanced diet containing the minimal calcium combined with the maximal phosphorus content, or the inverse, the Life Sciences Research Office and the Scientific Committee on Food of the European Commission recommend that the calcium-to-phosphorus ratio be maintained at more than 1.1 : 1 but less than 2.0 : 1.[5,36] The AAP recommended intakes of 75-140 mg/kg per day of phosphorus for very low birth weight (VLBW) infants.[1] Infants and children receiving amino-acid-based elemental formula as their sole source of nutrition may be at risk for hypophosphatemia and skeletal disease.[25]

Magnesium Physiology

The skeleton represents the largest magnesium store (60%), which is divided into two compartments: one firmly bound to apatite and nonmobilizing, and the other absorbed to the surface of the mineral crystals and contributing to magnesium homeostasis. The remaining magnesium is distributed in skeletal muscle, the nervous system, and other organs

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

with a high metabolic rate. Magnesium is the second-most abundant intracellular cation, playing a crucial role in many physiologic functions. It is critical in energy-requiring metabolic processes, protein synthesis, membrane integrity, nervous tissue conduction, neuromuscular excitability, muscle contraction, hormone secretion, and intermediate metabolism.

Serum Magnesium

In serum, about one-third of the magnesium is bound to protein, mainly albumin; the remaining two-thirds is ultrafilterable, being about 92% free and 8% complexed to citrate, phosphate, and other compounds. The plasma magnesium concentration is elevated in preterm and term infants (0.8 ± 0.16 mmol/L, or 2.0 ± 0.4 mg/dL) and decreases soon after infancy to adult values. The sum of ionized and complexed magnesium constitutes its diffusible or ultrafilterable form. Although the concentration of this form of magnesium in plasma remains almost constant (0.45 ± 0.1 mmol/L, or 1.1 ± 0.2 mg/dL), the proportion of this diffusible form in relation to total magnesium increases progressively with age (preterm newborn infants, 52%; term newborn infants, 62%; infants, 66%).

Placental Transport

Magnesium freely crosses the placental barrier and accumulates in the fetus mainly during the first trimester of pregnancy. Placental transfer continues throughout gestation at a daily rate of 3-5 mg. The transfer of magnesium across the placenta depends on an active transport mechanism different from that of calcium, which is necessary to maintain higher fetal than maternal concentrations. Situations of magnesium excess or deficiency in the mother are also reflected in the fetus.

Intestinal Absorption

About 40% of ingested magnesium is absorbed in the intestine, mainly in the proximal parts. There are two mechanisms of absorption: one is passive and the other active and saturable. Passive absorption occurs by means of a paracellular pathway, following a favorable electrochemical gradient as a function of water and solute movement, and appears to be proportional to dietary intake. Regulated, active transport depends on a saturable carrier present in the luminal membrane and operates only under conditions of low magnesium intake. The factors regulating the intestinal absorption of magnesium are largely unknown. The magnesium concentration in the digestive tract is the most important determinant of the amount of magnesium absorbed, nevertheless. Substances that increase magnesium solubility favor its absorption, whereas substances that form insoluble complexes decrease its likelihood. Magnesium absorption in the gut is not regulated by $1,25(OH)_2D_3$.

Renal Excretion

The kidney plays a major role in magnesium homeostasis. It conserves magnesium in response to a deficiency and increases excretion in proportion to the load presented to the kidney. About 70%-80% of serum magnesium is filtered through the glomerular membrane, but only 5%-15% of the filtered magnesium is reabsorbed along the proximal tubule, which is considerably less than the amount of fractional reabsorption of sodium or calcium. The primary site for magnesium reabsorption is the thick ascending limb of the loop of Henle, where about 65% of the filtered magnesium is reabsorbed. When the magnesium intake is severely restricted in humans with normal kidney function, urine output decreases. Supplementing a normal intake increases urinary excretion without altering normal serum levels as long as renal function is normal and the amounts given are not excessive. Overall, the tubular reabsorption of magnesium is a process that is quantitatively limited; the maximal rate of this reabsorption appears to be lower than that of calcium and phosphorus.

Renal homeostasis of magnesium is regulated by many hormonal and nonhormonal factors. The hormonal factors interact to modify the transepithelial electric gradient, tubular permeability at the level of the loop of Henle, or mechanism of active transport at the level of the distal convoluted tubule. Calcitonin, glucagon, vasopressin, PTH, and insulin all increase the tubular reabsorption of magnesium. The nonhormonal factors include the concentration of magnesium in the tubular lumen, acid-base equilibrium, and plasma concentrations of potassium and inorganic phosphate. The tubular reabsorption of magnesium is closely linked to that of calcium. It has been recently shown that epithelial cells of the loop of Henle and the distal convoluted tubule have receptors that sense the extracellular concentrations of both Mg^{2+} and Ca^{2+}. Metabolic acidosis also increases the urinary excretion of magnesium. Daily urinary excretion in normal children oscillates between 1.6 and 2.8 mg/kg of body weight daily. An increased value observed during infancy does not represent a higher excretion of magnesium but is related to the diminished excretion of creatinine per unit of lean body mass during this age period.

Intake

Mature human milk contains about 26 mg of magnesium per liter.[32] Guidelines for infant formulas during the first 6 months of life recommend minimal and maximal contents of 4-5 mg and 15-17 mg/100 kcal, respectively. For preterm infants, the recommendations are based on fetal accretion rates, and values similar to those at term have been suggested (6.8-17 mg/100 kcal and 7.9-15 mg/kg per day, respectively).[5,32,36,59,70]

Hormonal Regulation of Mineral Metabolism

Parathyroid Hormone

The parathyroid glands, through the secretion of PTH, regulate serum calcium concentrations and bone metabolism.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

PTH is synthesized as a larger (115-amino acid) precursor (prepro-PTH) but is stored and secreted mainly as an 84-amino acid peptide, with the 1-34,N-terminal portion conferring bioactivity.[46]

Effects

Parathyroid hormone increases serum calcium concentrations directly by increasing bone resorption and renal calcium reabsorption and indirectly by increasing renal synthesis of $1,25(OH)_2D_3$, thereby increasing intestinal calcium absorption. In addition, PTH lowers serum phosphorus concentrations through its phosphaturic action on the renal proximal tubule. This action minimizes the possibly adverse effect of hyperphosphatemia related to bone resorption on calcium homeostasis.

Regulation of Hormonal Secretion

Serum calcium concentration regulates PTH secretion; high concentrations inhibit the secretion of PTH, and low concentrations stimulate it. Low or falling serum calcium concentrations act within seconds to stimulate PTH secretion, initiated by means of a calcium-sensing receptor on the surfaces of parathyroid cells. This receptor is expressed in the parathyroid glands, where it regulates PTH secretion, and in the kidneys, where it regulates tubular calcium reabsorption. Decreases in ionized calcium of as little as 0.4 mmol/L stimulate PTH secretion, and increases suppress it. Acute decreases in magnesium concentrations also stimulate PTH secretion, and increases depress it. However, chronic magnesium deficiency paradoxically decreases PTH secretion, probably by altering the calcium-sensitive, magnesium-dependent adenylate cyclase involved in PTH secretion.[40]

Vitamin D and its metabolites 25-OHD and $1,25\text{-}OH_2D$, acting through vitamin D receptors, decrease the level of PTH mRNA. The human calcium receptor gene contains six exons and is located at 3q13.3-21 (*Online Mendelian Inheritance in Man*, OMIM, 601199). In the parathyroid gland, the calcium receptor mediates inhibition by extracellular Ca^{2+} concentration of PTH secretion, of *PTH* gene expression, and of parathyroid cellular proliferation. In the kidney, the receptor mediates the direct inhibition of the reabsorption of divalent cations in the thick cortical ascending limb of the loop of Henle.[62] Inactivating or activating mutations of this receptor cause inherited human conditions.

Both activating and inactivating calcium-sensing receptor (CaSR) mutations have been identified. Loss-of-function CaSR mutations lead to familial hypocalciuric hypercalcemia, which is an autosomal dominant condition usually characterized by mild degrees of hypercalcemia, inappropriately normal PTH levels, and low (or inappropriately low) urinary calcium excretion. Gain-of-function CaSR mutations are associated with dominant hypocalcemic hypercalciuria. Some cases of nonfamilial idiopathic hypoparathyroidism may also be caused by gain-of-function CaSR mutations.

Fetal Parathyroid Function

Maternal immunoreactive PTH, like other polypeptide hormones, does not cross the placenta. Concentrations of PTH increase from the first to the second trimester, declining again in the third trimester to the levels of the first trimester. However, PTH is significantly increased postpartum. In contrast, PTHrP concentrations increase continuously throughout pregnancy and lactation. Human parathyroid glands are functionally active as early as 12 weeks of gestation. However, fetal parathyroid glands are functionally suppressed by high intrauterine calcium concentrations, and PTH levels in cord blood are frequently below the detection limit. Loss of PTH has no effect on overall fetal growth (crown-rump length, weight); loss of PTHrP has a modest effect on fetal growth; loss of PTH and PTHrP has a more pronounced effect on fetal growth; and loss of the PTH1 receptor causes the most marked fetal growth restriction.

Maternal hyperparathyroidism results in maternal hypercalcemia, which leads to fetal hypercalcemia and suppression of fetal and neonatal parathyroid glands. Conversely, untreated maternal hypoparathyroidism leads to maternal hypocalcemia, fetal hypocalcemia, and secondary fetal and neonatal hyperparathyroidism.

Neonatal Parathyroid Function

After birth, with the abrupt termination of the maternal calcium supply, serum calcium in the newborn decreases, and serum PTH increases correspondingly. Both term and preterm infants may show a PTH response to falling serum calcium. Infants with VLBW have a decreased PTH surge compared with full-term infants. Infants of diabetic mothers may have impaired PTH production during the beginning days of life. Infants with severe perinatal depression may also have decreased PTH responses to hypocalcemia.

Parathyroid Hormone Reference Values

Current assays for serum PTH are conducted at two sites that are designed to detect both amino-terminal and carboxy-terminal epitopes of the peptide. PTH molecules that are reactive in these two-site immunoassays are considered intact.

In full-term newborn infants, serum PTH concentrations tend to be low in cord blood but increase within the first 48 hours of life in response to the decrease in serum calcium. In preterm infants, PTH concentrations increase immediately after birth, indicating that, in them, the secretion of the hormone responds physiologically to the hypocalcemic stimulus. This increase in PTH concentration could be blunted when premature infants receive calcium by infusion, with the calcium load buffering the postnatal depression of serum calcium. By day of life 10, the serum concentrations of intact PTH return to euparathyroid values (Table 87.4). The multiplication factor for serum PTH from picograms per deciliter to picomoles per liter (pg/dL to pmol/L) is 0.11.

Vitamin D

Synthesis and Metabolism

Vitamin D is synthesized endogenously in the skin (cholecalciferol or vitamin D_3) after sunshine exposure to high-energy ultraviolet photons (ultraviolet B, 290-315 nm) or is absorbed from dietary sources in the duodenum and jejunum as either vitamin D_3 (from animal sources) or vitamin D_2 (ergocalciferol, from vegetable sources). Regardless of its origin, vitamins D_2 and D_3 are transported bound to the vitamin D–binding protein to the liver, where it is hydroxylated at carbon 25 to form vitamin D_3 (25(OH)D_3, or calcidiol), the most abundant vitamin D metabolite. The generation of calcidiol is regulated by CYP2R1.[14] Circulating concentrations of 25(OH)D_3 provide a useful index of vitamin D status (reflecting both dietary intake and sunshine exposure). Subsequently, 25(OH)D_3 is further hydroxylated at carbon 1 to form the final active metabolite, 25-hydroxyvitamin D_3-1α-hydroxylase (1α-hydroxylase), which is classically expressed in the kidney. However, 1,25$(OH)_2D_3$ can also be synthesized by various cells, including monocytes and skin cells, as well as by the placenta during pregnancy.

Effects

Normal vitamin D status is necessary to maintain calcium and phosphorus homeostasis. The effects of 1,25$(OH)_2D_3$ (calcitriol) on target tissues are initiated by its binding to a steroid receptor (vitamin D receptor) distributed in numerous tissues, leading to the synthesis of a variety of proteins. Therefore 1,25$(OH)_2D_3$ acts on the small intestine, increasing the absorption of calcium and phosphorus by the synthesis of calcium-binding (calbindin-D) proteins; on bone, mobilizing calcium and phosphorus by increasing the number of osteoclasts; and on the kidney, increasing calcium reabsorption in the distal nephron segments by increasing the expression of the epithelial calcium influx channel.

Regulation of Secretion

Renal 1-hydroxylation, which leads to the active metabolite, is tightly regulated. The main factors increasing the synthesis of calcitriol through stimulation of renal 25(OH)D_3-1α-hydroxylase are PTH, PTHrP, hypocalcemia, hypophosphatemia, and other hormonal factors such as IGF-1, estrogen, prolactin, and growth hormone. The production of calcitriol is inhibited by elevated serum levels of calcium and phosphorus and by FGF23.[58]

Fetal Vitamin D Function

Serum 25(OH)D concentration depends on vitamin D intake and production. The production of vitamin D is influenced by geographic location, season, skin pigmentation, and latitude. Vitamin D deficiency is very common during pregnancy, especially in areas with a prolonged winter season.[35] It is lower in African-American pregnant women in contrast to Caucasian pregnant women. In the United States, nearly half of African-American pregnant women are vitamin D deficient with a serum 25(OH)D less than 37.5 nmol/L, as opposed to less than 30% of Caucasian women.[12,31]

The serum 1,25-dihydroxyvitamin D concentration increases from the beginning of pregnancy. In humans, a proportion of the circulating active metabolite appears to be derived from maternal decidual cells, but increased 1,25$(OH)_2D$ synthesis by the mother's kidneys is not excluded. In addition, serum concentrations of vitamin D–binding protein increase during pregnancy.

Cord concentrations of the major vitamin D metabolites are consistently lower than those measured in the mother's serum. Placental venous 25(OH)D concentrations correlate significantly with those found in the maternal circulation, suggesting that calcidiol easily diffuses across the placental barrier and that the vitamin D pool of the fetus depends entirely on that of the mother. Most of the 1,25$(OH)_2D$ in fetal plasma is owing to fetal kidney activity, as suggested by studies in fetal plasma from infants with renal agenesis.

In undernourished populations with vitamin D deficiency, osteomalacia in the mother and abnormal skeletal metabolism in the fetus and infant have been reported. Infants of severely malnourished mothers may be born with rickets and can suffer fractures during the neonatal period. Therefore, bone mass of the newborn infant may be related to the vitamin D status of the mother. Comparison of the results of dual-energy x-ray absorptiometry (DEXA) from different countries shows that infant whole-body bone mineral content values are lower in countries in which milk products are not supplemented with vitamin D than in those in which milk products are supplemented. In contrast, vitamin D supplementation of malnourished mothers results in improved growth of the fetus and child in terms of both birth weight and subsequent linear growth during infancy. Moreover, maternal vitamin D status during

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

pregnancy may have influence on the fetal skeletal development starting as early as 19 weeks' gestation and can persist long after infancy.[45] At the age of 9 years, children whose mothers had deficient or insufficient concentrations of 25-OHD in late pregnancy had a reduced bone size and bone mineral content.[33]

Maternal vitamin D deficiency and insufficiency during pregnancy have been associated with an increased risk for preeclampsia, insulin resistance and gestational diabetes mellitus, and primary cesarean delivery.[2,15,48]

Current guidelines from the Institute of Medicine as endorsed by the American Academy of Pediatrics recommend a total dietary and supplement intake (RDA) of 600 IU/day of vitamin D during pregnancy and lactation.[8,31] Although some, including the Canadian Paediatric Society,[26] have suggested higher doses may be preferred, more safety and efficacy research is needed regarding high-dose vitamin D supplementation in pregnancy and lactation. Practitioners seeking to ensure that an adequate dose of vitamin D is transferred via breast milk without providing any supplementation directly to the breastfed infant recommend doses of about 6400 IU/day for mothers. Further studies are needed before this becomes routine policy, but limited data support this approach, especially for women who are breastfeeding and are unwilling or do not desire to give their infant a supplement.[28]

Neonatal Vitamin D Function and Recommendations

Serum or plasma 25(OH)D concentration is a useful vitamin D biomarker reflecting vitamin D supply (exposure) over a period of time. Nevertheless, several surveys show a high rate of poor maternal vitamin D status throughout the world, particularly in countries without vitamin D supplementation, with poor sun exposure, extensive clothing, or with deeply pigmented skin. Thus, the rate of cord blood vitamin D deficiency (<20 nmol/L; <8.3 ng/mL) may reach up to 70% in European populations.[56]

Vitamin D content in human milk is usually low.[31] A daily intake of 400 IU (10 micrograms/day) of vitamin D is recommended by the Institute of Medicine and endorsed by the American Academy of Pediatrics for all infants beginning soon after birth.[8] In addition, vitamin D is metabolized in the liver, and anticonvulsants such as phenobarbital and diphenylhydantoin increase its hepatic catabolism and requirements. There are some questions about what is meant in terms of timing of initiation by the available statements. In most practices, it is considered ideal to begin healthy full-term infants who are being partly or wholly breastfed on vitamin D supplements prior to their hospital discharge or not later than a week of age for those with longer initial hospitalizations.

In preterm infants, as a result of the decrease in serum calcium during the first days of age, the postnatal surge in PTH induces increased synthesis of $1,25(OH)_2D_3$ during the first days of life. Provision of vitamin D_3 increases the 25(OH)D pool of the newborn infant at birth, followed by rapid renal synthesis of $1,25(OH)_2D$ during the early postnatal days. In preterm infants, immaturity of the vitamin D activation pathway, either alone or in combination with other abnormalities, particularly transient hypoparathyroidism, hypercalcitoninemia, and end-organ resistance to its hormonal effects, may promote late neonatal hypocalcemia.

Reference Values

At the present time, consensus has not been reached with regard to the concentration of plasma 25(OH)D to define vitamin D insufficiency. The Institute of Medicine considered a value of 20 ng/mL (50 nmol/L) to be sufficient, and that is the value most commonly used.[31] The European Society for Pediatric Gastroenterology, Hepatology, and Nutrition in 2013 supported a value of 50 nmol/L as defining sufficiency and a concentration below 25 nmol/L (10 ng/mL) as representing severe deficiency in all age groups.[11] Although some groups recommend a minimum 25(OH)D target of 30-32 ng/mL, there are no data to suggest any clear benefit in infants to this higher target.[4] Achieving a plasma 25(OH)D level in all infants above 32 ng/mL would require careful monitoring of blood levels and dosing of some infants with more than 1000 IU/day, which is the currently established safe upper limit in infants less than 6 months of age.[4,23] In contrast, the vast majority of infants will achieve a plasma 25(OH)D of 20 ng/mL with a dose of 400 IU/day.[3] The risk:benefit and cost:benefit ratios of frequent monitoring of blood 25(OH)D levels in large groups of preterm or full-term infants are unclear at this time.[1,53]

Calcitonin

Synthesis and Metabolism

Calcitonin is a 32-amino acid peptide secreted by the thyroidal C cells, which also produce the calcitonin gene-related protein (CGRP). Calcitonin is also produced in other tissues, notably pituitary cells and other neuroendocrine cells in which calcitonin has a local paracrine effect but does not contribute to its peripheral effect. Both the *calcitonin/CGRP* and *PTH* genes are located on chromosome 11. CGRPα is produced throughout the central and peripheral nervous systems, acting as a vasodilator and a neuromodulator. The physiologic effects of CGRPα on bone are unclear.

Effects

The CaSR regulates serum calcium by suppressing the secretion of PTH; it also regulates renal tubular calcium excretion. The CaSR has a dual physiologic response to acute increases in ionized calcium, which includes the inhibition of PTH release, the stimulation of calcitonin release, and the reverse effects in response to a decrease in calcium.

The effects of calcitonin are independent of PTH and vitamin D action. The principal effect of calcitonin is to decrease osteoclastic bone resorption and the amount of calcium and phosphorus released from bone. Additionally,

calcitonin increases calcium and phosphorus excretion, so the overall effect of calcitonin is to decrease serum calcium and phosphorus concentrations. With regard to magnesium, calcitonin may decrease both its release from bone and renal tubular reabsorption. In humans, serum calcitonin rises during pregnancy, growth, and lactation. It is during these periods of calcium stress that a tonic antiresorptive hormone will best exert its effects to limit skeletal loss and promote mineral accretion. Calcitonin has a very short half-life and is cleared mainly by the kidney.

Fetal Calcitonin Function

Calcitonin is expressed by human thyroidal C cells early in gestation, and it circulates in fetal blood at levels that are higher than those in the mother. In a study using a *calcitonin/CGRP* gene knockout model in mice, McDonald and colleagues suggested that calcitonin and CGRP are not needed for normal fetal calcium metabolism.[47] They may instead regulate some aspects of fetal magnesium metabolism.

Neonatal Calcitonin Function

At birth, serum calcitonin concentrations are higher in cord blood than maternal blood, and they increase further in the first 24 hours of life. Serum calcitonin may be higher in preterm than full-term infants and higher in hypocalcemic preterm infants than normocalcemic ones. Serum calcitonin is also higher in asphyxiated than nonasphyxiated full-term infants. The physiologic importance of the postnatal increase of calcitonin is unclear. It may protect the skeleton from excessive bone resorption; however, it may contribute to neonatal hypocalcemia in some infants. It is uncertain whether calcitonin plays a specific role in neonatal hypocalcemia. Excess calcitonin would not explain the hyperphosphatemia commonly associated with neonatal hypocalcemia.

Bone Development

Ontogenesis

The perinatal development of bone occurs through two separate but interrelated processes: intramembranous and endochondral. Bone is formed in a precursor area occupied by fibrous mesenchyme or in an area of cartilaginous tissue. Intramembranous bone is the first to begin ossification. The elaborated bony trabeculae fuse to form the primary spongiosa. Osteoblasts cover the surface of the spongiosa and deposit new layers of the bone matrix, while new bone is being removed from other surfaces by a special group of multinucleated phagocytic cells called *osteoclasts*.

In contrast, all bones of the appendicular and axial skeleton grow by the transformation of growth plate cartilage into bone through a series of cell and matrix changes referred to as *endochondral ossification*. Calcium salts precipitate in the matrix partitions separating the hypertrophic cells, and capillary buds penetrate the perichondrium and begin to invade the hypertrophic cell area. The hypertrophic cells undergo apoptosis, which is phosphorous dependent and enables capillary invasion and osteoblasts to lay down a thin collar of osteoid around the midsection of the cartilage model.

Therefore, a medullary cavity is formed in the area that will become the midshaft of the long bone, establishing the first center of ossification. The perichondrium is called the *periosteum*. In this vascularized environment, the osteoblasts deposit layers of osteoid on the residual calcified cartilage, and bone tissue gradually replaces the formerly solid mass of cartilage.

Histomorphometric data from femoral metaphyses in fetuses and newborns with gestational ages ranging from 16-41 weeks established morphometric reference data and provided the opportunity to gain insight into long-bone growth in humans. Despite a rapid rate of net bone gain, osteoid indexes were relatively low, indicating that mineralization occurred very rapidly after bone deposition, and then suggesting that modeling, not remodeling, is the predominant mechanism responsible for the development of femoral metaphyseal cancellous bone in utero. Therefore, during fetal life, various environmental factors are specifically oriented to promote growth, high mineral transfer, and increases in the physical mineral density of the skeleton.

Factors Affecting Growth and Mineralization

During gestation, the fetus receives an ample provision of nutritional supply through the placenta. Nitrogen, energy, minerals, and vitamins allow a high velocity of body length growth, representing about 1.2 cm per week during the last trimester of gestation. The fetus maintains its hypercalcemic state in a high calcitonin and estrogen environment, promoting the modeling-to-remodeling ratio in favor of modeling and thus increasing endocortical bone. In addition, according to the mechanostat theory of bone development, fetal bone is also driven by the mechanical force applied to the fetal skeleton during the intrauterine resistance training provided by regular fetal kicks against the uterine wall.[60] Consequently, at term, the newborn skeleton has a high physical density (bone mass divided by bone volume), with elevated cortical thickness and relatively small marrow cavities.

Various factors influence the processes of growth, mineralization, and bone structure. Growth is directly related to protein and energy supplies but also to the hormonal environment comprising insulin, IGF-1, and IGF-2, among others. Bone formation, mineralization, and structure are related to mineral supply and hormonal factors such as PTH, vitamin D, and calcitonin, as well as others, such as genetics and physical activity. Several factors have been found to have a significant impact on newborn bone mineral content and developing fetal bone.[52] Reduced calcium supply, vitamin D deficiency, ethanol consumption, and smoking during pregnancy are all factors affecting fetal skeletal development in addition to low weight related to gestation and diabetes in the mother.

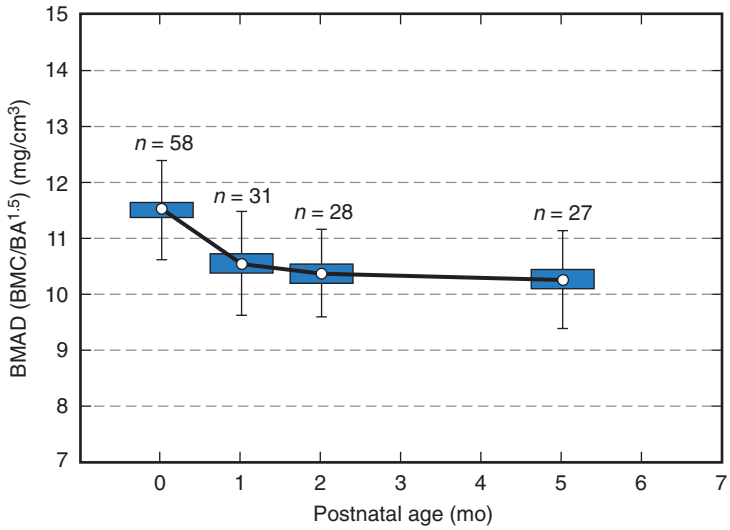
Evaluation of Fetal Mineral Accretion

From studies in stillborn infants and other cadavers, it appears that in preterm and term infants who are appropriate for gestational age, whole-body calcium accretion is exponentially related to gestational age and linearly related to body weight. Similar values have been obtained with the use of neutron activation techniques.[20]



Dual-energy x-ray absorptiometry is becoming the most accurate and precise noninvasive technique for assessing bone mineralization in vivo. Normative data for bone mineral content (BMC) and projected bone area in 106 healthy preterm and term infants near birth have been established (Fig. 87.6).[61] Bone area and BMC are positively related to body weight, body length, and gestational age. However, in multivariate analysis, body weight was the major and also the only significant predictor of those parameters. The high level of agreement between the in vivo calcium estimations and reference values suggests that the translation equation calculated in newborn piglets may generally be applied to newborn infants scanned with identical equipment soon after birth. Normative data for preterm and newborn full-term infants are extremely limited and the results frequently difficult to compare because of the different equipment and software used.[38]

Quantitative ultrasound (QUS) has been proposed as a diagnostic tool to evaluate bone mineralization in newborn infants. It measures the speed of sound (SOS) propagation through the bone, which reflects mainly the cortical bone density. Advantages of QUS include being nonionizing, inexpensive, and portable. At birth, there is a significant correlation between tibial SOS values and gestational age, birth weight, and birth length. The SOS values are significantly lower in preterm infants at birth compared with term infants and appear to fall when measured longitudinally in preterm infants. The relationship between SOS values and biochemical markers of osteopenia of prematurity is uncertain. QUS may have potential uses to assess bone health in

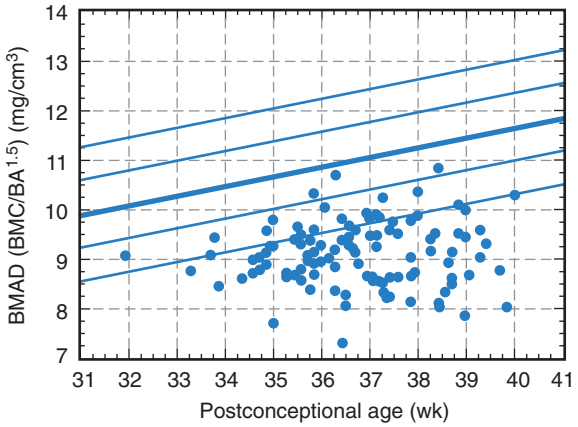
the newborn, but it is not widely available, nor has it gained traction in clinical use.[9]

Physiologic Skeletal Changes in the Early Postnatal Period



Term Infants

After birth, the switch from placental to dietary minerals causes the relatively hypercalcemic fetus to become a relatively hypocalcemic neonate, inducing a stimulation of PTH secretion. This leads to a large reduction in calcium availability for bone mineralization compared with the prenatal situation. The hormonal environment changes postnatally, because the placental supply of estrogen and many other hormones has been cut off. In addition, mechanical stimulation is likely to be lower postnatally. Therefore, there is a need for postnatal adaptation of the skeleton, and some of the factors implied in the fetal modeling-to-remodeling ratio disappear, inducing an increase in endosteal bone resorption. The physical density of long bones such as the femoral diaphysis decreases by about 30% during the first 6 months of life. This change is mostly the result of an increase in marrow cavity size, which is faster than the increase in the cross-sectional area of the bone cortex.

In term infants, these postnatal changes have been classically called *physiologic osteoporosis of infancy*, but they appear to occur without an increase in bone fragility. This phenomenon is well illustrated by the evolution of bone mineral apparent density (BMAD, g/cm^3) during fetal life, in which there is a continuous increase that contrasts with that obtained from birth to the first months of life, at which time a rapid reduction in BMAD is observed (Fig. 87.7).

Very Low Birth Weight Infants

The goal of feeding regimens for VLBW infants is to obtain a prompt postnatal resumption of growth to a rate approximating intrauterine growth. Postnatal adaptations of the skeletal system to extrauterine conditions also occur in premature infants, with the difference being that they take place earlier than they do in term babies. The process of birth interrupts fetal bone mineralization and, combined with the reduction in calcium availability, contributes to a reduction in bone physical density. These postnatal changes have been classically called osteopenia of prematurity, and these changes can be accompanied by an increase in bone fragility and the risk for fracture. In this situation, there is a sharp postnatal decrease in bone mineral areal density during the early postnatal weeks of life up to discharge near term (Fig. 87.8). Radiologically, however, identifying "osteopenia" is difficult and its clinical interpretation is uncertain. Thus, an emphasis on clearly defining infants as having rickets may be more clinically relevant.[1]

• **Fig. 87.8** Comparison between bone mineral apparent density (BMAD) at discharge in infants with very low birth weight (•, *N* = 108) and reference values (regression lines, *N* = 106). BMC, Bone mineral content; BA, bone area.

Clinical Conditions Associated With Calcium Disturbances

Neonatal Hypocalcemia

Neonatal hypocalcemia has been variously defined as a total serum calcium level of less than 2 mmol/L (8 mg/dL), less than 1.87 mmol/L, or less than 1.75 mmol/L. This variance in definition is at least partially due to the lack of clinical signs in many neonates, even at a very low serum total calcium concentration.

A better definition of neonatal hypocalcemia would be based on the metabolically active component of calcium, ionized calcium, because changes in ionized calcium concentration are more likely to have physiologic significance. Under conditions of normal acid-base status and normal albumin levels, the serum total calcium level and Ca^{2+} are linearly correlated, so total serum calcium measurements remain useful as a screening test. However, because Ca^{2+} is the physiologically relevant fraction, in sick infants, it is preferable to directly determine Ca^{2+} in freshly obtained blood samples.

Neonates at the greatest risk for symptomatic or asymptomatic neonatal hypocalcemia, such as the infants of diabetic mothers or preterm or asphyxiated neonates, are frequently sick for a multitude of reasons, and the contribution of neonatal hypocalcemia to signs related to their primary illness can be easily obscured. From a clinical viewpoint, because Ca^{2+} concentrations are maintained within narrow ranges under normal circumstances, the potential risk for disturbances of physiologic function increases as the Ca^{2+} concentration decreases. A useful approach to the classification of neonatal hypocalcemia is by time of onset. The early and late forms of hypocalcemia have different causes and occur in different clinical settings.

Early Hypocalcemia

See Box 87.1 and Box 87.2.

Term Infants

Early neonatal hypocalcemia occurs during the first 4 days of life and represents an exaggeration of the normal fall in serum calcium concentration that occurs during the first 24-48 hours of life. At birth, there is an interruption of maternal calcium supply, and the serum calcium concentration in infants is maintained by either the increased calcium flux from bone or sufficient exogenous calcium intake. Trabecular bone, which is richly vascularized, represents the main source of potentially rapidly mobilized calcium. Because intestinal calcium absorption is correlated with intake, and dietary calcium is usually low on the first day of life, the serum calcium concentration decreases on the first day of life.[30]

Normal serum concentrations for Ca^{2+} in full-term newborns reach a nadir at about 24 hours of age (1.10-1.36 mmol/L or 4.4-5.4 mg/dL) and rise slowly thereafter. In full-term infants, hypocalcemia is usually defined as an ionized calcium concentration of less than 1.10 mmol/L (4.4 mg/dL), which is the standard nadir in normal infants. This concentration represents two standard deviations below the mean at 24 hours. This definition is a statistical one and is based on assumptions of normal distributions of

• BOX 87.1 Causes of Neonatal Hypocalcemia

Early Hypocalcemia (1-4 Days of Age)

- Prematurity
- Maternal diabetes
- Perinatal stress, asphyxia
- Intrauterine growth restriction
- Maternal anticonvulsants

Late Hypocalcemia (5-15 Days of Age)

- Hyperphosphatemia (high phosphate load, advanced renal insufficiency)
- Hypomagnesemia
- Vitamin D deficiency
- Parathyroid hormone resistance (transient neonatal pseudohypoparathyroidism)
- Hypoparathyroidism
- Primary: parathyroid agenesis, 22q11 deletion, parathyroid hormone gene mutation
- Secondary: maternal hyperparathyroidism
- Calcium-sensing receptor defects, autosomal dominant hypocalcemic hypercalciuria
- Acquired or inherited disorders of vitamin D metabolism
- Neonatal hypocalcemia associated with skeletal dysplasia
- Other causes (alkalosis, citrated blood transfusions, phototherapy, viral gastroenteritis, lipid infusions)

• BOX 87.2 Diagnostic Steps for Hypocalcemia

History

- Family
- Pregnancy (diabetes mellitus, hyperparathyroidism, intrapartum events, fetal distress, asphyxia)
- Nutritional supplies of the newborn infant

Physical Examination

- Jitteriness, apnea, cyanosis
- Seizures
- Associated features (prematurity, dysmorphism, congenital heart defect)

Investigations

- Total serum and ionized calcium, magnesium, phosphorus, glucose
- Acid-base balance
- Chest radiograph (e.g., thymic shadow, aortic arch position)
- Urinary calcium, magnesium, phosphorus, creatinine, drug screen
- Vitamin D metabolites
- Parathyroid hormone
- Calcitonin
- Others (e.g., malabsorption, lymphocyte count, T-cell numbers and function, maternal and family screening, molecular genetic studies)
- Genetic studies for chromosome 22q11 deletion

physiologic variables. Further investigation needs to define physiologically important limits for term and preterm neonates. Characteristically, early neonatal hypocalcemia occurs most frequently in preterm infants, infants with evidence of respiratory depression at birth, infants of diabetic mothers, infants with significant growth restriction, and infants of mothers treated with anticonvulsants during pregnancy.

In preterm infants, the reference values for ionized calcium are available only for moderately premature infants who show values very similar to those for full-term infants. These cutoff values might not apply to smaller infants. Clinical symptomatology is rarely, if ever, identified in a VLBW infant with an ionized calcium greater than 0.80 mmol/L, although few recent data are available regarding this issue.

Preterm Infants

The frequency of hypocalcemia varies inversely with birth weight and gestational age. In preterm infants, the postnatal decrease in the serum calcium level typically occurs more rapidly than it does in term infants, the magnitude of the depression being inversely proportional to gestation. The fall in Ca^{2+} is not proportional to that in total calcium concentration, and the ratio of ionized to total calcium is higher in these infants. The reason for the maintenance of Ca^{2+} is uncertain but is probably related to low serum protein concentration and pH associated with prematurity. The sparing effect of Ca^{2+} may partially explain the frequent lack of signs in preterm infants with low total calcium levels.

Early neonatal hypocalcemia apparently results from the abrupt interruption of the placental supply and the low intake provided by oral and parenteral nutrition and also by the insufficient release of PTH by immature parathyroid glands or the inadequate responsiveness of the renal tubular cells to PTH. An exaggerated rise in calcitonin secretion in premature infants may play a contributory role.[30] In VLBW infants, the high renal sodium excretion probably aggravates calciuric losses, and relative end-organ resistance to $1,25(OH)_2D_3$ may exist.

Hypocalcemia is temporary, and usually the serum calcium concentration gradually reverts to normal after 1-3 days. Factors contributing to serum calcium normalization include increased calcium intake with feedings, increased renal phosphorus excretion, and improved parathyroid function.

Maternal Diabetes

Infants of diabetic mothers (IDMs) (see Chapter 18) have an exaggerated postnatal drop in circulating calcium levels compared with controls of gestational age. Prematurity and birth asphyxia are frequently associated problems that independently increase the risk for hypocalcemia. In IDMs, hypocalcemia may be related to hypomagnesemia, the maternal form of which is caused by urinary magnesium losses with diabetes and leads to fetal magnesium deficiency and secondary functional hypoparathyroidism in the fetus and newborn. Hypocalcemia in IDMs is also correlated with the severity of maternal diabetes. The natural history is usually similar to that of early neonatal hypocalcemia in preterm infants, but hypocalcemia sometimes persists for several additional days. Improved metabolic control for pregnant diabetic women has markedly diminished the occurrence and severity of early neonatal hypocalcemia in IDMs. As with IDMs, infants of gestational diabetic mothers are at increased risk of hypocalcemia related to hypomagnesemia.

Severe Cardiorespiratory Depression at Birth

In these infants, the following factors may contribute to early hypocalcemia: a decreased calcium intake owing to delayed feedings, an increased endogenous phosphorus load resulting from the reduction of the glomerular filtration rate, and an increased serum calcitonin concentration. Hyperphosphatemia may induce relative PTH resistance. Theoretically, the correction of acidosis with alkali may further aggravate hypocalcemia by inducing decreased calcium flux from bone to the extracellular fluid and by lowering the ionized calcium concentration.

Late Hypocalcemia

Hypocalcemia is conventionally considered late when it occurs after the first 3 days of life. Late neonatal hypocalcemia usually develops at about 4-7 days of age (see Box 87.1) and more frequently in term than preterm infants. It is not correlated with maternal diabetes, birth trauma, or asphyxia.

Phosphate Loading

Hypocalcemia induced by an elevated phosphorus supply usually occurs at the end of the first week of life. Late-onset hypocalcemia is considered to be a manifestation of relative resistance of the immature kidney to PTH. In these infants, the renal tubular cells are unable to respond appropriately to PTH, leading to renal retention of phosphorus and hypocalcemia. These biochemical features strongly resemble those of pseudohypoparathyroidism.[30] The normally low neonatal GFR may also play a role in limiting the ability to excrete the phosphorus load. Late hypocalcemia was frequently observed in infants fed cow milk or evaporated milk because of their high phosphorus content. With the introduction of adapted infant formulas, late hypocalcemia, although not abolished, has become uncommon, although it appears to occur more frequently in the Southwestern part of the United States. It may also be more common among Hispanic and male infants, but further information is needed regarding these possibilities.[6,66]

Even using currently marketed infant formulas, formula-fed infants have lower serum ionized calcium and higher serum phosphorus in the first week of life than breastfed infants. These differences correlate with the absolute phosphorus amount but not with the different calcium-to-phosphorus ratios in formulas. The phosphate load increases calcium bone deposition, leading to hypocalcemia. The normal response to hypocalcemia is an increase in PTH secretion, inducing an increase in both the urinary excretion

of phosphate and the tubular resorption of calcium. The pathogenesis of this transient hypoparathyroidism in late neonatal hypocalcemia is poorly understood. The inadequate secretion of PTH, immaturity of PTH receptors, or transient change in the threshold of CaSR may play an important role. Serum calcium levels frequently increase when these infants are given human milk, lower-phosphate formulas, and calcium supplements. After several days to weeks, serum PTH usually increases, and the infants are able to tolerate a higher dietary phosphate load and routine infant formulas without calcium supplements.

Hypomagnesemia

Neonatal hypocalcemia usually accompanies hypomagnesemia, because magnesium deficiency inhibits the secretion of PTH and reduces responsiveness to its action. Depression of the serum magnesium levels in newborns is caused by primary hypomagnesemia with secondary hypocalcemia or transient hypomagnesemia.

Primary hypomagnesemia with secondary hypocalcemia presents in infancy with persistent hypocalcemia and seizures that cannot be controlled with anticonvulsants or calcium gluconate. It is a rare autosomal recessive disorder resulting from primary defects in the intestinal transport of magnesium. The gene has been segregated to chromosome 9. Serum magnesium is frequently less than 0.8 mg/dL (normally, 1.6-2.8 mg/dL), and circulating levels of PTH are low despite the presence of hypocalcemia. The administration of magnesium to these infants leads to spontaneous parallel increases in serum PTH levels, serum calcium levels, and renal phosphate clearance.

Transient neonatal hypomagnesemia often occurs in association with hypocalcemia. The decrease in the serum magnesium level is usually less severe (0.8-1.4 mg/dL) than that in magnesium transport defects. In many infants with transient hypomagnesemia, the serum magnesium level increases spontaneously as the serum calcium level returns to normal after the administration of calcium supplements.

Transient hypomagnesemia secondary to renal magnesium wasting can be caused by the administration of loop diuretics, aminoglycosides, amphotericin B, urinary tract obstruction, or the diuretic phase of acute renal failure. The disorder may be mistaken for a form of neonatal hypoparathyroidism because of tetany and hypocalcemia or confused with Bartter syndrome (hypokalemic alkalosis with hypercalciuria) because of secondary potassium wasting. The diagnosis can be made by finding low serum magnesium levels with inappropriately high urinary magnesium excretion. A common laboratory feature of magnesium depletion is hypokalemia. Attempts to restore the potassium deficit with potassium therapy alone are usually not successful without simultaneous magnesium therapy.

Neonatal Hypoparathyroidism

The biochemical characteristics of hypoparathyroidism are hypocalcemia and hyperphosphatemia in the presence of normal renal function. Serum PTH concentrations are low or undetectable. The causes of hypoparathyroidism are diverse, representing disruptions of one or more of the steps in the development and maintenance of PTH secretion.

Secondary Hypoparathyroidism Related to Maternal Diseases. This transient condition may occur in the offspring of mothers with hyperparathyroidism or hypercalcemia from any cause. Maternal history may not be contributory, because the maternal disease (usually a benign adenoma) may be asymptomatic and discovered only after the diagnosis is made in the newborn. Maternal hypercalcemia leads to fetal hypercalcemia and secondary fetal hypoparathyroidism. This condition resolves spontaneously in days to weeks, and supportive therapy with calcium, $1,25(OH)_2D_3$, or both, usually suffices, but it may be temporally exacerbated by the feeding of high-phosphate diets.

Developmental Defects in the Parathyroid Glands. The isolated absence of parathyroid gland development may be inherited in an X-linked or autosomal recessive fashion. The most well described example is DiGeorge syndrome. DiGeorge syndrome, or velocardiofacial syndrome, is caused by an embryologic defect in the development of the third, fourth, and fifth branchial pouches and results in hypoparathyroidism. It is also characterized by cardiac defects, cleft palate, dysmorphic facial features, renal and ocular defects, and hypoplasia or agenesis of the thymus in addition to the parathyroid glands. The mutation isolated that causes DiGeorge syndrome is a de novo heterozygous deletion of chromosome 22q11 that includes the gene *TBX1*, which encodes a transcription factor necessary for thymic and parathyroid gland development. The constellation of abnormalities in DiGeorge syndrome has been referred to as CATCH 22 (*c*ardiac defects, *a*bnormal facies, *t*hymic hypoplasia, *c*left palate, and *h*ypocalcemia). DiGeorge syndrome is usually sporadic; however, autosomal dominant transmission has also been reported.[37]

Hypoparathyroidism has also been described in the hypoparathyroidism-deafness-renal dysplasia syndrome. In this syndrome, an autosomal dominant mutation leads to reductions in GATA3, a transcription factor essential for parathyroid, renal, and otic vesicular development.

Two other syndromes that include hypoparathyroidism, Kenny-Caffey syndrome and Sanjad-Sakati syndrome, have been described. The former is associated with short stature and ocular and bony abnormalities. Both syndromes have been linked to autosomal recessive loss of function mutations of *TBCE*, a gene involved in microtubule assembly in target tissues. Both syndromes are referred to generally as hypoparathyroidism-retardation-dysmorphism syndrome.[26]

Maternally inherited mitochondrial DNA defects have been associated with hypoparathyroidism in addition to other features as seen in the MELAS syndrome, as well as other disorders including the mitochondrial trifunctional protein deficiency syndrome, and the Kearns-Sayre syndrome.[46] An isolated hypoparathyroid defect has been described caused by mutations in the PTH glial cells missing

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

the homolog B (*GCMB*) gene. The *GCMB* gene regulates the development of the parathyroid glands.

Defects in the Parathyroid Hormone Molecule. A few cases of familial hypoparathyroidism have been described in which the cause was a mutation in the gene for PTH that resulted in the synthesis of a defective PTH molecule and undetectable amounts of PTH in serum.

Defective Regulation of Parathyroid Hormone Secretion. Hypocalcemia and hypercalciuria are the chief features of autosomal dominant hypercalciuric hypocalcemia, which is caused by activating mutations of the parathyroid and renal CaSR. These mutations cause excessive calcium-induced inhibition of PTH secretion. Hypocalcemia is usually mild and asymptomatic. When it is mild, it should be treated cautiously, if at all, because raising serum calcium concentrations further increases urinary calcium excretion and may cause nephrocalcinosis.[57]

Hypocalcemia Resulting From Vitamin D Disorder

Maternal vitamin D deficiency is the major risk factor for neonatal vitamin D deficiency presenting as hypocalcemia. Vitamin D deficiency is unusual in countries in which it is common practice to supplement the diet with vitamin D dairy products and other foods. However, it occurs in women in whom both sunlight exposure and the dietary intake of vitamin D are inadequate. At high risk are immigrants from the Middle East or South Asia who continue to wear traditional clothing. Daily supplementation of 400 IU for infants and 600 IU for pregnant and lactating women is recommended in most cases, although this is a topic of ongoing research and controversy and some populations may benefit from higher intakes.[31]

Infantile Osteopetrosis

Osteopetrosis is a rare congenital disorder related to bone resorption abnormalities that may be fatal without hematopoietic stem cell transplantation. Impaired bone remodeling associated with the dysregulated activity of osteoclasts for such a condition may cause bony narrowing of the cranial nerve foramina, which typically results in cranial nerve (especially optic nerve) compression. Abnormal remodeling of primary woven bone to lamellar bone results in brittle bone that is prone to fracture. Therefore, fractures, visual impairment, and bone marrow failure are the classic features of this disease. A number of heterogeneous molecular or genetic defects can result in impaired osteoclastic function. These genetic defects include mutations in the following genes: *Tnfrsf11a* gene (OMIM 259710) that encodes RANK; *OSTM1* (OMIM 607649) that encodes osteopetrosis-associated transmembrane protein 1; *ATP6iTCIRG1* (OMIM 604592) gene that encodes the a3 subunit of the vacuolar proton pump, which mediates the acidification of the bone-osteoclast interface, the chloride channel-7 protein CLCN7 (OMIM 602727), and carbonic anhydrase IICA2 (OMIM 611492). Given that the trabecular bone represents the main source of potentially rapidly mobilized calcium by osteoclasts, osteopetrosis can present as late neonatal hypocalcemia (mean age at presentation, 12 days) and is diagnosed easily based on its typical radiographic features.

Other Causes of Neonatal Hypocalcemia

Bicarbonate therapy, as well as any form of metabolic or respiratory alkalosis, decreases ionized calcium levels and bone resorption of calcium. Transfusion and plasmapheresis with citrated blood can form nonionized calcium complexes, thus decreasing Ca^{2+}. Furosemide and xanthine therapy promotes calciuresis as well as nephrolithiasis. Phototherapy appears to be an additional possible cause of neonatal hypocalcemia, although the mechanism is still uncertain. Lipid infusions may increase serum free fatty acid levels, which form insoluble complexes with calcium. Most of these effects are transient, and cessation of therapy is associated with a return to normal serum calcium levels.

Clinical Manifestations of Hypocalcemia

The clinical manifestations of neonatal hypocalcemia in infants may be easily confused with other neonatal disorders (e.g., hypoglycemia, sepsis, meningitis, asphyxia, intracranial bleeding, narcotic withdrawal). The neonate with hypocalcemia may be asymptomatic; the less mature the infant, the more subtle and varied are the clinical manifestations. In the neonatal period, the main clinical signs of hypocalcemia are jitteriness (increased neuromuscular irritability and activity) and generalized convulsions, although focal seizures have also been reported. Infants may also be lethargic, eat poorly, vomit, and have abdominal distention.

The degree of irritability does not appear to correlate closely with serum calcium values. Furthermore, hypocalcemia may be asymptomatic. Therefore, suspicion of hypocalcemia should be confirmed by the measurement of Ca^{2+}. The diagnostic workup for hypocalcemia (see Box 87.2) includes a history, physical examination, and relevant investigations. In clinical practice, the diagnosis of hypocalcemia is based on the determination of ionized calcium. Serum magnesium should also be measured because hypomagnesemia may coexist and cause identical signs. The measurement of calcium-regulating hormones is not routinely recommended unless hypocalcemia is prolonged, refractory, or recurrent. Chest radiographic examination for a thymic silhouette is indicated if DiGeorge syndrome is suspected. The measurement of QT intervals, corrected for heart rate, has not been shown to be useful for the prediction or management of neonatal hypocalcemia. Assays of calciotropic hormones and plasma 25(OH)D may be useful in the diagnosis of uncommon causes of neonatal hypocalcemia, such as primary hypoparathyroidism, malabsorption, and disorders of vitamin D metabolism but are not routinely needed in many settings such as with VLBW infants who respond to calcium therapy. Molecular genetic studies may be needed to confirm a specific diagnosis and have potentially important clinical relevance for the patient's clinical outcome.

Other investigations, which are listed in Box 87.2, may be important in the differential diagnosis and understanding of the pathophysiology of hypocalcemia.

Treatment

Early Neonatal Hypocalcemia

The choice of treatment for early neonatal hypocalcemia is complicated by several factors, among them that (1) the condition may coexist with other neonatal complications (e.g., asphyxia, hypoglycemia) that cause similar signs; (2) it may be associated with seizures, which may have a different etiology; and (3) it may remain asymptomatic and in most newborn infants is a self-limited disorder.

Symptomatic Hypocalcemia. The treatment of symptomatic hypocalcemia consists of the administration of calcium salts, either calcium gluconate (usual) or, if more readily available in an emergency, calcium chloride. A 10% solution of calcium gluconate contains about 9.4 mg of elemental calcium per milliliter. In case of seizures, 1-2 mL/kg of calcium gluconate (about 18 mg/kg of elemental calcium) is given intravenously over 10 minutes accompanied by continuous heart rate monitoring. After the resolution of seizures, intravenous calcium solution may be continued at a dose of up to 1.87 mmol/kg (75 mg/kg) of elemental calcium per day until the serum calcium concentrations have remained consistently in the normal range. Thereafter, the intravenous calcium solution can be reduced in a stepwise fashion (e.g., 50% for 4-12 hours, 25% for another 4-12 hours) and then discontinued.

Complications of intravenous calcium therapy include extravasation into soft tissues (with calcium deposition and sometimes cutaneous necrosis) and bradycardia. Because of the many potential risks, arterial infusions of calcium should not be done. However, parenteral nutrition solutions containing standard mineral (including calcium) content can be safely infused through appropriately positioned umbilical venous catheters or percutaneous centrally placed catheters. The direct administration of calcium preparations with bicarbonate results in precipitation and must be avoided.

As an alternative, if infants can tolerate oral fluids and are not actively having seizures, the intravenous form of calcium gluconate can be given orally at the same dose after the initial correction. All calcium preparations are hypertonic, and there is the theoretical potential for precipitating necrotizing enterocolitis in infants at risk for this condition. Calcium absorption in neonates from calcium carbonate may be limited by the higher pH of the neonatal stomach, and other forms, such as calcium glubionate, are commonly used in the neonatal period. The duration of supplemental calcium therapy varies with the course of hypocalcemia. As few as 1-3 days of therapy are usually required. The serum ionized calcium concentration should be assessed frequently during the first few days of treatment and for 1 or 2 days after its discontinuation until the serum total calcium and Ca^{2+} concentrations are stabilized. Persistent hypocalcemia needs further investigation. A poor response to calcium therapy may often result from concurrent magnesium deficiency.

Asymptomatic Hypocalcemia. In asymptomatic hypocalcemia, opinions vary on the need for and intensity of therapy. Some do not favor treatment because, in most cases, hypocalcemia resolves spontaneously with time. However, hypocalcemia has potentially adverse effects on both the cardiovascular system and the central nervous system.

Late Neonatal Hypocalcemia

Because serum calcium is not routinely measured after the first few days of life, late hypocalcemia is usually symptomatic when diagnosed. In phosphorus-induced hypocalcemia, a relatively low-phosphorus infant formula (or human milk) and oral calcium supplementation are indicated to decrease phosphorus absorption and increase calcium absorption.

In hypomagnesemia, the magnesium deficiency usually has to be corrected before hypocalcemia can be treated successfully. Magnesium may be administered intravenously as a 50% solution of magnesium sulfate in a dose of 25 mg/kg with continuous ECG monitoring. The magnesium dose may be repeated every 12 hours, depending on the clinical response and the (monitored) serum magnesium levels. Many infants with transient hypomagnesemia respond sufficiently to one or two doses of intravenous magnesium.

True hypoparathyroidism requires therapy with vitamin D metabolites; $1,25(OH)_2D_3$ (or 1 alpha-hydroxyvitamin D_3, a synthetic analogue that undergoes hepatic 25-hydroxylation) has the advantage of a shorter half-life, and treatment may be more easily tailored to the individual patient. In the CaSR mutation the need for therapeutic correction of hypocalcemia remains an open question, considering that hypercalciuria and nephrocalcinosis may be deleterious to renal function. Attention should be directed toward a number of concomitant treatments. Because thiazide diuretics can increase renal calcium reabsorption, the inadvertent institution or discontinuation of these drugs may increase or decrease, respectively, the plasma calcium level. In contrast, furosemide and other loop diuretics can increase the renal clearance of calcium and depress serum calcium levels. The administration of glucocorticoids antagonizes the action of vitamin D (and the analogues) and may also precipitate hypocalcemia. The development of hypomagnesemia may also interfere with the effectiveness of treatment with calcium and vitamin D.[30]

Prevention of Neonatal Hypocalcemia

The most effective prevention of neonatal hypocalcemia includes the prevention of prematurity and birth depression, including the judicious use of bicarbonate therapy and the prevention of severe maternal vitamin D deficiency. In current clinical practice, early use of intravenous nutrition including protein and calcium for VLBW and other high-risk infants has decreased the need for additional therapy, including boluses of IV calcium. In most cases in which intravenous nutrition including protein is not needed (e.g.,

• BOX 87.3 Causes of Neonatal Hypercalcemia

Iatrogenic
- Calcium salts, vitamin A
- Hypophosphatemia (prematurity)
- Hypervitaminosis D
- Thiazide diuretics

Disorders of parathyroid function
- Maternal hypocalcemia, hypoparathyroidism
- Mutation of the parathyroid hormone–related protein receptor
- Jansen metaphyseal chondrodysplasia
- Calcium-sensing receptor defects
- Familial hypocalciuric hypercalcemia
- Neonatal severe hyperparathyroidism

Idiopathic infantile hypercalcemia
Hyperprostaglandin E syndrome
Severe infantile hypophosphatasia
Other causes
- Congenital carbohydrate malabsorption
- Distal renal tubular acidosis
- Tumor-related hypercalcemia
- Congenital hypothyroidism
- Williams syndrome
- Subcutaneous fat necrosis
- Blue diaper syndrome

• BOX 87.4 Diagnostic Steps in Hypercalcemia

History
- Familial or maternal calcium or phosphorus disease
- Traumatic birth
- High maternal or neonatal supplies of vitamin D and/or A
- Drugs during pregnancy (thiazide, lithium)

Physical Examination
- Growth restriction
- Lethargy, dehydration
- Seizures, hypertension
- Associated features (e.g., elfin facies, congenital heart disease, mental retardation, subcutaneous fat necrosis)

Investigations
- Total and ionized calcium, phosphorus, magnesium, alkaline phosphatase
- pH, total protein, creatinine
- Urinary calcium, phosphorus, creatinine, cyclic adenosine monophosphate
- Chest and long-bone radiographs
- Renal ultrasound
- Parathyroid hormone, 25-OH vitamin D, 1,25-OH vitamin D
- Ophthalmologic evaluation, electrocardiography (QT interval)
- Others: parathyroid hormone related protein, parental serum calcium and phosphorus concentrations, vitamin A
- Molecular genetic studies

larger preterm infants), it is not necessary to routinely add calcium to glucose-containing solutions from birth.

Neonatal Hypercalcemia

Hypercalcemia is defined as a pathologic elevation in plasma ionized Ca^{2+} concentration greater than 1.45 mmol/L.[30,62] Neonatal hypercalcemia is relatively uncommon in infants greater than 1000 g birth weight, but it needs to be recognized, because it can result in significant morbidity. The clinical symptoms of sustained hypercalcemia are not specific. Infants with mild increases in ionized calcium (<1.60 mmol/L) often fail to show specific symptoms of hypercalcemia. Nonspecific signs and symptoms such as anorexia, vomiting, and constipation, but rarely diarrhea, may occur with moderate to severe hypercalcemia. The presence of seizures, bradycardia, or arterial hypertension is rare. On physical examination, infants may appear dehydrated, lethargic, and hypotonic. Those with chronic hypercalcemia may present with failure to thrive as the principal source of physical distress. Renal function is generally impaired, and polyuria and hypercalciuria are observed. However, renal complications such as nephrocalcinosis, nephrolithiasis, and hematuria may be the earliest clinical manifestations of hypercalcemia.

Iatrogenic Hypercalcemia

Iatrogenic hypercalcemia (Box 87.3 and Box 87.4) is the most common type of hypercalcemia in the newborn and should be considered before starting extensive investigation of rare syndromes. It may result from excessive intravenous calcium administration during total parenteral nutrition or exchange transfusion. Other causes of iatrogenic hypercalcemia are the use of extracorporeal membrane oxygenation, which can cause transient hypercalcemia in up to 30% of infants, and vitamin D intoxication from the administration of excessive vitamin D supplements. It has been shown that idiopathic infantile hypercalcemia (IIH) or "vitamin D intoxication" is a result of mutations in the *CYP24A1* gene (MIM 126065) encoding $25(OH)D_3$. The enzyme 24-hydroxylase is primarily responsible for $1,25(OH)_2D_3$ degradation.[64] The *CYP24A1* gene mutation leads to the increased sensitivity of the patients to even prophylactic doses of vitamin D and to the development of severe symptomatic hypercalcemia in patients with IIH. Conservative therapy includes parenteral rehydration, diuretics, corticosteroids, bisphosphonates, and vitamin D prophylaxis withdrawal. Clinical symptoms generally resolve rapidly after normalization of serum calcium levels.

Vitamin A toxicity is rare and can cause severe hypercalcemia. Because vitamin A is metabolized by the kidney, renal insufficiency may cause toxic accumulation, which probably acts directly on bone to cause increased resorption and hypercalcemia. Moderate hypercalcemia may also be the result of phosphorus deficiency in premature infants receiving unbalanced calcium and phosphorus regimens in oral and parenteral nutrition. In this situation, hypercalcemia is accompanied by hypophosphoremia.

The low phosphorus concentration in human milk causes phosphorus deficiency in very premature infants, leading to a mildly increased calcium concentration and

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

hypercalciuria. The absorbed phosphorus is preferentially oriented for soft tissue formation, whereas the remaining phosphorus is insufficient to allow calcium deposition. Hypophosphatemia stimulates renal synthesis of calcitriol, which activates the intestinal absorption and skeletal resorption of calcium and phosphorus. Phosphorus supplementation and the use of human milk fortifiers can prevent hypophosphatemia and hypercalcemia. Similar situations have been reported in infants on parenteral nutrition, providing an unbalanced calcium-to-phosphorus ratio. Additionally, thiazide diuretics reduce renal calcium excretion and may represent a contributing factor.

Congenital Hyperparathyroidism

Neonatal hyperparathyroidism is defined as symptomatic hypercalcemia with skeletal manifestations of hyperparathyroidism during the first 6 months of life. It may present in the first few days of life with PTH-dependent hypercalcemia, hypotonia, constipation, and respiratory distress.

Secondary Hyperparathyroidism

Most of the cases are caused by poorly treated maternal hypoparathyroidism, pseudohypoparathyroidism, or clinically unsuspected hypocalcemia, as seen in mothers with renal tubular acidosis that had induced severe secondary hyperparathyroidism in the developing fetus during pregnancy. Secondary hyperparathyroidism is a transient condition with a good prognosis provided that supportive measures are instituted. Bone disease usually resolves by 6 months of age.

Primary Hyperparathyroidism

In other cases, heterozygous or homozygous loss-of-function mutations in the *CASR* gene cause neonatal hyperparathyroidism.[57] The main forms of primary familial hyperparathyroidism presenting in infancy are autosomal dominant familial hypocalciuric hypercalcemia and sporadic neonatal hyperparathyroidism owing to a de novo heterozygous *CASR* mutation that results from an inactivating mutation of the *CASR* gene.

Familial hypocalciuric hypercalcemia is characterized by lifelong and generally asymptomatic, modest elevations in serum calcium levels, with relative hypocalciuria and PTH levels that are not suppressed by hypercalcemia and are inappropriately normal. Hypercalcemia is accompanied by borderline hypermagnesemia and hypophosphatemia. The low urinary excretion of calcium is inappropriate considering the presence of hypercalcemia.

Neonatal Severe Hyperparathyroidism. In contrast, individuals who are homozygous for *CASR* mutations or double heterozygous mutations have neonatal severe hyperparathyroidism (NSHPT). This condition is characterized by marked hypercalcemia, skeletal demineralization, and parathyroid hyperplasia, which can be fatal without parathyroidectomy.

Generally, NSHPT is manifested in the first few days of life with failure to thrive, hypotonia, constipation, and respiratory distress. Bony abnormalities are major and include undermineralization, subperiosteal erosion, metaphyseal destruction, and multiple fractures of both the long bones and ribs. It is often a life-threatening disorder, with a mortality rate of more than 25% in historical series. Children who survive NSHPT but remain hypercalcemic may feed poorly, with resulting failure to thrive, hypotonia, and developmental delay, and may be at risk for subsequent neurodevelopmental deficits. After the infant is rendered aparathyroid by surgical treatment, there is a dramatic fall in the serum calcium level, necessitating vitamin D and calcium therapy. Constitutional symptoms quickly reverse, with resolution of the bony abnormalities over about 6 months. Subtotal parathyroidectomy is often ineffective. Total parathyroidectomy with partial autotransplantation could be performed, leaving a minimal amount of parathyroid tissue necessary for normal calcium homeostasis. The use of pamidronate may be helpful to stabilize life-threatening demineralization before parathyroidectomy in rescue situations.

Williams Syndrome

Williams syndrome (also known as Williams-Beuren syndrome) is a multisystem disorder now recognized to be caused by a microdeletion of chromosome 7. It is present at birth and affects boys and girls equally. Williams syndrome is characterized by dysmorphic, elfin facies (100%); cardiovascular disease (most commonly supravalvar aortic stenosis, 80%); mental retardation (75%); developmental delay (90%); and idiopathic hypercalcemia (15%). The microdeletion codes for the structural protein elastin explain some of the characteristics of Williams syndrome. The pathogenesis of other characteristics, such as hypercalcemia, mental retardation, and unique personality traits, remains unexplained. In a fascinating piece of medical history, Dr. J.C.P. Williams, a registrar in New Zealand after whom the syndrome is named, disappeared after being offered a job in the United States, and his ultimate fate was never determined (http://www.whonamedit.com/doctor.cfm/56.html, accessed January 8, 2018).

Subcutaneous Fat Necrosis

Subcutaneous fat necrosis is common in full- or late-term newborn infants who experience a traumatic or difficult delivery.[18] Fat necrosis occurs in tissues that sustain direct trauma, such as those on which forceps or vacuum extraction is used. It is characterized by multiple indurated plaques or nodules with or without erythema on the cheeks, buttocks, posterior trunk, or extremities. Many lesions become calcified or fluctuant with liquefied fat. The cause of this disorder is unknown, but it may be initiated by ischemic injury, hypoxia, or hypothermia. Subcutaneous fat necrosis may be clinically occult, with spontaneous resolution over several weeks to as long as 6 months.[18] Hypercalcemia is uncommon, but it is the most frequently reported and serious complication of subcutaneous fat necrosis. Hypercalcemia usually appears when the subcutaneous fat necrosis

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

begins to resolve, but it has been associated with long-term intellectual impairment and may be fatal if unrecognized, requiring the need for long-term monitoring of total and ionized calcium levels after the onset of skin lesions.[18]

The pathogenesis of hypercalcemia is not fully understood. Three hypotheses have been proposed. In the first, the calcium is released from the resolving subcutaneous plaques, but most individuals do not develop hypercalcemia or have calcium deposition in the subcutaneous fat necrosis lesions. In the second, the elevated levels of PTH and prostaglandin E_2 stimulate bone resorption, but most patients have levels within the normal range. Elevated prostaglandin levels may be the result of emesis and therapy with furosemide. The third, the most widely accepted theory, proposes that the elevated $1,25(OH)_2D_3$ secreted from the granulomas of subcutaneous fat necrosis lesions stimulates intestinal calcium uptake. Normally, PTH stimulates the production of $1,25(OH)_2D_3$ from $25(OH)D_3$ by the kidney. The findings of low-normal PTH concentrations and elevated $1,25(OH)_2D_3$ support the hypothesis of the extrarenal production of $1,25(OH)_2D_3$.

Other Causes of Hypercalcemia

Congenital carbohydrate malabsorption can cause hypercalcemia during the first few months of life. Congenital lactase, glucose-galactose, or sucrase-isomaltase deficiency may be associated with hypercalcemia and nephrocalcinosis. The etiology of hypercalcemia is unclear, but it is thought to be related to an increase in intestinal calcium absorption secondary to increased gut lactose or galactose or to metabolic acidosis, or both.

Distal renal tubular acidosis is another disorder associated with hypercalcemia and nephrocalcinosis. Metabolic acidosis also has a significant effect on calcium homeostasis. In chronic metabolic acidosis, the buffering of acidosis by bone salts is markedly enhanced. Bone demineralization results from the release of calcium carbonate from the bone to neutralize excess hydrogen ions. In addition to its other effects, metabolic acidosis reduces the urinary citrate concentration and increases the risk for the formation of insoluble calcium oxalate or phosphate crystals.

Severe infantile hypophosphatasia is an autosomal recessive disorder associated with a marked deficiency in serum and tissue alkaline phosphatase, skeletal demineralization and bone deformity, and hypercalcemia. One of the main actions of alkaline phosphatase is to split the pyrophosphate molecule in the extracellular space into two phosphate molecules. Given that pyrophosphate is the main inhibitor of mineralization, in the absences of alkaline phosphatase activity, pyrophosphate constantly inhibits mineralization. This disorder presents with a spectrum of clinical manifestations. The most severe form presents with polyhydramnios, extreme skeletal hypomineralization, short deformed limbs, and fetal death. Less severe forms are carried to term, but the infant has hypercalcemia, severe rachitic-like/undermineralized bone on radiograph. These less severe forms are generally lethal early in life. An additional clinical form, transmitted as an autosomal dominant trait characterized by perinatal symptoms but a better clinical course, has been described. Enzyme replacement therapy has been shown to improve the findings on skeletal radiographs and to improve pulmonary and physical function in infants and young children with life-threatening hypophosphatasia.[72]

Blue diaper syndrome is a rare familial disease in which hypercalcemia and nephrocalcinosis are associated with a defect in the intestinal transport of tryptophan. The mechanism of hypercalcemia is uncertain, although oral tryptophan loading in humans and experimental animals produces an increase in the serum calcium level. The bacterial degradation of tryptophan in the intestine leads to excessive indole production, which is converted to indican in the liver and causes indicanuria. The oxidative conjugation of two molecules of indican forms the water-insoluble dye indigo blue (indigotin), which causes a peculiar bluish discoloration of the diaper. The clinical course is characterized by failure to thrive, recurrent unexplained fever, infections, marked irritability, and constipation. Treatment consists of glucocorticoid administration and low calcium and low vitamin D diets.

Tumor-related hypercalcemia has been found in infants with increased levels of PTHrP, which is thought to be the causative agent of hypercalcemia.

Clinical Manifestations

Most infants are asymptomatic when diagnosed. Those with mildly elevated levels of calcium often fail to manifest specific symptoms of hypercalcemia. Infants with chronic hypercalcemia may present with failure to thrive as the principal source of physical distress. There are nonspecific signs and symptoms such as anorexia, vomiting, and constipation (but rarely diarrhea); polyuria may occur with moderate to severe hypercalcemia. In severe hypercalcemia, infants are often dehydrated, lethargic, and hypotonic. Alternatively, they may present with seizures. Clinically, these infants can have bradycardia, a short QT interval, and hypertension. However, renal complications such as nephrocalcinosis, nephrolithiasis, and hematuria may be the earliest clinical manifestations of hypercalcemia. Otherwise, the physical examination is usually normal except for the infants with subcutaneous fat necrosis, Williams syndrome, Jansen metaphyseal chondrodysplasia, and hypophosphatasia.

In clinical practice, the following approach may be useful. First, the possibility of iatrogenic hypercalcemia should be excluded. Second, a maternal history of calcium-phosphorus disease or excessive vitamin D intake during pregnancy should be investigated. Third, the signs of clinical syndromes associated with hypercalcemia, such as blue diapers, fat necrosis, and elfin facies, should be sought. Fourth, the initial laboratory evaluation should include serum calcium, phosphorus, alkaline phosphatase, PTH, the urinary calcium-to-creatinine ratio, and tubular reabsorption of phosphorus. In most cases, these tests allow the differentiation of hypercalcemia caused by parathyroid disorders from nonparathyroid conditions. In

hyperparathyroidism, the serum phosphorus concentration is low; renal tubular phosphorus reabsorption is decreased, usually to less than 85%; and the serum PTH concentration is elevated. Finally, additional tests may be performed. Serum $25(OH)D_3$, $1,25(OH)_2D_3$, and $24,25(OH)_2D_3$ determination may be useful when mutation in 24 hydroxylase vitamin D is suspected; long-bone radiographs identify demineralization, osteolytic lesions, or both (hyperparathyroidism), or osteosclerotic lesions; measurements of serum and urinary calcium in parents allow a diagnosis of familial hypocalciuric hypercalcemia; and renal sonography detects nephrocalcinosis.

Treatment

The treatment of neonatal hypercalcemia depends on the severity of the presentation. Conservative management is appropriate in the case of mild hypercalcemia in a preterm infant resulting from an inappropriate mineral supply, hypoalbuminemia, or chronic acidosis, with special emphasis on the phosphorus supply when hypercalcemia is associated with hypophosphatemia. Hypercalcemia seen in newborn infants exposed to maternal hypocalcemia is usually mild and transient, and treatment consists of no more than supplying the appropriate amounts of calcium and phosphorus in the milk.

Infants with moderate to severe hypercalcemia need more aggressive treatment. The initial steps are not specific: (1) Discontinue oral and intravenous calcium and vitamin D supplementation and dietary restriction; (2) increase the urinary excretion of calcium by maximizing glomerular filtration with the administration of intravenous fluids, which consist of standard saline at about twice the maintenance requirements, and encourage calcium excretion with furosemide after rehydration but with particular attention to maintaining electrolyte homeostasis; and (3) be aware that more specific therapy comprises the use of glucocorticoids, calcitonin, bisphosphonate, dialysis, and total parathyroidectomy.

Glucocorticoids (2 mg/kg of prednisone) decrease intestinal calcium absorption, decrease bone resorption, and increase renal excretion. They may be useful during a short period, mainly in cases of an excess of vitamin D, but are relatively ineffective in cases of hyperparathyroidism. Bisphosphonate therapy is limited in newborn infants. However, pamidronate (0.5-2.0 mg/kg) has been used in the treatment of subcutaneous fat necrosis and could be an ideal agent to stabilize cases of NSHPT, as recently suggested. A calcimimetic drug that reduces PTH secretion, approved by the US Food and Drug Administration for chronic secondary hyperparathyroidism in dialyzed patients, could be of major interest in primary hyperparathyroidism but needs to be evaluated during infancy. Dialysis could be prescribed with a low-calcium dialysate (1.25 mmol/L) in the face of severe and unremitting hypercalcemia. Total parathyroidectomy with partial autotransplantation could be a rescue treatment in the severe form of NSHPT.

In the chronic phase, dietary restriction with the use of a special formula without vitamin D supplementation is the mainstay of treatment. If the dietary regimen is insufficient, corticosteroids can be used with caution. Cellulose phosphate binders have been occasionally used in children, but there is limited experience in neonates, in whom they may not be safe to use, in part because they may contain unwanted free phosphate.

Nephrocalcinosis in Preterm Infants

Nephrocalcinosis refers to deposits of calcium crystals diffusely located in the parenchyma of the kidney. The incidence is particularly high in infants with VLBW and ELBW (extremely low birth weight). However, it varies widely between 1.7% and 64% depending on different study populations, ultrasonographic criteria, and equipment.[29] Ultrasonography has been found to be a sensitive and reliable method for the detection of nephrocalcinosis. It shows either bright reflections of 1 ± 2 mm without acoustic shadowing, defined as white flecks, or bright reflections larger than 2 mm with or without acoustic shadowing, defined as white dots. The etiology of nephrocalcinosis in preterm neonates has not been fully clarified. It develops as the result of an imbalance between stone-inhibiting and stone-promoting factors. Because of its hypercalciuric effect, furosemide therapy is most frequently mentioned as a provocative factor. Treatment with aminoglycosides, corticosteroids, and xanthines may also contribute to stone formation, and neonates with lower birth weight, shorter gestational age, and transient renal failure appear to run a higher risk. Immature kidneys have relatively better-developed deep nephrons, with a long Henle loop and probably a low urinary flow velocity. Therefore, conditions are favorable for the formation of crystals, which then stick to the surface and grow. Preterm neonates who develop nephrocalcinosis may have a high urinary calcium-to-creatinine ratio, and an accompanying high intake of ascorbic acid might contribute to the high urinary oxalate-to-creatinine ratio, which is a potent lithogenic factor. In contrast, a low urinary citrate-to-calcium ratio, considered a lithoprotective factor, may be seen in infants with ELBW, suggesting that supplementation with alkaline citrate may have a beneficial effect in the prevention of nephrocalcinosis.

The short- and long-term evolution of nephrocalcinosis has not been clearly defined. Ultrasonographic abnormalities that develop during the first months of life disappear in most patients within months to years. Although proximal tubular function is unaffected in children with neonatal nephrocalcinosis, high blood pressure and impaired glomerular and distal tubular function might occur more frequently than in healthy, term children.

The long-term outcome of nephrocalcinosis in preterm neonates has not been defined. Nephrocalcinosis was not a prognosis factor for long-term (3-18 years) renal disease in infants with ELBW who had neonatal renal failure.

Clinical Conditions Associated With Magnesium Disturbances

Hypomagnesemia

Hypomagnesemia occurs when serum magnesium concentrations fall below 0.66 mmol/L (1.6 mg/dL), although clinical signs often do not develop until they fall below 0.49 mmol/L (1.2 mg/dL). The signs of hypomagnesemia are the same as those of hypocalcemia: irritability, tremors, and seizures. Because serum magnesium does not reflect total-body magnesium, there is no strict correlation between the clinical signs and serum magnesium concentrations. Hypomagnesemia and hypocalcemia frequently coexist.

Etiology

See Box 87.5.

Maternal Diabetes

In diabetes, glycosuria causes polyuria and increased urinary magnesium losses. The severity and prevalence of hypomagnesemia in infants of insulin-dependent diabetic mothers are directly related to the severity of maternal diabetes, which is thought to reflect the severity of maternal magnesium deficiency. The incidence of hypomagnesemia is also increased in infants of gestational diabetic mothers. Hypomagnesemia in IDMs (and infants of gestational diabetic mothers) is associated with neonatal hypocalcemia and decreased parathyroid function. Cord serum magnesium concentrations and its stores are decreased. Magnesium supplementation improves both serum calcium and PTH.

Intrauterine Growth Restriction

Some infants with IUGR manifest hypomagnesemia at birth. This manifestation may represent conditions in which maternal supply, placental transfer of magnesium, or both, are deficient. Hypomagnesemia is seen especially in infants with IUGR born from young, primiparous, toxemic mothers.

Neonatal Hypoparathyroidism

Serum magnesium and PTH concentrations are interrelated, so it may not be clear whether hypomagnesemia is the cause or the effect of hypoparathyroidism. A magnesium infusion test may help resolve the issue. If PTH increases after the magnesium load, magnesium deficiency with secondary functional hypoparathyroidism is likely. If PTH does not increase, hypoparathyroidism is probably unrelated to the deficiency.

Inherited Disorders of Renal Magnesium Handling

The genetic basis and cellular defects of a number of primary magnesium-wasting diseases have been elucidated during the past decade.

Primary Hypomagnesemia With Secondary Hypocalcemia. This is a rare autosomal recessive disorder resulting from primary defects in the intestinal transport of magnesium, with the responsible gene mapping to the long arm of chromosome 9. It presents in early infancy with persistent hypocalcemia and seizures that cannot be controlled with anticonvulsants, calcium gluconate, or both. Serum magnesium is frequently less than 0.8 mg/dL (normal, 1.6-2.8 mg/dL), and circulating levels of PTH are low despite the presence of hypocalcemia. In older children with inadequate magnesium control, clouded sensorium, disturbed speech, and choreoathetoid movements have been observed. The administration of magnesium to these infants leads to spontaneous parallel increases in serum PTH levels, serum calcium levels, and renal phosphate clearance. The prognosis is favorable if a diagnosis is made early enough.

Infantile Isolated Renal Magnesium Wasting (Dominant). Hypomagnesemia as the result of isolated renal magnesium loss is an autosomal dominant condition associated with few symptoms other than chondrocalcinosis. Patients always have hypocalciuria and variable, but usually mild, hypomagnesemic symptoms.

• BOX 87.5 Neonatal Hypomagnesemia and Hypermagnesemia

Neonatal Hypomagnesemia

Decreased Magnesium Supply

- Maternal magnesium deficiency
- Intrauterine growth restriction
- Maternal diabetes, insulin-dependent and gestational
- Malabsorption syndrome
- Extensive small intestine resection
- Intestinal fistula or diarrhea
- Hepatobiliary disorders
- Defect of intestinal magnesium transport: primary hypomagnesemia with hypocalcemia

Magnesium Loss

- Exchange transfusion with citrated blood
- Decreased renal tubular reabsorption
- Primary:
  - Infantile isolated renal magnesium washing (dominant and recessive)
  - Hypomagnesemia with hypercalciuria and nephrocalcinosis
- Secondary:
  - Extracellular fluid compartment expansion, osmotic diuresis
  - Drugs (e.g., loop diuretics, aminoglycosides)
- Other causes
  - Increased phosphate intake
  - Maternal hyperparathyroidism

Neonatal Hypermagnesemia

Increased Magnesium Supply

- Maternal treatment with magnesium sulfate
- Neonatal magnesium therapy: asphyxia, pulmonary hypertension
- Parenteral nutrition
- Antacids, enema

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Infantile Isolated Renal Magnesium Wasting (Recessive). There is evidence of a variant form of hypomagnesemia that is more consistent with isolated renal magnesium loss with autosomal recessive inheritance. Patients also have variable symptoms, but they usually have normal urinary calcium excretion.

Hypomagnesemia With Hypercalciuria and Nephrocalcinosis. A distinct syndrome of hypomagnesemia with hypercalciuria and nephrocalcinosis (HHN) has been described. The HHN syndrome is an autosomal recessive disorder that is characterized by renal magnesium wasting and results in persistent hypomagnesemia and marked hypercalciuria, leading to early nephrocalcinosis. It is distinguished from other conditions by the absence of infantile hypocalcemic tetany and normal plasma potassium.

Other Causes of Hypomagnesemia

Secondary defects in the renal tubular reabsorption of magnesium may result from extracellular fluid expansion caused by excessive glucose, sodium, or fluid intake or by osmotic diuresis. Loop diuretics such as furosemide and high doses of aminoglycosides such as gentamicin may cause magnesuria. Any severe malabsorption syndrome can cause magnesium deficiency. In the neonatal period, multiple exchange blood transfusions with citrate as an anticoagulant result in the complexing of citrate with magnesium, which leads to hypomagnesemia.

Clinical Manifestations

Hypomagnesemia in the neonatal period is usually transient (except for malabsorption syndromes) and asymptomatic, but it can cause hyperexcitability and occasionally severe, intractable hypocalcemic seizures that are unresponsive to calcium infusion and anticonvulsants. Hypomagnesemia should be considered in any patient with hypocalcemia who does not respond clinically or biochemically to calcium or vitamin D therapy.

Treatment

Hypomagnesemia should not be treated with calcium or vitamin D, which may cause a further decrease in serum magnesium. The administration of magnesium salts is the treatment of choice. The average amount of magnesium sulfate required in the neonate is a 50% solution of magnesium sulfate, 0.05-0.1 mL/kg (0.1-0.2 mmol/kg, or 2.5-5.0 mg/kg of elemental magnesium), given by slow intravenous infusion over 30-60 minutes. Repeated doses may be required every 8-12 hours. Possible complications of intravenous infusion include systemic hypotension and prolongation or even blockade of sinoauricular or atrioventricular conduction.

Concomitant oral magnesium supplements can be started if oral fluids are tolerated. A 50% solution of magnesium sulfate can be given at a dose of 0.2 mL/kg per day. In specific magnesium malabsorption, daily oral doses of 1 mL/kg per day may be required. Daily serum magnesium concentrations should be measured until the values are stable to evaluate efficacy and safety. Oral magnesium salts are not well absorbed, and large doses may cause diarrhea due to hyperosmolarity. The maintenance magnesium supplement should be diluted fivefold to sixfold to allow for more frequent administration, maximizing gut absorption, and minimizing side effects.

Neonatal seizures caused by hypocalcemia and hypomagnesemia do not have a uniformly favorable outcome, although the outcome is generally better than many other causes of neonatal seizures.

Hypermagnesemia

Hypermagnesemia is defined as a serum magnesium concentration greater than 1.15 mmol/L (2.8 mg/dL). Hypermagnesemia is invariably an iatrogenic event caused by excessive magnesium administration to mother or infant. Because magnesium balance is regulated primarily by the kidneys, decreased renal function can be a contributing factor.

Etiology

See Box 87.5.

Maternal Treatment With Magnesium Sulfate

Magnesium sulfate is used to prevent seizures in preeclampsia and as a tocolytic agent. Maternal hypermagnesemia results in fetal and neonatal hypermagnesemia. Concomitant maternal hypocalcemia may also occur secondary to decreased serum PTH concentrations. With the current treatment of preeclampsia, the neonatal serum magnesium concentration usually does not rise to a potentially dangerous level and gradually returns to normal after a few days.

Excessive Magnesium Administration

Treatment with magnesium-containing antacids for the prevention and treatment of stress ulcers has been reported to cause hypermagnesemia. Excessive magnesium administration with total parenteral solution is a potential cause of hypermagnesemia, especially in sick neonates.

High doses of intravenous magnesium sulfate have been used in the treatment of persistent pulmonary hypertension in the newborn. At high doses, magnesium appears to reverse the hypoxia-induced increase in pulmonary arterial pressure.

Clinical Manifestations

Hypermagnesemia should be suspected in depressed infants born to mothers who have been treated with magnesium sulfate. In most cases, hypermagnesemia is associated only with hypotonia. However, in extreme cases, severe neuromuscular depression (a curare-like effect) and respiratory failure (CNS depression) may occur. In adults, the signs may include neuromuscular depression and hypotension (usually at magnesium concentrations of greater than 1.64-2.46 mmol/L, or 4-6 mg/dL), difficult urination (greater than 2.05 mmol/L, or 5 mg/dL), CNS

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

depression (greater than 2.46-3.28 mmol/L, or 6-8 mg/dL), and respiratory depression and coma (greater than 4.92-8.33 mmol/L, or 12-17 mg/dL).

Serum calcium concentrations may be normal, decreased, or increased in hypermagnesemic neonates. Hypermagnesemia may suppress PTH and $1,25(OH)_2D_3$ production and may result in lower serum calcium concentrations. Rickets has been reported when maternal magnesium therapy is prolonged (e.g., in tocolysis to prevent preterm delivery).

Treatment

In most cases of neonatal hypermagnesemia, supportive treatment is sufficient, because an excess of magnesium is gradually removed through urinary excretion. Calcium is a direct antagonist of magnesium, and intravenous calcium given at the same dosage as that given for the treatment of hypocalcemia may be useful for acute therapy. Optimal hydration is important to ensure adequate urinary flow. Loop diuretic therapy may increase magnesium excretion. Citrated donor blood is particularly useful, because the complexing action of citrate expedites the removal of magnesium from the infant. Peritoneal dialysis and hemodialysis may be considered in refractory patients. Supportive measures such as cardiorespiratory assistance and adequate hydration may be needed.

Osteopenia of Prematurity

Premature babies are at increased risk for developing bone disease by reduced bone mineral content. Increased survival of infants with VLBW has been associated with an increased incidence of osteopenia of prematurity, which is also called *metabolic bone disease* or *rickets of prematurity*. The incidence is inversely proportional to gestational age and birth weight, and two decades ago, it was estimated to be 50% in infants weighing less than 1000 g and 23%-32% in infants weighing less than 1500 g; however, the current incidence is difficult to estimate, because the nutritional strategy has changed. Maximizing calcium and phosphorus intake from parenteral and enteral nutrition, early initiation of feeding, and decreased use of paralysis during mechanical ventilation probably have decreased the incidence of the disease.

Etiology

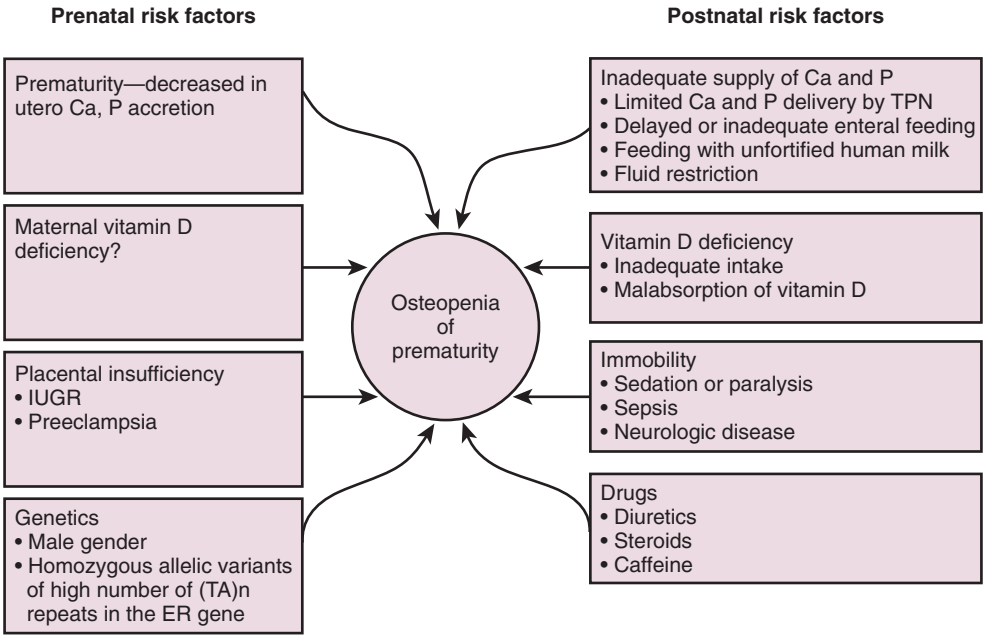
From birth, premature babies begin the process of physiologic postnatal adaptation, which is characterized by an increase in bone remodeling, with a progressive increase in marrow cavity size and a concomitant reduction in physical density. Primarily, the mineral supplies, especially calcium and phosphorus, may be low, whereas length and skeletal growth rates remain relatively high during the last trimester. In utero mechanical stimulation is likely to be higher, although there is inadequate information about the effects of this on bone mineral development after birth in VLBW infants.[60] Finally, the hormonal situation is different postnatally, because the placental supply of estrogen and many other hormones has been cut off.

Although vitamin D deficiency can cause rickets, it is not the primary cause in most cases in preterm infants, and provision of vitamin D supplementation alone does not reduce the incidence of rickets in preterm infants. The role of maternal vitamin D status in the development of osteopenia of prematurity is not clear, although low maternal vitamin D status is associated with reduced bone mineralization in term infants.[17]

Additional risk factors for bone disease in preterm infants include prolonged parenteral nutrition, feeding with unsupplemented human milk, fluid restriction, chronic illness, and the use of hypercalciuric drugs such as furosemide for the treatment of bronchopulmonary dysplasia and methylxanthines for the treatment of apnea and bradycardia, both of which increase calcium loss. The use of postnatal steroids can decrease bone formation. In addition, immobility, especially for prolonged periods of sedation during mechanical ventilation, could enhance calcium loss and demineralization. There is evidence that placental insufficiency has a role in increasing the risk of low bone mass as well. There may be an increased incidence of rickets in growth-restricted infants.

Development of osteopenia of prematurity or overt rickets in preterm infants may be associated with genetic polymorphisms. Candidate genes associated with adult osteoporosis have been evaluated for bone disease in infants with VLBW. A summary of the risk factors that contribute to the development of severe osteopenia of prematurity and rickets is illustrated in Fig. 87.9.

Diagnosis



Clinical Symptoms

Clinical symptoms of osteopenia are rare in infants with VLBW because of the widespread use of well-balanced parenteral solutions, human milk fortifiers, and preterm formulas. Fractures and rickets, which represent the major symptoms, have diminished, although they remain a concern in the smallest infants, especially those less than 1000 g.[50]

Biochemical Features

Biochemical features are relatively nonspecific. Usually serum calcium concentrations are within the normal range and serum phosphorus concentrations are normal or low at the time of diagnosis. The occurrence of a prolonged reduction of serum phosphorus during the early weeks of life could be predictive of the occurrence of rickets and osteopenia, because infants with ELBW are at risk for low renal phosphate reabsorption (tryptophan and GFR values), leading to urinary phosphate excretion even in the presence of low serum phosphate levels. Therefore, the absence of, or very low, urinary phosphate excretion also needs to be considered as an indicator of phosphate depletion. Alkaline phosphatase is frequently used to screen for osteopenia of prematurity despite conflicting evidence about its sensitivity

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• **Fig. 87.9** Prenatal and postnatal risk factors for development of osteopenia of prematurity. Ca, Calcium; IUGR, intrauterine growth restriction; P, phosphorus; (TA)n, thymine-adenine repeat; TPN, total parenteral nutrition; VDR, vitamin D receptor.

and specificity.[1] The peak alkaline phosphatase level is inversely related to the serum phosphorus concentration. Therefore, the combination of alkaline phosphatase and serum phosphorus concentration could be more useful to screen for osteopenia of prematurity than alkaline phosphatase alone. An alkaline phosphatase level higher than 900 IU/L has predicted radiographic osteopenia by DEXA scan with 88% sensitivity and 71% specificity, but the sensitivity is much higher with concomitant lower serum phosphorus concentrations (<1.8 mmol/L).[22]

Hormonal Features

In preterm infants, the serum PTH, serum $25(OH)D_3$, and serum $1,25(OH)_2D_3$ concentrations increase during the first month of life. Both 25- and 1,25-hydroxylation mechanisms are functionally active in preterm infants. The $25(OH)D_3$ and $1,25(OH)_2D_3$ levels are related to the mother's vitamin D status at birth as well as to the vitamin D supply to the newborn during the first weeks of life. In infants with VLBW supplemented with vitamin D, osteopenia does not appear to be related to the hormonal status.

Radiologic Features

Standard radiographs do not allow an accurate assessment of bone demineralization. Bone mineral density must decrease by 30% or more to be diagnosed by this method, and interobserver variability is considerable. However, standard radiographs can detect fractures, and a wrist or knee radiograph at or after 4-5 weeks of age in a high-risk infant remains a practical assessment of the presence of overt rickets. Currently, DEXA is the standard in whole-body mineral measurement, and normative data are available. The DEXA equipment is not portable, so performing a scan involves transportation of the infant, which may not be feasible for very small and sick infants who are at the greatest risk for metabolic bone disease.

Prevention and Treatment

A management strategy for rickets that is evident radiologically is shown in Box 87.6. Calcium and phosphorus requirements in preterm infants are usually based on demands for matching intrauterine bone mineral accretion rates and the maintenance of serum calcium and phosphorus concentrations comparable to those of normal term infants. However, more recent consideration of bone physiology suggests that the process of postnatal adaptation could modify the requirement, considering that the remodeling stimulation by itself provides part of the mineral requirement necessary for postnatal bone turnover. Under extrauterine conditions, the care of premature infants should not necessarily aim to achieve intrauterine calcium accretion rates. Subsequently, the skeletons of these infants will adapt to the mechanical requirements, whether intrauterine calcium accretion rates are achieved or not.

Parenteral Nutrition

Inadequate calcium and phosphorus intake has been associated with diminished bone mineralization in parenterally nourished premature infants. This deficiency occurs when protein and energy are adequate for growth, but calcium and phosphorus are insufficient to sustain appropriate skeletal mineralization. Calcium and phosphorus cannot be provided through parenteral solutions at the concentrations

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

needed to support in utero accretion because of precipitation. The solubility of calcium and phosphorus in parenteral solutions depends on the temperature, type, and concentration of amino acids; dextrose concentrations; pH of the calcium salt; sequence of the addition of calcium and phosphorus to the solution; calcium-to-phosphorus ratio; and presence of lipids. More acidic pediatric amino acid solutions improve calcium and phosphorus solubility. With a range of fluid intake of 120-130 mL/kg per day, it is advisable to supply a calcium content of 1.5-2.0 mmol/dL and a calcium-to-phosphorus ratio of 1.3 : 1 by weight and 1 : 1 by molar ratio in the total hyperalimentation solution. This quantity of calcium provided by the parenteral route is about 60%-80% of that deposited by the fetus during the last trimester of gestation.[51]

• BOX 87.6 Management Approach for Enterally Fed Preterm Infants With Radiologic Evidence of Rickets

1. Maximize nutrient intake. Consider increasing human milk fortifier and/or feeding volume of preterm formula, as clinically indicated. If unable to tolerate human milk fortifier or preterm formula, then will likely need elemental minerals added as described below.
2. If no further increases in these can be made, add elemental calcium and phosphorus as tolerated. Usually beginning at 20 mg/kg per day of elemental calcium and 10-20 mg/kg per day elemental phosphorus and increasing, as tolerated, usually to a maximum of 70-80 mg/kg per day of elemental calcium and 40-50 mg/kg per day elemental phosphorus.
3. Evaluate cholestasis and vitamin D status. May consider measuring 25-OH-D concentration, targeting serum 25-OH-D concentration of >20 ng/mL (50 nmol/L).
4. Follow serum phosphorus concentration and serum alkaline phosphatase weekly.
5. Recheck radiographs for evidence of rickets at 5- to 6-week intervals until resolved.
6. Advise caregiving team to be cautious in handling of infant.
7. Limit use of steroids and furosemide, as clinically feasible.

From Abrams SA, Committee on Nutrition. Calcium and vitamin D requirements of enterally fed preterm infants. *Pediatrics*. 2013;131:e1676-1683.

Enteral Nutrition

The exclusive use of human milk without phosphorus and mineral fortification promotes the occurrence of osteopenia and rickets in infants with VLBW. Both liquid and powdered human milk fortifiers are commercially available. Their use has dramatically reduced the incidence of fractures and radiographically diagnosed osteopenia. A similar reduction has also been observed in preterm infants fed preterm formulas.[7]

Although both the absorption and retention rates of calcium and phosphorus are higher in infants than adults, intestinal absorption of minerals remains a limiting factor of mineral accretion. In contrast, phosphorus is generally well absorbed, but phosphorus retention is related to calcium and protein accretion. Absorption of calcium is currently best evaluated using stable isotope techniques, taking into consideration the endogenous intestinal calcium secretion (Table 87.5).

Monitoring Mineral Supplementation

There are very few markers of adequate bone mineralization during the early weeks of life in newborn infants. Bone mineral content can be measured accurately by DEXA, but in clinical practice it is performed in very few centers.

An ideal approach to assess the adequacy of mineral intake in VLBW or other very high-risk infants may involve the following recommendations[1]:

1. Preterm infants, especially those less than 27 weeks' gestation or with birth weight less than 1000 g with a history of multiple medical problems, are at high risk of rickets.
2. Routine evaluation of bone mineral status using biochemical testing is indicated for infants with birth weight less than 1500 g but not those with birth weight greater than 1500 g. Biochemical testing should usually be started 4-5 weeks after birth.
3. Serum alkaline phosphatase greater than 800-1000 IU/L or clinical evidence of fractures should lead to a radiographic evaluation for rickets and management focusing on maximizing calcium and phosphorus intake and minimizing factors leading to bone mineral loss.

TABLE 87.5 Approximate Calcium Balance in a Typical Infant Receiving 120 kcal/kg per Day Intake*

	Calcium Concentration (mg/dL)	Intake (mg/kg per Day)	Absorption %	Total Absorption (mg/kg per Day)	Approximate Retention (mg/kg per Day)
Human milk	25	38	60	25	15-20
Preterm formula/fortified human milk	145	220	50-60	120-130	100-120

*Human milk assumed to be 20 kcal/oz, and preterm formula and fortified human milk assumed to be 24 kcal/oz.
Data from Abrams SA, and the Committee on Nutrition. Calcium and vitamin D requirements of enterally fed preterm infants. *Pediatrics*. 2013;131:e1676-1683.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

4. A persistent serum phosphorus concentration less than approximately 4.0 mg/dL should be followed, and consideration should be given for phosphorus supplementation.
5. Routine management of preterm infants, especially those with birth weight less than 1800-2000 g, should include human milk fortified with minerals or formulas designed for preterm infants.
6. At the time of discharge from the hospital, VLBW infants will often be provided higher intakes of minerals than are provided by human milk or formulas intended for term infants through the use of transitional formulas. If exclusively breastfed, a follow-up serum alkaline phosphatase at 2-4 weeks after discharge from the hospital may be considered.
7. When infants reach a body weight greater than 1500 g and tolerate full enteral feeds, vitamin D intake should generally be approximately 400 IU/day, up to a maximum of 1000 IU/day.

Outcome

Catch-up growth occurs after discharge in VLBW infants. At 6 months of corrected age, spine and total bone mineral density, corrected for anthropometric values, is in the range of normal term newborn infants. Nevertheless, peak bone mass may be less during adulthood. In older children, formerly preterm infants were shorter, lighter, and had lower bone mineral content (BMC) than controls. Of note is that long-term data do not demonstrate a relationship between feeding type in preterm infants and long-term bone mineral content.[22]

In most cases, prematurity-associated rickets appears to spontaneously resolve, although the potential long-term consequences on the attainment of peak bone mass are not clearly known. Even if BMC improves spontaneously in most infants, this discovery does not imply that a period of demineralization is acceptable. Although the long-term consequences are unclear, the benefits of prevention and treatment include avoidance of fractures and possibly improved linear growth and peak bone mass. Severe rickets may also limit pulmonary status, because historically it was thought that rickets was, in part, a pulmonary disease caused by poor lung expansion in the absence of a normal rib cage.

Acknowledgments

The authors and editors acknowledge the important contributions of S. De Marini, R. C. Tsang, J. Rigo, M. W. Mohamed, and M. De Curtis to the previous editions of this chapter, portions of which remain unchanged. They also wish to thank Keli Hawthorne for editing assistance.

Key Points

- The metabolism of calcium, phosphorus, and magnesium and subsequent mineralization of the skeleton are complex functions that require the interaction of numerous factors such as supply of nutrients, daily accretion in utero, and transport across membranes.
- After birth, the switch from placental to dietary minerals causes the relatively hypercalcemic fetus to become a relatively hypocalcemic neonate that leads to PTH secretion, leading to a reduction in calcium availability for bone mineralization.
- Neonatal hypercalcemia is defined as an elevation in plasma ionized calcium concentration greater than 1.45 mmol/L (5.8 mg/dL). Iatrogenic hypercalcemia is the most common and is often caused by excessive intravenous calcium administration during parenteral nutrition or exchange transfusion, use of extracorporeal membrane oxygenation.
- Causes of hypomagnesemia (<1.6 mg/dL) may include maternal diabetes, intrauterine growth restriction, neonatal hypoparathyroidism, inherited disorders of renal magnesium handling, primary hypomagnesemia with secondary hypocalcemia, infantile isolated renal magnesium wasting, or hypomagnesemia with hypercalciuria and nephrocalcinosis.

Thyroid Disorders in the Neonate

JANET CHUANG AND IRIS GUTMARK-LITTLE

Thyroid hormone is critical for linear growth and maturation of thyroid-dependent tissues, including the brain. Many physiologic factors influence fetal and neonatal thyroid function, including fetal–maternal relationships and the dynamic alteration of thyroid function with birth. Understanding the action of thyroid hormones, the synthesis and transport of these hormones, and mechanisms regulating thyroid function is also important in the evaluation and management of thyroid disorders. This chapter begins with a review of thyroid physiology and laboratory tests. Thyroid hormone abbreviations are defined in Box 88.1. Embryology and fetal development of thyroid function are then described. Finally, clinical conditions of altered thyroid function are discussed.

Physiologic Action of Thyroid Hormones

Functions of the Thyroid Gland

The principal functions of the thyroid gland are to synthesize, store, and release the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) into the circulation. The major secretory product of the thyroid is T_4. Thyroidal secretion of T_3 accounts for only about 20% of its production. The remaining 80% is derived from peripheral deiodination of T_4. Therefore, T_4 acts as a prohormone for T_3, because T_4 has negligible intrinsic metabolic activity in most tissues. Most of the physiologic effects of thyroid hormone are mediated by T_3 through its interaction with the thyroid response element on DNA.

Neurologic Effects

Prenatal and postnatal maturation of the brain, retina, and cochlea is thyroid hormone dependent.[22] Thyroid hormone modulates expression of thyroid hormone–responsive target genes at precise times during development, controlled by an interplay of deiodinases, thyroid receptor expression, transporters, cofactors, and transcription factors.[41,58] T_3 promotes the neural differentiation of embryonic stem cells at the dendritic level, and both T_3 and T_4 impact cerebral vascular development.[9,61] Genes that control neural migration are also regulated by thyroid hormone.

As normal levels of thyroid hormone are essential for neuronal migration, myelination, and other structural changes in the fetal brain, congenital thyroid hormone deficiency results in cretinism (severe mental retardation) if not treated. This effect is prevented by thyroid hormone replacement early in life. Early detection of congenital hypothyroidism occurs through newborn screening, which was initiated in the 1970s. Intellectual development is normal in children with congenital hypothyroidism who are treated early and aggressively.[8,51] The degree of mental retardation in cretinism is related to the severity and duration of the hypothyroid state of the infant. The brain is susceptible to a lack of thyroid hormone during its rapid growth and maturation. Defective growth and permanent damage do not occur if hypothyroidism begins after morphologic maturation of the brain is completed (after a postnatal age of 3 years).

Basal Metabolic Rate

Thyroid hormone stimulates basal metabolic rate primarily by increasing ATP production for metabolic processes and by maintaining ion gradients (Na/K^+ and Ca^{2+}), which consume ATP. Thyroid hormone is a key driver of thermogenesis. It uncouples oxidative phosphorylation in mitochondria and reduces activity of shuttle molecules that transfer reducing equivalents into the mitochondria. Thyroid hormone also increases sensitivity to catecholamine effect, which is required for maintenance of core body temperature.[36]

Clinically, the calorigenic action of thyroid hormone affects circulation by increasing heart rate, stroke volume, and cardiac output. The pulse pressure is widened mainly by a decrease in the diastolic pressure and by some elevation in the systolic pressure. Circulation time is also shortened.

Protein and Lipid Metabolism

Negative nitrogen balance occurs in hyperthyroidism unless the patient is protected by adequate caloric intake to provide for the increased energy requirements. Hypothyroidism results in increased serum total cholesterol and low-density lipoprotein (LDL) cholesterol. Thyroid hormone stimulates

Abstract

Thyroid hormone is critical for linear growth and for maturation of thyroid-dependent tissues, including the brain. Many physiologic factors influence fetal and neonatal thyroid function. They include embryogenesis of the thyroid, fetal–maternal relationships and the dynamic alteration of thyroid function with birth, the action of thyroid hormones, the synthesis and transport of these hormones, and mechanisms regulating thyroid function. For purposes of review, this chapter will provide a summary of thyroid hormone physiology and the use of laboratory and imaging studies to define thyroid function. Embryology and fetal development of the thyroid gland will also be reviewed. Thyroid pathology in the fetus and neonate are then discussed, with emphasis on diagnosis and treatment of congenital hypothyroidism and neonatal Graves disease.

Keywords

TSH
T4

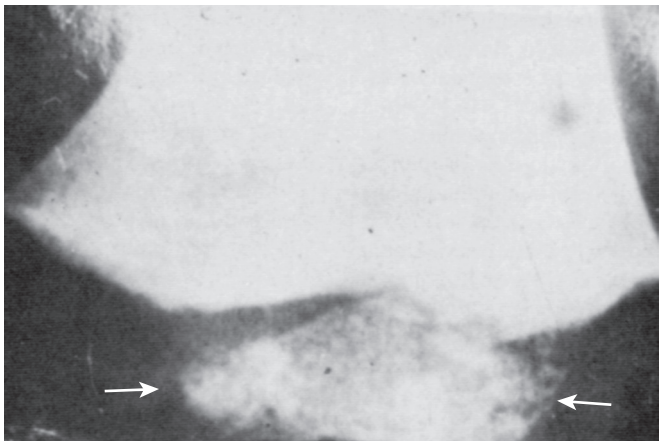
• BOX 88.1 Abbreviations Related to Thyroid Hormones

- ACTH, adrenocorticotropic hormone
- DIT, diiodothyronine (diiodotyrosine)
- FT_4, free T_4
- FT_3, free T_3
- GH, growth hormone
- IGF-1, insulin-like growth factor 1
- IQ, intelligence quotient
- KI, potassium iodide
- LDL, low density lipoprotein
- MIT, monoiodothyronine (monoiodotyrosine)
- MTZ, methimazole
- PTU, propylthiouracil
- rT_3, reverse T_3 (3,3′,5′-L-triiodothyronine)
- SGA, small for gestational age
- T_4, thyroxine (tetraiodothyronine)
- T_3, triiodothyronine (3,5,3′-L-triiodothyronine)
- TBG, thyroid (thyroxine)-binding globulin
- TBII, TSH-binding/inhibiting immunoglobulins
- TG, thyroglobulin
- TGAb, thyroglobulin antibodies
- TPOAb, thyroid peroxidase (formerly microsomal) antibodies
- TRAb, TSH-receptor antibodies
- TRH, thyrotropin-releasing hormone, TSH-releasing hormone (L-pyroglutamyl-L-histidyl-L-proline amide)
- TSH, thyrotropin; thyroid-stimulating hormone
- TSI, TSH receptor-stimulating immunoglobulins
- TTR, transthyretin (formerly T_4-binding prealbumin)

the expression of LDL receptors and in hypothyroidism the number of hepatic LDL receptors is reduced, leading to the decreased clearance of circulating LDL. Apolipoprotein B and lipoprotein (a) are also increased in hypothyroidism.[28]



Carbohydrates, Liver Function, Water Balance, and Calcium Metabolism

The rate of gluconeogenesis, glucose absorption, and use is increased by thyroid hormone. In hypothyroidism, the glucuronic acid conjugation mechanism of the liver may be impaired. In infants, hyperbilirubinemia associated with primary hypothyroidism is almost entirely indirect; in hypothalamic-pituitary hypothyroidism, it is both direct and indirect. Retention of water in the extracellular compartment occurs in hypothyroidism, producing deposition of myxedematous fluid in soft tissue.

In hyperthyroidism, calcium balance tends to be negative. Urinary and fecal calcium excretion is enhanced. Demineralization of bone also occurs. The efflux of calcium from the bones leads to higher plasma ionized calcium and phosphate and lower circulating $1,25(OH)_2D_3$, which in turn results in decreased calcium absorption from the intestine.

Growth and Skeletal Development

A principal action of thyroid hormone is its effect on growth and skeletal development. These effects may be tissue specific and synergistic with other hormones. Prenatal growth is highly dependent on nutrition and insulin secretion. Postnatal linear growth is dependent on thyroid hormone and growth hormone (GH), which are mediated through insulin-like growth factor type 1 and its receptor. Similar synergistic effects between thyroid hormone and growth hormone can be observed in skeletal maturation. When primary hypothyroidism occurs, dental eruption, linear growth, and skeletal maturation are retarded. Retardation of skeletal maturation may be severe and is associated with immature skeletal proportions and facial contours, which contribute to the characteristic body configuration of hypothyroidism (long torso compared to short length of arms and legs). Ossification of cartilage is also disturbed in hypothyroidism, leading to epiphyseal dysgenesis in radiographs of the ossifying epiphyseal centers (Fig. 88.1). Growth rate and adult height are normal in children with congenital hypothyroidism who are diagnosed in early infancy by newborn screening and treated appropriately.[17]

• Fig. 88.1 Epiphyseal dysgenesis of the distal femoral center.

Synthesis, Release, Transport, and Use of Thyroid Hormones

The biologically active thyroid hormones T_4 and T_3 are iodinated amino acids. Their synthesis starts within the follicular cells.

Iodine Metabolism

Iodine is supplied to the body mainly through dietary intake. Although some organic iodine compounds, including T_4 and T_3, can be absorbed unchanged from the gastrointestinal tract, most are reduced and absorbed as inorganic iodide. One-fourth to one-third of ingested iodide is taken up by the thyroid. Iodine can be absorbed readily from the skin, lungs, and mucous membranes. Application of iodine-containing ointment or lotion to the skin, common during procedures with premature or sick infants, causes very high levels of iodide in circulation and promptly blocks thyroid hormone release from the thyroid gland.

Iodide-trapping involves an active transport process through a sodium/iodide symporter that requires oxidative phosphorylation. Iodine uptake through the sodium/iodide symporter is a major rate-limiting step in thyroid hormone biosynthesis, and when it is defective, it is a rare cause of congenital goitrous hypothyroidism.[55] The iodide pump is present at both the basal and apical surfaces of follicular cells. At the basal cell surface, the pump concentrates iodide in the cells by transporting them from the extracellular space. At the apical cell surface, the pump pushes iodide into the follicular lumen as a secondary reservoir. The mechanism is capable of maintaining intrathyroidal iodide concentration at a 20- to 100-fold higher level than that of serum. Some anions—bromide (Br^{2-}), nitrate (NO_2^{2-}), thiocyanate (SCN^{2-}), perchlorate (ClO_4^{2}), and technetium pertechnetate (TcO_4^{2-})—are capable of competitively inhibiting iodide transport.

Iodide is immediately oxidized to an active form for iodination of thyroglobulin (TG) by a peroxidase enzyme system. Thyroglobulin, a glycoprotein, is synthesized by the ribosomes of the follicular cells. Iodination of TG (organification) appears to occur at the cell colloid-lumen interface. Almost all the iodine taken up by the thyroid is rapidly incorporated into the 3′ and the 5′ positions of the many tyrosyl residues of TG to form monoiodothyronine (MIT) and diiodothyronine (DIT). Once it is organically bound to tyrosyl residues, iodine can no longer be readily released from the thyroid. Defects in iodide oxidation or organification can be seen in several types of goitrous congenital hypothyroidism.[55]

Synthesis of Triiodothyronine and Thyroxine

The synthesis of T_3 requires the coupling of an MIT and a DIT molecule; T_4 is formed by the coupling of two DIT molecules. These reactions occur within the structure of TG and involve oxidative processes, probably catalyzed by thyroid peroxidase as well.

Secretion of Triiodothyronine and Thyroxine

Secretion of T_4 and T_3 into the circulation requires the liberation of these moieties from TG. Thyroglobulin molecules pass from the lumen of the follicles into the follicular cells (endocytosis), where colloid droplets are ingested by lysosomes and undergo proteolysis. After proteolysis of TG, the freed MIT and DIT are deiodinated by iodotyrosine deiodinase, and the liberated iodide is recycled by the thyroid for reiodination of new TG. Congenital hypothyroidism can result from both abnormal TG synthesis or defect in the deiodination of freed iodotyrosines, which results in iodine depletion through urinary losses.[55]

Serum Protein Binding and Transport

The thyroid is the only source of T_4, and its blood concentration is 50-100 times greater than that of T_3. T_4 and T_3 secreted into the circulation are transported by loose attachment, through noncovalent bonds, to three plasma proteins, which include thyroxine-binding globulin (TBG), transthyretin (TTR), and albumin. TBG has the highest affinity for thyroid hormone and carries about 70% of T_4 in plasma. TTR and albumin have lower affinity than TBG, but together they still provide significant binding capacity because of their higher plasma concentration.[50] The free T_4 (FT_4) concentration more accurately indicates the metabolic status of the individual than total T_4 or T_3 does, because only the free hormones can enter the cells to exert their effects. If the capacity of thyroid binding proteins is increased or decreased, a concurrent change in the concentration of total hormones will follow, but the concentration of free hormones will be maintained.

Monodeiodination of Thyroxine

Monodeiodination of T_4 occurs in many tissues through the action of three distinct deiodinase enzymes. Type I and II deiodinase through is found in peripheral tissues such as the liver and kidney. Deiodination at the 5′ position of T_4 in peripheral tissues generates T_3, the iodothyronine that mediates the metabolic effects of thyroid hormone. Eighty percent of circulating T_3 is produced by the monodeiodination of T_4. However, the relative serum levels of T_4 and T_3 do not reflect the intracellular proportions of the hormones. The tissue distribution of T_3 may differ greatly from that of T_4 from tissue to tissue. The plasma half-life of T_3 is 1 day, compared with 6.9 days for T_4. However, the plasma half-life of T_4 is much shorter (3.6 days) in neonates. Most T_3 is localized in cells, whereas T_4 is found mainly in the extracellular space. The metabolic effects of T_3 are mediated through binding to specific receptors in the DNA response element that regulates transcription. T_3 also interacts with membranous, mitochondrial, and cytosolic binding sites.

Neural tissue requires T_4 (and does not bind T_3). Thyroid hormone availability to neurons mainly takes place through astrocytic delivery. T_4 is taken up by astrocytes at the blood–brain barrier, and T_4 is converted to T_3 by astrocytic type II deiodinase; T_3 is then transported to neurons by transmembrane transporters.[21,60] Type III deiodinase regulates peripheral deiodination of T_4 at the 5 position on the thyronine molecule instead of 5′ and generates reverse T_3 (rT_3). Serum rT_3 concentration parallels that of T_3 in normal circumstances but not in fetal life, starvation, or patients with severe nonthyroidal illnesses (e.g., euthyroid sick syndrome, non-thyroidal illness syndrome). Reverse T_3 is generally metabolically inactive, although weak nuclear binding activity has been reported.

Regulation of Thyroid Function

Control of thyroid hormone secretion is centered in the hypothalamic-pituitary-thyroid axis. Basophilic cells of the anterior pituitary gland synthesize and store thyrotropin (TSH), a glycoprotein capable of rapidly increasing

intrathyroidal cyclic adenosine monophosphate (cAMP). TSH release from the pituitary causes an increased uptake of iodine by the thyroid, accelerates iodothyronine synthesis and release, and increases the size and vascularity of the thyroid. These changes are mediated by activation of adenylate cyclase and tyrosine kinase. Human chorionic gonadotropin (hCG) weakly competes with TSH for receptors on thyroid follicular cells. Hyperthyroidism seen in patients with choriocarcinoma can be explained by this mechanism. Similarly, certain immunoglobulins—TSH-binding inhibiting immunoglobulins (TBII) and TSH receptor-stimulating immunoglobulins (TSI) found in autoimmune thyroid diseases like Graves disease compete with TSH for binding to TSH receptors.

Secretion and plasma levels of TSH are inversely related to circulating levels of FT_3 and FT_4. The inhibitory feedback action of FT_3 and FT_4 involves a direct action of these hormones on the pituitary gland without involving the hypothalamus. Therefore, secretion of TSH is regulated directly by the ambient intrapituitary T_3 concentration and intrapituitary deiodination of T_4 to T_3 by type II monodeiodinase activity.

The hypothalamus secretes thyrotropin releasing hormone (TRH) that enters the portal system to reach the pituitary and stimulate synthesis and release of TSH from thyrotrophs. TRH is under negative feedback control by thyroid hormone, but other factors like nutritional status, external temperature, and circadian cycle regulate TRH independently of thyroid hormone level.[25]

A circadian variation of circulating TSH has been found in normal children and adults. A peak TSH concentration (≈3-4 mU/L) develops between 10:00 PM and 4:00 AM and is about 50%-300% higher than the afternoon (2:00-6:00 PM) nadir values. This nocturnal TSH surge is not directly related to sleep; it is blunted or absent in central (secondary or tertiary) hypothyroidism but maintained in primary hypothyroidism. The circadian pattern of TSH is not yet present in neonates but has been noted to be present in infants as young as 4 months of age. In children age 1 year and older, the AM to PM TSH ratio can be useful in identifying mild primary hypothyroidism and in differentiating this from central hypothyroidism.[49]

In addition to hypothalamic-pituitary regulation, the thyroid is under autoregulatory control that adjusts the degree of iodide trapping, thyroid hormone production, and release in response to changes in iodine exposure. This helps to maintain a euthyroid state despite fluctuation in dietary iodine intake.

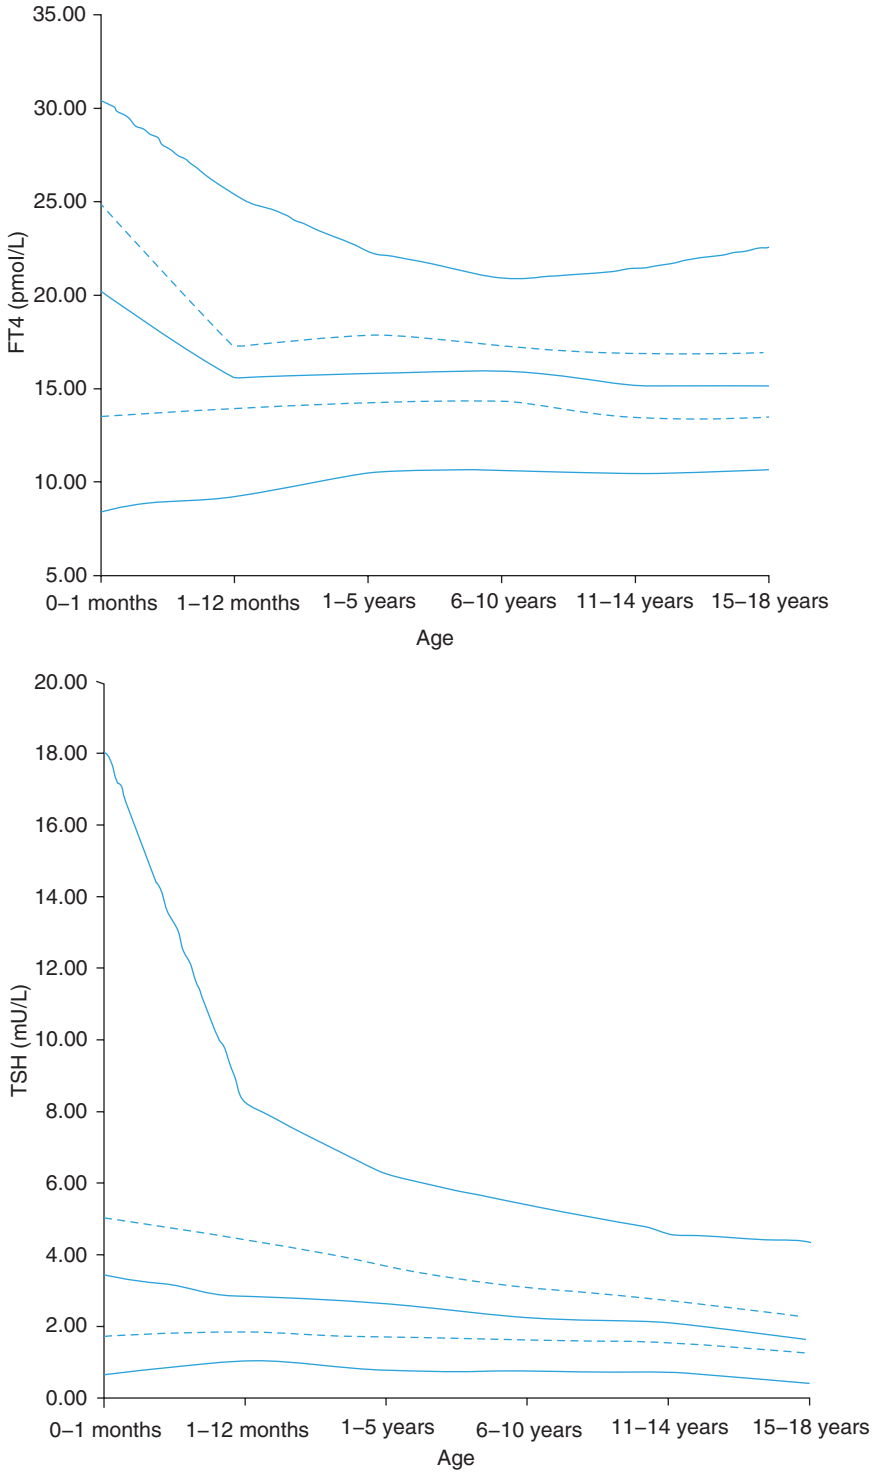
Laboratory and Imaging Tests Used in the Diagnosis of Thyroid Disease in Infancy and Childhood

Thyroxine (T_4)

The plasma pool of T_4 constitutes a large protein-bound reservoir; this pool turns over slowly. Therefore, T_4 measurement usually reflects the adequacy of the hormonal supply. The normal level of T_4 is age dependent in infancy and childhood. T_4 reaches a peak concentration shortly after birth and declines slowly, gradually approaching the adult normal range in puberty.[18] The range of normal levels for each age group is also wide (Fig. 88.2). However, it should be kept in mind that more than 99% of circulating T_4 is bound to serum thyroid hormone–binding proteins. Any change or abnormality in the concentration of these proteins, particularly TBG, can affect the T_4 level. Several clinical situations and pharmacologic agents can alter the levels of TBG or TTR**.** Certain anticonvulsants not only bind competitively to TBG but also interfere with T_4 assays without greatly influencing the TSH level in a person with an otherwise normal thyroid reserve. These drugs include phenytoin, valproate, primidone, and carbamazepine. Other drugs, such as furosemide, salicylate, and L-asparaginase, compete with thyroid hormone for binding with plasma proteins and can alter the levels of T_4, T_3, FT_4, and FT_3.

Triiodothyronine

When TSH becomes elevated, the percentage of T_3 produced by the thyroid gland is increased. Serum concentration of T_3 can vary from day to day. Because of the overall small quantity of T_3 in serum, its level may not fall below the normal range until T_4 is critically low. Therefore, serum T_3 is not very useful in evaluation of patients for possible hypothyroidism. T_3 is physiologically low in the fetus and cord blood, but rises promptly after birth to levels greater than those in older children and adults.



Reverse Triiodothyronine

Hormonally inactive rT_3 is derived primarily from deiodination of T_4. Serum half-life is very short, less than one-half that of T_3. Concentration of rT_3 usually parallels that of T_3. However, rT_3 is disproportionately high in the fetus, in the early neonatal period, and in severe nonthyroidal illness, probably reflecting altered tissue metabolism of T_4.[6,11]

Free Hormones

Because concentrations of T_4 and T_3 are affected by those of thyroid hormone–binding proteins and the degree of their saturation at the binding site, the simplest approach to determine thyroid hormone levels is to measure free T_4 (FT_4) and not measure T_4 at all. In clinical settings, FT_4 does not depend on the T_4-binding capacity, because a change in such a capacity is soon compensated for by a change in the amount of T_4 released from the thyroid. The gold standard for measuring FT_4 in serum is by direct dialysis. Serum is placed in a dialysis cell on one side of a semipermeable dialysis membrane, with a buffer solution on the other side. T_4 equilibrates across the membrane and bound T_4 remains with serum. Unbound FT_4 that crosses

• **Fig. 88.2** Age-related reference values for thyrotropin (TSH) and free T_4 (FT4). The central 95% range (2.5th, 25th, 50th, 75th, and 97.5th percentiles) is shown. Because of resolution reasons, lines start at zero, although no samples were taken within the first hours after birth. (From Kapelari K, et al. Pediatric reference intervals for thyroid hormone levels from birth to adulthood: a retrospective study. *BMC Endocrine Disorders*. 2008;8:15; doi:10.1186/1472-6823-8-15.)

the dialysis membrane can then be measured by radioimmunoassay or tandem mass spectrometry. FT_3 levels in the serum can be measured in the same dialysate as that used for FT_4.

Labeled analogue or antibody methods are also available to measure FT_4. They can be performed more rapidly and are less expensive than measurement of free hormone by direct dialysis. The principle of labeled analogue or antibody methods is that the rate of binding of labeled hormones to antibodies depends on the FT_4 concentration during a timed incubation. They are acceptable for routine testing in children. However, these methods may not provide an accurate assessment of FT_4 at extremes of thyroid hormone binding capacity or with significant changes in T_4 binding protein affinity.[12]

Measurement of FT_3 is not currently part of standard care. In the future, FT_3 measurements may be shown to be useful in assessing hypothyroidism. Currently, FT_3 may be

useful when the diagnosis of thyrotoxicosis is suspected and TSH is suppressed but values for T_4, T_3, or both are normal.

Proteins That Bind to Thyroid Hormones

Serum thyroxine-binding globulin (TBG) is determined by radioimmunoassay in commercial laboratories, and its measurement is useful in the quantitation of abnormal levels of TBG. Because most T_4 is bound to TBG, these measurements give a good approximation of the T_4-binding protein capacity. Increased TBG levels may be caused by pregnancy, hypothyroidism, liver disease, acute intermittent porphyria, or human immunodeficiency virus. Pharmacologic agents that increase TBG levels include estrogens, methadone, and heroin. The concentration of TBG may be decreased in preterm infants, acute illness, nephrotic syndrome, kidney failure, severe liver disease, malnutrition, hyperthyroidism, and acromegaly. Drugs that decrease TBG levels include androgens, danazol, glucocorticoids, and L-asparaginase. Pharmacologic agents that compete with T_4 for TBG-binding sites include salicylates, phenytoin, and possibly other anticonvulsants, hypolipemic agents, sulfonylureas, diazepam, heparin, and fenclofenac. These agents give falsely low T_4. TSH and FT_4 determinations by direct dialysis method are usually normal.

Thyrotropin

Measurements of TSH and FT_4 are the most important tools for screening thyroid function. Serum TSH is measured by specific competitive-binding isotopic and nonisotopic methods. TSH is the most sensitive test for primary hypothyroidism at any age and is used in many neonatal thyroid screening programs. Serum TSH is also an indicator of the adequacy of thyroid hormone replacement therapy and is used in assessment of the hypothalamic-pituitary-thyroid axis. TSH is elevated in primary hypothyroidism. A surge of TSH release occurs at parturition and reaches a peak within 2 hours after birth. TSH in the cord serum and a term infant's serum after the 1st day of postnatal life is usually less than 20 mU/L. Therefore TSH is the most important test to screen for primary congenital hypothyroidism. The target range for TSH during thyroid hormone therapy for primary hypothyroidism is 0.5-2 mU/L.

AM to PM Thyroid-Stimulating Hormone Ratio, Thyroid-Stimulating Hormone Surge Test

Central hypothyroidism is diagnosed in infants who have low or low-normal FT_4, no TSH elevation, and other common features of hypopituitarism (e.g., hypoglycemia, microphallus). More subtle central hypothyroidism (FT_4 in the lowest third of the normal range) can be confirmed in children older than 1 year by the AM to PM TSH ratio or the TSH surge test.[49] This test is not useful in infants before development of the circadian pattern of TSH secretion.

The TSH surge test is performed by obtaining blood for TSH assay at the usual time of the nadir of the circadian variation of TSH (the mean of two or three samples between 10:00 AM and 6:00 PM) and again at the usual time of peak TSH secretion (the mean of the three highest sequential samples between 10:00 PM and 4:00 AM). The mean nadir and peak TSH values are calculated. Normal night-time peak TSH values are 50%-300% higher than the nadir values obtained during the day. Blunting or absence of this rise confirms central hypothyroidism.[49]

Thyroid Autoantibodies

Numerous methods have been used for detection of a variety of thyroid antibodies. Assays for thyroglobulin antibodies (TGAb) and thyroperoxidase (microsomal) antibodies (TPOAb) are widely available. These antibodies are found in Hashimoto thyroiditis and in about 2% of the adult population. TSH receptor stimulating and blocking antibodies may be detected in the sera of patients with autoimmune thyroid diseases and are known as TSH receptor antibodies (TRAb). TRAb that are stimulatory are found in the sera of patients with active Graves disease and are known as thyroid-stimulating immunoglobulins (TSI); TRAb that are inhibitory are called TSH-binding/inhibiting immunoglobulins (TBII).

Mothers with primary hypothyroidism and Hashimoto thyroiditis may have circulating serum TBII or antibodies that block the TSH receptor. These mothers give birth to children with a transient form of congenital hypothyroidism as a result of the transplacental transfer of TBII. The half-life of immunoglobulins in the neonate is about 2 weeks, and TRAb usually disappear from the serum of affected infants by 6-8 weeks of age. The disease may recur in infants of subsequent pregnancies if the high-affinity antibody persists in the mother's circulation.

Mothers with Graves hyperthyroidism may have TBII but more commonly have TSI. These mothers give birth to children with a transient form of hyperthyroidism as a result of the transplacental transfer of TSI. Hyperthyroidism in the affected infant may persist for 2-6 months.

Thyroglobulin

Small amounts of thyroglobulin (TG) are co-secreted with T_4 and T_3 and are detectable in the serum with levels roughly correlating with thyroid size and TSH level. In complete thyroid aplasia, TG is not detectable. Therefore, TG level is helpful to determine if thyroid tissue is present. In autoimmune congenital hypothyroidism caused by antibodies that block the TSH receptor, TG may be detectable even when the radioactive iodine scan suggests an absent thyroid gland; ultrasound should then identify the thyroid gland. TG levels may be elevated when the thyroid gland is hyperactive, as in endemic goiter, subacute thyroiditis, toxic nodular goiter, and Graves disease. TG cannot be reliably measured when there are TGAb present, as these antibodies

interfere with the immunometric assays and often lead to falsely low results.

Thyroid Imaging

Ultrasonography of the thyroid gland is useful for visualization of eutopic thyroid glands and can provide information on size, homogeneity/heterogeneity, vascularity, and presence of nodules. Ultrasonography can also identify dysgenetic thyroid glands but does not appear to be as sensitive for detecting ectopic thyroid tissue as a radioiodine uptake scan. Ultrasonography should be used as the first imaging tool, with a scan performed to distinguish agenesis from ectopia.[13] When a scan is necessary, ^{123}I or ^{99m}Tc should be used to reduce radiation exposure to the child. ^{123}I or ^{99m}Tc does not emit beta particle gamma radiation, and their half-lives are much shorter compared to ^{131}I.

Radioiodine uptake studies are invaluable for diagnosing certain inborn errors of thyroid hormone synthesis, such as defects in iodide-trapping, iodide oxidation, and organification. In addition to the thyroid gland, the salivary glands, gastric mucosa, small intestine, mammary glands, and placenta are capable of concentrating iodine. In patients with goitrous congenital hypothyroidism, the inability of salivary glands to trap iodide can help identify defects in the sodium/iodide symporter. The perchlorate discharge test can also be performed during the radioiodine uptake test to detect the presence of a defect in iodide oxidation or organification.[13]

Embryogenesis

Factors such as FOXE1, NKX2-1, PAX8, TBX1, HOXA3, FGF10, and HHEX are involved in stem cell differentiation into thyroid follicular cells (Table 88.1).[5,19] Activin A, insulin, and IGF-1 are among the hormones required for generation of thyroid cells.[16] The major portion of the human thyroid originates from the median anlage, the tissue that arises from the pharyngeal floor (toward the back of the future tongue) and is identifiable in the 17-day-old embryo.[19] The median anlage is initially in close contact with the endothelial tubes of the embryonic heart. With the descent of the heart, the rapidly growing median thyroid is progressively pulled caudally until it reaches its final position in front of the second to sixth tracheal ring by day 45-50 of gestation. Abnormal descent leads to ectopic location of the thyroid gland. The pharyngeal region contracts to become a narrow stalk called the *thyroglossal duct*, which subsequently atrophies. The median anlage usually grows caudally so that no lumen is left in the tract of its descent. An ectopic thyroid gland or persistent thyroglossal duct or cyst results from abnormalities of thyroid descent. The lateral parts of the descending median anlage expand to form the thyroid lobes and the isthmus.

The second source of thyroid tissue is composed of a pair of ultimobranchial bodies arising from the caudal extension of the fourth pharyngeal pouch. These bodies are initially connected to the pharynx by the pharyngobranchial duct. The pharyngeal connection is subsequently lost, and the ductal lumen becomes obliterated. The ultimobranchial bodies are incorporated into the expanding lateral lobes of the median anlage. They contribute little to the future size of the thyroid, and their differentiation appears to require the influence of the median anlage. Parafollicular or C cells arise from the ultimobranchial bodies in mammals and are the source of calcitonin.

By the latter part of the 10th week of gestation, the histogenesis of the thyroid is virtually complete, although the follicles do not contain colloid.[19] A single layer of endothelial cells surrounds the follicular lumen. By the beginning of the second trimester, the fetal thyroid is capable of trapping and oxidizing iodide.[24] Therefore the fetal thyroid begins to secrete thyroid hormone and contributes to the fetal circulation of thyroid hormone.

At the same time as the development of the thyroid gland, the fetal pituitary and hypothalamus are also forming and beginning to function. The anterior pituitary gland is derived from the Rathke pouch, which originates at the roof of the pharynx. Histologic differentiation of pituitary cells can be observed by 7-10 weeks of gestation, and TSH can be detected in fetal blood by 10-12 weeks. The hypothalamus develops from the ventral portion of the diencephalon. Thyrotropin-releasing hormone has been found in fetal whole-brain extracts by 30 days and in the hypothalamus by 9 weeks of gestation.

Thyroid Function: Fetal–Maternal Relationship

In considering the fetal–maternal relationship, the placenta is of major importance. Thyroid stimulating hormone does not cross the placental barrier, whereas TRH does. Maternal-to-fetal transport of T_4 is highest in the first trimester. Rapid placental deiodination of T_4 into biologically inactive rT_3 and DIT limits transfer of maternal T_4 during later stages of pregnancy. However, maternally derived thyroid hormone continues to be important even in the third trimester. This third trimester T_4 placental transfer to a fetus with a total inability to synthesize T_4 results in a fetal T_4 concentration that is 25%-50% of that found in normal neonates.[59] Therefore, in a mother with normal thyroid function, the hypothyroid fetus is somewhat protected. It has been well documented that overt maternal hypothyroidism poses risk to the maternal–fetal unit. Untreated maternal hypothyroidism not only results in negative impact on neurocognitive development in offspring,[23] but there is also increased risk for gestational hypertension, premature birth, low birth weight, and pregnancy loss.[3,33] To prevent significant untreated maternal hypothyroidism, it is now recommended that upon confirmation of pregnancy, certain high-risk groups will be screened.[2]

Maternal dietary iodine deficiency results in impaired maternal and fetal thyroid hormone synthesis. Consequent maternal and fetal hypothyroidism can lead to increased TSH and goiter in both the mother and fetus and also

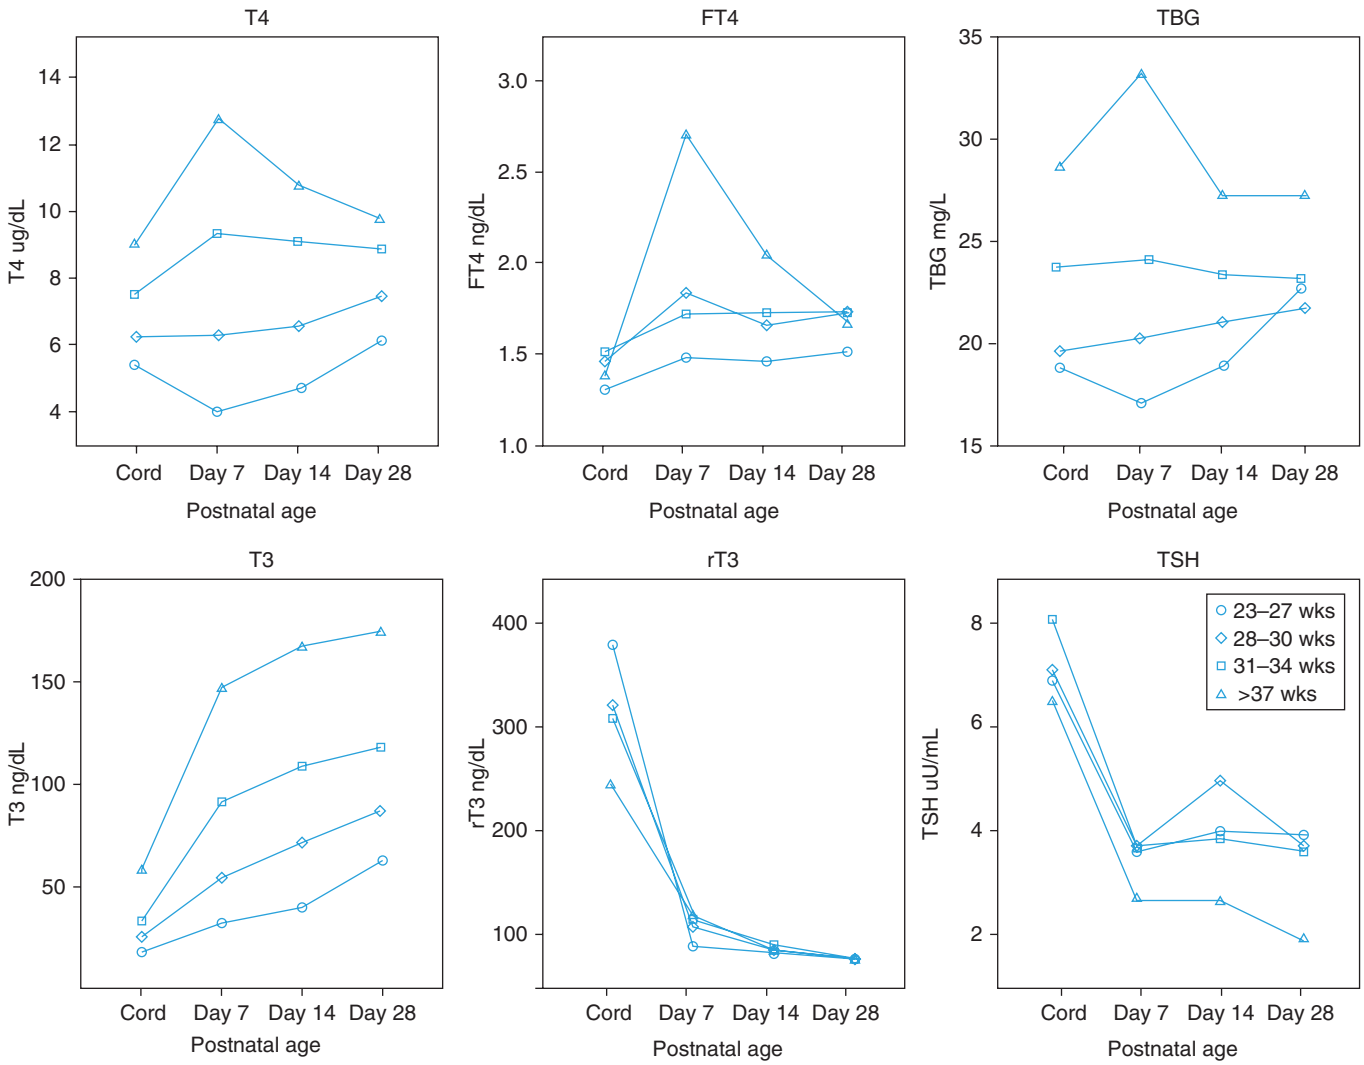
adverse neurocognitive development in the fetus.[14] Iodine requirements increase more than 50% during pregnancy, and it is recommended that all pregnant women ingest about 250 mcg of iodine daily.[2] Maternal iodine excess can also cause fetal goiter and hypothyroidism. Iodides and iodine, when given in large quantities, produce a transient inhibition of T_4 synthesis through an autoregulatory mechanism known as the Wolff-Chaikoff effect. Following several days of continued high exposure to iodine, there is escape from the Wolff-Chaikoff effect due to decreased active transport of iodine into the thyroid gland, and thyroid hormone production resumes. The fetal thyroid appears to be more susceptible to this inhibitory effect of iodine and has decreased ability to escape.[20] Maternal administration of medications containing iodides (expectorants, topical antiseptics, amiodarone) can cause neonatal goitrous hypothyroidism. Sustained iodine intake should not exceed 500 mcg daily to avoid potential for fetal thyroid dysfunction.[2]

Other clinically important compounds that can affect fetal thyroid function by crossing the placenta from the mother to the fetus are antithyroid drugs, environmental goitrogens, endocrine disruptors, and thyroid antibodies. Antithyroid drugs include propylthiouracil and methimazole. Transplacental transfer of these drugs can result in fetal goiter with or without hypothyroidism. Transfer of TSI across the placenta to the fetus can cause transient neonatal thyrotoxicosis; the placental transfer of TBII can cause transient neonatal hypothyroidism.



Fetal T_4 and T_3 metabolism differs markedly from that of postnatal life. TSH can be detected in fetal blood by

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

10-12 weeks. As a result of maturation of the HPT axis, fetal hypothalamic expression of TRH and production of TSH and T_4 progressively rise from mid gestation to peak during the month prior to term. TSH then remains higher than maternal levels, possibly reflecting a higher set-point for feedback.[30] T_3 levels in fetal blood remain low until 26-30 weeks of gestation, a consequence of high levels of type III deiodinase activity (which converts T_4 to inactive reverse T_3) in peripheral fetal and placental tissues.[41]

T_4-binding proteins can also be detected in the 12-week-old fetus. During early fetal life, T_4 appears to be bound mainly to TTR and albumin. Fetal TBG increases rapidly and by midgestation reaches a level approaching that in a full-term infant. The binding capacity of TBG in premature and full-term infants is about 1.5 times that in the normal adult but lower than that in the mother. The high TBG in the neonate is caused by transplacental transfer of estrogens from the mother and to a large extent accounts for the high T_4 in infants. TTR is low in both newborn and maternal sera and plays a minor role after midgestation.

Shortly after birth, transient but marked hyperactivity occurs in the thyroid function of neonates (Fig. 88.3). Within the first minutes of life, there is a dramatic release of TSH, reaching a peak level of about 100 mU/L at 30 minutes of age. This hypersecretion of TSH persists during the next 6-24 hours. Evidence shows that this acute rise in TSH may be stimulated at least partially by a drop in the body temperature of the fetus with birth. In response to the postnatal TSH surge, T_4, FT_4, and T_3 increase progressively during the first hours of extrauterine life, reaching a peak at about 48 hours of age. The increases in T_3 and FT_3 are more marked than those of T_4 and FT_4 during this period because of increased peripheral conversion of T_4 to T_3. Therefore neonates experience a physiologic

• **Fig. 88.3** Postnatal changes in T4, free T4, thyroxine-binding globulin (TBG), T3, rT3, and thyrotropin (TSH) according to gestational age. Note the increase in T4, free T4, and TBG in the full-term infant in the 1st week of life. T3 also rises strikingly, whereas rT3 and TSH decline. The increase in T4 and free T4 is blunted in infants less than 35 weeks and not seen at all in very premature infants in whom thyroid hormone levels may actually decline. (Reproduced with permission from *Disorders of the Thyroid Gland in Infancy, Childhood and Adolescence,* by Maria Segni, MD, in http://www.thyroidmanager.org/, the free online Thyroid Web-book, version April 4, 2017, published by Endocrine Education, Inc., South Dartmouth, MA.)

hyperthyroid state during the first few days of life. Concentrations of thyroid hormone remain elevated during the first 2 weeks of life and fall gradually thereafter, with FT_4 reaching high-normal adult values by 4-6 weeks of age. True adult levels of T_4 and T_3 are not reached until puberty, probably because TBG levels in children remain elevated compared with adults until mid-puberty (see Fig. 88.3).

The postnatal TSH surge occurs even in preterm infants and those who are small for gestational age (SGA), although the changes in TSH and iodothyronines are less than those in healthy full-term infants. In preterm infants, T_4 concentrations may decline for a week and then gradually rise, remaining lower than those of full-term infants during the first weeks of life. Thyroid-stimulating hormone returns to normal adult values after 3-10 days of postnatal life regardless of gestational age (see Fig. 88.3).

In human milk, T_4 is present in very small amounts. The concentrations of T_3 and rT_3 in human milk vary from specimen to specimen. The T_3 concentration in breast milk is insufficient to prevent the detrimental effects of hypothyroidism, although it may alleviate the symptoms in certain cases.

Congenital Hypothyroidism

Congenital hypothyroidism is a deficiency in thyroid hormone present at or before birth. Prompt diagnosis is critical, because a delay in treatment can lead to irreversible brain damage. However, overt signs of hypothyroidism are rarely present at birth, and 95% of affected babies are asymptomatic. Dynamic changes in thyroid function after birth, deprivation of maternal hormones, and antibodies acquired by transplacental transfer contribute to the difficulty in establishing a diagnosis. Newborn screening for hypothyroidism was first performed and consequently established in 1972 in Quebec, Canada, to permit early identification of infants at risk and allow prompt institution of thyroid hormone replacement therapy.

Etiology and Pathogenesis

The etiologic classification of congenital hypothyroidism:

1. Primary hypothyroidism
   - a. Defective embryogenesis of thyroid
     - i. Agenesis (athyreosis)
     - ii. Dysgenesis
       - (a) Thyroid remnant in normal location (hypoplasia)
       - (b) Maldescent or ectopic thyroid gland (ectopia)
   - b. Inborn error of hormone synthesis or metabolism (familial dyshormonogenesis)
     - i. Iodide-trapping defect
     - ii. Iodide organification (oxidation) defect
       - (a) Without deafness
       - (b) With deafness (Pendred syndrome)
     - iii. Deiodination defect
       - (a) Generalized
       - (b) Limited to thyroid gland
       - (c) Limited to peripheral tissues
     - iv. Thyroglobulin synthetic defect
     - v. Peripheral tissue resistance to thyroid hormone
2. Central hypothyroidism
   - a. Genetic mutation or deletion (see Table 88.1)
     - i. Isolated deficiency of TSH alpha-subunit
     - ii. Abnormality of hypothalamic-pituitary development, with multiple pituitary hormone deficiencies
   - b. Midline congenital defect (septo-optic dysplasia, holoprosencephaly, cleft lip, single central incisor)
   - c. Acquired birth injury (usually hypothalamic TRH deficiency; birth injury, hemorrhage, hydrocephalus, meningitis, trauma, nonaccidental injury)

Defective Embryogenesis of the Thyroid

In contrast to the clear preponderance of thyroid disorders in females compared with males during childhood and adult life, the gender difference in incidence of congenital hypothyroidism is much less obvious. In North America, the female-to-male ratio is about 2:1, as detected by neonatal screening programs.[4] The relative incidences of each type of congenital hypothyroidism vary widely in different geographic locations, but overall, congenital hypothyroidism occurs in 1:3000 to 1:4000 newborns.

In nongoitrous regions, defective embryogenesis of the thyroid accounts for 80%-90% of nonendemic congenital hypothyroidism. Most cases of thyroid dysgenesis are sporadic, but there is evidence of a familial or genetic component in some patients. Loss-of-function mutations of the TSH receptor gene lead to hypoplasia of the thyroid gland and TSH elevation (see Table 88.1).[10] Mutations in transcription factors (e.g., *PAX8* and *FOXE1*) may be responsible for some cases of congenital hypothyroidism.[19] Failure in the anatomic development of the thyroid gland may be complete or partial. Residual thyroid tissue in the normal position or in ectopic location is detected in 60%-80% of infants and children with hypothyroidism. An ectopic thyroid is usually composed of a remnant of undescended thyroid tissue that is usually situated in the midline. Undescended thyroid is located at the base of the tongue in about half of the cases, between the tongue and the hyoid bone in about one-fourth, and between the hyoid bone and the normal location in the remaining one-fourth. Ectopic tissue is often capable of undergoing compensatory hypertrophy when hormone production becomes inadequate, and thus may be found as a midline mass.

Familial Dyshormonogenesis

Genetically determined errors of T_4 synthesis or metabolism involve a deficiency of one or more enzymes necessary at various stages of the biosynthetic and metabolic pathways. Impaired secretion of T_4 and T_3 results in hypersecretion of TSH, usually leading to compensatory hyperplasia of the

thyroid. The familial forms of congenital hypothyroidism are usually referred to as *familial dyshormonogenesis*. Hypothyroidism, goiter, or both may be present in the newborn and infant, depending on the degree and time of onset of the hormonal deficiency.

Hypothyroidism caused by a defect in the trapping of iodide is due to a mutation in *SLC5A5*, the sodium-iodide symporter. *SLC5A5* mutations are inherited in an autosomal recessive manner. Infants will typically have a normal-sized or enlarged thyroid gland by ultrasonography and elevated serum thyroglobulin levels. Patients with iodide trapping defects can be confused with athyreosis because of the failure of administered radioiodine to be concentrated in the neck; however, there will also be lack of other physiologic iodine uptake (i.e., in the salivary glands, gastric mucosa, nasopharynx). The severity of hypothyroidism is variable and may depend on the amount of dietary iodine present.[22]

There are specific types of defects in the oxidation or organification of iodide. Among them, thyroperoxidase enzyme deficiency (due to mutations in thyroperoxidase) is the most frequent cause of dyshormonogenesis. Thyroperoxidase mutations are inherited in autosomal recessive manner and can result in severe hypothyroidism with large goiter. Impairment of normal generation of hydrogen peroxide caused by mutations in *DUOX1* and *DUOX2* also can result in congenital hypothyroidism. *DUOX* gene mutations demonstrate variable phenotype with the presence of some residual activity in one of the alleles, resulting in more mild or transient hypothyroidism.

In Pendred syndrome, patients have congenital sensorineural hearing loss and goiter, which typically develops later in childhood or adolescence. Incidence of this disorder is estimated to be about 1.5-3 per 100,000 schoolchildren. Affected individuals are either euthyroid or have mild hypothyroidism. Many will have an abnormal radioiodide discharge from the thyroid after perchlorate administration, indicative of defective iodide organification. Pendred syndrome is caused by biallelic inactivating mutations of the *SLC26A4* gene, located on chromosome 7 (7q31). The *SLC26A4* gene encodes the protein pendrin, which is expressed in the apical membrane of the thyroid and facilitates passive iodide efflux into the lumen. Pendrin is also expressed in the inner ear and is important for maintaining normal acid–base homeostasis of the endolymphatic fluid. The thyroid phenotype in Pendred syndrome is affected by nutritional iodide intake. With adequate dietary iodide, about 90% of patients remain clinically and biochemically euthyroid; in the other 10%, the TSH level is elevated and goiter is present.[22]

In patients with iodothyronine deiodinase defects, there is a rapid turnover of thyroid iodine and wasting of iodotyrosines into the urine. The defect may be generalized, or it may be limited to intrathyroidal or peripheral deiodination. The onset of goiter and hypothyroidism in these patients is variable and may be caused by dietary iodine intake and presence of partial activity of protein.

Defects in thyroglobulin synthesis can result in moderate to severe congenital hypothyroidism with goiter. These patients will have low or absent TG levels and abnormal iodoproteins in their sera. Mutations in the TG gene (8q24, stopping synthesis or causing conformational changes in the molecule) have been reported in these patients.[22]

Defects in TSH or Thyroid Hormone Action

Resistance to thyroid hormone is caused by mutations in thyroid hormone receptors, primarily point mutations in the thyroid hormone receptor-β. It is rare, with incidence of about 1:40,000. Patients have high serum T_4, free T_4, and T_3 with normal or mildly elevated serum TSH. In childhood, there may be development of tachycardia, failure to thrive, and attention deficit disorder. The severity of hormone resistance varies among tissues because of differences in relative expression of the two thyroid hormone receptors—β and α—with some tissues such as cardiac exhibiting more hyperthyroid state due to predominant expression of the α isoform of the thyroid hormone receptor.[37]

Unresponsiveness of the thyroid gland to TSH has been reported in some children with congenital hypothyroidism without goiter. Serum TSH was elevated, and exogenous TSH stimulation caused no increased radioiodine uptake or serum iodothyronine levels. Loss-of-function germline mutations of both alleles of the gene for the TSH receptor have been reported to cause resistance to the action of TSH and hypothyroidism.[10] The mutations were located in the extracellular, TSH-binding domain of the TSH receptor. The TSH receptor is coupled to the protein that binds to guanine nucleotide, or G protein. In these mutations, the TSH receptor does not activate G protein, and the effector adenylate cyclase (cAMP) signaling pathway remains inactive (*GNAS* mutations).

Iodine Deficiency

Endemic goiter and cretinism are still prevalent in large geographic areas where dietary iodine is deficient. Iodide deficiency results in decreased thyroid hormone production in both the mother and fetus. Iodine deficiency also causes preferential production of T_3 relative to T_4. Reduced maternal T_4 levels early in gestation may deprive the developing fetal brain of T_4, which may be the essential iodothyronine for early brain maturation. Severe iodine deficiency that remains untreated can result in two severe types of endemic cretinism: myxedematous cretinism with metabolic symptoms of hypothyroidism and neurologic cretinism with dominant neurologic disorders (severe mental deficiency, deaf-mutism, and motor spasticity).

Significant progress has been made to reduce iodine deficiency through programs of universal salt iodization. About 70% of households worldwide have access to iodized salt, but 30 countries have mild or moderate iodine deficiency. There is recent data that US women are mildly iodine deficient. Iodine deficiency has re-emerged in parts of the

developed world and may be related to initiatives to lower population sodium consumption.[43] Iodine supplementation before or during pregnancy improves thyroid function in the mother and newborn. The recommended daily iodine intake for all pregnant women is 250 mcg.[2]

Central Hypothyroidism

Secondary (pituitary) and tertiary (hypothalamic) hypothyroidism are not commonly recognized in neonates. Infants with central hypothyroidism can be detected through neonatal thyroid screening programs when T_4 measurements are included with TSH as the neonatal screening test. However, many infants with central hypothyroidism have normal TSH and are missed until they are older than 1 year.[38] A low FT_4 by direct dialysis is the confirmatory test that determines the need for continued treatment when the diagnosis is suspected on the basis of initial tests.

Overall, the prevalence of central congenital hypothyroidism is reported to be higher than previously thought (1 in 20,000 to 1 in 30,000).[1] Autosomal recessive disorders that cause severe hypothyroidism as a result of congenital central hypothyroidism have been reported. Mutations have been identified in the β subunit of TSH, the TRH gene, and the TRH receptor gene.[7,10] Multiple pituitary hormone deficiencies suggest a genetic defect in the signaling cascade leading to fetal pituitary formation, such as *PROP1*, *LHX3*, or *POU1F1*. When present, pituitary aplasia may be associated with anencephaly or other severe malformations of the brain.

Midline facial, cranial, or intracranial defects may also indicate the possibility of hypopituitarism. Septo-optic dysplasia, often associated with pituitary hormone deficiencies, can be manifested as secondary or (more commonly) tertiary hypothyroidism. A genetic mutation in *HESX1* has been described in septo-optic dysplasia. Clinical symptoms of hypopituitarism, such as neonatal hypoglycemia (from growth hormone and ACTH deficiencies), polyuria (from antidiuretic hormone deficiency), or a small phallus in boys (from gonadotropin deficiency), whether or not accompanied by the presence of blindness, congenital nystagmus, or midline defects of the brain, should alert the physician to suspect septo-optic dysplasia.

Diagnosis of Congenital Hypothyroidism

Neonatal Screening for Hypothyroidism

Every state in the United States and every province in Canada has legislatively mandated the screening of newborns for congenital hypothyroidism.[4] Screening programs have also been established in Western Europe, parts of Eastern Europe, Japan, Australia, and parts of Asia, South America, and Central America. However, many countries still do not have a nationwide program for neonatal thyroid screening, despite clear evidence that early detection and treatment of congenital hypothyroidism prevents neurodevelopmental disability.[32]

Most programs currently use the filter paper spot technique. Capillary blood specimens from a heel stick are obtained at 24 hours to 5 days of age. Most programs throughout the world screen for primary hypothyroidism with the measurement of TSH only. In some US states and some Canadian provinces, initial screening measures T_4. Those samples with T_4 values that fall within the lowest 10th percentile are tested for TSH. These methods effectively screen for congenital hypothyroidism for the following reasons: (1) they are easily incorporated into the existing metabolic-genetic screening programs (e.g., phenylketonuria screening); (2) primary T_4 with confirmatory TSH screening (T_4 + TSH) also rapidly identifies those infants with central hypothyroidism or TBG deficiency; (3) selectivity is high because TSH measurements discriminate between affected and nonaffected infants, with a low recall rate (0.3%-1%); and (4) cases of mild congenital hypothyroidism are identified by primary TSH screening and most cases are also identified by T_4 + TSH screening.

Both methods of screening (primary TSH and primary T_4 + TSH) appear to be capable of detecting almost all infants with primary congenital hypothyroidism, the only form of congenital hypothyroidism that carries a high risk for mental retardation if not detected early and treated adequately. Although a TSH level of greater than 40 mU/L is highly suggestive of congenital hypothyroidism, some affected infants have TSH values between 25 and 40 mU/L. These infants require prompt serum confirmation testing, because many will be shown to have primary congenital hypothyroidism. The practice of early hospital discharge (before 48 hours of age) has led to a higher rate of indeterminate results. Infants screened before 48 hours of age require recheck of the newborn screen by the primary care physician at 2 weeks. Infants who are preterm, of low and very low birth weight, ill, the result of a multiple gestation (particularly same sex), or have had sample collection done within the first 24 hours of life should have a second specimen collected and analyzed at 2 weeks of age or 2 weeks after initial sample collection. These infants may be categorized incorrectly based on initial screening due to multiple factors.[32,53]

From mass screening programs in multiple nations, the overall incidence of congenital hypothyroidism appears to be about 1 in 2000-3000 births. There is a female preponderance of 2:1 in the incidence of congenital hypothyroidism in North America, with ectopic thyroid tissue occurring in roughly half of congenital hypothyroidism cases. Aplastic or hypoplastic thyroid glands are found in about one-third of the cases. The prevalence of nonendemic, goitrous congenital hypothyroidism (typically thyroid dyshormonogenesis) depends on frequency of the defective gene in the population but usually occurs in 10% of infants with primary hypothyroidism. In the United States, the combined incidence of secondary and

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

tertiary hypothyroidism is about 1 in 80,000-100,000 births.

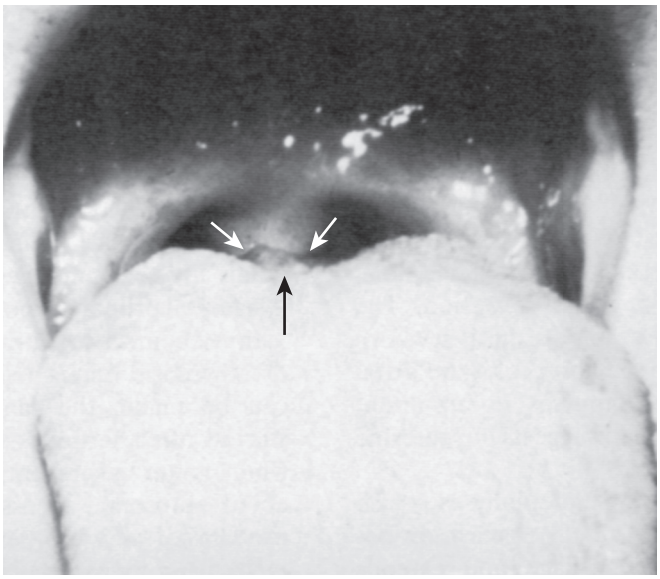
The prevalence of transient neonatal hypothyroidism differs by geographic location, related to variability in iodine intake. In areas with an adequate iodine supply, most infants with transient hypothyroidism were born to mothers who received goitrogens during pregnancy. Some cases result from placental transmission of maternal blocking antibodies or from exposure of the fetus or newborn to high doses of iodine (e.g., amiodarone, iodine-containing contrast, or topical absorption of iodine-containing antiseptic compounds).[56]

Incidence of congenital hypothyroidism (including dyshormonogenesis) is greatly increased in Down syndrome. Obvious congenital hypothyroidism occurs in about 2% of those with Down syndrome, and thyroid hormone replacement should be implemented in those individuals, followed by prudent and selective reassessment of the need for replacement at an older age (typically >3 years of age).[45] Many additional children with Down syndrome have mildly elevated TSH (5-15 mU/L). The underlying etiology of this observation is unclear, though thyroid-stimulating hormone bioactivity appears to be normal. It has been suggested that this may be reflective of a nonpathologic shift in the normal range of TSH, though this notion, as well as whether these individuals warrant intervention, is unclear. In a single randomized controlled study of infants and toddlers with Down syndrome, early replacement therapy resulted in modest growth and developmental benefits. However, these differences did not clearly persist in the follow up of this population at age 10 years.[35]

Screening programs that measure T_4 also identify infants with TBG deficiency. This predominantly X-linked trait (Xq22.2) occurs as frequently as 1 in 5000-10,000 births. Thyroxine-binding globulin deficiency has no clinical importance and, therefore, requires no intervention but leads to abnormal laboratory tests. T_4 concentrations are low, in the context of normal TSH and FT4 concentrations. Diagnosis can be confirmed by low TBG concentration on specific radioimmunoassay.

Clinical Manifestations

Even in athyreotic infants, classic clinical features of congenital hypothyroidism are usually absent at birth, resultant from some maternal T4 crossing the placenta, with umbilical cord levels of T4 reaching 25%-50% of those of normal newborns. Birth length and weight are generally normal, and manifestations appear gradually over several weeks in infants who do not receive thyroid hormone replacement. These manifestations include lethargy; inactivity; hypotonia; periorbital edema; large anterior and posterior fontanelles; feeding difficulty, including needing to be awakened to feed; respiratory distress; pallor; prolonged jaundice; perioral cyanosis; mottled skin; poor or hoarse crying; constipation; and hypothermia. In patients with a functional remnant of thyroid tissue and in those with familial dyshormonogenesis, clinical manifestations may be delayed several months or years, depending on the functional state of the thyroid.



Respiratory distress associated with myxedema of the airway is characterized by noisy breathing, nasal stuffiness, and intermittent cyanosis, especially in the perioral area. Respiratory symptoms may lead to suspicion of congenital anomalies of the airway or congenital heart disease. After the 1st week of life, prolonged physiologic jaundice may be an indication of hypothyroidism. In primary hypothyroidism, indirect hyperbilirubinemia predominates, whereas in central hypothyroidism, there is a mixture of indirect and direct hyperbilirubinemia. Serum creatinine may be elevated.

Classic features of congenital hypothyroidism in the infant usually become apparent after about 6 weeks of age (Fig. 88.4). They include typical facies, characterized by a

• **Fig. 88.5** Visualization of a lingual thyroid.

• **Fig. 88.6** Iodine-induced goiter in a neonate. The lateral bulging of the neck is caused by enlarged lateral lobes of the thyroid.

depressed nasal bridge, a relatively narrow forehead, puffy eyelids, dry and cold skin, long and abundant coarse hair, large tongue, abdominal distention, umbilical hernia, hyporeflexia, bradycardia, hypotension with narrow pulse pressure, anemia, and widely patent cranial sutures.

Lingual thyroid tissue can occasionally be seen in infants and children as a discrete round mass at the base of the tongue (Fig. 88.5). The base of the tongue must be firmly depressed to visualize the lingual thyroid. Because ectopic thyroid tissue may function normally at birth, the ectopic gland of a child may not be detected by newborn screening and may present during childhood or adolescence with a lingual mass associated with speech and feeding problems. In some instances, the sublingual thyroid is palpable as a round midline mass deep under the mandible or is visualized by ultrasonography.

Neonatal goiters may be extremely large, asymmetric, and confused with hygroma or other cervical masses (see Fig. 88.6). Alternatively, the goiter may be quite small and escape notice. The thyroid can be palpated in infants by placing them in the prone position, gently extending the neck, identifying the thyroid cartilage, and palpating inferiorly and laterally for the thyroid isthmus and lobes. The normal size of each thyroid lobe is about equal to the volume of the distal segment of the patient's thumb.

In infants with central hypothyroidism, there is no thyroid enlargement. Onset of symptoms tends to be gradual because some T_4 production continues. As a result, prognosis for mental development remains good. However, signs of other pituitary hormone deficiencies, congenital midbrain defects, or both are typically present. These signs may include neonatal hypoglycemia, a small penis, hypospadias, undescended testes, wandering nystagmus, cleft lip or palate, and combined direct and indirect hyperbilirubinemia. Growth failure gradually becomes evident in these patients.

Infants with congenital hypothyroidism are at higher risk to have certain comorbid congenital malformations, including cardiac malformations (such as septal defects) and renal anomalies, and a careful clinical evaluation of these infants should be done.

Laboratory Manifestations

When the diagnosis of congenital hypothyroidism is suspected, thyroid function tests should be performed (see Box 88.2). It is advisable to assess FT_4 and TSH, and in selected patients, TG levels.[34] Measurements of T_3, rT_3, FT_3, and T_3U are not currently indicated. Elevated serum TSH value is the most sensitive and specific test to confirm the diagnosis of primary hypothyroidism. The normal value for TSH in cord blood is higher than that at any other age (see Fig. 88.3). The physiologic TSH surge occurs during the first 6 hours of life, as noted earlier, and concentration of TSH may remain higher than 10 mU/L during the first 24-48 hours of life. Infants whose specimens were collected before 24 hours of life and who have mildly elevated TSH values very likely will have normal thyroid function tests on repeated testing.[53]

The typical laboratory findings for primary hypothyroidism are an elevated TSH, with T_4 and FT_4 values in the

• BOX 88.2 Laboratory Tests Used for the Diagnosis of Thyroid Disorders and Assessment of Thyroid Function in Infancy and Childhood

Serum Tests

- Thyrotropin (TSH)
- Thyroid hormones: thyroxine (T_4), free T_4 (FT_4) by analogue methods (initial screen), and direct dialysis (definitive method), triiodothyronine (T_3)
- Thyroid hormone-binding protein: thyroxine-binding globulin (TBG)
- Thyroid autoantibodies: thyroglobulin antibodies (TGAb), thyroperoxidase (microsomal) antibodies (TPOAb), TSH-receptor antibodies (TRAb) by TBII or TSI methods
- Thyroglobulin (TG)

Imaging Tests

- Thyroid scan with ^{99m}Tc-pertechnetate or ^{123}I-iodide
- Thyroid ultrasound

Miscellaneous Tests

- AM to PM TSH ratio
- Assessment of skeletal maturation
- Thyrotropin-releasing hormone (TRH) stimulation test
- Urinary iodine excretion

low or low-normal range. Occasionally, TG may be used as an adjunct to distinguish between etiologies of primary hypothyroidism if imaging is equivocal. A low or undetectable TG concentration with TSH elevation confirms a dysgenetic or absent thyroid gland, whereas a high TG with TSH elevation suggests an organification defect. In central hypothyroidism, TSH is usually normal or may be frankly low, T_4 is low or low-normal, and FT_4 is low or low-normal. Confirmation of suspected central hypothyroidism requires interrogation of the remainder of pituitary function and anomalies in pituitary anatomy.

In infants with acute or chronic illness, the euthyroid sick syndrome or nonthyroidal illness syndrome may be present and affects thyroid function test results but does not produce hypothyroidism. Typical laboratory findings in nonthyroidal illness are low or normal serum T_4, normal FT_4 by direct dialysis, and normal TSH. Total T_3 can be very low, and rT_3 is elevated.

Retardation of bone maturation is present in about half of the newborns with primary hypothyroidism and may suggest the fetal age at which a deficiency developed in the delivery of thyroid hormone to responsive tissues.[4] This assessment has been reported as a predictive indicator of persistent developmental delays, even in the setting of early intervention. Retardation of bone maturation in neonates is best assessed by radiographs of the knee and foot. The ossification centers of the calcaneus and talus appear at about 26-28 weeks of gestation, and those of the distal femur at about 34-36 weeks. The proximal tibial epiphyses appear at about 35 weeks of gestation. Absence of the distal femoral epiphyses in a newborn weighing 3000 g or more, or absence of the distal femoral and proximal tibial epiphyses in an infant weighing 2500-3000 g at birth, suggests an intrauterine thyroid hormone deficiency. Ossification of the cartilage of the epiphyses is also disturbed in hypothyroidism and normally begins from the center of the cartilage and extends peripherally in an orderly manner. In hypothyroidism, calcification of epiphyseal centers starts from multiple irregular foci scattered within the developing cartilage. The irregular calcification pattern appears on the radiograph as stippled or fragmented ossification centers and is referred to as *epiphyseal dysgenesis*, a finding that is highly characteristic of hypothyroidism (see Fig. 88.1). Stippled epiphyses may also occur in thyroid hormone resistance and also in multiple epiphyseal dysplasia, although thyroid function is normal in this familial disease.

Interpretation of Scanning Results

An enlarged, lingual, or dysgenetic thyroid may be identifiable by ultrasound.[54] Thyroid ultrasonography is highly user-dependent and also limited in its ability to detect lingual and sublingual ectopy.

The use of ^{123}I or ^{99m}Tc-pertechnetate is recommended, when practical, to distinguish dysgenesis from ectopia, as well as detect a large gland or one with high levels of uptake. Tracer uptake is obviously decreased or absent in hypoplastic or aplastic thyroid glands. A decrease in uptake may also be indicative of maternal blocking antibodies or acute iodine excess. Avid or high uptake is suggestive of iodine deficiency, or certain forms of dyshormonogenesis with defects downstream of iodine uptake or trapping (e.g., defects in thyroid peroxidase, dual oxidase 2, thyroglobulin, pendrin, or dehalogenase).

A perchlorate discharge test, which assesses the discharge of ^{123}I following the administration of perchlorate, may aid in the diagnosis of an organification defect. When rapid oxidation and organification of inorganic iodide fails to take place in the thyroid (i.e., a lack of conversion to iodine), an anion such as perchlorate can competitively inhibit the iodide accumulation, leading to a net loss of iodide from the gland. ^{123}I-iodide uptake is measured at 2 hours, immediately after which sodium or potassium perchlorate is given orally in doses of 10 mg/kg of body weight. Thyroid uptake is measured every 15-30 minutes for 2 hours. If the uptake decreases by more than 10% of the initial value, a defect in iodide oxidation or organification is confirmed.

Imaging should never delay the initiation of treatment in infants with suspected congenital hypothyroidism. Scintigraphy can be performed within 7 days of starting levothyroxine.[32] Patients can also be treated for a few years, with a definitive study undertaken at a later date. Ultimately, the findings of imaging studies can help to further guide diagnostic evaluation (i.e., molecular genetic testing) to confirm the presence of true congenital hypothyroidism and its etiology.

Differential Diagnosis

Errors in diagnosis of congenital hypothyroidism usually result from a failure of the newborn screening program (no specimen collected or a laboratory error), from a clinical failure to suspect the condition, or from the misdiagnosis of other disorders as hypothyroidism. These errors typically arise when the diagnosis is based on a few suggestive clinical features, and laboratory data are incorrectly interpreted. It is necessary to perform newborn screening even in sick newborns so that clear-cut abnormalities cannot be missed. Repeated screening is then indicated as the illness resolves.

During the early neonatal period, respiratory difficulty, pallor, and cyanosis in hypothyroid infants must be differentiated from other common causes of respiratory distress and from congenital heart disease. Lethargy, inactivity, hypotonia, and feeding difficulty may be mistaken for manifestations of sepsis or brain damage from a variety of causes. The prolonged jaundice in hypothyroidism must not be confused with icterus caused by hemolytic anemia, septicemia, or hepatic disease. The coarse facial features, macroglossia, and dry skin of hypothyroidism can mislead one to suspect Hurler syndrome, chondrodystrophy, or Down syndrome (see Fig. 88.4). A large goiter must not be confused with a hygroma, cyst, or tumor of the neck. A lingual thyroid, when visible or obstructing the airway, may be mistaken for a tumor of the pharyngeal area (see Fig. 88.5). Although epiphyseal dysgenesis may resemble osteochondritis deformans in its radiographic appearance (see Fig. 88.1), the latter does not occur during the neonatal period.

Transient Disorders of Thyroid Function

Transient neonatal thyroid dysfunction must be distinguished from permanent disorders of thyroid function. The results of neonatal screening tests from these patients may mimic those found in permanent hypothyroidism and may lead to an erroneous diagnosis and prolonged treatment. About 24%-36% of children diagnosed with congenital hypothyroidism by newborn screening are later determined to have transient hypothyroidism.[29]

In mothers with Graves disease, the transplacental passage of antithyroid drugs may cause transient hypothyroidism with goiter in the neonate. These drugs are rapidly cleared from the neonate within days.

Transplacental transfer of maternal inhibiting TSH-receptor antibodies (TRAb) can rarely result in transient neonatal primary hypothyroidism. These antibodies may persist in the infant's circulation for 2-3 months. No goiter is present, and absent or decreased uptake is seen on thyroid scintigraphy, although thyroid tissue can be seen on an ultrasonogram.

Premature neonates have many aberrations in thyroid status, including a delay and blunting of their postnatal TSH surge. In some very preterm infants (<31 weeks), T_4 concentrations do not rise and may fall within the first 1-2 weeks, termed transient hypothyroxinemia of prematurity. Free T_4 levels tend to be less affected, and the laboratory profile reflects abnormal protein binding or decreased TBG levels (affecting infants <30 weeks of gestation). Many other factors are thought to affect thyroid status in premature neonates, including immaturity of the hypothalamic-pituitary axis. In addition, given the prevalent neonatal morbidities in premature infants, laboratory anomalies consistent with the euthyroid sick syndrome are common. It is recommended that thyroid screening in preterm infants be repeated at 2 weeks of age or 2 weeks after initial screening was done.

Whether or not preterm infants should receive thyroid hormone replacement remains controversial. An association between hypothyroxinemia in preterm infants and neurodevelopmental problems and intellectual disability has been documented; however, these were observational studies that did not establish causality. Efficacy of thyroid hormone therapy has also not been established. A Cochrane review did not support use of thyroid hormone to treat transient hypothyroxinemia in preterm infants.[39] It was recommended that future controlled trials should be of adequate size to detect clinically significant differences in neonatal outcomes.

The incidence of transient primary hypothyroidism is higher in geographic areas where the dietary supply of iodine is insufficient, and premature infants are more susceptible, with incidence increasing with decreasing gestational age. Low urinary iodine concentration suggests this as the causative factor, and iodine supplementation may successfully correct hypothyroidism and goiter in these infants.

Conversely, iatrogenic iodine overload may also cause transient hypothyroidism, and premature infants appear to be more susceptible to iodine-induced transient hypothyroidism. Radiocontrast agents or the excessive application of iodine-containing antiseptics to mucous membranes (e.g., omphalocele) or intact skin can be sources of excessive iodine exposure.[31]

Heterozygous or homozygous DUOX2 mutations, impacting enzymes involved in iodine oxidation, may result in transient primary hypothyroidism in the neonate.

Finally, neonates who are the product of pregnancies complicated by uncontrolled hyperthyroidism during pregnancy may also be transiently centrally hypothyroid.

Euthyroid Sick Syndrome

Acutely ill patients commonly have alterations in thyroid function testing. The current hypothesis is that these alterations occur as an adaptive response to decrease basal metabolic rates in severely ill patients. The syndrome has been recognized in sick infants and children, with both acute and/or chronic illness.[52]

In the neonatal period, preterm infants with respiratory distress syndrome are the most frequently encountered patients with euthyroid sick syndrome.[42] An alteration in T_4 metabolism favors production of rT_3 over T_3, which appears to occur rapidly. The prevalence and severity of the euthyroid sick syndrome increases with decreasing gestational

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

age. The consistent finding is an abnormally low serum T_3 level, often accompanied by an increase in the rT_3 level. T_4 may be low or normal and FT_4 may be normal, depending on the metabolic clearance rate of T_4. Serum TBG may be low or normal, and TSH may be low or normal. In preterm infants, T_4, FT_4, and T_3 levels are typically lower than those in term infants, and rT_3 is high.[42] Therefore, thyroid tests in preterm infants may present a confusing situation when the infants are ill from nonthyroidal diseases.

Abnormal thyroid function gradually reverts to normal function as the patient's primary illness improves. During recovery, TSH may be transiently elevated (up to 15 mU/L). Treatment with thyroid hormone is not indicated in these patients. However, preterm infants at risk should be monitored by serial determinations of FT_4 and TSH, and T_4 treatment should be initiated if there is a progressive increase in serum TSH and decrease in FT_4.

Treatment of Hypothyroidism

Transplacental transfer of maternal T_4 during gestation initially offers some protection of brain development in the hypothyroid neonate. Serum T_4 concentrations at term in athyreotic babies are 25%-50% of those found in normal neonates. For this reason, the majority of newborns with congenital hypothyroidism are asymptomatic or have only mild symptoms. However, the half-life of serum T_4, including T_4 acquired from the mother, is short in infants (3-4 days) compared with adults (about 6 days), and within 1-2 weeks the infant's serum T_4 level will have dropped significantly. A delay in the initiation of thyroid hormone therapy can result in a decrease in IQ score, and replacement is recommended within the first 2 weeks of life.[32] Thyroid hormone replacement therapy for neonatal congenital hypothyroidism must be started as soon as blood is collected for serum confirmation tests.[4] Therefore, all hypothyroid infants, with or without goiter, should be rendered euthyroid as promptly as possible with replacement therapy. Those with mild TSH elevation and normal FT_4 may be monitored with serial TSH and FT_4 tests and not treated for up to 4 weeks. However, if TSH remains elevated, thyroid hormone therapy should be started. In rare instances in which the diagnosis of congenital hypothyroidism cannot be established expeditiously because of confounding laboratory results, it is the safest course to fully treat the infant for the first 3 years of life. At 3 years of age, after the brain has substantially completed its growth, treatment can be withdrawn or decreased by 50% and the patient re-evaluated 4-6 weeks later.

Asymptomatic infants and those with minimal clinical manifestations of congenital hypothyroidism can be given sodium-L-thyroxine, 10-15 μg/kg per day (administered orally once per day), beginning as soon as the diagnosis is established (optimally by 2 weeks of age).[4] There is no evidence that sole or combination therapy with L-T3 is superior to therapy with L-T4 alone and, therefore, it is not recommended. Bioavailability of brand L-T4 may be higher than generic and, therefore, generally preferred in use in athyreotic infants. The pill should be crushed and suspended in a small amount of formula, breast milk, or water (not the whole bottle). Human breast milk does not contain enough T_4 to alter thyroid hormone levels in the infant, and therefore breastfeeding can continue with appropriate replacement of L-T4. The suspension can be provided by way of a cross-cut nipple and followed later by the feeding. Administration can be either before or with feedings, although should be in the same way with every dose. Separation from intake of soy, iron, or calcium is advised, and in the first few weeks of life, from vitamin D administration.

The initial dose of T_4 need not exceed 50 μg/day. TSH and FT_4 values should be initially rechecked 1-2 weeks after initiation of therapy, and then at 2-week intervals until normalization of TSH. The thyroid hormone dose may need to be decreased to 37.5 μg/day or on rare occasions to 25 μg/day if FT_4 exceeds 2.5 ng/dL, TSH suppression occurs, or clinical symptoms of thyrotoxicosis develop. The target for TSH concentrations should be in the normal range for age during thyroid hormone replacement therapy, with FT_4 levels in the upper half of normal for age. Age-appropriate levels in children differ from those in adults (see Fig. 88.2).

In preterm infants, the same starting dose of T_4 (10-15 μg/kg per day) is recommended to promptly increase T_4 to normal. The dose may need to be decreased, as described, once free T_4 (FT_4) or total T_4 (TT_4) values reach the desired normal level. No adverse effects from this dose of T_4 replacement therapy were found in infants during their 1st year of life as long as they were frequently monitored, including FT_4 and TSH determinations.

In treatment of infants with severe myxedema with fluid retention, possible complications should be kept in mind. Cardiac insufficiency caused by pericardial effusions or overloading of the myxedematous heart through too rapid a mobilization of the myxedema fluid into the circulation is well-known in the adult. This complication in older children and adults is prevented by administering a small dose of thyroid hormone at first and gradually increasing the dosage. However, infants generally tolerate a rapid restoration to the euthyroid state better than adults, and a prompt restoration of T_4 to a normal value is important for the recovery of brain development and maturation. Nevertheless, excessive thyroid hormone therapy must be avoided, and the dose must be adjusted judiciously (starting at ~50% of the target dose, and increasing gradually after 2 weeks) if there is evidence of severe myxedema, particularly of the heart. Aspiration of food can occur in cases of severe myxedema resulting from impairment in swallowing (caused by myxedema of the pharyngeal area), compounded by an increased appetite as the euthyroid state is restored. Therefore, when myxedema is severe, the infant should be fed carefully and slowly during the early phase of treatment.

During the first years of life, patients should be monitored frequently—at least every 2 months during the first

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

6 months of life, every 3-4 months during the next 2 years, and then twice a year—to assess clinical progress and adjust levothyroxine to maintain FT_4 and TSH in target range.[4] Thyroid hormone requirement based on weight (μg/kg per day) will gradually decrease from a dose of 8-10 μg/kg per day at age 3-6 months to 2-3 μg/kg per day in adolescents. In adults, thyroid hormone requirement is approximately 1.7 μg/kg per day.

Goitrous cretinism caused by the maternal ingestion of goitrogens is a self-limited condition. The blocking effect of antithyroid drugs usually disappears several days after birth. Therefore, if the goiter is small, TSH is not elevated, and the patient is euthyroid, no treatment is required. However, if the patient is hypothyroid and TSH is elevated or if the goiter is large, it is safer to treat the infant until the age of 3 years, as described previously.

In nursing mothers with Graves disease, both propylthiouracil (PTU) and methimazole (MTZ) are secreted in breast milk in small concentrations. However, studies of breastfed infants of mothers taking these medications have demonstrated normal thyroid function and intellectual development.[26]

Prenatal diagnosis and intrauterine treatment of congenital hypothyroidism have been successful in only a number of cases. Optimal methods for monitoring fetal thyroid state still need to be established. Imaging studies alone are not sufficient, because goiter can result from hypothyroid or hyperthyroid states. Measurements of accurate TSH levels (compared to gestational age norms) are done by cordocentesis, but this increases the risk of fetal loss and should therefore only be done when intervention is contemplated. In utero treatment with intra-amniotic L-thyroxine injection is effective for reducing fetal goiter size, which may be considered for a fetus with progressive hydramnios, a risk for premature delivery, and/or concerns for tracheal occlusion. However, there are no clear recommendations for dosing regimens or outcome data to show neurodevelopmental benefit from therapy, because the number of cases treated in utero is small. Prenatal diagnosis and treatment of congenital hypothyroidism await further developments.

Prognosis for Congenital Hypothyroidism

Shortly after adequate substitution therapy is instituted, clinical manifestations of hypothyroidism resolve. If growth restriction was present before treatment, accelerated linear growth occurs. After a period of catch-up growth, an optimal rate of growth is maintained. Goiter or a hypertrophied ectopic thyroid gradually shrinks in size when the patient is properly treated. If there was a delay in skeletal maturation at diagnosis, treatment is associated with acceleration in bone maturation after a latent period of a few months, with subsequent osseous development that parallels chronologic age. Overtreatment should be avoided, because this can result in rapid epiphyseal closure and craniosynostosis. With substitution therapy, epiphyseal dysgenesis (see Fig. 88.1), present in ossification centers that failed to calcify while the patient was hypothyroid, develops calcification that coalesces to form a normal epiphysis.

Age of initiation of thyroid hormone therapy is a major determinant of neurodevelopmental outcome. Review of a number of studies comparing treatment at an earlier age (day of life 12-30) versus at a later age (>30 days of life) found that infants started at the earlier age averaged 15.7 IQ points higher. Initial starting dose of levothyroxine is also important. The majority of studies have found that children started on doses of 10-15 μg/kg per day had the best IQ outcome. Severity of hypothyroidism was also thought to contribute to poor outcome in prior studies. However, it appears that inadequate starting dose likely explains the association in these studies, and titrating levothyroxine dose to severity of hypothyroidism greatly improves outcome.[47] Last, continued compliance of thyroid hormone therapy during infancy and childhood is vital; recurrent episodes in childhood of insufficiently suppressed TSH are associated with school delay.

Current follow-up studies of patients treated within the first few weeks of postnatal life after identification by neonatal screening indicate that neurologic function overall is normal, with a few minor exceptions. Residual defects may include visual–spatial processing, sensorimotor defects, attention problems, and selective memory. There are only minor differences in intelligence, school achievement, and neuropsychologic test scores in affected congenital hypothyroidism adults treated early with thyroid hormone compared with control groups of classmates and siblings. Poor attention can also be seen in patients who have been overtreated.[32] Overall, intellectual and neurologic prognosis for patients with congenital hypothyroidism has greatly improved since the advent of newborn screening. We may still expect further improvement in the future, because thyroid hormone treatment regimens used today are more aggressive in targeting the early correction of TSH than the regimens used 15-30 years ago.

Neonatal Graves Disease

Etiology and Pathogenesis

Maternal Graves disease is the most common cause of neonatal hyperthyroidism and results from transplacental transfer of stimulating TSH-receptor antibodies (TRAb) from the mother to newborn. The disease can occur in the neonate of a mother known to have active Graves disease and also in mothers with a history of Graves disease previously treated with thyroidectomy or radioiodine ablation. Neonatal Graves disease occurs in 1%-5% of at risk pregnant mothers. There is an increased likelihood of neonatal Graves hyperthyroidism if there is higher maternal stimulatory TRAb concentration during the third trimester. The highest risk occurs when maternal TSI is greater than 5 index units.[44]

Clinical Manifestations

When neonatal thyrotoxicosis occurs in the infant born to a mother with untreated, active Graves disease, clinical manifestations of hyperthyroidism may become apparent within the first 24 hours of life. Infants may be born prematurely from such a mother. Clinical features that may be seen include hyperkinesis, diarrhea, poor weight gain, hepatosplenomegaly, jaundice, thrombocytopenia, craniosynostosis, tachycardia, exophthalmos, and goiter. Although a goiter is inevitably present in neonatal thyrotoxicosis, its size varies considerably; it may be small and escape notice on a cursory examination, or it may be large enough to cause tracheal compression. Exophthalmos is usually mild when present. In severe neonatal thyrotoxicosis, hyperthermia, arrhythmia, and high-output cardiac failure may occur. If the condition remains untreated, death may result. In most cases, the course of neonatal hyperthyroidism is self-limited because of the gradual depletion of transplacentally acquired stimulating TRAb. The signs and symptoms subside spontaneously after 3 weeks to 6 months; rapid resolution of symptoms occurs when the initial titer of serum-stimulating TRAb in the neonate is lower. However, goiter may persist for some time after all signs of hyperthyroidism disappear. The thyroid gradually returns to its normal size. In rare instances, neonatal thyrotoxicosis may not be a transient disorder and may persist for years, usually indicating the presence of activating mutations of the TSH receptor.

In the infant born to a mother who received antithyroid medications for the treatment of Graves disease during the latter part of pregnancy, the onset of clinical manifestations may be modified by transplacental acquisition of the antithyroid agent as well as stimulating TRAb. At birth, the infant may be euthyroid or even hypothyroid, and the presence of a goiter may be the only abnormal feature. Because the plasma half-life of antithyroid agents is short compared with the half-life of stimulating TRAb, the typical manifestations of neonatal thyrotoxicosis may appear several days to 2 weeks after birth. Although neonatal Graves disease is a disease mediated by monoclonal antibodies, polyclonal antibodies are sometimes produced by the mother and cause atypical disease in the infant. Hyperthyroidism may not develop until 1-2 months of age if a high-affinity TSH-binding/inhibiting immunoglobulin (TBII) in low concentrations initially predominates; once it is metabolized, a second population of stimulating TRAb prevails to cause late-onset hyperthyroidism.

Diagnosis and Differential Diagnosis

A maternal history of Graves disease before or during pregnancy is important to identify infants at risk for neonatal Graves disease. Information concerning both prior and current treatment of maternal hyperthyroidism must also be obtained. The infant should be examined sequentially for signs of thyrotoxicosis, and the neck should be palpated carefully to detect a goiter. Determination of stimulating TRAb in infant serum or cord blood should be obtained. A higher titer of TRAb in cord blood or neonatal serum strongly supports the diagnosis of neonatal Graves in a thyrotoxic infant. Serial measurements of TRAb in the infant also help monitor disease activity and aid the decision to decrease or terminate therapy. It is recommended that in at-risk infants, TSH and FT_4 be measured at day 3-5 of life or earlier if there is clinical concern. If these levels are normal, they should be repeated again at day of life 10-14. If there are no lab abnormalities after 2 weeks of life, routine testing can be discontinued as the majority of infants are diagnosed by 2 weeks. At-risk infants should continue to be assessed clinically at 4 weeks, 2 months, and 3 months of life to identify a minority of patients with delayed presentation.[57] Lab measurements should be interpreted in relation to age-appropriate reference ranges.

In the euthyroid or hypothyroid neonate born to a mother who received antithyroid medication during the latter part of pregnancy, it is almost impossible to predict whether thyrotoxicosis will ensue. Therefore, serial examinations of the infant must be undertaken during the first 10 days of life. Although neonatal thyrotoxicosis can be confused with various neurologic disorders, narcotic withdrawal in the infant of an addicted mother, congenital heart disease, or sepsis, a positive maternal history of Graves disease and presence of goiter should readily alert the physician to the correct diagnosis. In normal neonates and infants, the thyroid gland is difficult to palpate. Therefore, an easily palpable thyroid in such an infant should generally be regarded as a goiter.

More rarely, neonatal hyperthyroidism may result from defects in the TSH receptor or the downstream mediators, and unlike neonatal Graves disease, these forms of hyperthyroidism are persistent and are not mediated by TRAb. These germline mutations demonstrate autosomal dominant inheritance (see Table 88.1) and occur in the transmembrane domains of the receptor or affect receptor coupling to stimulatory G protein, which leads to constitutive activation of the adenylate cyclase.[46] Because of disease severity and frequent relapse, definitive therapy with surgery or radioactive iodine is eventually indicated when the patient is older.

Treatment

The treatment of thyrotoxicosis in a neonate is similar to that in an older child and involves use of antithyroid drugs. Care should be exercised not to induce hypothyroidism with excessive medication. Iodine (Lugol solution) and an antithyroid drug, methimazole (MTZ), are typically used. Lugol solution can be given at a dose of one drop three times daily. Although iodine rapidly inhibits the release of T_4 from the thyroid, its effects tend to disappear after several weeks. Iodine should be given at least 1 hour after methimazole to avoid exacerbating hyperthyroidism acutely. Methimazole is given in doses of 0.2-1 mg/kg per day in

one to three divided doses. Propylthiouracil (PTU) is no longer recommended for use in children because of association with liver failure.[48] Most symptoms of hyperthyroidism are closely related to increased adrenergic response. Therefore, beta-adrenergic blocking drugs can alleviate many of the potentially life-threatening manifestations of neonatal thyrotoxicosis. In contrast to antithyroid drugs, these agents can rapidly diminish the severity of thyrotoxicosis, and their effects are evident within a few hours. Propranolol, together with iodine and MTZ, may be used in the treatment of severe neonatal thyrotoxicosis. Propranolol is given orally in a dose of 0.5-2 mg/kg per day in two or more divided doses. In critically ill newborns, a short course of pharmacologic glucocorticoids, which inhibits thyroid hormone secretion and impairs peripheral conversion of T_4 to T_3, may be needed to help stabilize the infant.

Circulating T_4 has a half-life of 3-4 days in neonates and about 6 days in adults. Therefore, little or no clinical response to antithyroid drugs can be expected during the first few days of therapy. The TSH response to a hypothyroid state induced by the excessive treatment of thyrotoxicosis may be diminished for several months or longer in these infants. Therefore, lack of TSH elevation cannot be relied on to indicate the excessive treatment of thyrotoxicosis. It is recommended that thyroid function be measured weekly until FT_4 concentrations are stable and then every 2 weeks.[48] MTZ should be decreased and eventually discontinued when FT_4 concentrations have normalized. Monitoring of TRAb titers may facilitate decision making about when to discontinue therapy as well. Depending on the initial TRAb titers, neonatal Graves disease typically resolves by 6 months of age; treatment duration usually lasts about 1-2 months.

The hypothyroid infant born to a mother who received antithyroid medications during pregnancy should be managed as described in the section on congenital hypothyroidism. If the infant has already received thyroid hormone, such therapy should be decreased as soon as thyrotoxic manifestations occur, and the appropriate management of hyperthyroidism must be initiated.

Prenatal therapy is possible with the use of oral maternal antithyroid drugs and adjustment of the dose to normalize fetal TSH and cardiac function. It is recommended that when a pregnant woman has uncontrolled hyperthyroidism or elevated TRAb greater than three times the upper limit of normal, serial fetal ultrasounds should be performed.[2] Ultrasound can detect fetal tachycardia, rapid bone maturation, and goiter, which indicate a fetal hyperthyroid state. If fetal hypothyroidism results from maternal overtreatment with antithyroid drugs, serial ultrasound of the fetal thyroid can also be helpful to determine if subsequent dose reduction of antithyroid drug is sufficient.

Prognosis

Most infants diagnosed promptly and treated appropriately for neonatal Graves disease will improve quickly. However, it has been reported that some patients on long-term follow-up are found to have lower IQs. Craniosynostosis, hyperactivity, and other behavioral problems have also been seen.[15] There have also been cases described associating neonatal Graves disease and/or poorly controlled maternal hyperthyroidism with development of central hypothyroidism in the infant.[27,34] It seems as if fetal or neonatal exposure to high thyroid hormone concentrations can impair neurodevelopment and specifically the maturation of the hypothalamic-pituitary-thyroid axis. These findings highlight the importance of close monitoring of both maternal and neonatal thyroid function and drug management.

Familial Abnormalities of Thyroxine-Binding Proteins

Genetic disorders resulting in either increased or decreased levels of T_4-binding proteins have been reported. Affected individuals are healthy and asymptomatic because a change in the level of T_4-binding proteins does not lead to an alteration of FT_4. The disorders are usually discovered fortuitously by the measurement of T_4, which reveals unexpectedly high or low values. Therefore, the only clinical significance of these conditions lies in the abnormal T_4 level, possibly leading to an erroneous diagnosis. The TSH levels are normal in these individuals.

Thyroxine-Binding Globulin (TBG) Defects

TBG is one of the major serum transport proteins for thyroid hormone. TBG is encoded by one gene copy on the long arm of the X chromosome (Xp22.2). Inherited TBG defects typically follow an X-linked pattern. Complete TBG deficiency occurs in 1/15,000 newborns and partial deficiency in 1/4,000 newborns. Males with complete deficiency have undetectable TBG and heterozygous females typically have half the normal TBG concentration. In TBG excess, affected males have TBG concentration 2-4 times the mean level, and carrier females have levels slightly above half of affected males. TBG excess and deficiency are usually diagnosed incidentally with lab work, demonstrating abnormal T_4 with normal free T_4.[40]

Increased Transthyretin (TTR)

Families with increased levels of TTR have been reported and specific gene mutations identified. Serum T_4 is elevated, but FT_4 is normal. Only a small amount of T_4 is bound to TTR; therefore, T_4 level is only significantly elevated in variants with much higher binding affinity for thyroid hormone.[40]

Familial Dysalbuminemic Hyperthyroxinemia

Familial dysalbuminemic hyperthyroxinemia is caused by gain-of-function mutations in the human serum albumin

gene resulting in enhanced binding of T_4 by abnormal serum albumin. Its prevalence varies from 0.01%-1.8% depending on the ethnicity with frequency being highest in Hispanics.[40] Affected individuals typically have elevated T_4 or T_3 depending on the specific mutation. Free T_4 concentration measured by direct dialysis is normal, but if analogue methods are used, there may be interference from abnormal albumin, resulting in falsely elevated levels.

Key Points

- Maintenance of normal thyroid hormone levels is important for metabolism, linear growth, and brain development during infancy and childhood.
- The hypothalamic-pituitary axis along with iodine metabolism exert primary control over thyroid hormone production.
- In utero, maternal and fetal relationships have significant impact on thyroid hormone adequacy in the fetus.
- Early detection of congenital hypothyroidism by newborn screening has dramatically improved outcomes and reduced negative impact of hypothyroidism on neurocognitive development.
- Neonatal Graves disease is the most common cause of neonatal hyperthyroidism; even mothers who have already been treated for Graves disease are at risk for having offspring with neonatal Graves disease.
- Clinical awareness of abnormalities in thyroxine-binding proteins is important to avoid erroneous diagnosis of hypo- or hyperthyroidism.

Disorders of Sex Development

JULIA CATHERINE SORBARA AND DIANE KATHERINE WHERRETT

Genetic sex is determined at the time of fertilization, but carrying out the steps of sexual differentiation takes place over 14 weeks of embryonic and fetal development. An error in this process may result in a disorder of sex development (DSD), defined as a discrepancy in the genetic, gonadal, or genital makeup of an individual. This chapter reviews normal fetal sexual differentiation; the approaches to the recognition and diagnosis of neonates who may have a DSD; and the classification, clinical features, and general management principles of DSDs, with the focus on perinatal issues.

Fetal Sexual Determination and Differentiation

Genetic Control of Fetal Gonadal Determination and Differentiation

The embryo and early fetus, regardless of genetic sex (i.e., 46,XX or 46,XY), are bipotential with respect to sexual differentiation, having the anatomic and biochemical components necessary for both male and female development. For normal male differentiation to occur, a succession of genetic and hormonal signals must be intact and occur correctly.[14] The classic teaching is that there is an innate tendency of the embryo and early fetus to differentiate along female lines; that is, female differentiation is the default setting, occurring when signals for male differentiation are absent. However, there is growing evidence supporting female differentiation as an active process, induced and maintained by specific genes and signaling pathways.[5] The biopotential gonad begins to differentiate at 7 weeks of gestation under the direction of both sex and autosomal chromosome gene products, which function primarily as transcription factors.

Sex Chromosomes and Role of the SRY Gene

The presence of the *SRY* gene on the Y chromosome causes the bipotential gonad to differentiate as a testis, and male phenotypic development follows. The presence of one, two, or more X chromosomes does not alter this process. However, the presence of more than one X chromosome (e.g., 47,XXY syndrome, also known as Klinefelter syndrome) results in eventual meiotic failure, loss of germ cells, and infertility. Although autosomal factors that drive ovarian differentiation have been identified, an X-linked female-determining factor analogous to SRY has not yet been discovered.[5]

On the other hand, early ovarian differentiation does not require two X chromosomes and can proceed in 45,X fetuses. Later stages, however, of ovarian differentiation do require two X chromosomes, as this is necessary for normal formation of primordial follicles. From 15 weeks' gestation onwards, ovarian development will start to fail if part or all of the second X chromosome is missing as primordial follicles and oocytes degenerate rapidly. The resulting gonad appears as an elongated, whitish streak that microscopically demonstrates whorls of fibrous tissue without germ cells or epithelial elements. This "streak" gonad is characteristic of the gonadal dysgenesis syndromes.

Fetuses with Y chromosome material that fail to undergo normal testicular differentiation are believed to develop streak gonads through similar changes. Unlike gonadal dysgenesis in individuals without Y chromosome material, these structures carry a high risk for the development of gonadal tumors.[1] These tumors may result from the persistence of residual XY germ cells that did not degenerate or from tumorigenic loci on the Y chromosome.

Autosomal and X-Linked Genes

Although the presence or absence of the *SRY* gene determines the fate of the bipotential gonad, additional autosomal and X-linked genes, located upstream and downstream from the *SRY* gene, are involved in gonadal development and differentiation (Fig. 89.1).[80] Several of these genes encode transcription factors or transcription regulatory proteins, which activate or repress the expression of additional target genes, often in multiple tissues, influencing or controlling a diverse program of cellular differentiation and proliferation during embryonic and fetal development. When gene mutations occur, the functional domain of the transcription factor becomes altered, leading to abnormal or contrary regulation (e.g., from a repressor to an activator) of downstream genes. This results in abnormal cell differentiation or growth or neoplastic transformation. It is the occurrence of such mutations and the resulting pathologic conditions that have led to the identification and functional understanding

Abstract

Genetic sex is determined at the time of fertilization, but carrying out the genetic directives that lead to steps of sexual differentiation takes place over 14 weeks of embryonic and fetal development. An error or fault in this process may result in a disorder of sex development (DSD), defined as a discrepancy in the genetic, gonadal, or genital makeup of an individual. This chapter reviews (1) normal fetal sexual differentiation; (2) an approach to the recognition and diagnosis of neonates who may have a DSD; and (3) the classification, clinical features, and general management principles of DSDs, with the focus on perinatal issues.

• **Fig. 89.1** Gene regulatory networks in embryonic gonadal development. Genes shown are known to have a role in sex development on the basis of studies in humans and mice (*uppercase*) or in mice only (*lowercase*). Testis-related genes (*blue*) and ovary-related genes (*red*) are depicted in regulatory pathways leading to Sertoli- and granulose-cell specification, respectively. In XY gonads, SOX9 expression is subsequently upregulated by SRY and SF-1 binding to TESCO. SOX9 is a key hub gene for testis development. SOX9 maintains its own expression through binding to TESCO with SF-1. SOX9 also regulates expression of genes required for testis formation such as AMH, FGF9, PTGDS, and probably other genes. SOX9 also suppresses the expression of ovarian genes such as RSPO1 and FOXL2. Sexual dimorphism in the XX genital ridge is triggered by R-spondin-1 (encoded by RSPO1) and FOXL2. WNT4, β-catenin, and Fst are also expressed in a female-specific manner, promoting ovarian development. Additionally, R-spondin-1, FOXL2, WNT-4, and β-catenin have roles in preventing differentiation of testis by repressing SOX9 expression. (From Ono M, Harley VR. Disorders of sex development: new genes, new concepts. *Nat Rev Endocrinol.* 2013;9:79-91.)

of many of these genes. Examples of gene mutations that affect sex determination in 46,XY and 46,XX DSDs are listed in Table 89.1.[80]

Embryology and Endocrinology

The bipotential gonads as well as the anlagen for the genital ducts and external genitalia are derived from the mesodermal germ layer; the exception is the urogenital sinus epithelium, which is of endodermal origin. The bipotential gonadal and genital tissues undergo morphogenesis during the embryonic period, which extends from the end of the third week, or about 20 days gestational age, through the 7th to 8th week of gestation. Fetal sexual differentiation begins in the 7th week, when the bipotential gonad begins to differentiate as either a testis or an ovary. This process continues until 12-14 weeks of fetal age, at which point differentiation of the internal genital ducts and external genitalia along male or female lines is largely complete.

Development of the Gonads

The initial step in gonadal development is the formation of paired, bipotential genital ridges, which occurs at 4-4.5 weeks' gestational age on the medial aspect of each mesonephros. The somatic component of the gonad originates from coelomic epithelium and the underlying mesenchyme or adjacent mesonephros.[109] The germinal component comprises the primordial germ cells, which migrate from the yolk sac endoderm at 24 days to reach the genital ridge at 4.5-6 weeks. Following migration, there is ongoing proliferation up until 9 weeks' gestational age, which completes the formation of the indifferent gonad (Fig. 89.2).[72,109] Normal development of the potential gonads is directed by key transcription factors. Genetic changes to their encoding regions may lead to the development of streak gonads, having significant implications for further sexual differentiation.[30]

Testicular Differentiation

The expression of the *SRY* gene in XY gonads initiates testicular differentiation at 7 to 8 weeks' gestational age. Anatomical differentiation begins when the sex cords form loops in the cortex and differentiate as the seminiferous cords. In the hilum, they anastomose to form the rete cords. From 8 weeks on, the seminiferous cords become coiled and thickened and contain eight to ten layers of Sertoli cells. Spermatogonia, however, remain located near the basement

membrane of the cords. Under the influence of signals from Sertoli cells, Leydig cells appear in the interstitium between the seminiferous cords at 7.5-8 weeks. They increase strikingly in number during the third month, occupy half the volume of the testis at 13-14 weeks, and then show a significant fall in number. Some Leydig cells are present postnatally but histologically disappear after 3-6 months because of the physiologic decline in gonadotropin stimulation. As the fetus elongates, the testis descends and occupies a more caudal position. In the 6th and 7th months, the cremaster muscle differentiates in the caudal testicular ligament to form the testicular gubernaculum, which penetrates the inguinal canal and is anchored to the connective tissue of the scrotum. The testis descends behind the peritoneum and

TABLE 89.1 Examples of Gene Mutations That Affect the Sex Determination, Clinical Phenotype, and Associated Anomalies

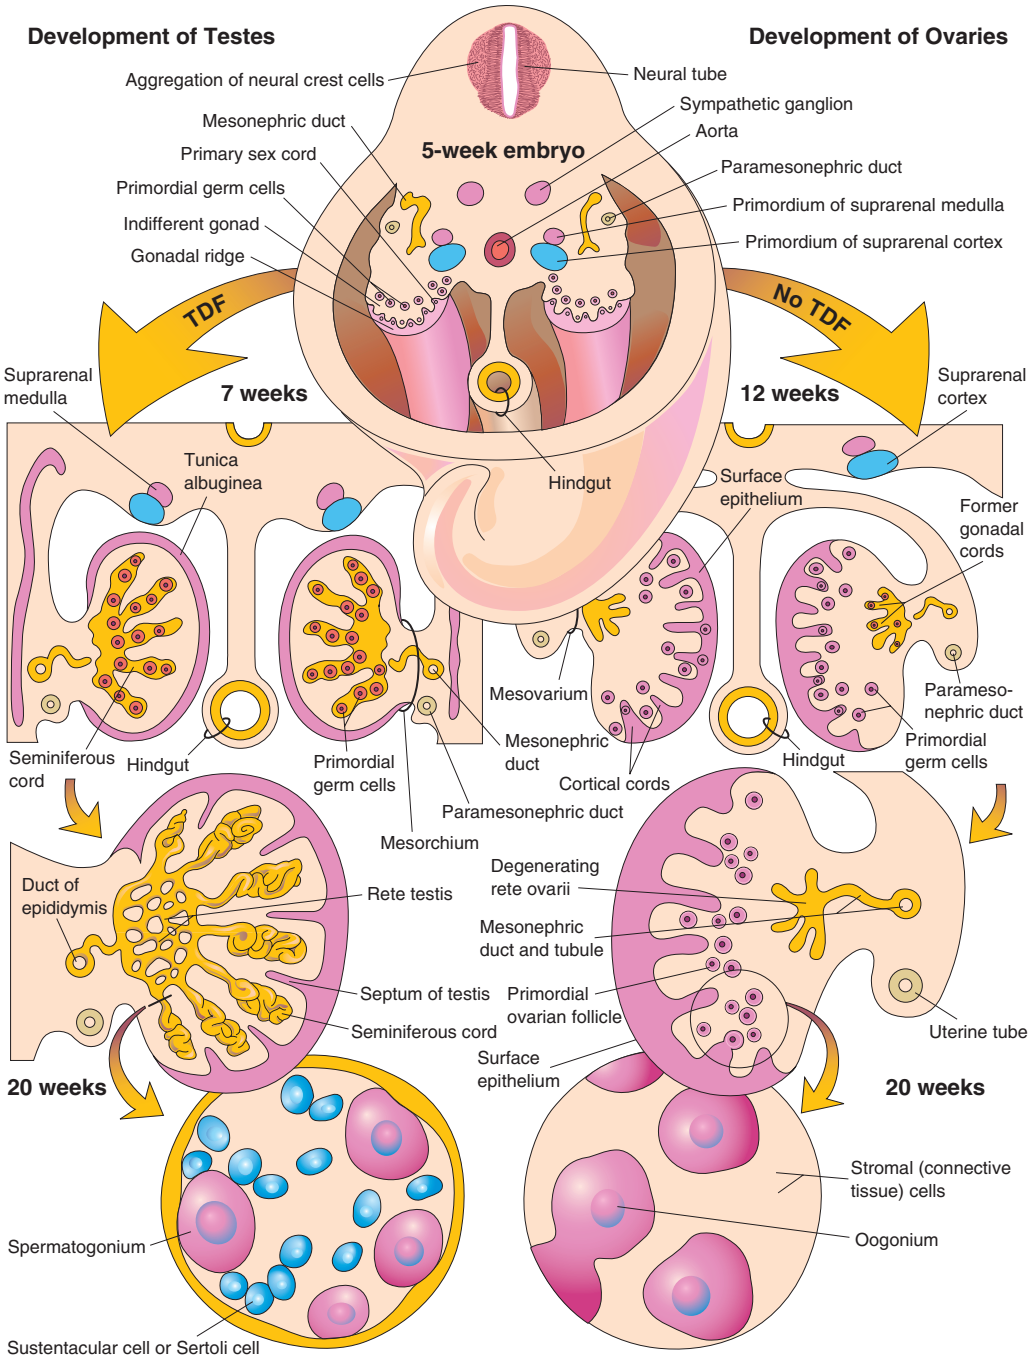
reaches the scrotum by the 8th or 9th month. The inguinal canal closes after testicular descent is complete.[44]



Ovarian Differentiation

Ovarian differentiation begins at 7 weeks, as outlined previously and in Table 89.2. Unlike in testicular differentiation, the presence of germ cells in an XX gonad is required for normal ovarian follicular development. The sex cords in the ovary show germ cells (oogonia) undergoing repeated mitotic divisions from 7 weeks through about the 5th month. Most oogonia differentiate into primary oocytes between about 10 and 24 weeks. During this process, they enter meiosis, proceeding through the first meiotic prophase. After reaching the meiotic prophase, from about 21 weeks until term, many oocytes become surrounded by a single layer of granulosa cells to form primordial follicles. Two X chromosomes are needed for differentiation of the primordial follicle into a mature follicle. Oocytes degenerate if they are not enclosed in a mature follicle. During ovarian differentiation, the number of germ cells greatly increases to several million oogonia and oocytes by the 5th month. Most germ cells degenerate thereafter, either before or during the primordial follicle stage, leaving about 150,000–295,000 follicles in each ovary at birth.[104] Theca cells, the ovarian steroid hormone–producing cells, first appear in midgestation.[109]

Development of the Genital Ducts

The internal genital ducts, unlike the gonads, develop from the mesonephric or wolffian ducts in the male and from the paramesonephric or Müllerian ducts in the female. The wolffian ducts are formed in 26- to 32-day-old embryos. The Müllerian ducts begin development at about 37 days in close association with the wolffian ducts, which serve as

• **Fig. 89.2** Schematic illustration showing differentiation of the indifferent gonads of a 5-week embryo (*top*) into ovaries or testes. The left side of the drawing shows the development of testes resulting from the effects of the testis-determining factor (TDF) located on the Y chromosome. Note that the gonadal cords become seminiferous cords, the primordia of the seminiferous tubules. The parts of the gonadal cords that enter the medulla of the testis form the rete testis. In the section of the testis at the bottom left, there are two kinds of cells: spermatogonia, derived from primordial germ cells, and sustentacular or Sertoli cells, derived from mesenchyme. The right side of the drawing shows the development of ovaries in the absence of TDF. Cortical cords have extended from the surface epithelium of the gonad, and primordial germ cells have entered them. They are the primordia of the oogonia. Follicular cells are derived from the surface epithelium of the ovary. (From Moore KL, Persaud TVN. *The developing human: clinically oriented embryology.* 10th ed. Philadelphia: Saunders; 2015.)

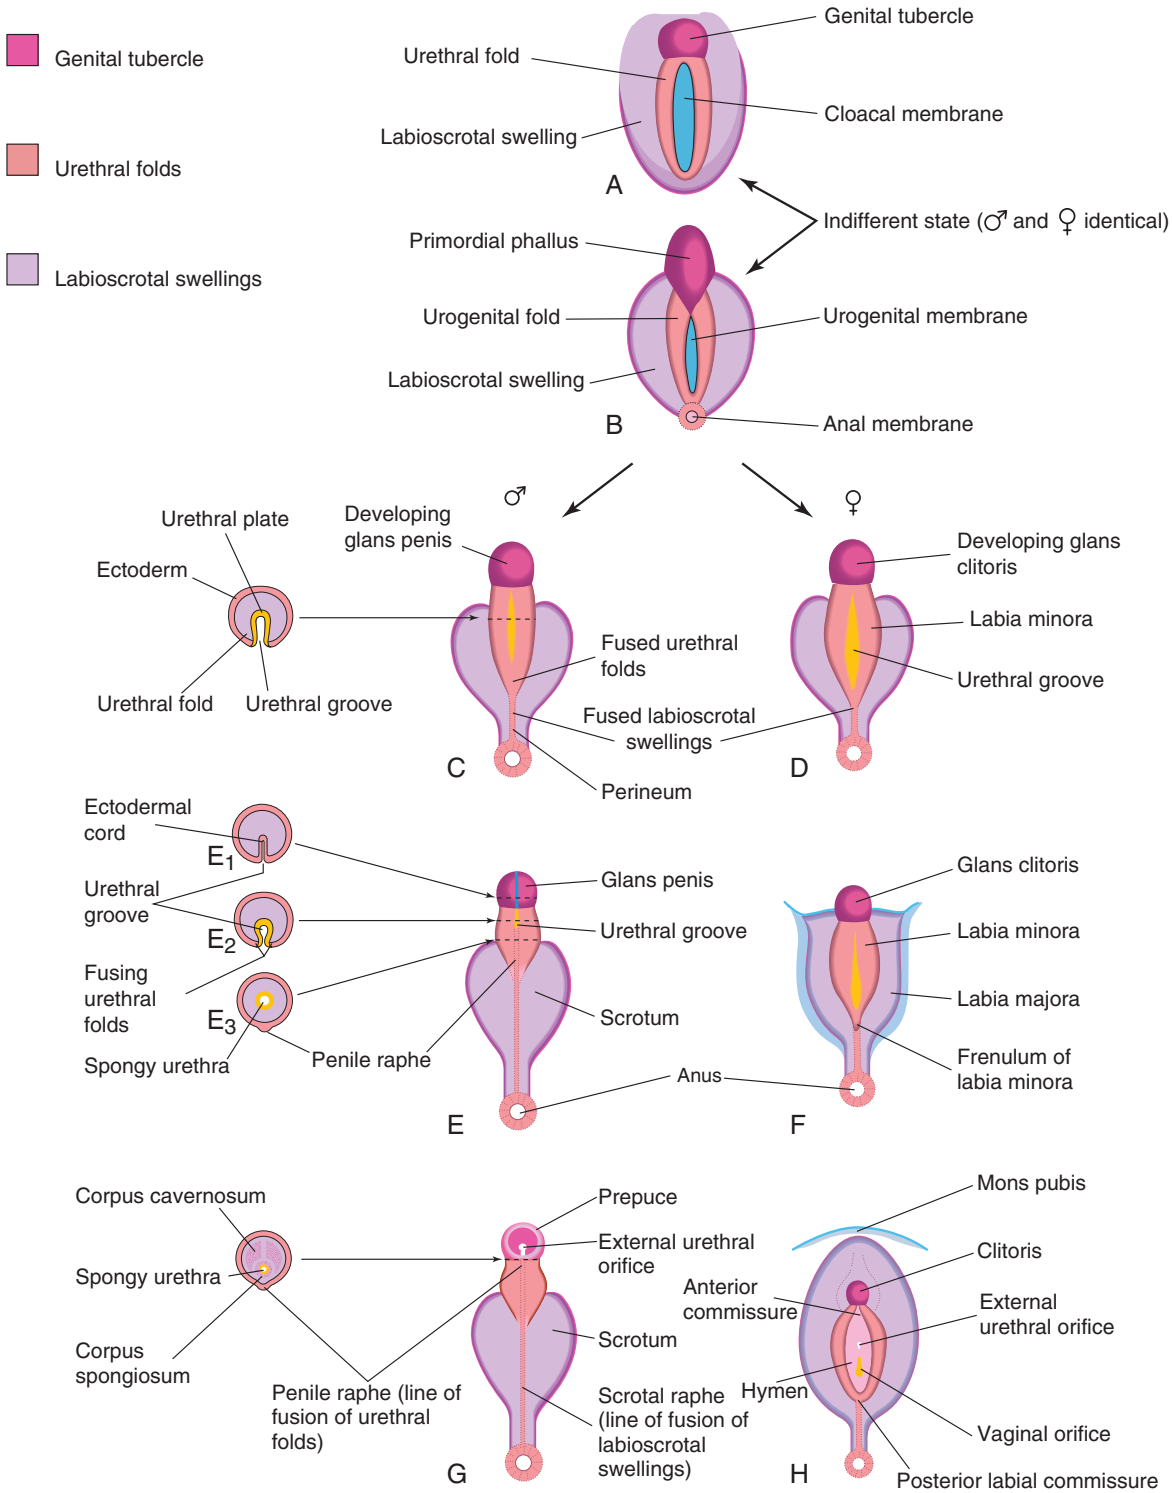
TABLE 89.2 Descriptive Features of Testicular and Ovarian Differentiation at 7 Weeks of Gestation

Gonadal Cells	Testicular Differentiation	Ovarian Differentiation
Cord somatic cells	Differentiate as Sertoli cells Synthesize anti-Müllerian hormone (AMH) at 7½ weeks Unable to aromatize androgens to estrogens	Differentiate as granulosa cells Do not synthesize AMH at this age Able to aromatize androgens to estrogens
Germ cells	Reduced mitotic activity results in small number of spermatogonia Meiosis is inhibited until puberty	High mitotic activity results in large number of oogonia Meiosis is promoted within several weeks
Interstitial cells	Differentiate as Leydig cells Synthesize testosterone de novo at 8 weeks	Remain undifferentiated until 15 weeks Lack steroidogenic capability at this age
Outer cortex	Sex cords lose connection with surface epithelium Mesenchymal tissue forms tunica albuginea that lacks germ cells	Sex cords retain connection with surface epithelium Thickened zone that contains germ cells

a guide to the caudal progression of the Müllerian ducts. In the absence of the wolffian ducts, the Müllerian ducts do not develop.

In the male fetus, the Müllerian ducts begin to regress at 7-7.5 weeks, shortly after the Sertoli cells have differentiated and begun to produce anti-Müllerian hormone (AMH), also known as *Müllerian-inhibiting substance* (MIS). This occurs before the onset of local testosterone production by Leydig cells and regression is complete by 9 weeks. Differentiation of the wolffian ducts into the male internal genitalia is testosterone dependent and begins at about 8.5 weeks. The wolffian ducts differentiate into the epididymis and vas deferens, and beginning at 10.5 weeks, the seminal vesicles and their ejaculatory ducts develop at the caudal end from lateral outpouchings (Fig. 89.3).

In the female fetus, Müllerian duct differentiation occurs in the absence of AMH and does not require the presence of any ovarian hormone. Beginning in the 3rd month, the Müllerian ducts form the fallopian tubes, uterus, and upper portion of the vagina, stimulated in part by epidermal growth factor. The wolffian ducts degenerate in the absence of local testosterone and disappear by 13 weeks (see Fig. 89.3). The fallopian tubes later descend with the ovaries and are included in a fold of peritoneum called the *broad ligament*. At birth and until puberty, the position of the uterus is vertical, and uterine development is disproportionate with the cervix being twice as large as the fundus. Maternal estrogens stimulate uterine growth in utero and, consequently, its size at birth is larger than at several months of age. Endometrial hyperplasia may occasionally result in transient neonatal uterine bleeding. The development of the vagina depends on the caudal Müllerian ducts contacting the endodermal epithelium of the urogenital sinus. At this junction, a multilayered, solid epithelial cord known as the *vaginal plate* is formed and it disintegrates beyond 4 months to form the vaginal lumen. It is not clear whether the lower portion of the vagina is derived from the urogenital sinus, with the upper portion of Müllerian origin, or if the vagina originates entirely from the urogenital sinus.



• **Fig. 89.3** Embryonic differentiation of female and male genital ducts from wolffian and Müllerian primordial tissue before descent of the testes into the scrotum. In females, Müllerian structures persist to form the fallopian tubes, uterus, and upper portion of the vagina. The lower portion of the vagina and urethra are derived from the urogenital sinus. In males, wolffian structures develop into the epididymides, vasa deferentia, and seminal vesicles, whereas the prostate and prostatic urethra are derived from the urogenital sinus. In some cases, a small Müllerian remnant can persist in males as a testicular appendage. (From Kronenberg H, et al. *Williams' textbook of endocrinology.* Philadelphia: Saunders; 2011.)

Development of the External Genitalia

The external genitalia in both sexes, like the gonads, are derived from common anlagen (Fig. 89.4). The inherent development is along female lines unless systemic androgens, specifically dihydrotestosterone (DHT), induce male

differentiation. The genital tubercle forms early in the 4th week at the cranial end of the cloacal membrane and, on each side, the labioscrotal swellings and urogenital folds develop. Fusion of the urorectal septum with the cloacal membrane in the 7th week creates a dorsal anal membrane and a ventral urogenital membrane, which rupture in the 8th week to form the anus and urogenital orifice. Abnormal development of the urorectal septum results in anorectal malformations.

In the male fetus, the indifferent stage of the external genitalia lasts until the 9th week when, in the presence of systemic androgens, masculinization begins with lengthening of the anogenital distance (see Fig. 89.4). Androgens also drive the urogenital and labioscrotal folds to fuse in the midline, beginning caudally and progressing anteriorly. The urethra develops with fusion of the urogenital folds, which form both the membranous urethra in the perineum and the penile urethra along the ventral surface of the phallus. Midline fusion of the labioscrotal folds forms the scrotal raphe, whereas the penile raphe represents the fused portions of the urogenital folds. These processes are complete by 14 weeks' gestation.

In the 9-week female fetus, without the presence of systemic androgens, the anogenital distance does not increase, and the urogenital folds and labioscrotal swellings do not fuse (see Fig. 89.4). The labioscrotal swellings develop predominantly in their caudal portions but less so than in male fetuses. They remain unfused as they are transformed into the labia majora. The unfused urogenital folds develop into the labia minora. The epithelium of the vaginal vestibule between the labia minora and the hymen is endodermal, derived from the urogenital sinus, whereas the epithelium between the labia minora and majora is ectodermal in origin.[73]

Hormonal Control of Fetal Sex Differentiation

The fetal testes play a major role in male sex differentiation by producing two hormones, AMH and testosterone, which are important determinants of internal and external genital differentiation. In contrast, the fetal ovaries play a negligible role or no role in female sex differentiation, although they may have some steroidogenic capacity.

Fetal Gonadal Endocrine Function

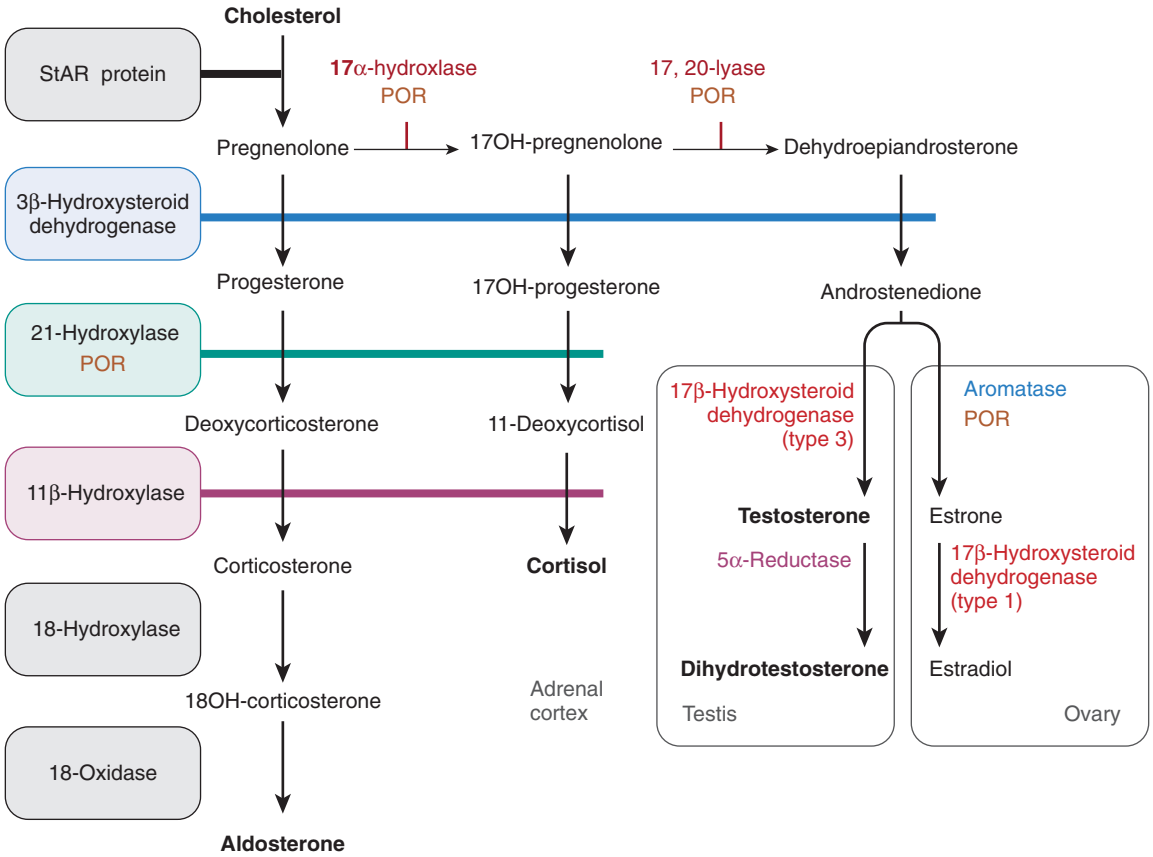
Anti-Müllerian hormone is a large glycoprotein. It is produced by the fetal Sertoli cells beginning at 7.5 weeks that induces irreversible involution of the Müllerian ducts. Regression of the Müllerian ducts can occur only during a fetal age of 8-9 weeks as, by 10 weeks' gestation, the Müllerian ducts become insensitive to AMH. The gene coding for AMH is located on chromosome 19p13.3 and for the AMH receptor on chromosome 12.[91]

The other major hormone produced by the fetal testis is testosterone (Fig. 89.5). It is synthesized by the Leydig cells beginning at 8 weeks, with peak testicular testosterone production occurring at 10-15 weeks. In the second half of gestation, serum testosterone levels decline in males and rise in females such that, by the third trimester, males have similar or only slightly higher levels than females.[95]

Between 8 and 14 weeks, the control of fetal testicular synthesis of testosterone is under the control of placental or fetal human chorionic gonadotropin (hCG). In the second and third trimesters, fetal serum luteinizing hormone (LH) stimulates testosterone synthesis and LH levels correlate with the maintenance and subsequent decline of serum testosterone.[9] Follicle-stimulating hormone (FSH) receptors are present in fetal testes from 8 weeks and FSH is involved in the proliferation of both Sertoli and germ cells during the second trimester. However, the degree to which FSH is required for these processes, independent of LH and testosterone, remains unclear.[81]

The fetal ovary in the first trimester is hormonally quiescent, lacking hCG and FSH binding sites as well as the enzymes necessary for steroid hormone synthesis. Starting at 8 weeks, the fetal ovary develops aromatase activity and is capable of converting androstenedione or testosterone to estrone or estradiol. However, actual steroidogenesis at this time has not been demonstrated. The majority of fetal estrogen is produced by placental aromatase. Amniotic fluid levels of estradiol at 12-16 weeks are slightly higher in females, raising the possibility of ovarian synthesis of estrogen.

Control of Genital Differentiation: Roles of Anti-Müllerian Hormone and Testosterone



In the absence of testes, female sex differentiation occurs regardless of whether a functional ovary is present or not. This activity is in keeping with the inherent tendency of the fetus to develop along female lines.

Normal male sex differentiation requires bilateral testes that produce AMH from the Sertoli cell and testosterone from the Leydig cells. Anti-Müllerian hormone acts locally to induce regression of the ipsilateral Müllerian duct. If only one testis is present, Müllerian duct structures persist on the contralateral side. Testosterone does not cause Müllerian duct regression. A 46,XX female with Müllerian duct regression resulting from a *WNT4* mutation suggests that proteins other than ß-catenin, are important mediators of Müllerian duct regression.[51]

Testosterone produced by the fetal testes is secreted both locally, where it stimulates differentiation of the ipsilateral wolffian duct, and systemically, where it serves as a prohormone in the masculinization of the external genitalia. If only one testis is present, the contralateral wolffian duct fails to differentiate, indicating that systemically circulating testosterone levels are insufficient for the development of wolffian duct structures.

Although the wolffian ducts are stabilized through the effects of testosterone, the external genitalia and urogenital sinus are stimulated to undergo male differentiation by dihydrotestosterone (DHT). This potent androgen is synthesized in peripheral tissues (external genitalia, liver, kidney, and bone marrow) through the action of 5α-reductase on testosterone. As testosterone is a weaker androgen than

• **Fig. 89.5** Diagrammatic representation of steroidogenesis pathway. POR, P450 oxoreductase; StAR, steroidogenic acute regulatory. (From Murphy C, et al. Ambiguous genitalia in the newborn: an overview and teaching tool. *J Pediatr Adolesc Gynecol.* 2011;24:236-250.)

DHT, it does not drive male external genital differentiation and serves instead as a prohormone for DHT in these tissues. Systemic testosterone derived from the fetal adrenals, as in CAH, or from maternal sources can induce variable masculinization of the external genitalia when it is metabolized to DHT.

Congenital absence of one testis (anorchia) is usually associated with incomplete masculinization of the external genitalia, suggesting that two testes are generally required to provide adequate systemic levels of testosterone substrate for conversion to DHT. The period in which DHT can induce male differentiation extends up to 12-14 weeks' gestation.

A Clinical Approach to the Infant With Suspected Disorder of Sex Development

The evaluation of the neonate with a suspected DSD requires prompt attention and a multidisciplinary team approach. Depending on the institution, the team may include neonatology, pediatric endocrinology, genetic counseling, pediatric urology, pediatric gynecology, pediatric surgery, psychology, psychiatry, nursing, and social work. Appropriate initial assessment and management of the newborn with a DSD is essential to helping the family cope with this difficult situation. This evaluation needs to begin as soon as possible and should be approached systematically.

Clinical Indications for Evaluation for a Possible Disorder of Sex Development

Most individuals with a DSD have some abnormality of their external genitalia that makes them identifiable at birth. An evaluation of a possible DSD should be considered for patients who have male-appearing external genitalia with defects, including isolated micropenis, severe hypospadias (perineal), bilateral cryptorchidism, or the presence of two defects such as hypospadias and unilateral cryptorchidism. In an infant with female-appearing external genitalia, the presence of posterior labial fusion, clitoromegaly, labial or inguinal mass that might represent a gonad, and difficulty in visualizing a separate vaginal introitus and urethra warrant evaluation for possible DSD, as does the finding of discordance of the prenatal karyotype with postnatal external genital phenotype.[3,58,59] Examples of conditions that can cause genital abnormalities are listed in Table 89.3.

Medical History

Most DSDs are isolated occurrences or inherited as autosomal recessive or X-linked traits. The family may not know

TABLE 89.3 Associations of Genital Abnormalities

Abnormal Characteristics	Examples of Associated Disorders
Male-Appearing Genitalia	
Micropenis	Growth hormone or luteinizing hormone deficiency Testosterone deficiency (in second and third trimesters) Partial androgen insensitivity Syndrome: idiopathic
Hypospadias (more severe)	Disorders of gonadal development 46,XX DSD Ovotesticular DSD 46,XX or 46,XX DSD Syndrome: idiopathic
Impalpable gonads	Anorchia Persistent Müllerian duct syndrome 46,XX DSD with 21- or 11β-hydroxylase deficiency Cryptorchidism
Small gonads	47,XXY, 46,XX DSD Dysgenetic or rudimentary testes
Inguinal mass (uterus or tube)	Persistent Müllerian duct syndrome, dysgenetic testes
Female-Appearing Genitalia	
Clitoromegaly	XX with 21- or 11β-hydroxylase or 3β-hydroxy dehydrogenase deficiency Other 46,XX DSD Gonadal dysgenesis, dysgenetic testes, ovotesticular DSD 46,XY DSD Tumor infiltration of clitoris Syndrome: idiopathic
Posterior labial fusion	As for clitoromegaly
Palpable gonad(s)	Gonadal dysgenesis, dysgenetic testes, ovotesticular DSD 46,XY DSD
Inguinal hernia or mass	As for palpable gonad(s)

the specifics about other family members with DSDs but may be aware of a family history of a trait that could be a manifestation of a DSD such as infertility, amenorrhea, or hypospadias or infants with unexplained deaths in the family. History of parental consanguinity, maternal intake of drugs during pregnancy (such as androgen or progestins), use of assisted reproductive technologies, and the results of prenatal tests should be explored. A history of maternal virilization during pregnancy, especially if assessing a virilized female infant, raises the possibility of aromatase deficiency or maternal androgen-secreting tumors such as luteoma.[106]

• BOX 89.1 Findings That Constitute a Normal Genital Examination in the Newborn

Female Newborn

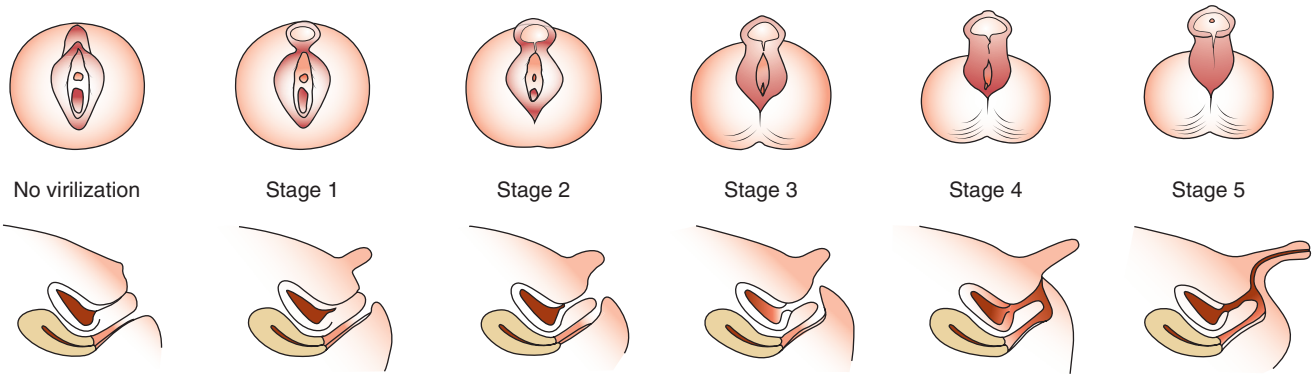
- Vaginal opening fully visible: 3- to 4-mm slit or stellate orifice with heaped-up mucosa (i.e., no posterior labial fusion)
- Clitoris width 2-6 mm
- Absence of gonads in labia majora or inguinal region

Male Newborn

- Urethra at tip of glans (which may be inferred by a fully developed foreskin)
- Penis of normal stretched length (2.5-5 cm) and diameter (0.9-1.3 cm)
- Bilateral testes of normal size (8-14 mm) in the scrotal sacs

Physical Examination

Considerable information can be obtained by performing a careful physical examination. The findings of a normal newborn external genital examination are listed in Box 89.1. The clinical findings do not need to be overtly ambiguous to qualify for a diagnostic evaluation for DSDs. Inferences can be made regarding gonadal development and status and the degree of androgen effects. When evaluating a newborn for possible DSD, the clinical features of the external genitalia that require examination include evidence for any asymmetry; presence of palpable gonads in the labioscrotal folds or inguinal canals; pigmentation and extent of labioscrotal fold fusion and rugosity; phallus length, breadth, and amount of erectile tissue; number of orifices in the perineum and their topography; and the position and patency of the anus (Table 89.4). A useful tool to describe and grade the extent of female genitalia virilization is the Prader scale (Stage I-V) (Fig. 89.6), whereas calculating the external masculinization score (EMS: scale 0-12) provides an objective aggregate score to describe the extent of masculinization of genitalia in boys (Fig. 89.7).[3]



Delivery Room or Nursery Examination of All Newborns

Every newborn must have a careful genital examination in the delivery room or nursery. The purposes of the examination are to verify the gender assignment; to avoid missing the diagnosis of a DSD, particularly in females with CAH; and to recognize mild abnormalities that are not likely to affect gender assignment but that require follow-up, such as mild hypospadias or unilateral cryptorchidism. Neonates with overtly ambiguous genitalia should have gender assignment deferred.

Gonadal Descent and Size

Gonads should be carefully palpated in the scrotum or labial area and along the inguinal canal. Only a gonad containing testicular tissue (testis or ovotestis) can descend to a position where it is palpable (an ovary almost never descends). A small gonad (longest diameter <8 mm) may be dysgenetic,

• **Fig. 89.6** Prader scale reflecting the degree of virilization of the external genitalia. The internal genitalia reflect the changes in the urogenital sinus that may be seen with a 46,XX DSD such as congenital adrenal hyperplasia. (From Allen L. Disorders of sexual development. *Obstet Gynecol Clin North Am.* 2009;36:25-45.)

TABLE 89.4 Initial Assessment of Disorder of Sex Development in the Newborn

History

Maternal History

Virilization during pregnancy, antenatal exposure to drugs (progestins and steroids), assisted reproductive technologies

Perinatal History

Prematurity, intrauterine growth restriction, results of prenatal investigations

Family History

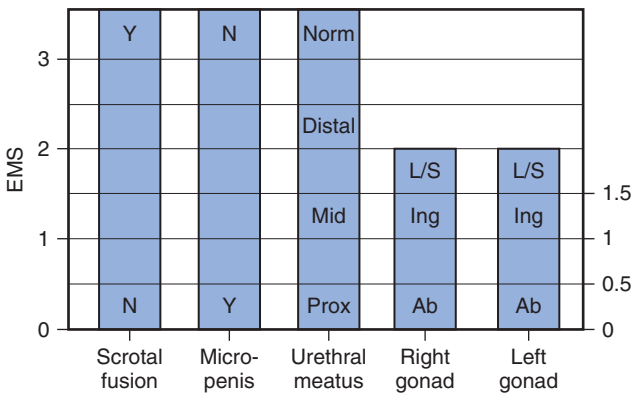
Parental consanguinity, unexplained infant death, infertility, amenorrhea, gonadal or urogenital malformation

Physical Examination

General

Signs of dysmorphic features, hyperpigmentation, associated anomalies including skeletal malformations

External Genitalia



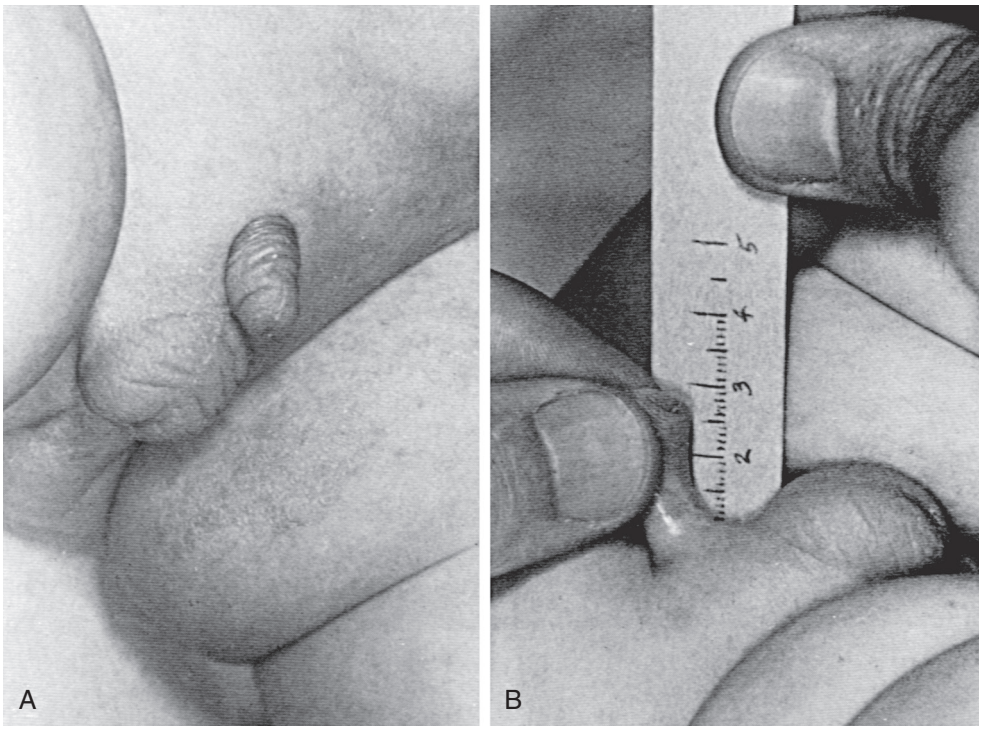
Symmetry of virilization
Gonads: location and size
Phallic structure: stretched length, breadth, and amount of erectile (corpora) tissue
Labioscrotal folds: degree of fusion, rugation, and pigmentation
Perineal orifices: number and topography
Anus: patency and anogenital distance

Prader Classification

Commonly used to stage virilization of female external genitalia (see Fig. 89.6)

External Masculinization Score

Helpful tool to grade male masculinization (see Fig. 89.7)



• **Fig. 89.7** External masculinization score (EMS) provides an objective aggregate score of extent of masculinization of external genitalia. Each individual feature of genitalia (phallus size, labioscrotal fusion, site of the gonads, and location of urethral meatus) is individually scored to provide a score out of 12. *Micropenis* refers to a phallus below the male reference range. Ab, Abdominal or absent on examination; Ing, inguinal; L/S, labioscrotal; Prox, proximal. (From Ahmed SF, et al. UK guidance on the initial evaluation of an infant or an adolescent with a suspected disorder of sex development. *Clin Endocrinol.* 2011;75:12-26.)

rudimentary, or result from lack of gonadotropin stimulation. The ability to detect gonads in the inguinal area can be enhanced by applying soap or oil to the skin and the examiner's fingers to decrease friction. With the infant supine, glide two or three fingers with gentle to firm pressure along the inguinal canal toward the scrotum, repeating this action numerous times if necessary. The gonad will be felt "popping" under the fingers. With this technique, less accessible or small gonads can be palpated that would otherwise be missed. Additionally, sit the infant in a frog-leg position and, particularly with crying or increased intra-abdominal pressure, the testis may descend into the lower inguinal or scrotal region.

Penis Size

It is important to assess both the length and the amount of erectile tissue of the penis. A penis that appears small must

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

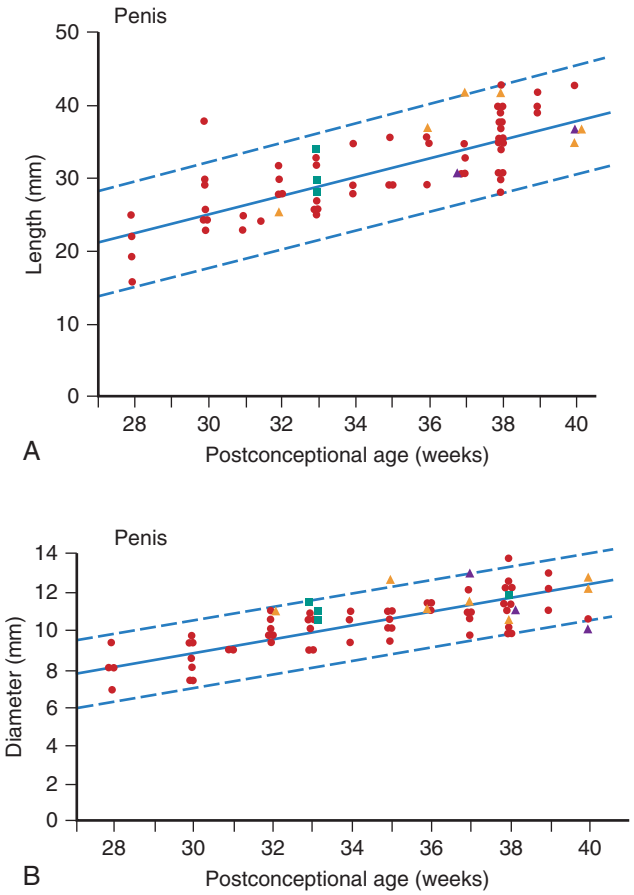
• **Fig. 89.8 A,** A 2-month-old boy with micropenis and cryptorchidism caused by luteinizing hormone and follicle-stimulating hormone deficiency. The scrotum is compact or "unlived in," and the testes are inguinal. **B,** Centimeter markings are inked on a wooden tongue blade, which is placed near the penis and depressed down on the pubic ramus. The penis is maximally stretched, with the measurement made to the tip of the glans (measurement here is 1.7 cm).

be measured fully stretched, pressing the ruler down against the pubic ramus, depressing the suprapubic fat pad completely, and measuring to the tip of the glans only, ignoring any excess foreskin (Fig. 89.8). An excellent ruler can be made by placing marks 0.5 cm apart on a wooden stick such as a tongue blade or a flexible strip. The width is measured at the midshaft of the stretched penis. A micropenis is arbitrarily defined as a penis with a normally formed urethra that opens at the tip of the glans in which the stretched length is less than 2.5 cm in the full-term neonate. The length criteria must be adjusted to take into account the smaller phallus in the premature neonate (Fig. 89.9).[33] The definition of a micropenis can also be used to describe a rare condition in which the penile corpora cavernosa are absent or severely deficient in size, resulting in an abnormally thin penis (Table 89.5).[58]

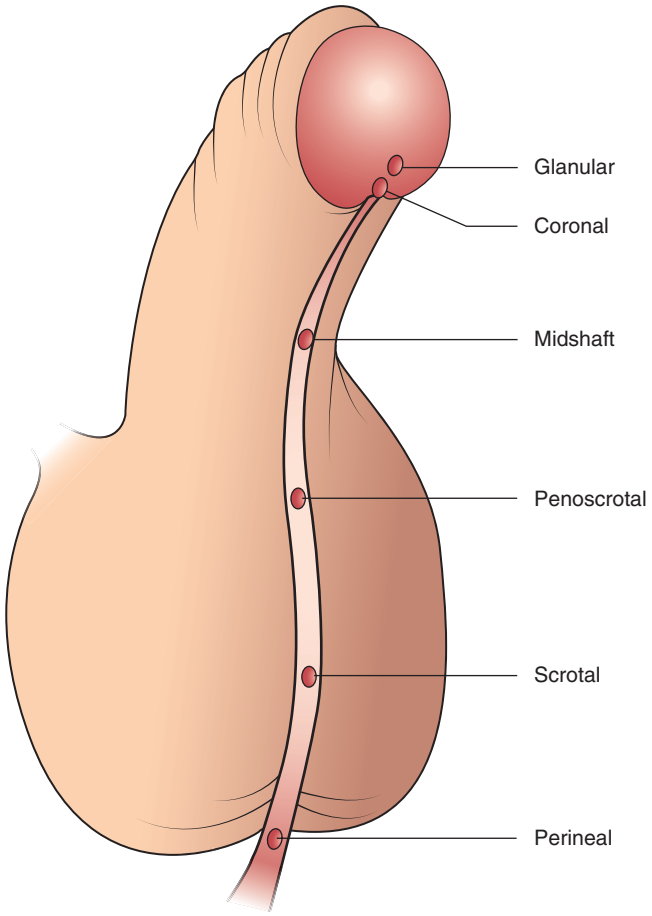
Clitoris Size

A clitoris that appears enlarged is best assessed by measurement of the width (diameter) of the paired corpora cavernosa that compose the erectile shaft of the clitoris. With clitoral enlargement caused by edema or birth trauma, a normal corporal width (<6 mm) is present, whereas clitoral enlargement caused by androgen stimulation (occurring in the second and third trimesters) results in increased corporal growth (>6 mm). The width of the clitoris is measured by gently but firmly pressing the shaft of the clitoris between the thumb and forefinger to exclude excess skin and subcutaneous tissue, thereby measuring predominantly the width of the corpora cavernosa.[78]



Urethral Opening

If the foreskin is fully formed, the urethra is almost always at the tip of the glans; on rare occasions, the foreskin covers hypospadias on the glans. Hypospadias can vary from mild (off the center of the glans) to severe (at the base of the penis or on the perineum) (Fig. 89.10). The prepuce in the hypospadiac penis is usually deficient ventrally and thus appears hooded. Chordee (ventral curvature of the penis) is caused by fibrotic contracture in the area of failed urethral development. The presence of severe hypospadias in a male infant indicates deficient testosterone or DHT action in the first trimester. In girls, the urethral meatus is normally a 1-mm pinhole-like or flat opening located just ventral to the vagina. Androgen exposure at 8-14 weeks of fetal age moves the urethral meatus ventrally on the perineum or the shaft of the phallic structure.



Vaginal Opening

The vaginal orifice, a 3- to 4-mm slit or stellate opening surrounded by heaped-up mucosa, is normally visible when the examiner lifts up the labia majora. The presence and direct visualization of the vaginal opening indicate the absence of androgen effects and the presence of a distal vagina (of urogenital sinus origin); whether a uterus (of Müllerian duct origin) is also present cannot be inferred from this finding. Conversely, at 8-14 weeks of fetal age, exposure of the female fetus to androgens or incomplete androgen stimulation of the male fetus results in variable masculinization. This process can be mild to moderate, with

• **Fig. 89.9** Stretched penile length (mean ± 2 SD) (**A**) and penile diameter (mean ± 2 SD) (**B**) in 63 normal premature and full-term male infants (●), two infants who were small for gestational age (▲), seven infants who were large for gestational age (▲), and four twins (■). (From Feldman KW, et al. Fetal phallic growth and penile standards for newborn male infants. *J Pediatr.* 1975;86:395.)

• **Fig. 89.10** Hypospadias classification based on the location of the abnormal urethral meatus. Proximal (glandular and subcoronal), middle (distal penile, midshaft, and proximal penile), and distal (penoscrotal, scrotal, and perineal) hypospadias. (From Barcat J. Current concepts of treatment. In: Horton CE, ed. *Plastic and reconstructive surgery of the genital area.* Boston: Little, Brown; 1973:249-262.)

posterior midline fusion of the labia majora that partially or completely covers the vaginal opening, thereby preventing its direct visualization. With more severe masculinization, there is formation of a common urogenital sinus (resulting from the internal junction of the vagina and urethra) that is seen as a single 1- to 2-mm flat orifice on the perineum or shaft of the phallus.

Labioscrotal Development

The labia majora are normally unfused in the female. Partial or complete midline fusion indicates androgen exposure at 8-14 weeks of fetal age and predicts ventral placement of the urethral meatus on the perineum or phallus. The scrotum in the male is normally completely fused, with a midline raphe. A compact or "unlived-in" scrotum indicates the lack of testes or undescended testes. In the male, incomplete or absent midline fusion indicates deficient or absent androgen effects at 8-14 weeks of fetal age and predicts a perineal location of the urethral meatus.

Associated Dysmorphology

A thorough physical examination should be done to identify any other dysmorphic features. Genital abnormalities are often part of dysmorphic syndromes and are frequently associated with midline defects.[45] Examples include the presence of the Turner phenotype in gonadal dysgenesis and campomelic dwarfism (bowing and angulation of the lower limbs, flat facies, shortened vertebrae) in XY gonadal dysgenesis. Some DSD patients appear phenotypically normal at birth, including many (but not all) cases of gonadal dysgenesis, XX male, 46,XY male with persistent Müllerian ducts, and complete androgen insensitivity syndrome (cAIS).

Discussion With Family and Professional Staff

It is important to recognize that the birth of an infant with a DSD is a major stress for the family. A physician

experienced in the evaluation of DSD should meet with the family as soon as possible to discuss the situation, ensuring confidentiality and privacy. Both parents should be present if possible. As part of the discussion, the infant's genitalia should be examined with the parents. Parents are frequently afraid to look at their child's genitalia. Showing the anatomic abnormalities to the family in a calm and professional manner helps the family bond with their child. Outline what will happen (procedures, consultations) and the time frame in which the results will be available. Review with the parents what they plan to tell relatives and friends, which is often a source of great anxiety. Many families and cultures have strong feelings about gender assignment, and these feelings must be known by the health professionals. Reassure the family that when the data from the tests are available, there will be much more information that will help determine the appropriate gender assignment. In most cases, the correct gender assignment will be apparent when the test results become available; in some cases, the gender assignment is not clear, and the options will need to be discussed with the parents.

Following are examples of scripts for answering questions commonly asked by families with children with a new diagnosis of a DSD. These are taken largely from the *Clinical Guideline for the Management of DSD in Childhood*, published by the Consortium on the Management of Disorders of Sex Development.[46]

Q: Is my child a boy or a girl?

A: Your question is very important. We wish we could tell you right this minute, but we really can't tell yet. We will have more information after we conduct some tests. It's hard for parents to wait for these test results, so we will try to update you every day, and you can call (give contact person's name). Although your baby has a condition you probably haven't heard much about, it isn't that uncommon. We've encountered this before, and we'll help you through this time of confusion. As soon as the tests are completed, we will be able to talk with you about the gender in which it makes most sense to raise your child, and we'll give you a lot more information, too, because quite a lot is known about these variations, and we are learning more each day. We want to reassure you that our focus is on supporting you and your child in this time of uncertainty.

Q: What do we tell our friends and family while we wait for the gender assignment?

The following script may be most appropriate for talking to close family and friends. When discussing the situation with others, you may feel more comfortable just letting them know that the baby is in the hospital for tests.

A: This is important. We strongly recommend being open and honest with your friends and family about your child's situation. Even if you don't intend to, lying or withholding information will create a sense of shame and secrecy. Although it can be awkward to talk with family and friends about a

child's sex development, being honest signals that you are not ashamed—because you have nothing to be ashamed of—and it also allows others to provide you with the love and support you may need. Isolating yourself at this time will probably make you feel unnecessarily stressed and lonely. Talking about it will help you feel connected with others. So here is what you can tell people: Our baby was born with a kind of variation that happens more often than you hear about. Our doctors are doing a series of tests to figure out whether our baby is probably going to feel more like a boy or a girl. We expect to have more information from them within (specify realistic time frame), and then we'll send out a birth announcement with the gender and the name we've chosen. Of course, as is true with any child, the various tests the doctors are doing are not going to tell us for sure who our baby will turn out to be. We're going to go on that journey together. We appreciate your love and support, and we're looking forward to introducing you to our little one in person soon.

It also helps to let your friends and family know whether your baby is healthy or whether there are some health concerns. Finally, take some pictures of your baby's face, and share those pictures with others!

Because of the stress produced by having a child with DSD, support from a behavioral scientist (social worker, psychologist, or psychiatrist) may be helpful for the family. It may be helpful for families to be informed about relevant credible resources listed at the end of this section.[105]

In addition to discussions with the family, it is important to keep the hospital staff who have contact with the family fully informed about the information that has been given to the parents. This professional candor reduces the possibility of insensitive comments made by hospital personnel to family members and is especially important in cases in which gender assignment must be delayed.

Initial Diagnostic Evaluation

In cases in which gender assignment is pending, all relevant tests should be obtained as soon as possible. A summary of the initial workup for DSD evaluation in newborns is shown in Box 89.2.

Chromosomes

Fluorescence in situ hybridization (FISH) or QF-PCR for X and Y markers may be available within 24-48 hours. Results reveal the number of X and Y chromosomes present. Most cytogenetic laboratories can provide a peripheral blood karyotype result within 2 or 3 days for cases of DSD. In cases in which the gender assignment is not clear, the laboratory should be personally contacted and asked to expedite the chromosome result.

Biochemistry

Interpretation of biochemistry tests is dependent on the timing of the sample and understanding of the normal levels of hormones at that time. A blood sample should be obtained after 24-48 hours of life, after the time of the neonatal surge of androgens, for measurement of testosterone and 17-hydroxyprogesterone (17-OHP). It is desirable to draw extra blood so that the laboratory can save the serum for analysis of other hormones that may be indicated as the evaluation continues. Increased serum levels of testosterone occur physiologically in neonates with functioning testes at 12-36 hours and at 2 weeks to 4-6 months of age.[110] The level may also increase pathologically at any time from the adrenal secretion of androgens in cases of CAH. Decreased levels of testosterone occur if Leydig cells are deficient or absent, LH activity is impaired, or there is a testosterone biosynthetic defect. Blood samples are also diagnostically useful at 1 or 2 months of age to assess the peak of hypothalamic-pituitary-testicular axis function in infancy.

An increased level of 17-OHP suggests 21- or 11β-hydroxylase deficiency and implies that any increased levels of testosterone were of adrenal rather than testicular origin in a 46,XX patient. The 17-OHP levels in premature infants are higher than those in full-term infants.[57] In CAH with 21-hydroxylase deficiency, the levels of 17-OHP are often 10-50 times the upper limit of the normal level, making the test virtually diagnostic.

The measurement of serum AMH has been shown to correlate with Sertoli cell function.[12] Similarly, inhibin B

• BOX 89.2 Initial Diagnostic Evaluation of Disorder of Sex Development in the Newborn

First-Tier Tests

- Chromosomes
- Karyotype and FISH or QF-PCR for X and Y chromosomes
- Additional blood work based on the presence or absence of palpable gonads
  If gonads palpable:
  - Testosterone, androstenedione, and dihydrotestosterone (DHT)
  - Luteinizing hormone and follicle-stimulating hormone
  If no gonads palpable:
  - 17OH-progesterone, testosterone, and androstenedione
- Renin and serum electrolytes (to be measured after 48 hours of life)
- Imaging
- Ultrasound: adrenal, kidneys, pelvis, inguinal regions, and labioscrotal folds
- Genitogram

Second-Tier Tests

- DHEA, 11-deoxycorticosterone, progesterone, 17OH-pregnenolone, anti-Müllerian hormone
- Stimulation tests: hCG (human chorionic gonadotropin) and ACTH (adrenocorticotropic hormone) tests
- Molecular androgen receptor studies
- Specific molecular testing for genetic disorders
- Microarray
- Whole exome sequencing
- Cystoscopy, vaginoscopy
- Laparoscopy/gonadal biopsy

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

levels have been shown to rise in males in the first week of life. Its measurement is, therefore, useful for identifying the presence of Sertoli cells and of functional testes in newborn boys with nonpalpable gonads.[12] Other tests that may be useful, depending on the clinical presentation, are measurements of LH, FSH, estradiol, precursors of testosterone, and DHT.

Ultrasonography

Ultrasound examination can usually determine the presence or absence of the uterus. If no uterus is seen, it suggests that there is testicular tissue producing AMH. If a uterus is present, it suggests bilateral ovaries, dysgenetic gonads that failed to produce AMH, or an AMH receptor defect. Intrapelvic gonads can sometimes be located. Fetal ultrasonography can identify abnormal genitalia in utero.[82] Adrenal ultrasonography has a sensitivity of 92% and a specificity of 100% for diagnosing CAH when read by an experienced pediatric radiologist.[4] Ovaries may be difficult to identify on ultrasound.

Genitography

Genitography is used to determine the presence or absence of a urogenital sinus and the anatomy of the urethra and vagina. Visualization of the cervix confirms the presence of Müllerian duct structures. If radiographs show filling of a fallopian tube, the gonad on that side has failed to produce AMH. Endoscopy may be needed to direct where the radiopaque contrast material is to be injected; otherwise, small vaginal openings into the urethra may be missed.

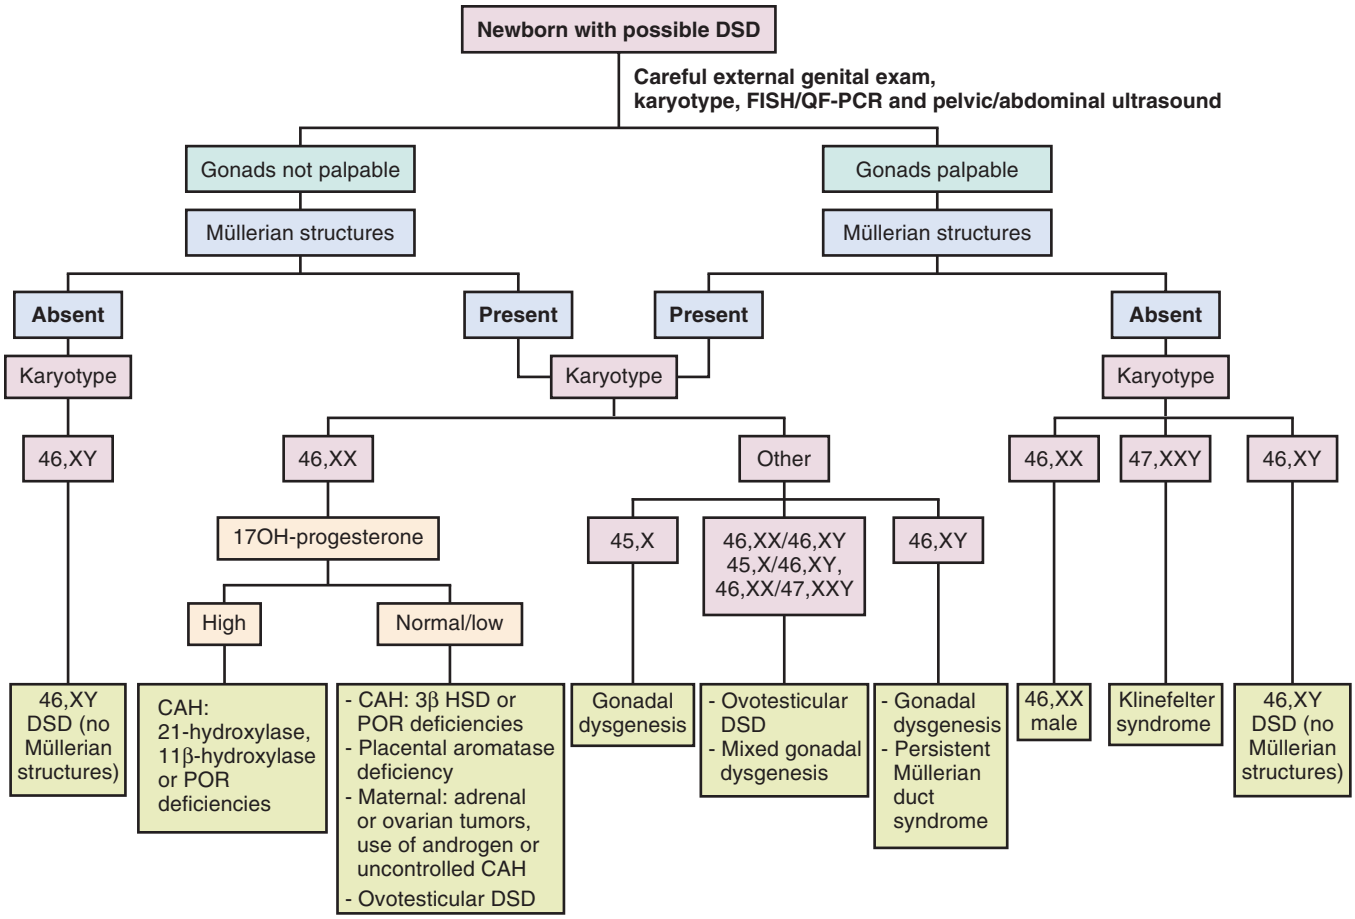
Human Chorionic Gonadotropin Stimulation Test

A short hCG stimulation test can be used to determine whether functioning Leydig cells are present and to detect disorders of androgen biosynthesis. One example of a protocol for doing the test is as follows: for full-term infants, 1000 units of hCG is given intramuscularly every day for three injections.[3] The testosterone level is measured on the day after the last injection and compared with the baseline value. There are a number of protocols but no consensus about the best way to do the test. Normal or low levels of testosterone in response to hCG should be interpreted in relation to LH, FSH, and AMH values.[3] A significant rise in testosterone concentration confirms the presence of Leydig cells and, by implication, testicular tissue.

Refining the Diagnosis

After the chromosome results are available, the initial diagnosis can be confirmed or refined. An approach that can be used to arrive at a final (differential) diagnosis is shown in Figs. 89.11 and 89.12. The use of microarray and next-generation sequencing are increasing, improving diagnostic accuracy.[2] Details of the specific diagnoses are discussed later.

Gender Assignment in Newborns



The decision about gender assignment is complex and stressful. It should, therefore, be made expeditiously by a thorough assessment of a multidisciplinary team, including the family and health care staff representing medical genetics; gynecology; pediatric urology; endocrinology; nursing; and psychiatry, psychology, or social work.[84] Guiding factors include the diagnosis, appearance of the genitals, internal genital and gonadal development, surgical options, need for lifelong sex-hormone replacement therapy, potential for fertility, and the views of the family and their cultural practices.[59] In addition, the prospect for a gender identity congruent with sex of rearing and good sexual function are very important.

In general, most patients with disorders of sex development identify with their gender of rearing as adults, but there are higher rates of gender dysphoria than in the general population.[20] Most 46,XX patients with CAH identify as females regardless of degree of genital virilization.[11] Sex of rearing decisions are difficult in patients with 5α-reductase deficiency and 17β-hydroxysteroid dehydrogenase deficiency, as up to 60% of those assigned female in infancy without gonadectomy, and all those assigned male, identify as males.[68] For individuals with cAIS assigned female in infancy, the vast majority continue to live as female.[27] Among both males and females with partial AIS (pAIS) and partial gonadal dysgenesis, about 75% were satisfied with their initial sex assignment.[111] In the case of infants with markedly ambiguous genitalia, including a micropenis and perineoscrotal hypospadias, the decision about sex of rearing should be made after thorough discussion of the results of all investigations, diagnosis, etiology, prognosis, and surgical options.[59] The gender assignment in XY infants with small phalluses remains controversial, but these infants are increasingly being assigned male gender because of lack of need for medical or surgical intervention and potential for fertility.[52,59] The availability of intracytoplasmic sperm injection has also created the possibility of fertility for males with a very low sperm count. If the phallus is small and associated with hypospadias, partial androgen resistance is a possible diagnosis. Androgen sensitivity can be assessed by the response of the penis to an intramuscular injection of testosterone. If the response is poor, the choice of gender assignment becomes very difficult and must be approached on a case-by-case basis, with extensive discussion with the family.

Nomenclature of Disorders of Sex Development

An improved understanding of the molecular and genetic causes of DSDs and increased awareness about patient sensitivity led to the development of an updated nomenclature for this group of disorders (Table 89.6).[58]

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

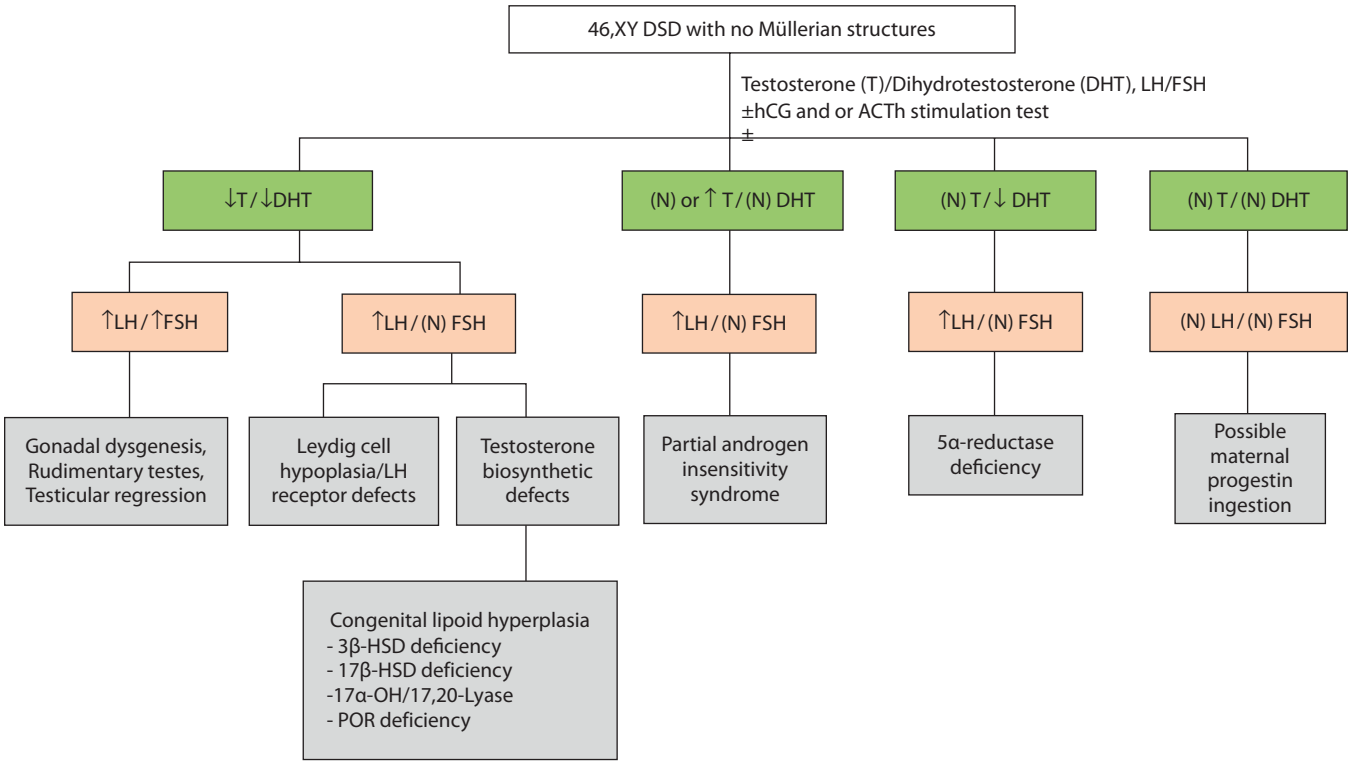
• **Fig. 89.11** General diagnostic algorithm for disorders of sex development (DSD). Differential diagnosis is based on the presence or absence of palpable gonads, Müllerian structures, karyotype, and serum 17-OH progesterone level. CAD, Congenital adrenal hyperplasia; HSD, hydroxysteroid dehydrogenase; POR, P450 oxidoreductase.

Disorders of Sex Development

Sex Chromosome Disorder of Sex Development

Abnormality in number or parts of sex chromosomes leads to failure of testes or ovaries to undergo normal development. This group can be classified into four main categories, including 45,X (Turner syndrome and variants); 47,XXY (Klinefelter syndrome and variants); 45,X/46,XY (mixed gonadal dysgenesis); and 46,XX/46,XY (chimerism).



45,X (Turner Syndrome and Variants)

Loss of the second X chromosome results in a syndrome consisting of a phenotypic female with bilateral streak gonads and accompanying somatic abnormalities. Variant forms include partial deletions of the second X chromosome, such as deletion of the short arm of the X chromosome (XXp−) or the long arm of the X chromosome (XXq−) or various forms of X chromosome mosaicism (e.g., 45,X/46,XX).

In fetuses with 45,X gonadal dysgenesis, normal ovarian differentiation occurs at up to 13-15 weeks of gestation, followed by rapid degeneration of the primordial ovarian follicles. In affected neonates and infants, the late stages of this process are usually evident, with scattered primordial ovarian follicles in varying states of degeneration. The final result is the streak gonad, a whitish streak consisting of whorls of connective tissue, suggestive of ovarian stroma, that contain no germinal elements or endocrine or other epithelial elements.

Affected patients have normal Müllerian duct development, an absence of wolffian ducts, and phenotypically female external genitalia. Because the genitalia are normal, the identification of neonates is limited to those who have the accompanying Turner somatic abnormalities, as listed in Box 89.3. The cardiovascular and lymphatic abnormalities, particularly lymphedema of the dorsa of the feet or hands, are diagnostically the most useful and may be pathogenetically related. In the 45,X fetus, impaired drainage of the lymph channels leads to stasis of lymph fluid, with distention of lymphatics, peripheral lymphedema. Large

• **Fig. 89.12** Clinical diagnostic algorithm for disorders of sex development (DSD) in 46,XY infant with absent Müllerian structures. The differential diagnosis is based on the results of testosterone, dihydrotestosterone (DHT), LH, and FSH. Further diagnostic investigations are then based on the most probable diagnosis.

• BOX 89.3 Features of Turner Phenotype in the Neonate

- Intrauterine growth restriction
- Head and facies: low-set ears, low nuchal hairline, asynchronous growth of scalp hair, epicanthus, folds below lower lids, micrognathia, high palate
- Lymphatic: lymphedema of dorsa of hands and feet, hypoplasia of nails, loose neck folds (cutis laxa) or cystic hygroma, ascites, pleural or pericardial effusion, gross edema
- Cardiovascular: coarctation of aorta, bicuspid aorta, aortic stenosis, hypoplastic left heart, partial anomalous pulmonary venous drainage, ventricular septal defect, patent ductus arteriosus, and secundum atrial septal defect
- Urinary tract: rotated or horseshoe kidneys, renal hypoplasia, duplications
- Skeletal: short fourth metacarpals, shield chest

Modified from Gordon RR, et al. Turner's infantile phenotype. *Br Med J*. 1969;1:483.

nuchal cystic hygromas and generalized edema occur frequently in utero. Distention of the cardiac lymphatics is hypothesized to compress the ascending aorta, altering flow in the left atrioventricular canal and affecting pulmonary venous return and consequently resulting in cardiovascular malformations. A strong association is observed between the presence of a webbed neck and the occurrence of aortic coarctation, partial anomalous pulmonary venous drainage, a hypoplastic left heart, and secundum atrial septal defect.

The mean maternal and paternal ages are not raised, so nondisjunction is not thought to be important; a postfertilization abnormality is thought to be the most likely etiology. The single X is of maternal origin in about 75% of cases.[43] The clinical features of Turner syndrome seem to be related to the haploinsufficiency of the short stature homeobox-containing gene (*SHOX*) and to the lymphogenic gene that causes lymphatic hypoplasia and, as a result, soft tissue and visceral anomalies.[79] The incidence of the 45,X karyotype in spontaneous abortuses is very high, generally estimated to be 6%-10%. However, the mean incidence of living 45,X newborns is only about 1 in 5000 female births, suggesting that more than 99% of 45,X fetuses abort. The reasons for this high mortality rate are unclear, but dysfunction of the 45,X placenta or fetal hypoalbuminemia, generalized edema, serous effusions, and cardiovascular abnormalities may play a role.

Individuals with X chromosome mosaicism or partial deletion of the second X chromosome tend to have fewer somatic and gonadal manifestations than those with the 45,X karyotype. In cases of mosaicism, the relative proportions of 46,XX to 45,X cells do not correlate well with the clinical phenotype.[61] Individuals having only a partial deletion of the X chromosome may also manifest a modified phenotype, depending on the part of the X chromosome that is deleted. Genes related to ovarian development

and Turner somatic abnormalities are located on both Xp and Xq. The combined incidence of 45,X, partial deletion, and mosaic Turner syndrome is about 1 in 2000 female newborns.[39]

About 40%-50% of patients with this diagnosis have a partial deletion or mosaicism of the X chromosome; at least 20 cells should be assessed for the possibility of mosaicism.[39] Those with XYp− gonadal dysgenesis and structural abnormalities of the Y chromosome may also have a Turner somatotype but carry a different prognosis. Y chromosome material is associated with about a 10% risk for gonadoblastoma.[39] About 10%-12% of patients with Turner syndrome have Y chromosome material.[39]

The antenatal diagnosis of Turner syndrome has been made after ultrasound identification of a cystic hygroma and pleural effusion.[17] Clinical practice guidelines exist that outline the suggested screening investigations in individuals with a new diagnosis of Turner syndrome.[39] These include a cardiovascular evaluation, renal ultrasound, hearing evaluation, and referral to appropriate support groups.[3] A 15%-35% incidence of heart anomalies is found. The most common are left-sided and include bicuspid aortic valve in 14%-34% and aortic coarctation in 7%-14%.[39] The most common renal/urinary tract abnormalities are horseshoe kidney and duplex/abnormal collecting system. Feeding difficulties in infancy, caused by oral-motor dysfunction, may result in a lower rate of weight gain. Patients who are not recognized in infancy come to medical attention later, usually because of short stature or failure of secondary sexual development. Most girls demonstrate absence of any ovarian function, but 5%-15% of patients do show variable secondary sexual development; a very small number of pregnancies have been reported.

47,XXY (Klinefelter Syndrome and Variants)

The major clinical manifestations of Klinefelter syndrome develop with the onset of puberty, and most patients are recognized at that time or later, at presentation with infertility. The constant features are small testes with histologic evidence of impaired spermatogenesis. Infants with 47,XXY

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Klinefelter syndrome occasionally have small testes or a micropenis that might permit their recognition, and cases with hypospadias have been reported. Other congenital abnormalities seen in this syndrome included cleft palate, cryptorchidism, and inguinal hernia.[40] The fetal testes at midgestation are normal. Testicular histology in the first year of life has varied from normal to abnormal, with decreased to absent spermatogonia.

The incidence of the 47,XXY karyotype in live newborn males is about 1 in 1000; if Klinefelter variants are added, the overall incidence is about 1 in 6600. Increased maternal age is associated with an additional X chromosome, although this effect is not as marked as it is in autosomal trisomies. Among the variant forms of Klinefelter syndrome, patients with 48,XXXY and 49,XXXXY karyotypes are more likely to be recognized early in life. All have somatic abnormalities and cognitive disability, and many have a hypoplastic penis. All males with the 49,XXXXY karyotype have cryptorchidism, and 14% have cardiac defects.

45,X/46,XY (Mixed Gonadal Dysgenesis)

This group of disorders is characterized by the presence of dysgenetic and often asymmetric gonads. The streak gonad represents the end result of failed gonadal (ovarian or testicular) differentiation. *Mixed gonadal dysgenesis* is a term used to describe individuals with a unilateral, functioning testis and a contralateral streak gonad (Fig. 89.13).

Ninety percent of prenatally diagnosed cases have a normal male phenotype, whereas those diagnosed postnatally show variable phenotypes.[100] Most have some degree of virilization of the external genitalia, ranging from clitoromegaly or partial labial fusion to normal male external genitalia. Slightly more than half have a urogenital sinus. All have some Müllerian development consisting of an upper vagina, a hemiuterus, and a fallopian tube, usually on the side with the streak or absent gonad. An epididymis or vas deferens is present on the testicular side in 50% of cases, and the testis is most frequently located in the inguinal canal. Normal to diminished or absent testosterone responses have been reported with hCG stimulation, and gonadotropins are normal or elevated.[63] Gonadal tumors occur in approximately 20%-30% but have been found in as many as 50% in those with severe genital ambiguity, affecting either the testis or the streak gonad.[26] This condition differs from ovotesticular DSD, previously referred to as *true hermaphroditism*, because of the presence of abnormal gonadal tissue.

In 45,X/46,XY, Turner somatic features such as lymphedema, cardiovascular abnormalities, or short stature are frequently seen and reflect the presence of 45,X cell lines. The prevalence of the XY cell line in the gonad and the extent of structural abnormality of the Y chromosome determine the degree of testicular development and masculinization.

Appropriate gender assignment in the newborn period should be based on functional considerations and fertility. Removal of dysgenetic gonads should be considered in infancy because of the increased risk for tumor formation.[64]

• **Fig. 89.13** A 45,X/46,XY neonate with sex chromosome disorder of sex development was noted at birth to have a male-appearing external genitalia with a phallus measured at 2.5 cm × 1.2 cm and penoscrotal hypospadias. The left gonad was palpable in incompletely fused scrotum, whereas the right gonad was not palpable. Gonadal biopsy revealed a testis on the left side and streak gonad on the right. The diagnosis was mixed gonadal dysgenesis.

The scrotal testis may be normal prepubertally, but many adults show a loss of germ cells and accompanying tubular sclerosis; a few have spermatocytes.

46,XX/46,XY (Chimerism)

The most common phenotype is that seen in ovotesticular DSD, discussed next.

Ovotesticular Disorder of Sex Development

Formerly known as true hermaphroditism, ovotesticular DSD is defined as the coexistence of normal ovarian and testicular tissue either in the same gonad or in opposite gonads. The ovarian tissue must contain ovarian follicles or corpora albicantia as fibrous stroma alone does not define ovarian tissue. The testicular tissue must contain seminiferous tubules or spermatozoa. Several karyotypes are seen in ovotesticular DSD. Karyotype distribution has ethnic variability. On average, around 60% are 46,XX; 20% have Y chromosome-containing mosaic or chimeric karyotypes (45,X/46,XY, 46,XX/47,XXY), with the most common

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

being 46,XX/46,XY; only 7% have 46,XY karyotypes.[54] The most frequently occurring gonadal combinations are an ovary and a testis or an ovary and an ovotestis. An ovotestis accounts for 44%-50% of all gonads in this condition, an ovary 20%-30%, and a testis 12%-20%. Less than 1% of patients have a unilateral streak gonad or a tumor. Ovarian tissue occurs more often on the left side, and gonads with any amount of testicular tissue are more often on the right.[54,102]

The internal genital ducts reflect the gonadal constitution. On the side with an ovary, a fallopian tube is almost always seen, and on the side with a testis, the vas deferens and epididymis are almost always present. On the side with an ovotestis, a vas deferens is seen 35% of the time and a fallopian tube, often closed at the fimbriated end is seen, 65% of the time. A uterus is described in about 86% of patients, but is usually hypoplastic, unicornuate, or otherwise underdeveloped.[102]

The external genitalia are usually ambiguous, although some cases have been reported with normal male or female appearances. The urethra most often opens on the perineum as a urogenital sinus. The phallus is usually larger than a normal clitoris and often has chordee; it is frequently of sufficient size to give the genitalia a masculine appearance. Gonads are descended or palpable in 61% of patients, more frequently on the right side. About 60% of palpable gonads are ovotestes, with the majority of the remainder being testes. An ovary will rarely descend past the inguinal canal. The ovotestis is more likely to descend if it contains a greater proportion of testicular tissue. The ovarian portion of the ovotestis tends to be firm and convoluted and is histologically normal except for a reduction in the number of primordial follicles. The testicular portion tends to be soft, smooth, and histologically normal in infants. However, it becomes abnormal in more than 90% of adults, marked by tubular atrophy with undifferentiated germ cells and the absence of spermatogenesis. The histology of an intact testis is similar, with spermatogenesis seen in only 12% of patients. The testosterone response to hCG stimulation is usually low but can be normal depending on the amount of testicular tissue present. Gonadal tumors occur in 3%-5% of patients with ovotesticular DSD and are more frequent in those who are Y chromosome positive.[54,102] Renal abnormalities have been noted in 5% of 150 cases.

Most cases of ovotesticular DSD are 46,XX and on karyotype have no separate Y chromosome material. Autosomal or X-linked mutations in genes downstream of *SRY*, such as several of the *SOX*-family genes, have been shown to induce testicular differentiation. Mutations in *RSPO1* and *WNT4* have also been associated with 46,XX DSD.[80] Other mechanisms include the translocation of Y chromosome material to an autosome and chromosome mosaicism in gonadal tissue. Familial cases of 46,XX DSD with male phenotype, and 46,XX ovotesticular DSD, show phenotypic similarity, typically having ambiguous genitalia and lacking the *SRY* gene or other Y sequences, indicating that these conditions are closely related.

Ovotesticular DSD may be identified in the neonatal period because of the finding of ambiguous genitalia. Definitive diagnosis requires a gonadal biopsy, but this is preferably delayed until after the neonatal period. Fertility is often impaired in this condition for both males and females. Gender assignment is guided by the same principles outlined for other DSDs.

46,XY Disorder of Sex Development

This can be classified further into disorders of gonadal development, androgen synthesis or action, and others.

Disorders of Gonadal (Testicular) Development

Complete and Partial Gonadal Dysgenesis

In testicular dysgenesis, the underlying defect is disordered testicular differentiation or development that results in anatomically or histologically abnormal testes and secondary impairment of hormonogenesis or spermatogenesis. Dysgenetic testes are defined by the following characteristics: a failure to induce regression of the ipsilateral Müllerian duct structures, an association with incomplete masculinization of the genitalia, variably abnormal histology, and an increased predisposition toward the development of tumors originating from the germinal structures. The testes may be of normal or small size and are usually cryptorchid. The karyotype is typically 46,XY, but other karyotypes are also seen. Dysgenetic testicular tissue can be seen in ovotesticular DSD.

Individuals with complete gonadal dysgenesis (Swyer syndrome) have a 46,XY karyotype and no testes but instead have streak gonads, female-appearing external genitalia, and normal Müllerian structures, and as a result, the condition is rarely diagnosed in infancy unless there is a known XY karyotype from prenatal testing.[50] A mutation in the *SRY* gene has been reported in 10%-20% of those with complete gonadal dysgenesis.[50] XY gonadal dysgenesis occurring in families has been described and attributed to mutations in the *SRY* gene that resulted in the reduction rather than loss of DNA binding. The reduced binding presumably leads to variability in phenotype, allowing some individuals to have near-normal gonadal development.

The clinical recognition of 46,XY partial gonadal dysgenesis may be possible in the newborn period in infants with clitoromegaly. There is a very high risk for the development of gonadal tumors in XY gonadal dysgenesis. Prophylactic removal of the streak or dysgenetic gonads is indicated in infancy. The gender assignment is most commonly female. Gonadal dysgenesis associated with a Y chromosome is significantly different from the Y-negative forms described previously. Both forms have in common the presence of bilateral or unilateral streak gonadal tissue but differ in tumor risk.

The causes of Y-positive gonadal dysgenesis are heterogeneous and include a small deletion of distal Yp (the short arm of chromosome Y) with loss of the *SRY* gene, an X chromosome or autosomal mutation that interferes

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

with or prevents testicular differentiation, and Y chromosome abnormalities or mosaicism. Causative genes include *NR5A1* (SF-1), *SOX9*, *MAP3K1*, *ARX*, *ATRX*, *DHH*, *DMRT1*, *GATA4*, *MAMLD1*, *NROB1*, *WNT4*, *WT1,* and *WWOX*.[80] A structurally abnormal Y chromosome frequently results in 45,X/46,XY or 45,X/47,XYY mosaicism. When the result is two streak gonads, a female phenotype is usually seen. Varying degrees of testicular development, reflecting the relative prevalence of the XY cell lines, may result in ambiguous or predominantly male genital development. The finding of genital ambiguity with asymmetry of the labioscrotal folds, Turner somatic stigmata, or associated malformations allows many patients to be identified in the neonatal period.

Yp gonadal dysgenesis is caused by an abnormal X-Y recombination involving the distal ends of Xp and Yp. This may result in translocation and thus loss of the *SRY* gene from the Y to the X chromosome. The resulting XYp– individual has bilateral streak gonads and a female phenotype; most have lymphedema or other Turner somatic features thought to be caused by the loss of certain Yp genes. Y autosome translocations may also result in loss of the *SRY* gene.

The risk for tumor development in those with 46,XY complete gonadal dysgenesis is 37%-45%.[64] Testis-specific protein on the Y chromosome (*TSPY*) is required for germ cell tumor risk.[90] The most common tumor is a gonadoblastoma, which may arise in a streak gonad or a dysgenetic testis, is frequently bilateral, and occurs from the first year of life up to the fourth decade. Although pure gonadoblastomas do not metastasize, they are frequently associated with dysgerminomas or other malignant germ cell tumors. The risk for a tumor is the greatest for poorly differentiated gonadal tissue and an intra-abdominal or inguinal position; only rarely is there tumor formation in a scrotal testis. Unexpected testosterone or estrogen formation may signal tumor development. Total gonadectomy is recommended for those reared as females and considered for undescended gonadal tissue for those reared as males.

Mutation and Deletion of WT1: Denys-Drash, Fraser, and WAGR Syndromes. The Wilms tumor suppressor gene (*WT1*), which is on chromosome 11p13, encodes a transcription factor that is expressed in the urogenital embryonic tissues that develop into the kidney and gonad. A mutation or deletion of *WT1* causes abnormal gonadal development, as seen in Denys-Drash syndrome (nephropathy, genital abnormalities, Wilms tumor), WAGR syndrome (*W*ilms tumor, *a*niridia, *g*enitourinary malformations, mental *r*etardation), and Fraser syndrome (gonadal dysgenesis and chronic renal failure). Therefore, *WT1* is to be required for the early commitment and maintenance of renal and gonadal tissue and to exert its effects upstream from the *SRY* gene (see Fig. 89.1 and Table 89.1). Both 46,XY and 46,XX individuals may be affected. Although many patients present at birth with ambiguous genitalia ranging from clitoromegaly with labial fusion to hypospadias with undescended testes, others have external genitalia that are phenotypically normal male or female but may be inappropriate for the karyotype.[60] Their underlying DSD defect is in the development of the gonads, which anatomically show wide variation, ranging from streak gonads (complete gonadal dysgenesis) to dysgenetic or rudimentary testes or ovaries to ovotestes; gonadoblastomas have developed in some of the dysgenetic gonads. The internal genital ducts usually reflect the gonadal makeup; Müllerian duct structures are usually present.

Mutation of *SOX9* (SRY-Like HMG Box-Related Gene 9). *SOX9* mutation is a cause of campomelic dysplasia and XY gonadal dysgenesis. In the presence of *SRY*, *SOX9* expression is repressed in the female gonad but is upregulated in the developing testis and is crucial in the pathway for testis development. *SOX9* is also responsible for synthesis of collagen type II, and mutations of *SOX9* result in campomelic dysplasia. Campomelic dysplasia is a cartilage and skeletal malformation syndrome with congenital angulation and bowing of long bones that is associated with 46,XY complete gonadal dysgenesis in about three-fourths of XY cases. Testicular development in XY patients ranges from streak gonads to dysgenetic testes to normal testes; the external genitalia show a gradation of defects, from the female phenotype in those with complete gonadal dysgenesis to ambiguous genitalia to a normal male phenotype.[7] The internal genital ducts reflect the gonadal makeup. Patients who have more severe skeletal dysplasia die in the first months of life from respiratory failure, but less severely affected patients may live into adulthood. The mode of inheritance is autosomal dominant, with haploinsufficiency for *SOX9* on chromosome 17 as the cause of both campomelic dysplasia and gonadal or testicular dysgenesis.

Duplication of Dosage-Sensitive Sex Reversal. Duplication of the dosage-sensitive sex reversal, adrenal hypoplasia congenita critical region, on the X chromosome, gene 1 (*DAX1*), located on the short arm of the X chromosome, overrides the *SRY* gene and impairs or prevents testicular development, resulting in partial or complete XY gonadal dysgenesis. Affected patients have either ambiguous genitalia or a female phenotype and may also exhibit adrenal insufficiency and hypogonadotropic hypogonadism.[37] Familial cases have been reported.

Steroidogenic Factor-1. The *NR5A1* gene codes for steroidogenic factor-1 (*SF1*), a nuclear hormone receptor, and regulates the expression of genes involved in gonadal and adrenal development. Mutations in *SF1* can be associated with 46,XY DSD with genital ambiguity and normal adrenal function or adrenal insufficiency and lead to impaired Leydig cell function and androgen biosynthesis.[105] Mutations are most commonly associated with partial gonadal dysgenesis.[29]

46,XY Ovotesticular Disorder of Sex Development

See the section Ovotesticular Disorder of Sex Development in this chapter.

Gonadal Regression

Early Regression With Genital Ambiguity (XY Gonadal Agenesis). This rare condition is characterized by the complete absence of testes, including the absence of gonadal streaks, and associated with the almost complete absence of both Müllerian and wolffian duct derivatives and female or partially masculinized genitalia (clitoromegaly and posterior labial fusion).[89] The gonadal and genital features may be explained by very early regression of the developing fetal testes between about 8 and 10 weeks. Testicular failure must have occurred after the initial production of AMH by Sertoli cells but before the Leydig cells could produce sufficient testosterone for a reasonable time. It has been suggested that testicular regression is part of the clinical spectrum of 46,XY gonadal dysgenesis.

Other XY individuals have testes with quite well-developed wolffian structures but incomplete masculinization of the external genitalia. Testicular regression presumably occurred slightly later than it did in those patients with the absence of internal genital ducts. Affected siblings have been reported, raising the possibility of autosomal recessive inheritance. In another family, there were subjects from two generations affected, with X-linked or autosomal dominant, sex-limited inheritance suggested. The differential diagnosis includes Leydig cell hypoplasia.

Late Regression: Congenital Anorchia (Vanishing Testes Syndrome). Many cases have been reported of cryptorchid 46,XY males who on exploration were found to have bilateral anorchia but with normal wolffian structures, the absence of Müllerian structures, and normal male external genitalia. The vas deferens ends blindly, often without an epididymis, in either the inguinal canal or upper scrotum (sometimes palpable as a small knot of tissue), which is retroperitoneally near the usual location of the internal inguinal ring or in the iliac fossa. Neonates and infants with congenital anorchia fail to show any rise in testosterone during either endogenous LH or exogenous hCG stimulation, and they lack AMH. In the 46,XY individual with a male phenotype, these findings are usually but not always diagnostic. If uncertainty exists, laparoscopy or surgical exploration may be necessary. The cause of congenital anorchia is not established, but infections, teratogens, immune mechanisms, or hereditary factors may play a role. Some of those with congenital anorchia also have micropenis.[89] The possibility that bilateral congenital anorchia is part of a continuum with early testicular regression has been suggested.[89]

Disorders of Androgen Synthesis or Action

In these disorders, there is abnormal differentiation of either the internal genital ducts or the external genitalia in a 46,XY individual who has bilateral testes with intact tubular elements (seminiferous tubules with Sertoli and germinal cells). Disordered synthesis or action of testosterone is the underlying cause of the observed abnormalities. Some cases of dysgenetic testes and rudimentary testes overlap phenotypically with this category, but their underlying cause is testicular dysgenesis and not a primary disorder of the testicular hormone synthesis. In patients with 46,XY DSD who are severely undermasculinized, a blind, distal vaginal pouch is present. It appears when a lack of androgen stimulation permits the urovaginal septum to persist.

Androgen Biosynthesis Defect

Five enzymatic steps are involved in the synthesis of testosterone from cholesterol (see Fig. 89.5).[75] A defect in any one results in decreased to absent androgen synthesis and 46,XY DSD (Table 89.7). Three of these enzymes are also necessary for the adrenal biosynthesis of cortisol: cholesterol

TABLE 89.7 Clinical and Hormonal Data for Forms of Congenital Adrenal Hyperplasia (CAH) in Male and Female Newborns

Enzyme Deficiency (Classical Forms)	External Genital Abnormalities		Symptoms		Plasma Steroid Hormones and Renin Levels

side-chain cleavage enzyme (P450scc), 17α-hydroxylase, and 3β-hydroxysteroid dehydrogenase. Their defects result in accompanying cortisol deficiency with or without aldosterone deficiency (see the section Congenital Adrenal Hyperplasia in this chapter). The remaining two testosterone biosynthetic enzymes, 17,20-desmolase and 17β-hydroxysteroid dehydrogenase, are not needed for cortisol synthesis. Their deficiencies primarily cause impaired testosterone synthesis that leads to abnormal male sexual differentiation. In addition, 5α-reductase deficiency is included under this category. Clinical diagnoses are made by finding biochemical evidence of disorders along the testosterone biosynthetic pathway, often accentuated by hCG stimulation testing.

Congenital Lipoid Adrenal Hyperplasia (StAR [Steroidogenic Acute Regulatory] Protein/P450scc Deficiencies). The first step in steroid hormone biosynthesis is the transport of cholesterol into the mitochondria mediated by the steroidogenic acute regulatory (*StAR*) protein followed by conversions of cholesterol to pregnenolone by the cholesterol side chain cleavage enzyme (P450scc).[70]

Congenital lipoid adrenal hyperplasia, rare in most countries, is the second most common form of CAH in Japan and Korea.[70] The underlying defect in lipoid CAH is inability to convert cholesterol to pregnenolone. Lipoid CAH is caused by either mutations in StAR protein or CYP11A1 (P450scc enzyme gene), resulting in deficiency of all adrenal and gonadal hormones (see Fig. 89.5). Patients present usually with salt-losing crisis during the first days of life but in milder cases may not be diagnosed until several months.[49] Male infants with this disorder have either undervirilization or complete female external genital phenotype, often with a blind vaginal pouch, and the testes may be descended. Hyperpigmentation and respiratory problems may occur.

Biochemically, there is decreased to absent production of all adrenal and gonadal steroids, depending on the severity of the defect (see Fig. 89.5). The adrenal glands are enlarged, with a characteristically enormous accumulation of lipid, thus the name *congenital lipoid adrenal hyperplasia*.

P450 Oxidoreductase Deficiency. The P450oxidoreductase (POR) enzyme acts as a cofactor for normal activity of key steroidogenic enzymes, including 17α-hydroxylase/17,20-lyase, 21-hydroxylase, and aromatase (see Fig. 89.5).[93]

P450 oxidoreductase deficiency is a rare form of CAH that manifests with variable phenotypes based on the extent of the involved enzyme deficiencies. Abnormal genital development can be seen in both sexes; males can be undervirilized, and females can be virilized.

The unique aspect in this form of CAH is the frequent association with skeletal malformations, termed *Antley-Bixler syndrome*. Antley-Bixler syndrome is a syndrome that includes craniosynostosis, midface hypoplasia, choanal atresia or stenosis, radiohumeral or radioulnar synostosis, femoral bowing, and joint contractures.[55] Maternal virilization and low maternal estriol and estrone levels during pregnancy may be seen. In infants, the risk for upper airway obstruction caused by skeletal abnormalities, including choanal obstruction, should be assessed. Because some hepatic P450 enzymes are dependent on POR, effects on drug metabolism owing to POR deficiency are possible. Insufficient information is currently available to describe the clinical implications.

Biochemically, affected patients may have elevated 17-OHP and low androgen levels; cortisol may be normal but is poorly responsive to adrenocorticotropic hormone. Both autosomal recessive inheritance and an autosomal dominant mutation in fibroblast growth factor receptor-2 (*FGFR2*) gene have been proposed as a cause of Antley-Bixler syndrome. Molecular diagnosis of POR can be made by mutation analysis.

Management includes hydrocortisone replacement if cortisol deficiency is confirmed by ACTH stimulation test. Salt-wasting secondary to mineralocorticoid deficiency is possible but rare and needs replacement with fludrocortisone and salt.

17α-Hydroxylase and 17,20-Lyase Deficiency. This form of enzyme deficiency accounts for 1% of CAH cases worldwide except in Brazil, where it represents the second most common form of CAH, accounting for 5%-7% of all cases. Combined 17α-hydroxylase and 17,20-lyase deficiency results in impaired production of cortisol and sex steroids, although mineralocorticoid production is intact. Although cortisol secretion is subnormal, patients can produce large amounts of corticosterone, which binds the glucocorticoid receptor with low affinity. Male 46,XY patients present with a mild form of glucocorticoid deficiency, high ratio of 17-OH progesterone to androstenedione, low DHEAS, and low renin hypertension caused by abnormally high 11-deoxycorticosterone (DOC).[6] Deficiency of 17,20-lyase impairs the production of androgen. Affected 46,XY neonates show incomplete masculinization ranging from mild undervirilization of external genitalia to completely female-appearing genitalia, depending on the severity of the defect. The inheritance is autosomal recessive. Hydrocortisone replacement in low doses is needed if adrenal insufficiency is present, which will suppress excessive mineralocorticoid production and normalize the blood pressure. Sex hormone therapy is required for puberty induction and subsequent maintenance replacement. If a 46,XY is assigned a female gender, concern for germ cell tumor formation in the testes exists but is not well quantified.[90]

3β-Hydroxysteroid Dehydrogenase Deficiency. 3βHSD deficiency is a rare autosomal recessive form of CAH characterized by marked clinical heterogeneity. The severity of the defect also varies, with some patients having no genital abnormality at birth but presenting with adrenal insufficiency and some having undervirilization. In severe 3βHSD deficiency, salt wasting, adrenal insufficiency, and abnormal development of male external genitalia are seen.[10] Sodium wasting varies, ranging from severe to mild to none. The characteristic biochemical finding is a marked elevation of ACTH-stimulated 17-OH pregnenolone and 17-OH pregnenolone to 17-OH progesterone ratio.[83] Aldosterone levels

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

are low, and plasma renin activity is increased. Multiple gene defects in the *HSD3B2* gene have been described.[96] As with other forms of CAH, hydrocortisone replacement will correct cortisol deficiency and abnormal steroid secretion. If mineralocorticoid deficiency exists, fludrocortisone and salt replacements must be also administered.

17β-Hydroxysteroid Dehydrogenase Deficiency. 17β-hydroxysteroid dehydrogenase catalyzes the only reversible step involved in testosterone and estradiol synthesis, the interconversion of androstenedione and testosterone and of estrone and estradiol (see Fig. 89.5). It is present in both gonadal and peripheral tissues but only minimally so in adrenocortical tissue. Its deficiency is associated primarily with diminished testosterone synthesis with a decreased plasma testosterone-to-androstenedione ratio. This results in failure of male differentiation in utero. Affected 46,XY patients have slightly masculinized genitalia (clitoromegaly, posterior labioscrotal fusion); a few have more masculinization.[66] The epididymis and vas deferens are well developed, and in many patients, the testes are descended in the inguinal canal or labioscrotal folds. Because the degree of undervirilization of the external genitalia can be severe, the diagnosis may not be possible in infancy.

Untreated 46,XY patients undergo significant masculinization at puberty and may have an accompanying change in gender identity from female to male (a similar change in gender identity is seen in patients with untreated 5α-reductase deficiency). The inheritance of 17-ketosteroid reductase deficiency is autosomal recessive. It has a high prevalence in the Arab population in the Gaza Strip, Lebanon, Syria, and Turkey.

5α-Reductase Deficiency. 5α-Reductase is located peripherally in the tissues of the urogenital sinus, external genitalia, liver, prostate, hair follicles, and sebaceous glands, where it catalyzes the conversion of testosterone to its 5α-reduced product, dihydrotestosterone (DHT). Its deficiency in the 46,XY fetus results in failure of the external genitalia to undergo male differentiation. Affected males have normally developed testes that may be descended, absent Müllerian duct structures, and male internal ducts (stimulated by testosterone) but phenotypically female or ambiguous external genitalia.[65] Most patients are potentially recognizable at birth, with apparent clitoromegaly, a single perineal orifice that is a urogenital sinus, and posterior labial fusion (Fig. 89.14). A few patients have hypospadias or a micropenis. Most are reared as females; however, in some cultures in which the disorder is widely known and recognized, individuals may be recognized as a third gender. At puberty, 46,XY individuals who have not undergone gonadectomy show striking virilization because of the increase in testosterone, and about 50% change from female to male as adults.[65] DHT-dependent secondary sexual characteristics such as acne, body and facial hair, and prostatic enlargement develop minimally or not at all. The inheritance of primary 5α-reductase deficiency is autosomal recessive.

Leydig Cell Hypoplasia. Patients with testicular unresponsiveness to hCG and LH fail to undergo male genital differentiation. It is caused by an autosomal recessive inactivating mutation in the LH receptor. This results in agenesis or hypoplasia of the Leydig cells. In the complete absence of hCG binding, a female phenotype with a blind vaginal pouch, but no wolffian ducts, is seen. Other patients have shown clitoromegaly, posterior labial fusion, or perineal hypospadias with good development of the epididymis and vas deferens, suggesting an incomplete defect. Anti-Müllerian hormone is produced, so Müllerian structures

• **Fig. 89.14** **A,** Male differentiation of the external genitalia and urogenital sinus structures is stimulated by dihydrotestosterone (DHT) (*pink areas*), whereas wolffian duct differentiation is stimulated by testosterone (*tan area*). **B,** 5α-Reductase deficiency results in impaired male differentiation of DHT-responsive tissues (*pink area*). The external genitalia appear female, and the vesicovaginal septum develops to create a distal, blind vaginal pouch opening into a urogenital sinus. The wolffian duct differentiation is normal (*tan area*). (From Imperato-McGinley J, et al. Male pseudohermaphroditism: the complexities of male phenotypic development. *Am J Med.* 1976;61:251.)

are absent. The testes are usually cryptorchid and small postpubertally, although possibly of normal size in infancy. The characteristic findings are a low basal level of testosterone and its precursors, high level of LH, the failure of testosterone response to hCG stimulation, and a marked paucity or absence of Leydig cells on biopsy of the testes.[56] The seminiferous tubules and Sertoli cells are normal, but spermatogenic arrest or absence is seen.

Defect in Androgen Action

Androgen Insensitivity Syndromes. The androgen insensitivity syndromes are disorders in which peripheral tissues are partially to completely incapable of responding to stimulation by any androgen because of an androgen receptor or postreceptor defect.[71] Many mutations in the X-linked androgen receptor gene have been described, leading to variable phenotypes in this disorder.[71] Androgen-mediated events, such as masculine differentiation in utero or virilization during puberty, fail to occur or are impaired to a variable extent, depending on the completeness of the defect.

Complete Androgen Insensitivity Syndrome. Affected individuals have a 46,XY karyotype with bilateral testes but a failure in wolffian duct development and complete absence of any masculinization of the external genitalia. They have female-appearing external genitalia with a distal vaginal pouch. The Müllerian structures are absent, but microscopic remnants have been reported, possibly from the interference of high, unopposed levels of estrogen with the action of AMH. The testes are of normal size and may be descended into the inguinal canal or labia majora, and more than half of these individuals have an inguinal hernia, which may lead to their clinical recognition in infancy. At puberty, these individuals undergo female breast development and acquire a female habitus because of peripheral conversion of testosterone to estradiol; however, they have primary amenorrhea. No masculinization is seen, and gender identity remains female.

The occurrence of cAIS is familial in about 30% of cases, and a family history of infertile female relatives is sometimes found. Spontaneous mutations are thought to account for the sporadic cases. Screening for the syndrome in an at-risk fetus can be carried out in utero by ultrasound examination of the genitalia and determination of the karyotype. The diagnosis is inferred in the phenotypically female neonate by establishing the absence of a uterine cervix and the presence of a Y chromosome. Both plasma testosterone and LH have been shown to be low at 30 days of age, suggesting that the expected postnatal testosterone rise requires the hypothalamic–pituitary axis to be responsive to testosterone.[15]

The differential diagnosis includes other causes of 46,XY DSD; hCG stimulation testing may be needed to rule out these possibilities. The gender is almost always female. There is a 2% risk for germ cell malignancy in childhood, with rates of 20%-30% reported in those who have had gonadectomy in their 20s-30s, probably related to the intra-abdominal location of the testes. For this reason, gonadectomy is indicated; however, current recommendations suggest delaying until after puberty, as testosterone is converted to estradiol peripherally and allows for spontaneous development of secondary sexual characteristics[27,87] and virtually all malignant tumors have occurred postpubertally.

• **Fig. 89.15** This 46,XY infant with partial androgen insensitivity had ambiguous genitalia at birth noted by a phallus with stretched length of 1.8 cm and perineal hypospadias. Both gonads were palpable in the inguinal canals. The labioscrotal folds showed posterior fusion with pigmentation and rugation. Before final decision for a male sex of rearing, a 3-month trial of testosterone was undertaken with increase in the size of the phallus.

Partial Androgen Insensitivity Syndrome. Affected 46,XY individuals have bilateral testes and absent Müllerian ducts, but incomplete masculinization of their external genitalia, ranging from female-appearing genitalia with clitoromegaly or posterior labial fusion to phenotypically normal male-appearing genitalia. Many have perineal, penoscrotal, or penile hypospadias and others have a micropenis (Fig. 89.15). There also is wolffian duct development, but it is often incomplete, which may not correlate with the extent of external genital masculinization. At puberty, both masculinization and feminization are seen, the extent depending on the severity of the androgen insensitivity.[71]

The causes of pAIS are heterogeneous. Most individuals have qualitatively abnormal receptors with variable function.[71] Others have reduced numbers of normal receptors, and a few have postreceptor defects. There is an X-linked recessive inheritance of the receptor-related mutations. The phenotype in pAIS is variable and does not necessarily correlate with the genotype even within the same family.[28]

Except for very few individuals with a normal male phenotype, all individuals with pAIS are infertile. The risk for development of gonadal tumors is not known, but intratubular germ cell neoplasia (a precancerous lesion) frequently occurs in patients with pAIS at as early as 2 months of age. Monitoring for the development of a testicular tumor is needed if the testes are not removed.[90] The testes are typically removed in those reared as females.

Other

Disorders of Anti-Müllerian Hormone and Anti-Müllerian Hormone Receptor (Persistent Müllerian Duct Syndrome)

Isolated AMH deficiency or AMH receptor abnormalities result in failure of the Müllerian ducts to regress. The clinical picture in the 46,XY individual is that of a phenotypic male with bilateral fallopian tubes, a uterus (occasionally hypoplastic or absent), wolffian duct development, and bilaterally normal testes.[88] Two clinical presentations are seen. The typical clinical presentation is in a male with bilateral cryptorchidism and inguinal hernias and normal male external genitalia. During surgery for hernia repair, a uterus and fallopian tubes are found in the inguinal canal. Alternatively, one testis is at least partially descended and accompanied by a fallopian tube and uterus that easily enter the inguinal canal. In addition, about one-third have transverse ectopia, the opposite testis being pulled to the side with the inguinal hernia, so that both testes are in the same inguinal canal. Such patients may have an inguinal mass or the appearance of an incarcerated hernia without evidence of intestinal obstruction. Less commonly, the uterus is fixed in the pelvis and the testes are in an ovarian position. The vas deferens and epididymis are typically enmeshed in the uterine wall and mesosalpinx, making it difficult to bring the testes down into the scrotum.

Persistent Müllerian duct syndrome is caused by a mutation in either the *AMH* gene or its receptor and is inherited according to an autosomal recessive pattern.[88] The gender assignment is male. Orchiopexy should be performed early in infancy to improve testicular outcome. Achieving testicular descent into the scrotum usually requires extensive dissection to free the spermatic cord. The Müllerian structures do not need to be removed, because they do not develop malignancy and there is a strong risk for damaging the vas deferens. Spermatogenesis is intact, but many patients are infertile, possibly because of abnormal epididymal development, cryptorchidism, or injury to the vas deferens. Intracytoplasmic sperm injection may produce fertility in some of these cases. There is no evidence of an increased risk for testicular tumors compared with other causes of cryptorchidism.

Common Male Genital Abnormalities in Small-for-Gestational-Age Newborns

Newborns with low birth weight and those who suffered from intrauterine growth restriction (IUGR) have higher incidence of cryptorchidism and hypospadias. Because fetal testosterone secretion is under the influence of placental hCG during the first 14 weeks, placental insufficiency might reduce fetal hCG levels and hence testosterone biosynthesis. Several studies have demonstrated that the earlier the placental compromise in IUGR, the more severe the genital abnormality.[97]

The estimated incidence of hypospadias in IUGR newborns in postnatal studies is variable, ranging from 3.83%-19% compared with an incidence of 0.3% in the general population. Severe proximal hypospadias occurred in up to 62% of all cases. A clinical correlation has been found between the severity of IUGR and that of hypospadias.[21] The strongest evidence of an association between IUGR and hypospadias comes from monozygotic twins. A study of 18 twin pairs in which one of the twins had hypospadias found that in 16/18 twin pairs the twin with hypospadias weighed on average 500 g less than the twin who had no hypospadias. Similarly, several studies have found that the risk of cryptorchidism increases two- to fourfold in boys with low birth weight. Population-based surveys confirmed that this increased risk persists during infancy, after correction for prematurity, and despite spontaneous postnatal descent in the majority of cases.[97]

Environmental Influences: Endocrine-Disrupting Chemicals

Over the past decade, several studies reported an increasing trend in male external genital malformations that has led to the suspicion that environmental chemicals, also called endocrine disrupting chemicals (EDCs), could influence the fetal sexual development. Animal studies have confirmed the influence of such chemicals on genitourinary development through exogenous manipulation of steroid levels or hormone receptors. Of the EDCs, there have been concerns about the effects of substances pertaining to the general population, including pesticides, phytoestrogen from vegetarian food sources, and occupational chemicals, including phthalates (commonly found in plastics and hair spray), alkyl phenols (used in detergents, fuel, and fragrance), and heavy metals.[8,38]

The most widely studied epidemiologic association is the role of EDCs in the development of male hypospadias. Studies showed mixed and inconclusive results on the effects of these factors in increasing the risk of hypospadias in the offspring of mothers and fathers who have occupations with high exposure to EDCs. Nevertheless, data from populations with high exposure rates because of industrial accidents or in utero exposure to diethylstilbestrol (DES) suggested that EDCs adversely affect genitourinary development. Given the multifactorial component of the genital malformation and the limitation of current epidemiologic studies, the cause–effect relationship can only be assumed and not proved. Further studies of these chemicals are needed to gain a better understanding of their role in human sexual development.[97]

46,XX Disorders of Sex Development

This group includes four main categories: disorders of gonadal development, androgen excess, syndromic defects, and structural defects.

Disorders of Gonadal (Ovarian) Development

Gonadal Dysgenesis

Patients with XX gonadal dysgenesis have bilateral streak gonads or hypoplastic ovaries with intact Müllerian duct

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

structures and female external genitalia. They differ from patients with Turner syndrome in that they usually have normal stature, an absence of Turner stigmata, structurally intact X chromosomes, and a positive family history as familial cases occur frequently. An abnormality of an autosomal gene that regulates germ cell migration, formation of the bipotential gonad, or ovarian differentiation may be the cause. Key regulatory genes in ovarian development that have been implicated in 46,XX disorders of ovarian development include *FOXL2*, *WNT4*, *β-CATENIN*, and *NR5A1*.[5,80] Associated features are seen in some families, including sensorineural hearing loss (*Perrault* syndrome), neurologic abnormalities, and renal disease. Isolated instances of clitoromegaly have been described, resulting from testosterone production by either hilar cells or luteinized gonadal stromal cells in a streak gonad. The differential diagnosis includes defects in estradiol synthesis, Slotnick-Goldfarb syndrome (streak gonad plus a hypoplastic ovary that may present as a neonatal ovarian cyst), Malouf syndrome (ovarian dysgenesis, dilated cardiomyopathy, ptosis, broad nasal bridge), and Denys-Drash and Fraser syndromes.

46,XX Ovotesticular Disorder of Sex Development

See the section Ovotesticular Disorder of Sex Development in this chapter.

Testicular Disorder of Sex Development (46,XX Male)

Individuals with 46,XX male phenotype have bilateral testes but lack of a Y chromosome on karyotype analysis. The incidence is about 3.5-4.7 per 100,000 male births. The most common cause is an abnormal X to Y translocation, occurring during paternal meiosis and involving a crossover of variable amounts of adjacent Y sequences to the distal end of the paternal short arm of the X chromosome.[13] Most, if not all, XX males inherit one maternal and one paternal X chromosome. The majority of 46,XX males have normal male internal and external genitalia. Around 15% have ambiguous genitalia due to decreased fetal testosterone production.[13] Testes are of normal size but may be cryptorchid. As with Klinefelter syndrome, the detrimental influence of the second X chromosome results in the absence of spermatogonia, hyalinization of the tubules, and small testes in adults. The testicular histology is almost normal in the first year of life, but after 1 year of age the spermatogonia are lacking. Most *SRY*-positive individuals have a normal male phenotype and no disability except infertility. A few have lost more of the X chromosome sequence, resulting in short stature or cognitive disability. Others with a very small Y interchange have hypospadias or other manifestations of incomplete male genital development, which is thought to be caused by altered *SRY* gene expression. A few XX males have been found to have no *SRY* gene and no detectable Y sequences. Most of these *SRY*-negative and Y-negative individuals have ambiguous genitalia and account for the majority of genital ambiguity among 46,XX males. A *SOX9* duplication was found in a family that resulted in 46,XX male phenotype.[25] A gain-of-function mutation in *SOX3* was reported in a 46,XX phenotypically male newborn who presented with hypospadias and bifid scrotum.[22] In both reports, the described mutations resulted in upregulation of *SOX9*, which acts downstream of *SRY*. This allowed for *SRY*-independent testicular induction leading to phenotypically male sexual differentiation. A loss-of-function mutation in *WNT4* has been shown to underlie SERKAL syndrome, involving 46,XX testicular DSD in association with adrenal, renal, and pulmonary dysgenesis.[80]

Androgen Excess

The external genital ambiguity is almost always androgen induced. Most cases are caused by fetal CAH and a few result from a maternal androgen source. More rarely, a source of androgens is not found, and an error in morphogenesis is presumed to be the cause.

Androgen exposure between 8 and 14 weeks of fetal age results in variable male differentiation of the external genitalia, particularly labioscrotal fusion, regression of the urovaginal septum to form a urogenital sinus, ventral displacement of the urethral (urogenital) meatus toward or on the phallus, and male phallus differentiation (Fig. 89.16).

• **Fig. 89.16** A 4-week-old 46,XX neonate with salt-losing 21-hydroxylase deficiency with significant virilization of external genitalia. A normal uterus and ovaries were seen in the pelvis, whereas both adrenal glands were enlarged with "cerebriform appearance." **A,** Clitoromegaly (1.6 × 1 cm) and rugated, hyperpigmented, partially fused labial majora. **B,** A single orifice visualized at the base of the clitoris, representing a common urogenital sinus. **C,** Genitogram showing an intermediate length urogenital sinus.

Androgen exposure occurring beyond 12 or 14 weeks produces growth but not differentiation of the external genitalia, namely, clitoral hypertrophy, defined in the neonate by a clitoral width of greater than 6 mm. Most 46,XX DSDs are identified at birth because of genital ambiguity, but the more severely affected neonates may be missed initially, being incorrectly identified as males with hypospadias or undescended testes. The major reason to identify 46,XX DSDs in the immediate neonatal period is to recognize underlying CAH that, if present, may be life threatening.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) comprises a group of autosomal recessive disorders in which there is an inherited defect in one of the enzymes required for the adrenocortical synthesis of cortisol from cholesterol. Each of the enzyme defects leads to impaired cortisol production, and the lack of negative feedback to the pituitary gland causes a secondary increase in adrenocorticotropic hormone (ACTH). The elevated ACTH stimulates adrenocortical steroidogenic activity in an attempt to normalize cortisol production. Clinical problems arise as a consequence of impaired synthesis of the steroid hormones (glucocorticoids, mineralocorticoids, or gonadal sex steroids) downstream of the enzymatic block and overproduction of the precursor steroids or their side products upstream of the block. Adrenal enzyme defects not involving cortisol synthesis are excluded from the CAH designation.

The five enzymes or enzymatic steps involved in the synthesis of cortisol from cholesterol are cholesterol side chain cleavage enzyme complex (P450scc), 3β-hydroxysteroid dehydrogenase (3βHSD), 17α-hydroxylase, 21-hydroxylase, and 11β-hydroxylase (see Fig. 89.5). All except 3βHSD are members of the cytochrome P450 group of oxygenases. Except for 17α-hydroxylase, these enzymes are also necessary for mineralocorticoid (aldosterone) biosynthesis. The first three enzymes are present in gonadal tissue, where they are necessary for synthesis of the sex steroids. A deficiency in one of these three enzymes in males results in inadequate testosterone formation and incomplete male sex differentiation. In females, it results in deficient estrogen synthesis, which will not be apparent in the neonatal period but becomes clinically significant at puberty.

The 21- and 11β-hydroxylases are found predominantly in the adrenal cortex and only minimally in gonadal tissue. They are not necessary for the synthesis of sex steroids. However, their deficiencies (and to a lesser extent the deficiency of 3βHSD) result in excess formation of precursor steroids, which yield an increased production of androgens that induce masculinization of affected female fetuses in utero (see Table 89.7). By this mechanism, 46,XX DSD occurs, and affected females should be identifiable at birth by their virilized genitalia. Affected males who have 21- or 11β-hydroxylase deficiency do not manifest recognizable penile enlargement or other virilization at birth but develop these symptoms postnatally if untreated. On the other hand, affected males with 3βHSD deficiency do have genital ambiguity at birth because of testosterone deficiency. Finally, all five enzyme deficiencies are clinically important because of the associated adrenal glucocorticoid deficiency (with or without mineralocorticoid deficiency). This condition is life threatening and must be recognized and managed early.

21-Hydroxylase Deficiency. 21-Hydroxylase enzyme deficiency is the most common cause of CAH, accounting for 95% of all cases. It is caused by a mutation in *CYP21A2*. Two classic forms are seen in neonates: a simple virilizing form caused by a partial enzyme deficiency and a salt-losing form caused by a more complete enzyme deficiency. A third form, late-onset or nonclassic 21-hydroxylase deficiency, represents a mild enzyme deficiency that does not have clinical manifestations in the fetus, neonate, or infant. Both of the classic forms are characterized by abnormal virilization of the female fetus. In simple virilizing CAH, salt wasting is mild and adrenal insufficiency does not tend to occur except in stressful circumstances. In salt-losing CAH, adrenal insufficiency is present at baseline and this tends to present in the neonatal period or soon thereafter as an adrenal crisis. Around 75% of all reported cases of CAH are salt wasting and 25% are not.[31] The incidence of the classic form estimated from data from 13 countries (United States, France, Italy, New Zealand, Japan, United Kingdom, Brazil, Switzerland, Sweden, Germany, Portugal, Canada, and Spain) is 1 in 15,000 live births, and the carrier frequency of classic CAH is about 1 in 60 individuals.[67] A deficiency of 21-hydroxylase results in an impairment of cortisol and aldosterone biosynthesis, which is compensated for by the increased secretion of ACTH and angiotensin. This process causes overproduction of the steroids before the enzyme block and a secondary increased secretion of adrenal androgens, which are converted to testosterone and DHT in peripheral tissues and cause abnormal virilization.

Affected fetuses produce increased amounts of androgens beginning in the first trimester. In the female fetus, this leads to varying degrees of virilization of the external genitalia and urogenital sinus. However, the internal genital ducts develop normally along female lines. At birth, the spectrum ranges from mild clitoromegaly, usually with some posterior labial fusion, to perineal or penile hypospadias, to occasionally complete male differentiation, with the urethra opening at the tip of a male-sized phallus; the latter phenotype may have a normal male appearance except for impalpable gonads that may be interpreted as bilateral cryptorchidism. The extent of virilization intends to reflect the severity of the enzyme defect. Females with simple virilizing CAH often display less extensive virilization than those with the salt-losing type. In males, the increased secretion of adrenal androgens is insignificant compared with the fetal production of testicular androgens. The external genitalia are usually normal at birth; some enlargement of the penis may occur, but it is rarely recognized as abnormal. Due to elevated circulating ACTH, female and male neonates may have increased pigmentation of the genitalia or areolae.

Simple Virilizing Form. Simple virilizing CAH is caused by a partial deficiency in the 21-hydroxylase enzyme.

Patients with untreated, simple virilizing 21-hydroxylase deficiency continue to produce excess androgens postnatally, resulting in accelerated growth and skeletal maturation as well as the signs of adrenarche. Patients with mild CAH generally do not develop symptoms of adrenal insufficiency unless they are exposed to major stress or significant salt depletion (reduced salt intake, vomiting, excessive sweating). A few patients with either form have received medical attention because of recurrent hypoglycemic episodes or seizures, usually occurring during common infections.

Salt-Wasting Form. Salt-wasting CAH is caused by a severe deficiency of the 21-hydroxylase enzyme that results in significant impairment of cortisol and aldosterone synthesis that cannot be compensated for by the increased levels of ACTH and angiotensin. The development of cortisol and aldosterone deficiency, usually in the first weeks of life, results in acute adrenal insufficiency and sodium wasting. Females with salt-losing CAH may show more complete masculinization of the external genitalia, and some are incorrectly identified as males at birth (see Fig. 89.16). If not identified by a newborn screening program, males generally present to medical attention when they develop a salt-losing crisis caused by adrenal insufficiency. The symptoms or signs of adrenal insufficiency are not present at birth and rarely occur before 3-4 days of age. About half of the untreated patients with salt-losing CAH develop adrenal crisis between 6 and 14 days of age; by 1 month of age, more than 75% have developed adrenal crisis. Less severely affected individuals may present later, at several months of age, usually in association with a stressful condition causing decreased salt intake or increased salt losses, and a few escape crisis entirely. The early symptoms and signs of adrenal crisis are nonspecific and include lethargy, poor appetite, regurgitation of feeds, failure to thrive, and weight loss. Hyperkalemia, hyponatremia, and metabolic acidosis may be seen early. The regurgitation of feedings may progress to projectile vomiting. Severe symptoms and signs may occur within 1-2 days, including dehydration (with accompanying azotemia), hypotension, muscle weakness, obtundation, a gray or cyanotic appearance, cold and clammy skin, hyperkalemic cardiac conduction abnormalities, and hyponatremic or hypoglycemic seizures.

The development of acute adrenal crisis is partially caused by hypoaldosteronism, which results in renal sodium wasting with depletion of total-body sodium content and an impaired ability to secrete potassium and hydrogen ions at the distal tubule. The decreased total-body sodium results in hyponatremia, hypovolemia, and decreased tissue perfusion, which account for many of the early symptoms and, eventually, results in hypovolemic shock.

Hypocortisolemia represents the other major component of adrenal insufficiency leading to impairment of cardiovascular, metabolic, and other systemic functions. The cardiovascular manifestations of glucocorticoid deficiency include decreased stroke volume and cardiac output and decreased peripheral vascular tone, resulting in decreased blood pressure. Depletion of the renin substrate occurs in the presence of cortisol deficiency and impairs the renin–angiotensin axis, contributing to circulatory failure. Norepinephrine acts in a cortisol-dependent manner to increase peripheral blood pressure, demonstrating another mechanism to protect hemodynamic stability that is impaired in the setting of cortisol deficiency. Cortisol sensitizes the renal-collecting tubules to vasopressin and, consequently, hypovolemia is further exacerbated by the urine concentration defect that results from adrenal insufficiency.

Cortisol plays a role in several elements of glucose homeostasis. It stimulates hepatic glucose production by inducing the activity of gluconeogenic enzymes. Cortisol also stimulates mobilization of hepatic glycogen stores via its permissive effects on glucagon and epinephrine mediated glycogenolysis. As a result, cortisol deficiency can lead to hypoglycemia during times of prolonged fasting. In the setting of impaired glucose production and mobilization, fat becomes the primary energy source, which may lead to lipid depletion.

Hormonal Abnormalities. Serum cortisol is normal or low with an inadequate rise in response to ACTH administration. Adrenocorticotropic hormone levels in untreated patients with either form of CAH are elevated. Plasma renin activity is also elevated, especially in salt-losing CAH.

Of the steroids preceding the enzyme block, 17-OHP is the most strikingly elevated. Serum concentrations are increased 40-400 times above the upper limit of normal and occasionally higher. Androstenedione can be up to 40 times higher than the normal limit. About 15% of the androstenedione produced is metabolized in peripheral tissues to testosterone, with the adrenals synthesizing very little testosterone. Serum testosterone levels in affected children can be elevated by 20 times the normal range.

Diagnosis. The diagnosis of 21-hydroxylase deficiency in a neonate or infant should be considered in females with any masculinization of the external genitalia, in presumed males with impalpable gonads (including males with hypospadias), in females or males who develop symptoms or signs of adrenal insufficiency or crisis (females should be recognized by their genital abnormalities), and in those who have a family history of CAH or an unexplained death in infancy. For 21-hydroxylase deficiency, the most useful diagnostic test is the determination of an increased level of serum 17-OHP (>80 times higher than normal in a full-term infant). The diagnosis of the salt-losing form of CAH is based on obtaining clinical or biochemical evidence of sodium wasting. High urinary sodium concentrations in the presence of normal or low serum sodium concentrations may indicate a salt-wasting infant. The measurement of aldosterone in the untreated state is not diagnostically useful because of the overlap with levels seen in untreated patients with simple virilizing CAH.[53] Patients with mild, salt-losing CAH may show normal electrolytes and lack

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

the clinical signs of hypovolemia. In this case, the diagnosis is made biochemically by finding an increased level of plasma renin activity during physiologic glucocorticoid replacement therapy, indicating that mineralocorticoid replacement is required. In response to administration of synthetic ACTH (Cortrosyn, 35 μg/kg to a maximum of 250 μg intravenously), pre- and post-17-OHP levels can be plotted on a nomogram to predict the genotype.[77] Confirmatory genetic testing can also be pursued. While plasma ACTH and serum cortisol are useful for demonstrating and investigating adrenal insufficiency, they do not contribute to defining the enzyme defect of CAH.[76]

Newborn Screening. Many jurisdictions have newborn screening programs that include the measurement of 17-OHP and allow for early identification of infants with 21-hydroxylase deficiency. The justification lies in the increased mortality that occurs in infants who are not recognized at birth and die of salt-losing crisis or sudden infant death as well as the increased morbidity that results from adrenal insufficiency, incorrect gender assignment, and premature virilization.[107] Caution is needed in interpreting 17-OHP values on newborn screening tests, as the levels in unaffected full-term neonates may be elevated in the first 12 hours of life before declining to the normal range after 24 hours of age. Levels in premature and sick neonates may overlap with those found in many affected infants in the first few days of life.[94] Many jurisdictions with newborn screening programs have cutoff values that are adjusted according to gestational age or weight, or both. False-positive results are usually associated with prematurity (presumably caused by decreased metabolic clearance of 17-OHP), low birth weight and, less often, serious illness (presumably due to increased 17-OHP production associated with stress). Age less than 24 hours (fetoplacental contribution of 17-OHP) or technical problems are additional reasons for false positive newborn screen results. Although antenatal exposure to corticosteroids has been shown to have variable effects on 17-OHP levels, infants treated with these agents should still undergo newborn screening, with repeat screening at several days of life.[107]

The overall incidence of 21-hydroxylase deficiency in screened neonates is about 1 in 15,000, ranging from 1 in 11,000 to 1 in 21,000 for most programs. As expected, the male-to-female ratio is about 1:1 with salt losers making up about 72% of confirmed cases. Although females identified by screening often have variable masculinization of the external genitalia, one-third to one-half were missed clinically, including some inappropriately assigned a male gender. Identification at 5-21 days of age has prevented adrenal crises in many affected but unrecognized neonates, particularly male infants in whom clinical signs may not be apparent at birth. However, a negative newborn screening result does not necessarily rule out the diagnosis of classical CAH. A false-negative rate of 22% on CAH newborn screening has been recently reported. The missed cases included both simple virilizing and salt-wasting types in male and female neonates. This report emphasizes that diagnostic testing for CAH should be pursued when clinically suspected, even in the context of a negative newborn screen result.[92]

Ultrasonography. An experienced pediatric radiologist reading an adrenal ultrasound can identify enlargement and lobulation of the adrenal glands with stippled echogenicity, findings consistent with CAH. Adrenal ultrasonography has been shown to have a sensitivity of 92% and a specificity of 100% for diagnosing CAH.[4]

Treatment. The goals of the treatment of CAH are to normalize ACTH secretion, thereby lowering ACTH-stimulated precursor steroids and their side products, and to provide replacement or correction of end-product (cortisol, aldosterone, gonadal sex steroid) deficiencies. Due to the interconnectedness of the synthetic pathways for glucocorticoids, mineralocorticoids, and sex steroids, these two goals are closely related. Insufficient replacement permits increased ACTH and sodium wasting while excessive replacement produces a cushingoid state, growth suppression, and hypertension.

In the simple virilizing form of 21-hydroxylase deficiency, normalization of ACTH requires only cortisol replacement. The adequacy of cortisol replacement is reflected by serum 17-OHP and androstenedione levels, with a goal of maintaining values mildly above the range for age. The addition of mineralocorticoid therapy may decrease the amount of cortisol that is needed. In the salt-losing form of 21-hydroxylase deficiency, normalization of ACTH requires the correction of sodium wasting and hypovolemia in addition to the replacement of cortisol. Increased levels indicate the presence of hypovolemia caused by sodium wasting and mineralocorticoid deficiency, while subnormal levels indicate sodium retention caused by excessive mineralocorticoid replacement.

Maintenance glucocorticoid requirements must take into consideration differences in potency, absorption, and duration of action among the available preparations. Hydrocortisone is the oral preparation of choice. Oral replacement dose in CAH usually ranges from 10-15 mg/m^2 per day, given in three divided doses.[108]

Increases in the dose of hydrocortisone (or other glucocorticoid) should be made during periods of stress, with doubling or tripling of the dose during moderate and severe illnesses. Major illnesses, surgery, or trauma should be covered by the intramuscular or intravenous administration of hydrocortisone at three to six times the maintenance dose to avoid adrenal crisis (Table 89.8).[108] For infants who require maintenance mineralocorticoid replacement therapy, 9α-fludrocortisone acetate (florinef acetate) at a dose of 0.05-0.2 mg daily is administered orally in one or two divided doses. A salt supplement such as sodium chloride oral solution at 0.5-5 mmol/kg per day divided in four to six doses is usually required during the first 6-12 months.[108] Measurements of blood pressure and the level of plasma renin activity are used to adjust the mineralocorticoid dosage and sodium supplementation. Unlike hydrocortisone or other glucocorticoids, the dose of florinef acetate does not change with increases in body size or during stress. As infancy progresses, mineralocorticoid requirements diminish; salt supplementation should be

TABLE 89.8 Treatment Guidelines for Neonate With Salt-Wasting Congenital Adrenal Hyperplasia (CAH)

Glucocorticoids: hydrocortisone	Maintenance: 12-20 mg/m^2 per day PO divided three times a day Stress dosing: Acute illness with stable hemodynamics: 40 mg/m^2 per day PO/IV/IM divided q 6-8 h Severe stress, such as major surgery or sepsis, or if hemodynamically unstable: 100 mg/m^2 (or 25 mg) IV/IM STAT once, then 25 mg/m^2/dose q 6 h for 24-48 h. Assess the need for ongoing stress dosing as per clinical status General anesthesia (either for surgery or procedure): 50 mg/m^2 IV/IM once 30-60 minutes before anesthesia induction
Mineralocorticoids: fludrocortisone	0.05-0.2 mg/day PO once or twice daily
Sodium chloride	0.5-5 mmol/kg per day divided in 4-6 doses as tolerated

discontinued, and the dose of florinef acetate may need to be lowered.

In acute salt-losing adrenal crises, fluid replacement (beginning with 20 mL/kg of body weight of 0.9% saline), sodium replacement, continuous glucose infusion, glucocorticoid therapy at 50-100 mg/m^2 (initially given intravenously as the phosphate or succinate ester of hydrocortisone), and mineralocorticoid replacement (at maintenance doses) are needed. Acidosis, hypoglycemia, and hyperkalemia may be present and should be managed, and the patient should be monitored for signs and symptoms of severe hyperkalemia. In patients stable enough for diagnostic testing, glucocorticoid therapy may be withheld until the tests are completed. However, glucocorticoids should be administered if blood pressure or other functions are not correctable with fluid, saline, glucose, and mineralocorticoid replacement.

Gender Assignment. (See subsection Gender Assignment in Newborns for a full discussion.) Here we discuss gender assignment issues specific to CAH. Female gender assignment is usually recommended in 46,XX CAH individuals regardless of the extent of masculinization of their genitalia, apart from those with complete virilization where either sex of rearing is considered. This recommendation is based on the observation that these patients have normal ovaries and Müllerian structures and have the potential for fertility as females and typically have a female gender identity. Surgical correction and its timing in females with masculinized external genitalia are controversial. If done, it is usually performed when a reasonable body size has been achieved, commonly in the first 2-6 months, but may be deferred until the patient can participate in decisions about surgery. Gender identity in girls with CAH is not related to the degree of genital virilization or the age at which genital reconstructive surgery was done.[69] Females with CAH have been shown to have more cross-gender role behaviors, such as more masculine play preferences and styles.[73] Lower rates of heterosexual orientation, marriage, and fertility have been reported, and although most identify as female, girls with CAH have an increased cross-gender identity compared to girls without CAH.[69,85,86]

Genetics. 21-hydroxylase deficiency is inherited as an autosomal recessive disorder. Molecular genetic studies show that two 21-hydroxylase genes are present on each chromosome 6. The first gene is nonfunctional (a pseudogene) and only the second one is functional. These two genes are named *CYP21P* and *CYP21*, respectively.

Diverse mutational abnormalities of the *CYP21* gene have been described for 21-hydroxylase deficiency, including point mutations, gene conversions (transfer of an abnormal sequence from the pseudogene to the active gene), and deletions. Point mutations and small-gene conversions represent most *CYP21* mutations. They may have mild or severe consequences, affecting messenger RNA stability, structural conformation, and enzyme function. Gene deletions and large-gene conversions account for the remaining *CYP21* changes, which usually result in defective or absent messenger RNA. More recently, intronic mutations affecting splice sites have been identified.[24] Patients with salt wasting have the most deleterious mutations and almost no residual enzyme activity, although there is overlap among phenotype–genotype correlations.[35] Genotyping to identify the mutation is available.[112]

Prenatal Diagnosis and Treatment. Prenatal diagnosis is available for pregnancies at risk of having a 21-hydroxylase CAH affected baby. A gene-specific diagnosis in utero can be made on fetal cells obtained by chorionic villus sampling or amniotic fluid analysis.[47]

There is general consensus that prenatal dexamethasone is effective, with a success rate of 80%-85%, in preventing or minimizing the virilization seen in classical 21-hydroxylase CAH affected female infants. However, prenatal therapy with dexamethasone remains controversial. To reduce or eliminate the masculinization of female fetus external genitalia, dexamethasone needs to be administered at a sufficient dose to suppress fetal ACTH and hence androgen production. As the genetic diagnosis cannot be made until 10-12 weeks, which is after virilization has already begun, all pregnancies at risk for CAH are treated empirically with dexamethasone from the time pregnancy is confirmed and preferably before 9 weeks of gestation. Treatment is discontinued once the genetic results confirm either a male fetal karyotype and or unaffected female fetus. The mother of the affected female fetus continues with treatment until delivery. With this approach, seven out of eight fetuses (boys and unaffected girls) are treated unnecessarily. Recent genetic advances have allowed for the determination of fetal sex by quantitative polymerase chain reaction of fetal Y-chromosomal DNA obtained directly from maternal blood. Such an approach can improve the probability of treating affected female fetuses from 1 in 8 to 1 in 4 by

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

eliminating the unnecessary treatment of male fetuses. Additionally, the presence of single nucleotide polymorphisms related to a disease-causing *CYP21* allele from a paternal carrier in a maternal serum sample has been used for prenatal genetic diagnosis. The use of targeted massive parallel sequencing of maternal cell-free fetal DNA has also been used to successfully determine the allelic composition of the fetal *CYP21* locus. At this point, these tests are not routinely available.[34,47,48]

There is accumulating evidence from animal studies and follow-up data on cohorts of children exposed to prenatal dexamethasone that have raised concern about potential neurocognitive adverse effects.[41] These findings indicate that long-term follow-up of this group of patients is of extreme importance.

Based on the limited data on the long-term neurocognitive outcomes in children exposed to dexamethasone prenatally, the Endocrine Society's task force concluded that such treatment should be considered experimental and that parents should be informed of potential risks and benefits of this treatment. If parents choose to pursue prenatal treatment, it should be done through a protocol approved by a research ethics review board at a designated center.[108]

11β-Hydroxylase Deficiency (Hypertensive Congenital Adrenal Hyperplasia). 11β-Hydroxylase (CYP11B) deficiency is the second most common form of CAH, accounting for about 0.2%-8% of all cases. The deficiency results in impaired synthesis of cortisol and aldosterone, virilization of the female fetus from increased androgens, and low-renin hypertension caused by overproduction of deoxycorticosterone (DOC), a moderately potent mineralocorticoid. The clinical presentation of this form of CAH is variable, and not all patients develop hypertension. Classically, females are born with virilization ranging from clitoral enlargement to extensive masculinization of the external genitalia, which may lead to incorrect gender assignment. There may be hyperpigmentation of the genitalia and the areolae. Sodium retention and volume-induced hypertension develop in 50%-80% of the classic cases. Severe hypertension may occur as early as the first 4 days of life, but more often blood pressure is normal in neonates. The relative severities of the hypertension, virilization, and biochemical findings do not always correlate. Serum sodium levels tend to be in the upper-normal range or minimally elevated, but hypokalemia is inconsistently present.

Unlike the classic presentations, some affected and untreated neonates present with salt wasting, which may lead to diagnostic confusion with 21-hydroxylase deficiency. The cause of their salt-losing conditions is unclear, but possibilities include a combination of physiologic renal immaturity of sodium reabsorption, more severe aldosterone deficiency and less potent DOC, and the presence of precursor steroids with mineralocorticoid antagonist properties from the fetal adrenal glands. Salt wasting often resolves spontaneously later in life and is rarely clinically significant.

The diagnosis 11β-hydroxylase deficiency is supported by the finding of increased levels of serum 11-deoxycortisol and DOC, demonstrating their suppressibility with glucocorticoid replacement, and ACTH stimulation testing showing elevation in 11-deoxycortisol. This is an autosomal recessive condition, and two 11β-hydroxylase genes have been identified. Both genes are located on the long arm of chromosome eight and are linked, showing greater than 90% sequence homology. The *CYP11B1* gene is responsible for 11β-hydroxylase deficiency, and the *CYP11B2* gene encodes for aldosterone synthase. Prenatal diagnosis by genotyping of the *CYP11B1* gene by chorionic villus sampling is available.[18]

Treatment with hydrocortisone corrects the excessive production of DOC and androgens. Decreased DOC formation leads to the correction of hypertension in most affected patients. Glucocorticoid therapy is adjusted based on the patient's growth, blood pressure, and levels of serum 11-deoxycortisol, DOC, androstenedione, and plasma renin activity. The gender is usually assigned in agreement with the gonadal sex, because normal sexual function and fertility can be attained. Glucocorticoid stress dosing is required, as in 21-hydroxylase CAH. Salt-wasting precipitated by stress dose glucocorticoids has been reported and is thought to be secondary to the suppressed ACTH leading to decreased production of DOC. Sodium supplementation and mineralocorticoid replacement may be required in these circumstances.[18]

3β-Hydroxysteroid Dehydrogenase Deficiency. Similar to the affected males, 3β-hydroxysteroid dehydrogenase deficiency in female infants results in defective production of cortisol, mineralocorticoid, and sex hormones with accumulation of DHEA. Besides salt wasting and adrenal insufficiency, female infants with this form of CAH may present with variable degrees of virilization at birth caused by conversion of DHEA to a more potent androgen by 3βHSD type 1, present in the liver, skin, and other tissues. Biochemical abnormalities, diagnosis, and treatment are similar to the 46,XY male with the same disorder. For details, please refer to the section Androgen Biosynthesis Defect, subsection 3β-Hydroxysteroid Dehydrogenase Deficiency.[83]

P450 Oxidoreductase Deficiency. P450 oxidoreductase (POR) enzyme deficiency was discussed earlier as part of androgen biosynthesis defect in 46,XY DSD. Depending on the type of the mutation and the extent of enzyme deficiencies, a 46,XX female fetus may present with a variable degree of salt wasting, adrenal insufficiency, and virilization. Treatment depends on the symptoms and hormone profile, with glucocorticoid being the mainstay of replacement therapy.[93]

Placental Aromatase (CYP19) Deficiency

Placental–fetal aromatase (*CYP19*) is a cytochrome P450 enzyme that is necessary for the conversion of fetal androgens to estrogen. Placental aromatase deficiency is a rare autosomal recessive disorder that can result in variable degree of maternal and female fetus virilization. There is wide phenotypic variation observed, owing to mutations in *CYP19*.[62]

Maternally Derived Androgenic Substances

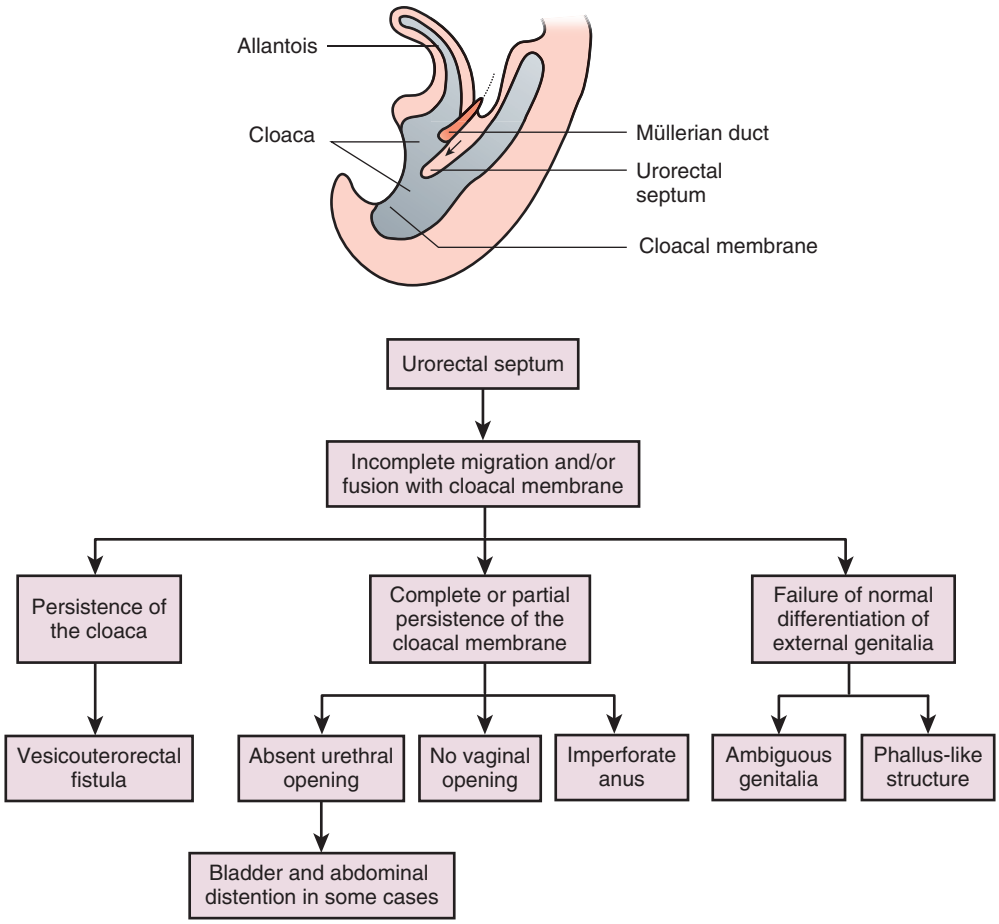
Masculinization of the female fetus occasionally occurs from exposure to androgens or certain other agents derived from the maternal circulation. The extent of masculinization is related to the compound, dosage, duration, and timing of exposure. Exposure at 8-14 weeks of gestation may result in midline fusion of the labioscrotal folds or opening of the vagina and urethra into a common urogenital sinus. Exposure beginning after 12-14 weeks results in only clitoromegaly and hypertrophy of the labia majora, but no midline fusion and no development of a urogenital sinus. Maternally derived androgens do not usually stimulate wolffian duct development, and the Müllerian duct structures and bilateral ovaries develop normally in the absence of AMH. A considerable number of female fetuses do not undergo masculinization because the placenta aromatizes most maternal androgens to estrogen before they cross over to the fetus. Additionally, high maternal levels of sex hormone binding globulin favors the concentration of these androgens on the maternal side.

Maternal androgens may be of ovarian, adrenal, or exogenous origin. The Krukenberg tumor and luteoma of pregnancy cause increased androgen production.[19,103] Maternal androgen-secreting tumors of the ovary rarely occur in pregnancy. Several cases of maternal adrenocortical tumor are reported; maternal virilization in some has been mild compared to the degree of virilization seen in the neonate.[74] Other cases of 46,XX DSD have been reported in association with maternal CAH and maternal polycystic ovarian disease. The measurement of maternal serum levels of testosterone and DHEA or its sulfate is diagnostically useful even in the absence of maternal virilization. Maternal ingestion of synthetic progestins and androgens may cause abnormal masculinization of the female fetus. In the male fetus, progestin exposure at 8-14 weeks of gestation may result in hypospadias. Because these medications are often used in only part of the pregnancy, the extent of clitoral enlargement, urethral displacement, and labioscrotal fusion are often discordant, contrasting with other causes of 46,XX DSD. Maternal androgenization is usually not apparent.

The masculinization of females that occurs with in utero exposure to androgen or other drugs does not progress postnatally. Biochemical studies of the neonate show normal levels of androgens or their metabolites and of 17-OHP. Mild clitoromegaly may not need to be corrected, because the clitoris will become less prominent as the body size increases.

Other

Dysgenesis of External Genital Primordia



On rare occasions, the external genitalia of a 46,XX fetus may have a masculinized appearance because of an error in morphogenesis occurring at 4-7 weeks of fetal age rather than abnormal androgen exposure at 8-12 weeks. The formation of the urorectal septum and differentiation of the cloacal membrane into the urogenital and anal membranes, followed by their breakdown into the urogenital sinus and anus, are critical for the development of the indifferent external genitalia at 7 weeks as well as for the lower genital, urinary, and intestinal tracts. In cloacal dysgenesis (Fig. 89.17), a small phallus-like structure develops from the genital tubercle (there is variable formation of a phallic urethra and corpora tissue), and the labioscrotal swellings may or may not develop. The absence of a urogenital groove makes for a more male-appearing perineum. Associated abnormalities include an imperforate anus, the absence of urethral and vaginal outlets (unless a phallic urethra forms), and urinary tract and Müllerian (uterine and vaginal) anomalies, which are usually not found in traditional forms of 46,XX DSD. The ovaries are usually normal. These abnormalities may be seen in the VATER/VACTERL association (*v*ertebral abnormalities, *a*nal atresia, *t*racheoesophageal fistula with *e*sophageal atresia, *r*adial and renal dysplasia). Pulmonary hypoplasia is often an associated condition and obstructive uropathy may infrequently be associated with Eagle-Barrett (prune-belly) syndrome. Less severe clinical forms are reportedly associated with a small phallus, partial vaginal outlet obstruction, and other urinary and genital tract anomalies.

Müllerian and Vaginal Dysgenesis

There is a frequent association of abnormal to absent Müllerian duct structures with vaginal agenesis in 46,XX females with normal ovaries known as Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome. Mayer-Rokitansky-Küster-Hauser syndrome is further classified as either type 1/Rokitansky sequence (isolated) or type II/MURCS association (Müllerian duct aplasia, renal dysplasia, and cervical somite anomalies). It is sometimes also referred to as CAUV (congenital absence of the uterus and vagina), MA (Müllerian aplasia), or GRES (genital renal ear syndrome).[23] The underlying pathophysiology is likely related to a disturbance in mesodermal organization partially involving the formation of the caudal segments of the Müllerian ducts in the 4th and 5th weeks of embryogenesis. Possible etiologies include teratogens and pleiotropic genetic etiologies. The differential diagnosis includes cAIS. An examination to determine the presence or absence of a vaginal orifice (absent in this disorder), the occasional occurrence of hydrometra, and the presence of somatic abnormalities helps to identify affected neonates. About 70% of female patients with unilateral renal agenesis have ipsilateral Müllerian duct abnormalities.[23]

Mayer-Rokitansky-Küster-Hauser syndrome is caused by a heterozygous mutation in *WNT4*. The *WNT4* gene is important in the development and maintenance of Müllerian duct formation and ovarian steroidogenesis. A homozygous missense mutation in *WNT4* was described in SERKAL syndrome, in which some individuals with 46,XX testicular or ovotesticular DSD have been found to have male or undervirilized male genitalia, along with dysgenesis of the kidneys, adrenal glands, and lungs.[23,80]

• **Fig. 89.17** Diagram showing proposed mechanism for urorectal septum malformation sequence. The resulting cloacal dysgenesis leads to malformation of the external genital primordia and other accompanying abnormalities. In the affected 46,XX fetus, the genital tubercle (between the cloaca and allantois) forms a small phallus-like structure. This development, coupled with the failure to form a urogenital groove, produces ambiguous or male-appearing external genitalia. (From Escobar LF, et al. Urorectal septum malformation sequence: report of six cases and embryological analysis. *Am J Dis Child.* 1987;141:1021.)

Common Presenting Problems

Hypospadias

Hypospadias is the second most common genital abnormality after cryptorchidism in male newborns. Estimated prevalence rates vary worldwide and range from 0.6-34.8 cases per 10,000 live births.[98] It results from incomplete fusion of urethral folds between the 7th and 14th week of gestation. Severity is graded based on the anatomic location of the meatus. In mild cases, the meatus opens on the ventral surface of the glans, corona, or upper penile shaft, and in severe cases, on the lower shaft, penoscrotal junction, or perineum (see Fig. 89.10). About 60% of cases are glandular or coronal, 20% penile, and 13% penoscrotal or perineal.[101]

Most cases of hypospadias are isolated with presumed multifactorial etiologies. A small percentage of severe hypospadias can be attributed to genetic syndromes or defects involving the androgen receptors. Hypospadias is equally transmitted from maternal and paternal sides of a family and has an overall heritability of 57%-77%. About 7% of cases have a family history, with a first-, second-, or third-degree relative having hypospadias. The sibling of an affected brother has an up to 17% chance of developing hypospadias.[101] A greater proportion of individuals with penoscrotal or perineal hypospadias have an affected relative compared to less severe forms. This familial tendency is thought to result from a polygenic mode of inheritance. *CXorf*, a gene on the X chromosome, has been identified as a causative gene for hypospadias.[36] Additional genes associated with hypospadias have been identified and studies investigating other candidate genes involved in male genital development are underway.[101] Mild hypospadias (glandular to penile) without other genital abnormalities or dysmorphic features is very unlikely to be associated with an identifiable endocrinopathy, disorder of sexual differentiation, or chromosomal abnormality. The risk of these conditions increases to about 15% in the setting of severe hypospadias (penoscrotal or perineal).

Newborns with hypospadias commonly have associated genital anomalies, including meatal stenosis, hydrocele, cryptorchidism (8%-10% of cases), and inguinal hernia

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

(8% of cases). More severe forms of hypospadias are often associated with a shawl scrotum or incompletely translocated labioscrotal folds and with a prostatic utricle. Patients with severe hypospadias, urinary tract symptoms, a family history of ureteral reflux, or multiple congenital anomalies are also more likely to have significant abnormalities and should have uroradiographic evaluation.

Rare causes of hypospadias include a deficiency in the potent androgen DHT caused by impaired conversion of testosterone to DHT via 5α-reductase deficiency, decreased function of the androgen receptor protein (pAIS), and maternal exposure to progestins; these conditions occur between 8 and 14 weeks of gestation. However, androgen production defects are not identified as an underlying etiology of hypospadias.[42] The differential diagnosis of hypospadias includes female neonates with CAH, other DSDs, various syndromes (e.g., Smith-Lemli-Opitz, Beckwith-Wiedemann), and unknown causes. A virilized female with CAH must be considered when evaluating hypospadias, as a missed diagnosis can be life threatening (see Fig. 89.17).

The evaluation of hypospadias in the newborn includes a history of possible maternal progestin or estrogen exposure as well as a family history of hypospadias, endocrine disorders, or DSD. Physical examination should evaluate stretched phallus length, urethral meatus location, chordee, and scrotal folds. Ultrasound can be used to determine the presence of gonads and a uterus, identify any anatomic renal abnormalities, and look for additional somatic abnormalities. If hypospadias is not associated with other abnormalities, diagnostic studies are usually not needed.

Micropenis

For a description of how to examine and interpret penis size please see the subsection Penis Size under Physical Examination. A micropenis is caused by a deficiency in the factors needed for normal penile growth to occur after 14 weeks of gestation, when formation of the urethra is complete. Important mediators of penile growth that have been implicated in micropenis are testosterone, DHT, and growth hormone. The major causes include hypopituitarism (LH deficiency with or without GH deficiency, 30%), primary hypogonadism (25%), pAIS (2%), and idiopathic or undiagnosed causes (43%). The association of a micropenis with early neonatal hypoglycemia (GH and ACTH-cortisol deficiencies), cryptorchidism (LH deficiency–see Fig. 89.8), persistent neonatal jaundice (hypothyroidism, ACTH-cortisol deficiency), or cleft palate should immediately raise the possibility of congenital hypopituitarism. Other congenital malformations (e.g., septo-optic dysplasia) and chromosomal abnormalities are occasionally seen along with hypospadias. Complete absence of the penis may rarely occur. The diagnostic evaluation of a micropenis includes the assessment of GH, testosterone, LH, and FSH status and consideration of testing for hypopituitarism. Karyotype may be considered if there is associated cryptorchidism or additional concerns with the appearance of the genitalia. An hCG stimulation test may be performed if testosterone levels are low to assess biosynthetic defects. A course of testosterone therapy to assess penile responsiveness may be administered to exclude significant androgen insensitivity. Testosterone therapy should be planned to normalize penis size and consequently promote a positive body image in childhood.

Cryptorchidism

Cryptorchidism, or testicular maldescent, is present when one or both testes have failed to descend completely into the scrotum, reaching a final position 4 cm or more below the pubic crest in full-term males weighing more than 2.5 kg. As this process occurs between 7 months gestation and several months postnatal age, most affected newborns are found to be normal when they are reevaluated. The incidence of cryptorchidism at birth is about 3.7% in full-term males and 21% in premature males, approaching 100% in the very premature. However, the postnatal completion of testicular descent is seen by 6 weeks in 50% and by 3 months of age in 67% of full-term cryptorchid males. 73% of premature cryptorchid males will have completed testicular descent by 3 months. A few additional individuals attain full descent by 6-9 months of age. The net result is that about 75% of full-term and 90% of premature cryptorchid newborns have full testicular descent by the age of 9 months without therapeutic intervention. Spontaneous testicular descent is very rare after 9 months of age. The incidence of cryptorchidism is about 1% at 1 year of age. In addition to prematurity and low birth weight, other factors associated with an increased incidence of cryptorchidism are birth by cesarean delivery and maternal obesity.

Testicular descent is a complex process involving hormonal, mechanical, and genetic factors.[16] Factors thought to affect descent include the gubernaculum, attachment of the epididymis to the testis, rising abdominal pressure, AMH, testosterone or DHT, the genitofemoral nerve, and possibly LH and FSH. Cryptorchidism frequently occurs with disorders of the hypothalamic-pituitary-testicular hormone axis, dysgenetic testes, and with anatomic defects of the epididymis and the abdominal wall. Cryptorchidism is seen with a higher incidence in patients with umbilical hernia (6%), gastroschisis (15%), omphalocele (33%), and Eagle-Barrett (prune-belly) syndrome (100%), in which intra-abdominal pressure may be important. It is also seen in individuals with meningomyelocele (25%), particularly when the defect is above L2, and in those with cerebral palsy (41%). True cryptorchidism is associated with lower LH and testosterone levels during the pituitary–testicular hormonal surge (mini puberty of infancy) that occurs between 1 and 3 months it is also seen frequently in association with hypopituitarism or hypogonadotropism, Prader-Willi syndrome, primary hypogonadism, and

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

androgen insensitivity. Cryptorchidism has been associated with persistent Müllerian duct syndrome, suggesting a role for AMH in this process.[32] An association is also seen with trisomies 13 and 18 and with Aarskog, Noonan, Robinow, Smith-Lemli-Opitz, and other syndromes. Familial cases are reported and cryptorchidism is found in 6.2% of the brothers and 1.5%-4% of the fathers of affected patients. The relative risk of developing cryptorchidism increases by 4-6 for the sons or brothers of individuals with cryptorchidism.[16]

Associated anomalies include an inguinal hernia in many patients, abnormal epididymal formation in 36%-66%, and hypospadias in about 3%. There are major upper urinary tract anomalies in about 3% of patients, but routine invasive diagnostic studies are not warranted. Complications of cryptorchidism include progressive histologic deterioration, with changes beginning after 6 months of age, impaired spermatogenesis, with a decrease in the number of germ cells after the first year of life (and later reduced fertility potential), a 4- to 10-fold risk of cancer in both the undescended and contralateral testis (in unilateral cases), trauma to the testis that is relatively fixed in position, testicular torsion, symptomatic inguinal hernia, and psychological concerns related to altered body image. An associated inguinal hernia may require repair in early infancy if it is large enough to permit the abdominal contents to enter or if it causes symptoms.

If both testes are impalpable, the differential diagnosis includes an XX female with CAH or other severe virilizing disorder, anorchia, which occurs in 1% of bilaterally cryptorchid patients, and intra-abdominal testes, which are either normal (as in persistent Müllerian duct syndrome) or dysgenetic (as in mixed gonadal dysgenesis or testicular dysgenesis). The evaluation of the infant with impalpable testes includes the determination sex chromosomes and 17-OHP. Hormone studies, including basal hormones levels (LH, FSH, and testosterone between 2 weeks and 3 months of age) and the response of testosterone to hCG, may provide information about Leydig cell function. The measurement of AMH, ultrasound, magnetic resonance imaging, and laparoscopy have been useful in locating intra-abdominal testes, but laparotomy with exploration to the ends of the spermatic blood vessels is definitive in cases that are not otherwise resolved. The presence of wolffian structures suggests that torsion, vascular accident, or other late in utero degeneration has occurred. Alternatively, a dysgenetic testis may be present. Parental counseling should be undertaken in anticipation of this likelihood.

Because of the early appearance of histologic changes in the cryptorchid testis and findings that early treatment improves the histologic outcome, the correction of cryptorchidism is recommended between 6 and 12 months of age or as soon as possible after diagnosis, if that occurs later.[99] Because spontaneous descent may occur up to 6-9 months of age, treatment before that time is not indicated unless the testis is ectopic or has other associated abnormalities. Orchidopexy is optimally performed by an experienced surgeon, because the risk for subsequent loss of the testis is high. Hormonal treatment with gonadotropin-releasing hormone is no longer recommended because of its poor efficacy and potentially serious side effects.[16]

• BOX 89.4 Causes of Clitoromegaly in the Neonate

Corpora Cavernosa of Normal Size

- Normal variation such as prominent clitoral hood or infant who is small for gestational age
- Swelling, edema, or both caused by bruising (e.g., breech presentation)

Corpora Cavernosa Enlarged Because of Androgen Stimulation

- 46,XX DSD, particularly 21-hydroxylase deficiency
- 46,XY DSD
- Gonadal dysgenesis, dysgenetic testes
- Ovotesticular disorder of sex development
- Tumor infiltration of clitoris (neurofibromatosis, lymphoma)

Clitoromegaly

For a description of how to examine clitoral size, see the subsection Clitoris Size under Physical Examination. Clitoromegaly is defined as the appearance of clitoral enlargement regardless of cause. The clitoris may be prominent (protruding from between the labia majora), swollen, widened, or elongated. The causes are listed in Box 89.4. The clitoris must be measured to determine whether the paired corpora cavernosa are abnormally enlarged and to rule out the extremely rare finding of a tumor. More commonly, the corpora cavernosa are of normal size and have no evidence of a tumor, making clitoromegaly a benign finding. No further diagnostic evaluation is necessary, and the parents should be reassured that their newborn girl is normal. If the corpora cavernosa are enlarged, a DSD is more likely, and an evaluation should be performed. Assessment should include other signs of androgenization or incomplete masculinization (posterior labial fusion, ventral placement of the urethra, or hypospadias), determination of whether the gonads are palpable, identification of internal genitalia (uterus), and measurement of androgens and 17-OH progesterone levels. A karyotype may also be warranted.

Acknowledgments

The authors would like to acknowledge the contributions of Drs. Mark Palmert, Rayzel Shulman, Sareea Al Remeithi, and William Dahms, who were authors of the chapter in previous editions.

Key Points

- There are four major components of sexual differentiation: chromosomes, gonads, internal genitalia, and external genitalia.
- Normal male differentiation requires (1) the actions of many genes that support testicular development, (2) normal local secretion of testosterone and AMH to ensure normal internal genital formation and (3) conversion of testosterone to dihydrotestosterone and normal androgen action for external genital formation.
- Normal female internal and external genital development occurs in the absence of androgen and AMH, but normal ovarian development requires actions of a number of genes.
- A careful physical exam can provide significant clues into the diagnosis of a child with a suspected disorder of sex development.
- First line investigations include karyotype and pelvic/abdominal ultrasound. Further investigations are guided by the karyotype and ultrasound results.
- Infants with significant genital ambiguity should be referred to a center with a DSD team that includes endocrinology, genetics, urology, and expert psychosocial support.

Inborn Errors of Metabolism

LAURA L. KONCZAL AND ARTHUR B. ZINN

The main problems facing the physician caring for a sick newborn infant are to know when to consider the possibility of a metabolic disorder, what to do to determine quickly and efficiently whether a child has a metabolic disease, and how to treat the patient until a diagnosis is established.[16,60] A listing of strategic clinical and laboratory findings characteristic of inborn errors of metabolism are presented. The differential diagnosis for these findings, and recommendations for further diagnostic testing to reach a tentative diagnosis, is provided. After a tentative diagnosis is reached, several reference sources can provide appropriate information about specific diseases.[2,102,103]

Two ongoing, complementary approaches to providing medical care for neonates with inborn errors of metabolism are (1) prospective care of the healthy newborn infant, and (2) reactive care of the clinically abnormal newborn infant. Prospective care seeks to identify neonates who have a specific metabolic disorder before clinical manifestations of that disorder develop. The aim of the prospective approach is to prevent the morbidity or mortality that often occurs in the period before recognition, diagnosis, and initiation of therapy for what might be a preventable or treatable disease. The reactive approach aims to arrest or minimize the sequelae of the disease state after the affected child shows recognizable symptoms or signs or becomes ill.

This chapter outlines several common misconceptions about inborn errors of metabolism, addresses prospective recognition of inborn errors, including newborn screening programs, and discusses reactive recognition and care of the abnormal newborn infant. In 1983, the US Orphan Drug Act was passed and has generated new therapies for inborn errors of metabolism.[122]

Common Misconceptions

Metabolic diseases of infancy are a difficult subject for many physicians and other medical professionals caring for newborns. Several misconceptions contribute to this difficulty. Eight of these misconceptions are stated in the following. These misconceptions are expressed in an exaggerated, tongue-in-cheek way to emphasize that, on reflection, most physicians would not acknowledge that these ideas are true. Nevertheless, experience suggests that in the intense atmosphere generated in response to the sick neonate, these misconceptions often influence the care of the child with an inborn error of metabolism.

Misconception 1

Inherited metabolic diseases are rarely a cause of disease in the neonate and should, therefore, be considered diagnostically as a last resort.

Although individual metabolic diseases are relatively rare, inherited metabolic diseases collectively represent a more common cause of disease in the neonatal period. The estimated incidence in the general population of inherited metabolic diseases varies by more than an order of magnitude, ranging from 1 case per 10,000 live births for phenylketonuria (PKU) to 1 case per 200,000 for homocystinuria. About 100 inherited metabolic disorders are identifiable in the neonatal period.

Assuming that most of these disorders have an incidence closer to the lowest incidence rather than the highest, the overall incidence of metabolic disease is about 1 case per 2000 persons. Newborn screening programs have found an incidence of approximately 1 in 4000 for a subset of these diseases. There is good reason to believe that this estimate of the incidence of metabolic disease in neonates is an underestimate, because many metabolic diseases are underdiagnosed and many diseases are yet to be identified.

Misconception 2

The possibility of a genetic metabolic disease should be considered only when there is a family history of the disease.

Most neonates with an inborn error of metabolism do not have a similarly affected sibling or relative.

The reasons for this pattern follow from the rules of Mendelian inheritance. Most inborn errors of metabolism are inherited as autosomal recessive traits, for which the odds are 3:1 in each pregnancy that two heterozygous parents will have an unaffected child. Small family sizes in developed countries make it unlikely to see two affected offspring in a sibship. In a family of two siblings, the odds are about 6% that both siblings will have the disease. In a family of three children, the odds are about 14% that two

Abstract

This chapter provides an overview of inborn errors of metabolism that manifest in the neonatal period. It discusses the principles, techniques, and disorders identified by newborn screening programs, along with recommendations for follow-up of patients with an abnormal screening result. This discussion is followed by a presentation of the abnormal clinical features and laboratory features, which suggest that a newborn might have, and should be evaluated for, a possible inborn error of metabolism. The abnormal clinical features that are discussed include encephalopathy and/or seizures, cardiomyopathy, eye abnormalities, hepatic dysfunction and/or hepatomegaly, hair and skin abnormalities, hematologic abnormalities, sepsis, unusual odor, and dysmorphism. A differential diagnosis for each of these abnormal clinical features is provided, followed by recommendations for further laboratory evaluation. The laboratory evaluation should begin with routine tests that have a rapid turn-around time and provide results that guide the choice of more specialized laboratory testing. The principles and interpretation of selected biochemical tests that are used in this evaluation are provided. Diagnostic algorithms for evaluating four key laboratory phenotypes—metabolic acidosis, lactic acidemia, hypoglycemia, and hyperammonemia—are presented in detail. The chapter closes with an overview of the treatment strategies available for inborn errors of metabolism.

Keywords

inborn errors of metabolism
metabolic disease of the newborn
neonatal metabolic disease
newborn screening

of the three siblings will be affected and about 2% that all three siblings will be affected.

There often is no forewarning of the birth of a sick male with an X-linked disorder, because he may have one or more healthy older sisters; heterozygous females do not express most X-linked disorders. Many X-linked disorders are the result of new mutations, and the birth of a sick newborn would not be anticipated. Similarly, because many autosomal dominant disorders are also the result of new mutations, a positive family history would not be expected.

Misconception 3

It is difficult to know when to suspect that a sick newborn infant may have a metabolic disorder, because presentation of such disorders often mimics that of sepsis in the newborn infant.

Three responses to this point may be made. First, the clinical manifestations of many metabolic diseases are similar to the presentation of many neonatal infections, but this does not mean that the physician should not investigate the possibility of a metabolic disorder. The "sepsis work-up" is a broadly focused approach to identifying a putative infection. The metabolic evaluation should be considered for most infants as part of the evaluation for suspected sepsis. Second, a neonate with a metabolic disease may be at greater risk of sepsis than other newborn infants, and the presence of documented sepsis does not exclude the possibility of an underlying metabolic disorder. Galactosemia is a well-documented example of a metabolic disease that predisposes an infant to serious infection. Third, many metabolic diseases do not have sepsis-like features.

Misconception 4

Many metabolic diseases are detectable in the neonatal period, and it is difficult to remember the presentation of each one.

Many metabolic diseases occur in the neonatal period, and it is impossible to remember the pattern of presentation of each; however, the great redundancy in clinical presentations simplifies evaluation. Relatively few algorithms are required to evaluate diseases that have overlapping phenotypes. Algorithms that have clear and multiple branch points are available to facilitate the clinical and laboratory evaluation of patients in whom a metabolic disease is suspected.

Misconception 5

The biochemical pathways and nomenclature of inborn errors of metabolism are impossible to remember.

The biochemical pathways and nomenclature of inborn errors of metabolism are often overwhelming for the expert in metabolic disorders as well as for the practitioner, but detailed knowledge of the pathways and nomenclature is not the important part of the metabolic evaluation. The important aspect of the metabolic evaluation is the development of general approaches to different clinical or laboratory findings that can rapidly reveal whether a metabolic problem exists and, if so, help direct the patient's care.

Misconception 6

It is difficult to diagnose a metabolic disease.

The examination of patients with suspected metabolic disease must be staged, progressing from broad screening tests, which should be available in all settings in which care is given to sick neonates, to highly specialized tests, which may be available in only a handful of centers. The idea of a staged evaluation is perhaps best illustrated by the congenital hyperammonemias. The ability to diagnose hyperammonemia should be available in most settings by measuring an ammonia level. However, the subsequent delineation of a specific cause of hyperammonemia and care of the patient are probably best reserved to a few specialized centers. The job of the physician faced with a sick newborn infant is to think of the possibility of hyperammonemia, to measure the blood ammonia level before the patient is irreversibly damaged by the effects of a disease, and to provide or refer them for appropriate treatment (this may require referral to a more specialized center with experts in metabolic diseases).

Misconception 7

Metabolic test results take forever to return.

There is often a sense of frustration on the part of physicians, especially house officers, who believe that they order many metabolic studies but rarely learn the results of these studies or find an answer. Some metabolic tests do take a long time to perform. It is important to stage the evaluation. It is generally best to begin with relatively broad-based screening tests that come back quickly and can then be followed by more specific diagnostic studies that usually take longer to perform. The aim is to use the screening studies to obtain preliminary indications on which to base further evaluation and care.

Misconception 8

Relatively few metabolic diseases can be treated, so why spend a great deal of effort looking for something that you cannot fix?

A number of metabolic disorders can be treated, often successfully. The approach to the differential diagnosis should give greater consideration to detecting potentially treatable entities. The initial screening studies should permit identification of classes of disease for which there are therapies. For example, the congenital hyperammonemias are a group of disorders for which generic therapy is available; therapy can be modified after a more specific diagnosis is made. It is also important to establish a diagnosis for the sake of the parents, who almost always seek to understand why they have a sick baby, and for the purpose of formal genetic counseling.

Prospective Approaches

There are two types of prospective care. The first type is the screening of a high-risk segment of the population—the siblings or other at-risk relatives of patients known to have a particular metabolic disorder. The second type is screening of the entire population or specific subset of newborn infants. The former is of much more limited scope than the latter.

The Newborn Infant at High Risk for a Particular Metabolic Disorder

Neonates at high risk for metabolic disorders are the siblings or other at-risk relatives of patients with a known metabolic disorder. These infants include those at risk for diseases for which there is no prenatal diagnosis and those who are at risk for diseases for which prenatal diagnosis is available but whose parents did not wish to have such testing performed. Also included are patients for whom prenatal testing was performed and who require postnatal confirmation of the prenatal test result. Postnatal confirmation is required for a positive or a negative prenatal test result. Postnatal confirmation is especially important for avoiding the unlikely situation of a false-negative prenatal test result that could lead to failure to treat an affected patient. Finally, siblings of an infant with an inborn error of metabolism that may have a variable age of onset might also be at risk for developing disease and should undergo evaluation and testing.

Management of pregnancies and neonates at high risk requires a coordinated effort among the obstetrician, biochemical geneticist, neonatologist, and/or pediatrician. The first decision is to determine where the at-risk baby will be delivered. If the baby will not be delivered at a center at which a metabolic expert is available, the indications for transfer after birth must be developed before birth. Regardless of where the baby is delivered, a detailed plan must be prepared and made available to all personnel caring for the newborn. The plan should include specific details of what tests will be needed to identify the disease, how the tests will be performed, where the samples for testing are to be sent after they are obtained, and who will follow up on the test results and inform the family.

Newborn Screening Programs

Newborn screening is an important issue for all physicians caring for neonates, because it combines a number of significant medical and legal issues. These issues will become progressively more complex and diverse as an increasing number of inborn errors of metabolism become amenable to newborn screening and as the role of physicians in the administration and follow-up of such testing becomes greater.[65,70,119]

Although there is ongoing discussion and some debate about which medical conditions should be screened and how they are to be screened, there is a consensus about the goals of mass newborn screening. The medical requirements of an acceptable mass screening program for a particular disease include the following:

- The availability of a reliable screening test with a low false-negative rate
- A test that is simple and inexpensive, because many tests will be performed for each case identified
- A rapid screening test that can provide results quickly enough to permit effective intervention
- A definitive follow-up test that is available for unambiguous identification of true-positive results and elimination of false-positive results
- A disorder of a sufficiently deleterious nature that, if untreated, would result in significant morbidity or death
- An effective therapy that significantly alters the natural history of the disease

Relatively few metabolic disorders satisfy all these requirements. These criteria have probably been demonstrated, in a strict sense, only for biotinidase deficiency and phenylketonuria (PKU). On the other hand, neonates with classic galactosemia or maple syrup urine disease (MSUD), for example, might become very sick within the first few days of life before the results of newborn screening tests are available, thereby compromising the benefit of the screening program. Ascertainment and diagnosis of these disorders depend on specific biochemical testing of a sick infant (see Specialized Biochemical Testing).

Principles of Screening Programs

A few principles apply to all screening programs. First, all screening tests are subject to false-positive results because of normal biologic variation, genetic heterogeneity, and human error. Accordingly, all positive screening results must be confirmed by definitive analysis. It is important that all patients who require therapy receive it and, conversely, that patients who do not require therapy not be treated.

Second, all positive results must be considered medical emergencies. Many positive results turn out to be falsely positive, but the concept underlying newborn screening is that identification of the few affected patients is crucial. In addition to the potential tragedy of a missed diagnosis of the individual neonate, lack of attention that permits delayed care of a single affected patient can seriously jeopardize the public's confidence in and the cost-benefit structure of an entire statewide screening program and can compromise the continuation of such programs.

Third, the disorders that are part of newborn screening may exhibit variable clinical expression even within families. Thus, the siblings of a patient identified by a screening program should be biochemically evaluated for the same disorder, because they could be affected, although they appear free of symptoms.

Fourth, all patients should be referred to an experienced specialist for definitive diagnosis, because these disorders are characterized by clinical and genetic heterogeneity, which can significantly affect care of the patient and genetic counseling for the family.

There is considerable variation in the screening programs of different states in the United States and in various nations. All states and US territories screen for PKU. Until relatively recently, most states performed newborn screening for three to six metabolic disorders (including PKU, homocystinuria, MSUD, and galactosemia), one endocrine disorder (congenital hypothyroidism), and the hemoglobinopathies. The requirements and procedures for the screening programs for congenital hypothyroidism and the hemoglobinopathies are discussed in Chapters 88 and 79, respectively.

Screening Techniques

Most state screening programs originally focused primarily on the classic inborn errors of metabolism. The testing programs employed separate tests for each disease of interest, which limited the scope of screening.[34,65,70] These assays could not be easily adapted to screen for other groups of disorders, such as disorders of organic acid metabolism and fatty acid oxidation. The other limitation in expanding newborn screening was that the standard methods being used to diagnose the organic acidemias and fatty acid oxidation disorders—gas chromatography, or combined gas chromatography and mass spectrometry (GC/MS)—could not be upgraded to large-scale newborn screening programs, because they require tedious sample preparation and long analysis times.

Since the 1990s, intensive efforts have been made to expand the scope of newborn screening using tandem mass spectrometry (MS/MS), which circumvents the limitations of the bacterial inhibition assay, gas chromatography, and GC/MS methods.[65,70,119] In brief, MS/MS permits analysis of a broad range of metabolites in hundreds of blood samples per day. Most states have adopted the MS/MS approach to newborn screening as part of their program. The process of expanding the scope of newborn screening programs is still continuing.[119]

Newborn screening by MS/MS starts, as did the traditional screening programs, by collecting by heel stick a small blood sample and applying it to a standardized paper card. The period for appropriate postpartum collection is 24-72 hours in the state of Ohio and is similar in other states. Samples collected from either premature infants or sick newborns are potentially more difficult to interpret and are subject to greater false-positive and false-negative rates. The blood samples are shipped to a centralized laboratory where a standardized amount of the specimen card is punched out, following which the metabolites of interest are extracted from the punch, subjected to specific chemical modifications to make them compatible for subsequent MS/MS analysis, and automatically introduced into and analyzed by the MS/MS system.

As opposed to traditional screening protocols that required different analytic approaches for each disorder, the current MS/MS techniques permit analysis of a large number of metabolites belonging to a particular category of disease—hence, many disorders—in each sample. Hundreds of samples can be prepared for analysis, analyzed, and interpreted each day. The analysis is performed by state-of-the-art mass spectrometers that permit highly sensitive, accurate, and concurrent identification of multiple metabolites. Computer software permits pattern recognition using several related metabolites, thereby improving the reliability of the testing. In summary, the MS/MS technology is ideally suited for newborn screening of many samples for many possible disorders.

As with traditional newborn screening programs, the current MS/MS screening programs must determine the normal range for the different metabolites they analyze in their system. More importantly, the programs must set cutoffs above or below, which they identify a case as at-risk. This is a difficult, ongoing task. Programs that set their cutoffs too high have an unacceptable false-negative rate, and programs that set their cutoffs too low have an unacceptable false-positive rate.

Experience has now demonstrated that MS/MS programs can detect PKU, MSUD, and homocystinuria as well as or better than the traditional screening approaches.[65,119] Nevertheless, the practitioner must still be aware that the MS/MS-based screening programs have similar problems with false-positive and false-negative results as their older counterparts, although they appear to have lower false-positive rates. The practitioner must still determine whether a particular result is truly positive or falsely positive as expeditiously as possible. The expanded newborn screening programs have found that approximately 1 in 4000 newborns have an identifiable inborn error of metabolism.

Screening for Disorders

Most states in the United States have adopted MS/MS screening to analyze disorders of amino acid metabolism (including several urea cycle disorders), organic acid metabolism, and fatty acid oxidation while still screening for several other disorders using test-specific methods (e.g., biotinidase deficiency or galactosemia).[119] The amino acid disorders and urea cycle disorders are detected by analyzing for increased blood concentrations of specific amino acids or combinations of amino acids. Most programs do not screen for disorders that are associated with reduced concentrations of specific amino acids, such as using a low serine concentration to screen for serine biosynthesis disorders. Similarly, the organic acidemias and fatty acid oxidation disorders are detected by analyzing for increased blood concentrations of specific acylcarnitines, which are the esters formed between carnitine and the acid(s) that characteristically accumulate in the various organic acidemias and fatty acid oxidation disorders. Many programs evaluate samples for combinations of particular acylcarnitines to increase the reliability of their results. Screening for the plasma membrane carnitine uptake defect (also known as carnitine uptake deficiency) is an exception to the rule of looking for increased concentrations of characteristic metabolites, because it is based on identification of a reduced (rather than increased) concentration of free carnitine.

More recently, significant progress has been achieved in developing and introducing newborn screening for two additional categories of inborn errors of metabolism: lysosomal storage disorders and peroxisomal disorders. Two lysosomal disorders, Hurler syndrome (aka mucopolysaccharidosis type I)[67] and Pompe disease (aka glycogen storage disease type II),[11] and one peroxisomal disorder, X-linked adrenoleukodystrophy (X-ALD),[54] have been added to the federally recommended newborn screening panel.[119] Screening for each of these disorders is currently available or approved for implementation in several states. The infantile form of Hurler disease typically manifests in the first year of life, whereas Pompe disease typically manifests in the first 6 months of life. Effective treatment is now available for Hurler syndrome (hematopoietic stem cell transplantation, HSCT)[12] and Pompe disease (enzyme replacement therapy)[17,59] if it is started prior to the onset of irreversible clinical manifestations. Similarly, hematopoietic stem cell transplantation significantly improves the prognosis for X-ALD, a peroxisomal disorder that does not manifest clinically until 2 years or older. Here too, follow-up studies have shown that the outcome for patients who have received HSCT are best when it is performed prior to onset of subclinical evidence of neurologic damage.[132] The screening protocol for X-ALD also identifies patients who have Zellweger syndrome, a generalized defect in peroxisomal assembly and function, or one of several single-gene defects in peroxisomal very long-chain fatty acid oxidation. Unfortunately, there is no effective therapy for these peroxisomal disorders.

It should be noted that there is ongoing concern regarding screening for these lysosomal and peroxisomal disorders, since it is possible to detect later-onset forms of these diseases with the screening tests, for which there are limitations in our ability to predict if, or when, the patient will develop significant clinical manifestations. For example, in the case of X-linked adrenoleukodystrophy, some patients identified by newborn screening and then found to have an *ABCD1* mutation might not develop clinically significant disease but might nevertheless undergo HSCT transplantation because of the requirement to initiate treatment for the childhood form of the disease as early as possible. This concern may also apply to other disorders detected by newborn screening, but the concern for the lysosomal storage disorders and peroxisomal disorders is heightened by the fact that the recommended treatment for these disorders is more invasive (and expensive) than that required for most other disorders detected by newborn screening. It is anticipated that newborn screening for the lysosomal storage disorders and peroxisomal disorders will become available in more states in the near future. Similarly, it is expected that additional inborn errors of metabolism will be incorporated into newborn screening programs as screening technology improves, more therapeutic options are developed and assessed, and better genotype/phenotype correlations are established.

Table 90.1 lists abnormal laboratory findings, along with the disorders associated with those findings and the additional testing recommended to evaluate the significance of the findings, for the currently recommended newborn screening panel. In many cases, a particular abnormal laboratory finding can be associated with more than one disorder, because different enzymatic defects can lead to excessive accumulation of that metabolite. For example, acylcarnitine analysis can yield ambiguity in identifying several of the acylcarnitines evaluated in the newborn screening program, such as C4-acylcarnitine. C4-acylcarnitine is composed of an acid group with four carbons and carnitine; the acid group can be either butyrylcarnitine (wherein the four carbons are arranged in a linear pattern) or isobutyrylcarnitine (wherein the four carbons are arranged in a branched pattern). The diseases associated with these two

α-Glucosidase activity (↓)	Pompe disease (GSD II)	α-Glucosidase enzyme, blood Urine hexose tetrasaccharide analysis (Hex4) Sequence analysis of *GAA* gene Clinical evaluation including chest X-ray and echocardiogram
Peroxisomal Disorders:		
C26:0 and/or C26:0-LPC (↑)	X-linked adrenoleukodystrophy (XALD) Other peroxisomal disorders (Zellweger spectrum disorder, acyl CoA oxidase deficiency, or D-bifunctional protein deficiency)	Plasma very long-chain fatty acids (VLCFA) Genetic testing of *ABCD1* gene If sequence analysis confirms diagnosis of *XALD*, no further testing If sequence analysis does not confirm XALD, obtain testing for other peroxisomal disorders: • Plasma plasmalogens • Plasma phytanic acid • Plasma pristanic acid

↓, Decreased; ↑, increased.

*All abnormal findings reflect increased blood concentrations except where otherwise indicated. The abnormal findings selected for this table are those used in the state of Ohio. Other states may select a different group of findings.

†The studies listed are those that should be done at the first encounter following receipt of the abnormal newborn screening result. Additional, more specific, confirmatory studies such as enzyme analysis or in vitro cell studies using blood cells, cultured skin fibroblasts, organ biopsies, or genetic studies are generally obtained after the results of the initial confirmatory tests are available.

‡The acylcarnitines associated with these disorders are designated by a capital C followed by the number of carbons contained within the fatty acyl group attached to the carnitine; for example, C8 refers to octanoylcarnitine. A colon followed by an Arabic numeral indicates one or more unsaturated carbons in the fatty acylcarnitine ester; for example, C10:1 refers to a monounsaturated C10 acylcarnitine. An OH in the designation indicates a hydroxylated acylcarnitine; for example, C5-OH refers to a monohydroxylated 5-carbon acylcarnitine. DC following the carbon number indicates a dicarboxylic acylcarnitine; for example, C5-DC refers to a dicarboxylic 5-carbon acyl group.

ABCD1, The gene that is involved in patients with X-linked adrenoleukodystrophy; AFP, alpha-fetoprotein; C26:0-LPC, a saturated, very long-chain fatty acid (26 carbon length) attached to lysophosphatidylcholine; GSD, glycogen storage disorder; LFT, liver function tests; MPS, mucopolysaccharidosis; RBC, red blood cells; WBC, white blood cells.

acylcarnitines are quite different, and further studies are required to determine which metabolite, or which disorder, is present.

The confirmatory studies listed in Table 90.1 are readily available or orderable in most clinical settings and are discussed in detail later (see Specialized Biochemical Testing). The confirmatory studies cited include tests that have a relatively rapid turnaround time, generally 1-2 weeks, hopefully leading to rapid confirmation or elimination of a possible diagnosis. Additional, more refined studies,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

including specific enzyme analysis, whole cell studies, or genetic mutational analysis, are often required to definitively establish a specific diagnosis, but these generally have a longer turnaround time.

The abnormal laboratory findings listed in Table 90.1 permit the diagnosis of more than 30 genetic disorders, including amino acid disorders, fatty acid oxidation disorders, organic acidemias, urea cycle disorders, and several unrelated enzymatic defects. The list of metabolites provided in Table 90.1 is not comprehensive. Many other metabolites have been identified or can theoretically be identified, but they are not listed because of the rarity or uncertain clinical phenotype of the associated disorder. Not all states test for this particular list of metabolites; some test for fewer and others for more. Practitioners should be familiar with the scope of their local newborn screening program. In any event, the laboratory findings listed in Table 90.1 should provide all practitioners with a foundation for interacting with their local program.

Table 90.2 provides basic information about the disorders cited in Table 90.1, including the name of each disorder along with its common abbreviation (if one is available), the underlying enzymatic defect, the clinical features and natural history, the general approach to treatment, and the prognosis. The frequency of these disorders ranges between approximately 1 in 10,000 for PKU to 1 in 200,000 for MSUD. However, several disorders have been reported in only a small number of patients. In addition to their rarity, most of these disorders are characterized by a high degree of clinical variability, making it difficult to provide a succinct but accurate summary. Hopefully, the information will provide the practitioner with a reasonable place to start when confronted with a patient who has an abnormal newborn screening result, following which he or she can turn to other resources after a diagnosis is established.

Handling Test Results

The first obligation of the practitioner who receives an abnormal newborn screening report is to inform the parents of the result. The practitioner should explain that the results are provisional and that confirmation is required. The physician must aim for an appropriate balance between his or her own natural desire to reassure the parents that the result might be falsely positive and the desire to instill a sense of appropriate concern in the parents so that they can carry through with appropriate follow-up evaluation. The practitioner's burden is generally more straightforward when the abnormal metabolite is associated with only a single disorder, but the principles of reassurance and follow-up are the same for metabolites that can be found in more than one disorder (see Table 90.1). The physician should then assess the newborn's clinical status and arrange to see the family as expeditiously as possible.

The primary physician should either see the patient or refer the patient to a metabolic disorders specialist for further evaluation and care. It is often best that the primary physician see the patient as soon as possible to assess the patient's status, discuss the newborn screening results with the family, and then work with the metabolic disorders specialist to develop an expeditious plan for evaluation. Confirmatory testing should be initiated as soon as possible.

The decisions about when to initiate treatment and how to treat are based on the nature of the laboratory abnormality found, the quantitative degree of the abnormality, the program's prior experience with false-positives for that metabolite, and the patient's clinical status. In general, starting a treatment immediately after the initial confirmatory studies are initiated is both safe and unlikely to compromise the ability to establish a diagnosis. However, this option is predicated on the ability of the physician to make certain that the diagnostic samples are collected properly, sent to the appropriate laboratory, and received in satisfactory condition by the laboratory. Failure to do this before starting treatment might significantly delay the time required to establish a diagnosis and initiate appropriate treatment.

Many of the disorders identified are treated, at least in part, by some form of dietary restriction. A family's desire to continue breastfeeding while the diagnostic studies are in progress should be carefully considered in all cases. However, depending on the disorder under consideration and the patient's clinical status, the default position should be in favor of pausing breastfeeding until a provisional diagnosis has been established. During that time, the mother can continue to express breastmilk via a breast pump and store it for later use. It is generally a matter of days to a week before the results of the initial confirmatory studies are available, when a more definitive decision can be made about the advisability of breastfeeding. Similar reasoning should be exercised about starting vitamin or cofactor supplementation.

Effect of Screening Programs

The impact of the expanded newborn screening programs is still being determined. There have clearly been many instances when the programs have led to the early recognition of an as-yet-unaffected newborn, followed by the introduction of appropriate treatment. In some cases, this has meant that a newborn with one of the organic acidemias or urea cycle defects that can manifest with an acute neurologic intoxication syndrome in the first few days of life does not suffer an insult that produces severe, irreversible neurologic damage. In other cases, the newborn screening result becomes available after a newborn is already ill, but the result provides a rapid diagnosis for the illness and leads to earlier introduction of appropriate therapy, thereby improving the patient's outcome.

However, it is not yet clear whether early recognition and institution of appropriate treatment changes the long-term prognosis for many of these diseases, such as recurrent hyperammonemic crises in the urea cycle defects or renal failure in methylmalonic acidemia. There may also be

TABLE 90.2 Inborn Errors of Metabolism That Can Be Ascertained by Newborn Screening Programs*

Disorder	Defect	Clinical Features and Natural History	Treatment	Prognosis With Treatment
Amino Acid Disorders				
Homocystinuria	Cystathionine β-synthetase deficiency	Generally asymptomatic at birth Developmental delay, dislocated lens, skeletal deformities, and thromboembolic episodes	Dietary protein restriction Selective amino acid restriction (methionine) Vitamin B_6 supplementation, plus betaine, folate, and vitamin B_{12} for vitamin B6–nonresponsive patients	Patients with vitamin B_6–responsive form of disease have fewer complications and later age of onset of complications than do patients with vitamin B_6–nonresponsive form
Maple syrup urine disease (MSUD)	Branched-chain α-keto acid dehydrogenase deficiency	Patients might present before newborn screening results are available Difficulty feeding, vomiting, lethargy progressing to coma, opisthotonic posturing, and possibly death Ketoacidosis	Emergency treatment is indicated for symptomatic neonates* Chronic care includes: • Dietary protein restriction • Selective branched-chain amino acid restriction (leucine, isoleucine, valine) • Thiamine supplementation for thiamine-responsive patients	Improved intellectual outcome can be expected if treatment is initiated before first crisis, but developmental delay in severe cases Recurrent episodes of ketoacidosis, especially when ill or fasting
Phenylketonuria (PKU)	Phenylalanine hydroxylase deficiency OR Tetrahydrobiopterin (BH_4) biosynthesis or recycling defects	Generally asymptomatic at birth After a few months, microcephaly, seizures, and pale pigmentation develop, followed in later years by abnormal posturing, mental retardation, and behavioral or psychiatric disturbances Patients with BH_4 defects have additional neurologic problems secondary to dopamine and serotonin deficiency	• Dietary protein restriction • Selective amino acid restriction (phenylalanine) • Sapropterin dihydrochloride (a synthetic BH_4 analogue) for responsive patients • Depending on specific disorder, may require sapropterin dihydrochloride plus dopa/carbidopa, 5-hydroxytryptophan, and/or other medications	Normal development can be expected (although a mild decrease in IQ and behavioral difficulties relative to unaffected sibs might be seen) if diet is instituted early Patients with biopterin defects are at increased risk for neurologic problems, e.g., seizures, dystonia
Tyrosinemia type I	Fumarylacetoacetate hydrolase deficiency	Patients might present before newborn screening results are available Severe liver failure associated with jaundice, ascites, and bleeding diathesis Peripheral neuropathy and seizures can develop Renal Fanconi syndrome leading to rickets Survivors develop chronic liver disease with increased risk of hepatocellular carcinoma	Emergency treatment is indicated for symptomatic neonates* Chronic care includes: • Dietary protein restriction • Selective amino acid restriction (phenylalanine and tyrosine) • Administration of an NTBC, a selective enzyme inhibitor of the tyrosine degradative pathway • Liver transplantation indicated when hepatocellular carcinoma suspected	Liver disease could progress despite dietary treatment NTBC treatment improves liver, kidney, neurologic function, and reduces risk for hepatocellular carcinoma Liver transplantation might still be required

Tyrosinemia type II	Tyrosine aminotransferase	Corneal lesions and hyperkeratosis of the soles and palms, and intellectual impairment in some cases	Selective amino acid restriction (phenylalanine and tyrosine)	Eye and skin lesions resolve with treatment, and intellectual outcome improves
Tyrosinemia type III	4-Hydroxy-phenylpyruvate dioxygenase	May include intellectual impairment	Low-phenylalanine, low-tyrosine diet	Improved intellectual outcome
Urea Cycle Disorders				
Argininemia	Arginase deficiency	Rarely symptomatic in neonatal period Progressive spastic diplegia or tetraplegia, opisthotonus, seizures Low risk of symptomatic hyperammonemia	Dietary protein restriction Alternative pathway drugs for removing ammonia (sodium benzoate and phenylbutyrate)*	Improved neurologic outcome
Argininosuccinic acidemia	Argininosuccinate acid lyase deficiency	Patients might present before newborn screening results are available: • Anorexia • Vomiting • Lethargy leading to coma • Seizures • Hyperammonemia	Emergency treatment might be indicated for symptomatic neonates Chronic care includes: • Dietary protein restriction • Essential amino acid supplementation • Arginine supplementation • Alternative pathway drugs for removing ammonia (sodium benzoate and phenylbutyrate)* • Liver transplantation	Improved intellectual outcome if treatment is initiated early, but developmental delay in severe cases. Recurrent hyperammonemic episodes
Citrullinemia type I	Argininosuccinate synthetase deficiency	Patients might present before newborn screening results are available Anorexia, vomiting, lethargy, seizures, and coma, possibly leading to death Hyperammonemia	Emergency treatment is indicated for symptomatic neonates Chronic care includes: • Dietary protein restriction • Essential amino acid supplementation • Arginine supplementation • Alternative pathway drugs for removing ammonia (sodium benzoate and phenylbutyrate)	Improved intellectual outcome can be expected if treatment is initiated early, but there is developmental delay in the severe cases Recurrent hyperammonemic episodes

TABLE 90.2 Inborn Errors of Metabolism That Can Be Ascertained by Newborn Screening Programs*—cont'd

Disorder	Defect	Clinical Features and Natural History	Treatment	Prognosis With Treatment
Citrullinemia type II	Citrin deficiency	Neonatal-onset form: • Failure to thrive • Hepato(spleno)megaly • Abnormal liver function • Hypoglycemia and abnormal amino acid profile • Mild-to-moderately (↑) plasma ammonia concentration Early childhood-onset form: • Patients display a dietary preference for protein-rich and/or lipid-rich foods and an aversion to carbohydrate-rich foods • Failure to thrive • Dyslipidemia • Pancreatitis • Normal–slightly elevated plasma ammonia concentration Adult-onset form: • Recurring episodes of hyperammonemia and neuropsychiatric problems • Fatty liver	• Lactose-free diet • MCT and fat-soluble vitamin supplementation Early childhood-onset form: • Same diet as above • MCT and fat-soluble vitamin supplementation • Sodium pyruvate supplementation Adult-onset form: • Low-calorie/low-carbohydrate/high-protein diet • MCT, arginine, and sodium pyruvate supplementation • Liver transplantation	Generally associated with transient neonatal cholestasis and variable hepatic dysfunction, but some affected patients develop cirrhosis and have a poor prognosis Early childhood-onset form • Variable Adult-onset form: • Poor prognosis, improved with liver transplantation
Organic Acidemias				
Glutaric acidemia type I (GAI)	Glutaryl-CoA dehydrogenase deficiency	Rarely symptomatic in neonatal period, although macrocephaly may be present: • Progressive macrocephaly • Ataxia • Dystonia and choreoathetosis • Developmental regression • Seizures • Strokelike episodes	Emergency treatment is indicated for symptomatic neonates Chronic care includes: • Dietary protein restriction • Selective amino acid restriction with lysine and tryptophan • Selective amino acid supplementation with arginine • Riboflavin and carnitine supplementation	Improved intellectual outcome if treatment is initiated early, but poor neurologic outcome if treatment is started after acute neurologic injury occurs Treatment might slow neurologic deterioration

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Glutaric acidemia type II (GAII)	Electron transfer flavoprotein (ETF) deficiency ETF dehydrogenase deficiency	Commonly manifests in neonatal period: • Hypotonia • Hepatomegaly • Abnormal odor • (±) Congenital anomalies including facial dysmorphism and cystic kidney disease • Metabolic acidosis • Hypoglycemia • Hyperammonemia • Generally lethal Late-onset forms variable, rarely have structural birth defects	Emergency treatment is indicated for symptomatic neonates Chronic care includes: • Dietary low-fat/low-protein diet • Carnitine supplementation • Riboflavin supplementation for responsive cases Modification of above	Treatment for neonatal-onset forms is of limited benefit Treatment might be helpful for patients with late-onset disease
3-Hydroxy-3-methylglutaric aciduria	3-Hydroxy-3-methylglutaryl-CoA lyase deficiency	Generally does not manifest in neonatal period: • Episodic hypoglycemia may contribute to developmental delay	• Frequent feedings • Low-fat/low-protein (leucine-restricted) diet • Carnitine supplementation	Improved intellectual outcome may be expected if treatment is initiated early, but developmental delay in severe cases Recurrent hypoglycemic episodes decrease in frequency and severity with age
Isobutyric acidemia	Isobutyryl-CoA dehydrogenase deficiency	• Uncertain because number of cases is small; may be benign • Case reports of cardiomyopathy associated with carnitine deficiency	Carnitine supplementation if deficiency present	Unknown
Isovaleric acidemia (IVA)	Isovaleryl-CoA dehydrogenase deficiency	Patients might present before newborn screening results are available • Vomiting, lethargy and coma, possibly death • Abnormal odor (“sweaty socks”) • Thrombocytopenia, leukopenia, anemia • Ketoacidosis • Hyperammonemia	Emergency treatment is indicated for symptomatic neonates Chronic care includes: • Dietary protein restriction • Selective amino acid restriction (leucine) • Carnitine supplementation	Improved intellectual outcome if diagnosed and treated early If treated appropriately, most have normal development Recurrent metabolic episodes

TABLE 90.2 Inborn Errors of Metabolism That Can Be Ascertained by Newborn Screening Programs*—cont'd

Disorder	Defect	Clinical Features and Natural History	Treatment	Prognosis With Treatment
3-Ketothiolase deficiency	Mitochondrial acetoacetyl-CoA thiolase deficiency	Patients might present before newborn screening results are available • Vomiting, lethargy and coma, possibly death • Abnormal odor • Thrombocytopenia, leukopenia, anemia • Possible basal ganglia damage • Ketoacidosis • Hyperammonemia	Emergency treatment is indicated for symptomatic neonates Chronic care includes: • Dietary protein restriction • Selected amino acid restriction (isoleucine) • Avoidance of fasting • Bicarbonate therapy and intravenous glucose in acute crises • Carnitine supplementation	Highly variable clinical course Improved intellectual outcome if diagnosed and treated early If recognized and treated appropriately, some patients have normal development Recurrent metabolic episodes
2-Methylbutyrylglycinuria	2-Methylbutyryl-CoA dehydrogenase deficiency (aka: short/branched chain acyl-CoA dehydrogenase deficiency	Most patients ascertained by newborn screening are clinically asymptomatic and remain so, although several patients have been described with a variety of problems	The need for treatment with a low-protein diet has not been established	Generally good
3-Methylcrotonylglycinuria	3-Methylcrotonyl-CoA carboxylase deficiency (3-MCC) Maternal 3-MCC deficiency	• Highly variable phenotype • Hypoglycemia and metabolic acidosis • Many patients asymptomatic • Transplacental transport of 3-methylcrotonylglycine from mother to fetus • Newborn is unaffected • Mothers have variable neurologic phenotype	• Dietary protein restriction • Selected amino acid (leucine) restriction • Carnitine supplementation • Mother might benefit from carnitine supplementation if she has carnitine insufficiency	Generally good Mother generally improves with treatment
2-Methyl-3-hydroxybutyric acidemia	2-Methyl-3-hydroxybutyryl-CoA dehydrogenase deficiency (aka:17-beta-hydroxysteroid dehydrogenase X deficiency)	Clinical variability has been observed in this X-linked disorder: • In severe cases, neurodegenerative disease, associated with mental retardation, rigidity, choreoathetosis, seizures, and cerebral atrophy, is often present • In milder cases, some males may have normal neurologic development. Affected females have less severe disease	Dietary protein restriction improves the metabolic markers but does not alter clinical outcome	Poor for severe affected patients but better for mildly affected patients

Methylmalonic acidemia (MMA)	Methylmalonyl-CoA mutase deficiency Defect affecting vitamin B12 (adenosylcobalamin) metabolism	Neonatal presentation: • Vomiting, lethargy and coma, possibly death • Thrombocytopenia, leukopenia, anemia • Ketoacidosis • Hyperammonemia • Seizures and risk of basal ganglia infarcts • Long-term sequelae include psychomotor retardation, seizures, pyramidal and extrapyramidal movement disorder, basal ganglia strokes, interstitial renal disease, cardiomyopathy, and pancreatitis Variable, depending on specific disorder	Emergency treatment is indicated for symptomatic neonates Chronic care includes: • Dietary protein restriction • Selective amino acid restriction (isoleucine, methionine, threonine, and valine) • Daily hydroxycobalamin IM injection if patient responsive • Oral carnitine supplementation • Antibiotic suppression of gut flora (metronidazole or neomycin) • Liver and/or kidney transplantation might be required Same as above, plus: • Daily intramuscular injection of hydroxocobalamin • Daily oral betaine supplementation, if methylcobalamin also involved	Improved outcome if diagnosed and treated early However, recurrent metabolic episodes and long-term sequela may still occur Renal failure often develops despite appropriate therapy Variable, depending on specific disorder
Propionic acidemia (PA)	Propionyl-CoA carboxylase deficiency	Patients might present before newborn screening results are available • Vomiting, lethargy and coma, possibly death • Seizures and risk of basal ganglia infarcts • Thrombocytopenia, leukopenia, anemia • Ketoacidosis • Hyperammonemia • Long-term sequelae include cardiomyopathy and pancreatitis	Emergency treatment is indicated for symptomatic neonates Chronic care includes: • Dietary protein restriction • Selective amino acid restriction (isoleucine, methionine, threonine, and valine) • Carnitine supplementation • Antibiotic suppression of gut flora (metronidazole or neomycin) • Liver transplantation might be considered	Improved outcome if diagnosed and treated early Recurrent metabolic episodes

TABLE 90.2 Inborn Errors of Metabolism That Can Be Ascertained by Newborn Screening Programs*—cont'd

Disorder	Defect	Clinical Features and Natural History	Treatment	Prognosis With Treatment
Multiple carboxylase deficiency	Holocarboxylase synthetase deficiency	May present in the newborn period: • Lethargy, hypotonia, seizures, and coma, possibly leading to death • Metabolic ketoacidosis • Hyperammonemia • Long-range, skin rash, impaired T-cell immunity, seizures, and developmental delay may develop	Biotin supplementation	Most patients respond to biotin supplementation, but those who have poor or no response to biotin supplementation may have significant residual neurologic impairment
Fatty Acid Oxidation				
Carnitine uptake defect	Carnitine uptake defect	Does not generally manifest in neonatal period • Cardiomyopathy • Skeletal myopathy • Inability to tolerate prolonged fasting (hypoketotic hypoglycemia)	Carnitine supplementation (high-dose, high-frequency)	Good response to treatment, prevents and/or reverses cardiomyopathy, skeletal myopathy, and impaired ketogenesis
Carnitine/acylcarnitine translocase (CACT) deficiency	Carnitine/acylcarnitine translocase deficiency	Commonly manifests in neonatal period • Lethargy leading to coma • Hepatomegaly/hepatic dysfunction • Cardiomyopathy with ventricular arrhythmia • Skeletal myopathy • Hypoketotic hypoglycemia ± hyperammonemia	Avoid fasting, continuous enteral feeding in severe cases High-carbohydrate, low-fat diet Carnitine supplementation	Severe neonatal cases generally have poor outcome and early death Patients with later onset might respond to treatment, but they often succumb to chronic skeletal-muscle weakness or cardiac arrhythmias
Carnitine palmitoyltransferase type II (CPT II) deficiency	CPT II deficiency	"Severe" form of disease manifests in neonatal period: • Lethargy leading to coma • Cardiomyopathy with ventricular arrhythmias • Hepatic dysfunction • Skeletal myopathy • Congenital malformation (brain and cystic renal disease) • Hypoketotic hypoglycemia "Intermediate" form of disease: • Presents in infancy with similar (but milder) features than the "severe" form, absent the congenital brain and kidney malformations "Mild, late-onset" form of disease: • Presents in childhood/adulthood and is characterized by weakness and exercise-induced rhabdomyolysis	"Severe" form: • Avoid fasting, may require continuous enteral feeding • High-carbohydrate, low-fat diet, including MCT oil • Carnitine supplementation "Intermediate" form: • Treated with an attenuated regimen of the above "Late-onset" form: • Treated with an attenuated regimen of the above	Severe neonatal cases generally have poor outcome and early death Patients with intermediate form of disease have milder problems than those with neonatal-onset form Patients with late-onset disease generally do well

Long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency OR Trifunctional protein (TFP) deficiency	LCHAD deficiency/TFP deficiency	"Severe" form of disease: • Manifests in neonatal period with cardiomyopathy with arrhythmia, hypotonia, hepatic dysfunction, hypoketotic hypoglycemia, and sudden death "Infantile/childhood" form: • Patients have milder form of "severe" disease and later develop rhabdomyolysis, peripheral neuropathy, and pigmentary retinopathy. Maternal disease: • Heterozygous pregnant women are at risk for acute fatty liver of pregnancy if they are carrying an affected (homozygous or compound heterozygous) fetus	"Severe" form: • Avoid fasting • High-carbohydrate, low-fat diet with MCT oil supplementation • Carnitine supplementation • Docosahexanoic acid supplementation "Infantile/childhood" form: • Treat with an attenuated regimen of the above, plus supplementation with docosahexanoic acid Maternal rx: • Early delivery • Carnitine supplementation if deficient	Prognosis for "severe" form is guarded despite therapy Early dx and rx generally improves outcome for patients with "infantile/childhood" form of disease, but risk of peripheral neuropathy and visual impairment persists Prognosis guarded for pregnant woman
Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency	MCAD deficiency	Generally does not manifest in neonatal period: • Recurrent episodes of lethargy, vomiting, coma, seizures, and possibly sudden death associated with prolonged fasting, especially when associated with infection • Cardiomyopathy not generally seen • Hypoketotic hypoglycemia	• Avoid fasting • "Heart healthy" diet (fat: 30% or less) • Nightly cornstarch supplementation (optional) • Carnitine supplementation	Excellent intellectual and physical outcome generally seen if treatment is initiated before irreversible neurologic damage occurs Fasting tolerance improves with age
Short-chain acyl-CoA dehydrogenase (SCAD) deficiency	SCAD deficiency	Generally does not manifest in neonatal period: • Hypoglycemia uncommon • Most patients detected by newborn screening program are asymptomatic	Normal diet Carnitine supplementation, if testing demonstrates deficiency	The need for and efficacy of treatment is unknown

TABLE 90.2 Inborn Errors of Metabolism That Can Be Ascertained by Newborn Screening Programs*—cont'd

Disorder	Defect	Clinical Features and Natural History	Treatment	Prognosis With Treatment
Very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency	VLCAD deficiency	"Severe" form of disease manifests in neonatal period: • Lethargy progressing to coma • Cardiomyopathy and ventricular arrhythmias • Hepatic dysfunction • Skeletal myopathy • Hypoketotic hypoglycemia "Intermediate" form of disease: • Presents in infancy with similar (but milder) features than "severe" form "Late-onset" form: • Manifests in childhood or adulthood with weakness and exercise-induced rhabdomyolysis	"Severe" form: • Avoid fasting, consider continuous enteral feeding • High-carbohydrate, low-fat diet supplemented with MCT oil • Carnitine supplementation "Intermediate" form: • Treated with an attenuated regimen of the above "Late-onset" form: • Treated with an attenuated regimen of the above	Severe neonatal cases generally have poor outcome and early death Patients generally do well Patients generally do well
Galactosemias				
Galactose-1-phosphate uridyltransferase (*GALT*) deficiency	Galactose-1-phosphate uridyltransferase deficiency	Patients may present in the neonatal period: • Lethargy and poor feeding • Jaundice with hepatic dysfunction • Possible sepsis (especially with *Escherichia coli*) Chronic problems include: • Growth failure • Cirrhosis • Cataracts • Seizures • Intellectual disabilities • In females, ovarian failure	Strict dietary galactose restriction must be started immediately	Improved intellectual outcome, but may have milder problems such as speech delay, if diagnosed and treated early Ovarian failure develops in most female patients despite appropriate therapy Recurrent metabolic episodes may occur
Galactokinase (GALK) deficiency	Galactokinase (GALK) deficiency	Cataracts, with no other medical problems	Milk restriction only. Rapid initiation of milk restriction may resolve cataracts that were already present	Good

UDP-galactose-4-epimerase (GALE) deficiency (aka: epimerase deficiency galactosemia)	UDP-galactose-4-epimerase deficiency	Neonates with generalized epimerase deficiency galactosemia: • Poor feeding, vomiting, weight loss, • Jaundice, liver dysfunction, hepatomegaly • Hypotonia • Cataracts • Generalized aminoaciduria Neonates with the peripheral or intermediate form of epimerase deficiency: • Generally remain clinically well • May tolerate a normal diet	Similar to *GALT* deficiency, i.e., a lactose/ galactose-restricted diet is required Galactose-restricted diet is not generally required for peripheral form but may be required for intermediate form	Similar to *GALT* deficiency, with no evidence of ovarian failure if maintained on proper diet Good
Other				
Biotinidase deficiency	Biotinidase deficiency	Generally does not manifest in neonatal period but may manifest with lethargy, hypotonia, seizures, and apnea in early infancy	Biotinidase deficiency	Biotinidase deficiency
Lysosomal Storage Disorders				
Hurler syndrome (MPS I)	α-Iduronidase deficiency	"Severe" form has onset within 1st year of life and is progressive over time: • Short stature • Coarse facial features, corneal clouding, and hearing loss • Cardiomyopathy/ valvular disease • Hepatosplenomegaly • Dysostosis multiplex and stiff joints • Hirsutism • Hydrocephalus & spinal cord compression • Intellectual disabilities • Death by cardiorespiratory failure usually occurs by age 10 years "Mild" form has normal intellectual development and moderate somatic manifestations at age 2 years, with variable disease progression	"Severe" form: • Initiate enzyme replacement therapy following diagnosis • Hematopoietic stem cell transplant (HSCT) if patient is <2 years of age; careful consideration of risk vs. benefit advised if patient >2 years of age "Mild" form: • HSCT not recommended for mild form because of treatment complications	"Severe" form: • Early initiation of enzyme replacement therapy followed by HSCT improves outcome, except for skeletal changes. • Comprehensive symptomatic treatment "Mild" form: • Symptomatic therapy alone

TABLE 90.2 Inborn Errors of Metabolism That Can Be Ascertained by Newborn Screening Programs*—cont'd

Disorder	Defect	Clinical Features and Natural History	Treatment	Prognosis With Treatment
Pompe disease (GSD II)	α-Glucosidase deficiency	Clinical features of early infantile form generally present within the first 6 months of life and are progressive: • Hypotonia • Macroglossia • Cardiomegaly/cardiomyopathy • Hepatomegaly • Progressive weakness • Elevated creatine kinase activity • Death in the first 2 years of life Later-onset form (generally >12 months): • Proximal muscle weakness • Respiratory insufficiency • Cardiac involvement uncommon • Other features described for infantile-onset form of disease	Clinical evaluation including for cardiomyopathy Start enzyme replacement therapy as soon as possible CRIM-negative patients should receive immune tolerance induction before initiating therapy Patients who develop enzyme neutralizing antibodies after starting ERT should receive immunomodulation therapy Later-onset form: • Enzyme replacement therapy	Rapid initiation of enzyme replacement therapy (ERT) improves outcome. Later-onset form: • Variable depending on age of onset and age of initiation of therapy
Peroxisomal Disorders				
X-linked adrenoleukodystrophy	Impaired peroxisomal metabolism of very long-chain fatty acids	Childhood-onset form: • Typically presents between 4-8 years of age • More likely to affect males than females (X-linked recessive disorder) • Adrenal insufficiency • Intracerebral inflammatory response leads to demyelination • Regression of cognition, behavior, vision, • Hearing and motor function follow the initial symptoms, often leading to total disability • Death generally by 2 years Later-onset forms: • More likely to affect males than females, with females more mildly affected • Adrenomyeloneuropathy beginning in late 20s (paraparesis, sphincter and sexual dysfunction, and adrenal insufficiency) • Adrenal insufficiency precedes and dominates neurologic abnormalities	Childhood-onset form: • Immediate HSCT (if neurologic involvement is not yet present) Later-onset forms: • HSCT • Corticosteroid replacement therapy	Childhood-onset form: • May improve neurologic outcome (further follow-up studies are underway) Later-onset forms: • Limited benefits of HSCT for neurologic problems after onset of symptoms

ABCD1, The gene mutated in patients with X-linked adrenoleukodystrophy; CRIM, cross-reactive immunologic material; CSF, cerebrospinal fluid; GSD, glycogen storage disease; HSCT, hematopoietic stem cell transplantation; MCT, medium-chain triglycerides; NTBC, 2-(2-nitro-4-trifluoro-methylbenzoyl)-1,3-cyclohexanedione; VLCFA, very long-chain fatty acids.

*This table does not provide a complete listing of all the inborn errors that have been identified or might be identified by tandem mass spectrometry. It is important to note that all these disorders are characterized by considerable clinical variability and that treatment must be individualized for each patient.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

negative consequences to these new programs. For example, the screening programs could produce undesirable effects on the family of a child with a false-positive result, including increased hospitalization of the child, parental stress, and parent–child dysfunction.[133] Carefully organized multicenter studies are needed to determine the long-term benefits of the expanded newborn programs.

In addition to the current MS/MS newborn screening programs for amino acid and acylcarnitine analysis, new methods for evaluating other groups of inborn errors of metabolism, including the lysosomal storage disorders, are being utilized in several states and are under development in others. It seems reasonable to anticipate that many of these methods will be introduced over the next several years, further expanding the responsibility and role of the pediatrician and neonatologist in caring for children with metabolic disorders.

Separate summaries of several disorders that were part of the traditional screening programs and that are now evaluated by MS/MS programs (e.g., homocystinuria, MSUD, PKU) are provided next because they are useful paradigms for understanding the benefit of the newborn screening programs and how they work.[138] A summary is also provided for MCAD deficiency, because it is the most common of the fatty acid oxidation disorders that are now evaluated by MS/MS programs, and it is one of the paradigms for this group of disorders. Summaries are also provided for biotinidase deficiency and galactosemia, which are disorders that are primarily evaluated by methodologies other than MS/MS. Other disorders that are now part of expanded newborn screening programs are discussed elsewhere in this chapter, including fatty acid β-oxidation disorders (see Hypoglycemia), nonketotic hyperglycinemia (see Metabolic Seizures), organic acidemias (see Metabolic Acidosis), tyrosinemia type I (see Hepatic Dysfunction), urea cycle defects (see Hyperammonemia), and most recently, certain lysosomal disorders and peroxisomal disorders.

Screening for Specific Disorders

Biotinidase Deficiency

Biotinidase is an enzyme necessary for recycling biotin, a vitamin cofactor required for four critical intracellular carboxylation reactions: acetyl-coenzyme A (acetyl-CoA) carboxylase, 3-methylcrotonyl-CoA carboxylase, propionyl-CoA carboxylase, and pyruvate carboxylase. Hence biotinidase deficiency is one cause of multiple carboxylase deficiency (the other cause is holocarboxylase synthetase deficiency).[138,139] These carboxylase reactions are involved in fatty acid biosynthesis, branched-chain amino acid metabolism, and gluconeogenesis.

Biotinidase deficiency is characterized by a variable clinical presentation but can lead to severe metabolic decompensation in the newborn period; features include ketoacidosis, hypotonia, seizures, and coma. Some infants also have significant dermatologic findings (including rash and alopecia) and immunodeficiency. If untreated, older children could have visual problems, hearing loss, and developmental delay. This disorder can be treated successfully with biotin supplementation (5-10 mg/day PO). Some residual neurologic deficits could persist if treatment does not begin before the onset of symptoms. Newborn screening allows for early diagnosis and initiation of treatment, which may reduce morbidity.

Serum biotinidase enzyme activity is the gold standard for newborn screening of biotinidase deficiency.[138,139] The disorder can also be detected using MS/MS to measure the blood concentration of C5-OH (3-hydroxyisovalerylcarnitine), the acylcarnitine that is formed due to the secondary deficiency of 3-methylcrotonyl-CoA carboxylase. However, the sensitivity of the MS/MS approach is unknown, and it might not provide a reliable method for newborn screening. A positive screening result should be confirmed by quantitative serum biotinidase analysis and by performing plasma carnitine analysis and urine organic acid analysis, looking for the characteristic plasma acylcarnitine pattern and organic aciduria that is present in a small percentage of affected patients.

Care must be exercised in collecting and processing the serum specimen used for biotinidase enzyme analysis. It is best to obtain a concurrent control from an unrelated individual to establish that the sample has been processed properly (i.e., eliminate the chance of a false-positive result) and was not exposed to environmental factors during transport that could affect the results (such as excess heat or cold).

Galactosemia

Classic galactosemia is the consequence of galactose-1-phosphate uridyltransferase (*GALT*) deficiency. Classic galactosemia can manifest in the newborn period with lethargy, poor feeding, jaundice, cataracts, and in some cases, *Escherichia coli* sepsis.[10,138] If unrecognized, this disorder can lead to early death or a chronic course characterized by cirrhosis, cataracts, seizures, and mental retardation. The mainstay of therapy for classic galactosemia is strict dietary galactose restriction.[10,138] Diet therapy is difficult to sustain because lactose (a disaccharide formed from galactose and glucose) is a ubiquitous food additive. Dietary galactose restriction should be started as early as possible (preferably within the first few days after birth) to have the best chance of precluding the development of the severe illness described above as well as long-term speech and learning problems. However, even children treated early often have mild growth failure, learning disabilities, and verbal dyspraxia. Affected girls almost invariably develop premature ovarian failure (~80%).[10,47] This observation serves as a caution to those caring for children with galactosemia that long-term follow-up is mandatory and further improvements in treatment are required over time as new recommendations and information becomes available.

There are two other forms of galactosemia: uridine diphosphate galactose-4′-epimerase deficiency and galactokinase deficiency. In most cases, epimerase deficiency is a

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

benign condition that does not require treatment. The rarer, systemic form of epimerase deficiency produces a clinical picture similar to classic galactosemia. Galactokinase deficiency is also rare and produces nuclear cataracts but none of the other manifestations of classic galactosemia. Early recognition and treatment of this disorder via dietary galactose restriction is generally successful.

One approach to newborn screening for galactosemia measures *GALT* enzyme activity in red blood cells. This assay can detect *GALT* deficiency without regard to prior dietary intake of galactose. It does not evaluate for either epimerase activity or galactokinase activity. Therefore, newborns with either epimerase deficiency or galactokinase deficiency are not ascertained by this approach to newborn screening. Another approach to newborn screening for galactosemia is to measure galactose and galactose-1-phosphate (the substrate for *GALT*), which evaluates for all three enzyme deficiencies. However, recent galactose intake (in the form of breastmilk or formula) may affect these results; patients not receiving a lactose-containing diet may have false-negative results.[16] Because of the rapid onset of symptoms in classic galactosemia and the presence of galactose in breast milk and many cow milk–based formulas, screening programs for galactosemia must provide rapid results. However, the screening results are not always available before the affected neonate becomes ill; initial evaluation of a sick newborn should, therefore, include testing for the presence of urinary-reducing substances (see Specialized Biochemical Testing). A newborn identified by newborn screen as possibly having classic galactosemia should have definitive biochemical testing by measuring whole blood or erythrocyte *GALT* activity and erythrocyte galactose-1-phosphate. In addition, genetic analysis for the common *GALT* mutations is often helpful in interpreting the results of the *GALT* activity measurements and making treatment decisions. Following initiation of these studies, galactose should be withdrawn from the diet, pending results of the laboratory investigations, by replacing breastmilk or cow's milk–based formula with a soy-based formula).

Widespread neonatal testing of erythrocyte *GALT* activity in various populations has revealed considerable genetic heterogeneity of this enzyme deficiency.[10] Some individuals have a partial enzyme deficiency that does not result in significant impairment of galactose metabolism or any discernible clinical disorder; there is no evidence of a need for dietary treatment of these cases. In other cases with partial enzyme activity, erythrocyte galactose-1-phosphate concentrations are increased, and minimal symptoms can develop. These cases can be managed with less severe restriction of dietary galactose intake.

Homocystinuria

Several inborn errors of metabolism produce homocystinuria.[77,97,138] The most common of these disorders is caused by cystathionine β-synthase deficiency, an autosomal recessive disorder. Cystathionine β-synthase is a pyridoxine (vitamin B_6)-dependent enzyme. Rare disorders that also lead to homocystinuria include defects in folate or cobalamin metabolism. Screening programs for homocystinuria are based on detection of elevated blood levels of methionine, a precursor of cystathionine. Hypermethioninemia is characteristic of cystathionine β-synthase deficiency but may not be associated with other causes of homocystinuria. In fact, patients who have homocystinuria due to a defect in cobalamin metabolism may actually have low methionine levels. Therefore, only some cobalamin disorders are detected by newborn screening for hypermethioninemia, while others are detected by their abnormal acylcarnitine profile. For example, cobalamin C disease will exhibit both methylmalonic acidemia and homocystinuria. These patients are ascertained by an elevated propionylcarnitine (C3), which is related to the methylmalonic acidemia associated with their disease. In the case of a related disorder, patients with cobalamin E disease exhibit homocystinuria/homocystinemia, megaloblastic anemia, and low methionine but are missed by newborn screening.

Other false-positive and false-negative results occur in screening programs for homocystinuria.[97,138] False-positive results are generally the consequence of artifacts (e.g., poor quality of sample), but they may also result from nongenetic causes of hypermethioninemia, such as parenteral administration of amino acids, generalized liver disease, hepatic immaturity, or rarely, from a genetic cause such as hereditary tyrosinemia, galactosemia, or citrin deficiency (see Hepatic Dysfunction). False-negative results are produced by the milder variants of cystathionine β-synthase deficiency, especially the pyridoxine-responsive form, which might not exhibit hypermethioninemia in the neonatal period.

The diagnosis of homocystinuria should be confirmed in patients with a positive newborn screening test by measuring total plasma homocysteine, plasma amino acids, and plasma methylmalonic acid. The diagnosis of cystathionine β-synthase deficiency can be confirmed by measuring the enzyme activity in cultured skin fibroblasts or by genetic testing.

Cystathionine β-synthase deficiency rarely manifests in the neonatal period, but it can cause lethargy, poor feeding, and thromboembolic phenomena when it does.[77,97,138] If untreated, the disorder can lead to musculoskeletal anomalies suggestive of a marfanoid habitus, ectopia lentis, thromboembolic vascular disease, behavioral or psychiatric problems, and mental retardation. Patients with pyridoxine-responsive defects tend to have milder disease than do patients with pyridoxine-nonresponsive defects. All patients should undergo a pyridoxine challenge test to determine whether they are pyridoxine responsive.

Patients with pyridoxine-responsive forms of homocystinuria might require only daily vitamin B_6 supplementation and mild methionine restriction, whereas nonresponders may require a stricter, low-methionine diet with cysteine supplementation (cysteine is the product of the cystathionine β-synthase reaction, and may, therefore, be deficient in patients with classic homocystinuria). Patients might also

benefit from folate, vitamin B_{12}, and betaine supplementation, which augment the remethylation of homocysteine to methionine, thereby reducing the toxic effects of excessive homocysteine. The outcome for vitamin B_6–responsive patients appears to be good, but the outcome for nonresponders has often been less satisfactory because of the irreversible damage caused by the presenting episode, the therapeutic inadequacy of the present dietary management, or both.

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common inherited disorder of fatty acid oxidation, with an incidence of approximately 1 in 15,000.[49,68] It has a highly variable clinical presentation, even within families. Patients are rarely symptomatic in the newborn period. Most patients present between 3 and 24 months of age, but others remain asymptomatic until they are much older, even into adulthood. The initial retrospective studies on MCAD deficiency found that in almost one-fourth of patients, the diagnosis followed sudden, unexplained death.

The typical presentation is that of an infant who has unexplained progressive vomiting, hepatomegaly, lethargy leading to coma, and seizures associated with an infectious illness or a period of prolonged fasting. The characteristic laboratory finding is nonketotic or hypoketotic hypoglycemia; signs of liver dysfunction may also be present. Older patients could have a more indolent course that is associated with failure to thrive, developmental delay, or chronic muscle weakness. A significant proportion of patients are asymptomatic. MCAD deficiency may be diagnosed in an "unaffected" older sibling after his or her younger sibling comes to medical attention for an acute metabolic crisis or a positive newborn screening result for MCAD deficiency.

The diagnosis of MCAD deficiency is confirmed by plasma carnitine analysis with an acylcarnitine profile, urine organic acid analysis, and urine acylglycine analysis.[68,138] The plasma total and free carnitine concentration can vary with the phase of the illness. The plasma acylcarnitine profile typically shows increased amounts of C6, C8, and C10 acylcarnitines. However, patients with secondary carnitine deficiency could have a relative increase, but not an absolute increase, in these acylcarnitines. Urine organic acid analysis generally shows a typical medium-chain dicarboxylic aciduria (C6-C10) in symptomatic patients, but it could be normal in asymptomatic patients. Urinary acylglycine analysis can be useful in detecting the characteristic metabolite (suberylglycine) in asymptomatic patients.

Genetic testing is useful for confirming the diagnosis. It used to be thought that at least 90% of patients carried at least one copy of the same abnormal allele, the A985G mutation, but the frequency of this particular allele is lower in patients identified by newborn screening programs compared with those who present symptomatically.

Patients with MCAD deficiency should receive frequent feedings and avoid fasting. Infants younger than 6 months require feeding every 3-4 hours. The older infant or child may be allowed to fast for progressively longer periods of time as they get older but not for more than 12 hours.[68] The potential metabolic stress of nocturnal fasting might be reduced for toddlers by providing them with uncooked cornstarch as a source of slow-release glucose immediately before going to bed for the night. Dietary fat restriction is no longer recommended, but oral carnitine supplementation may be indicated for patients with secondary carnitine deficiency. Carnitine supplementation should be monitored with periodic plasma carnitine analysis. Patients should be evaluated and admission to the hospital considered for patients with anorexia or vomiting associated with an acute infectious illness or other potential metabolic stressor. Acute metabolic crises should be treated with intravenous glucose and carnitine. The prognosis for patients who are identified and treated before the onset of irreversible neurologic damage due to severe or recurrent hypoglycemia and its sequelae is generally excellent.

Phenylketonuria

Several genetic disorders produce hyperphenylalaninemia. Classic PKU and non-PKU hyperphenylalaninemia are caused by defects in phenylalanine hydroxylase, and variant PKU is caused by one of several defects in tetrahydrobiopterin (BH_4) metabolism.[92,138] Several nongenetic factors also produce hyperphenylalaninemia in the newborn, but this hyperphenylalaninemia disappears in the first year of life. The most common causes of transient hyperphenylalaninemia are prematurity and high protein intake just prior to the blood draw. Newborn screening programs identify infants with genetic and nongenetic hyperphenylalaninemia. It is imperative that patients identified by the screening program receive a rapid, accurate, and definitive diagnosis, because the clinical implications and therapies for the various forms of hyperphenylalaninemia are different and early initiation of appropriate treatment minimizes morbidity.

All genetic forms of hyperphenylalaninemia are caused by defects that directly or indirectly affect the activity of the enzyme phenylalanine hydroxylase. This enzyme catalyzes the conversion of phenylalanine to tyrosine and requires BH_4 as a cofactor. Classic PKU and non-PKU hyperphenylalaninemia are caused by allelic defects of phenylalanine hydroxylase itself, whereas variant PKU is caused by defects of BH_4 biosynthesis or reutilization. BH_4 is also a cofactor for tyrosine hydroxylase and tryptophan hydroxylase, which are enzymes involved in neurotransmitter biosynthesis. Approximately 98% of patients with hyperphenyl have a defect in phenylalanine hydroxylase, whereas 2% have a defect in BH_4 metabolism.

Patients with milder deficiencies of phenylalanine hydroxylase (i.e., patients with transient hyperphenylalaninemia or non-PKU hyperphenylalaninemia) usually do not require dietary treatment. However, patients with more

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

severe deficiencies, that is, patients with classic PKU, require lifelong phenylalanine restriction. Treatment should start within the first month of life to avoid irreversible neurologic damage. Early treatment is generally effective in preventing the long-term neurologic sequelae of this disease. However, standard treatment may not prevent subtle intellectual and behavioral disabilities in some individuals.[92,138] Dietary restriction of phenylalanine should be lifelong. Women with PKU who fail to maintain the appropriate diet are at risk for having neurologically impaired offspring (maternal PKU syndrome; see Maternal Diseases Affecting the Fetus).

In recent years, clinical trials have demonstrated that some patients with milder forms of classic PKU respond to oral supplementation with a synthetic form of BH_4 known as sapropterin. They appear to tolerate a higher dietary protein intake while maintaining acceptable serum phenylalanine concentrations. However, most patients still require some degree of dietary phenylalanine restriction with or without a specialized metabolic formula. The drug is now available for clinical use.

Defects of BH_4 metabolism cause defective neurotransmitter synthesis as well as hyperphenylalaninemia and lead to a more generalized neurologic syndrome known as *variant PKU,* characterized by convulsions, abnormal tone and posture, abnormal movements (i.e., dystonia), hyperthermia, hypersalivation and swallowing difficulties, drowsiness, irritability, and developmental delay. Standard dietary management corrects the hyperphenylalaninemia that these patients have but does not improve the neurologic problems related to their neurotransmitter deficiencies. Only a small percentage of patients with hyperphenylalaninemia have BH_4-related defects, and these patients must be identified early to initiate appropriate therapy. A variety of approaches are being used to treat these patients with some success, depending on the specific biopterin defect present.[92,138]

Newborn screening for hyperphenylalaninemia is based on measuring the concentration of phenylalanine in the blood while the newborn infant is receiving breast milk or a standard formula (i.e., a phenylalanine-containing diet).[70,138] Blood samples are generally obtained for newborn screening between 24 and 48 hours of age. The results for samples collected before 24 hours of age may not be reliable, and a follow-up sample should be obtained for screening.

The rate of false-negative results is less a problem with MS/MS screening than the traditional approaches, partly because it is possible to measure the concentrations of phenylalanine and tyrosine (the product of the phenylalanine hydroxylase reaction) concurrently. Those who have a positive screening result require prompt attention, including plasma amino acid analysis. If the plasma phenylalanine concentration and the plasma phenylalanine-to-tyrosine ratio are increased, the patient should be placed on a low-phenylalanine diet. Therefore, breastfeeding should be stopped. In all cases of confirmed hyperphenylalaninemia, the patient should be evaluated by a metabolic disorders specialist to rule out a defect in BH_4 metabolism.

The Abnormal Newborn Infant: Clinical Phenotypes

On the whole, newborn infants with inborn errors of metabolism have relatively few types of presentation. The most common clinical presentations are listed in Table 90.3, along with a differential diagnosis of the categories of metabolic disorders that may be associated with each presentation. A more detailed discussion of each presentation follows.

Prenatal Onset

Several inborn errors of metabolism can manifest prenatally, affecting the pregnant mother and/or the developing fetus. These inborn errors can be grouped into three categories: maternal diseases affecting the fetus; fetal diseases affecting the mother; and fetal diseases affecting the fetus. The obstetrician and/or pediatrician should be aware of these metabolic disorders.[24,134]

Maternal Diseases Affecting the Fetus

The prototype of a maternal disease affecting the fetus is maternal PKU.[95] A pregnant woman who has poorly controlled PKU is at increased risk for spontaneous abortion. She also has an increased risk of having a child with major birth anomalies, including intrauterine growth restriction, microcephaly, mental retardation, and a congenital heart defect, as well as a broad range of minor anomalies. The risk of birth defects is proportional to the mother's serum phenylalanine concentration. There is no safe level below which the fetus is not at risk. Women with PKU should be placed on a strict low-phenylalanine diet before conception. This has proved difficult to do in practice, however, and maternal PKU syndrome remains a significant problem for women with PKU.

Fetal Diseases Affecting the Mother

As a rule, inborn errors of metabolism of the fetus do not affect the pregnant mother. However, reports began to appear in the 1990s describing mothers who had experienced acute fatty liver of pregnancy (AFLP) while carrying a fetus who subsequently manifested evidence of a long-chain fatty acid oxidation defect after birth. Acute fatty liver of pregnancy is the most extreme end of a clinical spectrum of maternal complications of pregnancy that includes HELLP syndrome (hemolysis, elevated liver enzymes, and a low platelet count) and AFLP. The HELLP syndrome and AFLP are potentially serious complications of pregnancy (see Chapter 17).

Clinical, biochemical, and histologic evidence of hepatic dysfunction mark both disorders. Patients with HELLP syndrome commonly develop epigastric pain, nausea, vomiting, headache, proteinuria, low platelets, elevated serum liver enzymes, and occasionally disseminated intravascular coagulation. Acute fatty liver of pregnancy is less common than HELLP syndrome and shows a greater degree of

Hair or Skin Abnormalities	Amino acid disorders Menkes disease Organic acidemias
Hematologic Abnormalities	Mitochondrial disorders Organic acidemias
Sepsis	Galactosemia Disorders of biotin metabolism
Unusual Odor (see Table 90.7)	Amino acid disorders Organic acidemias
Dysmorphic Syndromes (see Table 90.8)	Cholesterol biosynthesis disorders Congenital disorders of glycosylation Lysosomal storage disorders Organic acidurias Peroxisomal disorders Others

hepatic dysfunction. It often produces a severe coagulopathy, hypoglycemia, and fulminant hepatic failure. Microvesicular fatty deposits in the liver characterize both disorders. Both disorders can have life-threatening consequences for the fetus and mother. Women with either of these disorders improve remarkably after delivery, suggesting that the fetus is causing a toxic effect on the mother that resembles that seen in patients with inborn errors of fatty acid oxidation.

There is convincing evidence that a specific defect of fatty acid oxidation, long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency in the fetus, is associated with the HELLP syndrome and AFLP spectrum in the mother.[9,91] Long-chain 3-hydroxyacyl-CoA dehydrogenase is part of a trifunctional multimeric enzyme complex that performs the three terminal steps in the long-chain fatty acid β-oxidation: long-chain 2,3-enoyl-CoA hydratase, LCHAD, and long-chain 3-ketoacyl-CoA thiolase. Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency can be seen as an isolated deficiency or as part of trifunctional protein deficiency that affects all three enzyme activities. Both disorders are inherited as autosomal recessive traits.

Isolated LCHAD deficiency is marked by relative genetic homogeneity. More than 50% of the mutant alleles found in patients who have this disease carry the same mutation: a G1528C change in the gene that encodes for the α-subunit of LCHAD. Other mutations in the same gene that predispose a heterozygous mother to AFLP have also been identified. A relatively large number of at-risk pregnancies have now been identified and reviewed after the birth of a child with LCHAD deficiency.[9,91] These studies show that a woman who is heterozygous for LCHAD deficiency is at risk for developing HELLP syndrome or AFLP during a pregnancy in which she is carrying a fetus who is homozygous for the same deficiency. Thus, a heterozygous mother is only at risk if her fetus inherits a second LCHAD mutation from the father. The fetus, in turn, is at risk for significant postnatal problems associated with its enzyme deficiency. The diagnosis and care of a child with LCHAD deficiency is discussed later under Hypoglycemia. Rarely,

other inborn errors of long-chain fatty acid β-oxidation can also produce AFLP.

The current recommendation is to evaluate all pregnant women who develop AFLP for LCHAD deficiency and related fatty acid oxidation disorders by biochemical and genetic testing. This recommendation should also be considered for women who develop recurrent and/or severe HELLP syndrome.

Fetal Diseases Affecting the Fetus

The fetus does not generally suffer prenatal consequences of its own inborn error of metabolism, because the abnormal metabolites that it produces are removed by the maternal circulation, or conversely, metabolic deficiencies produced by the inborn error are replenished by the maternal circulation. There are, however, several groups of disorders that include significant exceptions: amino acid disorders, congenital disorders of glycosylation, fatty acid β-oxidation disorders, lysosomal storage disorders, mitochondrial disorders, and peroxisomal disorders (see Dysmorphic Syndromes).

Although most of the clinical disorders that affect the developing fetus are discussed later, the disorders that can lead to congenital ascites or hydrops fetalis are discussed here. A major group of inborn errors of metabolism that lead to hydrops fetalis are the lysosomal storage disorders, including β-glucuronidase deficiency and Morquio syndrome (which are mucopolysaccharidoses); Farber disease and GM1-gangliosidosis (which are spingolipidoses); galactosialidosis and sialidosis (which are oligosaccharidoses); and free sialic storage disease (a lysosomal transport defect).[24,113] Other disorders that can also lead to hydrops fetalis are congenital disorders of glycosylation (specifically type Ia), glycogen storage diseases (specifically type IV), Niemann-Pick disease type C, and transaldolase deficiency,[24,134] as well as several inborn errors of red cell glycolytic enzymes (see Chapter 23).

Central Nervous System Disease

Newborn infants have a limited number of responses to an illness such as an inborn error of metabolism.[16,60] These responses generally include cardiorespiratory, feeding, and neurologic difficulties. The neurologic difficulties, such as altered consciousness (encephalopathy), altered tone, or seizures, are discussed elsewhere in this book (see Chapters 52, 54, and 55). As noted in these chapters, these neurologic difficulties are most commonly caused by infection, brain malformations, or hypoxemic-ischemic encephalopathy, and less commonly by inborn errors of metabolism. Although it is important to evaluate a patient for these common problems, it is also important to remember that inborn errors of metabolism can also produce brain malformations and can mimic the clinical picture of hypoxic-ischemic encephalopathy.[29]

This section discusses inborn errors of metabolism that cause two different clinical phenotypes: (1) metabolic encephalopathies—inborn errors of metabolism that produce a clinical picture in which encephalopathy predominates; and (2) metabolic seizures—inborn errors in which seizures predominate. The distinction between these two groups is somewhat arbitrary, because patients with a disorder that produces metabolic encephalopathy often have seizures, and conversely, patients with a disorder that produces metabolic seizures often have encephalopathy. Nevertheless, the distinction is useful, because patients generally fall more easily into one group than the other. In addition, many of the disorders that produce neonatal seizures yield negative results on the standard metabolic evaluation for metabolic encephalopathy and require additional specialized testing, including biochemical analysis of numerous metabolites in the cerebrospinal fluid (CSF).

Metabolic Encephalopathy

The inborn errors of metabolism that can produce metabolic encephalopathy in the neonatal period or early infancy are associated with what appears to be a cascade of biochemical effects. A number of specific metabolites are overproduced as a result of a particular enzyme deficiency. In excess, these metabolites serve as endogenous toxins that impair other metabolic or physiologic processes. Disruption of these processes leads, in turn, to production of additional metabolites, which further impair cellular processes. Early interruption of the cascade through such relatively simple measures as fluid and caloric support might abort episodes of metabolic decompensation. Physicians who care for children who present with a metabolic disorder in late infancy, childhood, or even adulthood often receive a retrospective history of "sepsis" in the neonatal period that was never confirmed by culture and that resolved spontaneously; these episodes might have represented an interrupted metabolic intoxication syndrome. Early nonspecific supportive treatment may abort the pathologic cascade or delay the onset of a more fulminant course until a provisional metabolic diagnosis and specific treatment become available.

The symptoms and signs of neonates who develop metabolic encephalopathy generally do not appear on the first day of life but usually begin later in the first week. The initial symptoms are often poor feeding associated with a poor suck and irritability. Muscle tone is decreased, sometimes marked by a fluctuating pattern of decreased and increased tone. Reflexes are sometimes abnormal, and seizures can develop. The poor feeding is sometimes accompanied by vomiting. Diarrhea is uncommon. Disorders accompanied by a metabolic acidosis (e.g., the lactic acidemias or organic acidemias) can lead to a compensatory increase in respiratory rate. In the case of urea cycle defects, hyperammonemia increases the respiratory drive, leading to hyperpnea. The neonate shows lethargy, which can progress to coma and death. These symptoms often progress rapidly, sometimes within a matter of hours, but more often during the course of a few days. It is important to suspect a metabolic disorder as early as possible in its course to interrupt the progression of symptoms because many of these disorders are life threatening.

The diagnostic evaluation of a newborn suspected of having a metabolic encephalopathy should include testing for disorders of amino acid metabolism, organic acid metabolism, the mitochondrial respiratory chain, and the urea cycle (see Table 90.3). The differential diagnosis for these patients can often be narrowed by the presence of other clinical or routine laboratory findings, such as acidosis, hyperammonemia, hypoglycemia, ketosis, or lactic acidemia. The diagnosis will be narrowed further by performing more specialized laboratory testing, including plasma amino acid analysis, urine organic analysis, plasma carnitine analysis with acylcarnitine profile, and urine carnitine analysis with acylcarnitine profile. Effort should be made to perform a prompt and vigorous laboratory evaluation of the patient suspected of having a metabolic encephalopathy, because many of them are potentially treatable. The disorders that produce metabolic encephalopathy are discussed later in this chapter (see The Abnormal Newborn Infant: Laboratory Phenotypes).

Metabolic Seizures

There are an ever-growing number of inborn errors of metabolism that have been recognized as a cause of seizures in the neonatal period or early infancy.[32,88,129] These disorders produce a variety of seizure types, including partial, tonic, and myoclonic seizures, and EEG patterns, including burst-suppression (see Chapter 55). The seizure type and EEG pattern may evolve over time. As in the case of patients who present with a metabolic encephalopathy, many of the disorders that produce neonatal seizures are potentially treatable. The approach to laboratory testing of these patients should include the same laboratory testing noted in the preceding for the evaluation of patients with suspected metabolic encephalopathy. In addition, the patient with a suspected metabolic seizure disorder should undergo additional, specialized testing for both potentially treatable and untreatable disorders, with emphasis directed toward identification of potentially treatable disorders. As a rule, different specialized testing must be obtained for each disorder.[32,88,129] The physician caring for these patients should strongly consider starting therapy after the samples for laboratory testing have been obtained rather than awaiting the receipt of test results.

The clinical features, biochemical basis, diagnostic testing, treatment, and prognosis for several of the disorders that produce metabolic seizures are presented in three groups: treatable disorders, potentially treatable disorders, and untreatable disorders, to allow the attending physician to prioritize the diagnostic evaluation. The listing of disorders is by no means complete.

Treatable Disorders

The treatable disorders include folinic acid-responsive seizures, glucose transporter type I deficiency, pyridoxine-dependent epilepsy, and pyridoxal 5′-phosphate–dependent epilepsy.

Folinic Acid–Responsive Seizures. Folinic acid–responsive seizures are defined operationally as isolated neonatal seizures (and associated EEG abnormalities) that respond rapidly to treatment with folinic acid (3-5 mg/kg per day) with response expected within 2-3 days. Recognition of this and related disorders of neurotransmitter metabolism has increased with the clinical availability of biochemical analysis of neurotransmitters in CSF.[48,89] Studies have shown that most cases of folinic acid–responsive seizures are variants of pyridoxine-dependent epilepsy (see Pyridoxine-Dependent Epilepsy). More specifically, patients with both disorders share the same biochemical abnormalities (i.e., increased concentrations of α-aminoadipic semialdehyde and related metabolites) and genetic defects (e.g., *ALDH7A1* mutations). Patients who are identified as having folinic acid–responsive seizures based on clinical responsiveness to folinic acid and then shown to have the biochemical and genetic evidence of pyridoxine-dependent epilepsy should be treated with a combination of folinic acid (3-5 mg/kg per day) and pyridoxine (15-30 mg/kg per day).

Other forms of folinic acid–responsive seizures that have no relationship to pyridoxine-dependent epilepsy have been described. The biochemical hallmark of these seizure disorders is cerebral folate deficiency.[89] More specifically, these disorders are characterized by a decreased concentration of 5-methyltetrahydrofolate in the CSF, without evidence of systemic 5-methyltetrahydrofolate deficiency (i.e., normal serum and red cell 5-methyltetrahydrofolate concentrations, normal serum homocysteine, and normal hematologic findings). Two disorders can be associated with this phenotype: (1) the presence of autoantibodies to the folate receptor that transports 5-methyltetrahydrofolate across the choroid plexus (FRα)[90]; and (2) mutations in the gene that encodes for this folate receptor (*FOLR1*).[115] These two disorders are characterized by psychomotor retardation, cerebellar ataxia, pyramidal tract signs, dyskinesias, and seizures starting at 4-6 months of age or later in infancy. Neither disorder has been reported to produce seizures during the neonatal period. Nevertheless, it is prudent to investigate the patient who has electroencephalographic evidence of folinic acid–responsive seizures without evidence of the biochemical or genetic markers of pyridoxine-responsive seizures for antibodies to the FRα and mutations in the *FOLR1* gene, because confirmation of either diagnosis would improve evaluation and treatment of the patient and of at-risk, presymptomatic family members.

Glucose Transporter Type 1 Deficiency. The glucose transporter type 1 (GLUT1) is the primary protein that facilitates glucose transport across the blood–brain barrier and into astrocytes. Glucose transporter type 1 deficiency is (in almost all cases) an autosomal dominant disorder that reduces glucose transport by approximately 50%, leading to impaired energy production by the brain and a range of neurologic abnormalities.[56,137] Patients with GLUT1 deficiency syndrome typically develop seizures between 1 and 6 months of age. They can have a variety of seizure types,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

including partial, generalized, or myoclonic seizures. The seizures are refractory to standard anticonvulsants and may be exacerbated by phenobarbital and diazepam, which inhibit GLUT1 function. Many affected infants also develop episodic eye movements, ataxia, oculomotor apraxia, developmental delay, microcephaly, and "stroke-like events with reversible hemiplegia" as they get older.[56,137] There are less common variants of GLUT1 deficiency that do not manifest problems until later in life.

Once considered, the diagnosis can be readily established by concurrently measuring glucose and lactate in the plasma and CSF. The characteristic findings are a low CSF glucose concentration (<60 mg/dL in all cases, and almost always <40 mg/dL) and a decreased CSF glucose/plasma glucose ratio (<0.40; normal, 0.60). The plasma lactate concentration is normal in patients with GLUT1 deficiency, whereas the CSF lactate concentration is either normal or less than normal. The diagnosis can be confirmed by measuring erythrocyte uptake of 3-methylglucose (a nonmetabolizable glucose homologue) or by mutational analysis of the *SLC2A1* gene.

Glucose transporter type 1 deficiency can be treated successfully with a low-carbohydrate, high-fat diet (ketogenic diet), which provides ketones as an alternative fuel source for the brain (as opposed to glucose). Treatment also includes oral supplementation with carnitine and several vitamins that are missing from the ketogenic diet, and the avoidance of barbiturates (including phenobarbital), valproic acid (which inhibits fatty acid oxidation), and methylxanthines (including caffeine). It is important that the diagnosis be made as early as possible to initiate treatment before irreversible neurologic damage occurs.

Pyridoxine-Dependent Epilepsy. Another disorder that should be considered in the evaluation of a newborn infant with unexplained seizures accompanied by negative findings on a standard metabolic evaluation is pyridoxine (vitamin B_6)-dependent epilepsy.[35] This disorder typically begins in the neonatal period, although in some cases the seizures begin in utero.

Studies have demonstrated that the metabolic basis of pyridoxine-dependent epilepsy is complicated. It now appears that pyridoxine-dependent epilepsy is caused by genetic defects in the *ALDH7A1* gene. This gene encodes for a protein called antiquitin, which functions as an α-aminoadipic semialdehyde dehydrogenase in the lysine catabolic pathway. Antiquitin deficiency leads to accumulation of α-aminoadipic semialdehyde, pipecolic acid, and Δ^1-piperideine 6-carboxylic acid. Δ^1-Piperideine 6-carboxylic acid reacts with and inactivates the active form of pyridoxine (i.e., pyridoxal 5–phosphate). Thus, patients with pyridoxine-dependent epilepsy have an autosomal recessive disorder in lysine metabolism that inactivates pyridoxal 5′–phosphate, which is required for GABA synthesis and other vitamin B_6–dependent enzyme reactions. GABA is a critical inhibitory neurotransmitter. The CSF concentration of GABA is decreased in patients with pyridoxine-dependent epilepsy. Pyridoxine supplementation compensates for the increased loss of pyridoxal 5′–phosphate, as does direct supplementation with pyridoxal 5′–phosphate itself.

The disorder can be diagnosed most quickly by demonstrating clinical and electroencephalographic responses to a pharmacologic challenge dose of pyridoxine (initial dose is 30 mg/kg per day, followed by 15-30 mg/kg per day for 3 days). The response to parenteral pyridoxine (50-100 mg) is often dramatic, with normalization of the electroencephalographic pattern within minutes. This pyridoxine challenge test must, however, be done with caution, because patients can experience apnea, hypotonia, and hypotension. The test should be done in an intensive care setting with electroencephalographic monitoring. Once the diagnosis is established, daily oral pyridoxine supplementation (5-10 mg/kg per day) is continued. The diagnosis should be confirmed by biochemical analysis of lysine metabolites (α-aminoadipic semialdehyde, pipecolic acid, and/or Δ^1-piperideine 6-carboxylic acid) in the blood, urine, and/or CSF. It has been shown that α-aminoadipic semialdehyde may also be increased in patients with sulfite oxidase deficiency or molybdenum cofactor deficiency, so these disorders must be ruled out before concluding that the patient has pyridoxine-dependent epilepsy based on measurement of α-aminoadipic semialdehyde alone. It is also possible to confirm the diagnosis of pyridoxine-dependent epilepsy by genetic analysis of the *ALDH7A1* gene. The prognosis for this disorder, if recognized early and treated, is improved.

Pyridoxal 5′-Phosphate–Dependent Epilepsy. A variant of pyridoxine-dependent epilepsy has been recognized in which the patient does not respond (or responds partially) to parenteral or oral pyridoxine but responds to oral pyridoxal 5′–phosphate (pyridoxal phosphate).[109] Pyridoxal 5′–phosphate is the "active" form of vitamin B_6; that is, it serves as the cofactor for the enzymes involved in neurotransmitter biosynthesis. The patients who respond to pyridoxal 5′–phosphate have a clinical presentation similar to that of patients with pyridoxine-dependent epilepsy. However, they have a number of unique biochemical findings: decreased CSF concentrations of homovanillic acid (an L-dopa metabolite) and 5-hydroxyindoleacetic acid (a serotonin metabolite), increased CSF concentrations of two other L-dopa metabolites (3-O-methyldopa and vanillactic acid), and increased CSF concentrations of two amino acids (glycine and threonine). These changes are thought to be secondary to a generalized dysfunction of three vitamin B_6–dependent enzymes, aromatic L-amino acid decarboxylase, glycine cleavage enzyme, and threonine dehydratase. The underlying genetic defect is a deficiency of pyridox(am)ine 5′–phosphate oxidase (*PNPO*), which is required for the conversion of dietary pyridoxine and pyridoxamine phosphate to pyridoxal 5′–phosphate.

A patient suspected of having this disorder can be evaluated biochemically for the CSF abnormalities enumerated in the preceding or, more simply, by using pyridoxal 5′–phosphate in place of pyridoxine in an oral challenge test (pyridoxal 5′–phosphate is not available in a parenteral

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

form). The patient should receive 50 mg of pyridoxal 5′–phosphate by nasogastric tube while in an intensive care unit with EEG monitoring because of the risk of apnea, hypotonia, and hypotension. In some cases, the EEG response was relatively rapid (within an hour), but the patient remained unresponsive for several days following administration of pyridoxal 5′–phosphate. If the challenge test is positive, the patient should continue to receive pyridoxal 5′–phosphate (10 mg/kg every 6 hours), and the diagnosis should be confirmed by genetic testing of the *PNPO* gene. See Chapter 55 for further details on evaluating and managing patients with this disorder.

Potentially Treatable Disorders

There are also several disorders for which treatment may be available for a subset of patients. Further study is required to determine which patients may benefit from the currently available therapies. These disorders include congenital glutamine synthetase deficiency, Menkes disease, nonketotic hyperglycinemia, serine biosynthesis defects, and sulfite oxidase deficiency/molybdenum cofactor deficiency.

Congenital Glutamine Synthetase Deficiency. A new disorder of glutamine metabolism has been described in recent years; the disorder affects systemic glutamine metabolism and produces cerebral malformations and intractable seizures. Glutamine synthetase catalyzes the conversion glutamate and ammonia to glutamine, thereby detoxifying ammonia. In the brain, glutamine is the source of glutamate (an excitatory neurotransmitter) and GABA (an inhibitory neurotransmitter). The two patients who were initially described with congenital glutamate synthetase deficiency presented in the neonatal period with severe neurologic compromise (with severe hypotonia and/or seizures); very low plasma, urine, and CSF concentrations of glutamine (but normal glutamate); hyperintensity of white matter, enlarged ventricles, and severe lissencephaly on cranial MRI; and a small brain with no visceral malformations on autopsy. Both infants died within the first days or weeks of life.[39] A third patient with a milder course survived until 3 years of age, with severe seizures and chronic hyperammonemia. This patient was treated with progressively increased doses of enteral or parenteral glutamine supplementation, monitored biochemically, electrophysiologically, and by brain MRI and MRS.[40] The patient's plasma glutamine concentration normalized, while the CSF glutamine concentration increased but remained lower than normal. The plasma ammonia concentration did not increase from the pretreatment baseline. The EEG showed improvement, and the MRS showed increased concentrations of glutamine and glutamate in the brain. Overall, the patient showed biochemical improvement and mild clinical improvement, suggesting that early intervention with glutamine supplementation might provide beneficial therapy for patients with congenital glutamine synthetase deficiency.

Menkes Disease. Abnormalities of the skin and hair are characteristic of several inborn errors of metabolism. Menkes disease is an X-linked disorder that is caused by a defect in intracellular copper metabolism and generally presents soon after the neonatal period with hypotonia, failure to thrive, and seizures.[51] Characteristic hair changes are either already present or manifest soon thereafter. The scalp and eyebrow hair is sparse, short, brittle, and may be lightly pigmented (hence the eponymic term kinky-hair disease). The hair is morphologically abnormal (e.g., pili torti). Other clinical features that develop later include facial dysmorphism (sagging cheeks), skin laxity, umbilical or inguinal hernias, skin hypopigmentation, hypotonia, and neurodevelopmental delays. The pathogenetic bases of these clinical features are presumably related to the deficiency of multiple copper-dependent enzymes. For example, seizures may be the consequence of cytochrome c oxidase (also known as complex IV of the respiratory chain) deficiency, which impairs energy metabolism in the brain, and/or dopamine-β-hydroxylase deficiency, which impairs neurotransmitter (catecholamine) production in the brain.

The biochemical hallmarks of this disorder are decreased serum copper and ceruloplasmin concentrations.[51] However, the normal concentrations of these markers are low and can be difficult to interpret. Definitive diagnosis requires CSF catecholamine analysis to measure the absolute and relative amounts of catecholamines, which depend on the activity of the copper-dependent enzyme dopamine-β-hydroxylase. The diagnosis can also be confirmed by genetic testing of the *ATP7A* gene, the only gene known to be associated with Menkes disease. In classic Menkes disease, treatment with subcutaneous injections of copper histidine or copper chloride before 10 days of age normalizes developmental outcome in some individuals, improves the neurologic outcome in others, and is of no benefit in the remainder.[51,52] Clearly, there is a brief window available for the initiation of beneficial therapy, which would only be available for newborns already known to be at risk for Menkes disease by virtue of a positive family history or those identified prenatally. The option for effective treatment for older patients is more guarded.

Nonketotic Hyperglycinemia. Nonketotic hyperglycinemia (also known as glycine encephalopathy) is an autosomal recessive disorder caused by a defect in the glycine cleavage enzyme that leads to increased concentrations of glycine in the blood, urine, and CSF.[45,128] Prenatal onset of hiccups and seizures has been observed. Patients typically present in the first days of life with profound hypotonia, poor feeding, hiccups, severe (generally myoclonic) seizures, apnea, and lethargy, often leading to coma. The disorder often leads to death in the neonatal period. Electroencephalogram analysis in typical cases initially shows a burst-suppression pattern, which evolves with time into hypsarrhythmia. Patients who survive this initial period generally have intractable seizures and profound intellectual impairment. A small minority of patients with neonatal-onset disease have a better prognosis. There is no way of predicting outcome for the severely affected neonate.

The biochemical hallmarks of nonketotic hyperglycinemia are increased CSF glycine and plasma glycine

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

concentrations, with an increased CSF/plasma glycine ratio. Standard laboratory analysis of plasma amino acids might not suffice to establish the diagnosis, because the plasma glycine concentration varies over the course of the day and may be normal or only be minimally elevated at certain times. The diagnosis of this disorder requires amino acid analysis on concurrently collected plasma and CSF samples to demonstrate an elevated CSF/plasma glycine ratio (>0.08; normal: <0.04). In addition, patients who are suspected of having nonketotic hyperglycinemia should undergo urine organic acid analysis to confirm that the patient does not have one of the organic acidurias associated with ketotic hyperglycemia (see Specialized Biochemical Testing).

Treatment for nonketotic hyperglycinemia is limited. The plasma glycine concentration can be reduced by oral administration of sodium benzoate, and dextromethorphan can be administered to reduce the activity of glycinergic *N*-methyl-D-aspartate receptors. These medications appear to be beneficial for some patients, especially those with milder forms of disease. Valproate should not be used to control seizures, because it inhibits the glycine cleavage enzyme.

Serine Biosynthesis Defects. Whereas most inborn errors of amino acid metabolism are the consequence of enzyme deficiencies that impair the catabolism of one or more particular amino acids, the serine biosynthetic defects represent a class of disorders that affect de novo anabolism of a particular amino acid, namely, serine. Three enzymes are required for the biosynthesis of serine in the central nervous system: (1) 3-phosphoglycerate dehydrogenase (3-PGDH); (2) 3-phosphoserine aminotransferase (3-PSAT); and (3) 3-phosphoserine phosphatase (3-PSPH). The clinical phenotypes have been well described for patients with 3-PGDH deficiency and PSAT deficiency but not for 3-PSPH deficiency.[41,120]

Patients with 3-phosphoglycerate dehydrogenase deficiency or phosphoserine aminotransferase deficiency typically present with congenital microcephaly, severe psychomotor retardation, and intractable seizures; hence, these disorders may have prenatal onset. The seizure type is variable and may include infantile spasms, multifocal clonic seizures, and myoclonic seizures. The seizure pattern often changes over time. Some patients may also develop spastic quadriparesis, adducted thumbs, nystagmus, cataracts, hypogonadism, and megaloblastic anemia. The characteristic finding on cranial MRI is severe hypomyelination with cortical and subcortical atrophy. The pathogenesis is, at least in part, the consequence of the underlying serine deficiency that leads to impaired sphingomyelin and cerebroside production, which are required for the synthesis of myelin.

Biochemical studies show decreased concentrations of serine in CSF and, to a lesser extent, in blood. Glycine, the transamination product of serine, is also decreased in CSF and blood but to a relatively milder degree than serine. The diagnosis can be confirmed by enzyme analysis in cultured skin fibroblasts or by genetic testing. Effective treatment is available using oral supplementation with serine (500-600 mg/kg per day) and glycine (200-300 mg/kg per day), using four to six doses per day and careful biochemical monitoring of serine and glycine concentrations in the CSF and blood. This treatment leads to improved seizure control and increased myelination of the brain, especially when it is started early. Treatment for an affected fetus identified prenatally is available by maternal serine and glycine supplementation during pregnancy.

Sulfite Oxidase Deficiency/Molybdenum Cofactor Deficiency. Sulfite oxidase deficiency exists in two forms: (1) an isolated genetic deficiency of sulfite oxidase and (2) a genetic defect affecting synthesis of the molybdenum cofactor, which is required for the function of sulfite oxidase, xanthine oxidase, and aldehyde oxidase.[7,123] Sulfite oxidase is involved in the degradation of three sulfur-containing amino acids, methionine, homocysteine, and cysteine, to sulfate. Xanthine dehydrogenase and aldehyde oxidase are involved in the purine degradation pathway leading to production of uric acid. The clinical role of aldehyde oxidase deficiency is uncertain. Both sulfite oxidase deficiency and molybdenum cofactor deficiency are characterized clinically by early onset, refractory seizures, hypotonia evolving to hypertonia, and if the patients survive long enough, microcephaly, lens dislocation, and severe psychomotor delay. Many affected infants die in the first year of life.

The key biochemical findings of sulfite oxidase deficiency, either in cases of isolated deficiency or in cases of molybdenum cofactor deficiency, are increased excretion of urinary sulfite and thiosulfate, increased plasma and urinary S-sulfocysteine, and decreased plasma cystine. In addition, the plasma homocysteine concentration is very low in these patients and provides a biochemical marker that can be obtained rapidly. Patients with molybdenum cofactor deficiency produce the same set of metabolites as patients with the isolated deficiency, plus they excrete increased amounts of xanthine and hypoxanthine and decreased amounts of uric acid. As in the case of homocysteine, the serum uric acid is sometimes very low in patients with molybdenum cofactor deficiency and provides an easily measured marker for this form of the disease.

Isolated sulfite oxidase deficiency and molybdenum cofactor deficiency are both autosomal recessive disorders. The sulfite oxidase enzyme is encoded by the *SUOX* gene. The molybdenum cofactor is synthesized from guanosine triphosphate (GTP) in three steps: (1) the conversion of GTP to cyclic pyranopterin monophophate (cPMP); (2) the conversion of cPMP to molybdopterin; and (3) the conversion of molybdopterin to molybdenum cofactor. Molybdenum cofactor deficiency type A, type B, and type C are associated with genetic defects impairing step 1 (the *MOCS1* gene), step 2 (the *MOCS2* and *MOCS3* genes), and step 3 (the *GPHN* gene), respectively. Approximately two-thirds of patients with molybdenum cofactor deficiency have type A disease.

There is no proven treatment for either isolated sulfite deficiency or molybdenum cofactor deficiency. Efforts to treat patients with either disorder with a low-methionine,

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

low-cysteine diet have been tried and may have been beneficial in a few patients with mild disease but not for those with severe disease. However, one patient with molybdenum cofactor deficiency who had a defect in the *MOCS1* gene was treated intravenously with purified cPMP and showed clinical and metabolic improvement. This was reported in 2012.[130] Since then, other patients have been treated with encouraging results. This treatment remains experimental but is available for compassionate use. However, this approach will not benefit patients with isolated sulfite oxidase deficiency or with the other genetic forms of molybdenum cofactor deficiency (i.e., patients with defects in the *MOCS2*, *MOCS3*, or *GPHN* genes).

Untreatable Disorders

In addition to evaluating the patient for treatable or potentially treatable inborn errors of metabolism, the physician will want to consider other inborn errors of metabolism that are not treatable at this time. A partial listing of currently untreatable inborn errors of metabolism that can cause neonatal seizures is provided in the following.

Adenosylsuccinate Lyase Deficiency. Two disorders of purine biosynthesis may present in the neonatal period, adenosylsuccinate lyase deficiency and AICA-ribosiduria. Both disorders are rare, but AICA-ribosiduria has been described in only a single patient and is not discussed further here. Adenosylsuccinate lyase catalyzes two distal steps in the purine synthetic pathway: (1) the conversion of SAICAR (succinylaminoimidazole caboxamide riboside) to AICAR (5-phosphoribosyl-5-amino-4-succinoimidazolecarboxamide) in the de novo purine synthesis pathway and (2) the conversion of adenosylsuccinate to adenylic acid for recycling and synthesis of nucleic acids. Adenosylsuccinate lyase deficiency can present in the neonatal period with intrauterine growth restriction, microcephaly, fetal and neonatal hypokinesia, lack of fetal heart rate variability, severe hypotonia, severe seizures, and early death.[76] The biochemical hallmarks of adenosylsuccinate lyase deficiency are increased urinary concentrations of 5-phosphoribosyl-5-aminoimidazole-4-(N-succino)caboxamide and adenosylsuccinate. Clinical analysis for these purine precursors is clinically available. The diagnosis can be confirmed by enzyme analysis or genetic testing.

Congenital Disorders of Glycosylation. The congenital disorders of glycosylation are an increasingly recognized group of disorders that present with an extraordinarily diverse range of phenotypes.[50,64] These disorders are discussed in sections provided elsewhere in this chapter (see the subsection on Hepatic Dysfunction and the subsection on Dysmorphic Syndromes in the section discussing The Abnormal Newborn Infant: Clinical Phenotypes). One group of disorders that is discussed in the Dysmorphic Syndromes section is called the dystroglycanopathies, which produce a form of congenital muscular dystrophy that is associated with skeletal muscle and brain abnormalities.[111] The dystroglycanopathies are caused by defects in O-glycosylation (i.e., glycosylation of the protein is via the hydroxyl group of serine or threonine) rather than a defect in N-glycosylation (i.e., glycosylation of the protein is via the amide group of asparagine). Two of these disorders in O-glycosylation are called Walker-Warburg syndrome and muscle-eye-brain disease, both of which are characterized by severe muscle weakness, psychomotor retardation, ocular abnormalities (including unilateral or bilateral microcornea, microphthalmia, hypoplastic or absent optic nerves, retinal coloboma, cataracts, iris hypoplasia, and abnormal anterior chamber angle leading to glaucoma), and epilepsy. Some patients may have cardiac involvement. Laboratory evaluation often reveals increased serum creatine kinase activity, whereas cranial MRI shows brain malformations including structural abnormalities (e.g., hydrocephalus, brainstem hypoplasia, cerebellar hypoplasia or cysts) or neuronal migration abnormalities (e.g., cobblestone lissencephaly or polymicrogyria). Diagnosis of these disorders can be made by morphologic examination of a skeletal muscle biopsy or by genetic testing. Mutations of several different genes can produce Walker-Warburg syndrome, including *POMT1*, *POMT2*, *FKTN*, *FKRP*, *LARGE*, or *ISPD*, whereas muscle-eye-brain disease is associated with mutations in the *POMGnT1* gene. Additional disorders within this category of disease are still being described.

Congenital Neuronal Ceroid Lipofuscinosis. The congenital form of neuronal ceroid lipofuscinosis (NCL) is caused by deficiency of a lysosomal enzyme called cathepsin D.[88] This disorder may present prenatally or neonatally, distinguishing it from the other forms of NCL, which present later than 6 months of age. The diagnosis can be established by microscopic examination of a skin biopsy, by enzymatic testing (measurement of tripeptidyl peptidase 1 [TPP1] and palmitoyl-protein thioesterase 1 [PPT1] in leukocytes), or by genetic testing.

Dihydropyrimidine Dehydrogenase Deficiency. Dihydropyrimidine dehydrogenase is an enzyme involved in the catabolism of pyrimidine metabolism, more specifically the catabolism of thymine and uracil. Patients with deficiency of this enzyme generally present in the first year of life with growth delay and seizures and subsequently manifest microcephaly with craniofacial dysmorphism, growth restriction, and autistic features. A minority of patients present earlier with neonatal seizures. The biochemical hallmark of the disease is increased urinary excretion of thymine and uracil. The diagnosis can be confirmed by enzyme analysis or genetic testing. No therapy is available.

There is also an adult form of this disease in which patients present with severe, potentially life-threatening toxicity after receiving chemotherapy with 5-flourouracil, a pyrimidine analogue. The neonatal or infantile form of this disease is inherited as an autosomal recessive disorder, whereas the adult form may affect heterozygous or homozygous individuals. Thus, first-degree relatives of infants identified with this disorder should also be tested and counseled regarding their risk of adverse reactions to 5-fluorouracil therapy.

Gamma-Aminobutyric Acid Disorders. Gamma-aminobutyric acid (GABA) is an essential neurotransmitter.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

There are two rare disorders of GABA metabolism that can produce isolated neonatal seizures: GABA transferase deficiency and succinic semialdehyde dehydrogenase (SSADH) deficiency.[88] Gamma-aminobutyric acid transferase deficiency presents with poor feeding, psychomotor delay, hypotonia, hyperreflexia, and intractable seizures. Cranial diffusion-weighted MRI demonstrates increased signal in the internal and external capsules and the subcortical white matter. The biochemical findings include increased concentrations of GABA, β-alanine, and homocarnosine in the CSF. There is no effective treatment for this disease. Succinic semialdehyde dehydrogenase deficiency generally produces a nonspecific encephalopathy that evolves into a neurobehavioral disorder associated with global developmental delays, most notably including severe speech delay, and seizures that may develop in infancy. Cranial T_1-weighted MRI demonstrates increased signal in the basal ganglia. The biochemical hallmark is an increased GABA concentration in the blood, urine, and CSF. The diagnosis can be confirmed by enzyme analysis of white cells or genetic testing. Currently available treatment for this disorder is poor.

Mitochondrial Glutamate Transporter. Glutamate is a strategic excitatory neurotransmitter in the brain. The mitochondrial glutamate transporter is involved in intracellular trafficking of glutamate between the mitochondrion and cytosolic compartments and is expressed ubiquitously and both pre- and postnatally. For reasons that remain unclear, deficiency of this receptor causes an exclusively neurologic picture characterized by neonatal onset of microcephaly, myoclonic seizures with a burst-suppression EEG pattern, low-amplitude visual evoked potential, and MRI findings of cerebellar hypoplasia and abnormal corpus callosum.[73] Standard biochemical testing reveal normal plasma amino acids, plasma carnitine and acylcarnitines, and urinary organic acids. The biochemical hallmark of the defect is impaired mitochondrial glutamate oxidation, as demonstrated by polarographic analysis of cultured skin fibroblasts (see the subsection Specialized Biochemical Testing under The Abnormal Newborn Infant: Laboratory Phenotypes). Alternatively, the diagnosis can be established by genetic testing of the *SLC25A22* gene, which encodes for the mitochondrial glutamate transporter. No effective treatment is available.

Peroxisomal Disorders. The peroxisomal disorders can be divided into two groups: (1) defects of peroxisomal biogenesis that affect synthesis and assembly of the peroxisomal organelle that affect most or all of the peroxisomal enzymes and (2) defects in single enzymes that function within the assembled peroxisome (see The Abnormal Newborn Infant: Clinical Phenotypes, Dysmorphic Syndromes).[114,135] Zellweger syndrome is the paradigm of the peroxisomal biogenesis disorders. It is an autosomal recessive disorder characterized by craniofacial dysmorphism, failure to thrive, renal cortical cysts, epiphyseal stippling, profound hypotonia and severe psychomotor retardation, seizures, and early death. Epiphyseal stippling is an unusual radiographic finding of ectopic calcification found most characteristically in the ankle, patella, vertebrae, hips, and trachea. Other peroxisomal assembly disorders may also present with seizures. In addition, single enzyme defects of the peroxisomal fatty acid β-oxidation pathway (which is genetically and functionally different from the mitochondrial fatty acid β-oxidation pathway) can mimic the physical and neurologic features of Zellweger syndrome. The biochemical hallmarks and diagnosis of these disorders are discussed elsewhere in this chapter (see the subsection Specialized Biochemical Testing in The Abnormal Newborn Infant: Laboratory Phenotypes and the subsection Dysmorphic Syndromes in The Abnormal Newborn Infant: Clinical Phenotypes). The diagnosis can be confirmed by genetic testing.

Cardiomyopathy

See Chapter 76. Inborn errors of metabolism that can produce cardiomyopathy and associated arrhythmias in the neonatal period can be divided into five major diagnostic categories: (1) congenital disorders of glycosylation; (2) fatty acid β-oxidation disorders; (3) glycogen storage disorders; (4) lysosomal storage disorders; and (5) respiratory chain defects (Table 90.4).[55,127]

Another group of disorders that can cause cardiomyopathy in children, the lysosomal storage disorders, does not generally produce cardiomyopathy in early infancy.

The different groups of inborn errors of metabolism that can lead to cardiomyopathy do so via different pathophysiologic mechanisms. The glycogen storage disorders lead to impaired gluconeogenesis, depriving the heart of an essential energy source during fasting. The glycogen storage disorders may also lead to an infiltrative process, resulting from the accumulation of partial breakdown products of glycogen in the myocardium. Fatty acid β-oxidation disorders also lead to an energy-deficient state after glucose and glycogen stores have been depleted. The mitochondrial disorders also compromise energy production in the heart and/or lead to production of toxic metabolites.[33,43,101]

Congenital Disorders of Glycosylation

An inborn error that may be associated with cardiomyopathy in early infancy is congenital disorder of glycosylation type Ia (CDG-Ia). The CDG-Ia syndrome is a highly pleiotropic disorder that can produce pericardial effusions, cardiomyopathy, or both, in addition to a broad range of other abnormalities, including neurologic abnormalities, hepatic dysfunction and, in some cases, a characteristic pattern of malformation (see Dysmorphic Syndromes).[50,64] Other, less common forms of CDG may also produce cardiomyopathy.

Fatty Acid β-Oxidation Disorders

The myocardium derives a significant fraction of its energy from the mitochondrial oxidative metabolism of fatty acids, especially long-chain fatty acids.[43,58] The oxidation of these fatty acids requires a carnitine-mediated system to transport long-chain fatty acids into the mitochondrion, a

TABLE 90.4 Disorders Associated With Cardiomyopathy

Category of Disorder	Disorder
Congenital disorders of glycosylation	CDG-Ia and others
Fatty acid oxidation disorders	Carnitine-acylcarnitine translocase deficiency Carnitine palmitoyltransferase II deficiency Carnitine transporter deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency/trifunctional protein deficiency Multiple acyl-CoA dehydrogenase deficiency Very-long-chain acyl-CoA dehydrogenase deficiency
Glycogen storage disorders	GSD type II (Pompe disease) GSD type IX (phosphorylase kinase deficiency)
Lysosomal storage disorders	Glycolipidoses Mucopolysaccharidoses Oligosaccharidoses
Mitochondrial disorders	mtDNA disorders Genes involved in protein synthesis of RC complexes Complex I and IV ($tRNA^{Leu}$) Genes that encode for RC complexes Complex III (cytochrome b subunit) Complex V (*ATP6* and *ATP8*) nDNA Genes that encode for RC complexes Complex I (*NDUFS2*, *NDUFV2*) Complex II (*SDHA*) Genes that encode for assembly or stabilization of RC complexes Complex IV (*SCO2*, *COX10*, *COX15*) Complex V (*TMEM70*) Genes that encodes for other necessary components of the RC complexes Coenzyme Q_{10} biosynthesis (9 genes) Mitochondrial phosphate carrier (*SLC25A3*) Genes involved in maintaining mitochondrial milieu Barth syndrome (*TAZ*) Mitochondrial DNA depletion syndrome 13 (*FBXL4*)

ATP6, Gene that encodes for structural subunit 6 of complex V; *ATP8,* gene that encodes for structural subunit 8 of complex V; CDG, congenital disorder of glycosylation; *COX10,* gene that encodes assembly protein for complex IV; *COX15,* gene that encodes assembly protein for complex IV; *FBXL4*, F-box/LRR-repeat protein 4, which involved in maintenance of mtDNA; GSD, glycogen storage disease; mtDNA, mitochondrial DNA; nDNA, nuclear DNA; *NDUFS2*, gene that encodes for subunit 1 of complex I; *NDUFV2*, gene that encodes for subunit 1 of complex I; *RC*, respiratory chain; *SCO2*, gene that encodes assembly protein for complex IV; *SDHA*, gene that encodes subunit A of complex II; *SLC25A*, gene that encodes for the mitochondrial phosphate carrier; t^{Ile}, transfer RNA for isoleucine; t^{Leu}, transfer RNA for leucine; *TAZ*, gene that encodes for taffazin; *TMEM70*, gene that encodes for protein required for assembly of complex V.

β-oxidation pathway to break down the fatty acids in the mitochondrion, and the mitochondrial respiratory chain to derive energy from the breakdown products. Cardiomyopathy would be expected to develop in the context of a defect in carnitine-mediated transport of long-chain fatty acids into the mitochondrion, defects of the fatty acid β-oxidation pathway, and defects of the respiratory chain itself. Studies have demonstrated that defects of long-chain fatty acid β-oxidation are a significant cause of cardiac disease in the neonatal period, whereas defects affecting primarily medium- or short-chain fatty acid β-oxidation are less so.

Several defects of long-chain fatty acid transport across the mitochondrial membranes and β-oxidation pathway can cause hypertrophic cardiomyopathy in the neonatal period, including carnitine-acylcarnitine translocase (CACT) deficiency, carnitine palmitoyltransferase II (CPT II) deficiency, long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency/trifunctional protein (TFP) deficiency, and very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency (see Approaches to Specific Abnormal Laboratory Findings, Hypoglycemia).[104,105] Multiple acyl-CoA dehydrogenase deficiency (also known as glutaric aciduria type II), a defect in the transfer of reducing equivalents from the enzymes of the β-oxidation pathway to the respiratory chain, can also produce cardiomyopathy (see Dysmorphic Syndromes). Two other defects associated with long-chain fatty acid β-oxidation, plasma membrane carnitine transporter deficiency (also known as carnitine uptake defect or systemic primary carnitine deficiency) and carnitine palmitoyltransferase I (CPT I) deficiency, do not generally cause cardiomyopathy in the neonatal period. The plasma membrane carnitine transporter deficiency does, however, lead to dilated cardiomyopathy in later infancy and childhood.

The clinical features, diagnosis, treatment, and prognosis of these disorders are discussed further in later sections of this chapter (see the subsection Hypoglycemia in The Abnormal Newborn Infant: Laboratory Phenotypes).

Glycogen Storage Disorders

The glycogen storage disorder that most commonly causes hypertrophic cardiomyopathy in early infancy is Pompe disease, also known as α-glucosidase deficiency, acid maltase deficiency, or glycogen storage disease type II. α-Glucosidase is the only enzyme involved in glycogen metabolism that is located within the lysosome. Pompe

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

disease can also be considered a lysosomal storage disorder, and it is probably helpful to consider its pathogenesis from this perspective. Acid maltase is a key enzyme responsible for degrading glycogen; it cleaves the α-1,4-glucoside linkages of the glycogen polymer, converting glycogen to glucose.

Generalized hypotonia, failure to thrive, and cardiomyopathy characterize the neonatal form of Pompe disease.[24] Hepatomegaly does not develop in patients with Pompe disease (except as a consequence to heart failure), as it does in patients with some other glycogen storage disorders (most notably types I and III). The diagnosis is supported by an increased serum creatine kinase activity and increased urinary excretion of a specific glucose tetrasaccharide and then confirmed by enzyme analysis using skeletal muscle, cardiac muscle, or cultured skin fibroblasts, or by genetic testing. Enzyme replacement therapy for the infantile form of Pompe disease appears promising.[17,59,152]

Cardiomyopathy is not generally seen in the neonatal period in association with the other glycogen storage disorders, except in rare cases of cardiac-specific phosphorylase b kinase deficiency. Studies have shown that most, if not all, cases of cardiac-specific phosphorylase kinase deficiency (glycogen storage disease type IX) are really caused by mutations in the γ_2-subunit of adenosine monophosphate (AMP)–activated protein kinase (*PRKAG2*).[24]

Lysosomal Storage Disorders

Many of the lysosomal storage disorders produce cardiomegaly, valvular disease, and/or cardiomyopathy (dilated or hypertrophic).[33,113] Lysosomal storage disorders should be considered in the differential diagnosis of the newborn infant with cardiac disease who has other physical findings suggestive of a lysosomal storage disorder, such as craniofacial dysmorphism, corneal clouding or retinal abnormalities, hepatosplenomegaly, or skeletal anomalies (see Dysmorphic Syndromes). Examples of lysosomal storage disorders that may, on rare occasion, present with cardiomyopathy in the newborn period include those with multiple enzyme defects (multiple sulfatase deficiency, galactosialidosis), sphingolipidoses (e.g., GM1-gangliosidosis, Sandhoff disease), and transport/trafficking disorders (e.g., infantile free sialic acid storage disorder and sialidosis).[113]

Mitochondrial Disorders

Several mitochondrial defects are associated with cardiomyopathy in the neonatal period.[44,101,108,117] These disorders may be classified according to whether they are the consequence of an error in a mitochondrial-encoded (mtDNA) component or in a nuclear-encoded (nDNA) component of the respiratory chain (see Table 90.4).

Several mtDNA defects can cause cardiomyopathy. One group of defects involves the mitochondrial-encoded tRNAs required for protein mitochondrial protein synthesis; for example, the C3303T point mutation in the $tRNA^{Leu(UUR)}$ affects the synthesis of complexes I and IV.[14] This mutation causes Leigh syndrome, which produces a variable clinical pattern that can include hypotonia, optic atrophy, nystagmus, developmental delay, hepatic dysfunction, myopathy, and cardiomyopathy. A second group of defects involves the genes that encode for the mitochondrial-encoded protein subunits of the respiratory chain. For example, the G15498A point mutation in the gene that encodes for the cytochrome b subunit of complex III causes neonatal cardiomyopathy, whereas another mutation affects the ATP6 and ATP8 subunits of complex V.

The classification of nDNA defects that cause neonatal cardiomyopathy includes three groups of disorders: (1) defects affecting individual subunits of the respiratory chain complexes; (2) defects affecting proteins required for assembly or stabilization of the respiratory chain complexes; and (3) defects affecting the mitochondrial milieu, including substrates for the respiratory chain and oxidative phosphorylation.[24,27,108] Examples of the first group of disorders include mutations affecting the mitochondrial-encoded subunits of complex I (i.e., *NDUFS2* and *NDUFV2*), complex II (*SDHA*), and coenzyme Q_{10} biosynthesis. Group 2 includes mutations of the *SCO2*, *COX10*, and *COX15* genes, which are required for assembly of respiratory complex IV (also known as cytochrome c oxidase), and *TMEM70*, which is required for assembly of complex V (ATP synthase).[26,62,83] Group 3 involves genes associated with the mtDNA depletion syndrome. This includes mitochondrial DNA depletion syndrome 13, which is inherited in an autosomal recessive manner and is caused by mutations in the *FBXL4* gene. These mutations lead to an impairment of phosphorylation-dependent ubiquitination, which is involved in protein degradation affecting multiple mitochondrial pathways. Clinically, patients with this disorder present with encephalomyopathy, failure to thrive, developmental delay, seizures, movement disorders, cerebral atrophy, hepatic dysfunction, arrhythmias, and occasionally hypertrophic cardiomyopathy. Finally, group 3 includes Barth syndrome, an X-linked disorder that impairs production of the lipid membrane required for normal mitochondrial function. This disorder is characterized by cardiomyopathy, cataracts, deafness, and neutropenia.[21] Group 3 also includes defects in the gene that encodes for the mitochondrial phosphate carrier (*SLC25A3*).

Eye Anomalies

Many inborn errors of metabolism manifest with unusual ophthalmologic findings (see Table 90.3). A careful ophthalmologic examination is a crucial part of the clinical evaluation for a suspected inborn error of metabolism; conversely, patients with unusual ophthalmologic findings might require a metabolic evaluation (see Chapter 95).

Inborn errors of metabolism can affect any of the structural components of the eye.[85] Cataracts are classically associated with carbohydrate disorders (e.g., galactosemia), Lowe syndrome (oculocerebrorenal syndrome), and certain forms of other groups of disorders, including lysosomal disorders (e.g., galactosialidosis), mitochondrial disorders

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

(e.g., Barth syndrome), and peroxisomal disorders (e.g., Zellweger syndrome). Corneal clouding may be seen in early infancy in patients with several lysosomal storage diseases, such as GM1-gangliosidosis, β-glucuronidase deficiency, I-cell disease, and sialidosis. Lens dislocation does not generally occur during the neonatal period in patients with homocystinuria or sulfite oxidase deficiency but may occur in older patients with these disorders.

Several inborn errors of metabolism affect retinal development.[85] The so-called cherry-red spot is found in several of the lysosomal storage disorders (e.g., Farber disease, galactosialidosis, GM1-gangliosidosis, Tay-Sachs disease, Sandhoff disease, infantile free sialic acid storage disorder, and sialidosis). Abnormal deposits in the retinal pigment epithelial layer leading to retinitis pigmentosa may develop in older patients who have congenital disorder of glycosylation type Ia (CDG-Ia), fatty acid oxidation disorders (LCHAD deficiency), peroxisomal disorders (Zellweger syndrome and its variants), and mitochondrial disorders.

Gastrointestinal Abnormalities

Newborn infants with inborn errors of metabolism might have various gastrointestinal abnormalities. Common clinical findings include poor feeding, jaundice, hepatomegaly, and splenomegaly, while abnormal liver function studies are a common laboratory finding (see Hepatic Dysfunction and Hepatomegaly and Splenomegaly). Many of the organic acidurias and urea cycle disorders are associated with vomiting. Several patients with an organic acidemia have undergone surgery for and been found to have pathologically confirmed pyloric stenosis. Researchers hypothesize that the organic acidemias produce toxic metabolites that affect pyloric sphincter tone. Similarly, pancreatitis is a well-documented problem in patients with several organic acidemias, fatty acid β-oxidation disorders, and mitochondrial disorders.[63]

Diarrhea is a relatively uncommon finding, but it can occur in patients who have defects of bile acid synthesis (see Hepatic Dysfunction), CDG-Ia and CDG-Ib (see Dysmorphic Syndromes), CDG-Ib, congenital chloride diarrhea (see Chapter 83), intestinal disaccharidase and monosaccharide transport deficiencies, lysosomal storage disorders (e.g., Wolman disease) (see Hepatomegaly and Splenomegaly), and mitochondrial disorders (see Hematologic Abnormalities). Lastly, several lysosomal storage disorders can produce congenital ascites and hydrops fetalis (see Prenatal Onset). Inborn errors are associated with hepatic dysfunction, and hepatomegaly/splenomegaly are discussed in the next two sections.

Hepatic Dysfunction

A number of inborn errors of metabolism are associated with hepatic disease. Excluding disorders that are associated primarily with defects in bilirubin metabolism (see Chapter 91), several groups of disorders lead to hepatic dysfunction and some degree of hepatomegaly. One approach to categorizing these disorders is to divide them into those that impair one or more aspects of hepatic function to a more significant degree than they produce liver enlargement and those for which the reverse is true. The former group of disorders is discussed in this section; the latter group, composed primarily of storage disorders, is discussed under Hepatomegaly and Splenomegaly.

The inborn errors of metabolism that can cause hepatic dysfunction can be categorized further according to the function or functions that they impair: defects that cause hypoglycemia, defects that cause hepatocellular damage leading to liver failure and cirrhosis, and defects that cause cholestatic disease. Although this approach is useful from a physiologic perspective, many inborn errors affect more than one of these hepatic functions, and an alternative scheme based on biochemical classification may be applied more practically. The biochemically based approach has been adopted in organizing this section. It is recommended that defects of the following biochemical categories be considered in evaluating patients with hepatic dysfunction: amino acid metabolism, bile acid metabolism, carbohydrate metabolism, congenital disorders of glycosylation, fatty acid β-oxidation, peroxisomal disorders, respiratory chain defects, and a miscellaneous group of disorders (Table 90.5).[22] The clinical aspects of these disorders are presented in greater detail in Chapter 91.

Amino Acid Defects

Tyrosinemia Type I. Tyrosinemia type I, also known as hepatorenal tyrosinemia, is the classic aminoacidopathy that can produce a fulminant disorder characterized by progressive hepatocellular damage leading to cirrhosis, proximal renal tubular dysfunction, and peripheral neuropathy.[110] The biochemical basis of this disorder is a defect in fumarylacetoacetate hydratase, an enzyme acting late in the tyrosine catabolic pathway. Fumarylacetoacetate accumulates secondary to this enzyme deficiency and is nonenzymatically converted to succinylacetone, which is the characteristic urinary metabolite identified in patients with this disorder. Succinylacetone can be identified by urine organic acid analysis or liquid chromatography/tandem mass spectrometry.

Until recently, the only treatment for this disorder that appeared to be effective was liver transplantation. However, a new treatment based on pharmacologic inhibition of 4-hydroxyphenylpyruvate dioxygenase (an enzyme upstream of the hydratase in the tyrosine catabolic pathway) with Nitisone (Orfadin) [2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC)] has been introduced and is effective in preventing liver disease, especially when therapy is begun before the onset of acute liver failure and is combined with a tyrosine-restricted diet.

Citrin Deficiency. Urea cycle defects are generally associated with mild hepatocellular dysfunction during their acute presentation, but the neurologic manifestations of these disorders are the predominant signs (see Hyperammonemia). The degree of hepatocellular disease can become

TABLE 90.5 Disorders Associated With Hepatic Dysfunction

Category of Disorder	Defect
Amino acid metabolism	Tyrosinemia type I Citrin deficiency
Bile acid biosynthesis	*See text for specific disorders*
Carbohydrate metabolism	Galactosemia Hereditary fructose intolerance Glycogen storage disease type IV
Congenital disorders of glycosylation	CDG-Ib and other forms
Fatty acid oxidation	Carnitine-acylcarnitine translocase deficiency Carnitine palmitoyltransferase Ia deficiency Carnitine palmitoyltransferase II deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency/ trifunctional protein deficiency Multiple acyl-CoA dehydrogenase deficiency Very-long-chain acyl-CoA dehydrogenase deficiency
Lysosomal storage disorders	Gaucher disease type 2 Niemann-Pick disease type C
Mitochondrial disorders	mtDNA disorders Genes involved in protein synthesis of RC complexes • Multiple complexes ($tRNA^{Glu}$) Large-scale deletions (Pearson syndrome) nDNA Genes that encode for assembly or stabilization of RC complexes • Complex III (*BCS1L*) • Complex IV (*SCO1*) • Complex V (*TMEM70*) Genes involved in intergenomic communication • mtDNA depletion syndromes (*DGUOK*, *FBXL4*, *MPV17*, *POLG*, *SUCLG1*)
Peroxisomal disorders	Single enzyme disorders Biogenesis disorder

BCS1L, Gene required for assembly of complex III; CDG, Congenital disorder of glycosylation; *DGUOK*, gene that encodes for deoxyguanosine kinase; *FBXL4*, gene associated with regulation of protein degradation; *MPV17*, gene associated with mitochondrial DNA depletion syndrome 6; mtDNA, mitochondrial DNA; nDNA, nuclear DNA; *POLG*, gene that encodes for polymerase γ; RC, respiratory chain; *SCO1*, gene required for insertion of copper into Complex IV; *SUCLG1*, gene that encodes for subunit 1 of succinyl-CoA ligase; $tRNA^{Glu}$, transfer RNA for glutamic acid; *TMEM70*, gene required for assembly of complex V (ATP synthase).

more significant later in the course of these diseases, especially in argininosuccinic aciduria. There is, however, a urea cycle–related disorder called *citrin deficiency* that may produce neonatal intrahepatic cholestasis.[79,98]

Citrin deficiency is a genetic disorder caused by a defect in the mitochondrial aspartate-glutamate carrier, which plays a strategic role in the urea cycle, gluconeogenesis, and the malate shuttle (which moves NADH between intracellular compartments). Impaired citrin function would limit the conversion of citrulline and aspartate to argininosuccinic acid, a strategic component of the urea cycle. Absent aspartate, citrulline accumulates and urea production is impaired. Hence, citrin deficiency is also known as citrullinemia type II, whereas citrullinemia type I (or more simply, citrullinemia) is a urea cycle disorder caused by argininosuccinic acid synthetase deficiency (see Hyperammonemia).

Citrin deficiency was originally identified as a self-limited disorder associated with hepatic dysfunction that resolves by 1 year of age and can be treated successfully with a low-lactose diet and support for the hepatic dysfunction. However, more severe, progressive cases have been identified subsequently that produced severe neonatal intrahepatic cholestasis.[79,98] Patients with this form of citrin deficiency have increased serum concentrations of citrulline, methionine, and phenylalanine, as well as galactose. It does not lead to hyperammonemia. These patients are often ascertained by newborn screening that identified the increased amino acid concentrations and by programs that measure serum galactose as their screen for galactosemia (but not by programs that measure *GALT* activity) (see Newborn Screening). It is a treatable disease. Citrin deficiency can also present as a mild, adult-onset form of hyperammonemia (hence its other name, citrullinemia type II).

Bile Acid Biosynthesis Defects

Heritable defects in bile acid biosynthesis can cause severe hepatobiliary disease (cholestatic jaundice and intestinal malabsorption) in the newborn infant.[23,36] These defects are probably underdiagnosed, because they are not ascertained by the standard methods of metabolic screening of the sick neonate. However, once considered, they can be diagnosed with relative ease. Recognition of these disorders is especially important because effective treatment exists for some of these defects.

In simple terms, bile acid biosynthesis involves conversion of cholesterol to two bile acids, cholic acid and chenodeoxycholic acid. The first steps in this conversion involve transformation of the cholesterol nucleus, and the last few steps involve transformation of the cholesterol side chains. Several defects in conversion of the cholesterol nucleus to bile acids have been described, including 3β-hydroxy-Δ^5-C_{27}-steroid dehydrogenase deficiency and 3-oxo-Δ^4-steroid-5β-reductase deficiency.[23,36] Both of these disorders can result in severe cholestatic disease in the newborn period and can lead in later months to steatorrhea, clinically significant malabsorption of fat-soluble vitamins D and K, failure to thrive, and chronic hepatitis. The patients

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

generally have no or relatively mild hepatomegaly, mildly elevated hepatic aminotransferase values, and nonspecific findings on liver biopsy. If untreated, many patients progress to irreversible liver disease and die in early childhood. Early recognition is crucial, because it permits institution of bile acid replacement therapy using a combination of cholic and chenodeoxycholic acids, which is effective in reversing the hepatotoxic manifestations of these enzyme deficiencies.

Several of the peroxisomal disorders also impair bile acid biosynthesis, because they affect enzymes required for the final steps of cholesterol side-chain oxidation.[23,36,135] These enzymes (i.e., the bifunctional enzyme and the thiolase) are also involved in peroxisomal oxidation of very-long-chain fatty acids, and their deficiency leads to a highly pleiotropic dysmorphic syndrome associated with severe neurologic consequences. Bile acid replacement therapy does not ameliorate the neurologic consequences of these disorders. The peroxisomal disorders, including those that produce cholestatic disease, are discussed further under Dysmorphic Syndromes.

Carbohydrate Disorders

Two disorders of monosaccharide metabolism, galactosemia (see Newborn Screening) and hereditary fructose intolerance, are associated with hepatocellular disease.[104] These disorders manifest only when the newborn's diet contains the monosaccharide to which the newborn is intolerant, such as galactose in the case of galactosemia and fructose in the case of hereditary fructose intolerance. Similarly, these disorders are detectable by urinary screening tests only when the affected newborn is receiving a diet containing the offending monosaccharide. Because fructose is not a component of breast milk and is a component of only the infant formulas that contain sucrose, hereditary fructose intolerance usually does not manifest in the neonatal period. Both disorders can be detected by the presence of reducing substances other than glucose in urine (see Specialized Biochemical Testing). The diagnosis of galactosemia or hereditary fructose intolerance must be confirmed by specific biochemical analysis or genetic testing.

Treatment of these disorders consists of dietary restriction of the hepatotoxic monosaccharide. Such restriction is not easily managed because of the nearly ubiquitous presence of galactose (as a component of lactose) and fructose (as a component of sucrose) in many processed foods. Nevertheless, dietary restriction can be successful and is associated with improved long-term outcomes.

Several other disorders of carbohydrate metabolism can also cause hepatic dysfunction, including the glycogen storage disease types I and III, fructose-1,6-bisphosphatase deficiency, and pyruvate carboxylase deficiency. However, these disorders affect gluconeogenesis and, in contrast to galactosemia and hereditary fructose intolerance, result primarily in hypoglycemia and hepatomegaly rather than generalized hepatocellular dysfunction (see Hypoglycemia). In contrast to these disorders, glycogen storage disease type IV (branching enzyme deficiency) causes severe hepatic dysfunction.

Congenital Disorders of Glycosylation

Congenital disorder of glycosylation type Ib (CDG-Ib) is discussed herein because it manifests exclusively with hepatic and intestinal problems including vomiting, hypoglycemia, protein-losing enteropathy, failure to thrive, diarrhea, hepatomegaly and hepatic dysfunction associated with congenital hepatic fibrosis, and thrombosis or an increased bleeding tendency.[50] Congenital disorders of glycosylation type Ib are caused by phosphomannose isomerase deficiency, an enzyme involved in N-glycosylation of numerous glycoproteins. Patients with CDG-Ib can be identified by transferrin isoelectric focusing or mass spectrometry (see Dysmorphic Syndromes and Specialized Biochemical Testing), and the diagnosis then confirmed by enzyme analysis or genetic testing. Unlike the situation for other forms of CDG, effective treatment exists for patients with CDG-Ib. The clinical problems of several patients with CDG-Ib have been reversed with oral mannose supplementation.

Fatty Acid Oxidation Defects

In general, the disorders of long-chain fatty acid β-oxidation cause hepatic dysfunction to a greater degree than do the disorders of medium- or short-chain fatty acid β-oxidation. The disorders of long-chain fatty acid β-oxidation include carnitine palmitoyltransferase type Ia (CPT Ia) deficiency, carnitine-acylcarnitine translocase (CACT) deficiency, carnitine palmitoyltransferase type II (CPT II) deficiency, very long-chain acyl-CoA dehydrogenase (VLCAD) deficiency, long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency, and trifunctional protein (TFP) deficiency.

A related disorder of fatty acid β-oxidation that is associated with hepatic dysfunction is multiple acyl-CoA dehydrogenase deficiency. This deficiency is a genetically heterogeneous disorder caused by defects in either electron transfer protein (ETF) or ETF dehydrogenase, which function as intermediates between several acyl-CoA dehydrogenases that are involved in fatty acid β-oxidation or amino acid catabolism, and the mitochondrial respiratory chain. This disorder can also be classified as an organic aciduria and is also called glutaric aciduria type II because glutaric acid is a major metabolite observed on urinary organic acid analysis (see Specialized Biochemical Testing). More severe forms of this disorder are associated with dysmorphic features (see Dysmorphic Syndromes).

All of these long-chain fatty acid β-oxidation disorders produce several forms of disease, ranging from a severe neonatal/early infantile form to a relatively benign adult-onset form. The severe neonatal form is usually associated with hepatic dysfunction, presumably due to the impaired mitochondrial energy production from long-chain fatty acids and/or hepatotoxic metabolites that might accumulate secondary to the impaired fatty acid oxidation. The diagnosis and treatment of these disorders is discussed elsewhere in this chapter (see Hypoglycemia).

Lysosomal Storage Disorders

Two lysosomal storage disorders may cause hepatic dysfunction in the newborn period: Gaucher disease type 2 and Niemann-Pick disease type C. Gaucher disease type 2 is a lysosomal storage disease involving sphingolipid metabolism that presents with neonatal cholestasis, thrombocytopenia, and hepatosplenomegaly, as well as severe neurologic dysfunction (including bulbar signs, opisthotonus, and nystagmus). Niemann-Pick disease type C is a lysosomal disorder of intracellular cholesterol trafficking that may cause neonatal liver disease with prolonged jaundice and pulmonary infiltrates or progressive neurologic disease in childhood or later in life.[113]

Mitochondrial Disorders

Multiple mitochondrial disorders are associated with hepatic dysfunction in the neonatal period.[31,44] These disorders can be classified according to whether they are the consequence of an error in a mitochondrial-encoded (mtDNA) component or in a nuclear-encoded (nDNA) component of the respiratory chain and the function of the affected gene (see Table 90.5).

Several mtDNA defects can cause hepatic dysfunction. One group of defects involves a large-scale deletion in the mtDNA, affecting many transfer RNA genes and protein coding genes. Pearson syndrome (also known as Pearson marrow-pancreas syndrome) is the prototype of this group of diseases.[121] It manifests in the newborn period with a variable pancytopenia (characterized by severe macrocytic anemia) and ring sideroblasts in the bone marrow; exocrine pancreatic dysfunction leading to fat malabsorption and diarrhea; hepatic dysfunction (steatosis and cirrhosis, potentially leading to liver failure and death); renal tubular dysfunction; and skeletal muscle weakness. 3-Methylglutaconic aciduria is a biochemical marker for this disorder, and it can be detected by urine organic acid analysis. A second group of mtDNA defects involves genes that encode for the mitochondrial tRNAs required for mitochondrial protein synthesis. For example, defects of the $tRNA^{Glu}$ gene lead to hepatic dysfunction and myopathy.

The classification of nDNA defects that cause neonatal hepatic dysfunction includes two groups of disorders: (1) defects affecting proteins required for assembly or stabilization of the respiratory chain complexes and (2) defects involved in intergenomic communication.[19,31] Examples of the first group of disorders include: mutations in the *BCS1L* gene, which encodes for a protein required for assembly of complex III; mutations of the *SCO1* gene, which encodes for a protein required for assembly of complex IV; and mutations of the *TMEM70* gene, which is required for assembly of complex V (ATP synthase).[26,62,83] Mutations of the *BCS1L* gene lead to GRACILE syndrome, an eponymic association of *g*rowth *r*estriction, *a*mino aciduria due to a Fanconi-like tubulopathy, *c*holestasis, *i*ron overload, *l*actic acidosis, and *e*arly death. *SCO1* mutations produce an encephalohepatopathy. The diagnosis of *BCS1L* and *SCO1* deficiencies can be facilitated by detailed biochemical studies that identify the impaired respiratory chain complex. However, definitive diagnosis requires genetic testing. There is no effective therapy for either disorder.

The second group of nDNA defects affects intergenomic communication (i.e., the defects impair the nDNA-encoded factors that regulate mtDNA replication, producing the mtDNA depletion syndromes).[31,74,75] This is a group of autosomal recessive disorders characterized by reduced mtDNA copy number. Several nuclear genes have been identified as a cause of mtDNA depletion syndromes: (1) the *DGUOK* gene encodes for an enzyme (deoxyguanosine kinase) involved in the mitochondrial nucleotide salvage pathway; (2) the *FBXL4* gene is involved in phosphorylation-dependent ubiquitination that is involved in protein degradation in several key mitochondrial pathways; (3) the *MPV17* gene encodes for an inner mitochondrial membrane protein; (4) the *POLG* gene encodes for polymerase γ, which performs mtDNA replication; and (5) the *SUCLG1* gene encodes for a subunit of succinyl-CoA ligase, a Krebs cycle enzyme. Mutations of these genes have been identified as a cause of neonatal liver disease. *DGUOK* mutations produce a hepatorenal syndrome characterized by hepatic failure, failure to thrive, abnormal eye movements, lactic acidosis, hypoglycemia, and elevated α-fetoprotein. *FBXL4* mutations produce a disorder characterized by encephalomyopathy, failure to thrive, developmental delay, seizures, movement disorders, cerebral atrophy, hepatic dysfunction, arrhythmias, and occasionally hypertrophic cardiomyopathy. *MPV17* mutations produce progressive hepatic failure with hepatomegaly. *POLG* and *SUCLG1* mutations produce hepatocerebral syndromes with lactic acidosis; *SUCLG1* mutations are also associated with mild elevations in urinary methylmalonic acid that can be detected by urine organic acid analysis. These disorders can be identified by a combination of classical biochemical studies followed by genetic testing (see Lactic Acidemia).

Peroxisomal Disorders

Several of the peroxisomal disorders cause significant hepatocellular disease in the neonatal period. Many of these disorders also produce dysmorphic manifestations and are discussed later (see Dysmorphic Syndromes).

Hepatomegaly and Splenomegaly

Several inborn errors of metabolism are associated with hepatomegaly in the newborn period. In many of these disorders (e.g., congenital disorders of glycosylation, organic acidemias, peroxisomal disorders, urea cycle disorders), liver enlargement develops as a result of primary hepatocellular disease; these disorders are not discussed further in this section. Fatty acid oxidation disorders produce hepatomegaly through excessive storage of fat and are discussed elsewhere in this chapter. Another group of disorders, the lysosomal storage disorders, results in hepatomegaly because of excessive storage of incompletely metabolized macromolecules in the liver.

TABLE 90.6 Lysosomal Storage Disorders in Neonates

Category of Disorder	Substrate	Disorders
Glycogenoses	Glycogen	GSD type II (Pompe disease)
Lipidoses	Glycolipids or other complex lipids	Farber disease GM1-gangliosidosis Gaucher disease Krabbe disease Niemann-Pick disease type A Wolman disease
Mucopolysaccharidoses	Mucopolysaccharides	β-Glucuronidase deficiency
Oligosaccharidoses	Glycoproteins Glycolipids	Free sialic acid storage disease Fucosidosis Galactosialidosis I-cell disease Sialidosis

GSD, Glycogen storage disease.

Lysosomes contain a large number of enzymes involved in degrading macromolecules. In the absence of one or more of these enzymes, the macromolecules are only partially degraded. Depending on the origin and nature of the macromolecules, the partially degraded products accumulate in one or more tissues or organs and produce a range of clinical phenotypes. The lysosomal storage disorders can be classified according to the types of macromolecules that accumulate in the lysosome: glycogen, glycolipids or other complex lipids, mucopolysaccharides, or oligosaccharides (Table 90.6). Another group of lysosomal storage diseases is associated with defects of lysosomal transport (e.g., cystinosis, which does not manifest clinically in the neonatal period).

Several lysosomal storage disorders manifest in the neonatal period and should be considered in the differential diagnosis of patients who present with hepatomegaly, with or without other signs of storage disease (see Table 90.6).[16,113] Type II glycogen storage disease (Pompe disease) is the only glycogen storage disease caused by a defect in a lysosomal enzyme, but it generally is associated with hypotonia or cardiomyopathy rather than severe hepatomegaly (see Cardiomyopathy). Other glycogenoses, such as glycogen storage disease types I, III, IV, and VI, may be associated with hepatomegaly and, especially in the case of type I and type III, with hypoglycemia. However, these disorders do not generally present in the neonatal period. Similarly, defects of gluconeogenesis can present with hepatomegaly, but they will also be discussed elsewhere (see Hypoglycemia).

Several glycolipidoses or related disorders of complex lipid catabolism can manifest with hepatomegaly or splenomegaly in the newborn period.[16,113] Farber disease is an untreatable autosomal recessive defect of acid ceramidase. There are different clinical forms of this disorder, and patients can have joint swelling and pain, hoarseness, disturbance in swallowing, macular cherry-red spots, or central nervous system (CNS) dysfunction. Gaucher disease type 2, the acute neuronopathic form of Gaucher disease, results in hepatosplenomegaly during the first months of life (see earlier, Hepatic Dysfunction section under the Other Disorders subheading). This autosomal recessive disorder is caused by a deficiency of glucosylceramidase. Niemann-Pick disease type A (i.e., sphingomyelinase deficiency) usually begins in early infancy with hepatosplenomegaly and progresses with failure to thrive, psychomotor retardation, pulmonary infiltrates, macular cherry-red spots, and early death. One of the most striking of these disorders associated with hepatomegaly is Wolman disease, which is characterized by massive hepatomegaly and splenomegaly, abdominal distention, vomiting, diarrhea, anemia, failure to thrive, and adrenal calcifications. The prognosis for this disorder, caused by lysosomal acid lipase deficiency, has improved with the introduction of HSCT and, more recently, enzyme replacement therapy.

β-Glucuronidase deficiency (also known as mucopolysaccharidosis type VII) occasionally manifests in the neonatal period, although it usually begins later. It presents rarely with hydrops fetalis rather than the more common signs of a mucopolysaccharidosis, such as hepatosplenomegaly, inguinal or umbilical hernias, skeletal dysplasia, corneal clouding, and coarse facial features.

I-cell disease, also known as mucolipidosis type II, is caused by a processing defect that leads to multiple lysosomal enzyme deficiencies and is characterized by coarse facies and disproportionate craniofacial features, limitation of joint movement, hepatosplenomegaly, corneal clouding, and gingival hypertrophy. Severe forms of fucosidosis, galactosialidosis, infantile free sialic acid storage disease, and sialidosis may have similar manifestations. Patients with defects of mucopolysaccharide or oligosaccharide catabolism may also present with hydrops fetalis.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

Two other lysosomal storage disorders can manifest in the neonatal period, but neither is associated with hepatomegaly in the first month of life. Patients with the infantile form of GM1-gangliosidosis (i.e., β-galactosidase deficiency) have psychomotor delay and coarse facial features but do not develop hepatomegaly until later in the first year of life. These patients might also have cherry-red spots.[85] Rarely, Krabbe disease (i.e., galactosylceramidase deficiency) begins in the neonatal period with progressive psychomotor retardation, but hepatomegaly does not develop in affected patients.

Preliminary clinical assessment of a patient with a suspected lysosomal storage disease should include a careful eye examination to detect corneal clouding, cataracts, or abnormal retinal pigment changes; a cardiac evaluation, including an electrocardiogram and echocardiogram; a peripheral blood smear to detect leukocyte inclusions; and a radiologic study of the skeleton for identification of dysostosis multiplex. Leukocyte inclusions are characteristic of the oligosaccharidoses (i.e., fucosidosis, α-mannosidosis, sialidosis) and mucolipidoses (I-cell disease), are the exception in the glycolipidoses (they can be associated with Niemann-Pick type C disease), and are not found in glycogen storage disease type II. Laboratory evaluation of patients with suspected lysosomal storage disorders is presented in Specialized Biochemical Testing.

Enzyme replacement therapy is now available for several lysosomal storage diseases, including Fabry disease, Gaucher disease, Hunter disease, Hurler disease, Maroteaux-Lamy syndrome, Morquio syndrome type A, lysosomal acid lipase deficiency, and Pompe disease, with therapy for other disorders under development. Hematopoietic stem cell transplantation has also been shown to be effective for many disorders and may arrest or even reverse some of the somatic disease and neurologic degeneration associated with some of these disorders.[12,81,113,152]

Hair and Skin Abnormalities

See Chapter 94. Abnormalities of the skin and hair are characteristic of several inborn errors of metabolism. Menkes disease, an X-linked disorder involving intracellular copper transport, leads to defects in several copper-dependent enzymes.[51] Menkes disease is a highly pleiotropic disorder characterized by sparse and kinky scalp hair (hence the name kinky-hair disease), hypopigmentation, hypotonia, hypothermia, intractable seizures, profound developmental delay, and early death. The disorder may be associated with lactic acidosis and seizures caused by impaired activity of cytochrome c oxidase, a copper-dependent enzyme. The hair is brittle and coarse in the childhood-onset form of argininosuccinic aciduria, a urea cycle defect, but this is not typically seen in neonates with this disease (see Hyperammonemia).

A number of disorders include abnormalities of skin pigmentation. Phenylketonuria may be associated with fair hair and skin in affected Caucasian neonates. Similarly, newborn infants with cystinosis have fairer hair and skin than their unaffected siblings. However, cystinosis, an autosomal recessive defect affecting lysosomal transport of cystine, a sulfur-containing amino acid, does not produce symptoms until several months of age, when it results in renal Fanconi syndrome and, ultimately, renal failure caused by cystine crystal deposits in the kidney.[28]

An eczema-like rash and partial alopecia may be associated with multiple carboxylase deficiency, an organic aciduria caused by two defects in biotin metabolism: holocarboxylase synthetase deficiency and biotinidase deficiency (see Newborn Screening and Abnormal Laboratory Findings).[139] Both defects can produce severe ketoacidosis, feeding difficulties, apnea, lethargy, hypotonia, and coma in the newborn period. Holocarboxylase synthetase and, in some cases, biotinidase deficiency can be detected by urinary organic acid analysis. Both conditions respond to biotin therapy.

Hematologic Abnormalities

Several organic acidemias, including isovaleric acidemia, propionic acidemia, and methylmalonic acidemia, are characterized by neutropenia, thrombocytopenia, anemia, or pancytopenia.[124] The thrombocytopenia may be severe enough to lead to clinically significant bleeding and bruising. The precise pathophysiologic basis of these findings is not well understood but is thought to be caused by direct bone marrow suppression by the abnormally elevated metabolites (organic acids) associated with these disorders.

Hematologic abnormalities may be associated with certain mitochondrial disorders, including Barth syndrome[21] and Pearson syndrome.[121] Barth syndrome is characterized by neutropenia and cardiomyopathy, whereas Pearson syndrome is characterized by sideroblastic anemia, pancreatic exocrine insufficiency, and lactic acidosis. Pearson syndrome is the consequence of a heteroplasmic mutation (large deletion) of the mtDNA (see Lactic Acidemia). Neutropenia is a characteristic feature of glycogen storage disease type Ib, and this diagnosis should be considered in the patient who presents with hypoglycemia, hepatomegaly, hypertriglyceridemia, neutropenia, inflammatory bowel disease-like symptoms (i.e., diarrhea), and recurrent infections (see Hypoglycemia).[131] Last, inborn errors of cobalamin metabolism, folate metabolism, and pyrimidine metabolism (e.g., hereditary orotic aciduria) can produce macrocytic anemia.

Sepsis

A newborn infant with a metabolic disease may be at greater risk for sepsis than other neonates, and the presence of documented sepsis does not exclude the possibility of an underlying metabolic disorder. Several inborn errors of metabolism predispose the newborn infant to infections. The best-documented of these associations is the risk of *E. coli* infection in patients with galactosemia. Infections with other bacteria can also develop, but an *E. coli* infection is

relatively specific. The diagnosis of galactosemia should be suspected in all neonates with *E. coli* sepsis, and these infants might need a galactose-free formula until the diagnosis has been excluded.

Disorders of biotin metabolism, including biotinidase deficiency and holocarboxylase synthetase deficiency, are associated with impaired B- and T-cell function, predisposing patients to mucocutaneous candidiasis and other immunologic problems. Recurrent mucocutaneous candidiasis may also develop in patients with maple syrup urine disease.

Unusual Odor

Several inborn errors of metabolism are characterized by unusual odors (Table 90.7). In many of these disorders, the odor is an inconsistent finding and can be detected only during episodes of acute metabolic decompensation. In some cases, the odor is difficult to appreciate during a bedside examination and can more easily be detected by smelling a urine specimen that has been kept at room temperature for several hours. Cerumen is another secretion that may contain increased concentrations of abnormal metabolites and allow the early detection of an inborn error of metabolism, such as maple syrup urine disease.

Dysmorphic Syndromes

In most cases, newborn infants with inborn errors of metabolism do not have physical abnormalities identifiable by physical examination; that is, they do not have a characteristic pattern of dysmorphism or identifiable congenital malformations. The pragmatic corollary to this observation is that metabolic evaluations of dysmorphic patients are not likely to be fruitful (see Chapter 30). However, there has been a growing appreciation of the fact that many inborn errors of metabolism do cause dysmorphic syndromes, and a steadily increasing number of such inborn errors have been identified. These inborn errors can be classified into several groups depending on the metabolic pathway(s) involved and the pathogenetic mechanism(s) by which they produce physical abnormalities.

Several groups of disorders will be considered in this section, including: (1) defects in cholesterol biosynthesis; (2) congenital disorders of glycosylation; (3) lysosomal storage disorders; (4) mitochondrial disorders; (5) peroxisomal disorders; and (6) miscellaneous pathways of small molecule metabolism (Table 90.8). Disorders associated with isolated malformations that are not detectable by physical examination will not be discussed in detail.

Cholesterol Biosynthesis

Several defects of cholesterol biosynthesis manifest in infancy. Inborn errors of cholesterol biosynthesis include defects in the early steps of the pathway and defects in the late steps. For example, mevalonic aciduria is caused by a defect in an early step in cholesterol biosynthesis (i.e., mevalonate kinase deficiency) and is discussed later (see Organic Acidurias).

Smith-Lemli-Opitz (SLO) syndrome is the prototypic example of a recognizable malformation disorder that is

TABLE 90.7 Characteristic Odors of Several Neonatal Inborn Errors of Metabolism

Disorder	Nature of Odor

caused by a defect in a late step in cholesterol biosynthesis.[42,86,126] Smith-Lemli-Opitz syndrome was recognized in the 1970s as a highly variable malformation syndrome. The mild form of this disorder is characterized by prenatal and postnatal growth restriction, microcephaly, characteristic craniofacial dysmorphism (including ptosis, low-set ears, epicanthal folds, and micrognathia), strabismus, syndactyly of the second and third toes, hypospadias, hypotonia, and intellectual disability. In its most severe form, patients also exhibit postaxial polydactyly, cleft palate, eye malformations, holoprosencephaly, cardiac defects, and, in boys, pseudohermaphroditism ranging from hypospadias to sex reversal. At autopsy, a range of severe malformations of the brain, heart, and kidneys can be identified.

In 1994, the genetic basis of SLO syndrome was shown to be a heritable defect in cholesterol biosynthesis.[126] Patients were found to have an abnormally low plasma cholesterol concentration and a markedly increased concentration of 7-dehydrocholesterol and, to a lesser degree, 8-dehydrocholesterol in plasma and cultured skin fibroblasts. Further work established the enzymatic basis of this syndrome as an autosomal recessive defect affecting 7-dehydrocholesterol reductase. After recognition of the underlying defect causing the SLO syndrome and development of specific methods for diagnosis, SLO syndrome has been recognized as a relatively common inborn error of metabolism, with a frequency of approximately 1 case in 20,000 persons.

The diagnosis of SLO syndrome should be investigated in patients with suggestive clinical phenotypes. Because the clinical phenotype is so variable and may be difficult to recognize in female patients without obvious genital anomalies, the diagnosis should also be pursued in patients with low plasma cholesterol concentrations. The diagnosis should also be pursued in patients who have a suggestive clinical phenotype but normal plasma cholesterol concentrations, because many of the methods in standard clinical use for measuring the plasma cholesterol concentration could yield false-negative results for patients with SLO syndrome. SLO syndrome can be diagnosed more specifically by measuring 7-dehydrocholesterol in plasma or cultured skin fibroblasts using gas chromatography or combined gas chromatography/mass spectrometry, followed by enzymatic analysis or genetic testing.

Efforts to treat SLO patients with supplemental cholesterol began immediately after recognition of the biochemical basis of the disease. Cholesterol supplementation could improve some aspects of the outcome, including the behavioral aspects of the disease, especially when treatment is begun very early in infancy.[42] The outcome appears to be better for patients with milder forms of the disease than for those with the severe forms (patients with significant defects in prenatal morphogenesis). However, the long-term intellectual outcome of this form of treatment remains poor.

Other defects of cholesterol biosynthesis have been identified subsequent to the discovery of the genetic basis of SLO syndrome, including Conradi-Hunermann syndrome, the rhizomelic form of chondrodysplasia punctata, lathosterolosis, desmosterolosis, Greenberg skeletal dysplasia, and CHILD (congenital hemidysplasia, ichthyosiform erythroderma, and limb defects) syndrome.[42,86]

Patients with Conradi-Hunermann syndrome have chondrodysplasia punctata and rhizomelic skeletal dysplasia. Chondrodysplasia punctata is a distinctive radiologic finding that refers to the abnormal pattern of punctate calcification of epiphysial cartilage and related tissues. This finding can be seen in some of the neonatal forms of peroxisomal disease (e.g., Zellweger syndrome) as well as SLO syndrome.

Rhizomelic dysplasia is a pattern of proximal limb shortening that is found in several malformation syndromes. Using the same analytic methods required to diagnose and evaluate patients with SLO syndrome, a previously unrecognized defect in sterol biosynthesis was identified in a fraction of patients with the rhizomelic form of chondrodysplasia punctata and in patients with Conradi-Hunermann syndrome.

Desmosterolosis has an osteosclerotic form of skeletal dysplasia and malformations similar to SLO syndrome. It appears that defects of sterol biosynthesis will prove to be responsible for a family of recognizable malformation syndromes, including many characterized by unusual skeletal dysplasia.

Congenital Disorders of Glycosylation

The congenital disorders of glycosylation (CDG) are a large group of clinically diverse inborn errors of metabolism caused by genetic deficiencies in the pathways of glycoconjugate biosynthesis. Glycoconjugates are defined as molecules in which carbohydrates are covalently linked with proteins (forming glycoproteins) or lipids (forming glycolipids). From a pathogenetic perspective, the CDG represent the reverse of the lysosomal storage disorders. The CDG are the consequence of enzyme deficiencies in the endoplasmic reticulum or Golgi that impair the biosynthesis of glycoconjugates, whereas the lysosomal storage disorders are primarily the consequence of enzyme deficiencies in the lysosome that impair the biodegradation of glycoconjugates.

The most common group of CDG impairs the synthesis of N-linked glycoproteins (i.e., the carbohydrates are attached to the protein through the amide group of asparagine). The prototypic form of this group of disorders is CDG type Ia (CDG-Ia), which has a characteristic pattern of dysmorphism plus multisystem disease.[50,64] The nomenclature for the CDG has been changed recently to reflect more directly the underlying enzyme deficiency. Thus, CDG-Ia is now referred to as *PMM2-CDG* (PMM2 refers to phosphomannomutase 2, the enzyme deficiency responsible for this disease). The older nomenclature is used in the chapter because it is more commonly used in the existing clinical literature.

Most patients with CDG-Ia come to medical attention in the neonatal period or in early infancy with neurologic

abnormalities, including strabismus or other eye movement abnormalities, cardiac problems (cardiomyopathy and/or pericardial effusion), failure to thrive (usually attributed to poor feeding, vomiting, or diarrhea), hepatic dysfunction (mild elevations in liver enzyme values, hypoalbuminemia, and a characteristic coagulopathy), proteinuria, skeletal anomalies, recurrent infections (especially of the pulmonary tree), hypotonia, ataxia, and developmental delay. The patients typically have a characteristic pattern of dysmorphism that can be recognized in the neonatal period, which includes an abnormal pattern of fat distribution, with an especially prominent fat pad in the suprapubic area and buttocks, doughy skin texture, and inverted nipples.

Cranial imaging demonstrates cerebellar or olivopontocerebellar hypoplasia and a milder degree of cerebral hypoplasia. Microscopic examination of liver biopsy specimens reveals a characteristic form of fibrosis, whereas ultrastructural studies demonstrate a characteristic pattern of lysosomal inclusions and changes in the endoplasmic reticulum.

About 20% of patients with neonatal onset of the disease die in the first year of life as a result of cardiac failure, liver failure, or infection. Those who survive the first year of life manifest ataxia, peripheral neuropathy, retinal pigmentary degeneration, multiple endocrinopathies, skeletal dysplasia, strokelike episodes, and intellectual disabilities.

The characteristic biochemical marker of this disease is a generalized abnormality of glycosylation of circulating and cell membrane glycoproteins. The diagnosis of CDG-Ia is made by isoelectric focusing of transferrin, a circulating glycoprotein that contains two carbohydrate side-chains attached by N-glycosidic linkage to the protein backbone. Patients with CDG-Ia show an immunoisoelectric focusing pattern consistent with underglycosylation. The diagnosis is now being made by a modification of this method that uses mass spectrometry (see Specialized Biochemical Testing). The underlying cause of this syndrome is an autosomal recessive deficiency of phosphomannomutase 2 (PMM2), the major isozyme of phosphomannmutase. The diagnosis of CDG-Ia can be confirmed by measuring PMM2 activity in leukocytes or cultured skin fibroblasts or genetic analysis of the *PMM2* gene. There is no effective treatment for CDG-Ia disease.

Approximately three dozen forms of CDG have been described since type Ia was identified and the transferrin immunoisoelectric-focusing analysis was developed.[50,64] The immunoisoelectric-focusing test has provided a useful method for identifying additional forms of CDG with a remarkable range of clinical phenotypes. For example, CDG-Ib (also known as MPI-CDG; MPI denotes mannose-6-phosphate isomerase) is one of the most distinctive of these variants, because it manifests with hepatic dysfunction (abnormal liver function tests and coagulopathy) and protein-losing enteropathy rather than neurologic problems and is treatable (see Hepatic Dysfunction). The other CDG associated with impaired N-glycosylation are primarily neurologic disorders associated with severe developmental delay and mental retardation, but several of them also have distinguishing dysmorphic features.[64]

In addition to the forms of CDG that affect N-linked glycoproteins, several defects in the biosynthesis of O-linked glycoproteins (i.e., the oligosaccharide side-chains are attached to the protein through the hydroxyl group of serine or threonine) have been identified. Patients with these defects cannot be ascertained by the transferrin isoelectric-focusing test, because it only detects abnormalities of N-linked glycoconjugates. Several defects in O-linked glycoconjugation have been identified, including Walker-Warburg syndrome and muscle-eye-brain disease (a neuronal migration abnormality associated with malformations of the brain and eye, as well as congenital muscular dystrophy) (see Metabolic Seizures).[111] There is every reason to expect that additional disorders of N-linked and O-linked glycosylation will be identified in the future, particularly with the increased utilization of whole exome and whole genome sequencing.[50]

Lysosomal Storage Diseases

Most lysosomal storage disorders do not present in the neonatal period. However, several of these disorders do so, and they do so with a relatively limited spectrum of clinical features. The clinical manifestations of lysosomal storage disorders are the consequence of the disruption caused by storage of incomplete catabolism glycoconjugates. The particular set of clinical features associated with each disorder is determined by the chemical nature of the storage material, the quantity of material that accumulates, and the site(s) of storage.

The most extreme clinical feature is nonimmune hydrops fetalis or congenital ascites (see Prenatal Onset). Other clinical presentations may include dysmorphic (e.g., flattened nasal bridge, macroglossia, hypertrophic gums, coarse facies), ocular (cataracts, corneal clouding, glaucoma, cherry-red spot), cardiovascular (cardiomegaly, cardiomyopathy, arrhythmias, congenital heart failure), respiratory (hoarseness, recurrent respiratory infections), gastrointestinal (hepatomegaly, splenomegaly, cholestasis), skeletal (joint contractures, dysostosis multiplex, vertebral beaking, broad tubular bones), dermatologic (congenital ichthyosis, collodion infant), hematologic (anemia, thrombocytopenia), and endocrinologic (osteopenia, hyperparathyroidism) features. A differential diagnosis for the underlying storage disorder can be developed based on the pattern of features that is identified.

A sequence of laboratory studies, beginning with screening tests and progressing to more specialized testing (enzyme analyses and/or genetic testing), is required to diagnose the lysosomal storage disorders (see Biochemical Testing under the section The Abnormal Newborn Infant: Laboratory Phenotypes). An accurate and specific diagnosis is mandatory for developing a treatment plan. Effective treatment is now available for many of the lysosomal storage disorders, with options for enzyme replacement therapy, bone marrow transplantation, and stem cell transplantation.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Unfortunately, effective treatment is not available for all of the lysosomal storage disorders.

Organic Acidurias

Two inborn errors of organic acid metabolism are associated with dysmorphic syndromes: mevalonate kinase deficiency (mevalonic aciduria) and multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria type II).

Mevalonate Kinase Deficiency

Mevalonic aciduria is caused by a rare defect, mevalonate kinase deficiency, which catalyzes an early step in cholesterol biosynthesis.[37] The disorder is classified herein as an organic aciduria, because it is diagnosed by urine organic acid analysis. It can also be classified as a peroxisomal single enzyme disorder, because mevalonate kinase is located within the peroxisome (see Peroxisomal Disorders).

The pathogenesis of this disorder is complex, because mevalonic acid has a role in several strategic pathways. In addition to its role as a precursor of cholesterol, mevalonic acid is a precursor of dolichol, which is required for glycoprotein biosynthesis; heme, which plays a key role in oxygen transport; and ubiquinone, a component of the respiratory chain (see Lactic Acidemia).

Mevalonate kinase deficiency is a highly pleiotropic disorder associated in the newborn period with dysmorphic features (e.g., nonspecific craniofacial anomalies, cataracts), hepatosplenomegaly, lymphadenopathy, diarrhea, hypotonia, and anemia. In severe cases, it leads to profound failure to thrive, developmental delay, and early death. Although the defect would be expected to lead to lactic acidosis because of decreased synthesis of ubiquinone and malfunctioning of the respiratory chain, lactic acidosis is not a common feature of the disorder. The hypocholesterolemia seen in these patients is generally mild. Alternatively, mevalonate kinase deficiency can produce a very different clinical phenotype, hyper IgD syndrome, which is one of the periodic fever disorders. Mevalonic aciduria and hyper IgD syndrome appear to be allelic forms of mevalonate kinase deficiency.

The characteristic diagnostic feature is mevalonic aciduria, which can be documented by urinary organic acid analysis. No effective treatment exists for this disorder, although corticosteroids might be of some benefit.

Multiple Acyl-CoA Dehydrogenase Deficiency

Multiple acyl-CoA dehydrogenase deficiency is also known as glutaric aciduria type II because of the very large urinary excretion of glutaric acid, a product of amino acid catabolism (lysine, hydroxylysine, and tryptophan) (see Newborn Screening).[105] The organic acid pattern also shows many other metabolites, and the disorder came to be called multiple acyl-CoA dehydrogenase deficiency when it was recognized that the pattern reflected secondary impairment of several flavin-dependent acyl-CoA dehydrogenases required for amino acid catabolism, choline metabolism, and fatty acid β-oxidation. The biochemical defect affects one of two proteins (electron-transfer flavoprotein dehydrogenase [ETFDH] or ETF ubiquinone oxidoreductase [ETFQO]) involved in transferring electrons generated by flavin-dependent acyl-CoA dehydrogenases to the respiratory chain.

Multiple acyl-CoA dehydrogenase deficiency is a clinically heterogeneous disorder. The severe neonatal form of this disease is associated with metabolic abnormalities (e.g., acidosis, hypoglycemia, ketosis, hyperammonemia) and in some cases dysmorphic features (e.g., craniofacial dysmorphism, polycystic kidneys, cerebral cortical dysplasia, intrahepatic biliary hypoplasia). The patients often die in early infancy from cardiomyopathy. Less severe later-onset forms can present at any age thereafter and do not have congenital malformations. The dysmorphic form of the disease is found more commonly in patients with ETFQO deficiency. It is unclear how ETFQO deficiency leads to dysmorphism.

The diagnosis is initially made by urine organic acid analysis and then confirmed by in vitro cell studies using cultured skin fibroblasts or genetic testing. There is no effective treatment for the severe neonatal form of the disease, but more mildly affected patients may improve with riboflavin supplementation.

Peroxisomal Disorders

Many peroxisomal disorders produce dysmorphic syndromes. The peroxisomal disorders are a highly diverse group of disorders, reflecting the metabolic diversity of the enzymes contained within this organelle.[114,135] In contrast to the lysosome, which primarily contains a large number of degradative enzymes, the peroxisome contains biosynthetic and catabolic enzymes. Many of these enzymes are involved in unusual oxidation reactions; the name of this organelle was derived from one such reaction involving hydrogen peroxide.

The peroxisomal disorders can be classified into two groups: defects of peroxisome biogenesis and defects affecting a single enzyme (see Table 90.8).[114,135]

Biogenesis Disorders

The first group consists of disorders associated with absent or severely reduced numbers of peroxisomes and multiple enzyme deficiencies. These disorders are caused by defects in peroxisomal biogenesis, which lead to impaired import of proteins and enzymes into the peroxisome.[114] The paradigm of this group of disorders is Zellweger syndrome, an autosomal recessive trait characterized by craniofacial dysmorphism, optic atrophy, renal cortical cysts, epiphyseal stippling, failure to thrive, polymicrogyria, severe psychomotor retardation, and early death. Epiphyseal stippling is an unusual radiographic finding of ectopic calcification found most characteristically in the ankle, patella, vertebrae, hips, and trachea (see Cholesterol Biosynthesis). Other peroxisomal assembly disorders include neonatal adrenoleukodystrophy, infantile Refsum disease, and rhizomelic chondrodysplasia punctata.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

Genetic studies have identified approximately 20 different genetic loci associated with peroxisomal biogenesis defects. Genetic complementation studies have shown that Zellweger syndrome, neonatal adrenoleukodystrophy, and infantile Refsum disease represent allelic variants at many of these loci. Zellweger syndrome is the most severe variant, and infantile Refsum disease is the least severe variant. There is no cure or effective treatment for this group of disorders, although bile acid supplementation may be effective treatment for the gastrointestinal manifestations of this disorder.

Rhizomelic chondrodysplasia punctata is the consequence of mutations at one of the other loci involved in peroxisomal biogenesis. Peroxisomal deficiencies have been found only in the rhizomelic form of chondrodysplasia punctata, which is an autosomal recessive disorder characterized by severe shortening of the proximal extremities (hence the term *rhizomelic*), craniofacial dysmorphism, congenital cataracts, joint contractures, and severe psychomotor retardation. The skeletal abnormalities of this form of dwarfism are evident in the neonatal period. There is no treatment for this disorder.

Single-Enzyme Defects

The second group of peroxisomal disorders includes defects associated with a normal number of peroxisomes and a single enzyme deficiency. The best known disorder in this group is X-linked adrenoleukodystrophy, which does not produce dysmorphism and does not manifest in the neonatal period and, therefore, is not discussed further. However, several other peroxisomal monoenzymopathies with onset in the neonatal period have been recognized.[135] Several of these disorders have been identified in patients who appear to have the physical stigmata of Zellweger syndrome or its variants but have normal numbers of peroxisomes. The best characterized of these disorders are acyl-CoA oxidase deficiency, bifunctional enzyme deficiency, and thiolase deficiency. These three enzymes share a common biochemical role in peroxisomal (rather than mitochondrial) fatty acid oxidation and bile acid biosynthesis. Many of the dysmorphic and laboratory abnormalities associated with Zellweger syndrome and its variants, therefore, can be attributed to abnormal fatty acid metabolism or abnormal bile acid metabolism. Similarly, defects affecting the enzymes that catalyze plasmalogen biosynthesis produce a clinical phenotype that resembles rhizomelic chondrodysplasia punctata.

Several other single-enzyme deficiencies have been described that do not involve the peroxisomal pathways of fatty acid oxidation or plasmalogen biosynthesis. One of these disorders, mevalonic aciduria, is a defect in cholesterol biosynthesis and is described under the section Organic Acidurias.

Other Disorders

Vitamin K Metabolism

Vitamin K epoxide reductase deficiency is an autosomal recessive disorder that produces a phenocopy of the fetal warfarin embryopathy syndrome.[84] The enzyme deficiency is characterized by persistent coagulopathy, stippled epiphyses, nasal hypoplasia, brachydactyly with distal digital hypoplasia, and conductive hearing loss. Vitamin K epoxide reductase is the site of warfarin's pharmacologic action. The various dysmorphic features of fetal warfarin syndrome and vitamin K epoxide reductase deficiency are consequences of impaired activity of the vitamin K–mediated carboxylation reactions, which include proteins of the bone matrix and circulating coagulation factors. Vitamin K supplementation is an effective therapy for the coagulopathy associated with this disorder but might not be effective for the other manifestations because of their prenatal onset.

The Abnormal Newborn Infant: Laboratory Phenotypes

Biochemical Testing

The laboratory evaluation plays a strategic role in the differential diagnosis of the metabolic disorders of infancy. The laboratory investigation of these patients should be staged. It should begin with broadly focused screening tests, which are then followed by more specialized examinations. Laboratory findings helpful in the differential diagnosis of suspected metabolic disease are listed in Table 90.9. Further discussion of each of the findings in Table 90.9 is provided below and in the text accompanying other tables and figures provided elsewhere in this chapter.

Screening Studies

The precise composition of the metabolic screen varies from one institution to another. However, there should be a core of tests available at all institutions that care for sick neonates.[4,16] A suggested list of tests is presented in Table 90.10. These laboratory tests are chosen because they provide a relatively rapid, inexpensive evaluation for a wide range of disorders. It is strongly recommended that the specific details of collection and handling of all samples be clearly understood before samples are obtained and that there be collaboration with laboratory personnel throughout the process.

Blood Studies

A number of blood studies are indicated, many of which are routinely performed during the care of sick neonates.[4,16] The complete blood cell count should include examination of cell morphology and a differential cell count. Neutropenia and thrombocytopenia may be associated with a number of the organic acidemias, including isovaleric acidemia, methylmalonic acidemia, and propionic acidemia (see Hematologic Abnormalities).[124] Neutropenia may be found with glycogen storage disease type Ib, an uncommon variant of glucose-6-phosphatase deficiency.[131] This variant is caused by a defect of the glucose-6-phosphate translocase associated with the phosphatase rather than the phosphatase itself (see Hypoglycemia). Barth syndrome can also be a cause of neonatal neutropenia,[21] while Pearson syndrome

**A qualitative screening test that might direct provisional treatment and further diagnostic studies.
***Additional metabolic studies may be indicated depending on the clinical circumstances, e.g., amino acid analysis and neurotransmitters in a patient with seizures.

is a mitochondrial DNA disorder that causes pancytopenia and/or sideroblastic anemia[121] (see Lactic Acidemia for further discussion of these disorders). Megaloblastosis may be found in disorders of purine biosynthesis, such as some rare forms of homocystinuria or orotic aciduria.

Electrolytes and blood gases are required to determine whether acidosis or alkalosis exists and, if so, whether the abnormality is associated with an increased anion gap. Lactate and pyruvate analysis should be measured to identify the nature of any excess anions (see Lactate and Pyruvate Analysis). Lactic acidemia may be present without frank acidosis.

Hypoglycemia is a frequent finding in sick neonates, especially premature infants, but is also a critical finding in some metabolic disorders. Hypoglycemia should be investigated further when it is severe, when accompanied by other signs of metabolic disease, or when it proves refractory to conventional therapy.

Ketones (i.e., β-hydroxybutyrate and acetoacetate) are useful in developing a differential diagnosis for newborns with hypoglycemia. In particular, nonketotic or hypoketotic hypoglycemia is the hallmark of defects of fatty acid oxidation.

The blood ammonia concentration should be determined in all neonates with evidence of unexplained lethargy and neurologic intoxication. Early recognition of the congenital hyperammonemias is crucial, because they are a rapidly progressive group of disorders that can quickly lead to irreversible damage after hours rather than days. Effective treatment is available for many of these disorders, but it must be instituted early in the course of the disease.

A blood uric acid test is a convenient screen for the few inborn errors of metabolism that are associated with hypouricemia or hyperuricemia. Type I glycogen storage disease is probably the most common inherited disorder associated with hyperuricemia (see Hypoglycemia), whereas xanthine

oxidase deficiency associated with molybdenum cofactor deficiency causes hypouricemia (see Metabolic Seizures).

Urine Studies

A urine sample should be sent for metabolic screening using simple colorimetric agents or strips, if such testing is still available at one's institution (Table 90.10 and Table 90.11).[4,16] However, this approach to testing has been abandoned or replaced by more specialized forms of testing in most institutions and may no longer be possible to obtain. In this event, a urine specimen should be sent directly for the more specialized testing. In either case, an aliquot of urine should be collected, covered, and set aside by the infant's incubator when possible. After a few hours at room temperature, the specimen should be smelled for evidence of an unusual odor. Several inborn errors of metabolism, especially the organic acidurias, are associated with characteristic odors (see Table 90.7).

Urine specimens should be tested for reducing substances, which include principally the monosaccharides (i.e., simple sugar molecules). The Clinitest reaction detects excess excretion of galactose and glucose but not fructose. False-positive reactions are found with ampicillin and related penicillin derivatives and with some other drugs that are excreted as their glucuronide conjugates. A specimen that shows a positive reaction with the Clinitest reaction should be investigated further by means of the Clinistix reaction (i.e., glucose oxidase), which is specific for the monosaccharide glucose. A specimen with positive Clinitest and negative Clinistix results should be analyzed specifically for galactose. It is important to note that in the United States the Clinitest and Clinistix testing methods have not been available in recent years, following cessation of production of these tests. We include this testing in this chapter as it may still be available in other countries worldwide and may again become available in this country.

The urine pH should be determined to characterize the renal response to an alteration in blood pH. In the face of a significant acidemia, the kidneys should produce an acidic urine (pH <5). A renal acidification disorder should be considered in the absence of an appropriate urine pH.

Spot tests may be used to detect excessive urinary excretion of ketones, α-ketoacids, or other metabolites. Ketonuria should be investigated, especially in patients with hypoglycemia. The Acetest or Ketostix reactions are used to detect acetone and acetoacetate (β-ketoacid), whereas the 2,4-dinitrophenylhydrazone (DNPH) test and the ferric chloride test are complementary methods used to detect α-ketoacids. The Sulfitest detects excessive sulfite excretion and can be useful for screening patients with a hypoxic-ischemic encephalopathy–like picture who are suspected of having sulfite oxidase deficiency or molybdenum cofactor deficiency. The Sulfitest should be performed on freshly obtained urine specimens, because it otherwise has a significant false-negative rate.

Cerebrospinal Fluid Studies

Many sick infants undergo lumbar puncture for CSF analysis as part of a sepsis evaluation. In addition to obtaining the standard samples for CSF glucose and protein analysis, additional samples for more specialized testing, such as amino acid analysis, lactate (and pyruvate) analysis, and neurotransmitter analysis should also be obtained if clinically indicated for encephalopathy or seizures.[48] In certain cases, blood samples should be collected at the same time as the lumbar puncture is performed to permit comparison of blood and CSF concentrations. For example, concurrent plasma and CSF amino acid measurements (specifically including glycine) are required for the diagnosis of nonketotic hyperglycinemia, whereas concurrent plasma and CSF glucose measurements are required for the diagnosis of GLUT1 deficiency (see Metabolic Seizures).

Specialized Biochemical Testing

Screening studies help determine whether further metabolic testing is indicated and, if so, what testing should be done next (Table 90.12). In general, the more specialized tests require relatively sophisticated equipment and personnel to perform and interpret, take longer to perform (sometimes days to weeks), are more expensive, and are usually available in only a few centers. All physicians who might care for a sick neonate with a suspected inborn error of metabolism should develop their own referral system for patients with various metabolic abnormalities. It is a good idea to set up a referral system in advance of a specific emergency so that appropriate referral can be obtained more easily when the time comes.

Because not all patients require transfer or tolerate transfer to a tertiary care center, plans should also be on hand for collecting samples for various specialized tests. It is truly unfortunate when the often extraordinary and well-intentioned efforts of those caring for a sick newborn infant are subverted by improper collection or handling of samples.

TABLE 90.12 Specialized Laboratory Tests That May Be Required for the Care of Neonates With Suspected Metabolic Disease

Body Fluid or Tissue	Laboratory Tests
Blood	Acetoacetate and β-hydroxybutyrate * α-Aminoadipic semialdehyde (also known as Δ^1-piperideine-6-carboxylate) Amino acids* Carnitine (total, free, and acylcarnitine profile)* Creatine and guanidinoacetate 7-Dehydrocholesterol Galactose-1-phosphate Homocysteine, total Lactate and pyruvate* Methylmalonic acid Tests for congenital disorders of glycosylation* • Carbohydrate deficient transferrin analysis • N-Glycan profile Tests for peroxisomal disorders* • Very long-chain fatty acids • Phytanic acid Uric Acid
Urine	Acylglycines Amino acids* α-Aminoadipic semialdehyde (also known as piperideine-6-carboxylate) Carnitine (total, free, and acylcarnitine profile)* Creatine and guanidinoacetate Methylmalonic acid Organic acids* Orotic acid Pyrimidine panel Purine panel S-sulfocysteine Succinylacetone Tests for lysosomal storage disorders* • Mucopolysaccharides • Oligosaccharides (including free sialic acid)
Cerebrospinal fluid	Amino acids* Lactate and pyruvate* Neurotransmitters Tetrahydrobiopterin and related metabolites Tetrahydrofolate
Other	
Cultured skin fibroblasts	Metabolite analysis Enzyme analysis Genetic analysis
White blood cells	Metabolite analysis Enzyme analysis Genetic analysis
Other tissues (e.g., liver)	Metabolite analysis Enzyme analysis Genetic analysis

*These analyses are discussed in the subsection Specialized Biochemical Testing under the section The Abnormal Newborn Infant: Laboratory Phenotypes. The unmarked laboratory tests are discussed with their associated disorders elsewhere in this chapter.

Detailed requirements for collection and handling of samples for various metabolic analyses should be available in the nursery, and they should be kept in a place where they can be found in an emergency.

The distinction between a screening study and a specialized follow-up test is not always clear. In some circumstances, the physician would proceed directly to performing a specialized study. For example, a urinary organic acid analysis should be performed as soon as a neonate is thought to have a metabolic acidosis or has an unusual odor typical of one of the neonatal organic acid disorders. Similarly, it is generally best to perform some of the specialized studies during an episode of acute metabolic decompensation, such as hypoglycemia, when they are most likely to be informative rather than waiting until the results of the screening tests become available. As a rule, the sequence of ordering tests should be compressed in an acutely ill patient.

Amino Acid Analysis

The most commonly performed of the specialized studies is probably quantitative plasma and urinary amino acid analysis.[4,15,16] Some laboratories provide a qualitative amino acid screening study performed by paper or thin-layer chromatography as part of their screening protocol. Although this study may be useful, it does not substitute for a quantitative determination when the clinical findings suggest a disorder that is reflected in an abnormal amino acid pattern (Table 90.13). In most cases, a complete quantitative analysis is required, whereas in other situations, specific amino acids should be the focus of attention.

For example, when evaluating a patient with hyperammonemia, it is important to inform the laboratory personnel so that they will look for argininosuccinic acid and its anhydrides; otherwise, these metabolites could be overlooked or misinterpreted. This recommendation to inform the laboratory of the clinical context of the investigation applies equally to the other specialized studies discussed here.

Quantitative amino acid analysis of CSF is not usually indicated, but it should be performed when appropriate, such as in the context of a hypotonic newborn infant who has seizures and an elevated plasma glycine level that is not accompanied by acidosis or ketosis. These findings suggest the diagnosis of nonketotic hyperglycinemia. The plasma

TABLE 90.13 Neonatal-Onset Inborn Errors of Metabolism Characterized by Abnormal Plasma Amino Acid Patterns

Disorder	Finding
Amino Acid Disorders	
Glutamine synthetase deficiency	↓ Glutamine (Note: Plasma glutamine may be normal; CSF glutamine consistently ↓)
Maple syrup urine disease	↑ Isoleucine, leucine, valine, and allo-isoleucine
Nonketotic hyperglycinemia*	↑ Glycine (Note: Plasma CSF glycine may be normal, but CSF glycine/plasma glycine ratio consistently ↑)
Phenylketonuria	↑ Phenylalanine
Serine biosynthesis disorders	↓ Serine (↓ glycine) (Note: These abnormalities may be missed in blood samples but are more prominent in CSF samples)
Sulfite oxidase deficiency / molybdenum cofactor deficiency	↑ S-Sulfocysteine (Note: This abnormality is more prominent in urine and CSF than blood)
Tyrosinemia type I	↑ Tyrosine, methionine
Lactic Acid Disorders	
Mitochondrial disorders	↑ Alanine (± ↑ proline)
Pyruvate carboxylase deficiency	↑ Alanine, citrulline, lysine
Pyruvate dehydrogenase deficiency	↑ Alanine
Organic Acidemias	
Propionic acidemia	↑ Glycine
Isovaleric acidemia	↑ Glycine
Methylmalonic acidemia	↑ Glycine
Urea Cycle Disorders	
Urea cycle disorders	↑ Glutamine (±) plus …
Arginase deficiency	↑ Glutamine (±) plus ↑↑ Arginine
Argininosuccinic aciduria†	↑ Glutamine (±) plus ↑ ASA, ↑ citrulline
Carbamoylphosphate synthetase deficiency	↑ Glutamine (±) plus ↓ Citrulline, ↓ arginine
Citrullinemia type I	↑ Glutamine (±) plus ↑↑ Citrulline, ↓ arginine
Ornithine transcarbamylase deficiency	↑ Glutamine (±) plus ↓ Citrulline, ↓ arginine
N-Acetylglutamine synthetase deficiency	↑ Glutamine (±) plus ↓ Citrulline, ↓ arginine
Urea Cycle–Associated Amino Acid Transport Disorders	
Citrin deficiency (aka: citrullinemia type II)	↑↑ Citrulline, arginine, threonine (and threonine-to-serine ratio)
Hyperornithinemia-hyperammonemia-homocitrullinuria (HHH) syndrome	↑↑ Ornithine and ↓ citrulline; ↑ urine homocitrulline

ASA, Argininosuccinic acid (including its two anhydrides); CPS, carbamyl phosphate synthetase; OTC, ornithine transcarbamylase; PC, pyruvate carboxylase; ↑, increased; ↑↑ very increased; ↓, decreased; ±, with or without.
*Glycine concentrations are elevated in plasma and, to an even greater extent, in the cerebrospinal fluid.
†ASA is present in very large amounts in urine but is only marginally increased in plasma because of efficient renal clearance.

glycine level may be only minimally elevated in some patients with nonketotic hyperglycinemia. The biochemical hallmark of this disorder is an elevated ratio of CSF glycine to plasma glycine.

Carnitine Analysis

Plasma and urinary carnitine analysis is indicated for patients who show evidence of unexplained acidosis, hyperammonemia, hypoglycemia, or ketonuria when there might be a disorder accompanied by an abnormal organic aciduria, defect in fatty acid oxidation, or respiratory chain defect. In these settings, carnitine insufficiency or frank carnitine deficiency can develop.

Many of the organic acidurias or fatty acid oxidation defects are associated with overproduction of specific acyl-CoAs (e.g., CoA esters of an acid molecule). As they accumulate, these acyl-CoAs are transesterified with free carnitine to form acylcarnitines and free CoA. Many of these acylcarnitines then leave the cell, circulate in the bloodstream, and are ultimately excreted in the urine. If the production of a particular acyl-CoA is very large, comparably large amounts of the corresponding acylcarnitines are excreted in the urine, resulting initially in intracellular carnitine insufficiency and ultimately in carnitine deficiency (e.g., secondary carnitine deficiency). Abnormal acylcarnitines can also inhibit renal reabsorption of carnitine. Carnitine analysis should be performed whenever possible on samples of plasma and urine obtained concurrently.

Carnitine analysis should include measurement of total carnitine, free carnitine, and total acylcarnitines, as well as the individual acylcarnitine profile. Measurement of total carnitine, free carnitine, and total acylcarnitines will help

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

determine whether the patient has carnitine insufficiency or deficiency, whereas a quantitative acylcarnitine profile will help identify which, if any, acyl-CoA are accumulating and hence identify the locus of the patient's metabolic defect.

Lactate and Pyruvate Analysis

Blood lactate analysis is indicated when acidosis or an increased anion gap is found, and it is used to investigate the possibility of a defect in carbohydrate metabolism, fatty acid oxidation, organic acid metabolism, or the respiratory chain (see Lactic Acidemia).[4,16] Lactate should also be measured in patients who have skeletal myopathy, cardiomyopathy, encephalopathy, retinal pigmentary deposits, neutropenia, or thrombocytopenia and in patients with hypoglycemia or ketosis, even if they do not have frank acidosis. Many inborn errors of metabolism result in lactic acidemia without lactic acidosis.

When possible, the concentration of lactate and pyruvate should both be determined. These metabolites should be measured concurrently in blood and CSF, when a lumbar puncture is being performed for other reasons or the patient's presentation suggests the possibility of a CNS-specific defect. Measuring CSF lactate and pyruvate concentrations does not generally add useful information when the blood lactate and pyruvate concentrations have already been found to be elevated. Lactic acid is the reduction product of pyruvic acid. The lactate-to-pyruvate (L:P) ratio is a useful measure of the intracellular redox potential and is useful in approaching the differential diagnosis of the lactic acidemias (see Lactic Acidemia). Lactic acidemia and pyruvic acidemia are often accompanied by lactic aciduria and pyruvic aciduria, which can be detected, but poorly quantitated, by urinary organic acid analysis.

The significance of the finding of lactic acidemia can be investigated further by reviewing a quantitative plasma amino acid analysis for evidence of an increased alanine concentration, because alanine is the transamination product of pyruvate. Therefore, the evaluation for lactic acidemia should include measurement of lactate, pyruvate, and alanine.

Urine Organic Acid Analysis

Urinary organic acid analysis was originally used to document defects in amino acid metabolism distal to the removal of the amino group from the amino acid. As currently performed, urinary organic acid analysis detects and quantitates a large number of metabolites that represent intermediates of carbohydrate and fatty acid oxidation, as well as those of amino acid catabolism.[1,4,15,16,57] Accordingly, urinary organic acid analysis is a highly useful study and is performed in a wide variety of clinical contexts. Urinary organic acid analysis is indicated for patients who have unexplained acidosis, lactic acidemia, hyperammonemia, hypoglycemia, or ketonuria.

A partial list of the organic acidurias with onset in the neonatal period is presented in Box 90.1. The organic acid disorders are called *-emias* or *-urias* for historical reasons.

• BOX 90.1 Organic Acidurias With Onset in the Neonatal Period

- 3-Hydroxyisobutyric aciduria
- 3-Hydroxy-3-methylglutaryl-CoA lyase deficiency
- Isovaleric acidemia*
- 3-Ketothiolase deficiency
- Maple syrup urine disease
- 3-Methylcrotonyl-CoA carboxylase deficiency
- Methylmalonic aciduria*
- Mevalonic aciduria
- Multiple acyl-CoA dehydrogenase deficiency (glutaric aciduria type II)
- Multiple carboxylase deficiency (biotinidase deficiency; holocarboxylase synthetase deficiency)
- Propionic acidemia*
- Pyroglutamic acidemia
- Succinyl-CoA 3-ketoacid transferase deficiency

*Most commonly seen disorders.

In most cases, abnormal metabolites accumulate in blood and urine in these disorders, and the terms *organic acidemia* and *organic aciduria* are used interchangeably in this chapter. Isovaleric acidemia, methylmalonic acidemia, and propionic acidemia appear to be the most common of the organic acid disorders that appear in the newborn period. The incidence of the organic acidemias that are detected by MS/MS newborn screening differs from the incidence of disorders that appear in the newborn period. Urinary organic acid analysis is generally performed by gas–liquid chromatography or, with increasing incidence, by combined gas–liquid chromatography and mass spectrometry.

Tests for Congenital Disorders of Glycosylation

The possibility of a CDG syndrome should be suspected in a newborn infant with the characteristic dysmorphism of CDG-Ia (e.g., abnormal fat pads of the buttocks and inner thighs, orange peel skin, inverted nipples) or a child with pericardial effusion or cardiomyopathy, hepatomegaly, diarrhea, an increased bleeding tendency or thrombosis, or neurologic abnormalities (such as strabismus, hypotonia, and developmental delay). Several clinical forms of CDG syndrome have been described, each having a different genetic basis. Fortunately, most of the disorders described can be diagnosed using the transferrin immunoisoelectric-focusing assay or the mass spectrometric adaption of this method to identify patients with an abnormal pattern of glycosylation.[50,64] Patients found to have a positive test result will require further testing to determine their particular disorder, via either enzymatic analysis or molecular genetic testing.

Tests for Lysosomal Storage Disorders

Patients with coarse facial features, corneal clouding, cataracts, hepatomegaly, or dysostosis multiplex should be evaluated for a possible lysosomal storage disorder. Urine screening tests are available for quantitation of

mucopolysaccharide excretion. The test results should be interpreted with caution, because many of the tests have significant false-positive and false-negative rates. If the quantitative mucopolysaccharide screening test result is positive, chromatographic separation and quantification of the individual mucopolysaccharides may be performed. Alternatively, selective analysis of the enzymes involved in mucopolysaccharide metabolism whose deficiency would be consistent with the patient's clinical phenotype can be performed as the next step. Finally, enzyme analyses can be performed using white blood cells or cultured skin fibroblasts, as well as genetic testing.

Patients with clinical features suggestive of an oligosaccharidosis can be evaluated using one of the available chromatographic systems for separating and quantitating various oligosaccharides. A positive result can be investigated by performing a selective battery of enzyme assays using white blood cells or cultured skin fibroblasts, depending on the particular disorder that is suspected, or by using genetic testing.

Tests for Peroxisomal Disorders

Peroxisomal disorders include defects of biogenesis (group 1) and defects of individual enzymes (group 2). Almost all of the disorders in group 1 (Zellweger syndrome and its milder variants) and many of the disorders in group 2 (defects of peroxisomal fatty acid oxidation: acyl-CoA oxidase deficiency, bifunctional enzyme deficiency, and thiolase deficiency) have impaired very-long-chain fatty acid oxidation and are characterized by increased plasma concentrations of very-long-chain fatty acids (chain length longer than 22 carbons). In most cases, measurement of individual plasma very-long-chain fatty acids is the most useful single measure of peroxisomal function and serves as a useful initial test for these disorders.[135] Very-long-chain fatty acids can also be measured in cultured fibroblasts, thereby permitting premortem or postmortem diagnosis from a skin biopsy specimen established in culture.

Other measurements are required to diagnose some forms of peroxisomal disease, such as rhizomelic chondrodysplasia punctata, and to distinguish between the various forms of peroxisomal disease. These additional tests include plasma phytanic acid analysis, erythrocyte plasmalogen analysis, and plasma dihydroxycholestanoic and trihydroxycholestanoic acid analysis. Mevalonic aciduria is diagnosed with urinary organic acid analysis. More definitive testing, including complementation analysis, assays of peroxisomal fatty acid β-oxidation, or genetic testing, is required to establish a specific diagnosis.[114,135]

Definitive Biochemical Diagnosis

Judicious application of the various biochemical tests described in the preceding will in many cases, but not all, allow the physician to establish a diagnosis. However, it is important to remember that the diagnosis must be confirmed by definitive testing, because the same metabolite pattern (i.e., biochemical phenotype) can be associated with more than one inborn error of metabolism, which might differ in their treatment, prognosis, and inheritance pattern. Definitive diagnosis is generally done by specific enzyme analysis or genetic testing. Relatively few laboratories perform the specific enzyme study that is required to confirm the diagnosis of a particular rare genetic disorder. As a rule, these enzyme analyses are time consuming, relatively difficult to perform, and expensive. Specific enzyme analysis can often be done using blood cells (most commonly, white blood cells) but often require cultured skin fibroblasts or other tissue specimens.

It is, therefore, not surprising that laboratories performing these studies prefer (or require) evidence that there is a significant likelihood that the test being performed will demonstrate an abnormality. It behooves the physician caring for a sick neonate to obtain the preliminary evidence suggesting that a specific defect is likely before proceeding to specific enzyme analysis. This is often best done in consultation with local experts in metabolic disease, but when such expertise is not available, the laboratories performing such assays usually are willing to give advice that will ultimately maximize the benefit of their efforts.

Genetic Testing

The discussion in this chapter focuses almost exclusively on the classic methods of biochemical genetics, which include analysis of metabolites, structural macromolecules, and enzymes. For the most part, little consideration is given to the role that recent advances of molecular genetics are playing in facilitating the diagnosis, improving our understanding of the pathogenesis, and expanding the possibilities for treatment of inborn errors of metabolism. This has been an intentional omission, because a discussion of the tools of molecular genetics is presented in Chapter 10, and molecular diagnosis is generally performed after a clinical diagnosis has been established biochemically or enzymatically. The reasons for this omission notwithstanding, there are five clinical circumstances in which molecular testing has traditionally come to the forefront, and the clinician should be aware of them.

First, diagnosis can be accomplished easily and rapidly by mutational analysis for diseases that are characterized by relative genetic homogeneity (i.e., a few mutations account for most cases of the disease). Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency provides an excellent example. Approximately 90% of the disease-causing alleles found in affected patients have the same mutation (e.g., an A to G change at nucleotide 985). Second, diagnosis can be provided by mutational analysis but not by conventional biochemical studies. This is the situation for many disorders caused by mutations of the mitochondrial DNA (mtDNA), which are not amenable to metabolic approaches, such as errors in the mitochondrial mRNA or tRNA genes. DNA-based mutation analysis can provide a specific diagnosis for disorders associated with mutations in these genes, whereas classic metabolite or enzymatic studies cannot. Third, mutation analysis can provide useful prognostic information. For

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

example, in cases of galactosemia ascertained by newborn screening, mutation analysis can assist the clinician in determining the need to restrict the patient's dietary galactose intake. Fourth, mutation analysis of postmortem samples can be used to diagnose the condition in patients who have died without a diagnosis.[72,140] Fifth, knowledge of a patient's mutation can sometimes be used to direct therapy, as well as facilitate genetic counseling of other family members and prenatal testing.

In recent years, the scope and sensitivity of genetic testing has expanded remarkably with the development of new technologies (see Chapter 10). Classical sequence analysis and deletion/duplication analysis permitted analysis of only one gene at a time. This approach had two readily apparent limitations: (1) the patient in fact has a mutation in the gene tested, but the testing methods cannot not detect all mutations in a particular gene, and (2) the patient does not have a mutation in the gene tested but does have a mutation in another related gene. Ways of circumventing limitation 1 has been addressed further in Chapter 10. Limitation 2 has been addressed by developing more sophisticated methods of concurrent mutation analysis. The simplest approach was to initiate classical analysis for more than one gene. This approach worked well but was limited by its expense (the total cost was roughly equal to the cost of sequencing one gene times the total number of genes analyzed).

The next advance was the development of next generation sequencing (NGS), which performs parallel sequencing of a large number of genes. Large gene panels (usually including ten to several hundred genes) are commercially available to evaluate patients who have a particular symptom or sign. Large gene panels are currently available for a wide variety of disorders, including neonatal seizure, cardiomyopathy, cholestatic liver disease, hyperinsulinemic hypoglycemia, hyperammonemia, mitochondrial disorders, peroxisomal assembly disorders, and many more. The results of these panels are, in many cases, available within just a few weeks. These panels provide a diagnosis for many patients, but not all patients. The proportion of patients who receive a diagnosis from these panels depends on the particular panel but is generally greater than 50%.

In the case of a negative test result, further genetic testing should be considered, especially when the differential diagnosis for the patient's constellation of clinical features is broad. Further testing to be considered should include whole exome sequencing (WES) or whole genome sequencing, which both evaluate for approximately 25,000 genes. The diagnostic yield of whole exome sequencing of neonates is approximately 50%, depending on the patient's phenotype, the extent of prior metabolic and genetic testing, and whether the patient's parents were also analyzed (trio analysis). It is too early to provide an estimate for the yield for whole genome sequencing.

The various forms of gene and exome panels are often a more cost-effective approach to testing than sending successive rounds of individual gene tests, especially when a clear diagnosis is not identified by extensive biochemical testing. As discussed above for single gene testing, NGS of large gene panels may provide including a diagnosis early in the course of the disease to guide treatment, to allow physicians to better understand the expected disease course and prognosis, and to permit genetic counseling of other family members. These benefits have been demonstrated for patients in the neonatal intensive care environment.[72]

Postmortem Evaluation

Although the management of a very sick newborn who is at imminent risk of dying is a familiar issue in neonatal care, certain points must be considered in the case of a newborn infant with a suspected inborn error of metabolism.[13,30,94] Samples of blood, urine, and, if possible, CSF should be obtained before death. Serum and plasma samples should be obtained; a total of 10 mL should be collected, aliquoted, and saved for metabolite studies and for preparation and storage of DNA. As much urine as possible should be saved. All samples should be frozen to −20°C or below.

A thoughtful but direct discussion should be arranged before death with the parents, during which the reasons for a postmortem examination are presented. It should be explained that an autopsy performed for the purpose of investigating a suspected metabolic disorder may be different from autopsies performed for other purposes in that the autopsy examination must be performed within 4 hours of death, preferably within 2 hours. This urgency is dictated by the need to obtain tissue before postmortem changes compromise the integrity of enzyme systems and metabolite concentrations.

If the performance of a complete autopsy is not acceptable to the parents, the option of a limited autopsy should be discussed.[20,30,94] The selection of tissues or organs requested in a limited postmortem examination vary with the clinical situation but in general should include specimens of liver and skeletal muscle and/or at least a skin biopsy specimen for establishing a fibroblast cell culture. These specimens can be obtained with minimal disfigurement. Several small (1 cm^3) specimens of liver and skeletal muscle should be obtained. Similar specimens of heart tissue should be obtained from patients with cardiomyopathy. If permission for a limited postmortem examination is refused, permission for premortem percutaneous liver and open skeletal muscle biopsies should be sought; these procedures can be performed at the bedside. Once obtained, all tissue specimens should be stored at −70°C for future study.

Similar arrangements should also be made for neonates who die suddenly in the hospital or at home, because inborn errors have become a well-recognized cause of sudden death. Approximately 2% of sudden, unexpected deaths in the neonatal period are the consequence of a metabolic disorder.[25] It is understandably more difficult to make arrangements that comply with the recommendations for the sick infant, but experience has shown that a modified protocol can be successful.[94] These modifications are dictated in part

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

by the logistics of arranging for a prompt autopsy after an unexpected death, but equally important are the requirements dictated by the differential diagnosis of inborn errors that cause sudden death of the neonate.

The diagnostic entities that have to be considered primarily include defects in energy metabolism: glycogen storage diseases, defects in fatty acid oxidation, and electron transport chain defects. The most common pathogenetic mechanism that leads to sudden death in these disorders is cardiomyopathy or cardiac arrhythmia, which is the consequence of myocardial energy deficiency or disruption of the electrical conduction system by toxic metabolites that accumulate in these disorders.

Practically, recommendations are that a full autopsy be done within 72 hours of death. The autopsy should include particular attention to examination of the heart, liver, and skeletal muscle for evidence of glycogen or lipid storage. The following specimens should be obtained and stored frozen: liver, urine from the bladder (no matter how small the sample size), and bile from the gallbladder.[13,20,94] A skin biopsy should be obtained for establishing a cell line of cultured fibroblasts.

The choice of metabolic studies to perform is dictated by the clinical history and the results of the standard pathologic evaluation. For example, findings consistent with a possible fatty acid oxidation defect should include measurement of glucose, free fatty acids, and total and free acylcarnitines in the liver specimen; organic acids and an acylcarnitine profile in urine; and an acylcarnitine profile in bile. The possibility of an inborn error of metabolism can also be investigated by genetic testing of blood cells, cultured skin fibroblasts, or frozen tissue specimens. For example, autopsies performed for patients who died of sudden unexpected death in the neonatal period or infancy were evaluated for a possible inborn error of fatty acid oxidation using standard biochemical methods plus next generation sequencing (NGS) of a panel of 13 genes known to cause fatty acid oxidation disorders.[140] Genetic testing confirmed the biochemical results and, in some cases, established the diagnosis for patients with indeterminate biochemical results. This approach of combining pathologic finding, biochemical studies, and current genetic technology to postmortem diagnosis is expandable to many other circumstances.

Approaches to Specific Abnormal Laboratory Findings

Most newborn infants with an inborn error of metabolism have one or more of only a handful of strategic laboratory findings: metabolic acidosis, lactic acidemia, hypoglycemia, and hyperammonemia. An approach to differential diagnosis of inborn errors with each of these findings is now presented. As with all attempts to develop a useful approach to differential diagnosis, it is important to remember that the algorithm never quite fits all patients. Such probably will be the case for these algorithms as well because of the range of diagnostic possibilities and the considerable genetic heterogeneity that characterizes all inborn errors of metabolism. Nevertheless, the approaches presented should serve as useful first approximations.

Disorders Characterized by the Absence of Metabolic Acidosis, Lactic Acidemia, Hypoglycemia, and Hyperammonemia

There are many inborn errors of metabolism that do not generally manifest with any of the strategic laboratory findings mentioned in the preceding (e.g., metabolic acidosis, lactic acidemia, hypoglycemia, hyperammonemia). Among the most important of these inborn errors is maple syrup urine disease (MSUD), which is a cause of severe metabolic encephalopathy, and the neurotransmitter defects and related disorders, which are important causes of neonatal seizures. The neurotransmitter defects and related disorders are discussed earlier in this chapter (see The Abnormal Newborn Infant: Clinical Phenotypes). Maple syrup urine disease was not discussed in detail previously and is presented in the following section.

Maple Syrup Urine Disease

Maple syrup urine disease is an inborn error of branched-chain amino acid metabolism caused by branched-chain α-ketoacid dehydrogenase deficiency, which impairs isoleucine, leucine, and valine metabolism.[116,138] The classical clinical variant of this disorder manifests in the neonatal period and can lead to serious consequences if it is not recognized and treated quickly (i.e., within the first week of life). Patients with the severe neonatal form of MSUD are generally normal for the first 2 or 3 days of life but then develop lethargy, hypertonia with extreme opisthotonic posturing (even when unconscious), seizures, and progressive encephalopathy, which may lead to death. The disease does not generally produce metabolic acidosis, lactic acidemia, hypoglycemia, hyperammonemia, ketosis, or abnormal acylcarnitines. If untreated, however, it may lead to hypoglycemia and ketoacidosis. If the patient recovers from this initial episode, the disorder can be characterized by growth failure, mental retardation, and recurrent episodes of metabolic decompensation.

Newborn screening programs for MSUD are based on the detection of hyperleucinemia. There are relatively few false-positive results for healthy full-term infants. The rate of false-positive and false-negative results has been reduced by the use of MS (mass spectrometry)/MS technology, which can concurrently measure the concentrations of isoleucine, leucine, and valine, thereby permitting the use of amino acid ratios to more reliably identify at-risk newborns. However, a positive newborn screening result might not be received until after the newborn has already become ill and is in the neonatal intensive care unit. In either case, response to a positive screening result must be rapid.

Bedside detection of the characteristic odor of maple syrup by an alert parent or nurse might be the first clue to the diagnosis of this disorder. Once suspected, the diagnosis may be provisionally confirmed by a rapid screening test,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

the dinitrophenylhydrazine (DNPH) test, which detects the α-ketoacids that are formed from the isoleucine, leucine, and valine (see Screening Studies under Biochemical Testing). The diagnosis should then be established by plasma amino acid analysis and urine organic acid analysis. The characteristic plasma amino acid findings are increased concentrations of leucine, isoleucine, valine, and allo-isoleucine (the presence of allo-isoleucine is pathognomonic for MSUD), and the characteristic urinary organic acid pattern (see Specialized Biochemical Testing). Maple syrup urine disease is not associated with abnormal carnitine metabolism. Definitive enzyme analysis can be performed with leukocytes or cultured skin fibroblasts, but treatment should not be delayed pending definitive diagnosis.[116,138]

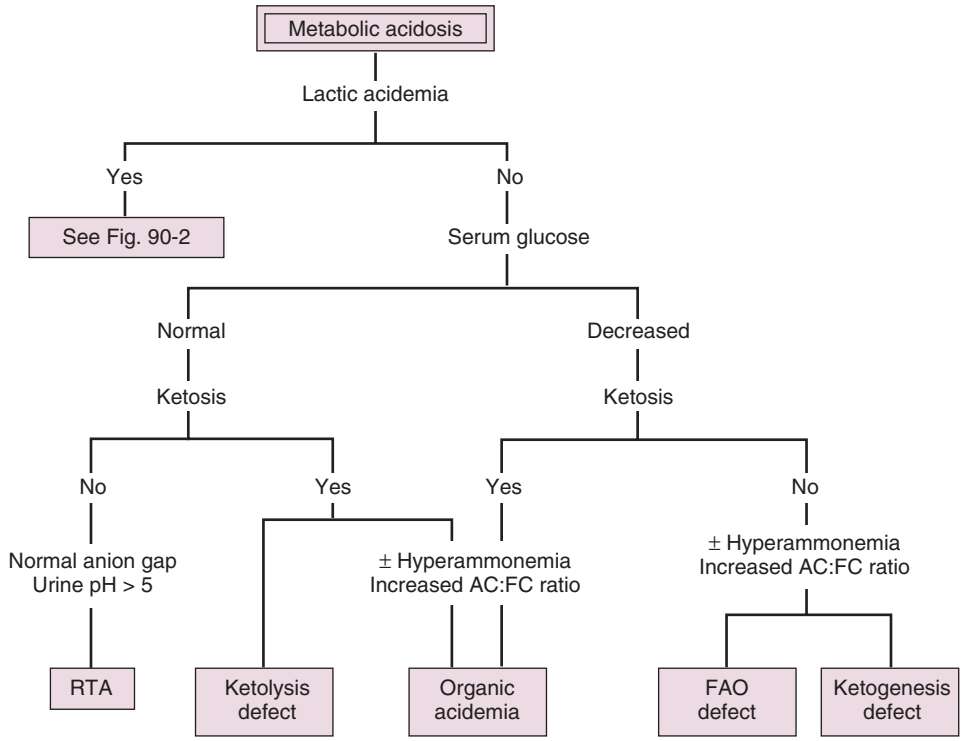
Treatment of an acutely ill newborn should include hypercaloric nutritional support that contains high concentrations of glucose (>10 mg/kg per minute); an insulin infusion (0.05-0.10 units/kg per hour) to avoid hyperglycemia; and a leucine, isoleucine, and valine-free protein source (intravenous, if available, or enteral, using specially prepared formula). The rationale for this treatment is to suppress protein catabolism (which will increase production of leucine and the other toxic branched-chain amino acids) and induce an anabolic state (which will stimulate de novo protein synthesis and thereby decrease the concentration of the free branched-chain amino acids). The concentrations of isoleucine and/or valine may become too low on this regimen and limit the rate of new protein synthesis. The progress of treatment must, therefore, be monitored frequently to determine when the branched-chain amino acids (isoleucine, valine, and ultimately leucine) must be added back to the diet. The offending amino acids should be carefully reintroduced, either parenterally or orally. In extreme cases, this approach may not reduce the leucine concentration and correct the other metabolic abnormalities rapidly enough, and hemodialysis may be required (see Metabolic Acidosis).

Treatment has prolonged the life expectancy and the quality of life for patients with MSUD, but the prognosis for intellectual outcome remains guarded, because treatment is often not initiated until after onset of the first metabolic crisis and because most patients experience recurrent episodes of ketoacidosis.[116,138] The strategic factor that correlates with ultimate intellectual outcome is the age at initiation of therapy. Initiation of therapy after 10 days of age for a patient with the severe neonatal form of MSUD is rarely associated with normal intellectual outcome.

Metabolic Acidosis

Metabolic acidosis is a common laboratory finding in sick neonates. It is most often a consequence of shock or severe organ failure of the kidney or liver. In other cases, acidosis is a discrete finding suggesting that the patient has an inborn error affecting acid production or renal acid excretion. It is important to determine the cause of the acidosis, because many cellular functions rapidly deteriorate at reduced pH. The most common treatment of acidosis is to "correct" the acidosis with bicarbonate; however, the most effective treatment of acidosis is to correct the cause of the acidosis. It is often possible to correct the acidosis caused by an inborn error of metabolism by reducing endogenous overproduction of specific acids.

Differential Diagnosis



The evaluation of metabolic acidosis should begin with an investigation for systemic shock, renal failure, and generalized liver disease. In the case of shock, the patient should be re-evaluated for recurrent acidosis after restoration of normal cardiopulmonary function. Shock might have been the consequence of an inborn error of metabolism. Similarly, patients with severe liver disease should be evaluated for an underlying inborn error of metabolism as the cause of their liver disease (see Table 90.5).

After assessing the patient's cardiopulmonary, renal, and hepatic status, the physician should initiate a diagnostic study for a possible inborn error of metabolism by measuring serum electrolytes, blood gases, and urine pH. The anion gap should be calculated. Acidosis that is associated with a normal anion gap and an inappropriate renal response to systemic acidosis (urine pH >5) implicates a renal tubular defect. The presence of a normal kidney response to the systemic acidosis (urine pH <5) and an increased anion gap suggests that the excess acid load is systemic in origin rather than renal (see Chapter 92). However, an increased anion gap is not always present in disorders associated with excessive production of abnormal acidic metabolites, and additional studies should be performed before concluding that a patient with a normal anion-gap metabolic acidosis has a renal defect rather than another disorder.

Additional studies that should be performed include determinations of blood lactate and pyruvate, serum glucose, plasma amino acids, plasma and urinary ketones, blood ammonia, plasma and urinary carnitine, and urinary organic acids. The results of these studies can be used to develop the algorithm for the differential diagnosis of metabolic acidosis shown in Fig. 90.1. This algorithm uses the blood lactate concentration as the discriminant at its first branch point, thereby dividing the causes of metabolic acidosis into the lactic acidemias and other acidemias. The advantage to this approach is that a discrete algorithm can then be used to evaluate patients with lactic acidemia. One limitation of this approach is that many categories of disease (e.g., the organic acidemias) include a subset of disorders that produce lactic acidemia and a subset that does not; another disadvantage is that the same disease might produce lactic acidemia in some patients but not in others. Therefore, the presence of lactic acidemia can serve as a useful discriminant as long as one is mindful of its limitations. The disorders associated with lactic acidemia are discussed later under Lactic Acidemia.

The serum glucose concentration is then used in Fig. 90.1 to differentiate among the disorders that cause metabolic acidosis without lactic acidemia. Several groups of disorders are associated with a normal or increased serum glucose

• **Fig. 90.1** Approach to neonatal metabolic acidosis. AC:FC, Ratio of acylcarnitine to free carnitine; FAO, fatty acid oxidation; RTA, renal tubular acidosis.

concentration at onset, whereas other groups of disorders are associated with hypoglycemia. These groups of disorders can be divided further into those that exhibit ketosis and those that do not. Ketosis is a relatively uncommon finding in the neonate. The possibility of ketosis should be searched for carefully in blood and urine in the sick newborn infant. If present, ketosis should be taken as strong evidence that the neonate has a metabolic disorder.[4,16] However, if ketosis is not present, especially in the premature newborn infant, the possibility of an underlying ketotic metabolic disorder should not be dismissed, because the pathways of ketone synthesis might not have developed sufficiently.

Other information from the initial screening studies should also be considered at this point. Serum electrolyte concentrations should be used to calculate the anion gap. The blood ammonia concentration should be assessed, because it has diagnostic and therapeutic implications. Plasma amino acid analysis and plasma and urine carnitine analyses should be reviewed, because they also might have diagnostic and therapeutic implications.

Patients who have a normal serum glucose concentration with ketosis might have an organic acidemia or a ketolytic defect. Approximately a dozen organic acidemias can have their onset in the neonatal period (see Box 90.1). Many of the organic acid disorders have a common set of features, including ketoacidosis, vomiting, seizures, coma, and in some disorders, an unusual smell (see Table 90.7). Because the main diagnostic test for the organic acid disorders—urinary organic acid analysis—can detect essentially all of these defects, the physician need only consider this diagnostic category and order the appropriate analysis.

In general, analysis of a urine sample collected early in the course of an acute episode of metabolic decompensation has the best chance of revealing the characteristic pattern of organic aciduria. In other cases, the sample obtained during an acute episode contains too many metabolites, and the primary defect is obscured. Accordingly, it is advisable to send at least two samples to the laboratory, one obtained during and the other after an acute episode, when an organic acid disorder is suspected.

In addition to an abnormal urinary organic acid pattern, patients with many of the relatively common organic acidemias generally have an increased serum anion gap, reflecting the accumulation of abnormal organic acids, and hyperammonemia. The degree of hyperammonemia may be so great (>200 μmol/L) that it generates concern and possibly confusion about whether the patient has a primary urea cycle defect rather than an organic acidemia (see Hyperammonemia).[3] However, the organic acidemias can generally be distinguished from the urea cycle defects. The organic acidemias are associated with a more significant metabolic acidosis than is seen in the urea cycle defects (especially early in the course of the illness, when the urea cycle defects are associated with a respiratory alkalosis); an abnormal organic acid pattern; and an increased acylcarnitine-to-free carnitine ratio, which is often accompanied by a pathognomonic acylcarnitine profile. The clinical features of individual organic acidurias are discussed later in this chapter.

Renal Tubular Defects

The most likely diagnosis when metabolic acidosis is associated with a normal serum glucose concentration, the absence of ketosis, a normal blood ammonia concentration, a normal anion gap, and an inappropriate renal response to systemic acidosis (urine pH >5) is a renal tubular defect.

Isolated renal tubular acidosis (RTA) is not discussed here, because it is more appropriately discussed in Chapter 93. However, certain inborn errors of metabolism are associated with RTA. In general, there are two forms of RTA that reflect the anatomic and functional locus of the defect: proximal RTA and distal RTA. The inborn errors of metabolism that are discussed in this chapter are associated with defects causing proximal RTA but not distal RTA. Most inborn errors of metabolism that cause proximal RTA also affect other components of proximal renal tubular function, producing the renal Fanconi syndrome (i.e., generalized aminoaciduria, glucosuria, phosphaturia, and RTA). Inborn errors of metabolism that cause renal Fanconi syndrome include defects of amino acid and carbohydrate and organic acid metabolism, as well as mitochondrial disorders (Table 90.14). The diagnostic approach and general treatment of these disorders are discussed in the respective parts of this chapter.

Disorders of Ketone Metabolism

The next category to consider includes disorders associated with hypoglycemia and a disorder of ketone formation or catabolism. Patients who have hypoglycemia without ketosis (i.e., nonketotic or hypoketotic hypoglycemia) have a defect in ketogenesis or mitochondrial fatty acid β-oxidation unless another cause is found. Patients with defects of mitochondrial fatty acid β-oxidation are unable to generate acetyl-CoA for ketone body synthesis, whereas patients with defects in ketogenesis are unable to use acetyl-CoA for ketone body synthesis. These disorders can also be associated with hyperammonemia, an increased anion gap, and disordered carnitine homeostasis. Defects of ketogenesis are discussed in the next section, followed by a discussion of defects of ketolysis. Defects in mitochondrial fatty acid β-oxidation are discussed in more detail under Hypoglycemia.

TABLE 90.14 Disorders That Cause Renal Fanconi Syndrome

Category of Disorder	Disorder
Amino acid disorders	Tyrosinemia type I
Carbohydrate disorders	Fanconi-Bickel syndrome Galactosemia Glycogen storage disorder type I Hereditary fructose intolerance
Mitochondrial disorders	Coenzyme Q biosynthesis defect (*COQ2*)* Complex III assembly (*BCS1L*)** mtDNA depletion syndromes (*DGUOK, MPV17, RRM2B, TWNK*)** Pearson syndrome
Organic aciduria	Pyroglutamic aciduria
Others	Lowe syndrome Wilson disease

**COQ2*, gene encoding parahydroxybenzoate-polyprenyl transferase
***BCS1L, DGUOK, MPV17, RRM2B, TWNK*: also see "Disorders Associated with Hepatic Dysfunction, Mitochondrial Disorders (Table 90.5)" and Disorders Associated With Lactic Acidemia in Neonates (Table 90.15) for further discussion of these disorders.

Defects of Ketogenesis. 3-Hydroxy-3-methylglutaryl-CoA lyase deficiency (also known as 3-hydroxy-3-methylglutaric aciduria) is an autosomal recessive disorder of ketogenesis.[99] This deficiency affects ketone body formation from fatty acid β-oxidation and from leucine catabolism. This disorder can, therefore, be classified as an amino acid disorder and a fatty acid β-oxidation defect, which is characterized by an abnormal urine organic acid pattern. The defect interferes with the major pathways of ketone body formation and consequently is a cause of severe nonketotic hypoglycemia and acidosis in the newborn infant. Patients generally have vomiting, hypotonia, or lethargy at presentation, but others present with seizures caused by the profound hypoglycemia associated with this disorder. This disorder is treated with frequent feedings of a combined low-fat/low-protein/leucine-restricted diet and carnitine supplementation. Other treatment modalities described above for the organic acidurias may also be helpful.

Defects of Ketolysis. Disorders of ketolysis are defects in the degradation of ketone bodies once they are formed. Ketolytic defects constitute a subset of organic acidemias. They are identified by urinary organic acid analysis but are considered separately here, because their pathogenesis is unique. In normal individuals, ketone bodies are formed in the liver and then transported to peripheral tissues, where they are used as a glucose-sparing energy source.

Ketolytic defects are primarily defects in extrahepatic ketone use rather than ketone body synthesis by the liver. These defects are characterized by normoglycemia or even hyperglycemia. Ketolytic defects are relatively rare, especially in the neonate. Two ketolytic defects with onset in the newborn period are succinyl-CoA:3-ketoacid CoA-transferase deficiency and 3-ketothiolase deficiency.[1,57] Both result in lethargy, hypotonia, a normal or decreased serum glucose concentration, and marked ketosis during the fed state and the fasted state.

The diagnosis of succinyl-CoA:3-ketoacid CoA-transferase deficiency should be considered in a patient with negative findings on organic acid analysis except for markedly increased concentrations of β-hydroxybutyrate, acetoacetate, and β-hydroxyisovalerate. Confirmation of the diagnosis requires specific enzyme analysis or genetic testing.

3-Ketothiolase deficiency impairs ketone body use and isoleucine metabolism, because the enzyme is involved

in both pathways. The urinary organic acid pattern seen in patients with this disorder shows increased amounts of 2-butanone, 2-methyl-3-hydroxybutyrate, and tiglylglycine, as well as increased excretion of acetoacetate and β-hydroxybutyrate. This disorder can be confused with diabetic ketoacidosis or salicylism when it occurs in the older child.

The treatment for both disorders is a low-protein diet and possibly a low-fat diet, especially during intercurrent illnesses. Carnitine supplementation might also be helpful.

Organic Acidemias

Patients who have hypoglycemia with ketosis should be evaluated for an organic acidemia. Methylmalonic acidemia and propionic acidemia, two of the most common organic acid disorders, are often associated with ketosis. This is also true of several other branched-chain organic acidemias. These common organic acidemias may be associated with hypoglycemia, an increased anion gap, hyperammonemia, hyperglycinemia, and an increased ratio of acylcarnitine to free carnitine with an abnormal pattern of specific acylcarnitines, but none of these findings is present invariably.[1,15,57] Definitive diagnosis can be accomplished by plasma amino acid analysis, urinary organic acid analysis, and plasma carnitine analysis with an acylcarnitine profile, followed by enzymatic or other specialized biochemical testing.

Defects in Branched-Chain Amino Acid Metabolism. The most common organic acidurias in the newborn period are isovaleric acidemia, methylmalonic acidemia, and propionic acidemia (see Box 90.1).[1,15,57] These three disorders share many of the same clinical and biochemical features. All three disorders are the consequence of defects in branched-chain amino acid metabolism, affecting the catabolism of isoleucine, leucine, or valine. Patients born with these disorders are generally healthy at birth and then become inexplicably ill on the second or third day of life. Standard supportive management might not halt the progression of the disease, and the neurologic status deteriorates until the patient develops a severe metabolic encephalopathy and in many cases dies (see Metabolic Encephalopathy).

Biochemically, these disorders are characterized by hypoglycemia plus a combination of many or all of the following features: severe ketoacidosis, hyperammonemia, lactic acidemia, hyperglycinemia, abnormal carnitine metabolism (i.e., relative carnitine insufficiency with an increased total acylcarnitine-to-free carnitine ratio and abnormal acylcarnitine profile), hypocalcemia, and neutropenia, thrombocytopenia, or pancytopenia. Occasionally, patients with an organic acidemia do not present with acidosis. The blood sugar level may be decreased, normal, or increased.

Other defects in branched-chain amino acid metabolism (such as 3-methylcrotonyl-CoA carboxylase deficiency) have similar clinical and biochemical phenotypes. Many patients with this disorder are ascertained by the alert nurse, physician, or parent who notices an abnormal odor emanating from the sick newborn infant's bed or diaper (see Table 90.7).

Multiple Carboxylase Deficiency. Several organic acidurias represent compound phenotypes, because the genetic defect affects the synthesis or functioning of several enzymes. The most common of these compound disorders is multiple carboxylase deficiency, which may be the consequence of either of two genetically distinct defects: biotinidase deficiency and holocarboxylase synthetase deficiency (see Newborn Screening Programs). Both enzyme deficiencies lead to functional deficiencies of four enzymes, all carboxylases: acetyl-CoA carboxylase, which is involved in fatty acid synthesis; 3-methylcrotonyl-CoA carboxylase deficiency, which is involved in branched-chain amino acid metabolism; propionyl-CoA carboxylase, which is also involved in branched-chain amino acid metabolism; and pyruvate carboxylase deficiency, which is involved in gluconeogenesis. Both forms of multiple carboxylase deficiency can cause lactic acidemia and a complex organic aciduria; both are also considered in the algorithm for lactic acidemia (see Lactic Acidemia).

Both forms of multiple carboxylase deficiency can lead to severe metabolic encephalopathy and/or neonatal seizures and require prompt diagnosis and treatment. The sick infant should be evaluated with plasma carnitine analysis, including an acylcarnitine profile, urine organic acid analysis, and serum biotinidase analysis. Treatment with oral biotin supplementation should be started at an initial dose of 20-40 mg/day.

Multiple Acyl-CoA Dehydrogenase Deficiency. Another disorder that represents a compound organic aciduria is multiple acyl-CoA dehydrogenase deficiency, or glutaric aciduria type II (see Dysmorphic Syndromes).[1,57] This disorder is the consequence of a defect in ETF dehydrogenase or ETF ubiquinone oxidoreductase, which are enzymatic components in the pathway that transfers reducing equivalents from the flavin-dependent dehydrogenases involved in mitochondrial fatty acid β-oxidation and the oxidation of several amino acids to the respiratory chain. This disorder is characterized by dysmorphogenesis of the brain, face, and kidneys, as well as the more expected clinical and biochemical phenotype of a combined amino acid and fatty acid β-oxidation defect. This disorder is also associated in many cases with lactic acidosis, especially during acute phases of the illness.

Other. Many of the other organic acidurias listed in Box 90.1 present in a different manner from the disorders listed in the preceding and need to be evaluated and treated differently once they are identified by urine organic acid analysis. For example, mevalonic aciduria is associated with hepatosplenomegaly, diarrhea, anemia, hypocholesterolemia, and craniofacial dysmorphism. The underlying defect in this disorder is deficiency of mevalonate kinase, which is a peroxisomal enzyme that catalyzes the first committed step in the biosynthesis of cholesterol and nonsterol isoprenoids (see Dysmorphic Syndromes).[37]

Similarly, pyroglutamic acidemia is caused by a defect in glutathione synthetase, an enzyme required for the biosynthesis of glutathione. Glutathione is a tripeptide involved in maintaining the redox status within the cell. This rare

disorder produces acidosis but not ketosis or hypoglycemia in the newborn period. Clinically, it causes RTA type I (see Table 90.14), hemolysis, and hyperbilirubinemia in the newborn period. It leads to acidosis during intercurrent illnesses later in childhood and progressive neurologic abnormalities, including ataxia, spasticity, and mental retardation. The primary objective of treatment is to correct the acidosis and electrolyte imbalances associated with the disorder, especially during acute illnesses. In the neonatal period, it is also important to aggressively treat any anemia or hyperbilirubinemia that develops. Early treatment with vitamin E and vitamin C is recommended, because it may be of long-term benefit. Of note, patients with particular organic acidemias, such as methylmalonic acidemia and propionic acidemia, may develop secondary glutathione deficiency and may benefit from similar treatment.

Management. Management of a patient with an organic acidemia that can produce a neurologic intoxication syndrome and metabolic encephalopathy (e.g., defect in branched-chain amino acid metabolism or multiple carboxylase deficiency) should include supportive care (i.e., administration of bicarbonate, a high rate of glucose infusion [>10 mg/kg per minute], no protein-containing feedings, cofactor supplementation if a specific diagnosis is suspected, and mechanical ventilation, if needed). If the patient has a severe encephalopathy, hemodialysis should be considered.[1,46,57,96,107] Centers unable to provide hemodialysis to newborn infants should consider transferring such patients, because exchange transfusion, peritoneal dialysis, and hemofiltration are considerably less effective than hemodialysis for managing these disorders.

Treatment should be modified as soon as a provisional diagnosis is available. For example, branched-chain amino acid–free parenteral nutrition and specially designed enteral formulas are used to manage acutely ill patients with MSUD. Insulin can be used to augment the anabolic state, starting at 0.05-0.10 units/kg per hour.

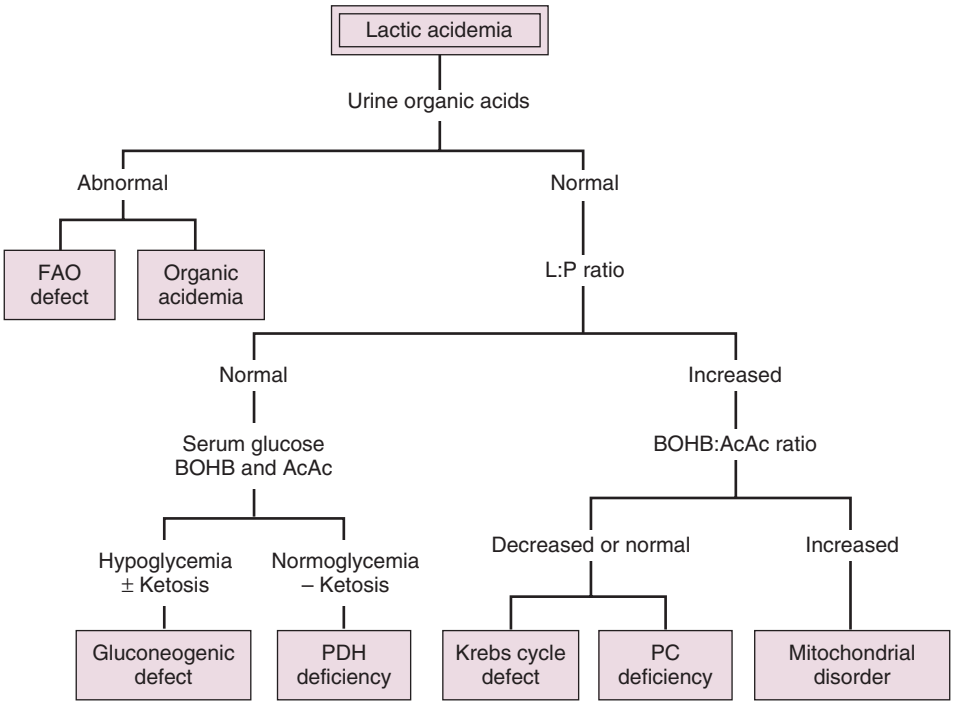
Carnitine is used in many of these disorders to remove toxic metabolites during the acute phase. Carnitine can be given orally or intravenously. During an acute crisis, it is probably best to provide intravenous carnitine at 100-200 mg/kg per day (larger doses are sometimes given) as a continuous drip or in four divided doses. If parenteral carnitine is unavailable, carnitine should be given orally at comparable amounts in three or four divided doses. Glycine has been given for similar reasons to patients with isovaleric acidemia and related disorders.[1,57] Glycine should be given orally at a dosage of 250-500 mg/kg per day in three divided doses during the acute crisis. Intralipid can be started after carnitine supplementation has begun and when it is certain that the patient does not have a defect of fatty acid β-oxidation.

After the patient's condition is stabilized, oral feedings should be initiated. In the absence of a specific diagnosis, a high-carbohydrate formula that contains proportionately reduced amounts of protein and fat should be started. The diet should be modified after the neonate's diagnosis has been established. As a rule, it is necessary to limit protein intake or, more correctly, the intake of certain amino acids, but restriction of both protein and fat intake may be required for some disorders. A range of special formulas is commercially available for these patients, but specialized diets should always be designed with the assistance of a dietitian experienced in managing patients with inborn errors of metabolism.

Efforts to reduce the endogenous production of toxic metabolites could also include antibiotic suppression of gut flora that produce metabolites that enter the patient's bloodstream (e.g., long-term metronidazole in patients with methylmalonic and propionic acidemias).[46,125] Specific vitamins may be provided as cofactors for certain enzyme deficiencies, possibly including biotin (10-40 mg PO), hydroxycobalamin (1 mg/day IM), pyridoxine (10 mg/day PO), riboflavin (20 mg/day PO), or thiamine (10 mg/day PO). Carnitine (100 mg/kg per day) is also used during the maintenance phase of treatment.

The various approaches to the acute and long-term management of organic acidemias have led to improved survival and outcome. However, the prognosis for patients with these disorders still varies widely for different disorders and for patients with the same disorder.[1,57] Efforts to establish correlations of genotype and phenotype for these disorders are under way and may soon provide a rational basis for providing prognostic information.

Lactic Acidemia



The lactic acidemias are a complex group of inborn errors of metabolism. The classification, diagnosis, and treatment of these disorders will almost certainly change as understanding of their pathogenesis improves. In particular, current understanding of the pathogenesis of defects of the respiratory or electron transport chain is evolving rapidly.

Lactic acidemia may be the consequence of overproduction of lactate, underuse of lactate, or both. A prerequisite for evaluating a patient with lactic acidemia is to assess the adequacy of tissue oxygenation. After it has been established that tissue oxygenation is adequate, several laboratory studies should be performed to determine the cause of the lactic acidemia, including measurement of blood lactate and pyruvate, blood gases and electrolytes, serum glucose, blood ammonia, plasma amino acids, plasma and urinary ketones, plasma and urinary carnitine, and urinary organic acids. If a lumbar puncture is planned to investigate the possibility of sepsis, a sample of CSF should be obtained for lactate and pyruvate analysis, along with samples for the more routine studies; a blood sample should be obtained concurrently for blood lactate and pyruvate analysis. The results of these studies can be used to generate an algorithm for establishing the diagnosis of a neonate with lactic acidemia (Fig. 90.2).

Differential Diagnosis

The differential diagnosis of the primary genetic lactic acidemias with onset in the neonatal period includes defects

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• **Fig. 90.2** Approach to neonatal lactic acidemia. AcAc, Acetoacetate; BOHB, β-hydroxybutyrate; *BOHB:AcAc,* β-hydroxybutyrate-to-acetoacetate ratio; FAO, fatty acid oxidation; L:P, lactate-to-pyruvate ratio; PC, pyruvate carboxylase; PDH, pyruvate dehydrogenase complex.

of gluconeogenesis, glycogenolysis, or pyruvate metabolism; defects of the Krebs (or tricarboxylic acid) cycle; and defects of the respiratory chain (Table 90.15). Many defects of fatty acid oxidation, organic acid metabolism, and the urea cycle are associated with lactic acidemia because of relationships among the various pathways of intermediary metabolism. These disorders are more properly considered secondary lactic acidemias and are discussed elsewhere in this chapter. Multiple carboxylase deficiency is an exception to this rule, because the underlying defect impairs biotin metabolism, which may produce pyruvate carboxylase deficiency and lactic acidemia.

The urinary organic acid pattern, along with the blood ammonia concentration and plasma and urine carnitine analyses, provides a practical means for discriminating between the primary and secondary lactic acidemias. The urinary organic acid pattern is by definition abnormal in patients with an organic acidemia and is abnormal in many of the disorders of fatty acid β-oxidation. Patients with fatty acid oxidation defects often excrete increased amounts of dicarboxylic acids, 3-hydroxydicarboxylic acids, or both. In contrast, the primary lactic acidemias are associated with a normal organic acid pattern or a nonspecific pattern of increased excretion of lactate and pyruvate, various Krebs cycle intermediates, dicarboxylic and 3-hydroxydicarboxylic acids, or 3-methylglutaconic acid. The dicarboxylic and 3-hydroxydicarboxylic acids are the consequence of secondarily impaired mitochondrial fatty acid β-oxidation.

Despite the potential overlap between the patterns of urinary organic acids produced by these disorders, urinary organic acid analysis generally provides a useful means of discriminating between the primary and secondary lactic acidemias, because qualitative and quantitative differences exist between the patterns seen in the two groups of disorders. The concentrations of urinary metabolites excreted in the primary lactic acidemias are generally less than those produced by the organic acidurias and fatty acid β-oxidation defects.

The plasma ammonia concentration and the plasma and urine carnitine analyses also provide useful information for distinguishing between the primary and secondary lactic acidemias. Patients with an organic aciduria or a fatty acid β-oxidation defect often have hyperammonemia and relative carnitine insufficiency, with an increased acylcarnitine-to-free carnitine ratio and specific acylcarnitine abnormalities.[78,93] In contrast, patients with one of the primary lactic acidemias generally have a normal plasma ammonia concentration and relatively mild and nonspecific changes in their plasma and urinary carnitine values.

The exception to this rule is the severe neonatal form of pyruvate carboxylase deficiency, because these patients can have hyperammonemia. Similarly, patients with a primary urea cycle defect could have lactic acidosis, but the degree of acidosis is relatively mild, especially early in the course of the disease, when respiratory alkalosis rather than metabolic acidosis is generally present (see Hyperammonemia).

Primary Lactic Acidemias

In practical terms, the first step in discriminating among the primary lactic acidemias is to examine the results of the lactate (L) and pyruvate (P) analyses in terms of the absolute and relative values of this pair of metabolites. The

TABLE 90.15 Disorders Associated With Lactic Acidemia in Neonates

Category of Disorder	Disorder
Disorders of gluconeogenesis, glycogenolysis, or pyruvate metabolism	Fructose-1,6-bisphosphatase deficiency GSD type I (glucose-6-phosphatase deficiency) GSD type III (debrancher deficiency) GSD type IX (liver phosphorylase kinase deficiency) Phosphoenolpyruvate carboxykinase deficiency Pyruvate carboxylase deficiency Pyruvate dehydrogenase complex deficiency
Krebs cycle disorders	Dihydrolipoamide dehydrogenase deficiency Fumarase deficiency α-Ketoglutarate dehydrogenase deficiency Succinate dehydrogenase deficiency
Organic acidemias	See Box 90.1
Mitochondrial Disorders	
mtDNA Mutations	
Point Mutations	
mRNA	Maternally inherited Leigh syndrome (*ATPase6*)
rRNA	Aminoglycoside-induced nonsyndromic deafness
tRNA	Hepatic dysfunction ($tRNA^{Glu}$) Isolated cardiomyopathy ($tRNA^{Leu}$)
Large deletions/duplications	Pearson syndrome
nDNA Mutations	
Mutations that directly affect protein subunits of the RC complexes	Complex I, II, III, IV, and V, or combined deficiencies
Mutations that affect nuclear genes required for transport, assembly, or stabilization of the RC complexes	Complex III (*BCS1L*) Complex IV (*SURF*, *SCO1*, *SCO2*, *COX10*, *COX15*) Complex V (*TREM70*)
Mutations that affect nuclear genes required for replication or maintenance of the mitochondrial genome	Mitochondrial DNA depletion syndromes (*DGUOK*, *FBXL4*, *POLG*, *TK2*)
Mutations that affect genes involved in other mitochondrial processes required for normal mitochondrial function	Barth syndrome (*TAZ*)

ATPase 6, Subunit 6 of ATP synthase; COX, cytochrome oxidase; GSD, glycogen storage disorder; nDNA, nuclear DNA; mtDNA, mitochondrial DNA; RC, respiratory chain; $tRNA^{Leu}$, transfer RNA for leucine (UUR); $tRNAG^{Glu}$, transfer RNA for glutamic acid; TAZ, tafazzin.

L:P ratio is a reflection of the redox state of the cytoplasm. The L:P ratio is normally between 10:1 and 20:1. Defects of gluconeogenesis or the pyruvate dehydrogenase complex are generally associated with a normal L:P ratio, whereas defects of the mitochondrial respiratory chain are often associated with an increased L:P ratio. The possibility of a mitochondrial respiratory chain defect should not be ignored in patients with a normal blood lactate concentration or a normal L:P ratio when the patient's clinical picture otherwise suggests a respiratory chain disorder.

Further differentiation of the primary lactic acidemias can be made with the results of the plasma β-hydroxybutyrate (BOHB) and acetoacetate (AcAc) analysis and the serum glucose analysis. As discussed in regard to the results of the blood lactate and pyruvate analyses, the results of plasma BOHB and AcAc analyses should be evaluated in terms of the absolute and relative values of this pair of metabolites. Whereas the L:P ratio is a reflection of the redox state of the cytoplasm, the BOHB:AcAc ratio is a reflection of the redox state within the mitochondrion. Both ratios must be examined to appreciate the redox state within the cell.

The primary lactic acidemias associated with a normal L:P ratio include defects of gluconeogenesis and defects of the pyruvate dehydrogenase complex (see Fig. 90.2). These two groups of disorders can be distinguished from each other by the presence or absence of hypoglycemia and ketosis. Defects of gluconeogenesis are generally associated with hypoglycemia and ketosis, whereas patients with pyruvate dehydrogenase complex deficiency are generally normoglycemic and do not have ketosis (see Hypoglycemia).

Pyruvate Dehydrogenase Complex Deficiency

Patients with pyruvate dehydrogenase complex deficiency can present in the neonatal period with severe lactic acidosis and rapidly progressive deterioration. Less severe deficiencies are compatible with survival but lead to psychomotor retardation. Most patients with pyruvate dehydrogenase complex deficiency have an X-linked form of the

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

disease, in which male patients are more severely affected than female patients. In many cases, patients with pyruvate dehydrogenase complex deficiency are born with structural CNS malformations, including agenesis of the corpus callosum and cystic lesions of cerebral cortex; in other patients, lesions of the basal ganglia and brainstem that are consistent with Leigh disease are present or develop later in infancy. However, the Leigh disease phenotype is not pathognomonic for pyruvate dehydrogenase deficiency, because Leigh disease is genetically heterogeneous; it can also be the consequence of PC deficiency[136] or defects of nuclear- or mitochondrial-encoded subunits of the mitochondrial respiratory chain.[19,27,44]

Efforts to treat patients with pyruvate dehydrogenase complex deficiency have included a high-fat, low-carbohydrate diet with thiamine and lipoic acid supplementation. The rationale for this therapy is that glucose is catabolized through the glycolytic pathway to pyruvate and then requires the action of the pyruvate dehydrogenase complex before it can enter the Krebs cycle, whereas fatty acids enter the Krebs cycle without passing through the pyruvate dehydrogenase complex. Thiamine and lipoic acid are cofactors for the first and second components of the pyruvate dehydrogenase complex, respectively. Some patients have been treated with dichloroacetate, a drug that maintains the pyruvate dehydrogenase complex in its activated state. These treatment efforts have met with mixed success.

As shown in Fig. 90.2, the primary lactic acidemias associated with an increased L:P ratio can be distinguished by considering the absolute and relative concentrations of BOHB and AcAc. Patients with PC deficiency, a Krebs cycle defect, or a mitochondrial respiratory chain defect all exhibit postprandial ketosis. However, for the reasons explained previously, severe PC deficiency and Krebs cycle defects may be accompanied by a decreased or a normal BOHB:AcAc ratio, whereas mitochondrial respiratory chain defects may be accompanied by an increased BOHB:AcAc ratio. PC deficiency is discussed elsewhere (see Hypoglycemia), whereas respiratory chain defects are discussed in this section.

Krebs Cycle Defects

Krebs cycle defects are rare. Four defects affecting the Krebs cycle have been described: α-ketoglutarate dehydrogenase complex deficiency, fumarase deficiency, succinate dehydrogenase deficiency, and dihydrolipoamide dehydrogenase deficiency. The clinical presentations of α-ketoglutarate dehydrogenase deficiency and fumarase deficiency are variable but always affect neurologic function. They can cause hypotonia, ataxia, and, in some cases, CNS malformations. Succinate dehydrogenase contains four subunits (SDHA, SDHB, SDHC, SDHD), as well as two assembly proteins (SDHAF1, SDHAF2). Succinate dehydrogenase deficiency associated with mutations in the *SDHA* gene produces clinical phenotypes consistent with a respiratory chain defect, such as Leigh syndrome or cardiomyopathy, which is not surprising because succinate dehydrogenase forms part of complex II of the respiratory chain. Defects of the other SDH subunits produce cancer predisposition syndromes for paraganglioma. Similarly, individuals who are carriers for fumarase deficiency have an increased disposition for leiomyomatosis and renal cell cancer. The connection between fumarase deficiency and SDH deficiency and hereditary cancer syndromes is not well understood and is an area of intense research.

Dihydrolipoamide dehydrogenase deficiency affects a protein that is a component of three different α-ketoacid dehydrogenase complexes: the α-ketoglutarate dehydrogenase complex (i.e., Krebs cycle component), the pyruvate dehydrogenase complex (i.e., the enzyme that converts pyruvate to acetyl-CoA and thereby permits its entry into the Krebs cycle), and the branched-chain α-ketoacid dehydrogenase complex (i.e., the enzyme that is deficient in MSUD). Dihydrolipoamide dehydrogenase deficiency is, therefore, a compound deficiency of these three α-ketoacid dehydrogenase complexes and is associated with severe ketoacidosis and a pathognomonic organic aciduria. The Krebs cycle defects can be detected by urinary organic acid analysis. Effective treatment does not exist for these Krebs cycle disorders.

Mitochondrial Disorders

Defects of the mitochondrial respiratory chain and oxidative phosphorylation (hereafter referred to as mitochondrial disorders) are a diverse group of disorders reflecting the large number of genes involved in this metabolic system.[19,27] The mitochondrial respiratory chain and oxidative phosphorylation system is composed of five multimeric protein units: complex I, II, III, IV, and V. The number of protein subunits in these complexes ranges from 4-43 proteins. An additional level of complexity is that some subunits are encoded by nuclear DNA (nDNA) and others are encoded by mitochondrial DNA (mtDNA). The nDNA encodes for approximately 85% of the subunits, whereas mtDNA encodes for approximately 15%. Complexes I, III, IV, and V contain subunits encoded by both genomes, whereas complex II contains only nuclear-encoded subunits. The common names, composition, and genetic origin of the subunits of the five respiratory chain complexes are listed in Table 90.16.

The mitochondrial genome differs in several strategic ways from the nuclear genome.[19,27] There are both structural and biologic differences between the two genomes. The structural differences include the following:

- mtDNA is much smaller than nDNA. It is a circular, double-stranded genome that contains about 16,500 base pairs (16.5 kb), which encode for 37 genes (compared with the 30,000 genes that are encoded by the nuclear genome). The mtDNA encodes for 13 mRNAs, two rRNAs, and 22 tRNAs. The mRNAs encode for the polypeptide subunits of the respiratory chain complexes. The two rRNAs and 22 tRNAs are necessary for translation of mtDNA.

TABLE 90.16 Respiratory Chain Complexes

Complex	Name	Composition and Genetic Origin		
		nDNA	mtDNA	Total
I	NADH-CoQ reductase	37	7	44
II	Succinate-CoQ reductase	4	0	4
III	$CoQH_2$-cytochrome c reductase	10	1	11
IV	Cytochrome c oxidase	10	3	13
V	ATP synthase	12	2	14

CoQ, Coenzyme Q (ubiquinone); $CoQH_2$, reduced coenzyme Q (ubiquinol); nDNA, nuclear DNA-encoded subunits; mtDNA, mitochondrial DNA-encoded subunits; NADH, reduced nicotinamide adenine dinucleotide.

- The genetic codes of the mtDNA and nDNA differ in several key codons, such that the two genomes require their own translational apparatus.
- Almost all regions of mtDNA are part of coding sequence; that is, the mtDNA has few introns. This is very different from the situation for nDNA, which contains a high proportion of noncoding regions.
- The mutation rate for mtDNA is approximately 10-fold greater than that of nDNA, in part because it does not have histones and in part because it has a poor mutation repair apparatus.

Combining the high mtDNA mutation rate with the high proportion of coding sequence in mtDNA, mtDNA mutations are thought to account for a disproportionate percentage (based on their relative size) of human disease compared with the nuclear genome. Conversely, the number of nuclear genes involved in mitochondrial structure and function is far greater than the number of mitochondrial encoded genes, supporting the clinical observation that nuclear mutations are also a significant cause of mitochondrial disease, especially in children.

In addition to these structural differences, there are also several strategic biologic differences between the mitochondrial and nuclear genomes:

- mtDNA is inherited exclusively from the mother, leading to maternal or matrilineal inheritance of mitochondrial encoded disorders.
- Each mitochondrion contains multiple copies of mtDNA, varying between 2 and 10 copies per organelle. Each cell, in turn, contains a variable number of mitochondria, leading to hundreds to thousands of copies of mtDNA per cell. In contrast, each cell (except mature germ cells) contains two copies of nDNA.
- Each cell may contain only one form of mtDNA ("normal" or "abnormal") or more than one form of mtDNA ("normal" or "abnormal"). The presence of only one form of mtDNA is called *homoplasmy*; the presence of more than one form is called *heteroplasmy*. The cell can contain any proportion of abnormal mtDNA. The clinical consequences of abnormal mtDNA are proportional to the degree of heteroplasmy of that mutation. The phenomenon of mtDNA heteroplasmy differs sharply from that for nDNA, wherein an individual is either homozygous or heterozygous for a normal or abnormal allele.
- The proportion of normal and abnormal mtDNA in a cell can change over time, because mtDNA replication is not synchronous with nuclear division. A shift in the degree of heteroplasmy can occur prenatally or postnatally, lead to improvement or worsening of the clinical phenotype, or produce a change in the pattern of tissue and organ involvement.
- The clinical consequences of an mtDNA defect (homoplasmic or heteroplasmic) vary in different tissues and organs, depending on the mitochondrial (aerobic) energy requirements of each tissue or organ. This phenomenon has been termed the *threshold effect*.

The unique biologic properties of mtDNA provide a rationale for the unusual mode of inheritance, pattern of clinical involvement, and sometimes evolving clinical picture of some respiratory chain disorders.

An extraordinarily broad range of clinical phenotypes has been described among patients with mitochondrial disorders.[19,27,44] This is not surprising given the almost universal requirement that different cells, tissues, and organs have for mitochondrial energy production. The clinical abnormalities primarily observed in newborns with respiratory chain disorders involve the CNS (lethargy, apnea, hypotonia, near-miss episodes, and coma), skeletal muscle (decreased spontaneous movements, atrophy, hypertonia or hypotonia, recurrent myoglobinuria), heart (hypertrophic cardiomyopathy), liver (hepatomegaly, hepatic failure), kidney (proximal tubular dysfunction), exocrine pancreas, and hematopoietic system (sideroblastic anemia, neutropenia, and thrombocytopenia). In some cases, other clinical abnormalities can be identified (e.g., ocular abnormalities), which often provide a clue that facilitates further diagnostic evaluation. Thus, all patients suspected of having a mitochondrial disorder should undergo a comprehensive clinical evaluation to delineate the full pattern of organ involvement.

Similarly, all patients suspected of having a mitochondrial disorder should undergo a metabolic evaluation for

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

lactic acidemia and related biochemical abnormalities, as discussed in the beginning of this section (see Lactic Acidemia). These studies should be done in both the fasting and fed state (1 hour postprandial). The metabolic evaluation should include measurement of blood lactate and pyruvate, plasma, and urine ketones (β-hydroxybutyrate and acetoacetate), plasma amino acids (focusing on alanine, the transamination product of pyruvate), plasma carnitine analysis (including total carnitine, free carnitine, and the acylcarnitine profile), plasma coenzyme Q10 (which is required for normal functioning of the mitochondrial respiratory chain), and urine organic acid analysis. In addition to measuring the blood lactate and pyruvate concentrations, these metabolites should also be measured in the CSF (especially in patients with CNS symptoms) if they are normal in blood. Magnetic resonance spectroscopy (MRS) of the brain may also be helpful in identifying increased lactate. It is important to remember that the absence of lactic acidemia, or any of the other aforementioned biochemical findings, does not exclude the diagnosis of a mitochondrial disorder.

More specialized diagnostic evaluation for a suspected mitochondrial disorder entails a combination of enzyme and morphologic analysis of tissues, polarographic analysis of intact mitochondria, and genetic analysis of mtDNA and nDNA-encoded genes.[27,38] Polarographic analysis measures oxygen consumption by intact mitochondria using a variety of substrates. It requires freshly isolated mitochondria and is available in only a few centers. Interpretation of the results of all these diagnostic studies is complicated by the fact that many defects are tissue specific. In particular, many defects are not expressed biochemically in blood cells or cultured skin fibroblasts, which mandates the need for invasive studies to obtain a skeletal muscle, cardiac, or liver biopsy. Similarly, the biochemical defect may not be expressed in all these tissues. Enzyme and polarographic analysis can implicate deficiency of one or more of the respiratory chain complexes, but they do not permit the clinician to determine whether the patient has a defect in a nuclear- or mitochondrial-encoded subunit. Genetic analysis of the mitochondrial genome is available, but many mtDNA defects are not detectable in all tissues because of heteroplasmy. In recent years, considerable progress has been made in identifying the nuclear genes that encode for the respiratory chain subunits and related mitochondrial processes, and genetic analysis is becoming increasingly available for many nuclear-encoded defects. Genetic analysis of nuclear defects is not limited by the tissue-specificity issue that plays a role in the genetic evaluation of mtDNA-encoded defects.

A general consensus seems to have developed about the diagnostic evaluation of patients with a suspected mitochondrial disorder.[19,27,38] As noted, the first step is to perform a comprehensive clinical evaluation and a noninvasive metabolic evaluation to establish whether the patient is likely to have a mitochondrial disorder. If the patient appears likely to have a mitochondrial disorder and the clinical phenotype is characteristic of a specific, well-defined mitochondrial disorder that can be confirmed by genetic testing of a blood sample, then proceeding with specific genetic testing for that disorder is indicated. If, however, it appears that the patient has a mitochondrial chain disorder that can be the consequence of a defect in one of many genes, molecular genetic testing may also be indicated using a blood sample for a relatively limited phenotype-specific panel of genes (i.e., 10-50 genes) or using the more comprehensive approach of whole exome or whole genome sequencing.

The key to learning the well-characterized clinical phenotypes that can be diagnosed by focused genetic testing using blood samples is to acquire an understanding of the current classification scheme for mitochondrial disorders. The traditional approach to classifying mitochondrial disorders was based on clinical phenotypes, pathologic findings, and biochemical findings. This approach is still useful. However, a clinically based classification system is limited by two well-established characteristics of mitochondrial respiratory chain disorders: a particular clinical phenotype can be caused by more than one genetic defect, and conversely, the same genetic defect can produce more than one clinical phenotype. Recognition of these limitations led to efforts to classify mitochondrial disorders according to their genetic bases. This approach to classification is also imperfect, but it is improving as current understanding of the genetic bases of these disorders becomes greater.

The genetic classification divides the mitochondrial disorders into two broad categories, mtDNA defects and nDNA defects (see Table 90.15). The mitochondrial encoded disorders can be classified into those caused by point mutations and those caused by large deletions or duplications that affect multiple genes of the mitochondrial genome. Mitochondrial point mutations can be subclassified into those that affect mRNA, rRNA, or tRNA. The nuclear-encoded disorders can be divided further into mutations that directly affect the genes that encode for subunits of the respiratory chain complexes; genes required for transport, assembly, or stabilization of the respiratory chain complexes; genes required for replication or maintenance of the mitochondrial genome; and genes involved in other mitochondrial processes required for normal mitochondrial respiratory chain function.

The differential diagnosis of several mitochondrial disorders that produce recognizable clinical syndromes in the newborn period are listed in Table 90.15. Most patients whose respiratory chain disorder manifests in the newborn period have an nDNA defect; when the disorder manifests later in childhood or adulthood, mtDNA defects predominate. Many of the most common and best characterized mitochondrial respiratory chain disorders that manifest in late childhood or adulthood do not generally appear in early infancy or manifest as much more severe, markedly different clinical phenotypes. The list of disorders is not comprehensive; rather, it includes disorders that are relatively well-characterized and illustrates the basic approaches to diagnosis of these disorders.

Maternally inherited Leigh syndrome (MILS) is an example of a point mutation that affects an mtDNA structural gene (an mRNA) that encodes for a subunit of a mitochondrial respiratory chain complex (see Table 90.15). Maternally inherited Leigh syndrome is associated with a point mutation (generally T8993C, T8993G, or T9176C) in the gene that encodes for subunit 6 of complex V (*ATPase 6*). Leigh syndrome was originally defined as a subacute necrotizing encephalopathy that involves the thalamus, brainstem, and posterior columns of the spinal cord. Typically, it has a mean age of onset of 2 years of age and is characterized by psychomotor regression, tremor, dystonia, optic atrophy, ophthalmoplegia, and respiratory difficulty with apnea. Death usually occurs by 4 years of age. Some patients have a Leigh syndrome–like disorder that is associated with hypertrophic cardiomyopathy, skeletal myopathy, or renal proximal tubular dysfunction. The defects that produce Leigh syndrome or a Leigh syndrome–like disorder include (but are not limited to) nuclear-encoded subunits of complex I, II, or IV; nuclear-encoded assembly genes for complex I or complex IV; nuclear-encoded subunits of the pyruvate dehydrogenase complex; or mtDNA-encoded tRNAs.[19,27,118] Maternally inherited Leigh syndrome is an early-onset, severe form of Leigh syndrome that is caused by mutations in the mitochondrially encoded subunit 6 of complex V. Patients without the ATPase 6 mutations listed should be evaluated for the other causes of Leigh syndrome. Detailed biochemical studies might refine the diagnosis to a specific complex or protein and direct further genetic studies.

Aminoglycoside-induced nonsyndromic deafness is caused by the A1555G mutation in the mitochondrial rRNA gene that encodes for the 12S ribosomal complex component. The aminoglycoside-induced nonsyndromic deafness disorder is a pharmacogenetic disorder that physicians should be aware of when obtaining a family history of maternally inherited hearing loss thought to be attributable to aminoglycoside use. The use of aminoglycosides in neonates with this mutation may produce irreversible deafness and may cause cardiomyopathy. However, this mutation is not the cause of aminoglycoside-associated renal toxicity.

Isolated hypertrophic cardiomyopathy has been found in association with several tRNA mutations, principally involving a tRNA for leucine ($tRNA^{Leu}$). The $tRNA^{Leu}$ defects include the A3243G mutation and the C3305T mutation. The A3243G mutation is probably the most commonly identified mtDNA mutation and is the most common cause of MELAS (mitochondrial encephalomyopathy, lactic acidosis, and strokelike episodes), which manifests rarely in the newborn period as a severe encephalopathy syndrome. The C3305T mutation generally produces an infantile-onset hypertrophic cardiomyopathy with or without skeletal myopathy (see Table 90.15).

Pearson syndrome is an example of a mitochondrial-encoded disorder associated with large deletions or duplications of mtDNA. Pearson syndrome is characterized clinically by refractory sideroblastic anemia, neutropenia, thrombocytopenia, exocrine pancreatic dysfunction, and lactic acidosis.[121] Patients with Pearson syndrome who survive the neonatal period can subsequently have gradual regression of the symptoms and signs of Pearson syndrome and subsequently develop Kearns-Sayre syndrome, which is an encephalomyopathy associated with progressive external ophthalmoplegia, hearing loss, cardiac arrhythmias, diabetes mellitus, and renal dysfunction.[27] Kearns-Sayre syndrome is an alternate expression of the same mtDNA mutation and is an example of how the phenotypes of mtDNA-encoded disorders can evolve dramatically with time.

Nuclear-encoded defects that produce recognizable clinical phenotypes in the newborn period are also listed in Table 90.15. The first group of such disorders involves genes that encode for a specific subunit of the respiratory chain complexes. These disorders are often characterized by severe ketoacidosis that is associated with seizures, apnea, severe hypotonia, hepatomegaly, and renal proximal tubular dysfunction. Detailed enzymatic and polarographic studies are required to identify the biochemically deficient respiratory chain complex or complexes. The specific deficiency can then be investigated by genetic analysis. For example, genetic testing is now available clinically for 7 of the 37 nuclear-encoded subunits of complex I.

The second group of nuclear disorders involves genes that encode for proteins that are required for transport, assembly, or stabilization of the respiratory chain complexes. For example, defects of several genes involved in assembly of complex IV (cytochrome oxidase, COX) have been identified. These defects appear to produce distinctive clinical phenotypes. *SURF1* mutations produce Leigh syndrome. As noted earlier, Leigh syndrome does not manifest until later in infancy, but Leigh syndrome–like disorders can manifest in the newborn period.[19,27,118] *SCO1* mutations can lead to encephalomyopathy and hepatic failure. *COX10* mutations also lead to a Leigh syndrome–like phenotype (or encephalopathy), which is sometimes accompanied by hypertrophic cardiomyopathy, renal proximal tubular dysfunction, or anemia. *SCO2* mutations and *COX15* mutations lead to encephalopathy or hypertrophic cardiomyopathy. Mutations of the assembly factors required for the other respiratory chain complexes have also been described. GRACILE syndrome, an eponymic association of growth restriction, amino aciduria, cholestasis, iron overload, lactic acidosis, and early death, is the best described of these disorders; it is caused by mutations of the *BCS1L* gene, which is required for assembly of complex III.[19] The number of assembly and maintenance factors that are recognized continues to increase, providing new insights into the pathogenesis of many mitochondrial disorders and their diagnosis.[26]

The third group of nuclear-encoded disorders involves genes that are required for replication or maintenance of the mitochondrial genome. These disorders are characterized by a reduction in mtDNA copy number, a condition known as mitochondrial DNA depletion syndrome. This syndrome can result from a mutation of the mitochondrial DNA polymerase γ gene (*POLG*), which encodes for an enzyme

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

required for mitochondrial replication. It can also be the consequence of deoxyguanosine kinase (DGOUK) deficiency or thymidine kinase 2 (TK2) deficiency. DGOUK and TK2 are enzymes that are encoded by the *DGOUK* gene and the *TK2* gene, respectively, which are required for synthesis or recycling of the deoxyribonucleotides necessary for DNA replication. In brief, mitochondrial DNA is wholly dependent on the nucleus for production of the enzymes and deoxyribonucleotides it requires for its own replication. Absent these materials, the mitochondrion cannot replicate and its numbers decline. POLG deficiency leads to isolated encephalopathy or seizures, or to liver failure, hepatoencephalopathy, or Alpers syndrome (hepatopathic poliodystrophy); DGOUK deficiency presents with encephalopathy and liver failure; and TK2 presents with encephalopathy and severe skeletal myopathy.[19]

The fourth group of nuclear-encoded disorders is caused by mutations in genes required for other mitochondrial processes that are necessary for normal respiratory chain function. Barth syndrome is an example of such a disorder.[21] Clinical features of Barth syndrome include hypertrophic cardiomyopathy, cyclic neutropenia, and cataracts. It is an X-linked recessive disorder caused by a mutation in the *tafazzin* gene (*TAZ*), which encodes for a protein required for synthesis of the lipid milieu of the mitochondrial membranes. Mutations in the *TAZ* gene can also produce an unusual form of cardiomyopathy known as left ventricle noncompaction.

Treatment of patients with a respiratory chain defect is largely supportive.[19,27,44,106] Therapy includes symptomatic management, such as treating acute or chronic acidosis with bicarbonate or citrate and treating cardiac, renal, and other systemic disease with standard methods. It also includes avoiding certain drugs, such as valproate and barbiturates, which may be mitochondrial toxins. There is no dietary therapy of proven benefit for patients with mitochondrial disorder, although vitamins or other nutritional supplements are generally tried using the rationale that they might stabilize or augment residual enzyme activity of the mitochondrial respiratory chain complexes or serve as artificial electron acceptors or antioxidants.[106] Coenzyme Q10 is administered because it is a structural homologue of ubiquinone, which accepts electrons from complex I and complex II and passes them on to complex III. Riboflavin is used based on the rationale that complexes I and II contain flavin. Vitamins C and K are used in combination based on the rationale that they can provide an electron transfer shuttle to bypass a complex III deficiency. Thiamine is a cofactor in the pyruvate dehydrogenase complex, which serves as the point of entry for glucose into the Krebs cycle. The daily dietary supplements in use for a neonate with a mitochondrial disorder include coenzyme Q10 (20 mg), vitamin B_1 (thiamine, 20 mg), vitamin B_2 (riboflavin, 25 mg), vitamin C (250 mg), and vitamin K_3 (menadione, 5 mg). Carnitine may also be used, especially in patients with secondary carnitine deficiency (50-100 mg/kg per day). The doses cited are at the lower end of the range of doses recommended by various physicians; some investigators have recommended doses up to 10 times greater than these. However, none of these recommendations are based on controlled studies.

Dichloroacetate has been tried in patients with mitochondrial defects. The rationale for using dichloroacetate (50 mg per day) is that it maintains the pyruvate dehydrogenase complex in its activated state. PDC catalyzes the conversion of pyruvate (the final product of the anaerobic metabolism of glucose) to acetyl-CoA, which is further metabolized by the Krebs cycle and the mitochondrial respiratory chain. Recent clinical studies have shown that dichloroacetate is of no clinical benefit to patients with a mitochondrial disorder, and it can cause peripheral neuropathy in some patients.

Finally, all patients should receive a thorough clinical evaluation to determine whether they have an organ-specific mitochondrial defect that might be amenable to organ transplantation. However, the primary caveat in performing and then interpreting this evaluation is that mitochondrial disorders can have highly variable clinical presentations—in the pattern of organ involvement and/or the time of onset of different organ involvement—among patients with the same gene disorder or the same mutation, even among members of the same family. There have been reports of successful transplantation, e.g., a heart transplantation was reportedly successful for a patient with cardiomyopathy caused by a tissue-specific mtDNA depletion syndrome.[100] On the other hand, a patient who presents in childhood with *MPV17*-related hepatic failure might be found to have no evidence of other systemic manifestations, receive a successful liver transplant that cures his hepatic failure, and then develops severe cardiomyopathy later in life.[80] The current recommendation is that patients with mitochondrial disease should undergo a comprehensive clinical evaluation and have a specific, genetically confirmed diagnosis established before the risks and benefits of organ transplantation are discussed with the patient/family and a decision made whether to proceed with transplantation.[31,80]

Hypoglycemia

See Chapter 86. Recognizing hypoglycemia in the newborn may be difficult, because the symptoms of hypoglycemia (i.e., lethargy, poor feeding, hypothermia, and seizures) are nonspecific. Frequent blood sugar determinations are often required to confirm the suspicion of hypoglycemia. Because inborn errors of metabolism are a relatively infrequent cause of neonatal hypoglycemia, other diagnostic possibilities should be investigated concurrently.[104]

The first possibility to consider is neonatal stress secondary to perinatal asphyxia, hypothermia, or intrauterine malnutrition (e.g., placental abnormalities, prematurity, or multiple gestations). The second consideration is the possibility of a hormonal abnormality affecting insulin regulation. The inborn errors of metabolism associated with insulin dysregulation include 3-hydroxacyl-CoA dehydrogenase (HADH) deficiency[53] and hyperammonemia/

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

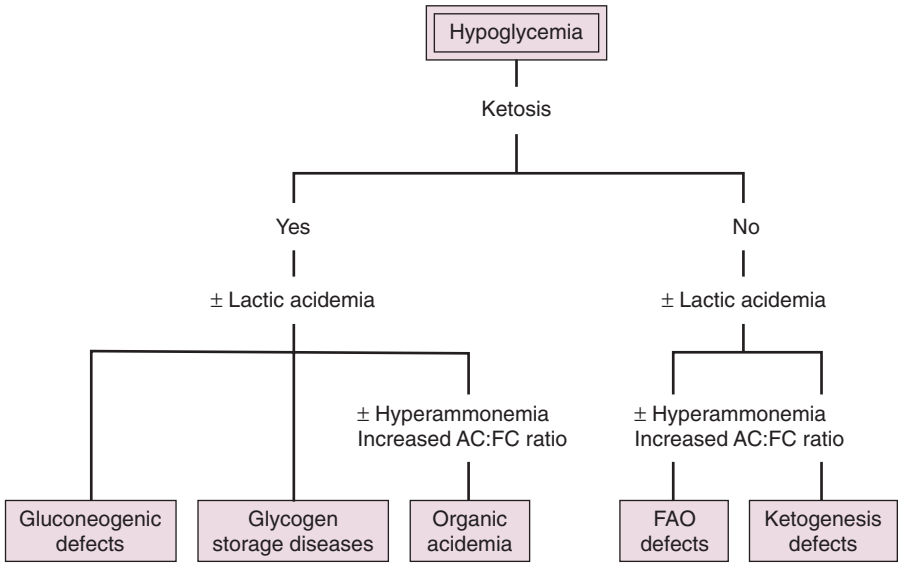
hyperinsulinism (HA/HI) syndrome,[82] both of which are diazoxide-responsive. The third possibility to consider is a malformation syndrome, specifically including those syndromes associated with hormonal dysregulation such as Beckwith-Wiedemann syndrome, which is discussed in Chapter 86. The fourth possibility is that the patient has a severe hepatocellular or cirrhotic liver disease that leads nonspecifically to fasting hypoglycemia. The inborn errors that can produce this degree of liver damage are presented in Table 90.5 (see Hepatic Dysfunction). Finally, the patient should be evaluated for inborn errors of metabolism not considered as part of the diagnostic possibilities listed above.

Differential Diagnosis

Hypoglycemia may be associated with five categories of inborn errors of metabolism: fatty acid oxidation defects, gluconeogenesis defects, glycogen storage diseases, ketogenesis defects, and organic acidemias (Table 90.17). The diagnostic approach to hypoglycemia, therefore, must give consideration to entities belonging to each of these categories. Usually, Krebs cycle defects and mitochondrial disorders do not produce hypoglycemia, but these defects should be considered when other evidence points in their direction. The diagnostic approach must quickly narrow the field of possible diagnoses so that specific treatment can be instituted.

The classic approaches to the differential diagnosis of hypoglycemic disorders in children are the fasting study and specialized challenge tests. These studies are, however, not feasible in newborn infants because of the significant risks and technical difficulties associated with performing such studies and because of the lack of control data derived from normal neonates. Alternatively, efforts to determine the cause of hypoglycemia in the newborn infant should include hormonal and biochemical studies before and after feeding and especially during an acute episode of hypoglycemia. Definitive diagnosis might have to be postponed several months until the child is old enough to tolerate a formal fasting study or specialized in vitro cell studies.

An algorithm (Fig. 90.3) for diagnosing the disorders that cause neonatal hypoglycemia can be generated from the results of the following studies: blood electrolytes and pH, plasma and urinary ketones, plasma free fatty acids, blood lactate and pyruvate, blood ammonia, liver function tests, plasma and urinary carnitine and acylcarnitine analysis, and urinary organic acids. A specific diagnosis might not be made by these studies, but they are necessary for providing a provisional diagnosis that can be confirmed by specific enzyme analysis.



The first laboratory finding that is used to discriminate between the disorders that cause hypoglycemia is the presence or absence of ketosis (see Fig. 90.3), because the physiologic response to fasting or hypoglycemia should be increased lipolysis, fatty acid oxidation, and ketone body formation. Defects of gluconeogenesis, glycogenolysis, and organic acid metabolism (especially the common branched-chain disorders) are generally accompanied by ketosis, whereas defects in fatty acid β-oxidation and ketogenesis are accompanied by increased plasma free fatty acids without a concomitant increase in plasma β-hydroxybutyrate and acetoacetate concentrations.

TABLE 90.17 Metabolic Disorders Associated With Neonatal Hypoglycemia

Category of Disorders	Disorder
Fatty acid oxidation	Carnitine-acylcarnitine translocase deficiency Carnitine palmitoyltransferase Ia deficiency Carnitine palmitoyltransferase II deficiency Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency/ trifunctional protein deficiency Short-chain acyl-CoA dehydrogenase deficiency Very-long-chain acyl-CoA dehydrogenase deficiency
Gluconeogenesis	Fructose-1,6-diphosphatase deficiency Hereditary fructose intolerance Phosphoenolpyruvate carboxykinase deficiency Pyruvate carboxylase deficiency
Glycogen storage disease (GSD)	GSD type I (glucose-6-phosphatase deficiency) GSD type III (debrancher deficiency) GSD type IX (phosphorylase kinase deficiency)
Ketogenesis	3-Hydroxy-3-methylglutaryl-CoA lyase deficiency
Organic acidemias	Isovaleric acidemia Maple syrup urine disease Methylmalonic acidemia Multiple acyl-CoA dehydrogenase deficiency Multiple carboxylase deficiency Propionic acidemia

The second laboratory finding used to distinguish among the neonatal hypoglycemias is lactic acidemia (see Fig. 90.3). Although the simple presence or absence of lactic acidemia is not useful for discriminating among these disorders because they all can exhibit some degree of lactic acidemia depending on the physiologic circumstances, the relative degree of lactic acidemia and its relationship to feeding are important discriminating factors. For example, the magnitude of the lactic acidemia seen in the organic acidemias is generally less than that seen in the gluconeogenesis defects and glycogen storage diseases. The lactate concentration decreases in the fed state for patients with glycogen storage disease type I, whereas it increases for patients with glycogen storage disease type III. Similarly, lactic acidemia becomes more pronounced with fasting in patients with fatty acid oxidation defects and organic

• **Fig. 90.3** Approach to neonatal hypoglycemia. AC:FC, Ratio of acylcarnitine to free carnitine; FAO, fatty acid oxidation.

acidemias but is greater in the fed state than in the fasted state for those with the glycogen storage disorders associated with hypoglycemia.

The third laboratory finding that may be useful is the plasma ammonia concentration. Hyperammonemia often accompanies hypoglycemia in patients with fatty acid oxidation defects, ketogenesis defects, and organic acidemias, but it is not seen in defects of gluconeogenesis (except severe PC deficiency) or the glycogen storage diseases. In addition, there is a disorder known as hyperammonemia/hyperinsulinism (HA/HI) syndrome, which is the consequence of a dominant activating mutation in the glutamate dehydrogenase gene (*GLUD1*).[82] Patients with this disorder have a consistent association of hypoglycemia and hyperammonemia. They typically have a relatively mild-moderate degree of hyperammonemia, and management is focused on insulin regulation rather than hyperammonemia. Hence, this disorder is discussed in more detail in Chapter 86.

Gluconeogenesis Defects

Gluconeogenesis is the pathway by which glucose is synthesized from non-carbohydrate metabolites. The principal gluconeogenic precursors are pyruvate and lactate, certain gluconeogenic amino acids, and glycerol, which is derived mainly from fat metabolism. Several inborn errors of gluconeogenesis cause hypoglycemia (see Table 90.17).

Fructose-1,6-bisphosphatase deficiency is an autosomal recessive disorder characterized by hyperventilation associated with severe ketoacidosis, hypoglycemia, seizures, and lethargy, sometimes leading to coma. Hepatomegaly and the degree of liver dysfunction are generally mild. The defect in gluconeogenesis leads to lactic acidosis. Diagnosis requires a liver, intestine, or kidney biopsy for specific enzyme analysis. Acute episodes are treated with glucose administration, which is generally successful in correcting the hypoglycemia and ketoacidosis. Long-term treatment requires avoidance of fasting and removal of most fructose from the diet. As discussed for the glycogen storage diseases, patients with fructose-1,6-bisphosphatase deficiency benefit from continuous nighttime feedings or the use of uncooked cornstarch.

Pyruvate carboxylase (PC) deficiency can manifest in the neonatal period with hepatomegaly, hyperammonemia, lactic acidosis, citrullinemia, hyperlysinemia, and structural CNS malformations.[136] Patients who present with the severe form of the disease in the newborn period might not survive beyond the first few months of life. Patients who have a less severe form of PC deficiency may do well when they avoid fasting, have nighttime feedings, and receive supplementation with citrate (which yields oxaloacetate, the product of the PC enzyme reaction).

Phosphoenolpyruvate carboxykinase (PEPCK) deficiency is a rare cause of neonatal hypoglycemia associated with lactic acidemia. There are two forms of this deficiency, corresponding to deficiency of the cytosolic form and the mitochondrial form of the enzyme, respectively. The clinical features of both forms are incompletely characterized owing to the rarity of these disorders. The diagnosis can be accomplished by enzyme analysis or genetic testing.

Glycogen Storage Disorders

Glycogen storage disease type I is the most common defect of gluconeogenesis or glycogenolysis.[6] This diagnosis should be considered if, in addition to increased plasma free fatty acid and ketone body concentrations, clinical examination demonstrates hepatomegaly and additional laboratory studies reveal lactic acidosis, hypertriglyceridemia, and hyperuricemia.

The most common form of glycogen storage disease (GSD) is GSD type Ia (commonly known as von Gierke disease), which is caused by glucose-6-phosphatase deficiency. Another form of this disorder is caused by deficiency of glucose-6-phosphate translocase and is known as GSD type Ib. In addition to the clinical features of type Ia disease,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

glycogen storage disease type Ib is also characterized by neutropenia and neutrophil dysfunction, which lead to a propensity for serious bacterial infections. The long-term complications of both forms of type I glycogen storage disease include intellectual delay as a result of unrecognized or untreated hypoglycemia, short stature, gout, renal disease, and hepatic adenoma.

Glycogen storage disease type III does not typically present in the neonatal period but may do so rarely. The hypoglycemia associated with GSD type III can be as severe as that seen with GSD type I, but GSD type III does not lead to increased concentrations of lactic acid and uric acid in blood. GSD type III may involve the skeletal muscle and heart, as well as liver, and be associated with increased serum CK activity.

Definitive diagnosis of GSD type I requires detailed enzymatic analysis of a liver biopsy specimen; the liver specimen must be fresh if studies for type Ib are to be done. GSD type III disease can be diagnosed by enzyme analysis of white blood cells, liver, or skeletal muscle. Alternatively, the diagnosis of GSD Ia, Ib, or III can be established by genetic testing.

The mainstay of treatment for these forms of glycogen storage disease is to avoid prolonged fasting. Older affected patients should be provided with frequent daytime feedings and continuous nasogastric infusion or uncooked cornstarch at night. These treatments appear to be successful in controlling the hypoglycemia and other metabolic consequences associated with these disorders, but they might not eliminate the long-term sequelae (e.g., development of hepatic adenoma in glycogen storage disease type Ia).[6]

Organic Acidemias

Several organic acidurias or acidemias cause neonatal hypoglycemia (see Table 90.17 and Metabolic Acidosis). These disorders should be suspected when there is a metabolic acidosis, an anion gap, ketosis, abnormal results on urine spot tests for α-ketoacids, or an abnormal smell. Urinary organic acid analysis is the strategic diagnostic study. Many patients with an organic acid disorder have significant hyperammonemia. Plasma and urinary carnitine measurements are useful in diagnosing and possibly managing these disorders. Many of the organic acidurias are characterized by an increased acylcarnitine-to-free carnitine ratio in plasma and urine and overproduction of a particular acylcarnitine.

Fatty Acid Oxidation Disorders

Two groups of disorders cause neonatal hypoglycemia without ketosis: defects of fatty acid oxidation and defects of ketogenesis. It should be pointed out that inborn errors of metabolism, which cause severe hepatocellular or cirrhotic liver disease, also produce nonketotic or hypoketotic hypoglycemia associated with lactic acidosis. The disorders of fatty acid oxidation are discussed further in this section, whereas the defects of ketogenesis (e.g., 3-hydroxy-3-methylglutaryl-CoA lyase deficiency) are discussed in the preceding section on metabolic acidosis.

The primary pathway of fatty acid oxidation takes place within the mitochondrion.[58,93] Most forms of dietary fat contain primarily long-chain fatty acids. For these long-chain fatty acids to be oxidized, they must be transported across the mitochondrial membranes into the mitochondrial matrix. The system for transporting these fatty acids across the mitochondrial membranes includes three components: carnitine palmitoyltransferase I (CPT I), carnitine-acylcarnitine translocase, and carnitine palmitoyltransferase II (CPT II). Medium- and short-chain fatty acids do not require this special system for transport across the mitochondrial membranes. Another transporter facilitates the uptake of free carnitine across the plasma membrane into the cytoplasm, making it available for transporting fatty acids into the mitochondrion.

Inside the mitochondrion, fatty acids exist as their acyl-CoA derivatives. These fatty acid acyl-CoAs are degraded by the mitochondrial fatty acid β-oxidation system to form acetyl-CoA. The acyl-CoAs are degraded sequentially by a series of four enzymes: acyl-CoA dehydrogenase, enoyl-CoA hydratase, 3-hydroxyacyl-CoA dehydrogenase, and 3-ketothiolase. Different forms of these enzymes exist for fatty acid acyl-CoAs of different chain lengths. These enzymes sequentially degrade the acyl-CoAs two carbon groups per turn of the β-oxidation cycle, from long-chain acyl-CoAs, to medium-chain acyl-CoAs, and finally to short-chain acyl-CoAs. An intact mitochondrial respiratory chain is required for normal functioning of the fatty acid β-oxidation pathway, because it replenishes the oxidized forms of flavin adenine dinucleotide and nicotinamide adenine dinucleotide needed by the acyl-CoA dehydrogenases and the 3-hydroxyacyl-CoA dehydrogenases, respectively. Genetic deficiencies of each of these enzymes have been described.[58,93,105]

As a rule, defects of long-chain fatty acid oxidation are more likely to manifest in the neonatal period and cause serious problems than are defects of medium- or short-chain fatty acids.[93,105] Defects in long-chain fatty acid oxidation that may manifest in the neonatal period include CPT II deficiency (but generally not CPT I deficiency), carnitine-acylcarnitine translocase (CACT) deficiency, very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency, long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency, and the related disorder, mitochondrial trifunctional protein (TFP) deficiency. Plasma membrane carnitine transporter deficiency (the cause of carnitine uptake deficiency) does not generally manifest in the neonatal period.

These disorders are a recognized cause of hypoglycemia, liver disease, cardiomyopathy, cardiac arrhythmias, and sudden death. The association of these defects with cardiomyopathy is consistent with the role of long-chain fatty acids as the chief energy source for the myocardium. The cause of the arrhythmias is less certain but may be a toxic effect of the long-chain acylcarnitines that accumulate in these disorders. Hyperammonemia may be seen in patients with the most severe forms of these deficiencies, for example, CACT deficiency and LCHAD deficiency.[78]

Neonatal CPT II deficiency is also associated with renal microcysts and CNS malformations. LCHAD dehydrogenase deficiency and other defects of long-chain fatty acid oxidation have gained attention as a cause of acute fatty liver of pregnancy in pregnant women who are carrying a fetus that is homozygous for this deficiency (see Prenatal Onset).[9,91]

Defects of medium- or short-chain fatty acid β-oxidation include medium-chain acyl-CoA dehydrogenase (MCAD) deficiency, short-chain acyl-CoA dehydrogenase (SCAD) deficiency, isobutyryl-CoA (IBD) deficiency, and short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD) deficiency.[93,105] The clinical features of all these disorders differ significantly from those of the long-chain fatty acid β-oxidation disorders. MCAD deficiency is the most common of the fatty acid β-oxidation disorders when all age groups are considered, but it does not generally appear in the neonatal period (see Newborn Screening Programs).[68] Care should be taken, however, to promptly initiate diagnostic evaluation and treatment for a neonate who is at risk for MCAD deficiency by virtue of family history or identified by newborn screening (see Tables 90.1 and 90.2). In contrast, the clinical phenotype of SCAD deficiency and IBD deficiency are ill-defined. The original clinical reports on SCAD deficiency described patients with a variable pattern of medical problems, including developmental delay. However, few patients who were subsequently ascertained by newborn screening with SCAD deficiency have manifested any medical problems, suggesting that the originally described patients represented an ascertainment bias. A single patient with IBD deficiency was described with cardiomyopathy associated with carnitine deficiency. Carnitine deficiency has been observed subsequently in other patients with IBD deficiency, and patients identified by newborn screening may benefit from ongoing monitoring for carnitine deficiency. Last, SCHAD deficiency does not manifest as a classical disorder of fatty acid β-oxidation but rather manifests with hypoglycemia secondary to hyperinsulinism. The diagnosis and treatment of this disorder is discussed in Chapter 86.

Acute management of the newborn with a suspected fatty acid oxidation defect should begin with prompt infusion of high concentrations of glucose to correct the hypoglycemia and the underlying energy deficit. The patient should receive glucose at a rate of 10 mg/kg per minute or greater to maintain the serum glucose concentration greater than 100 mg/dL. A patient suspected of having a defect in short- or medium-chain fatty acid oxidation can continue to receive breast milk or formula. On the other hand, a patient suspected of having a defect in long-chain fatty acid oxidation should not receive breast milk or be on formula that contains long-chain fats (especially if symptomatic) until it is determined whether the patient has a defect of fatty acid oxidation. However, there is some debate regarding this approach among physicians who treat asymptomatic patients with VLCAD deficiency; some physicians restrict long-chain fats in the diet while others do not. The use of parenteral intralipids is advised against in patients with medium- and long-chain fatty acid oxidation disorders.

A related consideration is the use of carnitine in patients with a suspected or proven fatty acid oxidation disorder. Carnitine has been used in patients with these disorders, because they are often carnitine depleted. However, there is also concern about the use of carnitine supplementation in patients with long-chain fatty acid oxidation defects, because carnitine supplementation might increase the production of long-chain acylcarnitines, which can be arrhythmogenic.[58] The relative merits of using carnitine in the acute or chronic care of these patients with long-chain fatty acid β-oxidation defects are uncertain, but judicious use of a moderate carnitine dose (50 mg/kg per day) is often used until a diagnosis is established and then adjusted depending on the patient's diagnosis, clinical status, and plasma carnitine analysis.

When the initial hypoglycemic episodes are controlled, the patient should be started on a high-carbohydrate diet, while making certain to avoid fasting. Formulas enriched with medium-chain triglycerides (which are very commonly used in nurseries and in neonatal intensive care units) should not be started before the infant's diagnosis has been established, because they can be dangerous to patients with defects in medium-chain fatty acid oxidation. In contrast, patients suspected of having a defect in long-chain fatty acid oxidation might benefit from one of the long-chain fat–restricted, medium-chain fat–enriched formulas that are available. Once a diagnosis is established, a decision can be made regarding the infant's tolerance for fat and an appropriate diet started. Riboflavin supplementation (50 mg/day) should be tried and its benefit evaluated, especially for a patient suspected of having glutaric aciduria type II. Long-term carnitine supplementation may be of benefit in some patients.

Hyperammonemia

The neonate with a hyperammonemia syndrome generally does well for the first few days of life and then develops poor feeding, lethargy, vomiting, and tachypnea. If unrecognized and untreated, the illness may progress rapidly to coma, seizures, autonomic instability, and death. When hyperammonemia is suspected, the possibility should be investigated immediately, because these illnesses can produce irreversible neurologic sequelae and are life threatening.

Differential Diagnosis

Many inborn errors of metabolism can cause significant hyperammonemia in the newborn infant, and an attempt must be made to quickly reach a provisional diagnosis (Box 90.2). By convention, the primary hyperammonemias include deficiencies of the six enzymes that make up the urea cycle:

- N-acetylglutamine synthetase (NAGS);
- carbamoylphosphate synthetase I (CPS1), referred to simply as CPS elsewhere in the chapter;
- ornithine transcarbamylase (OTC);

• BOX 90.2 Genetic Disorders Associated With Hyperammonemia in Neonates

Fatty Acid Oxidation Disorders

- Carnitine-acylcarnitine translocase deficiency
- Carnitine palmitoyltransferase II deficiency
- Long-chain acyl-CoA dehydrogenase deficiency
- Long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency

Lactic Acidemias

- Gluconeogenic disorders
  - Pyruvate carboxylase deficiency
- Mitochondrial disorders
  - Mitochondrial DNA depletion syndromes
  - *FBXL4*-associated deficiency
- Mitochondrial complex assembly
  - *TMEM70*-associated deficiency

Organic Acidurias

- 3-Hydroxy-3-methylglutaryl-CoA lyase deficiency
- Isovaleric acidemia
- 3-Ketothiolase deficiency
- Methylmalonic acidemia
- Multiple acyl-CoA dehydrogenase deficiency
- Propionic acidemia

Urea Cycle Disorders

- Argininemia
- Argininosuccinic acid lyase deficiency
- Argininosuccinic acid synthetase deficiency
- Carbamoyl phosphate synthetase deficiency
- Ornithine transcarbamylase deficiency
- N-Acetylglutamate synthetase deficiency
- Urea cycle-associated amino acid transport disorders
  - Citrin deficiency
  - Hyperornithinemia-hyperammonemia-homocitrullinuria syndrome

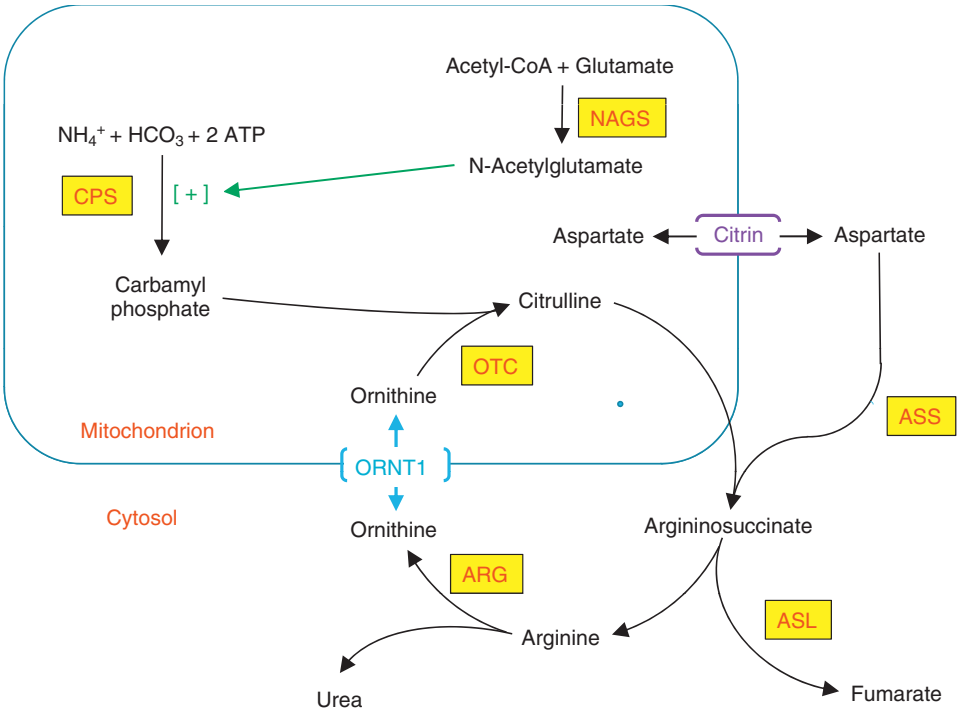
- argininosuccinic acid synthetase (ASS1), referred to simply as ASS elsewhere in the chapter;
- argininosuccinic acid lyase (ASL); and
- arginase (ARG1), referred to simply as ARG elsewhere in the chapter.

In addition, two amino acid transporters are required for normal functioning of the urea cycle:

- an ornithine transporter (ORNT1); and
- an aspartate transporter (citrin).

See Fig. 90.4 for an illustration of the urea cycle. The various steps in the urea cycle are described in the next section, Urea Cycle Disorders. The secondary hyperammonemias include genetic disorders that lead to overproduction of toxic metabolites that inhibit the urea cycle or depletion of substrates that are required for normal functioning of the urea cycle: fatty acid oxidation disorders, lactic acidemias, organic acidemias, and several other inborn errors.

A systematic approach to the differential diagnosis of these disorders is presented in Fig. 90.5. It is imperative that the possibility of a primary hyperammonemia syndrome (a urea cycle defect) be distinguished from a secondary hyperammonemia syndrome (e.g., an organic aciduria), because the best way of treating the hyperammonemia in the latter would be to treat the underlying disorder.



The first step in evaluating a patient with a suspected hyperammonemia is to obtain an accurate plasma ammonia concentration. The plasma sample for ammonia determination must be collected, transported on ice to the laboratory, and then rapidly analyzed. A plasma ammonia concentration greater than 150 μmol/L suggests the possibility that the patient has an inborn error of metabolism and should be evaluated further.

Most primary disorders of the urea cycle do not begin in the first 24 hours of life. Hyperammonemia that develops within the first 24 hours of life is generally associated with prematurity or a secondary hyperammonemia, usually a disorder of organic acid metabolism or fatty acid oxidation.[3,60] The severe hyperammonemia associated with prematurity has been designated transient hyperammonemia of the newborn. It is a mistake to believe that transient means that this disorder is benign. The degree of hyperammonemia found in this disorder can be as great as that found in many of the primary hyperammonemia syndromes, sometimes exceeding 1000 μmol/L. This disorder, therefore, requires the rapid and vigorous therapy, as do the other defects of the urea cycle.

Following confirmation that the patient has significant hyperammonemia, several laboratory studies should be obtained to determine whether the patient has a primary or secondary hyperammonemia: blood gas, electrolytes, glucose, and blood and urine ketones. It is generally advisable to obtain additional studies with the initial testing, or when the results of the initial studies are available, in order to establish a more specific diagnosis. The additional testing should include plasma amino acid analysis, plasma carnitine analysis with an acylcarnitine profile, urine amino acid analysis, urine organic acid analysis, and urine orotic acid analysis. Treatment should be started before the results of all these studies are available and modified as the nature of the underlying cause of the hyperammonemia is clarified.

The results of the initial testing provide information about several key laboratory features that can be used to distinguish between a primary and a secondary hyperammonemia syndrome: the presence or absence of acidosis, an increased anion gap, hypoglycemia, and/or ketosis (see Fig. 90.5). The urea cycle defects are generally associated with respiratory alkalosis during the initial phase of the illness in response to the increased ventilatory rate induced by the cerebral edema that often accompanies hyperammonemia. Later in the course of the illness, a component of acidosis can be superimposed on the initial respiratory alkalosis as the patient's clinical status deteriorates. As a result of the evolving acid–base balance associated with urea cycle defects, the presence or absence of acidosis is not a reliable finding to distinguish between patients with primary and secondary hyperammonemia and is not included in the algorithm provided in Fig. 90.5.

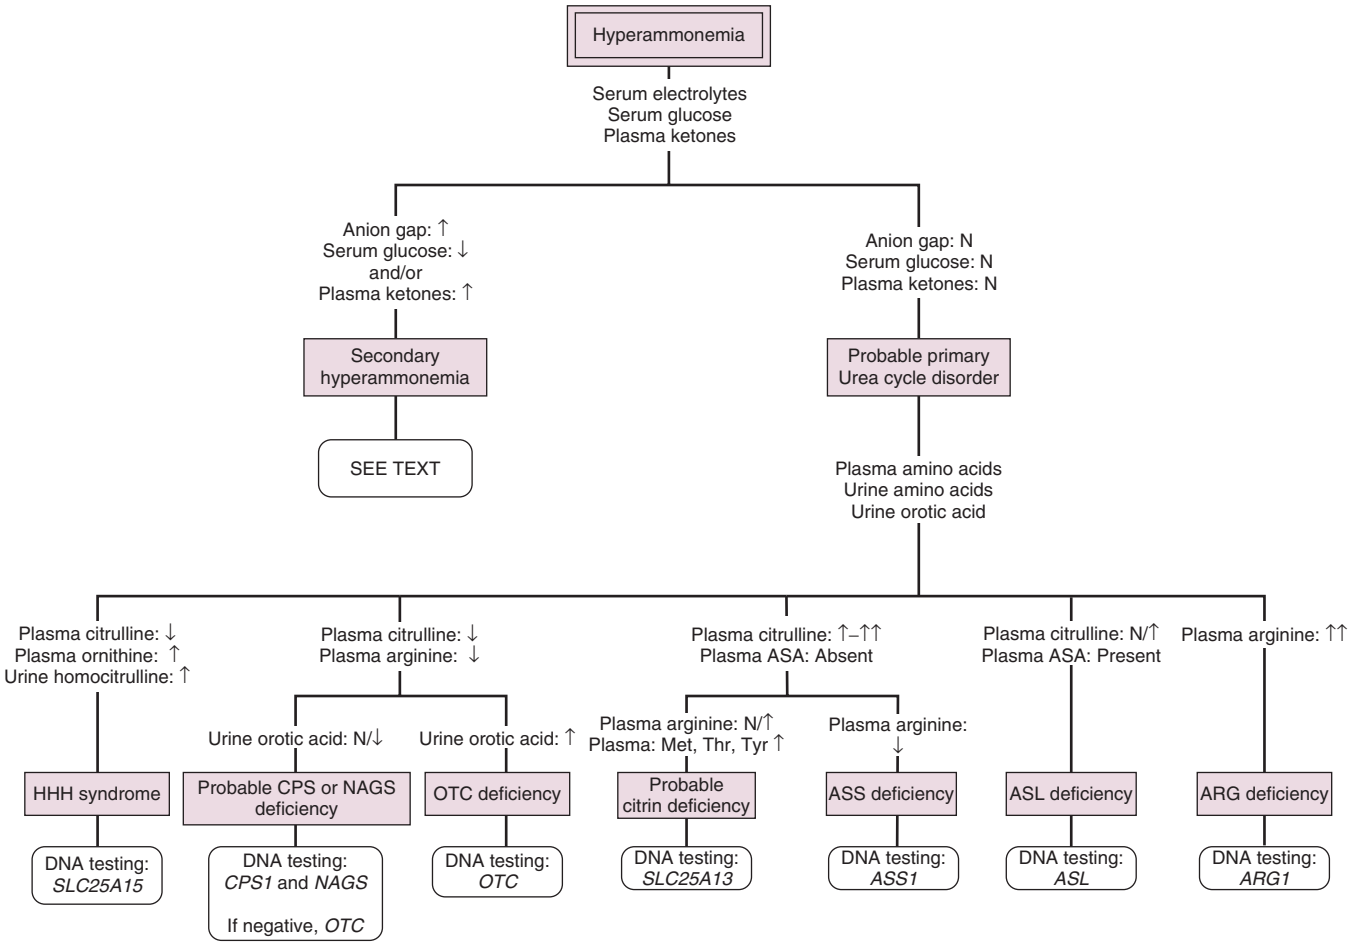
Available from: https://www.ncbi.nlm.nih.gov/books/NBK1217.)

However, patients with a urea cycle disorder generally do not have an increased anion gap, hypoglycemia, or ketosis and can be distinguished from the secondary hyperammonemias using these laboratory findings. The organic acidemias are generally characterized by metabolic acidosis and an increased anion gap (see Fig. 90.1). Metabolic acidosis can also be seen with fatty acid oxidation defects and the severe neonatal form of pyruvate carboxylase (PC) deficiency, a gluconeogenic disorder that is associated with lactic acidemia, especially during fasting (see Fig. 90.2).

Hypoglycemia is not typically associated with urea cycle defects but is typically observed in fatty acid oxidation disorders and gluconeogenic disorders and can be observed in several organic acidemias and mitochondrial disorders (see Fig. 90.3).



Ketosis is not a characteristic feature of urea cycle defects, but it is a hallmark of the several organic acidemias and PC deficiency and can be observed in mitochondrial disorders. In contrast, the distinguishing feature of the fatty acid oxidation disorders is nonketotic or hypoketotic hypoglycemia.

In summary, urea cycle disorders are characterized by a normal anion gap, a normal serum glucose concentration, and the absence of ketosis, whereas the secondary hyperammonemias are characterized by an increased anion gap (>20 mEq/L), hypoglycemia, and/or ketosis (see Fig. 90.5).[3] Further diagnostic evaluation and care of the patient with a suspected urea cycle disorder is presented in the following section, followed by a section dealing with the secondary hyperammonemias.

Urea Cycle Disorders

Patients with a urea cycle defect are generally well at birth but develop clinical signs of hyperammonemic encephalopathy at 48-72 hours of age. The initial clinical manifestations often include poor feeding, lethargy, hypothermia, hyperventilation, abnormal posturing, and seizures. The lethargy may progress to lethargy and coma, and ultimately death secondary to brain stem compression caused by cerebral edema. This course is typical of severe forms of N-acetylglutamate synthetase (NAGS) deficiency, carbamoyl phosphate synthetase 1 (CPS1) deficiency, ornithine transcarbamylase (OTC) deficiency, argininosuccinic acid synthetase (ASS) deficiency (also known as citrullinemia type I), and argininosuccinic acid lyase (ASL) deficiency (see Fig. 90.4). This pattern is not typical of arginase (ARG1) deficiency, ORNT1 deficiency, hyperornithinemia-hyperammonemia-homocitrullinuria (HHH) syndrome, or citrin deficiency, which have different

clinical phenotypes.[3,66,98] The prognosis for neonates with hyperammonemic encephalopathy depends on the severity of the underlying genetic defect and the duration of symptoms before treatment is started. Long-term neurologic sequelae are common, even for patients who are recognized and treated early.

The first step in the urea cycle is the formation of carbamoyl phosphate from ammonia by carbamoyl phosphate synthetase 1 (CPS1). N-acetylglutamate synthetase (NAGS) catalyzes the conversion of acetyl-CoA and glutamate to N-acetylglutamate, which is required for activation of CPS1. The next enzyme in the cycle, ornithine transcarbamylase (OTC), converts carbamoyl phosphate and ornithine to citrulline. Citrulline and aspartate are converted to argininosuccinate by argininosuccinic acid synthetase (ASS). Argininosuccinic acid is then cleaved by argininosuccinic acid lyase (ASL) to produce arginine and fumarate. Finally, arginine is cleaved by arginase to form urea and ornithine. The urea is excreted in the urine, and the ornithine is available to restart the cycle. Ornithine, citrulline, argininosuccinate, arginine, and aspartate are all amino acids. In addition to these enzyme reactions, two amino acid transporters are required to provide substrates for the urea cycle: an ornithine transporter (ORNT1) and an aspartate transporter (citrin). The role of these enzymes and transporters is illustrated in Fig. 90.4.

Urea cycle disorders can be differentiated from each other by performing plasma amino acid analysis, urine amino acid analysis, and urine orotic acid analysis (see Specialized Biochemical Testing).[3] The amino acids proximal to the enzyme deficiency are increased, whereas the amino acids distal to the enzyme deficiency block are decreased. Except in the case of arginase deficiency, the urea cycle disorders are characterized typically by an increased plasma concentration of glutamine, glycine, and alanine, and a decreased plasma arginine concentration.

The plasma citrulline and argininosuccinate concentrations provide the initial keys to distinguishing among the urea cycle defects that manifest with hyperammonemia in the neonatal period (see Fig. 90.5). The plasma citrulline concentration is generally low in NAGS deficiency, CPS1 deficiency, and OTC deficiency, because citrulline synthesis requires the sequential action of these enzymes. Measurement of urinary orotic acid, which is formed from excessive amounts of carbamoyl phosphate that leave the mitochondrion and enter the cytosolic pyrimidine biosynthetic pathway, can be used to distinguish among NAGS deficiency, CPS deficiency, and OTC deficiency. The urinary orotic acid concentration is low or normal in NAGS deficiency and CPS1 deficiency but elevated in OTC deficiency.

Once formed, citrulline is converted to argininosuccinate by ASS. In the absence of ASS, citrulline produced by the earlier steps of the urea cycle accumulates in high concentration. For this reason, ASS deficiency is commonly called citrullinemia type I. Argininosuccinate lyase deficiency leads to increased excretion of argininosuccinate (and its anhydrides) and moderate elevation of plasma citrulline. Deficiency of the last step in the urea cycle, arginase, is rarely a cause of hyperammonemia in the neonatal period but is a cause of neurologic disease and occasionally hyperammonemia in later childhood. N-acetylglutamate synthetase deficiency resembles CPS1 deficiency, and it requires enzyme analysis of a liver biopsy or genetic testing to distinguish between the two disorders. Plasma and urine amino acid analysis are required to distinguish ORNT1 deficiency and citrin deficiency from the other urea cycle disorders and from each other.[3]

Treatment for the acute phase of the urea cycle disorders includes stopping dietary protein intake, suppressing endogenous protein catabolism through hypercaloric parenteral administration of glucose and intralipids (using an insulin infusion if necessary to avoid hyperglycemia), and providing drugs that serve as alternate pathways for ammonia detoxification and excretion. Hemodialysis is required for severe cases in which the patient has a plasma ammonia concentration greater than 200 umol/L that has not responded to the previously listed modes of therapy and in severe cases in which the patient presents with a plasma ammonia concentration greater than 400 umol/L.[3,96,107,112] Physicians who are unable to offer these forms of therapy should consider transferring their patients to centers that have such capability.

The protocols for detoxifying ammonia employ drugs that form excretable compounds with amino acids that accumulate during hyperammonemic crisis. The first drug to be developed was sodium benzoate, which conjugates with glycine to form benzoylglycine (hippurate); formation and excretion of one molecule of hippurate eliminates one molecule of ammonia. The second drug to be developed was sodium phenylacetate, which conjugates with glutamine to form phenylacetylglutamine; formation and excretion of one molecule of phenylacetylglutamine eliminates two molecules of ammonia. Sodium phenylacetate is still available for intravenous use, but it has been replaced for oral use by sodium phenylbutyrate and more recently by glycerol phenylbutyrate (Ravicti).

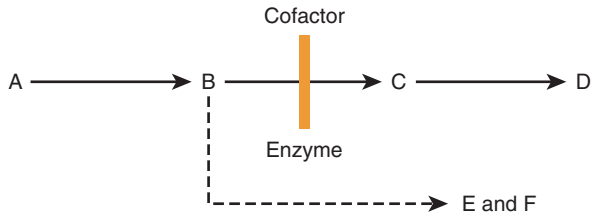
In addition to these drugs, arginine (or citrulline, if diagnosis has been made and indicates that citrulline is the preferred medication) is provided to prime the urea cycle (i.e., regenerate ornithine), which is the precursor for the next turn of the cycle. N-carbamylglutamate (Carbaglu) is an analogue of N-acetylglutamate that can be taken orally and appears to be an effective treatment for N-acetylglutamate synthetase deficiency. Long-term management of these disorders after the acute illness entails modification of this basic plan.[3]

The prognosis for neonates who present with a urea cycle defect in the newborn period is guarded.[5,61] Without treatment, the mortality rate is high. With treatment, the mortality is reduced, but survivors are often left with significant neurologic impairments and a lifelong illness that predisposes them to recurrent life-threatening metabolic crises. The prognosis is particularly guarded for patients with defects affecting the early part of the cycle, namely, NAGS deficiency, CPS deficiency, and OTC deficiency. The prognosis for patients with more distal defects in the urea cycle (i.e., ASS deficiency and ASL deficiency) is better, although these patients also experience recurrent hyperammonemic crises. The guarded prognosis for these patients has led many groups to perform early liver transplantation for these patients, especially those with severe NAGS, CPS, and OTC deficiency. The results of these efforts appear promising.[69,80,112]

Secondary Hyperammonemias

As noted above in the Differential Diagnosis section, the secondary hyperammonemias are differentiated from the primary hyperammonemias (the urea cycle disorders) by the presence of acidosis, an increased anion gap, and/or ketosis (see Fig. 90.5). The secondary hyperammonemias can, in turn, be distinguished from each other by further laboratory testing, including plasma amino acid analysis, plasma carnitine analysis with an acylcarnitine profile, plasma lactate analysis, and urine organic acid analysis. This testing will permit identification of five groups of disorders: fatty acid oxidation disorders, lactic acidemias (gluconeogenic disorders and mitochondrial disorders), organic acidemias, and a miscellaneous group (see Fig. 90.1, Fig. 90.2, and Fig. 90.3 for the diagnostic algorithms

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.



for metabolic acidosis, lactic acidemia, and hypoglycemia, respectively). Further discussion of these disorders is presented in the sections of this chapter that accompany these figures.

Although the secondary hyperammonemias are a clinically diverse group of disorders, they all exhibit hyperammonemia as the result of a defect outside the urea cycle that indirectly affects urea cycle function via enzyme inhibition or substrate deficiency. The secondary hyperammonemias can be classified into three groups of disorders based on their pathophysiology:

- Enzyme inhibition
  - *Organic acidemias*. Several organic acidemias, including the three most common organic acidemias—methylmalonic acidemia, propionic acidemia, and isovaleric acidemia—lead to overproduction of toxic metabolites that interfere with the ability of NAGS to produce N-acetylglutamate, which is required for activation of CPS1, the first step in the urea cycle. Thus, these disorders lead to a CPS1-like syndrome, which can present with plasma ammonia concentrations >1000 umol/L in the neonatal period. These disorders are discussed elsewhere in this chapter (see Metabolic Acidosis subsection under Abnormal Newborn Infant: Laboratory Phenotypes).
- Substrate deficiencies
  - *Fatty acid oxidation and carnitine cycle disorders.* One of the final products of mitochondrial fatty acid oxidation or the carnitine cycle is acetyl-CoA. Defects in either fatty acid oxidation (especially those affecting long-chain fatty acid oxidation) or the carnitine cycle (which is required for transport of long-chain fatty acids into the mitochondria where they undergo oxidation) leads to decreased acetyl-CoA production and possibly acylation and decreased activity of the VLCAD enzyme. These disorders may also lead plasma ammonia concentrations >1000 µmol/L in the neonatal period. These disorders are discussed elsewhere in this chapter (see Fatty Acid Oxidation Disorders in the section Abnormal Newborn Infant: Laboratory Phenotypes).
  - *Mitochondrial disorders.* Several mitochondrial disorders are associated with hyperammonemia including several mtDNA depletion syndromes and respiratory chain deficiencies. One proposed mechanism for the hyperammonemia in these disorders is that they interfere with ATP production, which is a required substrate for the CPS1-mediated synthesis of carbamyl phosphate. It is also likely that the several of these disorders also lead to more global structural impairment of mitochondrial structure and indirectly affect the urea cycle and related pathways. Two recently described examples of these severe mitochondrial phenotypes are associated with mutations in *FBXL4* and *TMEM70*. Both are inherited in an autosomal recessive manner because of mutations in these nuclear genes.

    Encephalomyopathic mitochondrial DNA depletion syndrome, type 13 (MTDPS13) is caused by mutations in the *FBXL4* gene, which appears to encode for a protein required for maintaining intramitochondrial architecture.[75] Patients with this deficiency may manifest intrauterine growth failure, cardiomyopathy, congenital heart defects, feeding difficulties, failure to thrive, global developmental delay, and brain atrophy. Laboratory abnormalities include lactic acidemia (and increased CSF lactic acid), hyperammonemia, elevated serum creatine kinase activity, nonspecific mitochondrial respiratory chain enzyme deficiencies, and mtDNA depletion. The diagnosis is established by genetic testing of the *FBXL4* gene. No specific treatment is available. The *TMEM70* gene encodes for *t*rans*mem*brane protein *70*, a mitochondrial membrane protein that is required for biogenesis of the mitochondrial ATP synthase (also known as complex V of the oxidative phosphorylation system).[62] *TMEM70* deficiency is characterized by neonatal onset of hypotonia, hypertrophic cardiomyopathy, and apneic spells, accompanied by lactic acidosis, hyperammonemia, decreased concentrations of tricarboxylic acid (TCA) cycle intermediates, and 3-methylglutaconic aciduria. No specific treatment is available.
  - *Pyruvate carboxylase (PC) deficiency.* PC converts pyruvate to oxaloacetate, which is in turn converted to aspartate. Aspartate is a required substrate for argininosuccinate synthetase (ASS). Thus, PC deficiency leads to hyperammonemia. The clinical features and management of PC deficiency are provided elsewhere in this chapter (see Gluconeogenic Disorders in the section The Abnormal Newborn Infant: Laboratory Phenotypes).[136]
- Others
  - *Glutamine synthetase (GS) deficiency.* GS catalyzes the conversion of glutamate to glutamine, which is an alternate mechanism of ammonia detoxification. GS deficiency increases the ammonia load that the urea cycle must handle. This disorder leads to moderate hyperammonemia and neonatal seizures (see Seizures subsection under Abnormal Newborn Infant: Clinical Phenotypes).[39,40]
  - *Hyperinsulism/hyperammonemia (HI/HA syndrome).* The HI/HA syndrome is caused by an autosomal dominant mutation in the *GLUD1* gene, which encodes for glutamate dehydrogenase.[82] Glutamate dehydrogenase plays a key role in insulin release in response to a protein-containing (specifically, more leucine) meal. This disorder is associated with postprandial hypoglycemia and mild-moderate hyperammonemia. The hyperinsulinism associated with this disorder is diazoxide-responsive, whereas the hyperammonemia is not. See Chapter 86 for more details about the clinical features and management of this disorder.

• **Fig. 90.6** Schematic depiction of the pathogenesis of many inborn errors of metabolism. See text for details.

Treatment

It is not possible in an overview of inborn errors of metabolism to discuss treatment of all the individual diseases that might be encountered in the newborn period. Treatments for some of these inborn errors of metabolism were discussed in the relevant sections of this chapter. General principles that are relevant to many of these diseases are discussed in the following section.

With few exceptions, the inborn errors of metabolism expressed in the newborn period are inherited as recessive traits. Disorders inherited in this manner generally have a common mechanism of pathogenesis, which is depicted in Fig. 90.6. In simple terms, patients with these metabolic diseases are lacking a specific enzyme that converts substance B to substance C. In some cases, the enzyme requires one or more cofactors for its activity. Deficient enzyme activity may be caused by an error in apoenzyme function or cofactor availability.

The absence of enzyme activity can produce disease in a number of different ways. First, there is accumulation of substance B proximal to the enzyme block, leading to increased concentrations of substance B that might be toxic. The congenital hyperammonemias are a good example of this mechanism. Without one of the urea cycle enzymes, ammonia accumulates and causes significant neurotoxic effects. Second, excess substance B can be converted by alternate pathways to toxic metabolites E and F. It is thought that tyrosinemia type I, for example, produces its hepatotoxic and neurotoxic effects through overproduction of toxic secondary metabolites. Third, the disease state may be caused by deficiency of substance C or D, which is distal to the enzyme block. Defects of gluconeogenesis, such as pyruvate carboxylase deficiency, presumably work through this mechanism. Hypoglycemia results from impaired production of gluconeogenic precursors.

The disease state may be produced by a combination of these mechanisms. It is thought that many of the organic acidemias produce their toxic effects through a combination of mechanisms. In many of these disorders, acyl-CoA molecules accumulate proximal to the enzyme block and interfere with a number of other metabolic pathways (e.g., the urea cycle), and there is underproduction of metabolites distal to the enzyme deficiency that are essential for other cellular processes.

TABLE 90.18 Approaches to Treatment of Inborn Errors of Metabolism

Approach	Examples
Treatment at the metabolite level	Dietary modification to reduce production of toxic metabolites Diversion of toxic metabolites Reduction of the effects of toxic metabolites Supplementation of metabolite deficiencies
Treatment at the protein level	Stimulation of residual enzyme activity Inhibition of toxic metabolite production Replacement of missing enzyme Substrate reduction therapy
Treatment by transplantation	Hematopoietic stem cell transplantation (HSCT) Organ transplantation
Treatment at the genetic level	Somatic cell gene therapy

Traditional approaches to treating inborn errors of metabolism have focused on this model of pathogenesis. The general approaches in use or under development include: (1) treatment at the metabolite level; (2) treatment at the protein (or enzyme) level; (3) treatment by transplantation; and (4) treatment at the genetic manipulation level (Table 90.18).[18,34]

Treatment at the Metabolite Level

The most common form of metabolite manipulation is dietary modification or restriction, which decreases the amount of precursor A that the impaired enzyme must handle. The dietary management of PKU is an example of successful application of this approach. Dietary restriction is often combined with other treatment approaches, such as metabolite diversion.

The therapy for the urea cycle defects is perhaps the best studied of the metabolite diversion strategies. Two drugs, sodium phenylacetate and sodium benzoate, are provided to these patients to serve as ammonia traps (see Hyperammonemia). Phenylacetate can also be provided as phenylbutyrate. Phenylacetate conjugates with glutamine to form phenylacetylglutamine, eliminating two ammonia molecules per molecule of drug as the nitrogen component of glutamine; benzoate conjugates with glycine to form benzoylglycine (hippurate), eliminating one ammonia molecule per molecule of drug as the nitrogen component of glycine. Arginine is also provided to prime the urea cycle, because it is the last amino acid in the urea cycle and is split to release urea and ornithine, the precursor for the next turn of the cycle.

Another example of diversion of toxic metabolites is carnitine supplementation for the organic acidurias. Carnitine is transesterified with acyl-CoAs to form acylcarnitines. These transesterifications release free CoA, making it available for essential intracellular processes, whereas the potentially toxic acyl groups are excreted in the urine as acylcarnitines and acylglycines.

Reduction of the effects of toxic metabolites is another approach to treatment. One example of this approach is the use of N-methyl D-aspartate (NMDA) receptor agonists such as dextromethorphan or ketamine to treat patients with nonketotic hyperglycinemia. These medications block the excitatory effects that excess glycine has on the NMDA receptors of the central nervous system. The result is reduction (but not complete resolution) of seizure activity in these patients.[45,128]

The deficiency of substances distal to the enzyme block (e.g., C or D) can be overcome by supplementing with exogenous C or D. An example of this approach is the feeding of uncooked cornstarch to patients with the hepatic forms of glycogen storage disease who cannot generate glucose from endogenous glycogen and are predisposed to fasting hypoglycemia. The uncooked cornstarch is metabolized slowly to provide a steady source of glucose while these patients are sleeping.

Treatment at the Protein Level

There are several approaches to treating at the protein level. Historically, the first example of this approach was to stimulate residual enzyme activity by providing pharmacologic amounts of cofactor required by the deficient enzyme. This approach has been used successfully to reduce the clinical severity of several vitamin-dependent enzymopathies, including vitamin B_6–responsive homocystinuria, vitamin B_{12}–responsive methylmalonic acidemia, thiamine-responsive MSUD, and tetrahydrobiopterin (BH4)–responsive phenylketonuria. Unfortunately, only a fraction of patients with any of these disorders respond to vitamin supplementation for reasons that are still not completely understood.

The converse of the first approach is to inhibit enzyme activity at a step proximal to production of toxic metabolites. The use of NTBC to treat tyrosinemia type I is an example of this approach. Tyrosinemia type I is a defect in the distal portion of the catabolic pathway for tyrosine. The enzyme deficiency that causes tyrosinemia type I leads to overproduction of toxic metabolites that produce the hepatic and neurologic complications of the disease. NTBC is a drug that inhibits an enzyme, *p*-hydroxyphenylpyruvate dioxygenase, which is proximal in the catabolic pathway to the enzyme deficiency that causes tyrosinemia type I. NTBC successfully suppresses overproduction of the toxic metabolites that produce the hepatic and neurologic complications of tyrosinemia type I.

A more direct approach to treating an enzyme deficiency is to replace the dysfunctional enzyme. It has been very difficult to provide "enzyme in a bottle" for a number of reasons, including the need to produce large amounts of pure enzyme; the need to direct the enzyme to the organ, cell, or organelle where it is needed; the tendency of the body to reject foreign proteins; and the great expense of such efforts. Among the earliest successes of this approach has been for the hematologic clotting disorders, such as factor VIII deficiency (see Chapter 79), and for α_1-antitrypsin deficiency (see Chapter 91). In the case of α_{1+}-antitrypsin deficiency, enzyme replacement therapy is effective for the adult-onset pulmonary manifestations of the disease but not for the hepatic problems expressed in the neonatal period.

Direct enzyme replacement therapy is now available for several lysosomal storage disorders.[8,113] In the case of nonneuropathic Gaucher disease, enzyme replacement therapy has been successful in treating the hematologic and visceral manifestations but less successful in treating the skeletal manifestations of children and adults. Enzyme replacement therapy is now available for Fabry disease, Hurler syndrome (MPS I; mucopolysaccharidosis I), Hunter syndrome (MPS II), Maroteaux-Lamy syndrome (MPS VI), Morquio syndrome (MPS IVA; mucopolysaccharidosis IV type A), and Pompe disease (GSD II; glycogen storage disorder type II).[8,113,152]

Another approach that can be used is substrate reduction therapy, either alone or in conjunction with enzyme replacement therapy. In this approach, a drug is provided that inhibits the production of the storage material. This approach is most commonly used for patients with Gaucher disease type 1; however, this disorder rarely manifests in the newborn period. This form of therapy (miglustat) is also effective for patients with Niemann-Pick disease type C, which can present in the newborn period with fetal ascites or cholestatic jaundice and pulmonary infiltrates (see Lysosomal Storage Disorders in the section The Abnormal Newborn Infant: Clinical Phenotypes).[113]

Treatment by Transplantation

This approach is being pursued vigorously for a number of inborn errors of metabolism. Perhaps the best-studied approach is liver transplantation, which has been performed successfully for about two dozen different inborn errors of metabolism, including glycogen storage disorders, organic acidemias, urea cycle disorders, and several other disorders.[69,71,80] This approach has been particularly successful for disorders in which the liver is the sole source of the enzyme and the only organ affected by the disease. Heart transplantation has been used successfully for patients with propionic acidemia. Many inborn errors of metabolism cannot be treated with liver transplantation or even multiple organ transplantation, because the abnormal genotype produces a multisystem disease and the overall prognosis remains poor. This appears to be the case for some patients with a mitochondrial disorder, but not all.[80,100]

Bone marrow transplantation or stem cell transplantation is sometimes used to treat multiorgan disease, because the pluripotent cells provided by these transplants can serve as precursors for many related cell types in different organs. The benefit of bone marrow transplantation or stem cell transplantation for several of the lysosomal storage diseases appears promising and is an area of intense interest.[12,81,87,113] For example, these forms of transplantation are the treatment of choice for patients with Hurler syndrome who are diagnosed early, since they are essentially curative except for the skeletal manifestations that still develop.

Treatment at the Genetic Level

Treatment of inborn errors of metabolism has focused on modification of the phenotype rather than the genotype, but vigorous efforts have been under way for many years to develop methods for manipulating the genotype of somatic cells (i.e., cells other than germ cells).[34] Efforts have focused on somatic cell gene therapy rather than altering germ cells for numerous ethical reasons. Additionally, there is the very practical reason that most children born with inborn errors of metabolism are not known to be at risk before they manifest symptoms of disease.

Somatic cell gene therapy requires insertion of a functional gene into a patient's somatic cells in such a way that they are introduced into the appropriate target organs, are functionally active, and are appropriately regulated. Somatic cell gene therapy has the goal of treating the affected patient's disease; it cannot correct the affected patient's germline. Successful somatic cell gene therapy has not been demonstrated conclusively for any inborn error of metabolism. The approaches to somatic cell gene therapy employ viral vectors or physicochemically modified DNA as a means of delivering a suitably tailored normal gene to its appropriate target. In vivo and ex vivo approaches also are being used to introduce the corrective gene. One source of concern with this approach has been that gene insertion into the patient's genome would be random and could lead to harmful mutagenesis. Homologous recombination has been explored as a means of circumventing this risk. In homologous recombination, a new gene (or DNA fragment) is inserted in exchange for the defective gene (or DNA fragment) rather than inserted randomly into the patient's genome. Homologous recombination could, therefore, provide a means of selectively excising the deleterious gene in exchange for the normal gene without the risk of producing harmful random insertional mutagenesis. Recent efforts have focused on altering gene functioning, such as genome editing, RNA interference, and cell reprogramming. None of these approaches has reached the stage of clinical availability.[34]

Along with these efforts to surmount the technical difficulties of somatic gene therapy, considerable effort is being expended to address the larger clinical, ethical, and societal issues of this form of treatment. These issues will undoubtedly prove to be as formidable a challenge as the technical issues, and they deserve the same attention.

Conclusion

Inborn errors of metabolism are an important cause of morbidity and mortality in newborn infants. These disorders are probably underdiagnosed because of their relative rarity, the nonspecific way many of them are expressed, and the difficulty clinicians have with recognition and diagnosis. This chapter hopefully reduces this difficulty by providing a practical approach to the diagnosis of these disorders based on sets of common clinical and laboratory findings.

Key Points

- Inborn errors of metabolism are an underdiagnosed cause of neonatal morbidity and mortality, because they are individually relatively uncommon, they manifest with a wide diversity of symptoms and signs, they may not be identified by the usual battery of diagnostic laboratory testing, and many physicians are relatively unfamiliar with these disorders.
- Recent expansion in the scope of newborn screening has increased the awareness of physicians and other medical professionals who care for newborns regarding the need to understand better the scope, benefits, limitations, and follow-up care of patients who are found to have an abnormal newborn screen.
- Key clinical and laboratory findings will alert the physician caring for a sick newborn to the possibility that the newborn might have an inborn error of metabolism.
- The sick newborn with a suspected inborn error of metabolism should be evaluated expeditiously, because many inborn errors of metabolism can lead to rapid clinical deterioration, often with irreversible consequences. The evaluation should start with broad-based laboratory tests that will provide a provisional diagnosis and direct initial therapy. The evaluation should then progress to more specialized laboratory testing to establish a definitive diagnosis and optimal treatment.
- The treatment for newborns with an inborn error of metabolism has improved both in the number of disorders that are treatable and the efficacy of treatment for many of these disorders. Treatment includes dietary modification, metabolite manipulation, enhancement of enzyme activity, enzyme replacement, cell or organ transplantation, and genetic therapies.

Neonatal Jaundice and Liver Diseases

MICHAEL KAPLAN, RONALD J. WONG, JENNIFER C. BURGIS, ERIC SIBLEY, AND DAVID K. STEVENSON

Bilirubin is one of three biologically active end-products of heme catabolism. Its clinical significance in the neonate relates to its propensity for deposition in the skin and mucous membranes, producing easily identifiable jaundice (French *jaune*, yellow) or icterus (Greek *ikteros*). The yellow color, or the serum (or plasma) total bilirubin (TB) concentration at any point in time, represents the combined processes of bilirubin production and bilirubin elimination from the body, the latter process comprising bilirubin uptake into the hepatocyte, bilirubin conjugation, and excretion of the conjugated product. As long as these functions remain in balance, a moderate degree of jaundice may develop but should not endanger an otherwise healthy, nonhemolyzing infant. Imbalance between bilirubin production and its elimination may result in increasing jaundice or hyperbilirubinemia. In rare cases, the degree of bilirubin production relative to bilirubin elimination may be so great that bilirubin may deposit in the brain, where it may cause dysfunction in the form of acute bilirubin encephalopathy (ABE). Although some cases of ABE may be transient and reversible, chronic bilirubin encephalopathy with resultant permanent neuronal damage, a form of cerebral palsy known as kernicterus, may ensue. As many as 80% of otherwise healthy, term newborns develop some degree of elevated TB levels. In contrast, severe hyperbilirubinemia with its potentially devastating sequelae is rare. It is, therefore, important to distinguish between normal processes of bilirubin physiology from pathologic metabolism. Medical caretakers of newborns should possess a thorough understanding of normal bilirubin physiology as well as its abnormal metabolism and the potential complications of severe hyperbilirubinemia.

Bilirubin Metabolism

Bilirubin Biochemistry

Overview

Throughout life, there is a continuum of bilirubin production and elimination from the body. Ongoing lysis of red blood cells (RBCs), whether physiologic or at increased rates (e.g., due to hemolysis), releases iron protoporphyrin (heme), the oxygen-carrying component of hemoglobin. Catalyzed by heme oxygenase (HO), heme is then converted to biliverdin and subsequently to bilirubin (Fig. 91.1). This bilirubin in its unconjugated form is transported to the liver bound to albumin. In the hepatocyte, bilirubin is conjugated to glucuronic acid by the enzyme uridine diphosphoglucuronate (UDP)-glucuronosyltransferase 1A1 (UGT1A1). Water-soluble conjugated bilirubin can be now excreted into the bile from which it reaches the bowel and is ultimately eliminated from the body. This simplified overview of bilirubin biochemistry will be reviewed in greater detail later in this chapter.

Heme Degradation

Heme oxygenase-1 (HO-1), the inducible isoform of HO, is a membrane-bound enzyme found in cells of the liver and other organs that catalyzes the first step in the pathway by which heme is converted to biliverdin through oxidation of the former molecule's α-methene bridge carbon (Fig. 91.2). HO-1 is inducible by its substrate heme. This rate-limiting step produces biliverdin; free iron (which can be reutilized for hemoglobin synthesis); and carbon monoxide (CO), which is excreted in the lungs in equimolar amounts. This process occurs in all nucleated cells except for mature, anucleated RBCs. Biliverdin is a blue-green water-soluble pigment that can be readily excreted by the liver and kidneys. In amphibians, reptiles, and certain avian species, the major pigmented end-product of heme catabolism is biliverdin. In mammals, however, biliverdin is converted to bilirubin by biliverdin reductase in the cytosol.

The degradation of 1 g of hemoglobin forms 34 mg of bilirubin. The isomeric form of bilirubin produced in this two-step process is IX-α (*Z,Z* isomer), defining the relative positions of the four pyrrole rings and the hydrogen molecules on the two linking lateral carbons. This form of bilirubin is water-insoluble, owing to tertiary structural changes that internalize the keto and carboxy groups that would otherwise interact with water molecules. Intramolecular hydrogen bonding maintains this folded bilirubin structure.

Abstract

Neonatal hyperbilirubinemia, usually transient and benign, is one of the most common neonatal problems, but if extreme and untreated, can potentially cause bilirubin neurotoxicity, manifesting as chronic choreoathetotic cerebral palsy (kernicterus) and death, or bilirubin-induced neurologic dysfunction (BIND). In industrialized countries, bilirubin neurotoxicity has been limited to a large extent, but the condition still occurs in developing countries and is a major cause of mortality and morbidity globally. The etiology of hyperbilirubinemia stems from conditions increasing bilirubin production (e.g., hemolysis) and those diminishing bilirubin elimination, resulting in an imbalance between these two processes. Hemolysis appears to be a primary risk contributor to developing bilirubin neurotoxicity. Bilirubin conjugation is immature in the newborn and even more so in the preterm infant. The total serum/plasma bilirubin, when primarily indirect or unconjugated, is used for clinical assessment and therapeutic decision making. While unbound bilirubin may be a better prognostic value, its measurement is not universally available clinically. The mainstay of treatment is intensive phototherapy, with the option of exchange transfusion in those infants not responding to that treatment. Drug therapy using metalloporphyrins has potential for the treatment of hyperbilirubinemia in the future. Conjugated hyperbilirubinemia results from interference with the hepatic excretion of conjugated bilirubin into bile. Idiopathic neonatal hepatitis and biliary atresia together account for the majority of cases of conjugated hyperbilirubinemia. Extrahepatic biliary atresia requires early surgical intervention with hepatoportoenterostomy. Clinical management of conditions with prolonged cholestasis includes supportive measures to prevent sequelae of malabsorption of dietary fat and fat-soluble vitamins.

• **Fig. 91.1** Metabolic pathway of the degradation of heme and the formation of bilirubin. Heme released from the hemoglobin of red blood cells or from other hemoproteins is degraded by heme oxygenase (HO), the first and rate-limiting enzyme in a two-step reaction requiring nicotinamide adenine dinucleotide phosphate (NADPH) and oxygen, and resulting in the release of iron and the formation of carbon monoxide (CO) and biliverdin. Metalloporphyrins, synthetic heme analogs, can competitively inhibit HO activity (indicated by the *X*). Biliverdin is further reduced to bilirubin by the enzyme biliverdin reductase. CO can activate soluble guanylyl cyclase (sGC) and lead to the formation of cyclic guanosine monophosphate (cGMP). It can also displace oxygen from oxyhemoglobin or be exhaled. The bilirubin that is formed is taken up by the liver and conjugated with glucuronides to form bilirubin mono- or diglucuronide (BMG and BDG, respectively), in reactions catalyzed by uridine diphosphoglucuronate glucuronosyltransferase (UGT1A1). The bilirubin glucuronides are then excreted into the intestinal lumen but can be deconjugated by bacteria so that the bilirubin is reabsorbed into the circulation, as shown. (Modified from Vreman HJ, et al. Carbon monoxide in breath, blood, and other tissues. In: Penney DG, ed. *Carbon monoxide toxicity*. Boca Raton, FL: CRC Press; 2000:22-30.)

Because bilirubin is a weak acid and is neither water soluble nor readily excreted at pH 7.4, to facilitate its excretion the molecule must be conjugated to mono- and diglucuronic acids by the specific hepatic enzyme isozyme (UGT1A1).[130] The evolutionary advantage derived by mammalian species in the development of such an intricate energy-dependent system that first produces bilirubin from a water-soluble precursor and then converts it back to a water-soluble form for excretion is presently uncertain. The mammalian placenta is capable of removing unconjugated bilirubin but not biliverdin. Biliverdin accumulation in the mammalian fetus would presumably result in the accumulation of large amounts of potentially toxic metabolites. Evidence has shown that bilirubin[257] and even CO may be biologically useful molecules.[175] The inducibility of HO-1 would appear to indicate that bilirubin production is helpful to cells when they are stressed. Bilirubin is a potent antioxidant that readily binds to membrane lipids and is capable of limiting membrane damage by preventing peroxidative injury. Biologic evidence of potentially beneficial effects of moderate concentrations of bilirubin is tempered by the association of high levels of unconjugated bilirubin with neuronal dysfunction and necrosis. Although cells may be potential beneficiaries of small amounts of bilirubin, in greater circulating quantities, the same bilirubin molecule may be a causative factor of severe neuronal damage. The dilemma that faces the clinician is determining the desirable or "safe" level of bilirubin appropriate for a particular neonate.

The CO formed by heme degradation binds to hemoglobin to form carboxyhemoglobin (COHb) and is then transported in the circulation to the lung. Here, the CO separates from hemoglobin and is exhaled in breath. Although there are other potential endogenous and exogenous sources of CO, such as lipid peroxidation and photo-oxidation, the main source of endogenous CO is derived from heme catabolism. Therefore, quantitative estimation of its synthesis or excretion (in infants without significant lung disease or oxygen exposure) offers a reasonably accurate assessment of the rate of heme degradation from which the rate of bilirubin production can be derived. It is believed that other hemoproteins undergo the same degradative process.

Bilirubin Production

The pathway of bilirubin synthesis, transport, and metabolism is summarized in Fig. 91.3. In the normal adult, bilirubin is derived primarily from the degradation of heme, which is released from senescing RBCs in the reticuloendothelial cells. Normally, about 20% of the bilirubin excreted into bile is derived from heme and other hemoproteins (mainly cytochromes, catalase). CO excretion in humans and more direct measurements in animals have demonstrated that, on the first day of life, bilirubin production

• **Fig. 91.3** The pathways of bilirubin synthesis, transport, and metabolism. Hgb, hemoglobin; RBCs, red blood cells. (From Assali NS. *Pathophysiology of gestation*. New York: Academic Press; 1972.)

is increased two to three times the rate of adults, to an estimated average of 8-10 mg/kg body weight per day. Bilirubin production decreases rapidly during the first 2 postnatal days. Several factors may explain this increased production in the newborn. The circulating RBC life span is shortened to 70-90 days compared with 120 days in the adult. Increased heme degradation arises from the very large pool of hematopoietic tissue, essential to intrauterine well-being, but ceases to function shortly after birth. An additional factor may possibly include an increased turnover of cytochromes. Another major contributor to the bilirubin pool in the neonate is an increase in bilirubin absorbed from the bowel as part of the enterohepatic circulation. This mechanism results from both reformation of unconjugated bilirubin from conjugated bilirubin in the bowel and enhanced absorption of unconjugated bilirubin by the intestinal mucosa back to the circulation (see Enterohepatic Absorption of Bilirubin).

Transport of Bilirubin in Plasma

Unconjugated bilirubin is mostly insoluble in water at pH 7.4, with a solubility of less than 0.01 mg/dL, and when released into the circulation by the reticuloendothelial cells, it is rapidly bound to albumin. Each molecule of adult albumin is capable of binding at least two molecules of bilirubin; the first molecule is more tightly bound than the second. Additional binding sites with weaker affinities may also exist but are probably of little clinical importance. On average, 7-8 mg/dL of unconjugated bilirubin can be bound to each gram of albumin. Physiologically, newborns have a lower plasma-binding capacity for bilirubin compared with adults or older children. This occurs because of reduced neonatal albumin concentrations and reduced molar binding capacities. Binding of unconjugated bilirubin by albumin is believed to be of importance in determining bilirubin neurotoxicity, because the unbound bilirubin fraction is thought to be a more sensitive predictor of bilirubin-induced neurologic dysfunction (BIND) than the TB used clinically.[284] However, except for Japan, there is currently no reliable and clinically available measurement to make the determination of unbound bilirubin concentrations a useful clinical tool in evaluating a newborn's risk for developing BIND[32,123] or in the therapeutic decision-making process.

The TB (serum or plasma) concentration is the conventional clinical laboratory measurement of bilirubin and is the basis for decision making for the management of hyperbilirubinemia. Bilirubin exists in four different forms in circulation: (1) unconjugated bilirubin reversibly bound to albumin, which makes up the major portion; (2) a relatively minute, but potentially neurotoxic, fraction of unconjugated bilirubin not bound to albumin (known as free or unbound bilirubin); (3) conjugated bilirubin, comprising mainly mono- and diglucuronides, which have effluxed from the hepatocyte to the circulation and are readily excretable through the renal or biliary systems; and

• **Fig. 91.4** Separation of serum bilirubin fractions by high performance liquid chromatography, showing bilirubin profiles at 450 nm (*upper tracing*) and 280 nm (*lower tracing*). α, Unconjugated bilirubin; β, monoconjugated bilirubin; δ, delta fraction bilirubin; γ, diconjugated bilirubin; Abs, absorption. (From Wu TW. Bilirubin analysis: the state of the art and future prospects. *Clin Biochem*. 1984;17:221.)

(4) conjugated bilirubin covalently bound to albumin, known as δ-bilirubin. Indirect, or unconjugated, bilirubin may increase in the serum or plasma in the presence of exaggerated hemolysis or diminished bilirubin glucuronidation. Conjugated or direct bilirubin will increase in association with excretory immaturity or with cholestatic diseases in which bilirubin is conjugated but its excretion is impaired.[179] A similar effect may be seen following acute hemolytic episodes in which indirect bilirubin is conjugated, but the large amounts of conjugated bilirubin are unable to be excreted via the bile. δ-Bilirubin has a plasma disappearance rate similar to that of serum albumin (Fig. 91.4).

"Conjugated" versus "Direct" Bilirubin

Conjugated bilirubin, but not δ-bilirubin, gives a "direct" reaction with standard diazo reagents; whereas, bound or unbound unconjugated bilirubin yields an "indirect" reaction. The terms *indirect* and *direct* bilirubin tend to be used interchangeably with unconjugated and conjugated bilirubin, respectively. However, the terms are not identical and measure differing bilirubin components. Direct bilirubin assays measure all conjugated bilirubin including mono- and diglucuronides as well as δ-bilirubin and some unconjugated bilirubin. Conjugated bilirubin implies measurement of mono- and diglucuronides only.

Therefore, conjugated bilirubin determinations may be lower than direct measurements performed on an identical serum sample.[110]

Conjugated bilirubin usually comprises a small fraction of the TB concentration. δ-Bilirubin can be measured only with newer techniques. It is found in detectable amounts in normal older neonates and children and in significantly increased concentrations in those with prolonged conjugated hyperbilirubinemia resulting from various liver disorders. However, it is virtually absent from the serum during the first 2 weeks of life.

Hepatic Uptake of Bilirubin

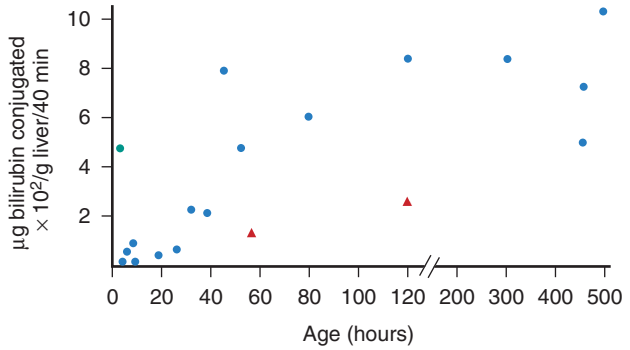
Bilirubin dissociates from circulating albumin before entering the liver cell. The latter process occurs partly by a passive process of carrier-mediated diffusion and partly by mediation by organic anion transporter proteins. In the liver cell cytoplasm, the unconjugated bilirubin is bound to glutathione-S-transferase A, also known as ligandin, or with B-ligandin (Y protein). These are major intracellular transport proteins, and their bilirubin binding ability helps keep the potentially toxic unbound level low. Z protein, another hepatic cytoplasmic carrier, also binds bilirubin but with a lower affinity.

Equilibrium Between Bilirubin Production and Elimination Processes—The Major Determinant of TB Levels

The equilibrium between the rates of bilirubin entry into the circulation, including *de novo* synthesis, enterohepatic circulation, and tissue shifts, and the bilirubin elimination process, including hepatic cell uptake and conjugation and excretion of bilirubin, determines the TB concentrations at any specific time. This concept is equally applicable under normal physiologic and pathologic circumstances alike.

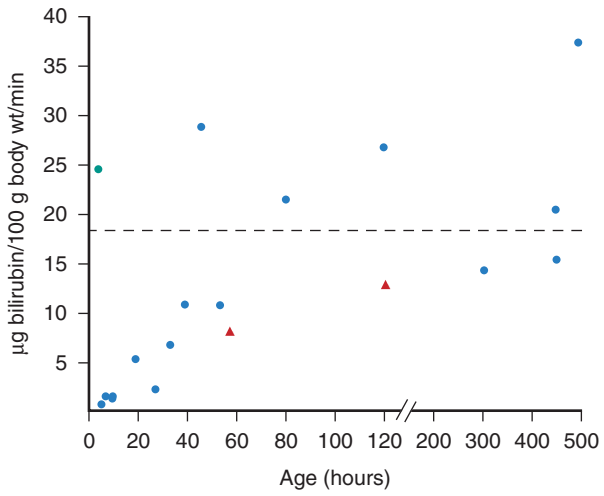
A reduced capacity of net hepatic uptake of unconjugated bilirubin has been implicated in the development of physiologic jaundice. In the newborn monkey, deficiency of B-ligandin and reduced clearance of sulfobromophthalein were demonstrated in the first 3 days of life, the period during which this animal frequently has physiologic jaundice. Studies in the human indicate that a deficiency of bilirubin uptake is probably of less importance in the pathogenesis of unconjugated hyperbilirubinemia than an immaturity of the bilirubin conjugation system during the first 3 or 4 postnatal days. However, the relative contribution of uptake deficiency may be greater during the second week of life, when the rate of bilirubin conjugation increases and approaches that of normal adults.

Conjugation of Bilirubin



In order for bilirubin to be excreted into the bile, the nonpolar, water-insoluble unconjugated bilirubin must be converted to a more polar, water-soluble substance. The aim of this process is to alter the bilirubin molecule by solubilizing bilirubin IX-α. Bilirubin is presumed to be transported by hepatic ligandin from the liver cell plasma membrane to the endoplasmic reticulum, where the conjugating enzyme UGT1A1 is situated. Conjugation is a two-step enzymatic process in which each molecule of bilirubin is conjugated with two molecules of glucuronic acid. Glucuronic acid derives from activated uridine diphosphoglucuronic acid (UDPGA), itself synthesized by the soluble cytoplasmic enzyme uridine diphosphoglucose dehydrogenase from uridine diphosphoglucose, which is, in turn, synthesized from free glucose. The UGT1A1 enzyme first catalyzes the transfer of one glucuronic acid molecule from one of the two propionic acid side groups on one of the central pyrrole rings of bilirubin, in an ester linkage, to form bilirubin monoglucuronide. The physiologic reduction in enzyme activity in the newborn to less than 1% of normal may, therefore, result in unconjugated hyperbilirubinemia.

Although bilirubin monoglucuronide is water-soluble and capable of being excreted into bile without further alteration, about two-thirds of the total bilirubin excreted into bile in the adult human is in the form of a diglucuronide. The second step of the enzymatic conjugation process involves the esterification of a second glucuronide molecule to the now monoconjugate. This process is catalyzed primarily by the same UGT1A1 enzyme on the endoplasmic reticulum, although a second enzyme, UDP-glucuronate glucuronosyltransferase (transglucuronidase), located in the canalicular portion of the hepatocyte plasma cell membrane, may also play a role. The substrate for the canalicular transglucuronidation is believed to be bilirubin monoglucuronide. The enzyme transfers one molecule of glucuronic acid from one molecule of bilirubin monoglucuronide to another, resulting in the formation of one molecule of bilirubin diglucuronide. The latter molecule is excreted into the bile canaliculus; whereas, the remaining molecule of now unconjugated bilirubin is returned to the endoplasmic reticulum for subsequent reconjugation. In circumstances such as in severe chronic hemolysis, increased loads of bilirubin are delivered to the liver. Limited excretory ability may result in retention of conjugated bilirubin in the form of bilirubin monoglucuronide.



The result of the esterification is to disrupt the intramolecular hydrogen bonds, thereby opening the molecule and rendering the conjugated bilirubin water-soluble. The water-soluble form of bilirubin is excretable in the bowel. Water solubility also decreases the amount of bilirubin reabsorbed from the bowel, because hydrophilic agents do not pass through the intestinal wall easily.

In the normal adult, glucuronide conjugation accounts for the disposal of about 90% of all bilirubin. The remaining portion is converted to water-soluble substances by conjugation with substances other than glucuronic acid, or by oxidation, hydroxylation, or reduction. In humans, bilirubin forms a conjugate with glucose, xylose, possibly other carbohydrates, sulfates, and taurine. These non-glucuronide

The *horizontal dashed line* represents mean normal hepatic bile bilirubin excretion for nine adult rhesus monkeys (18.2 ± 1.0 SEM). (From Gartner LM, et al. Development of bilirubin transport and metabolism in the newborn rhesus monkey. *J Pediatr*. 1977;90:513.)

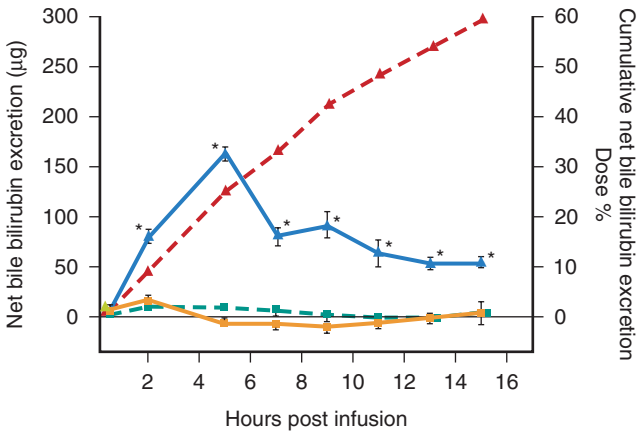
conjugates account for no more than 10% of the TB conjugates excreted in the bile.

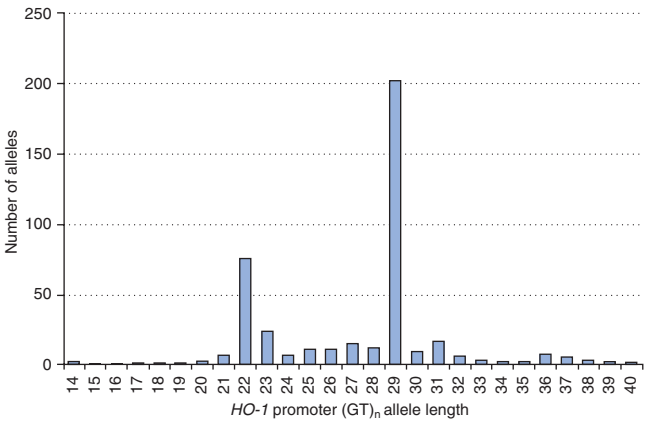
A number of *in vitro* studies have demonstrated the existence of deficiencies in hepatic UGT1A1 activity in newborns of many species, including humans. In newborn rhesus monkeys, hepatic bilirubin conjugating capacity is extremely low during the first hours of life and functions at about 5% of adult capacity (Fig. 91.5). However, by 24 hours of age, UGT1A1 activity increases sufficiently to process the bilirubin load presented to the liver, and the TB concentration begins to fall. In 1-day-old rats, the proportion of both xylose and glucose conjugates of bilirubin equals that of glucuronide conjugates. Total conjugating capacity increases to adult levels by the fourth day of life, when a mature pattern of glycoside distribution is present, with 75% of all conjugates being glucuronides. In human newborns, the monoglucuronide conjugate is the predominant bile pigment conjugate. UGT1A1 activity in term infants is about 1% of that of healthy adults (and even less in premature infants), and increases at an exponential rate until 3 months of age, when adult levels are reached. Non-glucuronide conjugates are insignificant in this period.

Excretion of Bilirubin



Excretion of the now polar, water-soluble bilirubin appears to be an energy-dependent concentrative process. The bilirubin conjugates are incorporated into mixed micelles along with bile acids, phospholipids, and cholesterol. The conjugates are excreted against a concentration gradient, and as a result, bile bilirubin concentration is about 100-fold that of the hepatocyte cytoplasm. Although the capacity for bilirubin excretion into bile is limited in newborn rhesus monkeys (Fig. 91.6), excretory deficiency is not a rate-limiting factor in the overall hepatic elimination of bilirubin in the human newborn. In newborn babies, bilirubin uptake into the hepatocyte and the enzyme-mediated conjugation processes are the more restrictive steps and may result in a "bottleneck" effect. However, a large bilirubin pool requiring elimination, such as in hemolytic disease of the newborn, may overwhelm the excretory capacity with efflux of backed up conjugated bilirubin into the circulation.[251] By contrast, in older humans and in the mature rhesus monkey and other mammals beyond the newborn period, hepatic excretion of conjugated bilirubin into bile predominates as the rate-limiting step in the presence of a large bilirubin load. At any age, in the presence of hepatic cell injury and biliary obstruction, hepatic excretory transport is the step most severely restricted, resulting in efflux of conjugated bilirubin from the hepatocyte to the serum with resultant conjugated hyperbilirubinemia. Thus, the hepatic excretory step may have the least reserve capacity of all the processes contributing to bilirubin elimination.

Enterohepatic Absorption of Bilirubin



Conjugated bilirubin is not absorbed from the intestine. However, the mono- and diglucuronides of bilirubin are relatively unstable conjugates that are readily hydrolyzed to unconjugated bilirubin. Reverted unconjugated bilirubin may now be readily absorbed across the intestinal mucosa, contributing, through the enterohepatic circulation, to the circulating unconjugated bilirubin pool and again being presented to the liver for conjugation. Of importance in the mechanism of the enterohepatic circulation is the enteric mucosal enzyme β-glucuronidase, which is present in both term and premature neonates in high concentrations. Mild alkaline conditions present in the duodenum and jejunum contribute to the deconjugation process.

A study in adult rats demonstrates that enteric absorption of unconjugated bilirubin occurs predominantly in the duodenum and colon. The extent of absorption varies widely, depending on diet and caloric intake (Fig. 91.7). Although quantitative estimates of the disposal of bilirubin

• **Fig. 91.8** Distribution of *HO-1* (GT)n repeats according to allele length of 199 newborns. Note the bimodal distribution common to other population groups. (From Kaplan M, et al. Heme oxygenase-1 promoter polymorphisms and neonatal jaundice. *Neonatology*. 2014;106:323.)

have been performed only for adult humans, these data do indicate that about 25% of the TB excreted into the intestine is reabsorbed as unconjugated bilirubin. About 10% of the total is excreted in stool as unaltered bilirubin. The remaining pigment is converted to urobilinoids, most of which are excreted in stool, with a small portion being reabsorbed in the colon for subsequent excretion by both the liver and kidney.

Neonates have relatively high concentrations of unconjugated bilirubin in the intestine, which contribute to the enterohepatic circulation. Intestinal bilirubin is derived from increased bilirubin production, exaggerated hydrolysis of bilirubin glucuronide, and high concentrations of bilirubin found in meconium. The relative lack of bacterial flora in the newborn bowel to reduce bilirubin to urobilinogen further increases the intestinal bilirubin pool in comparison with that of the older child and adult. The increased hydrolysis of bilirubin conjugates in the newborn is enhanced by high mucosal β-glucuronidase activity and the excretion of predominantly monoglucuronide conjugates (in the newborn) rather than diglucuronides (in the adult). Oral administration of nonabsorbable bilirubin-binding substances, such as agar, activated charcoal, or a lipase inhibitor (e.g., Orlistat),[104,199] may retain bilirubin in the bowel, thereby further increasing stool bilirubin content and reducing bilirubin reabsorption, thereby decreasing TB levels. Studies of intestinal bilirubin binding contribute to our understanding of the contribution of the enterohepatic circulation to unconjugated hyperbilirubinemia of the newborn.[70]

Genetic Control of Bilirubin Production

Heme Oxygenase-1

HO-1 is the rate-limiting enzyme that catabolizes heme to biliverdin and then to bilirubin, with the simultaneous release of equimolar quantities of ferrous iron (Fe^{3+}) and CO. Polymorphisms of the HO-1 gene promoter region may modulate its transcriptional activity, with increased HO activity being associated with the overproduction of bilirubin.

The *HO-1* Gene and Its Promoter Polymorphisms

The *HO-1* gene promoter region has a polymorphic $(GT)_n$ repeat sequence with lengths ranging from 12-40 repeats. As can be seen in Fig. 91.8, the $(GT)_n$ repeat distribution is bimodal with the main alleles at or around 23 and 30 repeat lengths.[137] The number of $(GT)_n$ repeats can modulate the rate of transcriptional activity (hence, gene expression), with short sequences (less than 25) being associated with increased transcriptional activity compared with those with long (25 or greater) sequences.

The prevalence of the short $(GT)_n$ lengths is cardinal to the analyses of the gene's contribution to the pathophysiology of hyperbilirubinemia. Higher HO activity associated with short alleles should lead to increased heme catabolism and hyperbilirubinemia. Newborn studies, however, have shown contradictory results. Most published studies demonstrated no effect of *HO-1* promoter polymorphisms on the TB levels. In two studies, however, from Taiwan and Japan, a modulating effect of short $(GT)_n$ repeats in increasing TB was reported.[142,283] A potential role of short $(GT)_n$ repeats to exacerbate hyperbilirubinemia in the presence of hemolysis in which large amounts of released hemoglobin result in *HO-1* induction has been suggested.

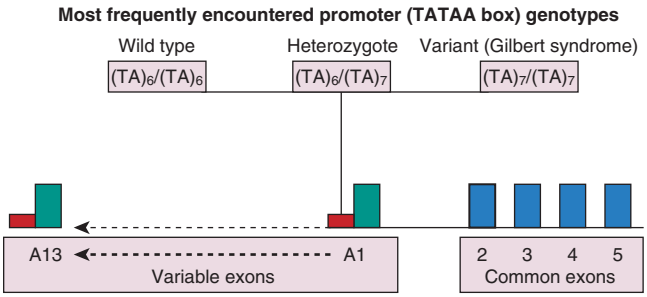
Genetic Control of Uptake of Bilirubin into the Hepatocyte



This process by which unconjugated bilirubin is taken up from the hepatic sinusoids and crosses the hepatocyte membrane to enter into that cell is facilitated by a carrier molecule, organic anion-transporting polypeptide-2 (*SLCO1B1*). In humans, this carrier may play an important role in the metabolism of bilirubin and in the prevention of hyperbilirubinemia by facilitating the entry of bilirubin into hepatocytes. A mutation in the gene leading to an impaired maturation of the protein with reduced membrane localization and abolished transport function has been described,[182] and a number of single-nucleotide polymorphisms (SNPs) have been identified, some of which are associated with an altered *in vitro* transport capability.[261]

Genetics of Diminished Bilirubin Conjugation

Perhaps one of the most important advances in our understanding of the genomics of bilirubin metabolism is the elucidation of the *UGT1A1* gene encoding the bilirubin-conjugating enzyme, UGT1A1. It is becoming more apparent that the modulation of bilirubin metabolism and whether TB levels remain within physiologic or hyperbilirubinemic ranges lie within genetic control. Although not limited to the neonatal age group, Skierka et al. demonstrated that 146/181 neonatal and pediatric age group patients referred for hyperbilirubinemia had at least one heterozygous *UGT1A1* variant, indicating that many cases of unconjugated hyperbilirubinemia could be attributed to variations at the *UGT1A1* locus.[248] Next is a short overview to allow the reader to comprehend mutations of this gene and interactions of these mutations with genetic or environmental factors in the mechanism of jaundice.[38,65,160,262]

The *UGT* Gene

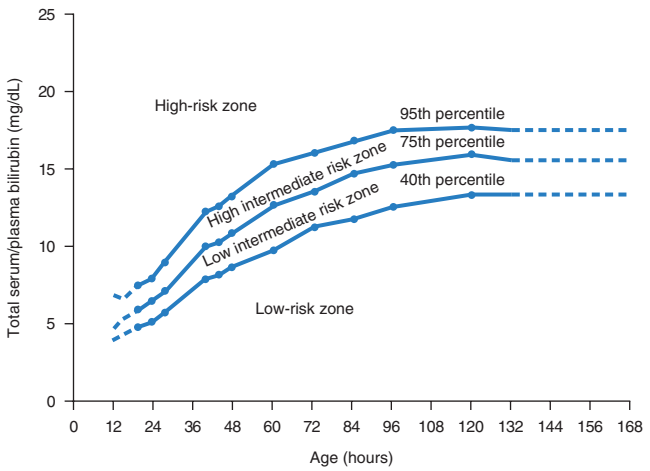
The *UGT* gene is a superfamily of genes whose function is to encode a biochemical reaction leading to the conjugation of glucuronic acid to certain target substrates to facilitate their elimination from the body. The *UGT2* genes are located on chromosomes 4q13 and 4q28. The enzymes encoded by this family preferentially conjugate endobiotic substances, such as steroids and bile acids, and although of physiologic and pharmacologic importance, they are of little relevance to bilirubin metabolism. In contrast, the UGT1A1 gene isoform, which belongs to the UGT1 gene family, is of major importance to the conjugation and, therefore, elimination of bilirubin. This gene isoform has been mapped to chromosome 2q37. *UGT1A1* was cloned by Ritter and associates in 1991.[226] The gene consists of 4 common exons (exons 2, 3, 4, and 5) and 13 variable exons, of which only variable exon A1 is of any importance regarding bilirubin conjugation; the remaining exons play a role in the detoxification of a diverse range of chemical substances

• **Fig. 91.9** The human *UGT1* gene locus. Schematic representation of the genomic structure of the *UGT1* gene complex. Variable exon 1A1 and common exons 2 to 5 of the gene complex have been identified as those sites encoding the bilirubin conjugating enzyme, UDP-glucuronosyltransferase. Variable exons 1A2 to 1A13 do not participate in bilirubin metabolism. Genetic mutations associated with absent or decreased enzyme activity, which cause deficiencies of bilirubin conjugation, have been localized to this variable exon 1A1 (*green boxes*), its promoter (*red boxes*), or the common exons 2 to 5 (*blue boxes*). The upper section of the diagram demonstrates the common exon 1A1 promoter TATAA box genotypes. (Redrawn from Kaplan M, Hammerman C. Bilirubin and the genome: the hereditary basis of unconjugated neonatal hyperbilirubinemia. *Curr Pharmacogenom*. 2005;3:30.)

(Fig. 91.9). The variable exon A1 functions in conjunction with common exons 2 to 5: in response to a specific signal, transcription processing splices mRNA from the variable exon to the common exons. This process provides a template for the synthesis of an individual enzyme isoform. Upstream of each variable exon is a regulatory noncoding promoter that contains a box sequence of thymidine-adenine (TA) repeat (TATAA) of nucleic acids. Mutations of variable exon A1, its promoter, or the common exons 2 to 5 may result in deficiencies of bilirubin conjugation. Single nucleotide polymorphisms of the noncoding promoter area affect bilirubin conjugation by diminishing expression of a normally structured enzyme, whereas mutations of the gene coding area may affect enzyme function by altering the structure of the enzyme molecule. Further information is supplied in the section on Conjugated Hyperbilirubinemia.

Co-expression of Genes Modulating the Risk of Neonatal Hyperbilirubinemia

In a genome-wide study performed on adults in Sardinia, three loci were associated with the modulation of TB levels: UGT1A1, glucose-6-phosphate dehydrogenase (G6PD), and SLCO1B3, the latter a member of the SLC family implicated in bilirubin uptake into the hepatocyte.[233] Pursuing this finding in relation to neonatal hyperbilirubinemia, Lin et al.[152] studied the allele frequencies of mutations and polymorphisms of UGT1A1, G6PD, and SLCO1B1 in DNA samples, which were obtained from the DNA Polymorphism Discovery Resource of the National Human Genome Research Institute, and thought to be representative of the current US population. Although no clinical information was available for the individuals whose DNA was



Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

included in the sampling, a high rate of gene co-expression does suggest a potentially important role for genetic polymorphism co-inheritance in neonatal hyperbilirubinemia. Co-expression of genes with another, with mutations or polymorphisms, or with environmental factors may potentiate their role and exacerbate the pathophysiology of neonatal hyperbilirubinemia to a greater extent than each gene individually.[152]

Nonpathologic Unconjugated Hyperbilirubinemia

Elevations in unconjugated bilirubin occur ubiquitously in the human neonatal population. In a sense, this "normal" increase in TB levels is not true hyperbilirubinemia when compared with a reference group of all newborns. A more appropriate term that would add to our understanding of the phenomenon and distinguish the normal or physiologic state from the pathologic entity implied in the term *hyperbilirubinemia* may be *physiologic bilirubinemia*. Although the 40th percentile is spuriously elevated, the hour-specific TB nomogram (Fig. 91.10), or more recently published transcutaneous bilirubin (TcB) nomograms, reflect the natural increase in TB during the first days of life, reaching a peak at about 5 days.

Unconjugated hyperbilirubinemia in the human, regardless of age, is defined as an indirect-reacting bilirubin concentration of 2.0 mg/dL (34 μmol/L) or greater, depending on the standard used in calibration of the reaction. Nearly all adults and older children normally have indirect-reacting bilirubin concentrations in circulation of less than 0.8 mg/dL (14 μmol/L) and δ-bilirubin of 0.2-0.3 mg/dL (3-5 μmol/L). Conjugated hyperbilirubinemia is defined as an elevation of the direct-reacting fraction in the van den Bergh diazo reaction of greater than 1.5 mg/dL (26 μmol/L) provided it comprises more than 10% of the TB concentration. The latter portion of the definition is added to guard against over-interpretation of direct reactions in newborns with markedly elevated indirect-reacting bilirubin concentrations, because up to 10% of the unconjugated pigment behaves as direct-reacting pigment in the van den Bergh–type methods.

• **Fig. 91.10** Zones of risk for pathologic hyperbilirubinemia based on hour-specific TB levels. (Reproduced with permission from Bhutani VK, et al. Predictive ability of a pre-discharge hour-specific TB level for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics*. 1999;103:6. Copyright © 1999 by the American Academy of Pediatrics.)

Clinical situations in which the direct-reacting bilirubin concentration is equal to or close to the TB concentration are extremely rare, especially in the newborn period. In the neonate with conjugated hyperbilirubinemia, the hyperbilirubinemia is usually "mixed," the elevated direct-reacting fraction accounting for 20%-70% of the total pigment. Thus, a neonate with mixed hyperbilirubinemia should be considered primarily to have *conjugated* hyperbilirubinemia. Except in cases of extreme hemolysis, such as in hemolytic disease of the newborn, pathology resulting from interference with hepatic cell excretion and bile transport, rather than from abnormalities of increased bilirubin production or deficient hepatic bilirubin uptake or conjugation, should be sought.

Fetal Bilirubin

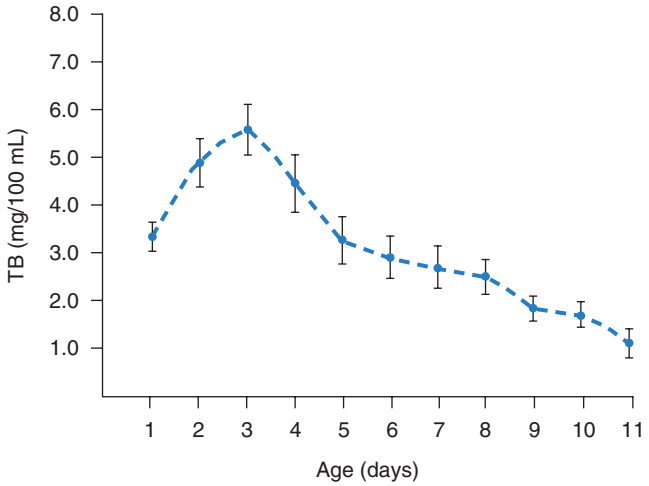
During the last stages of human gestation, the normal degradation of erythrocytes formed earlier in fetal life results in about a 150% increase in bilirubin production per unit of body weight compared with adults. The mammalian fetus of all species appears to be capable of degrading heme without limitation through the two enzymatic steps responsible for the formation of unconjugated bilirubin IX-α, CO, and biliverdin (see Fig. 91.2). However, notable species differences exist in the pattern of development of hepatic bilirubin conjugation. Marked deficiency in UGT activity is noted in rat, rabbit, guinea pig, sheep, dog, monkey, and human fetuses. At term, UGT activity in the rhesus monkey is only 1%-5% of that in the adult. In the human fetus, UGT activity is extremely low before 30 weeks of gestation at about 0.1% of adult activity and gradually increases to about 1% at term.

Diminished UGT activity is the central rate-limiting step that, in conjunction with additional processes, including increased bilirubin production, enhanced enterohepatic circulation, and diminished uptake into the hepatocyte, manifests as physiologic jaundice in monkeys and humans.

Significant hyperbilirubinemia is unusual in the human fetus, because the placenta transports unconjugated bilirubin from the fetus to the mother. Administration of radioactive unconjugated bilirubin into the fetal circulation of a dog, guinea pig, or monkey shows a rapid disappearance from the fetal side and recovery in the maternal bile. Even in states of severe intrauterine hemolysis from conditions such as Rh or other isoimmunizations, the degree of anemia by far exceeds the level of hyperbilirubinemia, and clinical jaundice is usually mild at birth.[36] Indeed, intrauterine therapeutic interventions in this condition are indicated by fetal anemia rather than fetal hyperbilirubinemia. After delivery and separation of the placenta from the infant,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

increases in TB may be expected and may be excessive in the face of hemolytic disorders. By contrast, the placenta is barely permeable to conjugated bilirubin. Thus, in the absence of evidence of hemolytic disease, if clinical jaundice is present at birth, a conjugated hyperbilirubinemia caused by intrauterine hepatic pathology should be suspected.



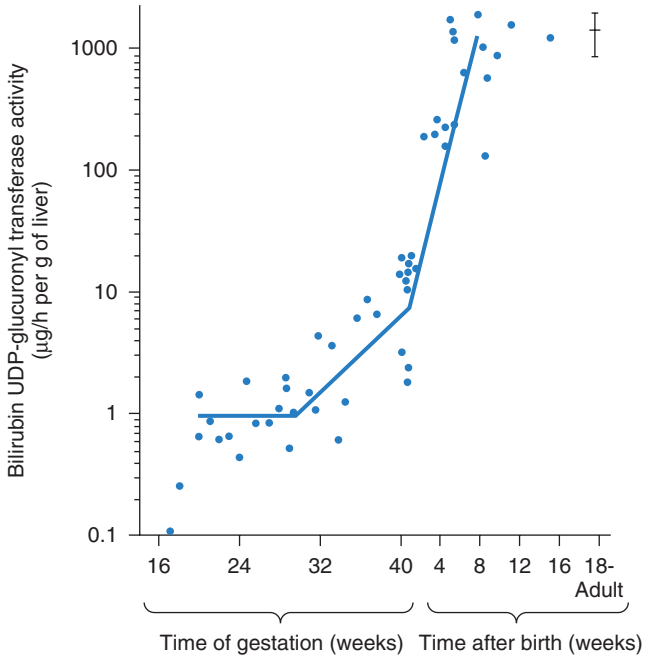
A large amount of bilirubin is found in meconium, indicating appreciable activity of fetal hepatic bilirubin conjugation. A significant level of β-glucuronidase activity is found in meconium, suggesting that conjugated bilirubin in the fetal intestine can be hydrolyzed back to unconjugated bilirubin and then absorbed from the bowel into the portal circulation. This absorbed bilirubin may reenter the hepatocyte for subsequent reconjugation and re-excretion or may be transferred through the placenta into the maternal circulation. The efficiency of this process is protective to the fetus against severe hyperbilirubinemia, even when hemolysis is severe.

Conjugated hyperbilirubinemia in the mother, which may occur in hepatitis or recurrent jaundice of pregnancy, is not reflected in the cord blood. Severe hemolytic disease in the fetus results in small, but significant increases in amniotic fluid bilirubin concentrations. How bilirubin enters the amniotic fluid pool is not known, but suggestions have ranged from direct transfer across the placenta from the maternal circulation, to transudation of pigment across the amniotic membranes or cord vessels, to secretion of bilirubin in the pulmonary fluids flowing from the fetal lung into the fetal pharynx and oral cavity and then into the amniotic fluid. Although to a great extent replaced by noninvasive measurement of anterior cerebral artery flow as an index of fetal anemia, in recent decades, measurement of amniotic fluid bilirubin concentrations by spectrophotometry, combined with percutaneous umbilical blood sampling allowing for serial hematocrit determinations and fetal intravascular transfusions, resulted in markedly improved outcome for the now rare fetus and infant with Rh erythroblastosis (see Chapter 23).

Neonatal Hyperbilirubinemia

Term Neonate

In the full-term newborn, physiologic jaundice is characterized by a progressive rise in TB concentration from about 2 mg/dL (34 μmol/L) in cord blood to a mean peak of 5-6 mg/dL (86-103 μmol/L) between 48 and 120 hours of age in Caucasian and African-American infants, with most TB levels peaking at 72-96 hours of age, and 10-14 mg/dL (171-239 μmol/L) between 72 and 120 hours of age in Asian-American infants. This is followed by a rapid decline to about 3 mg/dL (51 μmol/L) by the 5th day of life (Fig. 91.11) in Caucasian and African-American neonates and by the 7th-10th in Asian-American neonates. This early period of physiologic jaundice has been designated as *phase 1* physiologic jaundice. During the period from the 5th-10th days of life in Caucasian and African-American infants, TB concentrations decline slowly, reaching the normal adult



• **Fig. 91.11** Mean total bilirubin (TB) concentrations in 22 full-term normal white and African-American infants during the first 11 days of life. *Vertical bars* represent standard error of the mean. (From Gartner LM, et al. Development of bilirubin transport and metabolism in the newborn rhesus monkey. *J Pediatr*. 1977;90:513.)

value of less than 2 mg/dL (34 μmol/L) by the end of that period. This late neonatal period of minimal, slowly declining hyperbilirubinemia has been designated as *phase 2* physiologic jaundice. The epidemiology is dependent, in part, on the prevalence of breastfeeding in a population, because lower peak TB values will be found among predominantly formula-fed infants.

Studies in the newborn rhesus monkey, an animal with a pattern of physiologic jaundice of the newborn that is similar to that in humans, show that phase 1 results from the combination of a six-fold postnatal increase in the load of bilirubin presented to the liver combined with a markedly diminished UGT activity. The presence of either of these factors alone would result in retention of unconjugated bilirubin to a lesser extent than when in combination. Hepatic uptake and excretion of bilirubin are also decreased during this period, although their function as rate-limiting steps in the transport of bilirubin from plasma into bile is dwarfed by the combination of increased bilirubin load to the liver and diminished conjugative capacity. The very large increase in bilirubin load appears to result from both increased *de novo* bilirubin synthesis and enteric reabsorption of unconjugated bilirubin. In the newborn monkey, the markedly increased load persists for 3-6 weeks, primarily because of enhanced intestinal bilirubin absorption. Similar data are not yet available for the human neonate.

In the human, UGT1A1 activity is extremely low in the fetal period. After birth, UGT1A1 activity increases at an exponential rate, reaching the adult level by 6-12 weeks of age (Fig. 91.12). The early deficiency in enzyme activity may result from insufficient enzyme synthesis, inhibition of enzymatic activity by naturally occurring substances, deficient synthesis of the glucuronide donor UDPGA, or a combination of these factors. Phase 2 physiologic jaundice appears to result from an imbalance in which hepatic uptake

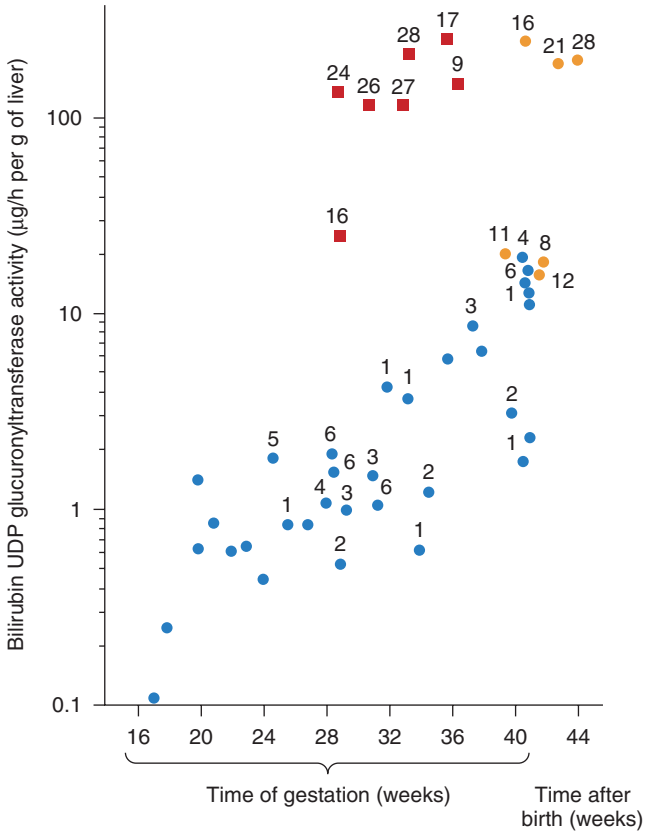
• **Fig. 91.12** Developmental pattern of hepatic bilirubin uridine diphosphoglucuronate (UDP)-glucuronosyltransferase activity in humans. (From Kawade N, Onishi S. The prenatal and postnatal development of UDP-glucuronyltransferase activity towards bilirubin and the effect of premature birth on this activity in the human liver. *Biochem J*. 1981;196:257. Reprinted by permission of the Biochemical Society, London.)

of bilirubin remains diminished while an increased bilirubin load presented to the liver persists. Developmental deficiency of B-ligandin may contribute to deficient uptake of bilirubin.

Despite the development of physiologic jaundice of some degree in nearly every newborn, only half of all Caucasian and African-American term newborns become visibly jaundiced during the first 3 days of life. A greater proportion of exclusively breastfed infants can be expected to display some degree of jaundice. Cutaneous icterus in the newborn will not become evident until TB concentrations exceed 5-6 mg/dL (86-103 μmol/L). This situation contrasts with that of the older child and adult, in whom jaundice may be noticeable in the conjunctiva and skin at TB concentrations as low as 2 mg/dL (34 μmol/L). Variations in duration of hyperbilirubinemia, in skin color, and in perfusion may account for these differences. As the intensity of jaundice increases, clinical icterus progresses in a caudal direction. At lower levels of TB, only the head and conjunctiva may be affected, with the chest, abdomen, legs, and feet becoming jaundiced in parallel to increasing TB concentrations. Because routine daily TB determinations are not usually performed on full-term or even premature newborns, in the past, careful scrutiny of the nursery population several times a day by experienced personnel was essential to detect infants who were becoming jaundiced, as some of these may subsequently develop significant hyperbilirubinemia and require further TB testing. Visual assessment of jaundice, however, is largely subjective, inaccurate, and dependent on observer experience. More recent developments of TcB monitoring devices intended to measure the skin color objectively and noninvasively and convert this color reading to a bilirubin estimation may improve on the reliability of visual estimation. Daily noninvasive TcB determinations may enhance the predictive value of the technique by allowing the actual trajectory to be plotted against those of the hour-specific TB or TcB nomograms (see Transcutaneous Bilirubinometry). This is especially important in predischarge assessment of newborns, especially those discharged before 72 hours of age.

Preterm Neonate



Physiologic jaundice in premature neonates is more severe than in term neonates. In larger preterm infants, mean peak TB concentrations may reach 10-12 mg/dL (171-205 μmol/L) by the 5th day of life. This delay in reaching the maximal concentration compared with term neonates primarily reflects the delay in maturation of hepatic UGT1A1 activity. Because mean peak unconjugated bilirubin concentrations as low as 10-12 mg/dL (171-205 μmol/L) may be associated with ABE or kernicterus in certain high-risk, low birth weight neonates, all degrees of visible jaundice in premature neonates should be monitored closely and investigated fully. Small premature infants cared for in an intensive care nursery will rarely be allowed to reach the TB levels mentioned but will be treated with phototherapy at much lower levels. The natural peak TB level in small premature infants is, therefore, mainly unknown.

Despite lower UGT1A1 activity in premature neonates than in term neonates at birth, UGT1A1 activity increases rapidly, far exceeding the expected maturational rate noted in utero (Fig. 91.13). This observation indicates that there are two components in the maturational process of hepatic UGT1A1: (1) chronologic maturation and (2) accelerated maturation related to birth. Nevertheless, normal TB concentrations in premature neonates may not be reached in many cases until the end of the first month of life.

Late Preterm Neonate

Late preterm gestation (34 0/7 to 36 6/7 weeks) is an important risk factor for the development of severe neonatal hyperbilirubinemia and kernicterus. These infants are physiologically immature and have limited compensatory responses compared with term infants. They are at greater risk of morbidity and mortality than term counterparts. Among the infants registered in the voluntary US-based Kernicterus Registry, late preterm infants were disproportionately represented compared with term. At this point of gestation, hepatic conjugative capacity is still immature and may contribute to the greater prevalence, severity, and duration of neonatal jaundice in these infants. Additional risk factors increasing the incidence of severe hyperbilirubinemia in these infants include feeding with human breast milk, large-for-gestational-age status, male sex, G6PD deficiency, and others. Suck-swallow immaturity

• **Fig. 91.13** Effect of premature birth on development of hepatic bilirubin uridine diphosphoglucuronate (UDP) glucuronosyltransferase (UGT) activity in humans. Numbers beside symbols represent age (days) at which activities were measured. Symbols represent enzyme activities for premature (*red squares*) and full-term (*orange circles*) infants who lived more than 8 days after birth, and for fetuses and premature and full-term infants who died within 7 days of delivery (*blue circles*). (From Kawade N, Onishi S. The prenatal and postnatal development of UGT activity towards bilirubin and the effect of premature birth on this activity in the human liver. *Biochem J*. 1981;196:257. Reprinted by permission of the Biochemical Society, London.)

may also contribute to the risk of hyperbilirubinemia.[113] These infants are at increased risk for readmission, primarily for hyperbilirubinemia. In a US survey, late prematurity increased the risk for neonatal hyperbilirubinemia more than fivefold.[224] Scrupulous attention to screening for jaundice in the newborn nursery, adequate lactation support, parental education, and appropriate postdischarge follow-up should facilitate institution of treatment when clinically indicated.[84,277]

Early-Term Neonate

Although within the definition of term, newborns born at the early end of term (37-38 weeks' gestation) may be, as a result of relative immaturity, at higher risk for neonatal hyperbilirubinemia than full-term counterparts, and unexplained jaundice may be twofold greater.[153] In a Canadian study, 37- and 38-week neonates had a higher risk of readmission for hyperbilirubinemia than those born ≥39 weeks.[230] Similarly, in Utah, late-term and early-term neonates had higher rates of readmission for hyperbilirubinemia than those born at term.[291]

Term Infant

Neonatal hyperbilirubinemia is the most common cause for readmission of otherwise healthy term infants. Many readmissions can be avoided by discharging the mother–infant dyad when both are ready to be discharged, when the mother has recovered sufficiently and is able to care for her newborn. Jaundice, if present, must be evaluated, and appropriate treatment or follow-up arranged according to the 2004 American Academy of Pediatrics (AAP) Practice Guideline.[12,22]

Post-Term Neonate

Nearly all post-term neonates and about half of all term neonates who are small-for-gestational age may be expected to have little or no physiologic jaundice, with peak TB concentrations of less than 2.5 mg/dL (43 µmol/L). The mechanism for this acceleration of hepatic maturation is unknown. Similarly, neonates of mothers treated with phenobarbital, a drug known to stimulate hepatic UGT activity and the concentration of ligandin, and neonates of heroin users have less than the anticipated severity of physiologic jaundice. Other drugs, less well investigated, also may have similar "maturing" effects.

Genetic, Ethnic, and Cultural Effects

The severity of physiologic jaundice varies significantly among different ethnic populations. Mean maximal TB concentrations in Chinese, Japanese, Korean, Native-American, and other Asian term newborns are 10-14 mg/dL (171-239 µmol/L), about double those of the Caucasian and African-American populations. The incidence of bilirubin toxicity as defined by autopsy-proven kernicterus is also increased significantly in Asian newborns. There is no clinical evidence for increased hemolysis in Asian newborns to account for these dramatic differences,[89] although some studies of CO production have suggested that bilirubin synthesis may be slightly increased compared with that in Caucasian or African-American neonates. A mutation (Gly71Arg) known as UGT1A1*6 in the gene for UGT frequently found in Japanese, Koreans, and Chinese, but rare in Caucasians, is associated with Gilbert syndrome in Asian populations and has been shown to be associated with an increased incidence of neonatal hyperbilirubinemia in these groups.[5,157] In contrast, variation in the number of TA repeats in the promoter for the *UGT1A1* gene are commonly encountered in Caucasians and are associated with Gilbert syndrome in that population group (see previous section Genetics of Diminished Bilirubin Conjugation). The promoter polymorphism is rare in Asian communities.[24] Thus, there is mounting evidence that the phenotypic variability in neonatal TB levels seen in different populations results in part from genotypic heterogeneity.

In contrast to Asians, the African-American race is often considered protective against hyperbilirubinemia, with a

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

lower risk of developing TB levels greater than 20 mg/dL (342 μmol/L) than Caucasian infants.[12] However, African-American infants are over-represented, relative to population statistics, in both the US-based Kernicterus Registry and a British and Irish series of severe hyperbilirubinemia. They also appear at greater risk of developing TB levels greater than 30 mg/dL (513 μmol/L) with resulting increased risk of kernicterus than Caucasian counterparts. This phenomenon may be explained in part by the high incidence of G6PD deficiency within this ethnic group.[135,173]

Certain geographically distinct populations may demonstrate a markedly increased incidence of neonatal unconjugated hyperbilirubinemia without associated hemolysis. The most dramatic of these are from certain Greek islands, especially the islands of Lesbos and Rhodes. Although the incidence of G6PD deficiency in these populations is markedly increased compared with the remainder of the Greek population and the world, the incidence of hyperbilirubinemia was not directly correlated with the frequency of G6PD deficiency, suggesting interaction of additional icterogenic factors. Unless aggressively treated with phenobarbital prophylaxis, phototherapy, and/or exchange transfusion, the incidence of kernicterus was also much greater in the newborns from these Greek islands than in those of the mainland population.

It has been speculated that the increased incidence of neonatal unconjugated hyperbilirubinemia in Asian and geographically identifiable populations may result either from environmental influences, such as the maternal ingestion of certain ethnically characteristic herbal medications or foods, or from a genetic predisposition to slower maturation of bilirubin metabolism and transport. Asian-origin infants born in the United States and Greek newborns born in Australia appear to be at similar risk for neonatal jaundice as natives of Asia and Greece, respectively, suggesting that geographic factors alone are not determinants. Differentiating the influence of drugs, foods, or traditional practices from that of genetic factors requires further investigation. Severe hyperbilirubinemia can result from hemolysis associated with sepsis or, if genetically vulnerable (e.g., in G6PD deficiency), exposure to chemicals (such as naphtha in mothballs) or pharmaceutical agents (such as antimalarials, sulfonamides, sulfones, antipyretics, and analgesics). In some societies with a high incidence of G6PD deficiency, application of henna to the skin or use of menthol-containing umbilical potions may precipitate severe hyperbilirubinemia and potentiate bilirubin encephalopathy. Even though some of these agents and stressors have received public attention, others represent generally unsuspected dangers, such as the intramuscular (IM) injection of vitamin K_3 (menadione) or the inhalation of paradichlorobenzene, which is used in moth repellents, air fresheners, and bathroom deodorizers.[247] In addition, newborn exposure to a hemolytic agent, especially in the presence of G6PD deficiency, can occur transplacentally or through breast milk as in the case of maternal ingestion of fava beans, or directly by inhalation, ingestion, or injection.

Pathologic Unconjugated Hyperbilirubinemia

Elevated concentrations of unconjugated bilirubin are of concern because of the danger of bilirubin encephalopathy or neuropathy associated with this fraction of bilirubin. Although there have been some reports of bilirubin encephalopathy associated with elevated levels of conjugated bilirubin, the role of conjugated hyperbilirubinemia in the mechanism of bilirubin encephalopathy is not clear. Most studies of kernicterus have related to the TB concentration, of which the conjugated fraction usually comprises only a small fraction. Elevated levels of conjugated bilirubin frequently indicate disease processes of hepatic origin. The following discussion, therefore, relates primarily to unconjugated, or indirect, hyperbilirubinemia and is followed by a section on conjugated hyperbilirubinemia.

The TB level at any point in time reflects a multiplicity of forces in delicate balance. Processes including bilirubin production, transport, uptake, conjugation, excretion, and reabsorption are not only interdependent, but are also influenced by tremendous physiologic flux present in this complex system in the first few days of the neonatal period. Examples of such changes include differences in the rate of heme catabolism and progressive maturation of the bilirubin conjugation system. Physiologically, the net result is an increase in TB levels up to about the fifth day of life, after which point TB values level off and then gradually decrease. Superimposed on these physiologic alterations of bilirubin metabolism may be specific disorders that may further exaggerate or prolong the normal pattern of an elevated TB level. These conditions may affect the entire spectrum of bilirubin metabolism and include disorders of bilirubin production as well as bilirubin conjugation and elimination.

Causes of Unconjugated Hyperbilirubinemia

Disorders of Bilirubin Production

Although increased bilirubin production could result from pathologic states in which degradation of nonhemoglobin heme (i.e., hemoproteins such as cytochromes, catalase) and erythrocyte hemoglobin precursor heme are increased, such disorders in fact have not been identified in the newborn period. The most common pathologic hemolytic causes of unconjugated hyperbilirubinemia in the newborn include isoimmune hemolytic disease, caused by blood group incompatibility between mother and fetus, and G6PD deficiency. Disorders associated with increased erythrocyte destruction are listed in Box 91.1 (see Chapter 23).

Neonates who are acutely hemolyzing appear to be at a higher risk for developing bilirubin-induced brain damage compared with those without hemolysis. Indeed, the first association to be recognized between increasing TB levels and the risk for kernicterus was made in newborns with Rh isoimmunization. Some reports suggested that kernicterus in hyperbilirubinemic newborns with hemolytic disease may occur more frequently than that in their counterparts without evidence of hemolytic disease. Sequestered Blood
- Subdural hematoma and cephalohematoma
- Ecchymoses
- Hemangiomas

the literature up to 1983, Watchko and Oski reinforced the concept that hyperbilirubinemia among neonates without hemolytic disease was less dangerous with regard to the development of kernicterus than in cases in which hemolysis was present.[280] However, there are few data to substantiate this view. A study shedding some light on this question was performed by Ozmert and colleagues.[213] In 102 children aged 8-13 years, indirect hyperbilirubinemia ranging from 17-48 mg/dL (291-821 µmol/L) associated with a positive direct Coombs' test (also known as the direct antiglobulin test [DAT]), presumed to reflect ongoing hemolysis, was associated with lower intelligence quotient (IQ) scores and a higher incidence of neurologic abnormalities. In these same children, the incidence of detected neurologic abnormalities increased as the time of exposure to high TB levels became more prolonged. Similarly, in Norway, Nilsen and coworkers found that of males born in the early 1960s who developed neonatal hyperbilirubinemia, those with a positive Coombs' test and hyperbilirubinemia for greater than 5 days had significantly lower IQ scores than average for that country.[198]

In a reanalysis of the data from the Collaborative Perinatal Project, no relationship was found between maximum TB levels and IQ scores. However, in those children who had had a positive DAT, a TB of greater than 25 mg/dL (428 µmol/L) was associated with a decrease in IQ scores.[147] A study of severe neonatal hyperbilirubinemia from Egypt reported the threshold TB level in identifying infants with bilirubin encephalopathy was lowered in those with identifiable risk factors associated with hemolysis, including Rh isoimmunization, ABO blood group incompatibility, and sepsis.[93]

Although there is to date no hard evidence demonstrating higher levels of unbound bilirubin in hemolyzing neonates, many believe hemolysis to be a potential factor that increases the risk for bilirubin-related brain damage. Although a TB concentration of 20-24 mg/dL (342-410 µmol/L) may be associated with kernicterus in a neonate with Rh isoimmunization, a healthy, term infant without an obvious hemolytic condition will rarely be endangered by TB in this range. Conditions associated with hemolysis, including direct Coombs'-positive Rh and ABO immunization or other isoimmunizations and G6PD deficiency, may pose an increased threat to an otherwise healthy newborn. The Subcommittee on Hyperbilirubinemia of the AAP includes jaundice developing within the first 24 hours, blood group incompatibility with a positive DAT, and other known conditions including G6PD deficiency, all associated with increased hemolysis, as major risk factors for the development of severe hyperbilirubinemia.[12] The AAP recommends initiating phototherapy or performing exchange transfusions at lower levels of TB in neonates with hemolytic conditions than in apparently nonhemolyzing counterparts. However, it is not proposed that a hyperbilirubinemic newborn without an obvious hemolytic condition will be unaffected by bilirubin encephalopathy. Patients with kernicterus have been reported in whom no evidence of hemolysis was evident.[168] Crigler-Najjar syndrome, a condition not associated with increased hemolysis, is frequently complicated by bilirubin encephalopathy.

Absence of a defined diagnosis associated with hemolysis should not lead to a state of complacency or belief that hemolysis is not, in fact, taking place. Blood counts are notoriously unreliable indicators of hemolysis in newborns. Studies utilizing the endogenous production of CO, an accurate index of heme catabolism, have demonstrated increased hemolysis in many jaundiced newborns, even in the absence of evidence of a specific hemolytic disorder. The term *nonhemolytic jaundice* should be used cautiously so as not to unwittingly potentiate bilirubin neurotoxicity in a possibly hemolyzing infant in whom it could have been prevented.[164,255]

Hemolytic conditions in the newborn are generally divided into two major etiologic groups: immune and nonimmune.

Isoimmunization

The hallmark of isoimmunization is a positive DAT (also known as the Coombs' test). This is indicative of a maternally produced antibody that has traversed the placenta and is now found within the fetus. The test is termed *direct* if the antiglobulin is adhered to the RBCs. An *indirect* test refers to the antibody being detected in the serum.

Rh Disease. In past decades, Rh hemolytic disease was the most common cause of severe hemolytic hyperbilirubinemia and a frequent cause of kernicterus. However, maternal prophylaxis with high-titer anti-D immunoglobulin G (RhoGAM), combined with aggressive fetal surveillance and intrauterine blood transfusions, has greatly reduced the incidence and severity of this disease. Mothers sensitized before the development of immune serum prophylaxis are no longer commonly encountered in industrialized countries. Additional technologies used antenatally, which have led to improvement in outcome, include antenatal blood group genotyping by polymerase chain reaction (PCR) from fetal cells obtained by amniocentesis or even from maternal blood samples.[34,184] Assessment of the degree of fetal anemia and determination of the need for intrauterine transfusion noninvasively by determining middle cerebral artery peak systolic velocity by the Doppler technique has reduced the need for invasive procedures.[88]

Those without access to preventive treatment, immigrants from countries in which prophylaxis is not widely available, or those who did not receive prophylaxis following abortion or invasive procedures may continue to deliver affected infants. The problem continues to be rife in developing countries. Although the incidence of Rh negativity is lower in countries such as India, Nigeria, Pakistan, Kenya, and Thailand than in North America or in Europe because of their large populations, large numbers of women from these countries may be at risk. Zipursky and Paul estimate that in these low income countries more than 1 million women annually do not receive anti-D prophylaxis[293] and that more than 100,000 children are born with Rh disease.[33]

The Rh blood group proteins are a highly antigenic group of proteins capable of causing severe isoimmunization with a high risk for fetal hydrops and death. Although several systems of nomenclature exist, the CDE system is most commonly used. These three loci each contain two major alleles (C,c; D,d; E,e) and several minor alleles. The D antigen may produce maternal sensitization with a fetomaternal hemorrhage as small as 0.1 mL. Whereas C and E alleles are relatively uncommon causes of isoimmunization, they can, on occasion, lead to severe hemolysis and hyperbilirubinemia. Indeed, Rh C disease may be as severe as Rh D isoimmunization.[222] Furthermore, women with multiple RBC antibodies may develop significant hemolytic disease of the fetus and newborn to a greater extent than those with a single antibody, especially in the presence of anti-(Rh)D. The pathophysiology of this phenomenon may represent a more aggressive immune response in those with more than one RBC antibody.[174] Rh disease in pregnancy is highly associated with both intrauterine hemolysis and severe hemolytic disease following delivery. Untreated, the condition can lead to intrauterine anemia and severe *hydrops fetalis*, with rapid postnatal evolvement of hyperbilirubinemia with the potential of kernicterus.

The immunization process may begin if an Rh-negative woman, usually D negative, is exposed to a D antigen. This usually occurs by ante- or intrapartum transplacental fetomaternal transfusion of fetal RBCs containing a D antigen, or by transfusion of Rh-positive RBCs during abortion, blood administration, or procedures including amniocentesis, chorionic villus sampling, or fetal blood sampling. Following exposure to the D antigen on the fetal RBCs, the mother's immune system responds by forming anti-D immunoglobulin G (IgG) antibodies. The IgG then crosses the placenta and adheres to fetal RBCs containing the D antigen. The subsequent antigen–antibody interaction leads to hemolysis and anemia. The immune response may become more severe and more rapid with progressive pregnancies. Resultant anemia causes bone marrow stimulation, with increased numbers of immature RBCs appearing in the circulation (*erythroblastosis*) and extramedullary hematopoiesis. *Fetal hydrops*, a condition characterized by generalized tissue edema and pleural, pericardial, and peritoneal effusions, may result from a combination of hypoproteinemia, tissue hypoxia, and capillary leak. Anemia with resultant poor myocardial function may further exacerbate the hydrops by causing congestive cardiac failure and venous congestion.

Elevated COHb levels detected in blood obtained by cordocentesis in affected fetuses of nonsmoking isoimmunized mothers confirm that destruction of erythrocytes begins in utero. However, the primary manifestation of the in utero hemolysis is that of anemia. Although large amounts of bilirubin are produced concomitantly, erythroblastotic infants are not severely icteric at birth. Concentrations of TB are usually kept below 5 mg/dL (86 μmol/L) by transfer of unconjugated bilirubin across the placenta. Jaundice may appear, however, shortly after delivery. Classically, in the initial stages, the TB is all indirect-reacting, although small amounts of conjugated bilirubin have been noted. After some days of excessive bilirubin load, the excretory system may become overwhelmed with efflux of conjugated bilirubin into the serum, and an increasing conjugated bilirubin fraction is not uncommonly seen.[251] Hepatic conjugation may mature more rapidly than excretory function as a result of stimulation by chronic exposure to high concentrations of bilirubin in utero. Furthermore, hepatic excretory function may also be adversely affected by development of hepatic congestion secondary to heart failure and swelling caused by extramedullary hepatic hematopoiesis, anemia, and poor hepatic perfusion.

ABO Heterospecificity. With the reduction of the incidence of Rh isoimmunization by immune prophylaxis, DAT-positive ABO incompatibility in industrialized countries with functional medical systems is now the single most prominent cause of immune hemolytic disease in the neonate. The clinical picture is usually milder than that of Rh disease, although infrequently severe hemolysis with hyperbilirubinemia may occur. In recent series of infants with either bilirubin encephalopathy/kernicterus or extreme hyperbilirubinemia reported from diverse countries including the United States, Canada, the United Kingdom,

Ireland, Denmark, Switzerland, China, and Nigeria, in whom the etiology of the hyperbilirubinemia was determined, infants with blood group A or B born to group O mothers comprised 19% to 55%.[35,122,173,204,242,292,294]

ABO blood group heterospecificity is the situation in which a blood group A or B infant is born to a group O mother, a setup occurring in about 12% of pregnancies. In some instances, women with blood group O have a high titer of naturally occurring anti-A or anti-B antibodies. High titers of anti-A or anti-B antibodies can sometimes be found in blood group O women even before their first pregnancy. This contrasts to Rh isoimmunization, in which immune sensitization occurs progressively with subsequent pregnancies. In contradistinction to blood group A or B individuals, in whom their respective anti-B or anti-A antibodies are IgM molecules with limited ability to cross the placenta, the respective antibodies of blood group O individuals are predominantly smaller IgG molecules and may cross the placenta. Attachment to corresponding fetal RBCs may follow, provided these cells have the A or B antigen. Extravascular hemolysis of the IgG-coated RBCs is thought to be mediated within the reticuloendothelial system by Fc-receptor-bearing cells. As with Rh isoimmunization, the immune process may commence in utero. However, unlike the Rh situation, there is little danger of severe hyperbilirubinemia, anemia, or hydrops in utero, and prenatal intervention is not indicated. Infants may sometimes be born with moderate anemia. After delivery, there is a potential danger of hyperbilirubinemia.

About one-third of blood group A or B neonates born to a blood group O mother will have a positive direct Coombs' test. Measurements of endogenous formation of CO, reflective of heme catabolism, have demonstrated, overall, an increased rate of heme catabolism in affected infants compared with controls.[239,255] In one study, those infants who developed hyperbilirubinemia (TB >95th percentile on the Bhutani nomogram) had even higher COHb values than the already high values of those who were nonhyperbilirubinemic.[134] Strength of DAT may also be predictive: ABO-heterospecific neonates with ++ DAT had a higher incidence of hyperbilirubinemia and higher COHbc values than those with ± or + DAT.[133] Not all DAT-positive neonates, however, develop severe hyperbilirubinemia. In one study, only 20% of DAT-positive neonates actually developed TB levels greater than 12.8 mg/dL (219 μmol/L); whereas, in another study, only 19.6% required phototherapy. Despite this apparent clinical mildness, newborns with severe hyperbilirubinemia of early onset who do not respond to phototherapy and require intravenous immune globulin (IVIG) therapy or exchange transfusion are occasionally encountered. In contrast to the above-mentioned studies, a study from Israel found that 52% of 164 DAT-positive, ABO-incompatible newborns developed a TB >95th percentile, many of these within the first 24 hours. At the extreme end of the spectrum, as already mentioned, kernicterus has been described.[242]

ABO blood group incompatibility with a negative DAT, not usually predictive of hemolysis or hyperbilirubinemia, may sometimes cause early and rapidly progressing jaundice, reminiscent of DAT-positive hemolytic disease.

Paucity of A and B antigenic sites on neonatal RBCs or weak expression of these antigens in neonates compared with adults may explain, in part, absence of clinical disease in many DAT-positive newborns. A or B antigenic sites situated in sites other than the RBC may bind with transplacentally acquired antibodies, limiting their availability to the RBC.

Because many ABO-incompatible, direct Coombs'-positive neonates have no evidence of ongoing hemolysis and do not develop early jaundice or hyperbilirubinemia, ABO heterospecificity with a positive DAT does not necessarily indicate ABO hemolytic disease. Some or all of the following criteria are necessary to support the diagnosis of ABO hemolytic disease:

1. Indirect hyperbilirubinemia, especially during the first 24 hours of life
2. Mother with blood group O; infant with blood group A or B
3. Spherocytosis on blood smear
4. Increased reticulocyte count
5. Evidence of hemolysis based on increased endogenous production of CO as assessed using end-tidal CO measurements, corrected for ambient CO (ETCOc) levels

In DAT-negative, ABO-heterospecific newborns, an interaction with a polymorphism for the $(TA)_7$ sequence in the promoter of the gene encoding UGT1A1, significantly increases the incidence of TB of at least 15 mg/dL (257 μmol/L) compared with controls and has been described.[131]

It is essential to closely observe any newborn born to a blood group O mother and to perform a TcB or TB measurement at the first appearance of jaundice. Routine blood group and DAT determination on umbilical cord blood is an option, which may allow for additional risk determination.

Isoimmunization Caused by Antibodies Other Than RhD. More than 50 RBC antigens may cause hemolytic disease of the newborn. The most important of these with regard to prenatal hemolysis include anti-C, anti-Kell, and anti-E,[103,124] although others may also infrequently be problematic. Alloimmunization caused by these autobodies can sometimes cause severe hemolytic disease of the fetus requiring prenatal intervention. Fetal surveillance protocols and clinical strategies developed for RhD alloimmunization are useful in monitoring all alloimmunized pregnancies. Similarly, the postnatal management should be based on the principles outlined in the management of the RhD-immunized newborn (see Therapy for Unconjugated Hyperbilirubinemia). Anti-Kell isoimmunization warrants special mention because fetal anemia, rather than hyperbilirubinemia, often predominates the clinical picture. This may be due to erythropoietic suppression in addition to a hemolytic process.[268]

Nonimmune Hemolysis

Erythrocyte Enzymatic Defects. The mature human erythrocyte lacks a nucleus and the organelles necessary for protein and lipid syntheses. Most of the protein present within its cell membranes is hemoglobin. Because the uptake and release of oxygen and carbon dioxide by hemoglobin in the tissues does not require energy, the erythrocyte relies on glycolysis (through the anaerobic Embden-Meyerhof pathway and the aerobic pentose phosphate pathway) and not on mitochondrial oxidative phosphorylation to generate adenosine triphosphate (ATP). Thus, defects in the glycolytic enzymatic machinery may have profound effects on erythrocyte function and life span.

G6PD Deficiency. An entity that is highly associated with extreme neonatal hyperbilirubinemia and bilirubin encephalopathy is G6PD deficiency. Because G6PD deficiency has major neonatal public health implications, it is discussed in some detail.[129]

G6PD deficiency is a common enzyme deficiency estimated to affect hundreds of millions of people worldwide.[200] From its original indigenous distribution, including areas in south Europe, Africa, the Middle East, and Asia, immigration patterns have transformed it into a condition that may now be encountered virtually in any corner of the globe. It is not surprising that in low- and middle-income countries with a high frequency of G6PD deficiency, the condition is associated with a high incidence of neonatal mortality and neurodevelopmental disorders.[208] It is remarkable, though, that the condition has been over-represented in reports of neonates with extreme hyperbilirubinemia and bilirubin encephalopathy relative to the background frequencies of this condition among the populations of the United States, Canada, the United Kingdom, and Ireland.[173,242] In the US-based Pilot Kernicterus Registry, more than 20% of reported neonates were diagnosed with G6PD deficiency, whereas its overall frequency in that country is estimated at only 4%-7%.[200] Recent immigration from African and Middle Eastern countries to Europe may increase the frequency of this condition in that continent, as demonstrated by detection of G6PD A– and G6PD-Mediterranean mutations among African and Middle Eastern immigrants to Denmark.[276]

Function of G6PD. G6PD plays a major part in stabilization of the RBC membrane against oxidative damage. The enzyme catalyzes the first step in the hexose monophosphate pathway, oxidizing glucose-6-phosphate to 6-phosphogluconolactone, thereby reducing nicotinamide adenine dinucleotide phosphate (NADP) to NADPH. NADPH is essential for the regeneration of reduced glutathione from oxidized glutathione, a substance that plays an integral part in the body's antioxidative mechanisms. The pathway is also instrumental in stimulating catalase, another important antioxidant. In the absence of G6PD, NADPH will not become available, reduced glutathione will not be regenerated, and cells may be rendered susceptible to oxidative stress. Unlike other body cells, no alternative source of NADPH is available in the RBC, which explains the extreme vulnerability of the G6PD-deficient RBC to oxidative damage. Oxidative membrane damage incurred to the cell membrane may manifest as hemolysis.

Genetics of G6PD Deficiency. Because G6PD deficiency is an X-linked condition, males may be normal hemizygotes or deficient hemizygotes, whereas females may be either normal or deficient homozygotes or heterozygotes. Because of X-inactivation, heterozygotes have two RBC populations: one G6PD deficient, the other G6PD normal. Because X-inactivation may be nonrandom, unequal ratios of normal and enzyme-deficient RBCs may coexist. Heterozygotes may, as a result, have either a normal, intermediate, or deficient phenotype. It was previously thought that heterozygotes had sufficient enzyme activity to protect them from the dangers of G6PD deficiency. However, reports suggest that heterozygotes may not be without risk, and fatal kernicterus has been described in a heterozygote.[112,126,132] The most commonly encountered mutation is G6PD A–, found in Africa and southern Europe and in African Americans. G6PD Mediterranean, regarded as a more severe type than G6PD A–, is found in Mediterranean countries, the Middle East, and India. Another variant encountered primarily in Asia is G6PD Canton. The number of mutations discovered is continually increasing and total 217 at the time of this writing.[95]

G6PD Deficiency and Hemolysis. Most G6PD-deficient individuals lead perfectly normal lives and will, for the most part, be unaware of their inherited condition. However, G6PD deficiency may be associated with severe hemolytic episodes with resultant jaundice and anemia, following exposure to a hemolytic trigger. Classically, these episodes often occur after ingestion of or contact with the fava bean (favism). Medications and chemical substances may be suspected, but sometimes no offending trigger is identified. Infection may play a role in the pathogenesis of acute hemolysis.

In neonates, extreme hemolytic hyperbilirubinemia may develop suddenly and without previous warning. Some identifiable substances associated with neonatal hemolysis include naphthalene (used to store clothes), herbal medicines, henna applications, or menthol-containing umbilical potions. Frequently, the trigger cannot be recognized and the hemoglobin concentration may not drop, leading to the erroneous diagnosis that hemolysis is not occurring. There can, however, be no other viable explanation for the exponential increase in TB to dangerous levels. G6PD deficiency may, therefore, be the one reason that kernicterus may not be completely preventable. Exchange transfusion may be the only recourse. Early hospital discharge with delayed follow-up may place these patients at risk for severe sequelae.

In a Nigerian neonatal cohort, G6PD-deficient and -intermediate (presumable heterozygotes) had higher TB, lower hematocrit values, and a greater need for phototherapy during the first postnatal week than G6PD-normal counterparts, suggestive of increased hemolysis.[20] Frequently, hematologic indices typical of hemolysis in older

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

children and adults, including falling hemoglobin and hematocrit values and increasing reticulocyte counts, may be absent despite a clinical picture of hemolysis. However, studies of endogenous CO formation, reflective of the rate of heme catabolism, have demonstrated an important role of increased hemolysis in association with this condition. Significantly higher levels of COHb have been reported in Nigerian G6PD-deficient neonates who developed kernicterus compared with neonates who were hyperbilirubinemic but did not develop signs of kernicterus.

More frequently and less life threatening, G6PD-deficient neonates may have a moderate form of jaundice, which occurs at a rate several-fold that of controls. The jaundice usually responds to phototherapy, although exchange transfusion may also be necessary. These infants have a low-grade hemolysis that cannot be implicated as the primary icterogenic factor.[135] Diminished bilirubin conjugation has been shown to be of major importance in the pathogenesis of the hyperbilirubinemia. An intriguing interaction has been noted between G6PD deficiency and a noncoding area $(TA)_7$ promoter polymorphism in the gene encoding UGT1A1.[138] This polymorphism, also known as UGT1A1*28, is associated with Gilbert syndrome. The incidence of a TB of at least 15 mg/dL (257 μmol/L) increased in a stepwise, dose-dependent fashion in G6PD-deficient neonates who were heterozygous or homozygous, respectively, for the polymorphism. This effect was not seen in the G6PD-normal control group. Furthermore, G6PD deficiency alone, in the absence of the promoter polymorphism, did not increase the incidence of hyperbilirubinemia over and above that of G6PD-normal counterparts. In Asians, in whom the $(TA)_7$ promoter polymorphism is rare, a similar interaction was noticed between G6PD deficiency and coding area mutations of the *UGT1A1* gene.[115] In a recent study of African-American neonates, although 20.6% had variations in both *UGT1A1* and *SLCO1B1* genes, these genetic variants did not have an effect on the incidence of hyperbilirubinemia.[238] This may be because very few neonates in that cohort were G6PD-deficient, confirming the concept of a gene interaction necessary to influence the incidence of hyperbilirubinemia.

The apparent mildness of this form of hyperbilirubinemia may be deceiving. Inherent to these infants is increased hemolysis, as demonstrated by endogenous CO production studies, in combination with a predilection for diminished bilirubin conjugation related to *UGT1A1*28*. Any further hemolysis, or additional conjugation decrease such as associated with prematurity, may upset the equilibrium between bilirubin production and elimination, thereby precipitating severe hyperbilirubinemia. Unlike the acute hemolytic form of jaundice, this milder form of jaundice can be predicted by predischarge bilirubin testing. G6PD-deficient neonates, who had a predischarge TB concentration below the 50th percentile, were unlikely to develop subsequent hyperbilirubinemia. However, as the predischarge TB increased progressively above the 50th percentile, the risk for subsequent hyperbilirubinemia increased in tandem.[128]

Testing and Screening for G6PD Deficiency. Many qualitative or quantitative screening tests are available that should accurately determine the hemizygous state in males or the homozygous state in females. Because many heterozygotes may have intermediate to normal G6PD enzyme activity, the result of nonrandom X chromosome inactivation, the heterozygote state is difficult to determine using standard biochemical tests. Females of high-risk groups (Mediterranean origin, African American, African, Middle Eastern or Asian, and Sephardic Jews) should have close follow-up to detect the development of jaundice despite a normal screening result. Also, biochemical tests may give a false normal result if performed during an acute hemolytic episode. The reason is that older RBCs, depleted in G6PD enzyme activity, may be destroyed, leaving younger cells with higher enzyme activity intact. In such cases, G6PD testing should be performed several weeks after the acute hemolysis has subsided. An alternative method is to analyze DNA for the specific suspected mutation. Some countries have introduced neonatal screening for G6PD deficiency combined with parental education in the hope that identification of an infant with G6PD deficiency should lead to avoidance of known triggers of hemolysis and speed the process of evaluation and treatment should an affected neonate become jaundiced. Reports have demonstrated a decrease in the number of cases of kernicterus following introduction of screening programs, as recently reviewed.[127] G6PD screening with rapid turnaround time is feasible.[7,201,225] Although discussion regarding neonatal screening for G6PD deficiency has started in the United States, there is as yet no national consensus regarding its need, effectiveness, or the best approach.[278]

The treatment of neonatal hyperbilirubinemia associated with G6PD deficiency should follow the 2004 AAP Practice Guideline[12] for neonates with hemolytic risk factors.

Pyruvate Kinase Deficiency. Pyruvate kinase catalyzes the conversion of phosphoenolpyruvate to pyruvate and the formation of ATP from adenosine diphosphate in the Embden-Meyerhof pathway. Deficiency of this enzyme results in a lack of ATP for erythrocytic metabolic activity and in chronic anemia. Pyruvate kinase deficiency, a condition prevalent in northern Europeans and inherited in an autosomal recessive manner, results in a lack of ATP, an important source of energy for RBC metabolism. In the newborn period, anemia, reticulocytosis, and severe, early, hemolytic jaundice may ensue.[59] Exchange transfusion may be required, and kernicterus has been reported.

Four isozymes are encoded by two genes, among which 250 mutations and 6 polymorphisms have been described.[48] Diagnosis is determined by an enzyme assay, which should be performed in cases of hemolysis and hyperbilirubinemia not associated with a positive direct Coombs' test or spherocytosis. Molecular studies may also confirm the diagnosis.[100]

Hexokinase catalyzes the conversion of glucose to glucose-6-phosphate, the initial step in glycolysis. Hexokinase deficiency predisposes the erythrocyte to oxidant damage and thus is another cause of hemolysis and neonatal

hyperbilirubinemia. Inheritance is autosomal recessive, and the gene has been localized to chromosome 10.

Congenital erythropoietic porphyria is an extremely rare, recessively inherited disorder of heme metabolism in which deficient uroporphyrinogen III cosynthase activity affects the conversion of hydroxymethyl bilane to type III uroporphyrinogen. Normal heme synthesis can occur only in the presence of greatly elevated levels of type I uroporphyrinogen and type I coproporphyrinogen. These porphyrins are deposited in massive quantities throughout the cells of the body, including the erythrocytes. The disease may present at birth with anemia, jaundice, and splenomegaly. Pink to brown staining of diapers soaked with porphyrin-rich urine is an early clue to the diagnosis. Because porphyrins are photoreactive, the diapers readily fluoresce under ultraviolet light. The same photoreactive properties of porphyrins lead to hemolysis, hyperbilirubinemia, and cutaneous photosensitivity with subepidermal bullae formation.

Deficiencies of other enzymes in the glycolytic pathway, including glucose phosphate isomerase, can produce severe hemolysis and hyperbilirubinemia in the neonatal period.

Erythrocyte Structural Defects. Defects in erythrocyte membrane and cytoskeletal structure (see Chapter 79) alter the shape and deformability of the cell and result in sequestration within the narrow splenic sinusoids. Hemolysis, hyperbilirubinemia, and splenomegaly are the clinical hallmarks of these disorders.

Hereditary Spherocytosis. Of the hereditary RBC membrane defects that may lead to acute hemolysis and hyperbilirubinemia in the newborn, hereditary spherocytosis is probably the most common.[119] In spherocytosis, the normal biconcave shape of the erythrocyte is altered such that the cell assumes a spherical shape—the shape with the smallest possible diameter for its volume. In addition to a reduction in surface area with consequential diminished oxygen uptake and delivery, the limitation in deformability may result in massive splenic sequestration. This condition may be inherited in both an autosomal dominant and recessive fashion, and frequently there may be a history of acute hyperbilirubinemia in a sibling or parent. The condition should be suspected in individuals of Northern European ancestry. Microvesiculization of the RBC membrane results from deficiency of proteins, including ankyrin, band 3, α-spectrin, β-spectrin, and protein 4.2 in that membrane. These osmotically fragile RBCs are trapped in the spleen, the microvesicles aspirated by macrophages, and the cell destroyed. The diagnosis can be made microscopically by identifying spherocytes in the peripheral blood smear, with confirmation by the osmotic fragility test. The latter test may be especially important in differentiating infants with hereditary spherocytosis from those with DAT-positive ABO isoimmunization, a condition that may also result in microspherocytosis. Mutations of at least five genes encoding the previously mentioned proteins have been recognized.

Hereditary spherocytosis is frequently associated with neonatal hyperbilirubinemia. Of 178 affected Italian term, predominantly breastfed newborns, 112 (63%) developed neonatal hyperbilirubinemia requiring phototherapy. The incidence of hyperbilirubinemia was even higher in those who also had a genetic variation of the *UGT1A1*28* gene promoter, similar to that described in G6PD deficiency.[119] Kernicterus has been described.[23] A mean corpuscular hemoglobin concentration (MCHC) of 36.0 g/dL or greater had an 82% sensitivity and a 98% specificity for identifying hereditary spherocytosis and should alert caregivers to the possibility of this diagnosis.[62]

Hereditary Elliptocytosis, Hereditary Pyropoikilocytosis, Hereditary Ovalocytosis, and Hereditary Stomatocytosis. These are rare conditions affecting the erythrocyte membrane. The diagnosis may be made by microscopic examination of the peripheral blood smear. Hemolysis may occur in the neonatal period and result in anemia and hyperbilirubinemia.

Infantile pyknocytosis is a transient abnormality of erythrocyte morphology associated with hemolysis and neonatal jaundice. Small, irregular, dense RBCs with spiny projections are seen in the peripheral smear and account for more than 5% of the total RBC population. Anemia and hemolysis persist throughout the first month of life and often into the second and third months. Jaundice is most severe during the first 2 weeks of life.

Blood Transfusion. In preterm infants, increases in TB levels have been documented, sometimes warranting phototherapy following blood transfusion. This may be because of a large bilirubin load caused by lysis of the transfused RBCs either prior to, during, or following the transfusion.[58]

Infection. Bacterial infection is a known cause of hemolysis and hyperbilirubinemia. Sepsis causes hyperbilirubinemia by increasing TB concentrations through hemolysis, or by impairing conjugation, thereby resulting in decreased excretion of bilirubin. Several theories have been proposed for the mechanism of hyperbilirubinemia in the septic neonate. Neonatal erythrocytes are particularly susceptible to cell injury and Heinz body formation in response to oxidative stress. In addition, HO-1 can be induced by oxidants, which could lead to increased catabolism of heme to bilirubin. Because bilirubin is a protective antioxidant, initially in infection, TB levels may decrease as a result of its consumption. However, the frequent manifestation of hyperbilirubinemia associated with sepsis suggests that this protective mechanism may be overwhelmed in septicemia. Furthermore, disseminated intravascular coagulation resulting from sepsis may produce hemolysis as erythrocytes traverse the deposition of fibrin within the microvasculature. In addition, conjugated hyperbilirubinemia may result from hepatitis secondary to bacterial, viral, fungal, and protozoal infections.

Sequestration. Sequestration of blood within body cavities can result in increased bilirubin production as the body metabolizes and recycles the heme released as erythrocytes are catabolized. Birth trauma resulting in the collection of RBCs within the layers of tissue covering the skull and brain (cephalohematoma, subdural hematoma, subgaleal hematoma) or elsewhere (bruising associated with precipitous or

instrument-assisted delivery) has the potential to produce hyperbilirubinemia (see Chapter 29).

Large hemangiomas, as in Kasabach-Merritt syndrome, may be associated with hemolysis and hyperbilirubinemia in addition to thrombocytopenia and depletion of fibrinogen and other clotting factors.

Polycythemia. An increase in RBC mass with resultant increased breakdown of these cells has the potential to overload the already immature capacity of the newborn to eliminate heme degradation products. Polycythemia may be associated with delayed cord clamping, maternal–fetal transfusion, and twin–twin transfusion. Infants of diabetic mothers, especially those who are large-for-gestational age, are known to be at risk for polycythemia. Although the mechanisms underlying polycythemia in this group are unclear, CO excretion studies have shown that increased RBC breakdown, even in the absence of polycythemia, is the source of the hyperbilirubinemia in these neonates[254] (see Chapter 79).

Disorders of Hepatic Uptake and Conjugation

Uptake into hepatocytes may be affected by polymorphisms of the *SLCO* gene. Liu et al. reported that SLCO1B1 388G>A was associated with an increased risk of neonatal hyperbilirubinemia in Chinese but not in Caucasian, Thai, Malaysian, or Latin-American populations.[155]

Gilbert syndrome is a benign disorder that affects about 6% of the population and produces a chronic unconjugated hyperbilirubinemia. Both defective hepatic uptake of bilirubin and decreased hepatic UGT1A1 activity have been demonstrated. The basis of the reduced activity of UGT1A1 lies in the presence of additional TA repeats in the TATAA box in the promoter region of the gene.[37] The mutation is also known as *UGT1A1*28*. Because the noncoding, rather than coding, area of the gene is affected, individuals with Gilbert syndrome have a normally structured UGT1A1 enzyme but with diminished expression. The latter leads to a decrease in UGT1A1 enzyme activity. Although this disease usually does not manifest until after the second decade of life, some neonates with Gilbert syndrome may exhibit hyperbilirubinemia secondary to diminished uptake of bilirubin.[21] When mutations in both the gene for G6PD and the promoter for UGT1A1 occur, the degree of neonatal hyperbilirubinemia has been shown to be dose dependent.[138] In addition, in G6PD-deficient infants who had the wild-type $(TA)_6$ (normal) gene promoter, the incidence of hyperbilirubinemia was similar to that in infants who were G6PD-normal, with the wild-type promoter (9.7% versus 9.9%). The variant *UGT1A1* promoter, rather than the rate of heme catabolism as measured by blood COHb, was subsequently shown to be the crucial factor in determining the TB level and had a similar incidence of hyperbilirubinemia (>15 mg/dL [257 µmol/L]) to those infants with and without G6PD deficiency. However, in G6PD-deficient infants who were both hetero- and homozygous for the Gilbert variant, hyperbilirubinemia was more frequent in a stepwise, dose-dependent manner (32% versus 50%, respectively).[24,138] Polymorphisms of the *UGT1A1* promoter TATAA box, even in the heterozygotic form, may also play roles in the generation of extreme hyperbilirubinemia in G6PD deficiency-associated hemolytic episodes. Several studies have shown that *UGT1A1*28* in and of itself, in the absence of G6PD deficiency, is not associated with significant hyperbilirubinemia.[216]

As described earlier, UGT1A1 catalyzes the conjugation of bilirubin in the liver. Disorders of conjugation include both those in which there is a primary alteration in UGT1A1 and those in which UGT1A1 function is secondarily altered.

Crigler-Najjar Syndrome Type I

Crigler-Najjar syndrome type I is a rare autosomal recessive disease characterized by an almost complete absence of hepatic UGT1A1 activity. Because the coding area of the *UGT1A1* gene is mutated, the enzyme produced is structurally abnormal, with no bilirubin conjugating capacity. In the homozygous form, severe unconjugated hyperbilirubinemia develops during the first 3 days of life and progresses in an unremitting fashion, with TB concentrations reaching 25-35 mg/dL (428-599 µmol/L) during the first month of life. Kernicterus often occurs in the neonatal period, especially when the etiology of the disease is unsuspected and aggressive treatment is not initiated. Stools are pale yellow, and bile bilirubin concentrations are less than 10 mg/dL (171 µmol/L) (normal being 50-100 mg/dL [855-1710 µmol/L]), with total absence of bilirubin glucuronide in bile. Bilirubin glucuronide formation measured in vitro with liver obtained by biopsy is absent. Formation of most nonbilirubin glucuronides is either severely reduced or absent.

With either direct hepatic enzymatic assay or indirect measurement of glucuronide formation, both parents are found to have partial defects (about 50% normal). Enzyme activity reserve should be sufficient to keep TB concentrations within normal limits. Unless a family is known to be affected by the condition, the recognition of this disorder during the first week of life may be difficult because of confusion with other types of conditions causing exaggerated unconjugated hyperbilirubinemia. Persistence of unconjugated hyperbilirubinemia at TB concentrations of greater than 20 mg/dL (342 µmol/L) beyond the first week of life, or repeated need for phototherapy in the absence of obvious hemolysis, should prompt concern for existence of this syndrome.

Indirect methods of diagnosis, including microassay of UGT1A1 activity from a percutaneous liver biopsy specimen or analysis of bile conjugates, have been largely replaced by gene analysis. An update of the genetic mutations known to date has recently been published[49] (Fig. 91.9 includes many of the mutations known to be associated with the condition). Occurrence of the identical mutation in both parents of an affected homozygous infant suggests parental consanguinity.

The management of these neonates requires maintenance of TB concentrations to less than 20 mg/dL (342 µmol/L)

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

during at least the first 2-4 weeks of life. The risk for kernicterus persists into adulthood, but aggressive management may diminish this risk while awaiting liver transplantation.[258] Today, nearly all neonates with this disorder are treated with phototherapy as initial therapy or after one or more exchange transfusions. Phototherapy is generally continued throughout the early years of life in the hope that this will prevent the development of kernicterus. Despite attempts to expose older children to phototherapy at the highest intensities and longest durations possible, the response to phototherapy progressively decreases with years of use. This may result from increased skin thickness or a changing distribution of the bilirubin pool. Prompt management of all intercurrent infections, febrile episodes, and other types of illness may help prevent later development of kernicterus. Inducers of UGT1A1, such as phenobarbital, are not effective in Crigler-Najjar syndrome type I disease.

Liver transplantation offers the only definitive treatment for the disease. This procedure should not be delayed indefinitely, because phototherapy may become less effective with the passage of time, and intercurrent illnesses may precipitate high levels of TB, with the potential of kernicterus, even in children whose TB concentrations had appeared to be under control and who had appeared to be neurologically intact. In a multicenter report of a world survey, 7 of 21 (33%) transplanted children had already developed some form of brain damage at the time of their transplantation. Average age at transplantation was 9.1 ± 6.9 years (range, 1-23 years). Hepatocyte transplantation has been used.[91] Gene therapy may also have promise for these patients in the future.[183,228] Stem cell therapy using hepatocyte-like cells differentiated from human-induced pluripotent stem cells reduced bilirubin levels in Gunn rats, indicating that the transplanted cells expressed UGT1A1 activity.[53]

Crigler-Najjar Syndrome Type II

Crigler-Najjar syndrome type II (also known as Arias disease) is more common than type I and typically benign. Although unconjugated hyperbilirubinemia occurs in the first days of life, TB levels generally do not exceed 20 mg/dL (342 μmol/L). Fasting, illness, and anesthesia may cause temporary increases in bilirubin to above baseline. The occurrence of kernicterus is rare. Evidence of hemolytic disease is absent (although it may occur coincidentally), stool color is normal, and neonates are otherwise healthy.

Unconjugated hyperbilirubinemia persists into adulthood. Biochemically, hepatic UGT1A1 activity is nonexistent and indistinguishable from that found in type I disease. Less than 50% of the daily bilirubin production is excreted in bile, and the monoglucuronide is the predominant form.

Another difference between type II and type I diseases lies in the response to phenobarbital.[259] Jaundiced neonates and adults with type II disease respond readily to oral administration of phenobarbital with a sharp decline in TB levels, whereas individuals with type I disease demonstrate no such change. Phenobarbital may be used as a simple clinical tool to differentiate the two syndrome types. Beyond the neonatal period, there should be no long-term risk for kernicterus unless there is coincidental hemolytic disease.

Crigler-Najjar syndrome type II occurs both as an autosomal recessive and dominant inheritance. The range of expression in one or both parents can be from an asymptomatic defect in conjugation on testing to severe icterus. Other members of the family also may either appear icteric or have detectable low-grade unconjugated hyperbilirubinemia. Screening of the parents and other close relatives for hyperbilirubinemia is a useful method for supporting the diagnosis when it is suspected. Testing of the neonate and the parents for the capacity to form glucuronides of bilirubin were used diagnostically in the past, but these methods have been largely replaced by sequencing of the *UGT1A1* gene.[125]

Transient Familial Neonatal Hyperbilirubinemia (Lucey-Driscoll Syndrome)

Lucey-Driscoll syndrome is a rare familial disorder in which neonates of certain mothers may develop severe unconjugated hyperbilirubinemia during the first 48 hours of life. Kernicterus has been reported in untreated newborns. The sera of these neonates and their mothers contain high concentrations of an inhibitor of UGT1A1 when tested in vitro. The serum inhibitory effect gradually declines after delivery coincident with gradual decline in TB levels.

Pyloric Stenosis

Pyloric stenosis may be associated with unconjugated hyperbilirubinemia at the time vomiting begins. Hepatic UGT1A1 activity is markedly depressed in the jaundiced neonates. The mechanism of diminished UGT1A1 activity may be due to presence of the variant $(TA)_7$ *UGT1A1* gene promoter, which is associated in adults with Gilbert syndrome.

Duodenal and jejunal obstructions are also associated with exaggerated unconjugated hyperbilirubinemia. Surgical relief of the obstruction results in a decline of TB levels to normal within 2-3 days. Lower intestinal obstruction, as in Hirschsprung disease, also may result in unconjugated hyperbilirubinemia, although usually of a milder degree than with upper intestinal tract disease. In this situation, as well as when there is upper intestinal tract obstruction, hyperbilirubinemia may result from increased reabsorption of unconjugated bilirubin from the intestine due to stasis of the intestinal contents (see Chapter 84).

Hypothyroidism

UGT1A1 activity in congenital hypothyroidism is deficient and may remain suboptimal for weeks or months. Because about 10% of congenitally hypothyroid neonates may develop prolonged, exaggerated jaundice, testing for thyroid function should be performed in these cases. Treatment with thyroid hormone promptly alleviates the hyperbilirubinemia. The mechanism of this association in the human newborn is unknown, but in rats, hypothyroidism impairs hepatic uptake and reduces hepatic ligandin concentrations.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Thyroid hormone is also instrumental in many maturational processes. Its absence may delay hepatic bilirubin enzyme and transport development (see Chapter 88). It has also been suggested that thyroid hormone can cause changes in UGT1A1 protein expression.

Disorders of Excretion

Impaired hepatic excretion of bilirubin from disorders such as hepatocyte injury results in conjugated hyperbilirubinemia and is discussed later in this chapter.

Disorders of Enterohepatic Circulation

Jaundice Associated with Breastfeeding. Jaundice associated with breastfeeding is common, and breastfed newborns are more likely to develop prolonged hyperbilirubinemia than those fed formula. Two pathophysiologic mechanisms have been suggested for the early-onset association of jaundice with breastfeeding, although this differentiation is not clear, and overlap may exist between these suggested entities. Breastfeeding failure jaundice, or breastfeeding-associated jaundice, has been so labeled to distinguish it from breast milk jaundice. Breastfeeding failure jaundice is so labeled because the cause appears to be associated with poor feeding practices and not with any change in milk composition. In contrast, breast milk jaundice is apparently related to a change in the composition or physical structure of the milk. Both types result in an exaggerated enterohepatic circulation of bilirubin—one through "starvation" and the other through altered milk chemistry.

Breastfeeding Failure Jaundice. Breastfeeding failure jaundice occurs in the first weeks of life in breastfed newborns. Establishing effective breastfeeding may be difficult, especially in first-time mothers, who may find lactation to be an intricate process. Maternal factors, such as lack of proper technique, engorgement, cracked nipples, and fatigue may impair effective breastfeeding. Neonatal factors such as ineffective suck also may hamper attempts at breastfeeding. Even if the mother is experienced in breastfeeding and her baby is interested, her milk supply is usually limited to small amounts of colostrum in the first 24-48 hours after birth. A genetic predisposition including a $(TA)_7$ promoter polymorphism, or G71R mutation, both of the *UGT1A1* gene, can lead to the development of hyperbilirubinemia in breastfed infants and may contribute to the development of prolonged jaundice.[56,178,185,234] Breastfed newborns are more likely to develop prolonged hyperbilirubinemia than those fed formula.[235]

All these factors may act in combination, resulting in infrequent or ineffective breastfeeding. As a result, there may be little stimulus for milk production. Formula supplementation may further impair successful lactation. Exclusively breastfed neonates are, therefore, at risk for being relatively underhydrated and less well-nourished than formula-fed counterparts. Poor enteral intake may lead to a state of relative starvation with delayed meconium passage. Intestinal content stasis may lead to increased enterohepatic reuptake of bilirubin, increasing the bilirubin load presented to the liver, leading to unconjugated hyperbilirubinemia. This process is similar to "starvation jaundice" seen in older human patients as well as other animal species fasted for more than 24 hours.

Prevention of breastfeeding failure jaundice includes encouraging frequent (at least 8-12 times per day for the first several weeks) breastfeeding,[10] avoiding supplementation with water or glucose solutions,[71] and accessing maternal lactation counseling. Intensive support of the breastfeeding mother is necessary, especially in view of early discharge policies in place at many hospitals. Both during birth hospitalization and after hospital discharge, the newborn should be closely monitored for weight gain, adequate urination and stool formation, and the development of jaundice.[219]

Breast Milk Jaundice. Late breast milk jaundice occurs after the first 3-5 days of life and may last into the third week of life or beyond. Epidemiologic studies report that 10%-30% of breastfed infants in the 2nd-6th week of life are affected, with some having hyperbilirubinemia into the third month. In a recent study of predominantly breastfeeding North American Caucasian neonates at 3-4 weeks of age, 34%-43% had TcB levels >5.0 mg/dL, and many were clinically jaundiced.[163] Presence of the variant $(TA)_7$ *UGT1A1* (UGT1A1*28) gene promoter may be associated with prolonged breast milk jaundice in Caucasian populations[185] and G71R (UGT1A1*6) in Japanese.[178]

Typically, the TB level rises steadily, peaking at 5-10 mg/dL (86-171 μmol/L) at about 2 weeks of age, with a gradual decline over the first several months of life. More severely affected neonates may achieve peak levels as high as 20-30 mg/dL (342-513 μmol/L). There is no evidence of hemolysis, nor do these neonates appear ill; weight gain and intestinal function are normal. Pregnane-3-α,20-β-diol, a progesterone metabolite found in the breast milk fed to affected neonates, was historically thought to be the cause of this disorder, because this substance was shown to be a competitive inhibitor of UGT1A1 in vitro. Although milk and urine of mothers of these neonates contain this pregnanediol isomer, the inhibitory effect of this hormone has been questioned. Studies have indicated that the milk associated with this syndrome also contains high concentrations of non-esterified long-chain fatty acids. This suggests that certain of these fatty acids act as inhibitors of hepatic UGT1A1, causing retention of unconjugated bilirubin. It is unlikely that the non-esterified long-chain fatty acids would reach the sites of conjugation in smooth endoplasmic reticulum of hepatocytes without prior esterification. Triglycerides of these long-chain fatty acids do not inhibit in vitro activity of UGT1A1. Neither the pregnanediol nor the fatty acids have ever been substantiated as an inhibitor of hepatic conjugation in vivo, and their role in the cause of the breast milk jaundice syndrome remains questionable.

Studies of the enterohepatic circulation of bilirubin in the rat suggest that milk from mothers of neonates with this syndrome contains β-glucuronidase, an enzyme that could deconjugate bilirubin and, consequently, enhance enteric

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

reabsorption of bilirubin, thereby increasing the hepatic bilirubin load. The presence of this enhancer of intestinal bilirubin absorption in human milk strongly correlates with the presence of mild to moderate unconjugated hyperbilirubinemia in neonates during the second and third weeks of life. With more than 50% of all breastfed neonates manifesting this effect of breast milk, this phenomenon may be a normal physiologic development comparable to, and an extension of, physiologic jaundice of the early newborn period.

Usually, other than jaundice, the neonates appear healthy, and no abnormal findings are noted. Although not recommended unless TB concentrations reach phototherapy levels or those that might be of danger to the infant, interruption of nursing and substitution with formula feeding for 1-3 days frequently causes a prompt decline of TB levels. On resumption of nursing, TB levels do not usually increase substantially. Brief interruption of nursing may be useful to confirm the diagnosis, thereby allaying parental anxiety. Failure to respond in this manner indicates that the neonate's jaundice may be unrelated to breastfeeding, and other causes should be sought. Supplementation with milk formula may have an effect similar to complete cessation of nursing. An alternative to temporary cessation of breastfeeding would be to confirm that the TB is primarily unconjugated, that thyroid function tests are normal, and that there is no evidence of urinary infection. In the situation where the infant is thriving and the TB does not reach levels indicating the need for phototherapy, it may be prudent to just observe the infant. It should not be forgotten, however, that rare disorders of bilirubin conjugation may occur in breastfeeding infants and may lead to erroneous diagnoses. Effective nursing practices that prevent early "starvation" in breastfed newborns may reduce not only the incidence of breastfeeding failure jaundice but also the severity of breast milk jaundice.[8,177]

Sequelae of Unconjugated Hyperbilirubinemia

The recognition that unconjugated bilirubin may penetrate the brain cell under certain circumstances and its association with neuronal dysfunction and death are reasons for carefully managing newborn infants with significant hyperbilirubinemia.[9,11] There is some evidence that, despite the publication of national guidelines for the prevention and management of hyperbilirubinemia in several countries (United States, Canada, South Africa, the United Kingdom, Norway, Israel, Japan, and the Netherlands), kernicterus continues to occur in industrialized countries in which the condition was thought to have been "extinct."[69,79,172,242] ABE (defined as the acute manifestations of bilirubin neurotoxicity) and its resultant sequelae, kernicterus (defined as chronic and permanent sequelae of bilirubin neurotoxicity) should, for the most part, be preventable conditions. Concerns that risks for ABE or kernicterus have been exaggerated with regards to term, otherwise healthy neonates have been outweighed by the perpetuation of cases up to present times.[14]

There is no single TB concentration that can be regarded as safe or categorically dangerous. The TB level, although used clinically to determine the need for phototherapy and exchange transfusion, is a poor predictor of subsequent neurodevelopmental outcome. In a study of 140 newborns with TB values greater than 25 mg/dL (428 µmol/L) who were treated with phototherapy or exchange transfusion, 5-year outcomes were not significantly different from those of randomly selected controls. Re-analyzing data from the Collaborative Perinatal Project, Kuzniewicz and Newman found no relationship between maximum TB levels and IQ scores.[148,195] However, in both aforementioned studies, the presence of a positive DAT did result in a poorer prognosis than the general population studied. Of 249 newborns admitted to a children's hospital in Cairo, Egypt, with TB values 25 mg/dL (428 µmol/L) or greater, Gamaleldin et al. found little correlation between admission TB levels and ABE.[93]

It is unlikely that in an otherwise healthy term infant with no obvious hemolytic condition, bilirubin neurotoxicity will occur at TB concentrations below 25 mg/dL (428 µmol/L), or even higher.[265] In the presence of hemolysis, prematurity, or other risk factors (see later), or in the presence of poor relative health, the danger point may be reached at lower levels of TB.[68,121] In a term infant thought to be actively hemolyzing, a TB concentration of 18-20 mg/dL (308-343 µmol/L) should probably not be exceeded.[42,50] In California, any TB >30 mg/dL is rare (8.6 per 100 000 births), and chronic bilirubin-induced neurotoxicity is uncommon and occurrs only in the setting of additional risk factors and TB values substantially above the AAP exchange transfusion thresholds.[149] Until definitive scientific data indicate otherwise, hyperbilirubinemia should be seen as being capable of producing a spectrum of neurologic dysfunction in the newborn, ranging from transient mild encephalopathy to permanent severe neurologic impairment secondary to neuronal necrosis (kernicterus). In addition, it is important to understand that bilirubin metabolism is a dynamic process influenced by many factors. An isolated TB level obtained at one point in time is inadequate to fully assess the risk for sequelae for a particular neonate. Many other factors, including the gestational age and relative health of the newborn, need to be carefully evaluated.

Epidemiology of Kernicterus and Extreme Hyperbilirubinemia

Did Kernicterus Really Disappear and Then Resurface?

Some authorities refer to a disappearance and resurgence of kernicterus in Westernized countries during the last decades.[107] Others claim that the condition never completely disappeared and as a result is still being seen. Undoubtedly, phototherapy and exchange transfusion, along with

immune prophylaxis of Rh isoimmunization, have prevented many cases of kernicterus. The disappearance theory cannot explain cases of kernicterus still occurring owing to G6PD deficiency and DAT-positive ABO immunization, both common to this day.

The evidence for and against the disappearance/resurgence theory is inconsistent. In favor is a dearth of reported cases followed by several case reports and culminating in the US-based Kernicterus Registry report.[159,168] In Denmark, cases of bilirubin encephalopathy were found between 1994 and 2001 but not during the 20 years preceding that period. However, in the United States, Burke et al. reported a 70% decrease in the number of hospitalizations between 1988 and 2005 for kernicterus.[46] There was a constant incidence of kernicterus in California occurring during two time epochs: 1988-1993 and 1994-1997, whereas on a national United States basis, mortality data due to kernicterus from the Centers for Disease Control and Prevention databases remained consistent between 1979 and 2006.[46] Overshadowing this debate is the fact that cases of kernicterus with major public health implications are still occurring.

How Frequent Is Kernicterus?

The incidence of kernicterus varies from country to country, as well as between industrialized countries and countries with developing medical systems. Estimates in developed countries range from about 0.4-2 per 100,000.[45] Table 91.1 summarizes the frequency of the condition in some Westernized countries. In addition, recent cases of kernicterus have been reported from Italy and Germany.

These reports shared several common epidemiologic and etiologic features, including ABO heterospecificity, G6PD deficiency, other isoimmunizations, late prematurity, breastfeeding, sepsis, male gender, and discharge prior to 48 hours. It is remarkable that many of the infants were discharged as healthy from birth hospitalization but were subsequently readmitted for extreme hyperbilirubinemia.

TABLE 91.1 Incidence (per Live Births) of Kernicterus in Westernized Countries

Country/State	Years of Birth	Incidence of Kernicterus
Denmark	1994-1998	1/64,000
Denmark	1994-2003	1/79,000
United Kingdom	2003-2005	1/150,000
Canada	2007-2008	1/43,000
California*	1988-1997	0.44/100,000

*California data from Brooks JC, Fisher-Owens SA, Wu YW, Strauss DJ, Newman TB. Evidence suggests there was not a "resurgence" of kernicterus in the 1990s. *Pediatrics*. 2011;127:672-679.
Adapted, in part, from Maisels MJ. Neonatal hyperbilirubinemia and kernicterus—not gone but sometimes forgotten. *Early Hum Dev*. 2009;85:727-732.

African-American ethnicity and minority groups were over-represented, relative to the baseline population, in the United States and United Kingdom/Ireland reports.

Kernicterus in Developing Countries

Kernicterus, with a high incidence of bilirubin-attributable neonatal mortality, continues to occur in countries where G6PD deficiency is indigenous, as well as in developing countries with underdeveloped health services or in war zones as illustrated in a recent report from Baghdad, Iraq.[105] Other recent reports derive from Nigeria, Oman, Turkey, Kuwait, and Egypt.[93]

Surrogates for Assessing the Incidence of Kernicterus: Extreme Hyperbilirubinemia and Readmission

Although a devastating condition, kernicterus is in fact rare, and it is difficult to assess its incidence in any specific population group. Surrogates for the potential to develop bilirubin neurotoxicity have been sought, including the incidence of extreme hyperbilirubinemia [TB >25 mg/dL (428 μmol/L) or 30 mg/dL (513 μmol/L)] or the incidence of readmission for hyperbilirubinemia.[87] Overall, the rate of extreme hyperbilirubinemia or one of the alternatives should be low, provided surveillance for hyperbilirubinemia both during birth hospitalization and postdischarge is effective, although a zero rate will be difficult to obtain.

The reported range for readmission for hyperbilirubinemia lies between 0.17% and 3.2%.[40,180] The main reasons for readmission include lower gestational age, late prematurity, early discharge, unsuccessful breastfeeding, and lack of predischarge assessment of the risk for subsequent hyperbilirubinemia. The high risk for readmission of early term newborns in combination with early discharge was recently documented in Australia: Neonates born at 37 weeks' gestation and who were discharged at ≤48 hours were readmitted for hyperbilirubinemia at a ninefold higher frequency than those born at 39 weeks' gestation and remained in hospital for 3-4 days.[150] In Utah, late preterm and early term newborns were readmitted at higher rates than term counterparts, emphasizing the need to assess these babies' readiness for discharge and to vigilantly follow them for the development of hyperbilirubinemia after discharge.[291] Extreme hyperbilirubinemia, despite the close surveillance and ready availability of treatment in an organized health system in California, occurred in 0.14% of newborns (TB ≥25 mg/dL [428 μmol/L]), while 0.01% had TB values ranging from 30.5-45.5 mg/dL (522-778 μmol/L).[196] Within a health system in Detroit, Michigan, only 0.6% of infants compared to 2% in the California survey developed a TB of 20 mg/dL (342 μmol/L) or greater.[57] This difference was attributed to rigorous bilirubin screening, follow-up, and treatment.

Again in California, 0.12% of 18,089 newborns 35 weeks' or greater gestational age developed TB levels that exceeded the AAP[12] indications for exchange transfusion. It is remarkable that the majority of the affected infants were less than 38 weeks' gestational age.[90]

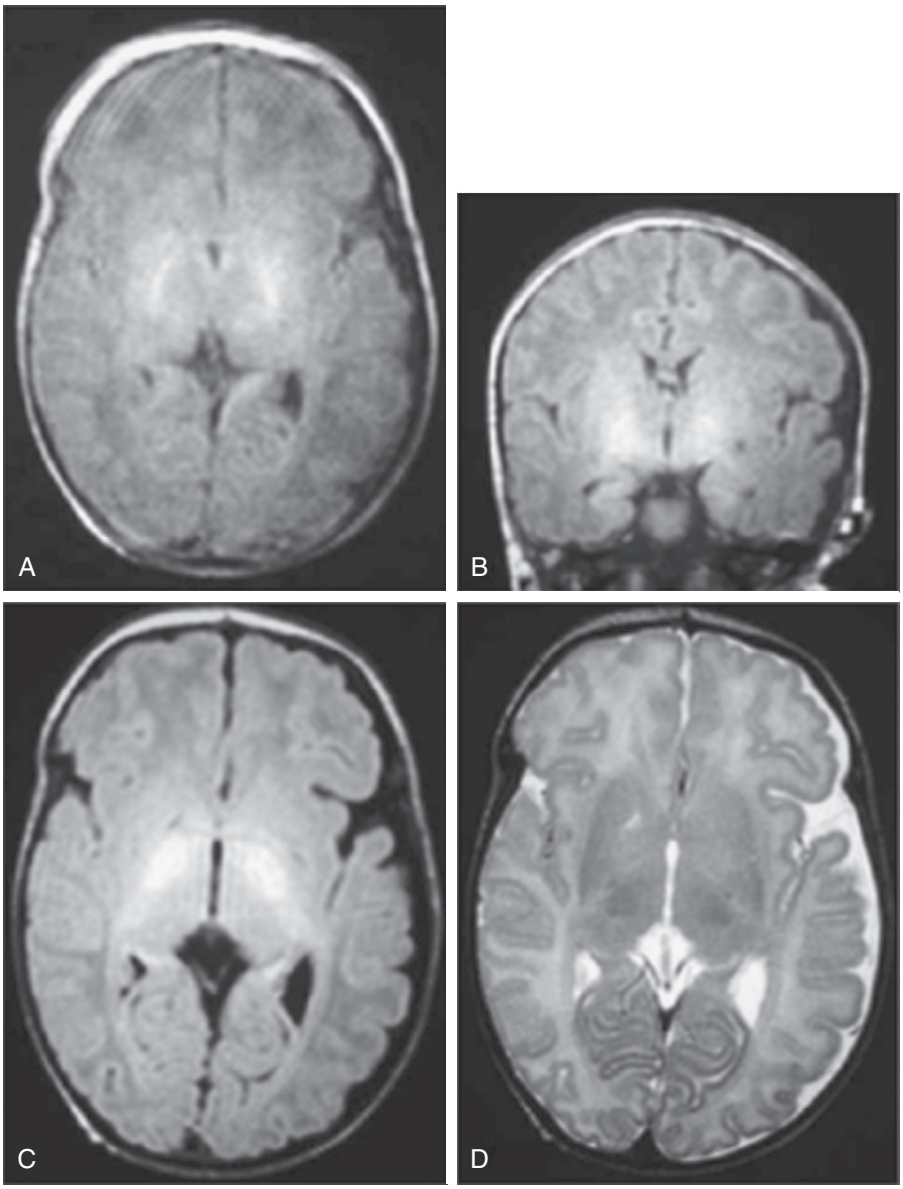
Transient Encephalopathy or Acute Bilirubin Encephalopathy (ABE)

ABE is characterized by lethargy, poor feeding, hypotonia, and a high-pitched cry in a severely jaundiced infant. Hyperextension of the extensor muscles and back arching may ensue.[241] Early bilirubin toxicity may be transient and reversible, and not all infants displaying signs of ABE will necessarily go on to the full-blown clinical picture of kernicterus.[35,108,111,173] This is suggested by clinical observations of increasing lethargy and other signs in tandem with rising TB levels, with reversal of the symptoms after exchange transfusion. In Egyptian newborns with severe hyperbilirubinemia, a BIND score, based on mental status, muscle tone, and cry patterns, was used to predict residual neurologic and hearing dysfunction at 3-5 months of age. Those with high scores either died or were left with residual neurologic and auditory impairments. Low BIND scores were associated with a high rate of normalcy at follow-up after aggressive intervention. However, the BIND score was not an absolute predictor; some infants with low BIND scores but very high TB levels did have neurologic residua at follow-up.[83] Moreover, extreme hyperbilirubinemia in the absence of clinical evidence of ABE may be indicative of a favorable prognosis. In a 10-year Danish study, no evidence was found of an increased risk of deficits in motor development, executive function, or hearing in children who had had extreme neonatal hyperbilirubinemia but did not have intermediate or advanced bilirubin encephalopathy.[266]

Brainstem auditory-evoked responses (BAERs) may show changes in the wave latency and magnitude, characteristic of early signs of ABE.[245] BAER signs typically encountered in neonates with moderate unconjugated hyperbilirubinemia (10-20 mg/dL [171-342 µmol/L]) include prolongation of latencies of waves III and IV-V, and interpeak I-III and I-V, compared with neonates of similar gestational and postnatal ages without hyperbilirubinemia. Prolonged latencies in peak IV-V and interpeak I-V suggest interference with brainstem conduction. These changes in evoked responses reverse with either exchange transfusion or spontaneous decline in TB levels.

Long-term follow-up of children with neonatal abnormalities in brainstem responses believed to be caused by hyperbilirubinemia is not yet available, and the significance of abnormal BAER findings remains unknown.[285] An abnormal BAER suggests an injury of the VIII cranial nerve. Bilirubin neurotoxicity affects the neural tissues of the auditory center and nerve but not the cochlea. Therefore, bilirubin-induced auditory neuropathy may occur even in the context of normal cochlear function as measured by otoacoustic emission (OAE). This emphasizes the need to perform BAER testing, and not to rely on OAE, in neonates who are suspected of having auditory damage due to hyperbilirubinemia. During the early stages of bilirubin neurotoxicity, a characteristic signal signature can be seen by magnetic resonance imaging (MRI) using T1- and T2-weighted imaging.[99] Consequently, the presence of an abnormal BAER, normal OAE, and focal changes in the globus pallidus and medial lobe of the hippocampus by MRI is highly suggestive of ABE (Fig. 91.14).



• **Fig. 91.14** Acute bilirubin encephalopathy. Coronal section through parietotemporal lobes. Note selective symmetric yellow discoloration in the hippocampus and subthalamic nuclei. Thalamus and globus pallidus are focally stained. (From Zangen S, et al. Fatal kernicterus in a girl deficient in glucose-6-phosphate dehydrogenase: a paradigm of synergistic heterozygosity. *J Pediatr*. 2009;154:616-619.)

Kernicterus

If early ABE is unrecognized or untreated, it may progress to permanent neurologic impairment. The term *kernicterus* (German *kern*, kernel or nucleus, and *ikteros*, jaundice) has been traditionally used to describe the pathologic findings of bilirubin toxicity within the brain: staining and necrosis of neurons in the basal ganglia, hippocampal cortex, subthalamic nuclei, and cerebellum, followed by gliosis of these areas in survivors (Fig. 91.15). The cerebral cortex is generally spared. About half of all infants with kernicterus observed at autopsy also have extraneural lesions of bilirubin toxicity. These include necrosis of renal tubular cells, intestinal mucosa, and pancreatic cells in association with intracellular crystals of bilirubin. Gastrointestinal hemorrhage may accompany these lesions.[263]

Kernicterus is also used to describe the clinical presentation of worsening encephalopathy. In the term newborn, several phases have been classically described, progressing from ABE in the early stages to chronic athetoid cerebral palsy later. Phase 1 is marked by poor sucking, hypotonia, and depressed sensorium. Fever, retrocollis, and hypertonia that may progress to frank opisthotonos are seen in phase 2. The hypertonia becomes less pronounced in phase 3, but high-pitched cry, hearing and visual abnormalities, poor feeding, and athetosis are manifest. Seizures may also occur. The usual time course for progression of the disease is about 24 hours. Long-term survivors often demonstrate the classic signs of kernicterus. These include a tetrad of: (1) choreoathetoid cerebral palsy; (2) upward gaze palsy; (3)

• **Fig. 91.15** Magnetic resonance images of a 21-day-old, preterm male neonate with acute kernicterus. Axial (**A**) and coronal (**B**) T1-weighted and axial FLAIR (**C**) images at the level of the basal ganglia show symmetric, hyperintense globus pallidus involvement. This is not apparent on the axial T2-weighted (**D**) image. (From Coskun A, et al. Hyperintense globus pallidus on T1-weighted MR imaging in acute kernicterus: is it common or rare? *Eur Radiol*. 2005;15:1263.)

sensorineural hearing loss; and (4) dental dysplasia during later infancy and childhood.[244] The intellect may be spared, and mental retardation is not universally encountered. However, children with normal intelligence frequently have severe physical handicaps, making rehabilitation, education, and independent living unlikely. These sequelae of bilirubin toxicity may also develop in neonates who never manifested clinical signs of ABE during the newborn period. In addition, some neonates may have sequelae of subclinical bilirubin encephalopathy characterized only by the later development of mild disorders of motor function or abnormal cognitive function, or both.

A recent report of 25 California cases of strictly defined kernicterus illustrates the dismal picture of these unfortunate children. At a mean age of 7.8 ± 3.9 years old, 60% did not walk at all, and only 16% were able to walk unaided. Self-feeding was possible in only 52%, while a feeding tube was in place in 12%. Severe or profound mental retardation or severe disabilities were found in 36%, with only 32% having no evidence of mental retardation. Epilepsy and severe, profound or untestable visual and auditory impairment were common, with only 36% having normal hearing. Motor spasticity, ataxia and dyskinesis, and hypotonia completed the clinical picture in many others.

Kernicterus in Preterm Infants and Low-Bilirubin Kernicterus

Presentation in preterm neonates is less stereotypical, and these patients may simply appear ill without signs specific for kernicterus. Bilirubin may enter the brain at lower levels of TB than would be expected in term infants. Moreover, bilirubin staining of central nervous system (CNS) structures in premature neonates may not be indicative of overt kernicterus and may result from developmental differences in CNS permeability to bilirubin and in situ bilirubin metabolism. Mortality occurs in about 50% of term newborns but may occur more frequently in the preterm population with kernicterus.[2,206,207] Based on a recent Japanese survey, it is estimated that 2/1000 preterm infants <30 weeks' gestational age developed kernicterus. Many did not have TB levels in the hyperbilirubinemic range, suggesting that the unbound bilirubin component may have been high in those affected.[186]

Low-bilirubin kernicterus can and does occur in premature infants at TB levels lower than what would be expected to be associated with neurotoxicity and at levels lower than those indicating phototherapy or exchange transfusion. Low-bilirubin kernicterus is a condition that was encountered in the past during autopsy examinations of premature infants in whom TB did not reach excessive levels that were thought to be neurotoxic. It is still encountered today in premature infant survivors who did not have very high TB levels, but who have clinical and MRI evidence of kernicterus. Low-bilirubin kernicterus has been defined as the occurrence of kernicterus at TB levels below commonly recommended exchange transfusion thresholds.[279] Because of the low nature of the TB in this situation, in the range not necessarily obligating phototherapy, the condition is unpredictable and the consequences refractory. Adherence to an accepted guideline is not a guarantee that some infants will not be unscathed. No guideline can be expected to prevent illness in every individual. It is not known what factors potentiate bilirubin neurotoxicity at low TB levels. Some factors that have been implicated include low serum albumin (almost ubiquitous in sick, unstable premature infants) and co-morbid CNS injury, including intraventricular hemorrhage, periventricular leukomalacia, and infection. Given the occurrence of the condition at low TB levels, it is unlikely that the condition will be eliminated barring a significant lowering of exchange transfusion thresholds, with the potential of bringing in its wake a plethora of complications (infections, hemorrhage, blood pressure instability, necrotizing enterocolitis, complications related to blood transfusion in general) associated with this procedure.

Bilirubin Entry into the Brain

Bilirubin is thought to enter the brain through multiple mechanisms. These include: (1) bilirubin production that overwhelms the normal buffering capacity of the blood and tissues; (2) alterations in the bilirubin-binding capacity of albumin and other proteins resulting in the presence of unconjugated bilirubin in the circulation; (3) increased CNS permeability to bilirubin secondary to disruption of the blood–brain barrier; and (4) other factors that may affect those previously mentioned or act through novel independent mechanisms.

Unconjugated bilirubin is nonpolar and lipid soluble, and its aqueous solubility in plasma water is extremely small, mandating its binding in plasma primarily to albumin. Binding to other components of blood (β-globulin, RBC membranes, and platelets) may also occur when the albumin-binding capacity for bilirubin is exceeded. It has long been believed that bilirubin toxicity occurs when the albumin-binding capacity for bilirubin is saturated and the unbound or "free" bilirubin (bilirubin in aqueous phase) concentration rises in blood. Whether this is, in fact, the basic pathophysiologic mechanism of kernicterus remains unresolved.

The human albumin molecule is capable of binding at least two molecules of bilirubin, with the first molecule more tightly bound than the second. Additional classes of binding sites, if operative in vivo, have much lower affinities than the first two. At a molar ratio of 1, each gram of human albumin binds 8.2 mg of bilirubin. Thus, at an average albumin concentration of 3 g/dL, the first binding site should be capable of binding 25 mg of bilirubin/dL of serum or plasma. The second binding site should be capable of binding an additional 25 mg/dL for a total binding capacity of 50 mg/dL.

Various techniques have been proposed to measure albumin binding of bilirubin, but their application and interpretation in clinical management are not generally accepted. The dye-binding methods using 2-(4'-hydroxybenzeneazo) benzoic acid and direct-yellow-7 are based on the measurement of reserve binding sites on the albumin molecule and should be capable of indicating impending risk. The column chromatographic methods (Sephadex G-25), the salicylate displacement spectrophotometric method (saturation index), the RBC uptake method, and the oxidation technique (peroxidase method) should all be capable of detecting small increases in unbound bilirubin or "loosely bound" bilirubin, in theory, denoting increased risk for developing kernicterus.[3,4] However, current laboratory and clinical data are still insufficient to permit a recommendation for the use of either a single method or a combination of methods to guide the clinical management of infants with neonatal unconjugated hyperbilirubinemia. Furthermore, it may be falsely reassuring to assume that in vitro binding capacities will remain reliably static in an in vivo system that changes so dynamically during the first postnatal days.

The bilirubin-binding capacity of albumin is thought to be decreased in sick term and premature human neonates. In addition, the serum albumin concentration is often lower in these patients than in healthy, term counterparts. Theoretically, both of these factors may act to place the sick term or premature neonate at higher risk for kernicterus at lower TB levels than seen in the healthy term newborn. There

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

is still debate about whether the bilirubin-binding capacity of albumin decreases as pH drops below 7.4, despite the known solubility decrease of bilirubin with increasing acidity. Numerous agents compete with bilirubin for binding sites on albumin, acting to displace bilirubin and increase the ratio of free to bound bilirubin. Free fatty acids, which are elevated in sepsis and hypoxemia, are capable of displacing bilirubin. Similarly, IV lipid emulsions rarely can contribute to elevated free fatty acids and thus displacement of bilirubin. Sulfisoxazole and other sulfa drugs, indomethacin, and salicylates readily displace bilirubin. Even ampicillin, when injected rapidly, has the potential to act in a similar manner. Benzyl alcohol, once used as a preservative in various medications, has been shown to competitively inhibit bilirubin binding. Finally, certain substances used in the preparation of albumin solutions may act to decrease its bilirubin-binding capacity.[275]

Disruption of the blood–brain barrier allows the passage of molecules otherwise prevented from entering the CNS. Hypertonicity of the serum, meningitis, and hypoxemia all increase CNS permeability to bilirubin.[109] It has been reported that unconjugated bilirubin is a substrate for phosphorylated glycoprotein (P-GP) and that P-GP in the blood–brain barrier may play a role in limiting the entry of bilirubin into the CNS. P-GP is an integral plasma membrane transport protein, dependent on ATP, which can transport a wide variety of substrates across biologic membranes.

Many other factors may play a role in regulating bilirubin entry into the brain. Kernicterus has been reported to occur in adults with Crigler-Najjar syndrome type I, but only when TB levels have reached 45-55 mg/dL (770-941 μmol/L). This contrasts with the situation in the full-term newborn in which kernicterus may be anticipated at somewhat lower concentrations, suggesting presence of a maturational process in the blood–brain barrier integrity.

In addition to bilirubin produced within the reticuloendothelial system, bilirubin may be produced within the brain. The mammalian brain has two isoforms of HO, HO-1 and HO-2, which convert heme to biliverdin. HO-1 normally shows little baseline activity in the brain but is capable of being rapidly upregulated in response to stress. Most HO activity in the brain is the result of the constitutive isoform HO-2. HO-1 and HO-2 are distributed in selected areas of the brain, many of which play roles in motor and auditory function. Biliverdin reductase is also found in the brain, catalyzing the conversion of biliverdin to bilirubin. Although bilirubin thus formed is normally rapidly cleared by bilirubin oxidase, it is possible that this fraction of the bilirubin pool does contribute to the development of kernicterus. These enzyme systems are developmentally regulated and may also be influenced by any of the disease states previously mentioned. Because the bilirubin produced and metabolized in situ must be transported out of the brain, interference with this transport mechanism may be another potential mechanism of contributing to kernicterus.

Once bilirubin has gained access to the CNS, there are several postulated mechanisms of neuronal injury: (1) passage through lipid moieties of cell membranes into the lipids of subcellular organelles such as mitochondria, interfering with critical steps in energy metabolism; (2) binding to specific membrane, organelle, or cytoplasmic proteins and inhibiting their function; and (3) damage and direct interference with the function of DNA.[64]

The neurotoxicity of bilirubin is currently being debated. As described earlier, HO catalyzes the conversion of heme to biliverdin, releasing equimolar amounts of CO. CO may function as a neurotransmitter within the CNS and has been implicated as playing a role in memory. However, CO may also act as a neurotoxin and have deleterious effects, including neuronal necrosis. The deposition of bilirubin in the brain of patients with kernicterus may not be the primary insult but rather may be a relatively innocuous marker of neuronal damage produced by other means. Bilirubin has antioxidant properties and may, at physiologic levels, provide protection from oxidative injury. Whatever the mechanism of bilirubin neurotoxicity, clinical decisions regarding the management of hyperbilirubinemia and the institution of therapy are based on the TB level, and given its apparent effectiveness in reducing the incidence of kernicterus, it would be unwise to alter the current approach to therapy.

Bilirubin-Induced Neurologic Dysfunction (BIND)

BIND represents a spectrum of neurologic disorders, less severe than classic choreoathetotic cerebral palsy, but nevertheless, attributable to bilirubin neurotoxicity. Neonates are usually exposed to TB levels of lesser severity than encountered in classic kernicterus, but the clinical picture may manifest as a range of subtle processing disorders including disturbances of vision, motor ability, auditory and speech function, cognition, and language.[32,122]

Diagnosis of Unconjugated Hyperbilirubinemia

About two-thirds of the more than 4 million neonates born annually in the United States become clinically jaundiced. Clearly, the number of jaundiced neonates who will develop sequelae of hyperbilirubinemia is substantially less than this. The challenge to the pediatrician is to determine which newborns may become or are already abnormally jaundiced and, therefore, are at risk for severe sequelae. The recommendations by the AAP[12] for the laboratory evaluation of the jaundiced infant at 35 weeks of gestation or later are listed in Table 91.2.

Total Bilirubin (TB) Measurements

When the clinical screening examination detects a jaundiced newborn, the mainstay of clinical management includes

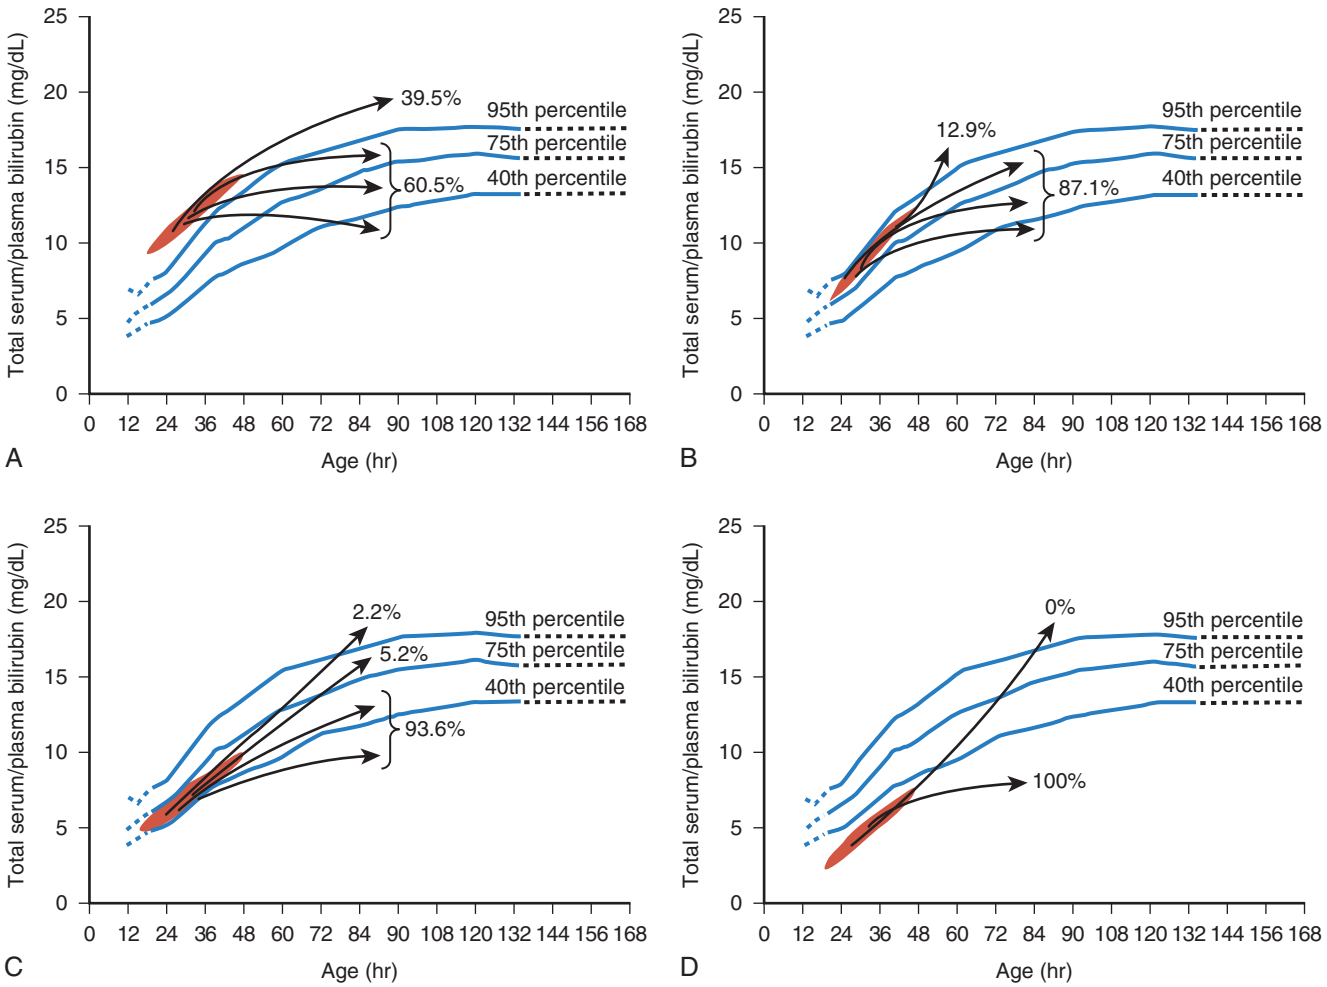
TABLE 91.2 Laboratory Evaluation of the Jaundiced Infant ≥35 Weeks of Gestation

Indications	Assessments
Jaundice in first 24 hours	TcB and/or TB
Jaundice appears excessive for age	TcB and/or TB
Infant receiving phototherapy or TB rising rapidly (i.e., crossing percentiles [see Fig. 91.16]) and unexplained by history and physical examination	Blood type and Coombs' test, if not obtained with cord blood CBC and smear Direct or conjugated bilirubin Optional: reticulocyte count, G6PD, ETCOc, if available Repeat TB in 4-24 hours, depending on infant age and TB level
TB concentration approaching exchange levels or not responding to phototherapy	Reticulocyte count, G6PD, albumin, ETCOc (if device available)
Elevated direct (or conjugated) bilirubin level	Urinalysis and urine culture Evaluate for sepsis indicated by history and physical examination
Jaundice present at or beyond age 3 weeks, or if the infant is sick	Total and direct (conjugated) bilirubin level If direct bilirubin elevated, evaluate for causes of cholestasis Check results of newborn thyroid and galactosemia screen; evaluate for signs and symptoms of hypothyroidism

CBC, Complete blood count; ETCOc, end-tidal carbon monoxide, corrected for inhaled CO; G6PD, glucose-6-phosphate dehydrogenase; TB, total bilirubin; TcB, transcutaneous bilirubin.
From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114:297.



determination of TB concentrations in serum or plasma. Direct bilirubin measurements will not contribute much information in the early stages of jaundice but should be performed in cases of prolonged hyperbilirubinemia or of hyperbilirubinemia not responding to therapy, or if a disease process is suspected. In most patients, repeat determinations will be necessary in the acute stage of jaundice to determine the trajectory, the peak TB level, and whether indications for instituting therapy have been reached. Following that, an at least daily determination should be performed until a clear pattern of decline is observed. Clinical judgment is necessary to determine whether TB concentrations may be monitored on an ambulatory basis, thereby eliminating the need for prolonged hospitalization, or whether the risk for severe hyperbilirubinemia warrants in-hospital observation. Thus, the clinician must determine whether any individual neonate is at high or low risk for developing severe hyperbilirubinemia or kernicterus. Neonates at high risk for kernicterus include those presenting with jaundice in the first 24 hours of life, with pallor or hepatosplenomegaly, and with documented immune or nonimmune hemolytic conditions.

Bhutani and colleagues, in a study performed in 1999 on a racially diverse population of term healthy newborns, established that a percentile-based, hour-specific bilirubin nomogram of predischarge TB levels can accurately predict an infant's level of risk for developing hyperbilirubinemia[26] (see Fig. 91.10). Infants with a predischarge TB in the 95th percentile or higher (high-risk zone) had a 57% risk for developing severe hyperbilirubinemia (TB of 17 mg/dL [291 µmol/L] or greater). Risk was 13% for infants in the high-intermediate zone (TB between the 75th and 95th percentiles). Infants with TB levels between the 40th and 75th percentiles (low-intermediate risk) had a risk of 2.1%. Infants with TB in the 40th percentile or less had no risk. However, an analysis of predischarge TB values in 143 neonates who were readmitted for hyperbilirubinemia demonstrated a false negative predischarge bilirubin screen in 6 (4.2%) in the low-risk zone (<40th percentile) and 40 (28%) in the intermediate low-risk zone (41st-75th percentile).[40] The results of this and another study[249] suggest that predischarge TB values in the low-risk zones may not be benign, confirming the 2004 AAP recommendations for follow-up for all neonates within a few days of discharge.[12]

All TB measurements should be plotted on the hour-specific Bhutani nomogram, which takes into account the rapidly occurring changes in TB concentrations. It is clear from a study of the nomogram that an individual TB reading may have different connotations depending on the postnatal hour at which the blood was sampled. The closer the TB reading to the 95th percentile, the greater becomes the risk for subsequent hyperbilirubinemia. Conversely, a TB reading below the 40th percentile is usually associated with a low risk for hyperbilirubinemia. A useful method of assessing whether the rate of rise of TB is greater than normal (0.2 mg/dL/h or greater) is to plot several TB points on the graph and determine whether the trajectory runs in parallel with the graph or at a more rapid rate or "jumping" to a higher percentile track (Fig. 91.16). TcB may provide a useful, quick, and painless method of assessing these bilirubin modalities (see Transcutaneous Bilirubinometry later).

Classification of hyperbilirubinemia as conjugated or unconjugated requires fractionation of serum or plasma bilirubin into direct- and indirect-reacting pigments, respectively. Simple techniques that fail to distinguish direct- from indirect-reacting fractions are not recommended, but they may be useful as less expensive methods for screening and frequent repeat determinations and in emergency situations. The prototype of colorimetric methods is the van den Bergh test, a modification of the Ehrlich diazo reaction. The Jendrassik-Grof method has also been used widely as an automated procedure in many hospital laboratories.

• **Fig. 91.16** Outcome of newborns as defined by the percentage of newborns that remain or move up to the high-risk zone after their risk assessment with the predischarge total serum/plasma bilirubin (TB) value (represented by the *red shaded areas*). **A,** Outcome for newborns designated in the high-risk zone ($N = 172$). **B,** Outcome of newborns in upper-intermediate-risk zone ($N = 356$). **C,** Outcome of newborns in the lower-intermediate-risk zone ($N = 556$). **D,** Outcome of newborns in the low-risk zone ($N = 1756$). (From Bhutani VK, et al. Predictive ability of a pre-discharge hour-specific TB level for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics*. 1999;103:6.)

Newer automated methods such as the Ektachem system provide greater precision and the ability to measure the covalently bound δ-bilirubin. Compared with the values of direct bilirubin obtained by high-performance liquid chromatography, the Jendrassik-Grof and other diazo methods exaggerate this fraction to variable degrees. These older, nonspecific diazo reaction methods also fail to measure the δ-bilirubin fraction, underestimating TB by 0.2-0.3 mg/dL (3-5 μmol/L) in the normal adult. High-performance liquid chromatography probably provides the most accurate measurement of TB but is impractical for routine clinical laboratory use. The Ektachem method has gained wide acceptance. It uses a dry film system for measurement of TB and subfractions (indirect, direct, and δ) for general clinical laboratory use. The adult upper limit of normal for TB by this method is 1.3 mg/dL (22 μmol/L) and for the conjugated fraction, 0.3 mg/dL (5 μmol/L), of which two-thirds is in the form of δ-bilirubin. For newborns younger than 2 weeks, a simpler and less expensive single-film method can be used, omitting measurement of δ-bilirubin, which is not found in this age group.

High levels of direct-reacting bilirubin reflect a different set of pathologic entities that do not respond to the usual interventions for unconjugated hyperbilirubinemia and will be considered later in this chapter. It is useful to consider four groups of newborns when making decisions regarding laboratory evaluation and therapy of unconjugated hyperbilirubinemia: (1) healthy term (more than 37 completed gestational weeks); (2) sick term; (3) healthy premature; and (4) sick premature neonates. Studies to date have dealt almost exclusively with the healthy term newborn. Although unconjugated hyperbilirubinemia is a disease of multiple causes, and neonates should be treated differently based on gestational age and relative state of health, some general comments can be made.

Further laboratory investigation should be considered when TB concentrations are: (1) 4 mg/dL (68 μmol/L) or greater in cord blood; (2) increasing at a rate of 0.5 mg/dL

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

(9 µmol/L) or greater per hour over a 4- to 8-hour period; (3) increasing at a rate of 5 mg/dL (86 µmol/L) or greater per day; (4) 13-15 mg/dL (222-257 µmol/L) or greater in full-term infants at any time; (5) 10 mg/dL (171 µmol/L) or greater in premature neonates at any time; or (6) when clinical jaundice persists beyond 10-14 days of life.

Further diagnostic studies are based on a thorough history and physical examination, which can narrow the differential diagnosis. A careful history from the parents may reveal familial patterns of neonatal hyperbilirubinemia or anemia or ethnic patterns associated with severe neonatal jaundice. Observation of the parents for jaundice and even determination of TB concentrations in them also may be useful in the diagnosis of familial types of hemolytic disease or inherited hepatic dysfunction. Patterns of feeding, the time of onset, and the frequency of breastfeeding also may be important. A careful physical examination with special attention to liver and spleen size, skin appearance, and neurobehavioral status should be performed in the evaluation of a jaundiced neonate.

Initial studies that may be indicated include determination of maternal blood group and Rh type; a screen for antibodies directed against minor erythrocyte antigens; determination of neonatal blood group and Rh type; direct antiglobulin titer (DAT), formerly known as the Coombs' test; hemoglobin or hematocrit; RBC morphology by peripheral blood smears; and reticulocyte counts. In the presence of significant jaundice with a potential ABO incompatibility (type O mother and type A or B infant), the DAT should be repeated at least once if originally negative, because initial false-negative results have often been noted. Hematologic indexes indicative of hemolysis in older children and adults may not be useful in the diagnosis of increased hemolysis in neonates because of overlap in these indices between hemolytic and nonhemolytic conditions. An elevated ETCOc level may be indicative of ongoing hemolysis (see End-Tidal Carbon Monoxide Measurements). Determination of erythrocyte G6PD activity may be useful in cases of unexplained hyperbilirubinemia, an exponential bilirubin trajectory, or hyperbilirubinemia not responding to intense phototherapy. Consideration of the family's ethnic group may be useful in deciding whether to perform a G6PD test. Cord blood should be saved in the event further testing is indicated.

More extensive studies for rarer forms of hemolytic disease and enzyme assays or genetic testing for UGT1A1 activity may be deferred until the chronicity of the disease has been established. Studies for hepatocellular disease (such as hepatitis and obstructive biliary disease), including serum glutamic-oxaloacetic transaminase (SGOT) and serum glutamic-pyruvic transaminase (SGPT), alkaline phosphatase, and cholesterol, need to be performed only when there is a significant elevation of conjugated bilirubin or liver disease.

Until a laboratory method is proved to accurately assess the risk for developing bilirubin neurotoxicity, the need for treatment and the progression from phototherapy to exchange transfusion must be based on clinical judgment in conjunction with consideration of TB, risk factors, gestational age, and the presence of hemolysis. The method of management chosen for an individual neonate is determined in part by the TB concentration at which therapy is instituted. The 2004 AAP Practice Guideline has formulated an established and uniform policy regarding the methods to be used and criteria for initiation of therapy.[12] The risk factors for the development of severe hyperbilirubinemia in infants 35 weeks' gestation or more are listed in Box 91.2.

Another problem in the assessment of any particular TB concentration involves variation within and between laboratories. High interlaboratory and interinstrument variations in the measurements of TB were reported. It was found that imprecision for a specific method or a given laboratory was acceptable, but inaccuracy was highly variable and should be taken into account in the interpretation of all TB measurements. Another factor contributing to these variations is the lack of appropriate bilirubin standards and consistent handling of clinical specimens. All these

• BOX 91.2 Risk Factors for Development of Severe Hyperbilirubinemia in Infants ≥ 35 Weeks of Gestation

Major Risk Factors

- Predischarge TB or TcB level in the high-risk zone (see Fig. 91.10)
- Jaundice observed in the first 24 hours
- Blood group incompatibility with positive DAT, other known hemolytic disease (e.g., G6PD deficiency)
- Gestational age 35-36 weeks
- Previous sibling received phototherapy
- Cephalohematoma or significant bruising
- Exclusive breastfeeding, particularly if nursing poorly and weight loss is excessive
- East Asian race

Minor Risk Factors

- Predischarge TB or TcB in the high intermediate-risk zone
- Gestational age 37-38 weeks
- Jaundice observed before discharge
- Previous sibling with jaundice
- Macrosomic infant of diabetic mother
- Maternal age ≥25 years
- Male sex

Factors Associated with Decreased Risk of Significant Jaundice*

- TB or TcB in the low-risk zone (see Fig. 91.10)
- Gestational age ≥41 weeks
- Exclusive bottle feeding
- African-American race
- Discharge from hospital after 72 hours

DAT, Direct antiglobulin test; G6PD, glucose-6-phosphate dehydrogenase; TB, total bilirubin; TcB, transcutaneous bilirubin.
*Listed in order of decreasing importance.
From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics.* 2004;114:297.

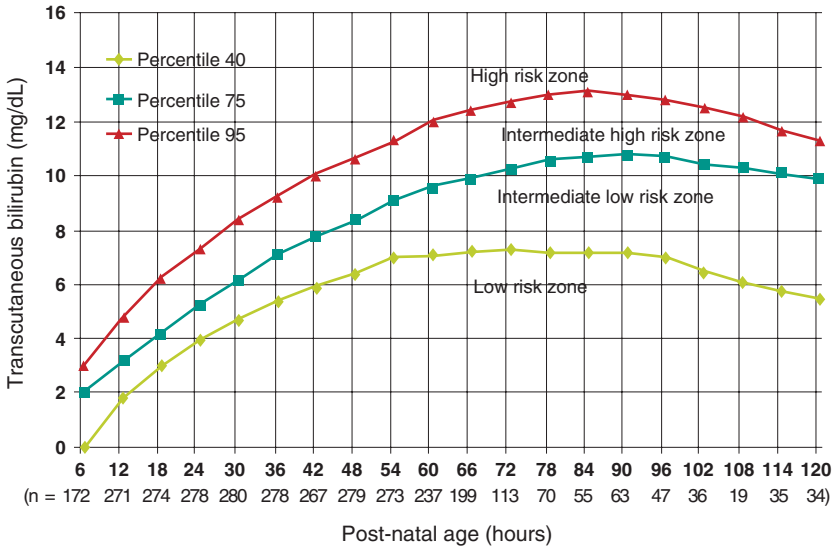
observations warrant the need for universal standardization of all bilirubin measurements. Lo and co-workers analyzed specimens of TB from the College of American Pathologists (CAP) Neonatal Bilirubin (NB) and Chemistry (C) surveys using the reference method.[156] They found that the use of different methods in the NB and C surveys, together with the presence of nonhuman protein base and ditaurobilirubin in the survey specimens, accounted for wide variations in accuracy and imprecision between instruments and laboratories. Furthermore, they recommend that survey samples should consist only of human serum enriched with unconjugated bilirubin.

The measurement of unbound or "free" bilirubin concentrations is another potential measure to assess the risk for developing bilirubin neuropathy or encephalopathy. Data are limited, but preliminary studies show that unbound bilirubin levels may be better correlated with BIND than the TB.[15,205,212,284] In late preterm and term infants with severe jaundice, it has recently been demonstrated that unbound bilirubin is a more sensitive and specific predictor of auditory neuropathy spectrum disorder than TB or bilirubin to albumin molar ratio (BAMR).[15]

Transcutaneous (TcB) Bilirubinometry

Historically, visual inspection has been the most commonly used means of screening newborns for hyperbilirubinemia. Jaundice progresses cephalocaudally. Digital pressure that blanches the skin diminishes the effects of pigmentation and local cutaneous perfusion and allows the detection of jaundice. Proper lighting is important in detecting subtle levels of jaundice. However, visual assessment is subjective, dependent on observer experience and is notoriously inaccurate.



TcB is a method using reflectance photometry or transcutaneous colorimetry as a noninvasive estimate of TB levels. The technique offers an objective measurement of skin color, from which a reading, reflecting the TB, is derived. The two devices most commonly used include the BiliChek (Philips Childrens Medical Ventures, Monroeville, PA) and JM-103 Jaundice Meter (Konica Minolta/AirShields JM 103 Jaundice Meter, Draeger Medical AG and Co, Lubeck, Germany), but others are also commercially available. They differ in their ease of use and their propensity to be affected by variations in skin color. A number of studies have shown that these instruments provide fairly accurate estimates of TB in term and near-term newborn infants of varying races and ethnicities, generally providing values within 2-3 mg/dL (34-51 µmol/L) of the TB if the TB is less than 15 mg/dL (257 µmol/L).[81] The technology tends to underestimate the actual TB level and should be regarded as a screening mechanism rather than an accurate reflection of the TB. The devices have been evaluated as potential predischarge screening tools to identify infants at risk (i.e., TB level at the 95th percentile or higher). As a result of these studies, hour-specific nomograms based on TcB measurements have been established both for term and late preterm infants.[165,267] It may be more prudent to plot TcB readings on a TcB nomogram than on a serum bilirubin-based nomogram such as that of Bhutani et al. However, additional studies are warranted to establish a strong and reliable correlation between TcB and TB at levels of 15 mg/dL (257 µmol/L) and higher, as well as during and after phototherapy and in premature or low birth weight infants, before its routine use can be advocated. The device has also been used successfully in community TcB screening.[273] Clinicians should be aware that there may be variation in results between devices[218,220] and overestimation of results in African-American neonates.[209] Akin to the TB-based nomogram, a recently developed TcB nomogram from Israel demonstrated a greater than 100-fold increase in neonates meeting requirements for phototherapy, from 0 in those whose highest TcB reading fell below the 40th percentile, through 27/120 (22.5%) for the >95th percentile group (Fig. 91.17).[41]

End-Tidal Carbon Monoxide (ETCO) Measurements

The breakdown of heme by the rate-limiting enzyme HO-1 produces equimolar quantities of CO and biliverdin, the latter which is reduced to bilirubin. Therefore, the measurement of CO in the end-tidal breath, corrected for ambient CO to derive ETCOc, can be used as an index of in vivo heme degradation and bilirubin production and, hence, hemolysis. Portable devices that provided automatic sampling and bedside analysis of ETCOc yielded results comparable to gas chromatography and have been used to accurately estimate heme catabolism in neonates, children, and adults. A new device is now currently available and has been used successfully.[30,51,60,61]

In a large multicenter study, Stevenson and colleagues found that a measurement of ETCOc at 30 ± 6 hours of age, alone or in combination with a TB measurement, did not improve the predictive ability of the age-in-hours-specific TB level, although it was as good as a measurement of TB alone for this purpose.[255] They did find, however, that the use of an ETCOc measurement in combination with the TB level aids in the following: (1) the discrimination between infants with increased bilirubin production rates and infants with decreased elimination; (2) the identification of infants with increased bilirubin production due to ABO incompatibility or other causes of hemolysis; and (3) the identification of infants with impaired conjugation defects, who have a normal ETCOc level in the face of rising TB levels. In other words, high producers of CO and bilirubin are most likely undergoing a hemolytic process, whereas infants with high TB levels and normal bilirubin production rates most likely have a defect in bilirubin conjugation. The measurement of ETCOc could provide direct information of the rate of bilirubin production. Bhutani and co-workers, using data from this study, constructed an age-in-hours-specific ETCOc nomogram for measurements taken between 4 and 48 hours postnatal age, revealing that an ETCOc value at the 75th percentile at 30 ± 6 hours of age is 1.7 ppm or less and is considered the threshold of increased bilirubin production.[25] The importance of

• **Fig. 91.17** Hour-specific transcutaneous bilirubin (TcB) nomogram constructed from 3303 measurements from 1059 neonates. The percentile values were divided into four groups following the pattern of the Bhutani hour-specific TB nomogram. (From Bromiker R, et al. Israel TcB nomogram predicts significant hyperbilirubinemia. *J Perinatol.* 2017;37(12):1315-1318.)

determining ETCOc levels and their application in identifying infants at risk for developing hyperbilirubinemia associated with hemolysis has recently been reviewed.[260]

Bilirubin-to-Albumin Molar Ratio (BAMR)

The molar ratio of bilirubin (mg/dL) to albumin (g/dL) correlates with unconjugated bilirubin levels in newborns and, therefore, can be used as a surrogate for unbound bilirubin or residual binding capacity of albumin. The serum albumin concentration is inherently low in preterm infants, and in addition, albumin levels and the ability of albumin to bind bilirubin vary significantly in sick infants. It has also been shown that binding increases with increasing gestational and postnatal age. The bilirubin/albumin molar ratio (BAMR) may be used as an adjunct to measurements of TB in determining the need for exchange transfusion. A serum albumin level <3.0 gm/dL (4.4 µmol/L) is suggested as a risk factor for bilirubin neurotoxicity[162] and can be used as an option for lowering the indication for commencing phototherapy.[12] The AAP (2004) has suggested bilirubin/albumin ratios that can be used together with, but not in lieu of, the TB level as an additional factor to be considered in determining the need for exchange transfusion (Table 91.3). However, use of the bilirubin/albumin ratio in addition to TB for the management of hyperbilirubinemia in a preterm population did not improve long-term neurodevelopmental outcome when compared with controls in whom TB alone was used.[117] In an Egyptian study of severely hyperbilirubinemic neonates both TB and bilirubin/albumin ratio were strong predictors of neurotoxicity, although bilirubin/albumin did not improve prediction over TB alone.[120] In a recent study of paired TB and albumin levels in preterm and term neonates, both gestational and postnatal age influenced TB, albumin, and

TABLE 91.3 Bilirubin/Albumin Molar Ratio (BAMR) as a Determinant of the Need for Exchange Transfusion

Risk Category	BAMR at Which Exchange Transfusion Should Be Considered	
	TB (mg/dL)/Albumin (g/dL)	TB (µmol/L)/Albumin (µmol/L)
Infants ≥38 0/7 wk	8.0	0.94
Infant 35 0/7 to 37 6/7 wk and well or ≥38 0/7 wk if higher risk or isoimmune hemolytic disease or G6PD deficiency	7.2	0.84
Infant 35 0/7 to 37 6/7 wk if higher risk or isoimmune hemolytic disease or G6PD deficiency	6.8	0.80

If TB is at or is approaching the exchange level, send blood for immediate type and cross-match. Blood for exchange transfusion is modified whole blood (RBCs and plasma) cross-matched against the mother and compatible with the infant.
G6PD, Glucose-6-phosphate dehydrogenase; TB, total bilirubin.

bilirubin/albumin ratios. Furthermore, hypoalbuminemia and extreme bilirubin/albumin ratios were associated with an increased risk of death.[281]

Newer Methods of Diagnosis

In the past, the etiology of many cases of nonimmune hemolysis were unidentified and termed idiopathic. Modern methods of diagnosis, including flow cytometry-based eosin-5-maleimide uptake to identify RBC membrane defects, and next generation sequencing-based panels to identify mutations responsible for hemolysis, may shed light on specific hemolytic conditions, the etiology of which may have remained unknown.[290] The same authors emphasize using this methodology only if simpler and less expensive technologies have failed to arrive at a diagnosis. One such technique includes studying RBC morphology, which may lead to diagnoses of spherocytosis, elliptocytosis, bite and blister cells, echinocytes, and schistocytes.[63]

Therapy for Unconjugated Hyperbilirubinemia

The current mainstay of treatment is phototherapy, which has been proved to be instrumental in containing the rate of rise and lowering the TB. In cases of failure of phototherapy, or in newborns presenting with extremely high TB concentrations, exchange transfusion will definitively lower the TB to a level that will no longer be of danger to the neonate. IVIG and phenobarbital therapy also have a role in the management of hyperbilirubinemia. The intensity and invasiveness of therapy are determined by the many factors discussed thus far, including the gestational age and relative health of the neonate, the current level of TB, and an estimation of the rate of rise in view of the dynamic nature of bilirubin metabolism in the newborn. An example of a clinical pathway for the management of the newborn infant readmitted for phototherapy or exchange transfusion is given in Box 91.3.

Indications for Therapy

Guidelines for the management and prevention of neonatal hyperbilirubinemia have been formulated in many countries, including the United States, Canada, Norway, South Africa, Israel, and others. There is some evidence that guidelines, complemented by statewide learning collaboratives, are instrumental in decreasing the rates of extreme hyperbilirubinemia and exchange transfusion. In California, from 2007-2012 (3 years after publication of the AAP guideline, discussed later) the rates of TB ≥25 mg/dL and exchange

• BOX 91.3 Examples of Management of the Newborn Infant Readmitted for Phototherapy or Exchange Transfusion

Treatment

- Use intensive phototherapy and/or exchange transfusion as indicated in Fig. 91.22 and Fig. 91.23.

Laboratory Tests

- TB and direct bilirubin level
- Blood type (ABO, Rh)
- Direct antiglobulin test (Coombs' test)
- Serum albumin
- CBC with differential and peripheral blood smear for RBC morphology
- Reticulocyte count
- ETCOc (if device available)
- G6PD screen, if indicated by ethnicity or geographic origin or if poor response to phototherapy
- Urinalysis for reducing substances
- If history or presentation suggests sepsis, perform blood culture, urine culture, and CSF examination for protein, glucose, cell count, and culture.

Interventions

- If TB ≥25 mg/dL (428 μmol/L) or ≥20 mg/dL (342 μmol/L) in a sick infant or infant <38 weeks of gestation, obtain a type and crossmatch, and request blood in case exchange transfusion becomes necessary.
- In infants with isoimmune hemolytic disease and a rising TB despite intensive phototherapy or rising to within 2-3 mg/dL (34-51 μmol/dL) of exchange level (see Fig. 91.22), administer IVIG (500-1000 mg/kg) over 2 hours and repeat if necessary.
- If infant's weight loss from birth is greater than 12% or there is clinical or biochemical evidence of dehydration, recommend formula or expressed breast milk. If oral intake in question, give IV fluids.

For Infants Receiving Intensive Phototherapy

- Breastfeed or bottle feed (formula or expressed breast milk) every 2-3 hours.
- If TB ≥25 mg/dL (428 μmol/L), repeat TB within 2-3 hours.
- If TB = 20-25 mg/dL (342-428 μmol/L), repeat TB within 3-4 hours.
- If TB <20 mg/dL (342 μmol/L), repeat TB in 4-6 hours.
- If TB continues to fall, repeat TB in 8-12 hours.
- If TB is not decreasing, or is moving closer to level for exchange transfusion, or the BAMR exceeds levels shown in Table 91.3, consider exchange transfusion.
- When TB is <13-14 mg/dL (222-239 μmol/L), discontinue phototherapy.
- Depending on the cause of the hyperbilirubinemia, it is an option to measure TB 24 hours after discharge to check for rebound hyperbilirubinemia.

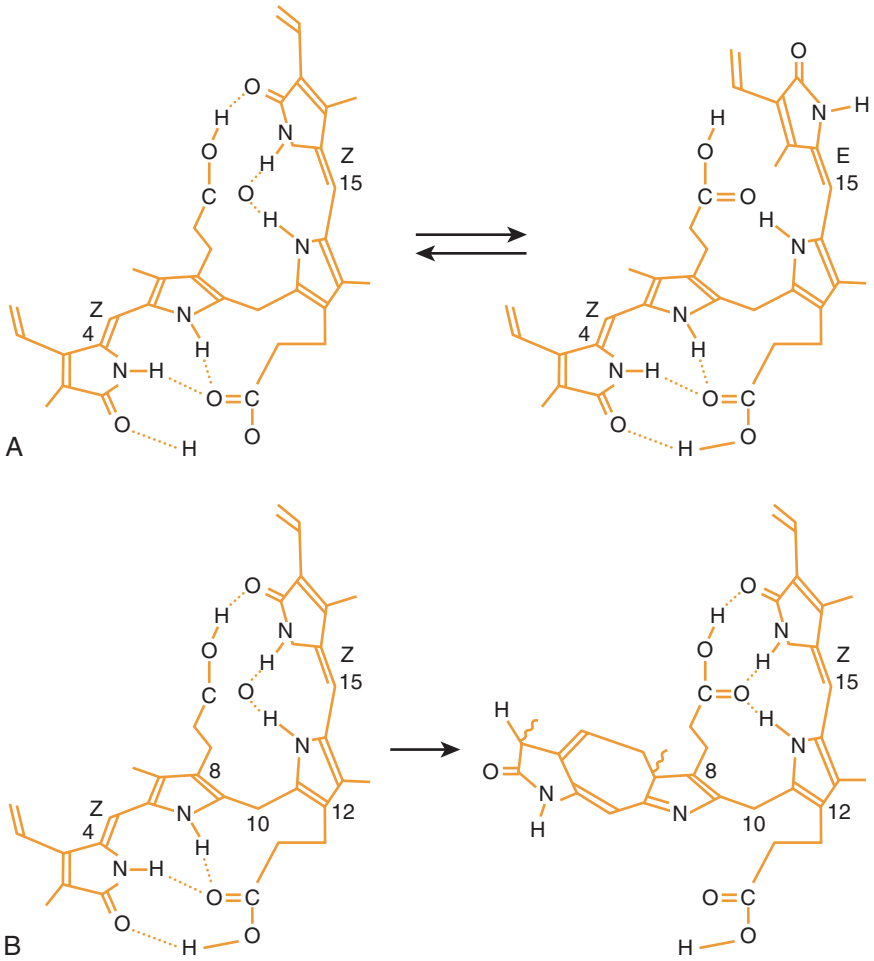
transfusion both decreased significantly.[27] A similar report emanates from Canada, where national guidelines were published in 2007. In the period prior to 2007, neonates were 3.5 times more likely to develop a TB ≥25 mg/dL than in the period 2011-2013. This improvement was attributed to introduction of the Canadian Pediatric Society guidelines and improved physician awareness of severe neonatal hyperbilirubinemia.[243] A significant decrease in the number of exchange transfusions was reported from New South Wales, Australia, following publication of guidelines related to this procedure.[54]

Guidelines were derived from consensus and were not evidence based. In surveys from California, both bilirubin-induced neurotoxicity and sensorineural hearing loss occurred at TB levels well above the AAP recommendations for exchange transfusion.[149,287] Cerebral palsy consistent with kernicterus was limited to infants with TB levels >5.0 mg/dL (85.5 μmol/L) above exchange transfusion indications and at least two risk factors for neurotoxicity, including prematurity, G6PD deficiency, and hypoxic-ischemia.[289] It has been suggested that, as kernicterus is rare and occurs only at very high TB levels (>35 mg/dL or 599 μmol/L), previously recommended phototherapy and exchange transfusion treatment thresholds may be unnecessarily aggressive.[194] Similarly, Maisels asks that if 3000 newborns need to receive phototherapy to prevent one exchange transfusion, could phototherapy have been avoided in many of these neonates?[166]

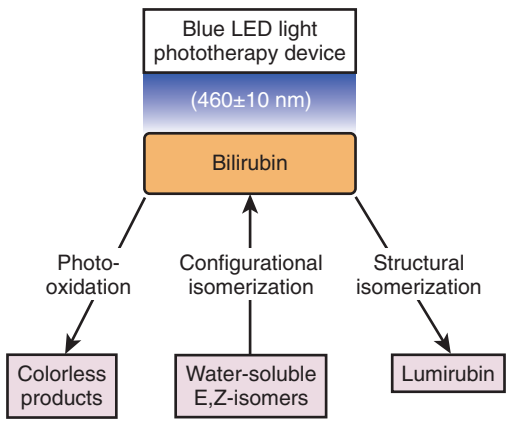
Phototherapy

Phototherapy is the most widely used form of therapy for the treatment and prophylaxis of neonatal unconjugated hyperbilirubinemia. In nearly all neonates, phototherapy reduces or blunts the rise of TB levels (regardless of maturity, the presence or absence of hemolysis, and the degree of skin pigmentation). Extreme hemolysis, however, especially when combined with immature conjugation, may result in phototherapy failure. Given the decades of experience with its use worldwide and the lack of reported serious long-term side effects thus far, short-term phototherapy appears to be safe. The initial report from the Collaborative Study on the Effectiveness and Safety of Phototherapy undertaken under the auspices of the National Institute of Child Health and Human Development (NICHD) demonstrated that neonates receiving phototherapy require significantly fewer exchange transfusions. More important, these infants had an incidence of gross kernicterus and subsequent neurobehavioral performance that was lower than those who received only exchange transfusions to control hyperbilirubinemia. Furthermore, subsequent follow-up studies revealed no adverse outcome in the infants who received phototherapy in the neonatal period.



Mechanism of Action

Three independent mechanisms have been proposed to explain the action of phototherapy in reducing TB levels in neonates. The first and most important pathway is geometric photoisomerization of the native unconjugated bilirubin IX-α (Fig. 91.18). Unconjugated bilirubin IX-α is normally in the *4Z,15Z* configuration. In this form, the –COOH group of each carboxymethyl side chain interacts through three hydrogen bonds with the C=O and N-H groups of the pyrrole rings in the opposite half-molecule. As a result, ionization of the two –COOH and two keto groups is inhibited, making the molecule nonpolar and water insoluble. When illuminated by wavelengths (peak, 460 ± 10 nm), light is absorbed by bilirubin, and unconjugated bilirubin undergoes *Z* to *E* (configurational) isomerization at either one or both of the bridge double bonds to yield potentially three isomers: *4E,15Z*; *4Z,15E*; and *4E,15E*. The *E* configuration spatially precludes hydrogen bonding of the molecule which, therefore, remains open or unfolded and free to ionize. Thus, the *E* isomer is more polar and soluble than the *Z* isomer. Because the liver can transport only soluble bilirubin into bile, the *E*-isomers can be excreted without the need for conjugation.



At least two pairs of geometric photoisomers have been identified *in vivo*. The first pair, photoisomers IA and IB, is presumably the two possible *E,Z* isomers. The second pair, photobilirubins IIA and IIB, is most likely two rotamers of the *4E,15E* isomer. Both pairs are presumably formed rapidly in the skin, subcutaneous tissue, and capillaries. Being more polar, all these isomers partition into the plasma, continuously shifting the equilibrium to promote more isomer formation. These isomers are rapidly taken up by the liver and transported into bile, where they are destabilized by bile acids, rapidly reverting to native unconjugated bilirubin IX-α in the bile ducts and intestine. The rotameric isomers remain mostly intact and are the major polar photoproducts found in bile. This photoisomerization pathway may be responsible for more than 80% of the augmented bilirubin elimination during phototherapy. Geometric photoisomerization is not, however, the only isomerization pathway open to photoexcited bilirubin. The proximity of the side-chain double bond at C-3 to the adjacent pyrrole ring allows an intramolecular cyclization, again rendering the bilirubin molecule more polar (see Fig. 91.18). This structural isomer of bilirubin is called *lumirubin*, and it is also excreted into bile without need for hepatic conjugation. Lumirubin, a soluble compound, is the major photoproduct excreted with the bile and urine, and its conversion is the rate-limiting step in the elimination of bilirubin by phototherapy.

The third pathway of phototherapy involves a variety of bilirubin oxidation reactions, resulting from an autosensitized reaction involving singlet oxygen. The products formed by these reactions are multiple but include biliverdin, dipyrroles, and monopyrroles. Many of these products are colorless, nonreactive in the van den Bergh test, and presumably excreted by the liver and kidney without need for conjugation. Compared with the photoisomerization pathway, the oxidation mechanism appears to play a very minor role in photocatabolism of unconjugated bilirubin in vivo (Fig. 91.19).[271]

• **Fig. 91.19** The major mechanisms of bilirubin photoalteration. (Redrawn from Vreman HJ, et al. Light emitting diodes for phototherapy for the control of jaundice. In: Holick M, ed. *Biology of light 2001: proceedings of a symposium.* Boston: Kluwer Academic; 2002:355-367.)

Technique

Phototherapy is not a standardized practice in the United States at this time, and there exist many different devices capable of delivering phototherapy with varying efficacies. Any physician using one of these devices must be cognizant of the variables influencing the efficacy of phototherapy and ensure that the device is used appropriately. The efficacy of phototherapy units varies widely because of differences in light source and configuration and depends on emission of light in the blue-to-blue-green range that overlaps the in vivo bilirubin absorption spectrum (≈460-490 nm), irradiance of at least 30 μW/cm^2/nm, illumination of maximal body surface area, and demonstration of a decrease in TB levels during the first 4-6 hours of exposure.[28]

The first variable to consider is the wavelength of light used to induce photoisomerization (Fig. 91.20). Bilirubin absorbs light maximally in the blue range (340-540 nm), with peak absorption for albumin-bound bilirubin at about 460 nm and for unbound bilirubin at about 440 nm. Daylight and cool white lamps have a spectral emission of 380-720 nm with a peak of 578 ± 10 nm and are less effective than blue lamps (F20 T12/B), which have a narrower spectral range and peak between 420 and 480 nm. Special blue lamps (F20 T12/BB and TL52 tubes [Philips, The Netherlands]) emit narrower spectra of light with greater irradiance at the main therapeutic spectrum and have been shown to be most effective. The blue hue that is produced by these lamps can interfere with skin color assessment in jaundiced neonates, and it has been reported to produce dizziness and nausea variably in those caring for these patients. These side effects may be readily tempered by the addition

• **Fig. 91.20** Emission spectra of phototherapy devices. The intensities are shown on a linear relative scale. The spectra of the three fluorescent lamps (cool white and special blue [F20 T12/BB and TL52]), tungsten-halogen (spotlight [Olympic Medical Mini-Bililite, Seattle, WA] and fiberoptic blanket [Biliblanket, Ohmeda, Columbia, OH]), and blue light-emitting diodes (LEDs [neoBLUE, Natus Medical, Inc., San Carlos, CA]) were measured under identical conditions on an S-2000 spectrophotometer (Ocean Optics, Inc., Dunedin, FL). *Dotted line* represents the peak absorption of bilirubin at about 460 nm. (From Vreman HJ, et al. *In vitro* efficacy of an LED-based phototherapy device [neoBLUE] compared to traditional light sources. *Pediatr Res*. 2003;53:400A.)

of daylight fluorescent lamps to the phototherapy unit.[67,86] However, incorporation of white fluorescence "dilutes" the blue intensity, thereby dramatically decreasing the effectiveness of phototherapy.[271]

Several studies showed that phototherapy with blue-green to green light (peak at 525 nm) is as effective as that with blue light and better than white light in reducing bilirubin levels.[80,82] Green light lacks the untoward side effects often associated with intense blue light. However, further study is needed to definitively determine the clinical benefit of green light, because green light phototherapy has not been widely adopted.[19]

The second variable that influences the efficacy of phototherapy is energy output or irradiance as measured in units of microwatts per square centimeter per nanometer (μW/cm^2/nm). Effective phototherapy must provide irradiance well above the levels that have been determined to be minimally effective in producing bilirubin degradation while not exceeding levels beyond which no significant increases in response are evident. This also helps avoid potential side effects such as elevation in body temperature. A standard phototherapy unit operating under optimal conditions would provide clinically significant, but minimally effective, levels of phototherapy (about 6-12 μW/cm^2/nm). In intensive phototherapy, irradiance is increased to 30 μW/cm^2/nm or greater.[12] Standard phototherapy lamps are normally positioned within 40 cm from the infant, but should more intensive phototherapy be required, the lamps may be placed within 15-20 cm of the patient, provided blue fluorescent or light-emitting diode (LED) lamps, and not heat-producing halogen lamps with a potential danger of causing thermal injury, are used. Conversely, increasing the

• **Fig. 91.21** Important factors in the efficacy of phototherapy (PT). The absorbance spectrum of bilirubin bound to human serum albumin (*white line*) is shown superimposed on the spectrum of visible light. Clearly, blue light is most effective for phototherapy, but because the transmittance of skin increases with increasing wavelength, the best wavelengths to use are probably in the range of 460-490 nm. Term and near-term infants should be treated in a bassinet, not an incubator, to allow the light source to be brought to within 10-15 cm of the infant (except when halogen or tungsten lights are used), increasing irradiance and efficacy. For intensive phototherapy, an auxiliary light source (fiberoptic pad, blue light-emitting diode [LED] mattress, or special blue fluorescent tubes) can be placed below the infant or bassinet. If the infant is in an incubator, the light rays should be perpendicular to the surface of the incubator in order to minimize loss of efficacy due to reflectance. (From Maisels MJ, McDonagh AF. Phototherapy for neonatal jaundice. *N Engl J Med*. 2008;358:920.)

distance from the lamp to the skin surface of the neonate results in a theoretical diminution of light energy by a factor equal to the square of the increase in the distance (Fig. 91.21).[167]

Skin pigmentation does not reduce the effectiveness of phototherapy. With use, fluorescent lamp energy output declines to a degree that varies from one type of lamp to another. A meter for monitoring lamp energy output should be used to ensure optimal treatment. Although commercially available photometers have been found to vary in their absolute measurement of irradiance because of differences in meter sensitivity (i.e., peak and range) and the emission characteristics of their light sources, they are still useful in determining relative lamp decay. Lamps that have lost more than 20% of the acceptable output should be replaced.

All lamps should be housed behind Plexiglas to reduce the danger to the patient should a lamp explode. Also, it has been shown that Plexiglas provides protection from any harmful ultraviolet irradiation arising from the available light sources. Patients may be cared for on an open warmer or in a crib. Use of a closed incubator may increase the distance of the light source from the infant, thereby attenuating the irradiance delivered to the patient.

The third variable affecting the efficacy of phototherapy is the body surface area of the neonate exposed to light. Ideally, neonates should be naked when under phototherapy; however, use of diapers, folded back to cover as little of the baby's surface as practically possible, may improve on the obvious disadvantages of leaving the infant unclothed. Positioning of several phototherapy units around the newborn, or placing the baby on a phototherapy mattress in addition to the overhead lights, may increase exposure. A white sheet draped around the periphery of the bed may also act to reflect light onto relatively under-exposed areas, thereby increasing the overall light irradiance.

Other conventionally used devices incorporate tungsten-halogen lamps as their light source for use as spotlights. Another technique involves transmission of light through a fiberoptic bundle to a pad or blanket around the infant. The advantage of the latter technology is that the source of light and, therefore, heat will be at a distance from the infant. In infants with severe hyperbilirubinemia, the previously mentioned techniques can be used in combination to increase light intensity (irradiance) and body surface area exposure.[1,85] Too frequently, currently used doses of phototherapy are well below the optimal therapeutic range. The AAP recommends the use of intensive phototherapy, especially for infants readmitted for hyperbilirubinemia, or if the threshold for exchange transfusion is approaching. Intensive phototherapy implies the use of high levels of

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

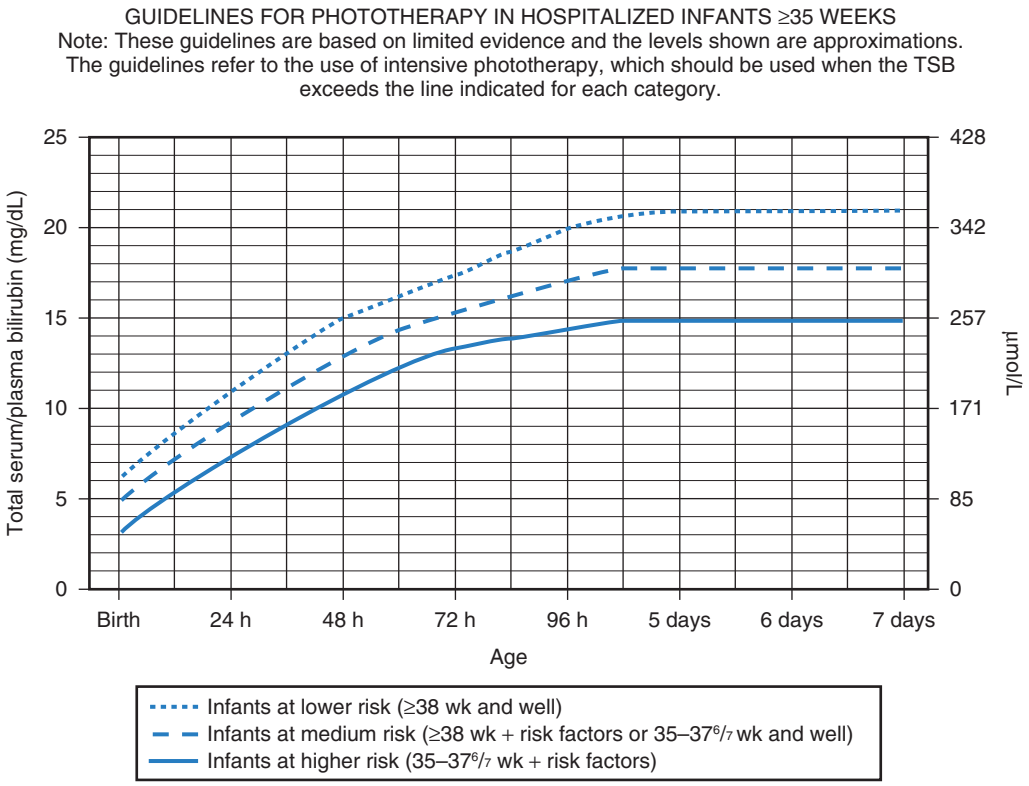
irradiance in the therapeutic range (usually ≥30 μW/cm²/nm) delivered to as much of the infant's surface area as possible.[12]

Use of arrays of blue LEDs, which can deliver high-intensity narrow band light in the absorption spectrum of bilirubin has nearly replaced fluorescent tube-based devices.[269,271] This technology has been shown to be an effective and safe alternative to other modes of phototherapy.[271] LED light sources are now available in many configurations, from mattresses, side panels, blankets, and overhead lights. Advantages of the LED technology include the ability to increase the light intensity to a level higher than many conventional technologies without significantly warming the baby and the long period during which the lamps remain effective without the need for replacement.[197]

Clinical studies comparing intermittent to continuous phototherapy have yielded conflicting results. Several studies failed to show effectiveness of the intermittent therapy. These results may have resulted from prolonged light-on and light-off cycles—for example, 6- to 12-hour on-off schedules. Photoisomerization of bilirubin occurs primarily in skin layers, and the restoration of the bilirubin pool in the skin takes about 1-3 hours. Thus, a prolonged on-off schedule may not be as effective as continuous therapy, but an on-off cycle of less than 1 hour is apparently as effective as continuous treatment. Phototherapy lights should be shut off and eye patches removed during feeding and family visiting for up to 1 hour, because this does not significantly reduce phototherapy effectiveness.

Some reports have demonstrated that home phototherapy may be an effective and safe alternative to prolonged hospitalization for healthy full-term neonates with jaundice. Clear advantages of home-centered phototherapy include: (1) reduced cost; (2) avoidance of parent–infant separation; and (3) parental satisfaction. However, complications of home phototherapy that might result from inadequate nursing supervision include corneal abrasion, eye patch misuse, excessive weight loss, temperature derangement, and ineffective bilirubin reduction. Whether there is any valid indication for phototherapy for those neonates who could be safely managed at home is questionable. Those with valid indications are generally too sick, too small, or too close to the exchange transfusion level to be safely treated at home. The Committee on the Fetus and Newborn of the AAP has not endorsed home phototherapy, but it has issued a strict guideline for its use.[13] Because the devices available for home phototherapy may not provide the same degree of irradiance or surface-area exposure as those available in hospital, the Subcommittee on Hyperbilirubinemia of the AAP recommends that home phototherapy should be used only in infants whose bilirubin levels are in the "optional phototherapy" range (see Indications).[12] It is not appropriate for infants with higher bilirubin concentrations or if the TB is approaching the exchange transfusion level. As with hospitalized infants, the TB must be monitored regularly.

Indications



Although not "evidence-based," the AAP has issued a comprehensive guideline for the commencement of phototherapy in infants greater than 35 weeks' gestation (Fig. 91.22).[12] This guideline takes into account the presence of risk factors as well as late prematurity and also is adapted to the dynamic changes in TB levels during the first days of life. Thus, there is no single TB level at which phototherapy should be commenced, but each newborn must be assessed individually, taking into consideration postnatal age, gestational age, and other risk factors. The TB level at which phototherapy may be discontinued must also be decided in view of these factors. It may be useful to continue plotting the TB concentrations of the hour-specific bilirubin nomogram during phototherapy and discontinue phototherapy once the TB has decreased below the 75th percentile for hours of age, or even closer to the 40th percentile in infants with lower gestational age or in the presence of risk factors. Chang et al. recently proposed a formula by which rebound hyperbilirubinemia can be predicted by an infant's gestational age, age at initiation of phototherapy, and relative TB at phototherapy termination. The formula comprises: Score = 15 (if gestational age <38 weeks) − 7 × (age in days at phototherapy initiation) − 4 × (AAP phototherapy threshold − TB at phototherapy termination) + 50. With a prediction score of <20, phototherapy can be discontinued with <4% probability of rebound.[52] Follow-up for rebound, not necessarily requiring continued hospitalization, should be performed in cases of newborns younger than 37 weeks' gestation, those with positive DAT, and those treated at or before 72 hours' postnatal age.[136] Phototherapy should be used during transport of hyperbilirubinemic newborns to centers for exchange transfusion.[282]

The 2004 AAP Practice Guideline does not extend to premature infants younger than 35 weeks' gestational age.[12] Previously, guidelines suggested by Maisels and Watchko were used.[171] These suggest a wide range of indications for phototherapy and exchange transfusion, offering options based on gestational age and birth weight. Guidelines published by the National Institute for Health and Clinical Excellence (NICE) include graphs incorporating indications for phototherapy and exchange transfusion for each week of gestational age, starting at 23 weeks. TB values can be plotted directly on the graphs (available at http://www.nice.org.uk/CG98). More recently, a revised guideline, albeit non-evidence-based, for the management of hyperbilirubinemia in preterm infants was formulated in the United States by neonatologists who were involved in the preparations of either the 2004 AAP Practice Guideline, the 2009 clarification, or both (Table 91.4).[169] Additional guidelines for use in premature infants have been published from Norway, Holland, and South Africa.[39,114,264]

Aggressive versus Conservative Phototherapy in Premature Infants

In an NICHD study, 1974 premature infants were randomized to aggressive (earlier timing) or conservative

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

- Use total bilirubin (TB). Do not subtract direct reacting or conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin <3.0 g/dL (if measured).
- For well infants 35–37⁶/₇ wk, can adjust TB levels for intervention around the medium risk line. It is an option to intervene at lower TB levels for infants closer to 35 wk and at higher TB levels for those closer to 37⁶/₇ wk.
- It is an option to provide conventional phototherapy in hospital or at home at TB levels 2–3 mg/dL (35–50 µmol/L) below those shown, but home phototherapy should not be used in any infant with risk factors.

• **Fig. 91.22** Guidelines for phototherapy in hospitalized infants aged ≥35 weeks' gestation. Infants are designated as higher risk because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood–brain barrier, and the susceptibility of the brain cells to damage by bilirubin. (Adapted from American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114:297. Used with permission of the American Academy of Pediatrics.)

phototherapy.[189] Two subgroups of infants, birth weight 501-750 g and 751-1000 g, respectively, were randomized at 12-36 hours to aggressive (phototherapy immediately after enrollment) or conservative (phototherapy started at 8.0 mg/dL [137 µmol/L] in the 501-750 g birth weight subgroup and 10.0 mg/dL [171 µmol/L] in the 751-1000 g subgroup). Aggressive phototherapy significantly reduced the mean peak TB, thereby confirming the efficacy of phototherapy in decreasing TB in the 1000 g or less birth weight group. In only seven infants were the criteria for exchange transfusion met. There was no difference (52% versus 55%) in the rate of the primary outcome (a composite of death or neurodevelopmental impairment (NDI), including blindness, severe hearing loss, moderate or severe cerebral palsy, or a Mental or Psychomotor Developmental Index [Bayley] <70). However, aggressive phototherapy was instrumental in reducing the rate of NDI when analyzed alone (26% versus 30%). This apparently was offset, however, by a 5% increase in mortality (39% versus 34%) in the very smallest infants (501-750 g birth weight), attributable to phototherapy. While aggressive phototherapy may be appropriate for relatively larger babies, these results emphasize the potential for phototherapy-related adverse effects. Aggressive phototherapy should be administered with caution in those less than 750 g birth weight. Suggested possible strategies for delivering safer but effective phototherapy to this premature very low birth weight group include reduced initial irradiance with subsequent increase should the TB increase,[170] use of narrow spectrum LEDs, and cycled phototherapy.[16]

Complications

Several potential complications may occur with the use of phototherapy.[227] The effect of high-intensity light exposure on the eyes of human neonates is uncertain, but animal studies indicate that retinal degeneration may occur after

TABLE 91.4 Suggested Guidelines for Initiating Phototherapy or Exchange Transfusion in Premature Infants

Gestational Age (wk)	Phototherapy TB (mg/dL) [µmol/L]	Exchange Transfusion TB (mg/dL) [µmol/L]
<28 0/7	5-6 [86-103]	11-14 [188-239]
28 0/7-29 6/7	6-8 [103-137]	12-14 [205-239]
30 0/7-31 6/7	8-10 [137-171]	13-16 [222-274]
32 0/7-33 6/7	10-12 [171-205]	15-18 [257-308]
34 0/7-34 6/7	12-14 [205-239]	17-19 [291-325]

TB, Total bilirubin.
Adapted from Maisels MJ, Watchko JF, Bhutani VK, et al. An approach to the management of hyperbilirubinemia in the preterm infant less than 35 weeks' gestation. *J Perinatol*. 2012;32:660-664.

several days of continuous exposure. It is essential, therefore, that the eyes of all newborns exposed to phototherapy be covered with sufficient layers of opaque material to guard against the possibility of damage. The use of fiberoptic phototherapy does not eliminate the need to cover an infant's eyes.

Phototherapy may produce an increase in body and environmental temperature. Fluid balance, especially in the premature neonate, is a key management issue in the patient being treated with phototherapy. There is increased insensible and intestinal water loss during phototherapy, which must be compensated for by an increase of about 25% above the estimated fluid need without phototherapy. In addition, stools may be slightly looser and more frequent. Fiberoptic phototherapy appears to result in lower insensible water losses and, therefore, slightly less need for increased maintenance fluids (see Chapter 92). Blue LED-based devices, however, do not release a significant amount of heat, and their use results in less insensible water loss. Term infants treated with blue LED light in open cribs should have their body temperatures monitored to detect excessive body cooling.

A well-recognized side effect of phototherapy is the *bronze baby syndrome*. In this disorder, the serum, urine, and skin become brown-black (bronze) several hours or more after a neonate is placed under the phototherapy lamps. All reported neonates with this syndrome have recovered without apparent sequela, except one term neonate who died and was found to have kernicterus on autopsy. In nearly all patients, conjugated hyperbilirubinemia and retention of bile acids have been noted either before light exposure or after the syndrome has developed. This syndrome has been reproduced in Gunn rats when their smaller bile ducts become obstructed by precipitated bile pigment during phototherapy. Photobilirubin II is shown to be degraded to brown pigments in vitro and when administered to Gunn rats in vivo. It seems likely that the bronze color of the plasma and urine in bronze baby syndrome results from retention of bile pigment photoproducts when biliary excretion is impaired by concomitant cholestasis. A study in two infants with this syndrome showed an increase in coproporphyrin in the blood, and photo-irradiation of this substance produced copper coproporphyrin degradation products similar to those found in neonates with this syndrome. It is generally recommended that phototherapy not be used in neonates with significant conjugated hyperbilirubinemia or other evidence of cholestasis. However, because there have been case reports of newborns who developed kernicterus in the presence of predominantly direct hyperbilirubinemia, the role of conjugated bilirubin in the pathophysiology of bilirubin encephalopathy is not clear, and affected infants should be assessed for the need for phototherapy on an individual basis.

Congenital erythropoietic porphyria is another syndrome in which phototherapy is contraindicated because it may lead to death. This rare disorder is characterized by hemolysis, splenomegaly, and pink to red urine that fluoresces orange under ultraviolet light. Exposure to visible light of moderate to high intensity and of wavelengths between 400 and 500 nm (blue to blue-green) produces severe bullous lesions on the exposed skin and accelerated hemolysis. Mixed hyperbilirubinemia with a significant direct-reacting fraction may also be seen in this disease.

Other theoretical dangers of phototherapy include electrical shock or fire from poorly grounded or defective equipment and unproven potential long-term effects on endocrine and sexual maturation and DNA repair mechanisms in skin epithelial cells. Phototherapy may cause DNA damage, but there is no evidence for long-term effects.[221]

In the main follow-up studies, except for the above-mentioned NICHD study, phototherapy-treated premature and full-term neonates have failed to demonstrate any increase in morbidity or mortality ascribed to the appropriate use of phototherapy. Recent studies have excluded phototherapy as an implication in the etiology of autism and diabetes mellitus,[288] although there may be a slight increase in the risk of infantile cancer.[286]

No scientific evidence exists indicating that hydration directly lowers TB levels. However, dehydration is not known to be beneficial to patients in this context and, therefore, all neonates should receive appropriate replacement and maintenance fluids. Conjugated bilirubin is water soluble and eliminated from the body in urine, bile, and stool. In as much as appropriate hydration maintains adequate urine output, bile flow, and stool excretion, fluid administration indirectly assists in the removal of unconjugated bilirubin. Ideally, this fluid is given enterally to stimulate gastrointestinal tract motility. The use of a milk-protein formula may be considered in infants not responding to phototherapy to inhibit enterohepatic reabsorption of bilirubin, thereby lowering TB levels.

Pharmacologic Therapy

Phenobarbital

In experimental animals, UGT1A1 activity can be increased or induced with administration of phenobarbital, ethanol, chloroquine, antihistamines, heroin, and chlorophenothane (also known as DDT). These substances are not specific for any one enzyme but stimulate many hepatic membrane-bound enzyme systems and hepatic protein synthesis in general. Because of the known and potential toxicity of these agents, only phenobarbital has been used with regularity in humans.

After the demonstration that phenobarbital administration to a child with Crigler-Najjar syndrome type II disease reduced TB levels, phenobarbital administration to pregnant mothers and their offspring was shown to reduce peak TB levels caused by physiologic jaundice by about 50%. Studies in newborn rhesus monkeys have demonstrated that the major effect of this therapy is to increase hepatic UGT1A1 activity and the conjugation of bilirubin. It also may enhance hepatic uptake of bilirubin in the newborn. The administration of phenobarbital to newborns at the time jaundice is first observed or even immediately after delivery is much less effective than its administration to the mother during pregnancy for at least 2 weeks before delivery. The drug is much less effective in premature neonates. As a prophylactic measure, it would be necessary, therefore, to administer phenobarbital to large numbers of pregnant women for prolonged periods during pregnancy, because the time of delivery could not be predicted with certainty. Even then, the premature neonates most susceptible to the toxic effects of hyperbilirubinemia would receive little or no beneficial effect.

Phenobarbital is potentially addictive, may lead to excessive sedation of the newborn, and has other potent metabolic effects in addition to those on bilirubin metabolism. For these reasons, its use has not achieved wide application but has been reserved largely for specific high-risk populations. For example, in the pre-phototherapy era, in unexplained severe hyperbilirubinemia of newborns from the Greek coastal islands, the frequency of kernicterus was significantly reduced by general administration of phenobarbital to pregnant women during the last trimester. A dosage of 60 mg/day is sufficient for maternal administration and 5 mg/kg per day for neonatal treatment. Similar effects have been observed in full-term Korean newborns. Phenobarbital is also useful in the differentiation of Crigler-Najjar syndromes types I and II. Combining phenobarbital treatment with phototherapy has no advantage, the effect being no greater than that of phototherapy alone.

Metalloporphyrins

The pharmacologic basis for using this class of compounds to control bilirubin levels is the targeted blockade of bilirubin production through the competitive inhibition of HO, the rate-limiting enzyme in the bilirubin production pathway.[237,256] Originally proposed by Maines in 1981 for use in modulating bilirubin production,[161] these compounds have been extensively studied. The first metalloporphyrin to be evaluated for use in preventing neonatal unconjugated hyperbilirubinemia was tin protoporphyrin (SnPP). Administration of this compound was shown to decrease bilirubin concentrations in newborn rats, rhesus monkeys, and adult rats with hemolytic anemia, and it was the first synthetic heme analogue used for the purpose of inhibiting HO in human neonates.[78] Although highly efficacious, the photoreactivity of this metalloporphyrin made it a less desirable drug.[270] In newborn rhesus monkeys, administration of SnPP produced skin ulcerations, whereas in human neonates who also received phototherapy, some mild erythema of the skin was observed.[161] Human trials with tin mesoporphyrin (SnMP) in preterm neonates have shown a dose-dependent reduction in peak TB levels irrespective of gestational age and a reduction in the need for phototherapy compared with controls.[139,140,176,223] Mild transient erythema in patients requiring phototherapy was the only side effect noted. In human studies, it has been shown that a single IM dose of 6 μM SnMP/kg body weight eliminates the need for phototherapy during the postnatal period.[176] In a recent study using SnMP, the drug was administered intramuscularly to newborns whose predischarge TcB reading was >75th percentile. In treated infants, compared with controls, phototherapy time was halved, the natural TB trajectory was reversed, and the TB at 3-5 days was sixfold lower.[29] The efficacy of SnMP has been well described by several investigators in patients with Crigler-Najjar syndrome,[69,92] but SnMP does contain a foreign metal, it induces the HO-1 promoter,[74,187] and it can inhibit other enzymes such as nitric oxide synthase and soluble guanylyl cyclase. An alternative compound, zinc protoporphyrin (ZnPP), has been proposed, but it has a much lower inhibitory potency and is not well absorbed after oral administration. Nevertheless, it is a naturally occurring metalloporphyrin possessing both in vitro and in vivo inhibition of both HO-1 and HO-2 isozymes in studies using neonatal rodents and nonhuman primates. Moreover, ZnPP is minimally photoreactive in vivo.

Other Nonmetalloporphyrin Inhibitors

Some nonmetalloporphyrin inhibitors of HO-1 have been identified. Originally designed for use in transplantation survival studies, peptide inhibitors have been reported not only to be immunosuppressive in vitro and in vivo, but also to inhibit in vitro total HO enzyme activity dose-dependently. However, in mouse studies, it has been found that administration of peptides may upregulate HO-1 mRNA and protein in the liver, spleen, and kidney. These findings have precluded human studies investigating the efficacy of peptides for the treatment of hyperbilirubinemia.

Imidazole dioxolanes, inhibitors of cholesterol production,[47] have also been found to inhibit in vitro[72,146,188] and in vivo HO activity, despite being structurally different from metalloporphyrins. It has been demonstrated that these compounds are highly selective for inhibiting the inducible

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

HO-1, but like metalloporphyrins, some imidazole dioxolanes may affect other important enzymes, such as nitric oxide synthase and soluble guanylyl cyclase.[146]

Miscellaneous Agents

As already discussed, reabsorption of unconjugated bilirubin may contribute to a significant portion of hepatic bilirubin load in the newborn period. Frequent milk feeding (cow or human) may slow the rise of TB levels and enhance the bilirubin-reducing effect of phototherapy. Oral administration of nonabsorbable substances that bind bilirubin in the intestinal lumen and presumably reduce enteric absorption of bilirubin may reduce peak TB levels in physiologic jaundice. Orlistat has been used to increase fecal fat excretion, thereby enhancing bilirubin elimination and decreasing the serum unconjugated bilirubin concentrations in Crigler-Najjar syndrome.[104] Feeding breastfed newborns β-glucuronidase inhibitors (L-aspartic acid or enzymatically hydrolyzed casein) during the first week reduced jaundice without affecting breastfeeding deleteriously.[98] Activated charcoal has been used but is effective only when administered during the first 12 hours of life.[70] Agar has also been shown to be effective. Further study of this type of therapy is needed before recommendations can be made regarding clinical applications. These pharmacologic agents may be no more effective than frequent milk feeding (every 2 hours).

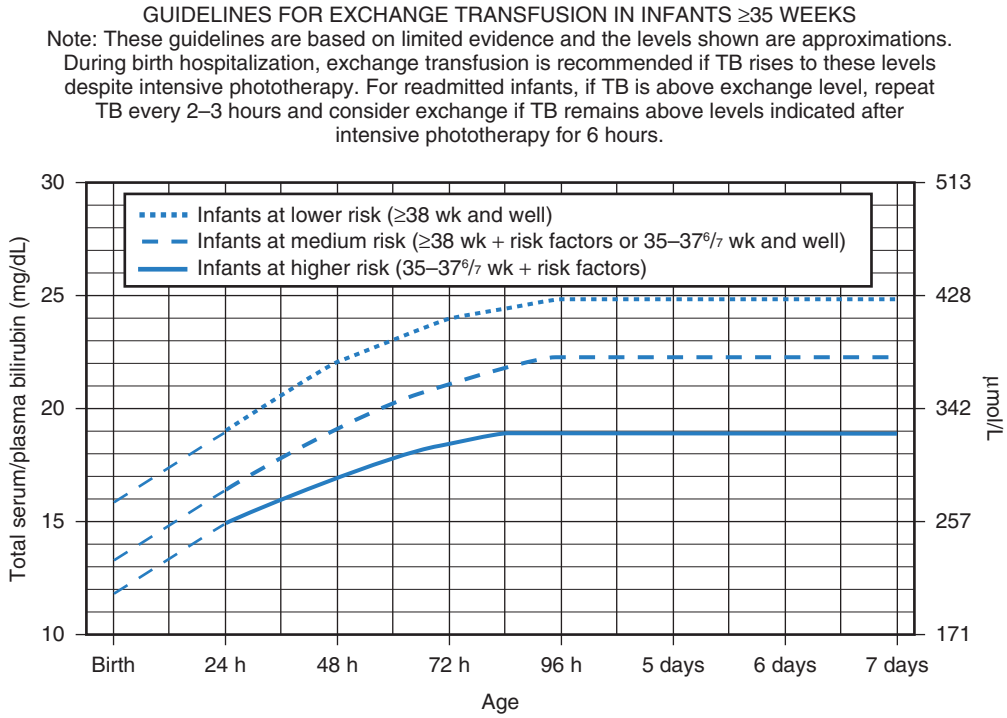
Intravenous Immunoglobulin

High-dose IVIG (500-1000 mg/kg) administered over 2-4 hours has been shown in several small studies to reduce TB levels and the need for exchange transfusion in fetuses and neonates with Rh or ABO immune hemolytic disease.[229] COHb studies performed 24 hours after IVIG infusion in DAT-positive ABO-heterospecific neonates have demonstrated that, in those infants who responded to IVIG infusion with a decrease in TB, hemolysis was inhibited compared with the pre-administration status. Exchange transfusion was avoided in responding newborns, but not in those in whom there was no response. Lack of response was attributed to higher rates of hemolysis, in which case use of a higher dose of IVIG was suggested.[106] The use of IVIG administration should be considered in neonates with DAT-positive immune hyperbilirubinemia who are not responding to intense phototherapy and whose TB level is approaching exchange transfusion indications. This dose can be repeated after 12 hours if necessary. Recommendations for IVIG have been included in the revised 2004 AAP Practice Guideline. While the use of IVIG may be effective in preventing exchange transfusion in ABO-heterospecific neonates, it may not be as valuable in hemolytic disease of the newborn because of Rh isoimmunization, although its administration may delay the increase in TB, thereby allowing for stabilization of the infant.[253]

Exchange Transfusion

Exchange transfusion (see Chapter 80), first described by Diamond and associates,[76,77] is the standard mode of therapy for immediate treatment of hyperbilirubinemia to prevent kernicterus and for correction of anemia in erythroblastosis fetalis. Its use in the past decade has actually been reduced as a result of the use of RhoGAM to prevent Rh isoimmune disease, the application of phototherapy, and more recently, the administration of IVIG in cases of isoimmunity. In infants with severe hyperbilirubinemia caused by isoimmunity or other hemolytic conditions, especially G6PD deficiency, exchange transfusion may be the only effective method of adequately reducing TB levels.

Objectives



With this technique, the equivalent of two neonatal blood volumes (160 mL/kg of body weight) is replaced in aliquots not to exceed 10% of the total blood volume. This results in the replacement of about 85% of the circulating RBCs. Bilirubin concentrations are usually reduced by 50%. Although the procedure is relatively safe when performed by experienced practitioners in term neonates, it nevertheless carries a risk for both mortality (0.1%-0.5% in term neonates) and morbidity as well as being time consuming and expensive. The procedure usually takes 1-2 hours. Slower exchanges should theoretically increase the quantity of bilirubin removed by permitting equilibration of pigment from tissue, but the differences are too small to justify the increased risk of prolonging the duration of the procedure. The indications for exchange transfusion need to be individualized, taking into account gestational age and severity of illness (Fig. 91.23). During acute hospitalization, exchange is recommended if TB rises to the indicated levels despite intensive phototherapy. For readmitted infants, if TB is above the exchange transfusion threshold level, intensive phototherapy may be considered, provided the infant does not display clinical signs of acute bilirubin encephalopathy. Serial TBs should be performed every 2-3 hours, and if TB remains at or above levels indicated, exchange is recommended after 6 hours of intensive phototherapy.[12]

Indications

In the past, it was regularly recommended that TB, even in healthy term infants, be kept below 20 mg/dL (342 μmol/L) during the first 28 days of life. This has been questioned, and a growing consensus has developed that levels as high as 25 mg/dL (428 μmol/L) are acceptable for otherwise healthy, full-term, asymptomatic infants with no obvious hemolytic condition. When the exchange level is considered, conjugated bilirubin should not be subtracted from the total. Despite the inability of direct-reacting bilirubin to enter the CNS, it is possible that direct-reacting bilirubin can partially displace unconjugated bilirubin from albumin-binding sites to increase the risk for kernicterus.

In the face of rapidly rising TB levels, as may be seen in Rh erythroblastosis or other types of hemolytic disease, the decision to perform an exchange transfusion should anticipate the rate of rise (from previous TB levels, hemoglobin concentrations, and reticulocyte counts). Such prediction permits blood for the exchange to be ordered so that the

- The dashed lines for the first 24 hours indicate uncertainty due to a wide range of clinical circumstances and a range of responses to phototherapy.
- Immediate exchange transfusion is recommended if infant shows signs of ABE (hypertonia, arching, retrocollis, opisthotonos, fever, high-pitched cry) or if TB is 25 mg/dL, (85 μmol/L) above these lines.
- Risk factors—isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin and calculate bilirubin/albumin (B/A) ratio.
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- If infant is well and 35–37⁶/₇ wk (median risk), can individualize TB levels for exchange based on actual gestational age.

• **Fig. 91.23** Guidelines for exchange transfusion in hospitalized infants aged ≥35 weeks' of gestation. Note that these suggested levels represent a consensus of most of the committee but are based on limited evidence, and the levels shown are approximations. (Adapted from American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114:297. Used with permission of the American Academy of Pediatrics.)

exchange transfusion is underway by the time the critical level is reached.

The indications for exchange transfusion are based on the infant's TB levels in combination with postnatal age, gestational age, and other risk factors, such as isoimmune hemolytic disease, G6PD deficiency, asphyxia, lethargy, temperature instability, sepsis, acidosis, and BAMR. In 2004, the AAP published a comprehensive guideline for initiating exchange transfusion for term and near-term neonates.[12] Indications for low birth weight neonates or those with lower gestational ages than those specified in the AAP guideline have also been published (see Phototherapy, discussed previously).[171]

In the severely affected erythroblastotic neonate, clinical judgment rather than laboratory data should be used to decide whether the neonate requires immediate exchange transfusion after delivery. In this situation, a partial exchange transfusion using packed RBCs, coupled with reduction in blood volume if venous pressure is elevated, and with measures to ensure adequate ventilation and correction of acidosis and shock, will often be lifesaving. In most exchange transfusions, fresh whole or reconstituted citrate-phosphate-dextrose anticoagulated blood should be used. If blood older than 5 days must be used, the pH should be checked and sodium bicarbonate added to correct the pH to 7.1. Full correction to pH 7.4 may result in later excessive rebound alkalosis as the citrate is metabolized. Repeat exchange transfusion may sometimes be required. In a developing country, acute bilirubin encephalopathy and TB >30 mg/dL were predictive of the need for repeat exchange transfusion.[158]

Technique

Although there are numerous different combinations of blood components that can be used safely and effectively, there is no single combination or component that

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

is superior. RBCs reconstituted with 5% albumin or fresh frozen plasma are most frequently used. Mixtures containing a citrate anticoagulant may cause hypocalcemia, but the administration of calcium during the exchange is seldom practiced. Transfused blood should not contain RBC antigens to which the mother has antibodies. Irradiation of blood is recommended for all exchange transfusions, especially if the infant had undergone an intrauterine transfusion, but may be omitted in clinical emergencies. Because the transfused blood is frequently deficient in platelets, the platelet count should be monitored after exchange transfusion, and platelet transfusion should be considered in infants who are severely thrombocytopenic or who have a bleeding tendency.

The administration of salt-poor albumin (1 g/kg) to neonates 1-2 hours before exchange transfusion to increase the efficiency of bilirubin removal by shifting more tissue-bound bilirubin into the circulation has been advocated and shown to increase the bilirubin removed by 40%. As the total amount of bilirubin removed during an exchange transfusion is only a small portion of the total-body pool of bilirubin, this increase may not significantly alter subsequent bilirubin concentrations or the need for additional exchange transfusions. In addition, theoretically, the transient increase in TB concentration after albumin administration could increase, rather than reduce, the risk for kernicterus if there are local phenomena at the brain level that enhance entry of bilirubin into neurons. Finally, constituents of some albumin solutions may act to displace bilirubin from its binding sites, potentially increasing the percentage of free bilirubin present in the plasma. Thus, pretreatment with albumin before exchange transfusion is not routinely recommended.

Complications

The AAP recommends that exchange transfusions be performed only by trained personnel in a neonatal intensive care unit with full monitoring and resuscitation capabilities.[12] Exchange transfusion is an invasive procedure, and complications may be related to the blood transfusion itself, catheter complications, and the procedure. The potential complications of exchange transfusion are listed in Box 91.4. Severe hemolysis caused by the use of incompatible RBCs may be life threatening. With modern-day screening for infection, there is only a slight chance of transmission of viral or bacterial infection. Hyperkalemia may result if the transfused blood has been stored for a long period. Rebound hypoglycemia may occur if the glucose load during exchange transfusion is large. Graft-versus-host disease is rare but may occur in premature infants or those who have had in utero transfusions. Umbilical venous catheterization may result in air embolism, hemorrhage, or infection.

Presently, serious complications of exchange transfusion are uncommon. Mortality rates are very low in healthy, term neonates but are increased for sick or extremely premature infants. In a study of 106 neonates who underwent 140 exchange transfusions between 1980 and 1995, the overall mortality was 2% but increased to 8% in the subset of infants who were ill. In a smaller series, no serious adverse effects or death occurred among 22 term neonates who had 26 exchange transfusions between 1990 and 1998.[55] In another review of 55 neonates who underwent 66 exchange transfusions between 1992 and 2002,[214] 74% had some form of adverse event, with the most common being thrombocytopenia, hypocalcemia, and metabolic acidosis. In a study of exchange transfusion in neonates with hemolytic disease of the newborn, the procedure was associated with an increased risk of sepsis, leukocytopenia, thrombocytopenia, hypocalcemia, and hypernatremia, but not mortality, when compared with a similarly affected group who did not undergo exchange transfusion.[252] Adverse events related to exchange transfusion, including thrombocytopenia, metabolic acidosis, hypocalcemia, seizures, and death were more frequent in preterm infants: 32 weeks or less (87%), 33-36 weeks (78%), and 37 weeks or more (67%).[214]

If performed under intensive care facilities and with appropriate expertise, the advantages of performing an exchange transfusion clearly outweigh the potential risk, albeit small, of serious complications. Preparations for emergency situations should be made before initiation of the procedure.

• BOX 91.4 Potential Complications of Exchange Transfusion

- Thrombocytopenia, particularly with repeat transfusions
- Portal vein thrombosis or other thromboembolic complications
- Umbilical or portal vein perforation
- Acute necrotizing enterocolitis
- Arrhythmia, cardiac arrest
- Hypocalcemia, hypomagnesemia, hypoglycemia
- Respiratory and metabolic acidosis, rebound metabolic alkalosis
- Graft-versus-host disease
- Human immunodeficiency virus, hepatitis B and C infections
- All other potential complications of blood transfusions

Individualization of Therapeutic Guidelines

The TB level is one of the major criteria to be evaluated when considering the initiation or escalation of treatment for unconjugated hyperbilirubinemia. Although it is believed that it is the unconjugated fraction that presents the danger of kernicterus, the exact ratio of unconjugated and conjugated bilirubin is difficult to assess, because its quantitation exhibits great variability among laboratories. In view of this, the conjugated bilirubin level should not be subtracted from the TB level unless it constitutes more than 50% of the total. As was stated previously, many variables other than the TB level influence the susceptibility of a particular patient to the sequelae of unconjugated hyperbilirubinemia; these include genotype, gestational age, chronologic age, and the presence of hemolytic or other disease

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

states. Therefore, it is useful to consider four groups of patients at risk for kernicterus and modify treatment based on the category: the healthy term (>37 weeks' estimated gestational age), the sick term, the healthy premature, and the sick premature neonate.

In 1994, the Provisional Committee for Quality Improvement and Subcommittee on Hyperbilirubinemia of the AAP published recommendations for the management of unconjugated hyperbilirubinemia in healthy term neonates.[14] The recommendations were revised in 2004,[12] clarified in 2009,[162] and are detailed in Figs. 91.16, 91.22, and 91.23. Whereas the 1994 AAP Practice Parameter did not offer suggestions for the management of newborns with hemolytic conditions, the 2004 AAP Practice Guideline takes into account both term and late preterm infants, with and without risk factors. Risk factors to be considered for the purpose of deciding whether to institute phototherapy or exchange transfusion include isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, and acidosis. Jaundice manifesting in the first 24 hours of life is emphasized as an important risk factor, and recommendations for infants with early jaundice are included in the therapeutic guidelines. Therefore, a more conservative approach should be taken to initiating therapy for hyperbilirubinemia (Table 91.4). Similarly, TB levels rising at a rate greater than 0.5 mg/dL per hour (9 µmol/L) or "jumping tracks" on the bilirubin nomogram indicate a state of active hemolysis; such patients should be considered as falling into the "sick," or risk factor, category. It is exceedingly important in these cases to institute and revise therapies on the basis not only of the current level of bilirubin but also of an estimate of the anticipated peak. Thus, early in the patient's course, phototherapy or exchange transfusion may be performed at a relatively lower TB level than for a similar level occurring at a later time (see Box 91.3).

Prediction of Hyperbilirubinemia and Postdischarge Follow-up

An examination of the hour-specific bilirubin nomogram will reveal that the TB continues to rise in a steady fashion throughout the first days of life, arriving at its peak at about 4-5 days. An infant who is discharged home at or around 48 hours of age will only have started to increase the TB, which will peak at home. Great responsibility is, therefore, placed on the parents to detect deepening jaundice and to approach the appropriate facilities should hyperbilirubinemia develop. Many cases of kernicterus have developed at home in newborns previously thought to be well and discharged from the newborn nursery as healthy. To assist in discharge planning and in an attempt to detect at least some of the infants with developing hyperbilirubinemia, the AAP has issued recommendations for postdischarge follow-up[12] (Table 91.5). It is recommended that every newborn should be seen by a pediatrician within 2-3 days of discharge, even those who were not jaundiced at the time of discharge.

TABLE 91.5 Post-Discharge Follow-Up

Infant Discharged	Should Be Seen by
Before age 24 hours	72 hours
Between age 24 and 47.9 hours	96 hours
Between age 48 and 72 hours	120 hours

From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114:297.

Clinical judgment should be used when scheduling follow-up, and infants with risk factors for hyperbilirubinemia may be seen earlier than recommended in Table 91.5, as judged clinically necessary.

In a clarification[162] to the 2004 AAP Practice Guideline, a predischarge measurement of TB or TcB is recommended and the risk for hyperbilirubinemia detected based on an infant's age in hours and the TB measurement, which may require readmission to the hospital for treatment. Moreover, all infants should be screened for risk factors prior to discharge, when planning for the postdischarge visit. Predischarge TB percentile risk assessment in combination with gestational age may be the most sensitive index of subsequent hyperbilirubinemia requiring phototherapy or readmission,[31,144] while complete absence of clinical jaundice is highly predictive of infants who will not develop significant hyperbilirubinemia.[145]

Hyperbilirubinemia in Resource-Limited Countries

Severe hyperbilirubinemia, frequently with clinical evidence of ABE, is one of the most frequent causes for admission in countries with limited resources. Management of hyperbilirubinemia is compromised by long distances to travel to obtain medical care, lack of adequate phototherapy devices, and erratic electricity supply. Exchange transfusion is frequently performed under inadequate circumstances. To cite only a few examples: in Nigeria, severe hyperbilirubinemia accounted for one in five neonatal admissions and has been associated with case fatality and neurodevelopmental sequelae, including cerebral palsy and auditory impairments. G6PD deficiency, prematurity, low birth weight, infection, and ABO incompatibility were prevalent among the etiologies of hyperbilirubinemia.[211] In Myanmar, half of all neonatal hospital admissions are for hyperbilirubinemia with a high rate of exchange transfusion.[17] In an attempt to circumvent the inability to provide adequate phototherapy, Slusher et al. have devised a method by which filtered sunlight can be as a surrogate for electric-powered phototherapy by using window tinting films to filter the broad spectrum of sunlight, allowing transmission of only safe and efficacious

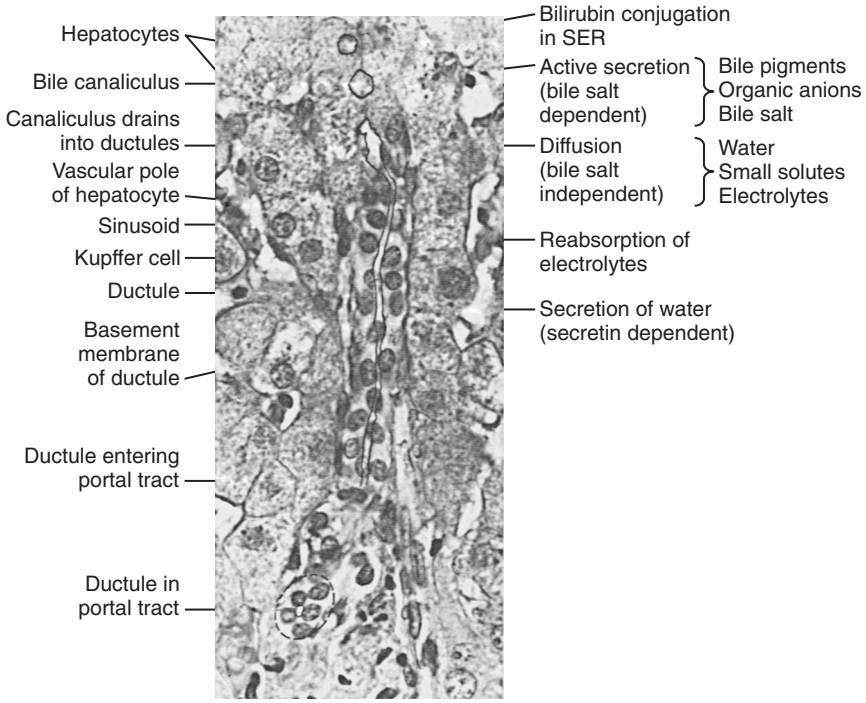
blue light. In a randomized, controlled noninferiority trial in which filtered sunlight was compared with conventional phototherapy for the treatment of hyperbilirubinemia in term and late-preterm neonates in Nigeria, filtered sunlight was noninferior to conventional phototherapy for the treatment of neonatal hyperbilirubinemia.[250] Because the need for exchange transfusion may be high, and blood banking and other supportive services lacking, it has been proposed that infants at high risk of kernicterus should be given priority over those at moderate risk. Factors to be taken into consideration include the presence of intermediate or advanced ABE, neurotoxicity risk factors, and TB levels.[210]

Conjugated Hyperbilirubinemia

Neonatal jaundice associated with a rise in conjugated bilirubin is indicative of a defect or insufficiency in bile secretion, biliary flow, or both and is always pathologic. It is commonly accompanied by a rise in serum levels of other constituents of bile, such as bile salts and phospholipids. The designation *cholestasis*, meaning reduction in bile flow, is used to describe this group of disorders. The rise of conjugated serum bilirubin may be the result of primary defects in the hepatocellular transport or excretion of bile, or secondary to abnormalities in bile duct function or structure.[18] Sequelae are specific to the many diverse diseases producing this clinical entity, and therefore treatment, when possible, is directed at the underlying disease.

The hepatocellular phase of bile secretion involves the transport of conjugated bilirubin across the hepatic cell membrane at the biliary pole. The lateral cell membrane at this site is folded to form microvilli and becomes part of the canalicular space, surrounded by two or more adjacent hepatocytes. Microvilli and the underlying cytoplasm contain microfilaments visible by electron microscopy. These structures consist of the contractile protein actin, which is necessary for normal canalicular contraction and microvillous motility, important elements in the generation of intrahepatic bile flow. At the border of the bile canaliculus, hepatocytes are joined in a "tight junction," which under normal circumstances forms an efficient barrier, preventing the contents of the bile canaliculus from entering the perisinusoidal space of Disse or the vascular compartments (Fig. 91.24). The bile canaliculus is an integral part of hepatocytes. It follows that any hepatocellular injury may result in impairment of the cellular phase of bile excretion and breakdown of the tight junctions, leading to the clinical and laboratory findings of cholestasis.

Hyperbilirubinemia resulting from hepatocellular injury may be associated with other abnormalities that reflect impairment of other hepatocellular functions. These abnormalities include hypoglycemia, fluid retention, toxin and medication metabolism, and bleeding. However, injury may selectively impair bile secretion at the biliary pole of hepatocytes, resulting in an isolated laboratory finding of conjugated hyperbilirubinemia. A liver biopsy taken in the early stages of one of the diseases caused by a hepatocellular



• **Fig. 91.24** Electron micrograph of two adjacent normal hepatocytes. Note the microvillar surface of the bile canaliculus (BC). Tight junctions (TJ) border the canaliculus. *Insert:* A high-power view of two adjacent hepatocytes as seen in the light microscope. Biempica, Albert Einstein College of Medicine, Bronx, NY.)

defect in bile secretion would characteristically show bile pigment granules in hepatocytes and canaliculi, referred to as *intracellular* and *intracanalicular cholestasis*. Bile pigment granules are not seen in either hepatocytes or canaliculi of normal liver parenchyma. In fact, the canalicular lumen is not visualized in routine sections of normal liver parenchyma, because it is partially obliterated by microvilli identifiable only by electron microscopy. In cholestasis, there is usually blistering, blunting, or destruction of these microvilli, transforming the bile canaliculus into a widened, round space containing bile (the bile plug). On rare occasions, liver biopsies from patients with conjugated hyperbilirubinemia fail to show any abnormalities when examined with the light microscope.

The ductal phase of bile excretion includes those events that take place in the biliary system distal to the bile canaliculus (Fig. 91.25). The intrahepatic biliary system comprises the bile ductules (the initial portion of which is frequently referred to as the *canals of Hering*); the interlobular (portal) bile ducts, recognized by their constant association with a vein and an arteriole; and the right and left hepatic ducts, which in some individuals may partially extend beyond the liver capsule at the liver hilum. The extrahepatic component includes the common hepatic duct, the cystic duct, the gallbladder, and the common bile

duct (choledochus). The extrahepatic biliary system and the major right and left hepatic ducts contain intramural and periductal glandular structures. Although the role of these structures in humans is not clearly understood, information derived from animal experiments suggests they may play an important role in bile duct regeneration or failure to regenerate. This is suggested by the presence of glands or ductules in duct remnants resected during portoenterostomy for biliary atresia (see under specific disorders in the following paragraphs). Most diseases affecting the extrahepatic bile ducts, and occasionally the left and right hepatic ducts, are associated with segmental or diffuse luminal obliteration and are primarily expressions of mechanical disturbance in bile flow.

Diseases involving the intrahepatic ducts, in the absence of concomitant extrahepatic disease, are complex and probably result from a combination of mechanical obstruction to the flow of bile, abnormalities of the biochemical pathways involved in the process of bile secretion, and in some cases, persistence of infectious agents or viral antigens. In rapidly occurring duct obstruction, dilation of proximal branches is noted. This change may not be present when luminal obliteration is incomplete or when it develops slowly, because these cases are frequently complicated by reduction in intrahepatic bile secretion and flow. A constant and characteristic tissue response to complete mechanical obstruction of a major bile duct is dilation and proliferation of proximal portions of the intrahepatic biliary system, including the ductules and canals of Hering, structures that are outside the confines of the portal tracts. A constant accompaniment to bile duct proliferation is an increase in surrounding connective tissue, which eventually leads to fibrous bridging between adjacent portal tracts, causing biliary cirrhosis. Although bile secretory defects may initially be purely hepatocellular or ductal, any long-standing abnormality in the flow of bile leads to some degree of hepatocellular damage.

Box 91.5 lists diseases that may manifest as conjugated hyperbilirubinemia in the neonatal period. This list is divided into those disorders caused by a primary defect in the hepatocellular phase of bile secretion and those caused by ductal disturbances. In most of these disorders, direct-reacting bilirubin accounts for 50%-90% of the TB level. A small amount of indirect-reacting bilirubin is always present, reflecting mild hemolysis, defective uptake and excretion, or hydrolysis of conjugated bilirubin. Early in the onset of conjugated hyperbilirubinemia in the neonate, the direct-reacting portion may account for only 10%-25% of TB. As hepatic conjugation and uptake of bilirubin mature, the indirect-reacting portion decreases, whereas the direct portion increases.

Causes of Conjugated Hyperbilirubinemia

Conjugated hyperbilirubinemia results from interference with the hepatic excretion of conjugated bilirubin into bile. Idiopathic neonatal hepatitis and biliary atresia together account for about 60%-80% of all cases of conjugated hyperbilirubinemia. It is possible that similar pathogenetic mechanisms produce a spectrum of disease, with biliary atresia being the final possible, but not the inevitable, outcome. Because of this, it is useful to discuss these two entities simultaneously.

Idiopathic neonatal hepatitis is defined as prolonged conjugated hyperbilirubinemia without the apparent stigmata of a generalized viral illness, the evidence of identifiable

• BOX 91.5 Diseases That May Manifest as Conjugated Hyperbilirubinemia in the Neonatal Period

Hepatocellular Disturbances in Bilirubin Excretion

Primary Hepatitis

Neonatal idiopathic hepatitis (giant cell hepatitis)
Hepatitis caused by identified infectious agents

- Hepatitis B
- Rubella
- Cytomegalovirus
- *Toxoplasma* organisms
- Coxsackie virus
- Echoviruses 14 and 19
- Herpes simplex and varicella-zoster viruses
- Syphilis
- *Listeria* organisms
- Tubercle bacillus

"Toxic Hepatitis"

Systemic infectious diseases

- *Escherichia coli* (sepsis or urinary tract)
- *Pneumococcus* organisms
- *Proteus* organisms
- *Salmonella* organisms
- Idiopathic diarrhea

Intestinal obstruction
Parenteral alimentation
Ischemic necrosis

Hematologic Disorders

Erythroblastosis fetalis (severe forms)
Congenital erythropoietic porphyria

Metabolic Disorders

α_1-Antitrypsin deficiency
Galactosemia
Tyrosinemia
Fructosemia
Glycogen storage disease type IV
Lipid storage diseases

- Niemann-Pick disease
- Gaucher disease
- Wolman disease

Cerebrohepatorenal syndrome (Zellweger syndrome)
Trisomy 18
Cystic fibrosis
Progressive familial intrahepatic cholestasis (PFIC)
Hemochromatosis
Idiopathic hypopituitarism

Ductal Disturbances in Bilirubin Excretion

Extrahepatic Biliary Atresia

Isolated
Trisomy 18
Polysplenia-heterotaxia syndrome

Intrahepatic Biliary Atresia (Nonsyndromatic Paucity of Bile Ducts)

Alagille Syndrome (Arteriohepatic Dysplasia)

Intrahepatic Atresia Associated with Lymphedema

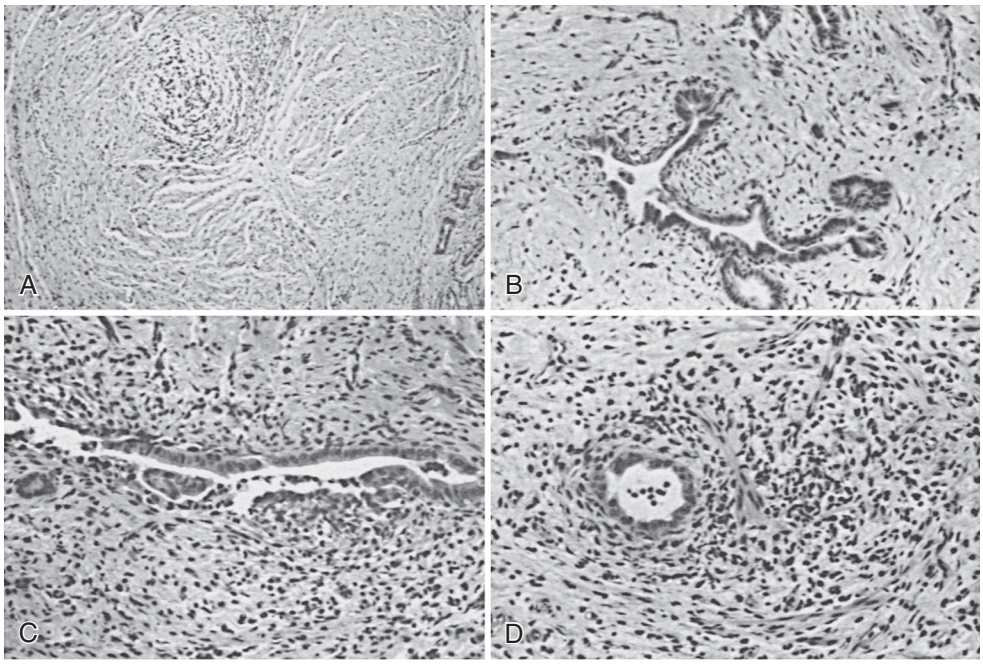
Extrahepatic Stenosis and Choledochal Cyst

Bile Plug Syndrome

Cystic Disease

Tumors of the Liver and Biliary Tract

Periductal Lymphadenopathy



infectious agents, or an etiologically specific metabolic abnormality. On liver biopsy, this group is characterized by extensive transformation of hepatocytes into multinucleated giant cells, and it is, therefore, sometimes referred to as *neonatal giant cell hepatitis*. Giant cell transformation of hepatocytes does not reflect any specific etiology. It is caused by rupture of lateral cell membranes of adjacent hepatocytes, with consequent reduction in the number of bile canaliculi and retention of conjugated bilirubin. It is seen in various inherited metabolic disorders and some infections. Necrosis of hepatocytes and inflammation are usually present, although special stains (e.g., silver impregnation) may be necessary to demonstrate loss of hepatocytes. Necrosis and inflammation may be transient, with giant hepatocytes persisting for many months or even years.

Extrahepatic biliary atresia is defined as a condition in which there is luminal obliteration or apparent absence of segments or all of the extrahepatic biliary system.

Differentiation between these two groups of diseases may be difficult in the early stages; however, an early accurate diagnosis is essential for the choice of proper clinical management.[190] Extrahepatic biliary atresia requires early surgical intervention with hepatoportoenterostomy. Unrelieved by surgery, the defect inevitably leads to death from biliary cirrhosis in the first 3 years of life. The prognosis in idiopathic neonatal hepatitis is uncertain and cannot be predicted based on clinical or laboratory findings. Familial cases have a poor prognosis, with recovery rates of less than 30%. Sporadic cases have a recovery rate of 65%-83% in various series. The poor prognosis in familial cases may be indicative of a metabolic defect.

The causes of idiopathic neonatal hepatitis and biliary atresia remain undetermined. The long-held view that biliary atresia represents a simple congenital developmental anomaly with failure of canalization is now thought untenable. In most cases, biliary atresia and neonatal hepatitis occur as isolated abnormalities, and both are considered to represent acquired conditions that may be initiated by the same or similar noxious factors. In support of the acquired nature of most cases of biliary atresia is the absence of reported cases in stillborn fetuses and the relatively rare association with other malformations. Similarly, clinical evidence of total obstruction to the flow of bile (such as acholic stools or colorless meconium) is not detected in the early stages of jaundice. The onset of acholic stools and conjugated hyperbilirubinemia is frequently delayed

• **Fig. 91.26** Microscopic preparations of fibrous remnant of extrahepatic biliary system resected during Kasai procedure for biliary atresia. **A,** Most distal portion of specimen, showing complete obliteration of lumen by fibrous tissue. **B** to **D,** More proximal segments, illustrating a spectrum of changes that includes necrosis of lining epithelium, acute and chronic inflammation, mural fibrosis with distortion of lumen, and great variation in size of ductlike structures. All micrographs x60.

until 2 weeks of life or later. Microscopic changes observed in the extrahepatic biliary system, or its fibrous remnant removed during the hepatoportoenterostomy (see Treatment of Extrahepatic Biliary Atresia, later), strongly suggest a sequence of changes that include acute cholangitis, necrosis, inflammation, attempted regeneration, and obliterative fibrosis (Fig. 91.26).

Clinical and pathologic observations over a long period indicate that some patients fulfill all known criteria for neonatal hepatitis, including surgical demonstration of patent biliary ducts in the early stages of jaundice, and then go on to develop extrahepatic biliary atresia.

Injury to the structures involved in bile secretion (hepatocytes and biliary epithelium) may occur either in utero or in the perinatal period, but the consequences of such injury and, therefore, clinically manifested disease, are delayed until sometime after birth. Clinical manifestations and eventual outcome may depend on the severity and persistence of lesions in a specific location. Thus, primary injury to hepatocytes may result in clinical manifestations of neonatal hepatitis, whereas injury to major bile ducts and gallbladder may result in biliary atresia. Reovirus type 3 has been implicated as an etiologic factor in extrahepatic biliary atresia as well as in neonatal hepatitis. These studies include an experimental model in which a hepatobiliary disease bearing a strong resemblance to human biliary atresia can be induced in very young mice by infection with reovirus type 3. No studies, however, have definitively proved a role for any of the known hepatotrophic viruses, including reovirus type 3 in the etiology of biliary atresia in humans.[231]

Other viruses such as cytomegalovirus and rubella virus have been implicated in intrahepatic bile duct destruction and paucity. Patients currently classified as having idiopathic neonatal hepatitis constitute a heterogeneous group that undoubtedly includes various, as yet undefined, hereditary metabolic disorders. A metabolic disorder may explain the recurrent incidence of this disease in some families.

Most patients with idiopathic neonatal hepatitis or biliary atresia represent isolated cases without familial incidence or associated anomalies. Neonatal hepatitis has a familial incidence of 10%-15%, whereas no familial cases of histologically proven extrahepatic biliary atresia have been observed.[94,151] Rare occurrences of neonatal hepatitis and biliary atresia in two siblings have been reported. Both neonatal hepatitis and biliary atresia occur more frequently in patients with trisomy 18 than in the general population. Biliary atresia has been observed in association with the polysplenia-heterotaxia syndrome in 10%-15% of cases. This syndrome is characterized by situs inversus of abdominal organs; intestinal malrotation; multiple spleens; centrally placed liver; and a variety of cardiac, pulmonary, and vascular malformations. The inferior vena cava is frequently absent.

Early clinical manifestations of both idiopathic neonatal hepatitis and biliary atresia may be limited to jaundice. In a small proportion of patients, especially among those who later develop neonatal hepatitis, jaundice may be apparent at birth, documented by increased concentrations of conjugated bilirubin in cord blood. No case of extrahepatic biliary atresia has ever been described in which elevation of

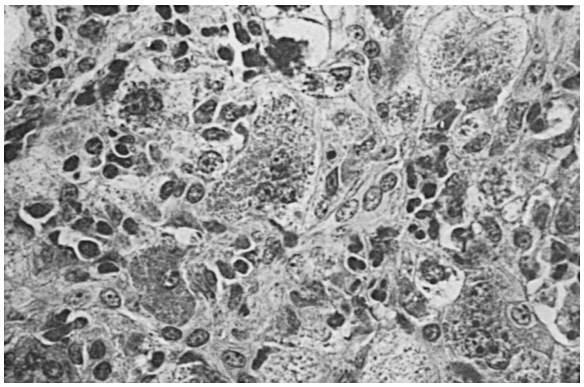
direct-reacting bilirubin was found in the cord blood. Jaundice usually becomes apparent between the 2nd and 6th weeks of life. The dark yellow staining of diapers from the presence of bilirubin in the urine often prompts the parents to seek medical advice. Jaundice is frequently first noted by the physician during a well-baby visit. Hepatomegaly may be present in both neonatal hepatitis and biliary atresia. Splenomegaly is more frequently present in neonatal hepatitis, but this is not a constant finding. Its presence in biliary atresia usually signifies cirrhosis. Obstruction to the flow of bile is reflected by acholic stools and may be observed in both neonatal hepatitis and biliary atresia. It is always transient and incomplete in neonatal hepatitis, but its duration is variable and may extend beyond the crucial period during which an accurate diagnosis must be established if surgical correction is needed. Routine clinical and laboratory findings usually do not distinguish between extrahepatic biliary atresia and neonatal hepatitis. A routine series of diagnostic laboratory tests is suggested, however, to establish the severity of hepatic involvement and to screen for possible causes (Box 91.6). The failure of routine tests to distinguish between neonatal hepatitis and biliary atresia has led to a continued search for other distinguishing biochemical characteristics. α-Fetoproteins are frequently present in the sera of patients with neonatal hepatitis but may be absent in patients with biliary atresia.

A reliable method for the evaluation of patency of extrahepatic bile ducts is the use of technetium-99m acetanilidoiminodiacetic acid (IDA) or IDA derivatives, such as paraisopropyl iminodiacetic acid or di-isopropyl iminodiacetic acid. These compounds are efficiently extracted by hepatocytes and are excreted with bile into the intestines. When complete obstruction exists, no activity is detected in the intestines. Pretreatment with phenobarbital for 3-7 days before testing promotes excretion of isotope in neonates with severe intrahepatic cholestasis and thus reduces the chance for a mistaken diagnosis of extrahepatic obstruction. Phenobarbital is given orally at the dose of 5 mg/kg daily. Patients are given nothing by mouth for 1 hour before and 2 hours after injection of the radiotracer to avoid gallbladder contraction and dilution of radiotracer excreted into the intestines. Combining cholescintigraphy with a less commonly used string test (determination of color and radioactivity count in duodenal fluid) increases the sensitivity and specificity of the diagnosis. Infants with biliary atresia will have a negative hepatobiliary scan at 24 hours or a string radioactive count of less than 197,007 counts per minute.[191]

Ultrasonography has also been applied in the evaluation of neonatal cholestasis. Although the demonstration of a normal gallbladder is usually indicative of an intrahepatic cause for cholestasis, it may be seen in extrahepatic biliary atresia and is, therefore, not a reliable sign. As intrahepatic bile ducts are usually not dilated in extrahepatic biliary atresia, their presence should suggest another cause.

Histopathologic examination of the liver is an integral part of the evaluation of any patient with persistent conjugated hyperbilirubinemia. It is best performed and analyzed after all other pertinent laboratory data have been gathered. A percutaneous liver biopsy usually yields adequate tissue for microscopic and, if desired, electron microscopic and virologic studies. If a metabolic disorder is suspected, as for example in familial cases, a liver core should be frozen and saved at –70°C for possible subsequent biochemical analysis. In most patients (90%-95%), liver biopsy establishes or confirms the correct diagnosis, sparing the neonate with neonatal hepatitis an unnecessary surgical procedure. Before the biopsy, the prothrombin time and platelet count must be ascertained and assessed to determine the safety of performing the procedure and the need for correction. A prolonged prothrombin time may be corrected in some patients by administration of vitamin K. In

• BOX 91.6 Laboratory Tests Recommended for Evaluation of Neonatal Conjugated Hyperbilirubinemia



- Liver Function Tests
  - TB and direct-reacting bilirubin, total serum protein, and serum protein electrophoresis
  - SGOT (AST), SGPT (ALT), alkaline phosphatase (and 5′-nucleotidase if alkaline phosphatase elevated), and γ-glutamyl transpeptidase
  - Cholesterol
  - Serum and urine bile acid concentrations, if available
  - α_1-Antitrypsin
  - Technetium-99m iminodiacetic acid scan
  - α-Fetoprotein
- Hematologic Tests
  - Complete blood count, smear, and reticulocyte count
  - Direct Coombs' test and erythrocyte G6PD
  - Platelet count
  - Prothrombin time and partial thromboplastin time
- Tests for Infectious Disease
  - Cord blood IgM
  - VDRL; FTA-ABS; complement fixation titers for rubella, cytomegalovirus, and herpesvirus; and Sabin-Feldman dye test titer for toxoplasmosis
  - HBsAg in both infant and mother
  - Viral cultures from nose, pharynx, blood, stool, urine, and cerebrospinal fluid
- Urine Tests
  - Routine urinalysis, including protein and reducing substances
  - Urine culture
  - Bilirubin and urobilinogen
  - Amino acid screening
- Newborn Screen for Galactosemia and Hypothyroidism
- Liver Biopsy
  - Light microscopy
  - Specific enzyme assay (if indicated)
- Radiologic and Ultrasound Studies (if indicated)
- Additional Diagnostic Studies for Metabolic Disorders (if indicated)

ALT, Alanine transferase; AST, aspartate aminotransferase; FTA-ABS, fluorescent treponemal antibody absorption (test); G6PD, glucose-6-phosphate dehydrogenase; HBsAg, hepatitis B surface antigen; SGOT, serum glutamic-oxaloacetic transaminase; SGPT, serum glutamic-pyruvic transferase; TB, total bilirubin; VDRL, Venereal Disease Research Laboratory.

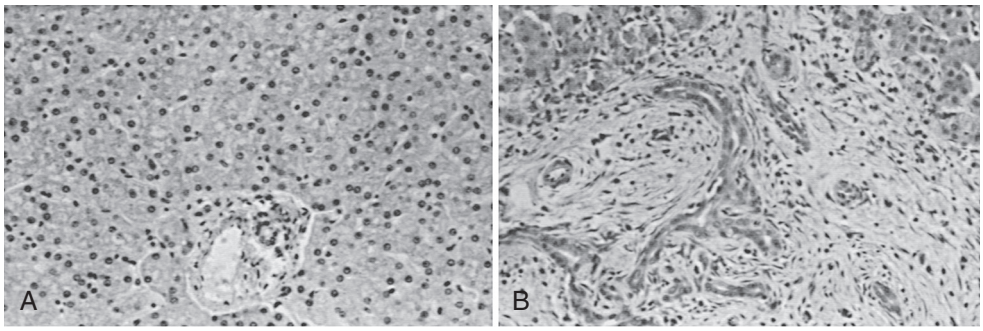
some situations in which a biopsy is urgently required, fresh frozen plasma and/or platelets may be administered during the percutaneous biopsy. Postoperatively, neonates must be observed closely for vital signs or clinical changes that indicate significant bleeding, bile peritonitis, or pneumothorax, the rare but significant complications of the procedure. In the final analysis, the isotope scan and a percutaneous liver biopsy are the only reliable means available without surgical exploration to distinguish between neonatal hepatitis and extrahepatic biliary obstruction.

The liver biopsy in neonatal hepatitis is characterized by marked irregularity in the size of hepatocytes and, in some cases, by numerous giant hepatocytes (Fig. 91.27 and Fig. 91.28). Giant cells may contain from 4-100 nuclei. The cytoplasm of these giant cells is usually foamy and contains bile pigment. Bile canaliculi appear to be reduced in number and proportion to the number of giant hepatocytes. Necrosis and inflammation are frequently detected. Kupffer cells are swollen and contain bile pigment, lipofuscin, iron, and phagocytosed debris of destroyed hepatocytes. Extramedullary hematopoiesis is almost always present. Although these findings may also be present in biliary atresia, it is the relative absence of bile duct proliferation that distinguishes neonatal hepatitis from biliary atresia. In some cases of neonatal hepatitis, there is evidence of inflammatory injury to portal bile ducts, with epithelial reduplication interpreted as regenerative activity. The aforementioned changes are usually seen in early stages, soon after onset of jaundice. Biopsies taken after 3 months of age may show little necrosis and inflammation and, instead, demonstrate fibrosis or cirrhosis. Giant cell transformation of hepatocytes may persist for months or years.

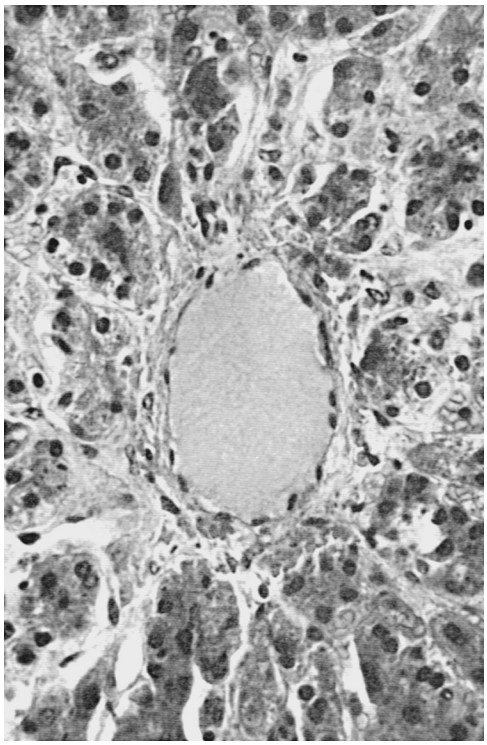
• **Fig. 91.27** Neonatal hepatitis. Note the marked cellular irregularity obliterating the normal orderly plate arrangement. Intracanalicular bile is present. Small cells in sinusoids are Kupffer cells and elements of extramedullary hematopoiesis. Paraffin embedding and hematoxylin-eosin staining, x60.

• **Fig. 91.28** High-power view of transformed giant hepatocytes. Most of the intracytoplasmic granules represent bile pigment. Paraffin embedding and hematoxylin-eosin staining, x200.



It has been shown in patients and in animal experiments that soon after obstruction of the common bile duct, ducts and ductules in portal tracts and in periportal zones begin to proliferate. This phenomenon involves most, if not all, portal tracts and is present even at the periphery of the liver, far removed from the site of obstruction. Therefore, in biliary atresia, changes suggesting blockage in the major (mostly extrahepatic) bile ducts are seen. At least three portal tracts should be available for examination. In biliary atresia, all tracts will show some degree of proliferation. In early stages, ductular proliferation may be present without increased fibrosis. The ducts have a varicose appearance and contain focal bile plugs. Later, ducts and ductules frequently appear distorted (Fig. 91.29) because of a discrepancy between the rate of proliferation of biliary epithelium and that of the surrounding fibrous tissue. An associated inflammatory exudate is occasionally seen around proliferated ductules, but a true cholangitis with epithelial necrosis and intramural inflammation is rarely encountered except in association with surgical complications. Other changes within portal tracts include dilated lymphatics and, occasionally, tortuous and thick-walled arterioles. In later stages of extrahepatic biliary atresia, ductular epithelium may disappear, having been replaced by collagen fibers, and this may lead to a secondary paucity of portal bile ducts.

Extensive paucity of bile ducts, whether primary or secondary, is associated with a clinical syndrome resembling that observed in primary biliary cirrhosis, or sclerosing cholangitis, with hypercholesterolemia, xanthomas, and pruritus. Hepatocytes in biliary atresia show intracellular and canalicular cholestasis, with the canalicular component predominating (Fig. 91.30). In about one-third of all patients with biliary atresia, there is giant cell transformation of hepatocytes. In most cases, this transformation is primarily centrolobular (around terminal branches of the hepatic vein) and is not associated with necrosis and inflammation. Extramedullary hematopoiesis may also be present.



Treatment of Neonatal Hepatitis

Clinical management of neonatal hepatitis consists of supportive measures, because no specific therapy is known. Many neonates have a transient but significant reduction in bile flow, often requiring replacement of fat-soluble vitamins, particularly vitamins D and K. Subclinical rickets is common in these neonates and may contribute to the increase in serum concentrations of alkaline phosphatase. Persistence of acholic or very pale stools without significant lowering of direct-reacting serum bilirubin concentrations

after 1 month should be viewed as an indication for repeat clinical study, including liver biopsy. This practice permits detection of patients whose extrahepatic bile ducts sclerose after an initial phase of hepatitis and who are, therefore, suitable candidates for exploratory laparotomy and corrective surgery. On rare occasions, patients with neonatal hepatitis and complete obstruction, as evidenced by acholic stools, may recover rapidly after operative cholangiography that shows normal extrahepatic ducts. This phenomenon is probably the result of flushing out of inspissated bile in the extrahepatic biliary system, with consequent relief of obstruction. This situation may be seen in cystic fibrosis or severe dehydration. Fluctuations in stool color should alert the clinician to the possible existence of a choledochal cyst, which can usually be diagnosed with ultrasound and treated surgically. There are no early reliable criteria on which the prognosis of a particular patient can be based.

Treatment of Extrahepatic Biliary Atresia

When the clinical evaluation indicates complete biliary obstruction or proves inconclusive, the patient should undergo an exploratory laparotomy. On entry of the abdomen and after initial scrutiny of the biliary system, an operative cholangiogram should be performed to confirm and characterize the extrahepatic lesion and define its extent. The classification proposed by the Japanese Society of Pediatric Surgeons divides extrahepatic biliary atresia into three types based on gross observations during laparotomy:

Type I: Atresia of the common bile duct with patent proximal ducts
Type II: Atresia of the common hepatic duct with patent proximal ducts
Type III: Atresia of the right and left hepatic ducts at the porta hepatis

Operative examination of these neonates should be performed only by surgeons prepared to proceed with corrective procedures if necessary. Reoperation after exploratory laparotomy increases the technical difficulties and delays the institution of corrective measures. Reconstitution of normal biliary drainage by direct anastomosis of grossly identifiable segments of patent bile ducts to the gastrointestinal tract is possible in only a very small proportion of patients with biliary atresia (estimated at 5%-10%). These include the rare cases of choledochal cyst and occlusion of a short segment of the common bile duct by a valve, a membrane, or fibrosis. In most patients with biliary atresia, there are no grossly visible ducts proximal to the atretic segment. In the past, all these patients were considered inoperable. Untreated patients, although jaundiced, often appear clinically well in the first few months of life, but they deteriorate rapidly after cirrhosis develops, with clinical manifestations of portal hypertension, ascites, hypersplenism, infection, hyperammonemia, and hemorrhage.[116,236]

In 1968, Kasai and associates described for the first time in American literature an operative procedure in which the periphery of the transected fibrous tissue of the porta hepatis, devoid of grossly identifiable ducts, was anastomosed to a Roux-en-Y loop of small intestine (portoenterostomy).[141] Kasai's portoenterostomy or variations of this procedure are currently performed in most medical centers.

The immediate goal for surgical correction is the reestablishment of bile drainage, which is now achieved in most neonates when operated on before 3 months of age. Cure rate, however, is still poor. In most operated patients, fibrosis increases with time and eventually progresses to cirrhosis despite adequate bile drainage. It is currently unclear whether progressive liver fibrosis represents a continuation of the same type of injury responsible for the initial obliterative process in extrahepatic ducts or if it is the result of ascending cholangitis complicating surgery. In addition to the age at the time of surgery, other factors that influence the outcome include the size and patency of microscopic ducts in the transected porta hepatis and the preservation of intact epithelial lining. Growth failure and TB between 2 and 6 mg/dL at 3 months after hepatoportoenterostomy was shown to be associated with need for transplantation or death by 24 months of age.[73]

Orthotopic liver transplantation is the definitive therapy for biliary atresia. Survival statistics have steadily improved since 1981, when cyclosporin A and steroid therapy were introduced. Other drugs that produce effective immunosuppression and fewer side effects, such as FK 506, lessen the mortality and morbidity of transplantation, resulting in longer and more productive lives for graft recipients.[236]

Known Infectious Causes

In a small proportion of neonates with neonatal hepatitis, a specific infectious agent may be identified either by direct isolation and culture or by serologic tests that detect specific antibodies. In addition, microbial antigens may be identified in liver biopsy using monoclonal antibodies and immunocytochemical staining methods. Among infectious agents reported in association with neonatal hepatitis are organisms, such as *Treponema pallidum* and *Listeria* species, and viruses such as rubella and Coxsackie virus, the herpes group of viruses (herpes simplex, varicella-zoster, cytomegalovirus), and adenovirus. The protozoan *Toxoplasma gondii* also has been implicated. Fetal infection may take place in utero either by transplacental spread or by an ascending infection of the amniotic fluid, usually after rupture of membranes. In some cases, infection may occur during delivery by aspiration or swallowing of vaginal contents. Clinically, patients in this group may appear sick and fail to thrive and also may have evidence of CNS and other organ involvement. In many patients, there are stigmata of generalized infection. Laboratory findings are similar to those seen in idiopathic neonatal hepatitis, but stools are not acholic, and therefore biliary atresia usually is not suspected. Although congenital infection with human immunodeficiency virus (HIV) is diagnosed with increasing frequency, cholestasis is rare in the neonatal period.

Liver biopsy may be helpful in the diagnosis of infectious agents, especially in infections with the herpes viruses. These DNA viruses replicate in the nucleus, resulting in intranuclear inclusion bodies that can be seen with the light microscope. Cytomegalic inclusion disease is characterized by marked enlargement of hepatocytes, biliary epithelium, and Kupffer cells caused by intranuclear as well as intracytoplasmic inclusions. In some cases, however, the virus has been isolated from patients in whom liver biopsy showed giant cell transformation of hepatocytes with no evidence of inclusions.

Hepatitis B surface antigen (HBsAg) may be transmitted from mother to infant, probably by aspiration of vaginal contents, including blood, during delivery. With few exceptions, infants born to HBsAg-positive mothers show no antigenemia in cord blood or in the first month of life. Repeated serologic tests indicate that HBsAg appears in the serum of these infants between 5 and 7 weeks of life and reaches a peak at 10 weeks. Antigenemia in the newborn may be associated with liver injury, and both may persist for many months or possibly years. It is necessary, therefore, to closely observe all infants of HBsAg-positive mothers for many years for clinical and laboratory evidence of chronic liver disease. Severe and even fulminant neonatal hepatitis associated with HBsAg has been described in infants of chronic carriers and after neonatal transfusions. Prophylaxis with concurrent administration of hepatitis B immune globulin (HBIG) and hepatitis B vaccine is effective in preventing neonatal infection in greater than 90% of exposed newborns. HBIG (0.5 mL IM) should be given within 12 hours of birth. In addition, hepatitis B vaccine should be given IM concurrently within 12 hours of birth at a different anatomic site and repeated at 1-2 and 6 months of age (for preterm infants who weigh less than 2000 g at birth, a total of four doses of vaccine should be given according to the immunization schedule for preterm infants; see Appendix C). Concurrent use of HBIG and vaccine does not appear to interfere with vaccine efficacy. High HBV DNA level in HBeAg-positive mothers is the most significant risk factor for vertical transmission despite appropriate vaccination.[44] There is a growing consensus for the use of antiviral therapy in the second or third trimester for pregnant HBsAg-positive women with high viral loads to reduce the risk of perinatal transmission. There is limited data on the level of HBV DNA that antiviral therapy is recommended.[43] Breastfeeding is not contraindicated for mothers with chronic hepatitis B infection.[246]

Hepatitis C virus (HCV), a single-stranded RNA virus in the flavivirus family, has been found to be the etiologic agent in most cases previously referred to as non-A, non-B hepatitis. Transmission occurs through both the percutaneous and the non-percutaneous route. The incubation period varies from 2 weeks to 6 months. The signs of acute disease include malaise, fever, elevation in hepatic transaminases, and jaundice. Fulminant hepatitis and acute hepatic failure

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

are rare. Although about three-fourths of acute infections are asymptomatic, about one-half of affected patients will develop chronic hepatitis, with 20% of these patients progressing to cirrhosis. Progression of the disease is slow, with an average of 10 years to chronic hepatitis, 20 years to cirrhosis, and 30 years to hepatocellular carcinoma. Although infected infants manifest biochemical features of hepatocellular injury, other manifestations of the disease are relatively mild throughout childhood.

The overall risk for vertical transmission of HCV has been shown to be as high as 10% in several studies. Women who are infected with both HCV and HIV and those with HCV viremia are at the greatest risk for transmitting HCV to their offspring.[101] The persistence of maternal antibody in the infant is variable but may be as long as 8-12 months. Diagnosis in the neonate and infant is made by measuring serial anti-HCV (IgG) titers (using enzyme immunoassays followed by recombinant immunoblot assays detecting antibody against HCV core antigen or other nonstructural proteins) or by directly detecting the presence of HCV ribonucleic acid through the reverse-transcriptase polymerase chain reaction. No proven therapy is currently available to neonates infected with HCV. The safety and efficacy of HCV therapies, including new direct-acting antiviral agents, are currently being investigated in children. HCV has been detected in the breast milk of HCV-infected mothers. Although theoretically possible, transmission of HCV through breastfeeding has not been documented in HCV-positive, HIV-negative mothers. Thus, according to most authorities, breastfeeding is not currently contraindicated in HCV-positive, HIV-negative women.

Sepsis

Microorganisms and their biologic products may have direct toxic effects on the cells and structures responsible for the hepatocellular and ductal phases of conjugated bilirubin excretion. This may be complicated by sepsis-induced hemolysis, further adding to the bilirubin load. Postmortem examination of neonates with severe sepsis has shown centrilobular cholestasis, focal hepatocellular necrosis, and giant cell transformation in some patients. In others, no hepatic lesions can be demonstrated by light microscopy. Severe urinary tract infection, particularly with coliform bacilli, is associated with this syndrome. In this case, generalized septicemia is not an essential feature, and cholestasis may be caused by massive endotoxin release. Antibiotic treatment is followed by prompt relief of hyperbilirubinemia.

Hepatic Metabolic Disease

Several metabolic disorders result in hepatocellular injury in the neonatal period and give rise to a clinical pathologic syndrome that may resemble neonatal hepatitis or biliary atresia. α_1-Antitrypsin deficiency in the homozygous state (PiZZ) may be manifested by neonatal liver injury. It is estimated that only 10%-20% of all individuals with this abnormality will have liver disease. Most PiZZ individuals never develop clinical evidence of liver disease, but they may develop pulmonary emphysema as adults. Patients with α_1-antitrypsin deficiency may show all the signs and symptoms of neonatal hepatitis or biliary atresia, including acholic stools. Liver biopsy also may show changes consistent with either one of the aforementioned conditions. Bile duct proliferation may be so pronounced that exploratory laparotomy is performed. Although in older children periportal hepatocytes frequently contain intracytoplasmic inclusions that give a positive reaction with periodic acid-Schiff stain and resist diastase digestion, these are rarely seen in the neonatal period. Immunocytochemical staining may be helpful in demonstrating granules of α_1-antitrypsin, present in hepatocytes of patients with deficient states but not in normal phenotypes. Phenotyping of the Pi system should be carried out in all suspected cases. In many infants, neonatal cholestasis may regress before the age of 6 months and reappear later in childhood or adolescence when the patient becomes cirrhotic. The pathogenesis of liver disease associated with this anomaly is not fully understood.[202] Studies suggest that the liver disease is a result of toxic gain-of-function mutations that cause the α_1-antitrypsin protein to fold aberrantly and be retained in the endoplasmic reticulum of hepatocytes rather than be secreted into the blood.[102,215]

Several defects in carbohydrate, protein, and lipid metabolism occur with conjugated hyperbilirubinemia. Deficient activity of galactose-1-phosphate uridyltransferase is inherited as an autosomal recessive disease with an incidence of about 1 in 50,000. It results in the accumulation of galactose-1-phosphate in the liver, producing hepatomegaly and conjugated hyperbilirubinemia. Other associated findings in galactosemia include hypoglycemia, emesis, failure to thrive, cataracts, and ascites. Mental retardation and cirrhosis occur if dietary treatment is not instituted early. The acute form of tyrosinemia is also an autosomal recessive disease and is characterized by elevations in plasma tyrosine and methionine accompanied by hepatic and renal dysfunction, emesis, and failure to thrive. A medication, 2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione (NTBC), has been shown to improve liver and renotubular function.[154] Dietary tyrosine restriction prevents cirrhosis and early death. Niemann-Pick disease (deposition of sphingomyelin and cholesterol) and Gaucher disease (deposition of glucosylceramide), both autosomal recessive diseases, have also been reported to be associated with conjugated hyperbilirubinemia (see Chapter 90).

Total Parenteral Nutrition–Induced Hepatic Injury

Prolonged use (2 weeks or greater) of total parenteral nutrition may produce conjugated hyperbilirubinemia, which may persist for some time after cessation of this mode of nutrition. Liver biopsy shows evidence of hepatocellular injury with swelling of hepatocytes, necrosis, cholestasis, and occasional giant cell transformation. Trace elements (specifically manganese and copper) should be removed from the total parenteral nutrition solution if conjugated

hyperbilirubinemia occurs. Baseline copper levels and monthly monitoring are recommended to avoid copper deficiency.[118]

Mechanical Obstruction

Inspissated Bile (Bile Plug) Syndrome

Obstruction of a major bile duct by thick bile or mucus is known as the *bile plug syndrome* or the *inspissated* (Latin *inspissatus*, thickened) *bile syndrome*. Although it may be seen in cases of cystic fibrosis, most often the cause is obscure. The obstruction usually resolves gradually, with or without phenobarbital therapy. Severe cases may require irrigation of the biliary tree or direct surgical extraction of the plug.

Choledocholithiasis

Choledocholithiasis is most commonly seen in neonates with a history of severe intrauterine hemolysis. The excessive bilirubin load results in the formation of gallstones, which have the potential to block the secretion of conjugated bilirubin. Gallstones may also be seen in patients receiving total parenteral nutrition. The diagnosis is suspected because of the presence of conjugated hyperbilirubinemia, bilirubinuria, acholic stools, and a palpable gallbladder. It is confirmed with ultrasound. Spontaneous resolution is common, but cholecystectomy may be necessary in cases of cholangitis or progressive elevation of conjugated bilirubin levels.

Cystic Diseases

Cyst formation in the biliary system may result in obstruction of bile flow and produce conjugated hyperbilirubinemia. Congenital hepatic fibrosis is an autosomal recessive disease marked by hamartomatous and fibrotic changes of the interlobular bile ducts. Most cases are associated with cysts of the renal collecting tubules, and the prognosis depends greatly on the degree of renal impairment. *Caroli disease* is the name given to cystic dilation of the major intrahepatic ducts. Cholangitis is a chronic problem, and the outcome is variable. Cysts found along the extrahepatic biliary tree (common hepatic duct, common bile duct, gallbladder) are known as *choledochal cysts*. These are more commonly seen in females and may lead to portal hypertension, cirrhosis, and carcinoma. Complete surgical excision is the definitive treatment. It is believed that these three disease entities may have a common etiology that differentially manifests itself depending on the timing, duration, and location of the insult. Taken together, they are rare causes of conjugated hyperbilirubinemia presenting in the neonatal period.

Masses

Obstruction of the extrahepatic biliary ducts may also rarely occur with tumors such as primary hepatoblastoma and metastatic neuroblastoma, enlarged periductal lymph nodes, and distended loops of bowel. Treatment is directed at the underlying disorder.

Miscellaneous Causes of Conjugated Hyperbilirubinemia

Alagille syndrome (arteriohepatic dysplasia) is an autosomal dominant disease with clinical variability characterized by a paucity of intrahepatic bile ducts in the presence of patent extrahepatic ducts. Other findings include unusual facies; vertebral anomalies; peripheral pulmonary stenosis; posterior embryotoxon (incomplete iridocorneal separation); and retarded mental, physical, and sexual development.[6] Mutations in Jagged1 (chromosome 20p12) have been identified in about 70% of patients studied with Alagille syndrome.[203] Jagged1 is a cell surface ligand for the Notch receptor. The interaction between Jagged1 and Notch is critical for proper cell differentiation during early development. The majority of Alagille syndrome cases (≈97%) are caused by haploinsufficiency of the *JAG1* gene. A small percentage (<1%) is caused by mutations in *NOTCH2.*

Early clinical manifestations and laboratory findings are identical to those observed in patients with extrahepatic biliary atresia. Later in the first year of life, however, serum cholesterol concentrations rise well beyond those observed in other forms of infantile liver disease. Levels higher than 1000 mg/dL may be seen as early as the third month of life. Cutaneous xanthomas are prominent in the later stages of untreated disease, usually after 1 year of age. It is important to recognize this condition before exploratory surgery, because the patency of the very narrow and collapsed extrahepatic ducts may be extremely difficult to demonstrate. Not only is portoenterostomy unsuccessful in establishing bile flow in this condition, but it actually accelerates the progression of liver disease.[143]

A nonsyndromic form of intrahepatic bile duct paucity has also been described. A familial form of cholestasis and paucity of intrahepatic bile ducts is associated with development of lymphedema of the lower extremities around the time of puberty. Although initially described cases in this group were from families of Norwegian extraction, similar cases have been reported from England, France, and Sweden.

Progressive familial intrahepatic cholestasis (PFIC) results from defects in specific transporter proteins that are responsible for traffic of bile components from hepatocytes into the bile canaliculus.[272] In addition to cholestasis, the group of PFIC conditions can present with diarrhea and growth failure. PFIC-1, previously known as Byler disease and Greenland-Eskimo familial cholestasis, is caused by mutations in the gene coding for the canalicular surface protein FIC1. PFIC-2 is caused by defects in the gene that codes for the bile salt export pump (BSEP) resulting in toxic retention of bile salts within hepatocytes. PFIC-3 is caused by mutations in the gene encoding multidrug resistant protein 3 (MDR3), resulting in lack of phosphatidylcholine in bile and predisposing to cholangitis. PFIC-3, in contrast to PFIC-1 and PFIC-2, is therefore associated with elevations of γ-glutamyl transpeptidase levels. Recently, two new subtypes of cholestatic liver disease have been reported, including PFIC-4 caused by a mutation in the *TJP2* gene,[232]

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

which results in a disruption of tight-junction structure and PFIC-5 caused by a mutation in the *NR1H4* gene, which encodes a bile acid–activated nuclear hormone (farnesoid X) receptor that regulates bile acid metabolism.[96]

Zellweger (cerebrohepatorenal) syndrome is a rare autosomal recessive disease marked by the absence of hepatic and renal peroxisomes. Because peroxisomes have many vital anabolic and catabolic functions within the cell, their absence results in profound cellular dysfunction. In addition to conjugated hyperbilirubinemia, affected patients manifest characteristic facies (high forehead, flat occiput, large fontanelle, shallow orbital ridges, micrognathia), feeding difficulties, hypotonia, seizures, and mental retardation. Death usually occurs early in infancy.

Isolated cases of conjugated hyperbilirubinemia have been described in connection with congestive hepatopathy associated with congenital heart disease, severe internal hemorrhage, gestational alloimmune liver disease, and rarely, in association with umbilical vein catheterization.

Clinical management of conditions with prolonged cholestasis includes supportive measures. Infants with chronic cholestasis are at risk for failure to thrive. Malabsorption of fat and fat-soluble vitamins results from poor solubilization of dietary fat in mixed micelles owing to reduced intestinal bile flow. In addition, excess catabolism predisposes infants with chronic liver disease to poor weight gain. Fat malabsorption and steatorrhea can be managed by providing a fat source enriched for medium chain triglycerides, which do not require bile salts for intestinal absorption. Fat-soluble vitamins should be supplemented and serum vitamin concentrations should be monitored. The hydrophilic bile acid ursodeoxycholic acid (UDCA, or Actigall) has been used in managing cholestatic disorders. Proposed anti-cholestatic mechanisms of UDCA action include stimulation of bile flow and displacement of more toxic bile acids from hepatocytes into the systemic circulation via Ca^{257+} and protein kinase C-α-dependent mechanisms and/or activation of p38 (mitogen-activated protein kinase [MAPK]) and extracellular signal-regulated kinases (ERK) to affect transporter molecules (e.g., bile salt export pump [BSEP] and the conjugate export pump [MRP-2]). UDCA can be helpful for severe pruritus associated with cholestasis, with the oral antibiotic rifampin often added for refractory pruritus.

Evidence is clear that a parenteral fish oil emulsion (Omegaven®, Fresenius Kabi, Bad Homberg, Germany), in contrast to the traditional soy-based products, reduces the risk of progressive intestinal failure–associated liver disease (IFALD).[217,240] Such a reduction can rescue patients from needing liver and/or intestinal transplants.[193] Recent studies suggest that the pro-inflammatory ω-6 polyunsaturated fatty acids in plant oil-based lipid emulsions (Intralipid, Liposyn III) and the presence of phytosterols contribute to the development of hepatotoxicity. In contrast, fish oil–based lipid emulsions are rich in anti-inflammatory ω-3 fatty acids, which are hepatoprotective and contain no phytosterols. In the United States, Omegaven® is not yet approved by the federal Food and Drug Administration (FDA), which means that institutions must obtain an IND from the FDA to provide Omegaven® for compassionate use. Expanding on the initial experience at the Children's Hospital in Boston, Omegaven® at 1 g/kg/d compared with patients on Intralipid has been demonstrated to improve IFALD in several case series from Canada, Hong Kong, and Seattle, as well as several national and international case reports. Although the reversal of cholestasis has been the most studied parameter in the fish oil and IFALD field, liver histology is lacking. Some studies indicate there may not be regression, but there may be stabilization of fibrosis despite resolution of cholestasis on fish oil emulsions.[181] Some centers are arguing for lipid minimization as the initial treatment for IFALD.[66] Other key factors in the management of IFALD include a focus on enteral autonomy, prevention of catheter line infection (including the use of ethanol locks), limitation of hepatotoxic medications, and multidisciplinary management by intestinal rehabilitation programs.[274] It is important to note that there is a risk of bleeding in patients receiving parenteral fish oil emulsions.[192] Finally, another lipid emulsion, SMOFlipid, also produced by Fresenius Kabi, which is composed of soybean oil, fish oil, olive oil, and medium-chain triglycerides, has been advocated by several groups.[75,97] It has a higher content of ω-3 fatty acids and a lower phytosterol content than soy-based emulsions, and there is some evidence suggesting that it may be beneficial in IFALD.

Key Points

- Neonatal hyperbilirubinemia is usually transient and harmless, but if severe and untreated, can lead to chronic choreoathetotic cerebral palsy (kernicterus) and death or bilirubin-induced neurologic dysfunction, including severe neurologic hearing impairment (auditory neuropathy/dyssynchrony).
- Although bilirubin neurotoxicity has been limited to a large extent in industrialized countries with functional medical systems, it is still rampant in developing countries and a major cause of mortality and morbidity globally.
- The etiology of hyperbilirubinemia results from an imbalance between the bilirubin production and elimination: hemolysis and prematurity appear to increase the risk of bilirubin neurotoxicity.
- The serum total bilirubin (TB), when primarily indirect or unconjugated, is used for clinical assessment and therapeutic decision making. While unbound bilirubin may offer better prognostic value, its measurement is not available universally in the clinical setting.
- The mainstay of treatment is intensive phototherapy, with the option of exchange transfusion in those infants

not responding to that treatment. Therapies using metalloporphyrins have potential in the future.
- The rise of conjugated serum bilirubin may be the result of primary defects in the hepatocellular transport or excretion of bile, or secondary to abnormalities in bile duct function or structure.
- The two most common causes of conjugated hyperbilirubinemia are idiopathic neonatal hepatitis, a noninfectious, nonmetabolic hepatocellular injury, and biliary atresia, a progressive obliteration or absence of extrahepatic bile ducts.
- Abdominal imaging with ultrasound and/or percutaneous liver biopsy for histopathology is a key step to differentiating the many potential causes of neonatal cholestasis.
- Hepatoportoenterostomy to re-establish biliary drainage is an imperative early surgical intervention for biliary atresia.
- New fish oil lipid emulsions compared to traditional soybased products may reverse the progression of intestinal failure–associated liver disease (IFALD).

Fluid, Electrolytes, and Acid-Base Homeostasis

KATHERINE MACRAE DELL

Fluid and electrolyte and acid–base management are essential components in the care of neonates who are considered high risk. This is particularly true for infants with very low birth weight (VLBW) for several reasons. Premature neonates typically require parenteral fluids, the quantity and composition of which can be highly variable. They also have important developmental limitations in renal homeostatic mechanisms. Finally, immature infants may be particularly susceptible to significant morbidity and mortality related to fluid and electrolyte and acid–base imbalances.

Fluid and Electrolyte Management

In this section, basic renal mechanisms for maintaining fluid and electrolyte homeostasis are reviewed, and factors that govern fluid and electrolyte requirements for term and preterm infants are outlined. Methods for monitoring fluid and electrolyte balance, and potential complications and treatments of fluid and electrolyte disorders, are discussed. Also, several specific situations in high-risk infants that require special consideration are addressed.

Body Fluid Composition in Fetuses and Newborns

Total body water (TBW) encompasses extracellular (interstitial and plasma) and intracellular water. Early in fetal development, TBW is almost 95% of the total body weight. As the fetus grows, there is a decrease in the proportion of body weight represented by water (Fig. 92.1).[20] At birth, TBW represents approximately 75% of body weight in a full-term infant. The progressive decrease in TBW is caused primarily by decreases in the extracellular water compartment. The TBW percentage in premature infants, therefore, is higher than that of term infants and is proportional to gestational age.[24] For instance, at 32 weeks, the infant's TBW is approximately 85% of the body weight, whereas that of a 23-week infant approaches 90%.[43]

During the first week of life, all healthy neonates experience a reduction in body weight. The major cause of this physiologic weight loss is a reduction in extracellular water.[56] In the first 24-48 hours after birth, infants have decreased urine output, followed by a diuresis phase, with urinary losses of water and sodium in the first week of life, resulting in weight loss.[34] Physiologic weight loss in the first few days of life in term and premature infants represents isotonic contraction of body fluids and seems to be part of a normal transitional physiologic process thought to be mediated through release of atrial natriuretic peptide.[40] In term infants, this weight loss can be up to 10%. In very premature infants, weight loss can be up to 15%.[58] Perturbations in this normal transitional physiology can lead to imbalances in sodium and water homeostasis. In ill term infants and premature infants, various factors (discussed subsequently) can lead to increased or decreased urinary or insensible water losses. Similarly, increased or decreased administration of intravenous fluids, with variable amounts of water and sodium, can have a significant impact on overall fluid balance.

Sodium Balance in Newborns

Sodium is the major component of the extracellular fluid (ECF) volume and plasma volume. The total sodium content (*not* the serum sodium concentration, which reflects only the relative relationship between salt and water) determines the volume of the ECF. Renal sodium handling is crucial in maintaining sodium balance and protecting against volume depletion or overload. Sodium is freely filtered by the glomerulus, and the bulk of the filtered sodium is reabsorbed in the proximal tubule. Additional sodium reabsorption occurs in the loop of Henle via the Na^+-K^+-2 Cl^- cotransporter, the therapeutic target of loop diuretics. In the distal convoluted tubule, sodium is further reabsorbed via the sodium chloride cotransporter, the therapeutic target of thiazide diuretics. The major site of fine regulation of sodium reabsorption is the collecting tubule, wherein aldosterone

acts on the principal cells to promote reabsorption through sodium channels located on the luminal membrane.

Healthy term neonates have basal sodium handling similar to that of adults, with a fractional excretion of sodium (FE_{NA}) of less than 1%, although a transient increase in FE_{NA} occurs during the diuretic phase on the second and third days of life.[34] In premature infants, however, renal sodium losses are inversely proportional to gestational age, with FE_{NA} equaling 5%-6% in infants born at 28 weeks' gestation (Fig. 92.2).[60] As a result, preterm infants may display negative sodium balance and hyponatremia during the initial 2-3 weeks of life because of high renal sodium losses and inefficient intestinal sodium absorption.[66] The mechanisms responsible for increased urinary sodium losses in preterm infants are multifactorial. The immature kidney exhibits glomerulotubular imbalance, a physiologic state that is present when the glomerular filtration rate (GFR) exceeds the reabsorptive capacity of the renal tubules. This imbalance is attributable to numerous factors, including a preponderance of glomeruli compared with tubular structures, renal tubular immaturity, large extracellular volume, and reduced oxygen availability.[49] Decreased responsiveness to aldosterone is also characteristic of fetal and postnatal kidneys compared with adult kidneys and results in a decrease in sodium reabsorption.

Urinary sodium losses in preterm and term neonates may be increased in certain conditions, including hypoxia, respiratory distress, hyperbilirubinemia, acute tubular necrosis, and polycythemia. Pharmacologic agents such as dopamine, beta blockers, angiotensin-converting enzyme inhibitors, and diuretics may also increase urinary sodium losses in neonates. The abnormalities in sodium and water balance seen in premature infants are attenuated, to some degree, by prenatal steroid administration. Prenatal steroid treatment is associated with decreased insensible water loss, a decreased incidence of hypernatremia, and an earlier diuresis and natriuresis.[44] This beneficial effect on water and sodium balance in infants with extremely low birth weight is thought to be mediated by maturation of the renal epithelial transport systems controlling fluid and electrolyte homeostasis.

Water Balance in Newborns

Water balance is controlled primarily by antidiuretic hormone (ADH), which controls water absorption in the collecting duct. ADH secretion is regulated by hypothalamic osmoreceptors that monitor serum osmolarity and baroreceptors of the carotid sinus and left atrium that monitor intravascular blood volume. Stimulation of ADH secretion occurs when serum osmolarity increases to greater than 285 mOsm/kg or when effective blood volume is significantly diminished. Increases in serum osmolarity also stimulate thirst receptors in the anterior hypothalamus to promote increased water intake. Intravascular volume has a greater influence on ADH secretion than serum osmolarity. Patients with hyponatremia and concomitant volume depletion are unable to suppress ADH in response to the decrease in serum osmolarity.

At baseline, when the serum osmolarity and effective blood volume status are normal, the collecting duct

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

is impermeable to water. In response to an increase in serum osmolarity or significant volume contraction, ADH produced in the hypothalamus binds to its receptor, arginine-vasopressin V2 receptor, located on the basolateral membrane of principal and inner medullary collecting duct cells. Receptor activation results in elevated levels of intracellular cyclic adenosine monophosphate. Downstream signaling pathways promote movement of preformed vesicles containing aquaporin 2 (AQ2) water channels to the apical surface. The presence of these water channels on the watertight apical membranes renders them permeable to water. Withdrawal of ADH stimulates endocytosis of AQ2-containing vesicles, which restores the collecting duct cells to a state of water impermeability.

This system may not be as straightforward as previously believed, however, because vasopressin V2 receptors have been shown to be expressed in nephron segments other than the collecting duct, notably the loop of Henle.[42] This study and others support the emerging concept of crosstalk between the ADH/vasopressin V2 receptor system (classically considered a regulator of water homeostasis only) and the renin-angiotensin system (classically considered a sodium regulator only), which may modulate renal handling of salt and water further.

Maximal renal concentration and dilution require structural maturity, well-developed tubular transport mechanisms, and an intact hypothalamic-renal vasopressin axis. In adults and older children, decreased water intake or increased water losses activate a highly efficient renal concentrating mechanism that can produce maximally concentrated urine with an osmolarity of 1500 mOsm/kg, resulting in fluid conservation. Conversely, excessive fluid intake triggers the diluting mechanism of the kidney that can produce maximally dilute urine with an osmolarity of 50 mOsm/kg, resulting in free water excretion.

Urinary concentrating ability is diminished in neonatal kidneys, particularly those of premature infants.[15,38] When challenged, term newborns can concentrate urine to an osmolarity of 800 mOsm/kg; preterm infants can concentrate urine to an osmolarity of only 600 mOsm/kg.[15] This diminished urinary concentrating ability, particularly in preterm infants, may limit a neonate's ability to adjust to fluid perturbations—notably perturbations that result in increased free water losses (e.g., increased insensible water losses). Multiple factors limit renal concentrating capacity in preterm infants. Structural immaturity of the renal medulla limits sodium, chloride, and urea movement to the interstitium. Preferential blood flow through the vasa recta limits generation of a medullary gradient. Diminished urea-generated osmotic gradient in the renal medulla limits production and maintenance of the countercurrent mechanisms that are essential in producing maximally concentrated urine. Finally, tubular responsiveness to vasopressin is diminished because of decreased transcription and protein synthesis of AQ2 water channels.[68]

Urinary dilution capability, in contrast, is normal in term neonates but diminished in preterm neonates. When challenged with a water load, term infants can produce dilute urine with an osmolarity of 50 mOsm/kg, similar to that of an older child or adult. The kidneys of preterm infants, however, may be capable of diluting the urine to an osmolarity of only 70 mOsm/kg.[38,52]

The diminished urinary diluting and concentrating capacities of neonates have important implications for their care. Excessive fluid restriction places newborns, particularly preterm neonates, at risk for dehydration or hypernatremia or both. Conversely, generous fluid intake poses the risk of intravascular volume overload or hyponatremia or both. High fluid intake has also been associated with an increased risk of symptomatic patent ductus arteriosus (PDA) and necrotizing enterocolitis.[7,10,11]

These facts underscore the importance of careful calculation of fluid and electrolyte requirements and close monitoring of fluid balance in high-risk neonates.

Calculation of Fluid and Electrolyte Requirements

Calculation of fluid and electrolyte requirements in newborns is based on maintenance needs, deficits, and ongoing losses. Crucial factors that determine these fluid requirements include gestational age, renal function, ambient air temperature and humidity, ventilator dependence, presence of drainage tubes, and gastrointestinal losses.[12]

Maintenance Fluids and Electrolytes

Maintenance fluid requirements represent the water required to maintain a newborn in neutral water balance. The total amount of maintenance fluid required is equal to urine production plus insensible losses. Table 92.1 summarizes maintenance fluid requirements during the first month of life for full-term and preterm infants. The numbers presented in Table 92.1 are only guidelines; they are to be used as a starting point for prescribing maintenance fluid for infants with low birth weight during the first week of life. Further adjustments must be based on the clinical situation. In particular, close attention to the patient's volume status and assessment of factors that may increase or decrease the baseline fluid requirements are essential to the appropriate management of these infants.

Insensible Losses

Insensible water losses (see Chapter 35) are primarily evaporative losses via the skin and respiratory tract. In newborns, one-third of insensible water loss occurs through the respiratory tract, and the remaining two-thirds occurs through the skin. Numerous physiologic, environmental, and therapeutic factors can influence insensible water loss, making it the most variable component of the maintenance fluid requirements in newborns. Table 92.2 summarizes the effect of various factors on the degree of insensible water loss in newborns. Transepidermal water loss contributes significantly to increased insensible losses of premature infants (Fig. 92.3).[21] There is an inverse relationship

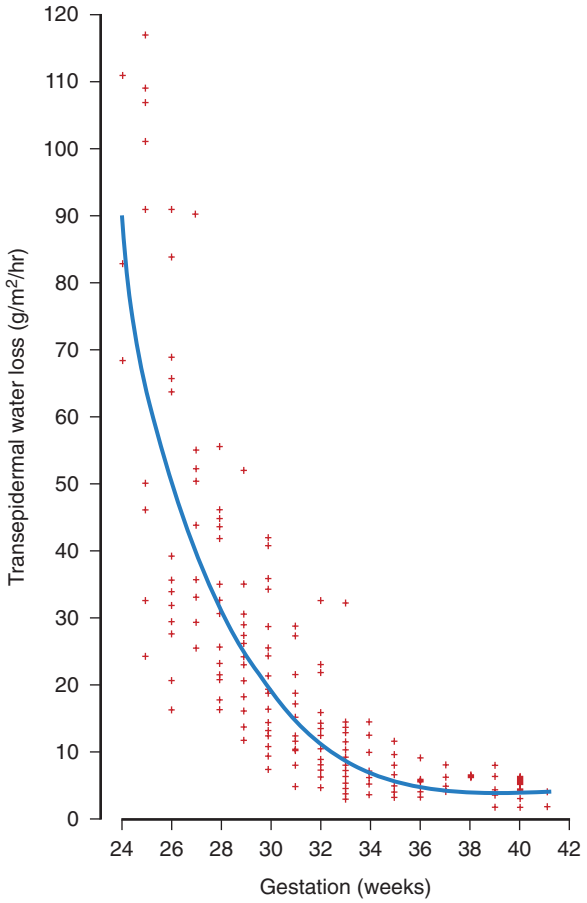
TABLE 92.1 Maintenance Fluid (Water) Requirements During the First Month of Life

Birth Weight (g)	Insensible Water Loss (mL/kg/d)	Total Water Requirements by Age (mL/kg/d)		
		Day 1-2	Day 3-7	Day 8-30
<750	100+	100-200	120-200	120-180
750-1000	60-70	80-150	100-150	120-180
1001-1500	30-65	60-100	80-150	120-180
>1500	15-30	60-80	100-150	120-180

Adapted from data from Veille JC. AGA infants in a thermoneutral environment during the first week of life. *Clin Perinatol*. 1988;15:863; Taeusch W, Ballard RA, eds. *Schaffer and Avery's diseases of the newborn*. 6th ed. Philadelphia: Saunders; 1991; and Lorenz J, et al. Phases of fluid and electrolyte homeostasis in the extremely low birth weight infant. *Pediatrics*. 1995;96:48.

TABLE 92.2 Factors Affecting Insensible Water Loss in Newborns



Factor	Effect on Insensible Water Loss
Level of maturity	Inversely proportional to birth weight and gestational age (see Fig. 92.3)
Environmental temperature above neutral thermal zone	Increased in proportion to increment in temperature
Elevated body temperature	Increased by up to 300% at rectal temperature >37.2°C
High ambient or inspired humidity	Reduced by 30% if ambient or respiratory vapor pressure equals skin or respiratory tract vapor pressure
Skin breakdown (e.g., burn)	Increased; magnitude depends on extent of lesion
Congenital skin defects (e.g., large omphalocele)	Increased; magnitude depends on size of defects
Radiant warmer	Increased by about 50% above values obtained in incubator setting with moderate relative humidity and neutral thermal environment
Phototherapy	Increased by up to 25%, depending on technique
Double-walled incubator or plastic heat shield	Reduced by 10%-30%

between body weight and insensible water loss in a neutral thermal environment with moderately high relative humidity.[67] Factors that contribute to these increased losses in preterm versus term infants include greater water permeability through a relatively immature epithelial layer of skin, a higher surface-area-to-body-weight ratio, and increased skin vascularity. Although prenatal glucocorticoids promote maturation of the renal tubules, they do not have a similar effect on skin maturation.[26] Infants who have conditions associated with skin breakdown, such as burns or large skin defects such as omphaloceles, also have increased transepidermal water loss. Phototherapy has been reported to increase insensible water losses by up to 26%.[35] However, with newer phototherapy techniques, this number may be substantially less.[36]

Ambient temperature and relative humidity play an important role in influencing transepidermal water loss.[8,9,21] An increase in ambient temperature results in increased insensible water loss. A decrease in ambient temperature has no effect on insensible water loss, however, despite the fact that it increases energy expenditure on the basis of cold stress. When ambient temperature is held constant, a lower ambient humidity increases skin water losses because of increased vapor pressure on the skin surface compared with the ambient vapor pressure; this is particularly true for very premature infants. A decrease in humidity from 60%-20% results in an increased water loss of 100% in infants of less than 26 weeks' gestation.[1] Use of newer humidified incubators has been reported to result in significant decreases in insensible fluid losses and fluid requirements in premature infants.[30] Alternatively, in the presence of high relative humidity, water evaporation is less. For example, infants on mechanical ventilation, which provides a humidified oxygen delivery system, have reduced water evaporation from the respiratory tract.

The quantity of water required for the formation of urine depends on two major factors: the degree of renal function and the renal solute load. Under normal conditions, a major determinant of renal water requirement is renal solute load. Renal solute load is derived from exogenous and endogenous sources. During the first 1-2 days of life, the exogenous solute load of infants with low birth weight may be low. Because these infants may not be fed enterally, caloric delivery by intravenous glucose-containing solutions

• **Fig. 92.3** Effects of gestation on transepidermal water loss. Measurements were made from abdominal skin and carried out in the first few days of life. (From Hammarlund K, et al. Transepidermal water loss in newborn infants. III. Relation to gestational age. *Acta Paediatr Scand*. 1979;68:795.)

does not meet basal energy needs. In the first 1-2 days of life, the basal energy requirement for infants with low birth weight is approximately 50 kcal/kg body weight. Currently, many infants are started on total parenteral nutrition (TPN) on day 1-2. If they are started at 70-90 mL/kg per day of a 10% glucose solution, the caloric intake is 35 kcal/kg per day. These infants must derive the remaining mandatory energy requirement from an endogenous source (i.e., catabolism). This catabolic state produces approximately 6 mOsm/kg per day of endogenous solute load presented to the kidney. Assuming the infant can produce a maximal urinary concentration of 600 mOsm/kg, a minimum of 10 mL/kg per day of free water is required to excrete this solute load.

As the infant ages, the exogenous intake from parenteral or enteral sources increases, resulting in increased caloric intake. The result is that the exogenous solute load increases, whereas catabolism decreases, resulting in a decreased endogenous solute load. It estimated that by 2 or 3 weeks of age, an infant consuming 80-120 kcal/kg per day has a total solute load of approximately 15-20 mOsm/kg per day. Assuming that the infant can produce a maximal urinary concentration of 800 mOsm/kg by this age, 20-25 mL/kg per day of free water is required to excrete the solute load.

Other Fluid Losses

Water loss through the gastrointestinal tract from stool output is minimal during the first few days of life, particularly in infants with low birth weight. When enteral feeds begin, the water loss in the stool is 5-10 mL/kg per day. In a growing infant, the amount of water required for new tissue formation should be considered in the calculation of maintenance fluid requirements. Because infants grow at the rate of 10-20 g/kg per day, and new tissue contains 70% water, the maintenance fluid required should provide a net water balance of 10-15 mL/kg per day.

Electrolyte Requirements

Maintenance sodium and chloride should not be provided in the first 1-2 days of life because of the relatively volume-expanded state of the newborn. Avoidance of sodium supplementation is particularly important in very premature infants, who have increased water losses and for whom early administration of sodium supplementation is associated with an increased risk of hypernatremia.[57] In contrast, sodium supplementation initiated after the first few days of life in premature infants was associated with improved weight gain in the neonatal period and improved developmental outcomes at age 10-13 years compared with a group of premature infants who did not receive supplementation.[2,25]

Potassium is not provided in parenteral fluid until urinary flow has been established and normal renal function is ensured and a normal serum potassium is confirmed. From postnatal days 3-7, maintenance sodium, potassium, and chloride requirements are approximately 1-2 mEq/kg per day. Beyond the first week of life, 2-3 mEq/kg per day or more of sodium and chloride is required to maintain the positive electrolyte balance that is necessary for the formation of new tissue. Because of high urinary sodium losses, premature infants may require 4 or 5 mEq/kg of sodium per day during the first few weeks of life.

Pathogenic Losses and Deficit Replacement

Many clinical situations require careful estimates of ongoing pathogenic losses and replacement of deficits. Commonly encountered conditions include diarrhea with dehydration, chest tube drainage, surgical wound drainage, and excessive urinary losses from osmotic diuresis. The important guiding principle in managing patients with these conditions is to measure the volume and composition of the pathogenic losses accurately. Electrolyte losses can be calculated by multiplying the volume of fluid loss by the electrolyte content of the respective body fluids (Table 92.3).

Estimating replacement for pathogenic fluid and electrolyte losses can be difficult, particularly in infants who accumulate fluid and electrolytes in static body fluid compartments. This phenomenon, commonly referred to as "third spacing," occurs in several conditions, including sepsis, hydrops fetalis, hypoalbuminemia, intra-abdominal

TABLE 92.3 Electrolyte Content of Body Fluids

Fluid Source	Sodium (mmol/L)	Potassium (mmol/L)	Chloride (mmol/L)
Stomach	20-80	5-20	100-150
Small intestine	100-140	5-15	90-120
Bile	120-140	5-15	90-120
Ileostomy	45-135	3-15	20-120
Diarrheal stool	10-90	10-80	10-110

infections, and after abdominal or cardiac surgery. An infant with necrotizing enterocolitis often accumulates fluid in the mucosal and submucosal tissues of the small and large intestine and in the peritoneal cavity. Under these circumstances, large amounts of fluid, electrolytes, and protein may leak into the interstitial tissue and cannot be accurately quantitated. Because fluid lost into these tissue spaces does not contribute to effective arterial blood volume and circulatory balance in these patients, they may appear edematous even though their intravascular volume is decreased. The most appropriate strategic approach in the management of these infants is to replenish the extracellular fluid compartments with colloid and crystalloid, as able.

Fluid and Electrolyte Balance

Interpretation of key clinical feedback is a crucial part of successful fluid and electrolyte management strategies in newborns. Fluid and electrolyte balance can be achieved by using a meticulous and organized system that obtains pertinent data and applies the physiologic principles outlined in the beginning of this chapter. A careful assessment of clinical indicators of volume status, including heart rate, blood pressure, skin turgor, capillary refill, oral mucosa integrity, and fullness of the anterior fontanelle, is essential. Other pertinent data that must be monitored include body weight, fluid intake, urine and stool output, serum electrolytes, and urine osmolarity or specific gravity.

During the first few days of life, appropriate fluid and electrolyte balance is reflected by a urine output of approximately 1-3 mL/kg per hour, a urine specific gravity of approximately 1.008-1.012, and an approximate weight loss of 5% in term infants and 15% in premature infants with very low birth weight.[58] Microsampling of serum electrolytes can be done at 8- to 24-hour intervals, depending on illness severity, gestational age, and fluid-electrolyte balance. Extracellular volume depletion is manifest by excessive weight loss, dry oral mucosa, sunken anterior fontanelle, capillary refill greater than 3 seconds, diminished skin turgor, increased heart rate, low blood pressure, elevated blood urea nitrogen, or metabolic acidosis. Serum sodium, which reflects sodium concentration but not sodium content, may be normal, decreased, or increased in states of volume depletion. Bedside monitoring of weight gain, as an indicator of volume status and growth, is essential for monitoring the adequacy of fluid and caloric intake in sick neonates. Beyond the first week of life, infants should gain approximately 20-30 g per day.

Hyponatremia and Hypernatremia

Hyponatremia and/or hypernatremia are extremely common in premature infants as well as in term infants with significant medical issues (such as perinatal asphyxia or septic shock). Hyponatremia, defined as a serum sodium less than 130 mmol/L, occurs in up to 30% of very low birth weight infants in the first week of life and 25%-65% after the first week.[6] Hypernatremia, defined as a serum sodium greater than 150 mmol/L, may occur in up to 40% of preterm infants born at <29 weeks' gestation.[23] Both hyponatremia and hypernatremia have been associated with significant complications. Large changes in serum sodium (either an increase or decrease) in the first month of life in premature infants have been associated with adverse long-term neurologic outcomes.[6] Alternatively, the presence of hypernatremia itself rather than rapid changes in sodium (up to 15 mmol/liter/day) has been identified as a risk factor for intraventricular hemorrhage.[17] Whether these long- and short-term poor outcomes are caused by the serum sodium changes themselves or, instead, reflect the severity of the infant's clinical situation, has yet to be established. However, given the potential risks, it is prudent to try attempt to maintain serum sodium levels within the normal range and avoid large fluctuations.

Hyponatremia

Hyponatremia is caused by one of three general mechanisms: (1) an inability to excrete a water load, (2) excessive sodium losses, or (3) inadequate sodium intake. Most commonly, sick newborns are unable to excrete a water load because of a decreased effective arterial blood volume preventing the suppression of ADH secretion. Hyponatremia may also occur because of decreased fluid delivery to the distal nephron diluting segments. Two common etiologies of this decreased delivery are decreased GFR caused by acute kidney injury (AKI) and increased proximal tubular fluid and sodium reabsorption associated with volume depletion. Defects in sodium chloride transport in the cortical and medullary ascending limb of the loop of Henle, which is essential in producing an osmotic gradient for distal water absorption via the countercurrent multiplier, also limit the diluting capacity of the nephron. The treatment for hyponatremia varies depending on the underlying etiology. A patient with hyponatremia and volume depletion should receive increased fluids, whereas a patient with oliguric acute kidney injury should have fluids restricted. These examples highlight the importance of assessing the neonate's volume status when determining therapy.

Hyponatremia in the newborn has historically been delineated as *early onset* (occurring in the first week of life) or *late onset* (occurring in the latter half of the first month

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

of life). Given the broad spectrum of gestational ages, underlying diseases, and clinical courses of neonates cared for in modern neonatal intensive care units, these distinctions may be less relevant. Assessing the individual neonate's clinical status is more important in determining the causes and appropriate interventions for hyponatremia. Increased free water load may be caused by one or more factors, including increased maternal free water intake during labor,[27] excess free water administration in the postnatal period, or perinatal nonosmotic release of vasopressin.[47] This latter phenomenon may be seen in conditions such as perinatal asphyxia, respiratory distress, bilateral pneumothoraces, and intraventricular hemorrhage[46] or with various medications, including morphine, barbiturates, or carbamazepine. Impaired free water clearance attributed to excessive vasopressin release has been reported in very low birth weight (VLBW) infants and may contribute to the development of chronic lung disease in those children.[64] Oliguric acute kidney injury or edematous disorders may also contribute to impaired ability to handle a water load. Alternatively, hyponatremia may be due to negative sodium balance. This condition may occur from either inadequate sodium intake or excessive renal losses because of a high fractional excretion of sodium, particularly in preterm infants of less than 28 weeks' gestation.[60]

Less common conditions, all of which result in pathologic urinary sodium losses, can cause hyponatremia in neonates and young infants. These conditions may be caused by inherited tubulopathies such as Bartter syndrome, or disorders of aldosterone production or responsiveness, respectively, including congenital adrenal hyperplasia (CAH) and pseudohypoaldosteronism. Aldosterone is a steroid hormone produced in the adrenal cortex that has a crucial role in maintaining sodium and potassium homeostasis in the kidney. It is produced in response to either volume depletion, via the renin-angiotensin-aldosterone axis, or an increase in serum potassium. Under the influence of aldosterone, apical epithelial sodium channels are inserted on the luminal (urinary) surface, allowing sodium to be reabsorbed down its concentration gradient. Potassium, as the primary intracellular cation, is excreted in return. This process is facilitated further by aldosterone-mediated increase in the activity of basolateral Na^+,K^+-ATPase.[51] Aldosterone also has a role in acid–base homeostasis and promotes hydrogen secretion (see Acid–Base Management) via actions on H^+-ATPase located on the luminal surface of adjacent intercalated cells. Abnormalities in either the production of, or the renal responsiveness to, aldosterone can result in variable degrees of renal sodium wasting, hyperkalemia, and metabolic acidosis.

Congenital adrenal hyperplasia (CAH) is an inherited disorder of cortisol synthesis that results in diminished aldosterone production[61] (See also Chapter 89). The most common form is complete absence of 21-hydroxylase activity, a key enzyme in the production of aldosterone. Affected girls have ambiguous genitalia at birth because of excess adrenal androgens. Patients typically present with shock and severe hyponatremia, hyperkalemia, and metabolic acidosis at 1-3 weeks of age as the result of a salt-losing crisis. Additional laboratory abnormalities typically seen with this disorder include elevated plasma levels of renin, adrenocorticotropic hormone, 17-hydroxyprogesterone, progesterone, androstenedione, and urinary 17-ketosteroids. Serum cortisol and aldosterone levels may be undetectable. Initial treatment is directed at correcting volume and electrolyte abnormalities, including fluid resuscitation and management of life-threatening hyperkalemia. Long-term glucocorticoid and mineralocorticoid replacement therapy should be instituted to facilitate normalization of serum electrolytes and to treat the underlying disease. Sodium supplements may be necessary for a prolonged period.

Pseudohypoaldosteronism (PHA) refers to a group of disorders characterized by renal tubular unresponsiveness to aldosterone as evidenced by hyperkalemia, metabolic acidosis, and variable degrees of renal sodium wasting. PHA can be primary (genetic) or secondary (acquired). The two subtypes of primary PHA include type I, which usually manifests in infancy with hypotension, severe sodium wasting, and hyperkalemia, and type II (Gordon syndrome), which typically presents later in childhood. Autosomal dominant type I PHA, previously designated the "renal" type I, is the most common type I PHA. Patients with this form usually present during early infancy with failure to thrive, weight loss, vomiting, dehydration, or shock. Sweat and salivary electrolytes are normal in this form of type I PHA. Although it is inherited in an autosomal dominant trait, expression may be variable. Treatment involves administration of large quantities of sodium chloride, 10 to 15 mEq/kg per day. Autosomal recessive type I PHA, previously designated "multiple target organ defects" type I PHA, is a severe, life-threatening systemic disease that affects sodium and potassium handling in the kidney, sweat glands, salivary glands, nasal mucosa, and colon.[22] Patients with this disorder usually present in the newborn period with severe salt wasting and life-threatening hyperkalemia. They also have increased sweat chloride that may mimic the presentation of cystic fibrosis. Sodium chloride supplementation alone often is inadequate in controlling hyperkalemia and metabolic acidosis in these patients. Dietary restriction of potassium intake and the use of rectal sodium polystyrene sulfonate resin (kayexalate), a sodium-potassium exchange resin, are often required. Indomethacin or hydrochlorothiazide may be necessary to control hyperkalemia and acidosis. Mutations in multiple different genes have been implicated in the pathogenesis of PHA type 1, including those encoding components or regulators of the mineralocorticoid receptor, epithelial sodium channels, and thiazide-sensitive sodium chloride co-transporter.[53] Secondary forms of PHA occur more commonly than primary forms and are typically caused by injury to the collecting tubules, the primary segment responsible for potassium balance. Causes of secondary PHA in the newborn period include unilateral renal vein thrombosis, neonatal medullary necrosis, urinary

tract malformations, pyelonephritis, or other tubulointerstitial diseases. Patients with congenital obstructive uropathies such as posterior urethral valves are particularly prone to exhibiting aldosterone resistance, manifest as a hyperkalemic metabolic acidosis, even in the face of relatively intact renal function.

Hypernatremia

Hypernatremia occurs as the result of increased insensible or urinary water losses, inadequate water intake, or excess sodium administration. Hypernatremia occurring in the first week of life is typically caused by increased insensible water losses, often coupled with the excess sodium intake that may occur after resuscitation with sodium bicarbonate. Many other medications can contribute to large "inadvertent" sodium loads, particularly in sick premature infants, including calcium gluconate, gentamicin, dopamine, dobutamine, heparin, and intravenous fluids used to maintain arterial or venous vascular lines.[12] Onset of hypernatremia later in the first month of life usually is attributable to either excess sodium supplementation or inadequate free water intake.

Excess urinary losses can occur as the result of diabetes insipidus (DI), which is characterized by severe urinary water losses reflecting an inability to produce concentrated urine. Diabetes insipidus results from either low levels of circulating ADH (central DI) or impaired renal response to ADH (nephrogenic DI). Newborns with this disorder present with hypernatremia, polyuria, polydipsia, chronic dehydration, irritability, fever, poor feeding, and growth failure.

Nephrogenic DI can be inherited (congenital) or occur as the secondary result of processes that cause renal tubular damage. The most common inherited form of nephrogenic DI is caused by mutations in the gene encoding the vasopressin receptor V2R and is inherited as an X-linked recessive disease.[65] Causes of secondary nephrogenic DI include congenital structural disorders such as obstructive uropathy or nephronophthisis, chronic kidney disease, hypercalcemia, and hypokalemia. Treatment of nephrogenic DI includes placement on a low sodium formula to reduce solute intake and resultant obligate water loss associated with solute excretion. Thiazide diuretics are also used to reduce extracellular sodium content, which enhances sodium reabsorption in the proximal tubule and diminishes sodium and water delivery to the distal nephron. Amiloride may also be necessary to reduce urinary potassium losses that may occur with the use of thiazide diuretics. Although prostaglandin inhibitors have been successfully used to treat nephrogenic DI, long-term use of these agents is not recommended because of gastrointestinal, hematopoietic, and renal complications.

Central DI may be caused by midline central nervous system malformations, anoxic encephalopathy, cerebral edema, or trauma.[16] Although some ADH secretion may be present in central DI, levels are insufficient to promote appropriate water absorption in the distal nephron. Desmopressin acetate (DDAVP) is generally an effective therapy for this condition, and DDAVP responsiveness can help distinguish central versus nephrogenic causes when the underlying etiology is unclear.

Fluid and Electrolyte Therapy in Common Neonatal Conditions

Perinatal Asphyxia

Renal parenchymal injury from perinatal asphyxia frequently results in acute tubular necrosis, which is commonly accompanied by oliguria or anuria. In the presence of acute kidney injury, fluid restriction to amounts equal to urine output plus insensible losses is crucial to avoid volume excess. In a term infant, insensible water losses are approximately 20-25 mL/kg per day, and stool loss is minimal. Fluid requirements during the first day of life in an anuric term infant are approximately 30 mL/kg per day. Insensible losses for an anuric premature infant may be as high as 80 mL/kg per day, depending on gestational age. Fluid restriction is often difficult to accomplish when relatively large volumes of intravenous medications are necessary or when the absence of central venous access limits the concentration of dextrose-containing fluid that can be delivered. High caloric density parenteral nutrition, delivered in as small a volume as possible, is often necessary when fluid restriction is undertaken to avoid fluid overload and water intoxication. When urine production normalizes, fluid intake can be liberalized to reflect urine output and insensible losses.

If the cause of oliguria or anuria is unclear, and the infant is believed to be intravascularly depleted, a test dose of 10 mL/kg body weight of normal saline can be given. During the oliguric or anuric phase of acute tubular necrosis, potassium should not be given to avoid hyperkalemia. During the recovery phase of acute tubular necrosis, small infants may experience large urinary sodium and potassium losses, which should be quantitated and replaced.

In severe perinatal asphyxia, the renal parenchymal injury may be severe enough to produce acute kidney injury (AKI) lasting for several days to weeks, or may be permanent in cases with cortical necrosis. In the presence of hyperkalemia, defined as serum potassium greater than 7 mEq/L, the cardiac rhythm of the infant should be monitored by continuous electrocardiogram to detect any cardiac arrhythmia. Treatment options for hyperkalemia include insulin given with glucose; sodium polystyrene sulfonate resin (kayexalate); sodium bicarbonate, if metabolic acidosis is present; and peritoneal dialysis. If a significant arrhythmia is present, calcium chloride or calcium gluconate infusion is also indicated to antagonize the toxic effects of hyperkalemia on the cardiac membrane.

In addition to acute kidney injury, other factors may influence fluid management in patients with severe perinatal asphyxia. Fluid restriction has been advocated by some for infants with perinatal asphyxia even in the absence of acute kidney injury. However, no systematic randomized

studies have determined whether this practice alters the long-term outcome for these patients. Over the last decade, use of hypothermia as a treatment for preventing mortality and neurologic sequelae of severe perinatal asphyxia has become common practice, although optimal duration and degree of hypothermia remains a subject of research.[37,59] To date, guidelines for fluid administration during hypothermia protocols have not been well delineated. However, hyponatremia has been reported as a complication of therapeutic hypothermia and has been associated with positive fluid balance, possibly related to decreased insensible losses from skin vasoconstriction.[45]

Hyperbilirubinemia

Severe hyperbilirubinemia (bilirubin >20 mg/dL after 72 hours of life) is not uncommon, occurring in approximately 1% of term neonates. Phototherapy is the mainstay of therapy[36]; however, several studies have also highlighted the importance of fluid therapy as an adjunct to phototherapy. A significant proportion of neonates with severe hyperbilirubinemia exhibit dehydration on admission.[39] In addition, intravenous fluids have been shown to accelerate the rate of decline in serum bilirubin and decrease the need for exchange transfusion in severely affected infants.[5] A recent meta-analysis, however, was unable to find evidence that intravenous fluids improve long-term neurologic outcome in otherwise healthy term infants.[31] It is still possible that intravenous fluids may prove to be beneficial to certain high-risk populations, including infants with dehydration or preterm infants, as these groups have been less well studied in this regard.

Symptomatic Patent Ductus Arteriosus

Patent ductus arteriosus (PDA) with left-to-right shunt and pulmonary edema is a common cause of morbidity in preterm infants, particularly infants with respiratory distress syndrome in the first few days of life. Fluid overload during this period has been associated with an increased incidence of symptomatic PDA,[10] possibly caused by the lack of isotonic contraction of body fluids in this group of infants. Fluid restriction, however, may not convey beneficial effects on pulmonary or systemic hemodynamics,[18] and could convey risks of increasing the risk of acute kidney injury, especially in infants receiving medical therapy for the PDA with indocin or ibuprofen.

Bronchopulmonary Dysplasia

Infants with bronchopulmonary dysplasia (BPD) present complex challenges in fluid and electrolyte management. Because of higher basal metabolic rates and increased caloric requirements, the caloric density or volume, or both, of parenteral or enteral feedings needs to be maximized. Care must be taken to provide optimal fluid and nutrient intake without incurring volume overload and worsening pulmonary disease. In addition, therapies used to treat the underlying lung disease—most notably, diuretics—may have significant effects on fluid and electrolyte balance.[28]

Furosemide, a potent loop diuretic, causes a marked increase in urinary sodium, potassium, and hydrogen ion excretion, leading to hypokalemic metabolic alkalosis. Long-term use of this diuretic may also result in enhanced urinary excretion of calcium leading to osteopenia of prematurity, urolithiasis, or nephrocalcinosis. Furosemide should be used with caution in neonates, particularly premature infants with acute kidney injury and infants receiving concomitant aminoglycoside therapy, to avoid complications of ototoxicity. Chlorothiazide, a less potent thiazide diuretic that acts at the distal tubule, also causes a hypokalemic metabolic alkalosis. In contrast to loop diuretics, thiazides decrease urinary calcium excretion. Treatment with spironolactone, a potassium-sparing aldosterone inhibitor, may be associated with hyperkalemia. Strategies used to avoid complications of diuretic use include minimizing diuretic dosages, obtaining serum electrolyte measurements to detect electrolyte imbalance, monitoring urinary calcium excretion (when applicable), and supplementing calcium to prevent osteopenia of prematurity. Sodium supplementation should be avoided because it may further contribute to hypervolemia and/or hypertension if present.

Acid–Base Management

In this section, normal acid–base homeostasis in neonates is reviewed, and how these processes are influenced during the stages of nephron development is discussed. The diagnostic and therapeutic approach to acid–base disorders is presented, and common acid-base disorders are discussed.

Acid-Base Homeostasis in Neonates

Normal neonatal metabolism occurs within a tightly controlled extracellular pH ranging from 7.35-7.43. Normal growth and development critically depend on this homeostasis, which is threatened in ill term newborns or premature infants. The maintenance of serum pH (i.e., hydrogen ion concentration) within the physiologic range requires two major processes: (1) acute compensation, which is accomplished by rapid acid or base buffering by intracellular and extracellular buffers in response to acute decreases or increases in serum pH, and (2) long-term compensation, which is accomplished by renal excretion of acid or base, including an obligate daily acid load of approximately 1-2 mEq/kg per day. Renal and extrarenal homeostatic mechanisms contribute to the maintenance of acid-base balance.

Acute Compensation: Body Buffer Systems

After an acute change in serum pH caused by losses or gains of acid or base to the body, intracellular and extracellular buffering mechanisms respond rapidly to return the serum pH to a physiologic level. In response to a decrease in pH, H^+ enters the cell in exchange for K^+ by way of an H^+/K^+ exchanger. H^+ is buffered by intracellular buffers, including

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

hemoglobin, organic phosphates, and bone hydroxyapatite. Conversely, when serum pH increases, H^+ leaves the cell in exchange for K^+. Acute acidosis often results in hyperkalemia, whereas alkalosis is associated with hypokalemia. Intracellular buffering accounts for about 47% of an acute acid load and can reach even higher levels during more prolonged episodes of acidosis. Much of this buffering capacity is in bone. In disorders characterized by chronic acidosis, increased bone resorption and loss of bone sodium, potassium, calcium, and carbonate occur. These effects on bone partially explain the invariable association of growth failure, a potentially significant issue for premature infants, with acidosis.

The major buffering mechanism in the extracellular fluid is mediated by the carbonic anhydrase system, as reflected in the following formula:

$$H^+ + HCO_3^- \overset{CA}{\leftrightarrow} H_2CO_3 \overset{CA}{\leftrightarrow} H_2O + CO_2$$

Regulation of carbon dioxide (CO_2) excretion by the respiratory system markedly improves the efficiency of this buffering system at physiologic pH. In the presence of carbonic anhydrase (CA), carbonic acid (H_2CO_3) is in equilibrium with CO_2. Addition or increased production of acid results in consumption of bicarbonate (HCO_3^-) and increased H_2CO_3 and CO_2. CO_2 then crosses the blood–brain barrier, resulting in a decrease in pH. This action stimulates central nervous system chemoreceptors, leading to increased respiration and resultant decreased CO_2 concentration within 12-24 hours. Similar respiratory compensation occurs in response to an alkali load, which leads to increased HCO_3^- concentration, resulting in hypoventilation and accumulation of CO_2.

Two formulas are particularly useful in understanding and evaluating acid–base disorders. The *Henderson-Hasselbach equation* expresses the relationship of pH, P_{CO_2}, and HCO_3^-:

$$pH = 6.1 + \log[HCO_3^- / (0.03 - P_{CO_2})]$$

where 6.1 is the pK_a of this equation.

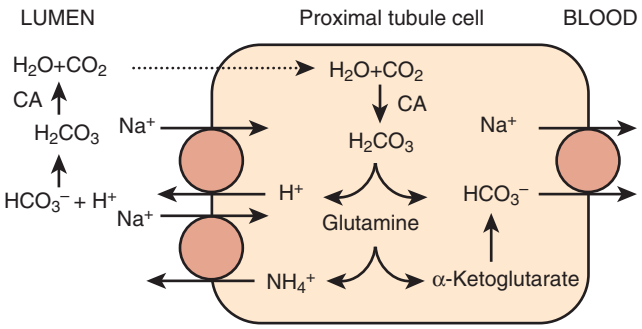
The *Winters formula*[3] can be used to predict the appropriate respiratory response (i.e., decrease in P_{CO_2}) to a primary metabolic acidosis:

$$P_{CO_2} = (1.5 \times HCO_3^-) + 8 \pm 2$$

Respiratory compensation in response to either metabolic acidosis or metabolic alkalosis does not completely normalize the pH. The Winters formula predicts that a decrease in HCO_3^- to 10 mmol/L would result in a decrease in P_{CO_2} to 21-25 mm Hg. By the Henderson-Hasselbach equation, the resulting serum pH is 7.22-7.29. This is markedly better than the serum pH of 7.02 that would be seen if no respiratory compensation occurred but is still not within the normal range. With "simple" metabolic acidosis or alkalosis, the respiratory compensation does not fully correct the serum pH. If serum pH is found to be in the normal range (or higher or lower than predicted), a mixed acid–base disorder, with an added primary respiratory abnormality, should be considered.

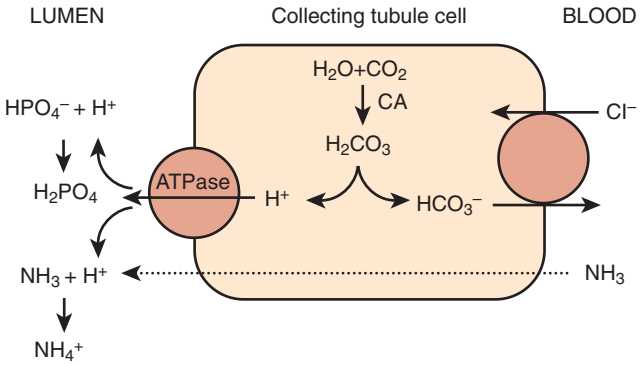
Long-Term Maintenance of Acid–Base Balance

Long-term maintenance of a normal serum pH depends on the balance between the production or intake of acid and base and their metabolism or excretion. Dietary intake accounts for a small amount of preformed acid, but most of the daily acid load is a product of obligatory metabolic functions. A large proportion consists of CO_2, which is carried to the lung as bicarbonate and carbamino groups bound to hemoglobin and ultimately excreted through respiration. This is termed *volatile* acid. Hypoventilation or hyperventilation leads to either retention or enhanced excretion of CO_2 and results in acidosis or alkalosis. Metabolic activity also produces an obligate nonvolatile acid "load" of approximately 1-2 mEq/kg per day. Most of this acid load is sulfuric acid, which results from metabolism of the sulfur-containing amino acids, methionine and cysteine. The remainder consists primarily of incompletely oxidized organic acids, phosphoric acid and hydrochloric acid. Successful maintenance of acid–base balance depends on renal excretion of this daily acid load.



The kidney plays an essential role in maintaining acid–base homeostasis by three major mechanisms:

1. Reabsorption of filtered bicarbonate and excretion of excessive bicarbonate in response to metabolic alkalosis
2. Excretion of the obligate daily acid load and any additional acid load from pathogenic processes, such as lactic acidosis related to sepsis or bicarbonate loss from diarrhea
3. Compensation for changes in serum pH that result from primary respiratory disorders



Bicarbonate reabsorption occurs primarily in the proximal tubule, wherein 60%-80% of the filtered bicarbonate load is reabsorbed. Bicarbonate is not reabsorbed via a specific transporter. Instead it is reabsorbed via an indirect mechanism. Bicarbonate present in the lumen is first buffered by H^+ that is secreted in exchange for sodium via a Na^+/H^+ exchanger located on the luminal membrane of proximal tubular cells (Fig. 92.4). Through the actions of carbonic anhydrase, CO_2 and H_2O are produced. CO_2 and H_2O diffuse into the cell, wherein HCO_3^- is regenerated and reabsorbed across the basal cell membrane in exchange for chloride. H^+ is also regenerated, making it available again for buffering of additional filtered bicarbonate. The net effect is that for every H^+ secreted, one molecule of filtered bicarbonate is reabsorbed.

Although proximal tubule bicarbonate reabsorption is essential in preventing bicarbonate wasting, no net H^+ excretion occurs in this process. Instead, excretion of the daily acid load is accomplished by two mechanisms: ammoniagenesis and production of titratable acids. Ammoniagenesis occurs in the proximal tubule (see Fig. 92.4) via the metabolic processing of glutamine produced in the liver. In the proximal tubule cell, glutamine is converted to ammonium (NH_4^+), which is secreted into the lumen in

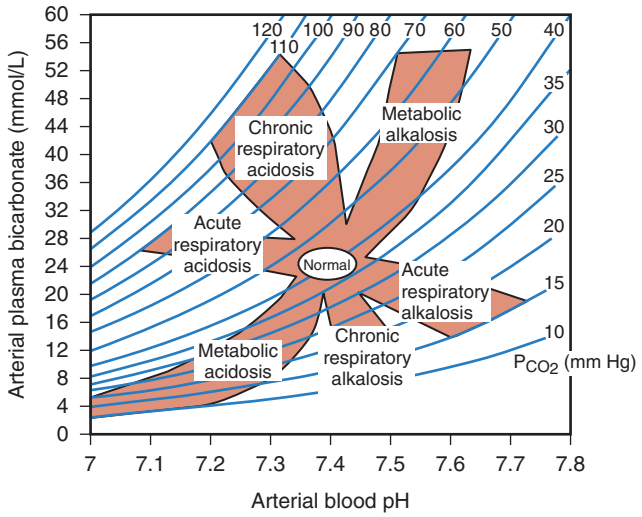
• **Fig. 92.4** Schematic drawing of proximal tubular HCO_3^- reabsorption and ammoniagenesis. See text for explanation. CA, Carbonic anhydrase.

• **Fig. 92.5** Schematic drawing of distal urinary acidification mechanisms. CA, Carbonic anhydrase.

exchange for Na^+. Deamination of glutamine also produces a-ketoglutarate, which buffers H^+. Through the actions of the intracellular carbonic anhydrase system, this process eventually results in the production of intracellular HCO_3^-, which can be reabsorbed across the basal membrane of the cell with Na^+. NH_4^+ secretion is the metabolic equivalent to H^+ excretion.

The remainder of acid secretion occurs in the cortical and medullary collecting tubule. H^+ is secreted into the collecting tubule against its pH gradient by H^+-ATPases located on the luminal membrane. This process is influenced by the luminal and peritubular pH, distal sodium delivery, and aldosterone. Secreted H^+ titrates filtered anions, including phosphates and sulfates, producing titratable acids (Fig. 92.5). The collecting tubule also secretes ammonia from the medullary interstitium, where it is buffered by H^+ to produce NH_4^+. Titratable acid formation and ammonia buffering require an acidic environment for protonation to occur. In addition to providing a source of H^+ for buffering, distal H^+ secretion is important in maintaining acidic urine (pH of 4.5-5.0).



The net acid excretion by the kidney is equal to the sum of titratable acids plus ammonium minus any filtered bicarbonate that is not reabsorbed. During steady-state, total acid secretion equals the production of acid from diet and metabolism. In response to an acid load, ammoniagenesis can increase dramatically because of enhanced production of glutamine by the liver. Ammoniagenesis is stimulated by hypokalemia and inhibited by hyperkalemia. In contrast, titratable acids are relatively fixed in their production except in instances of diabetic ketoacidosis, in which the ketone bodies themselves can form titratable acids. Alternatively, the kidney has the capacity to alter HCO_3^- reabsorption in response to changes in the filtered load of bicarbonate, further minimizing changes in pH.

Developmental Aspects of Acid–Base Physiology

Although nephron formation is complete by 34 to 36 weeks of gestation, maturation and functional changes of the nephron continue during the first year of life. The relative immaturity of the kidney, which is more pronounced in preterm infants, affects basal acid–base status and the response to additional acid and alkali loads.[33] During the initial 24-48 hours of life, acid–base balance is influenced by the degree of perinatal stress and environmental factors such as temperature and diet.[62] In the first 2 weeks of life, neonates are in a state of mild metabolic acidosis. In some infants, blood pH may decrease to less than 7.25, or base deficit may exceed 8 mEq/L. In ELBW infants, that deficit is even higher, averaging closer to 10.6 meq/L.[13]

The causes of this metabolic acidosis in neonates are multifactorial. The threshold for bicarbonate reabsorption in the proximal tubule is lower in neonates, especially premature infants, compared with adults, so that neonates tend to "waste" bicarbonate at a lower blood HCO_3^- concentration (15-21 mEq/L). Thus, the normal bicarbonate level in a healthy neonate is lower than that of older children or adults. Low GFRs, particularly in premature or stressed neonates, decrease the availability of phosphates and other buffers, decreasing the formation and excretion of titratable acids. Tubular immaturity results in reduced tubular secretory surface for organic acid secretion, diminished number of organic acid transport sites per unit area of renal tubular surface, and diminished energy available for organic acid transport. Premature infants are also unable to acidify their urine maximally at birth, exhibiting a minimal urine pH of 6, in contrast to full-term neonates and adults whose urine pH may reach 4.5. The ability of premature infants to acidify their urine maximally and to excrete an acid load correlates with gestational age. By 6 weeks of age, the capacity of premature and term infants to excrete hydrogen ions matures to permit maximal acidification. Premature infants, particularly extremely low birth weight infants, demonstrate impaired ammoniagenesis.[54] As noted previously, this is an important compensatory mechanism for excreting an acute acid load. The impairment in both bicarbonate conservation and net acid excretion related to tubular immaturity significantly limits the ability of premature infants to respond to additional stresses associated with acute acid loading such as sepsis-induced lactic acidosis.

TABLE 92.4 Expected Compensation in Acid–Base Disorders

	Primary Abnormality	Compensation
Respiratory	**ΔP_{CO_2}**	**ΔHCO_3^-**
Acute acidosis	↑ 1 mm Hg	↑ 0.1 mEq/L
Acute alkalosis	↓ 1 mm Hg	↓ 0.25 mEq/L
Chronic acidosis	↑ 1 mm Hg	↑ 0.5 mEq/L
Chronic alkalosis	↓ 1 mm Hg	↓ 0.5 mEq/L
Metabolic	**ΔHCO_3^-**	**ΔP_{CO_2}**
Acidosis	↓ 1 mEq/L	↓ 1.25 mm Hg
Alkalosis	↑ 1 mEq/L	↑ 0.2-0.9 mm Hg

Diagnostic Approach to Disorders of Acid–Base Balance

In generating a differential diagnosis of an acid–base abnormality, it is helpful to ask the following three questions:

1. What is the primary abnormality?
2. What is the secondary compensation?
3. Is the compensation appropriate?

The acid–base abnormality alone does not indicate if it is the primary disorder or a response to the primary disorder. A low serum bicarbonate level indicating metabolic acidosis could be caused by a primary metabolic acidosis or could represent a metabolic compensation for a primary respiratory alkalosis. Conversely, elevated serum bicarbonate could be a reflection of a primary metabolic alkalosis or a response to a primary respiratory acidosis. To distinguish the primary process from the secondary compensation, it is necessary to know the plasma pH, serum bicarbonate level, and CO_2 level. In addition to simple respiratory or metabolic acid–base disorders, "mixed" (combined) disorders may be seen, in which more than one primary process is present. Mixed disorders should be considered when the expected compensation falls out of the expected range.

The nomogram presented in Fig. 92.6 can aid in the diagnosis of simple and mixed acid–base disorders. It shows the 95% confidence limits of the expected compensatory response to a primary metabolic or respiratory acidosis or alkalosis. If the compensatory change in either P_{CO_2} or HCO_3^- falls beyond these limits (i.e., outside of the shaded region for each disorder), a combined disorder is present. Consider a newborn with pH of 7.17, P_{CO_2} of 34 mm Hg, and HCO_3^- of 12 mEq/L. The acidic pH and low serum HCO_3^- suggest a primary metabolic acidosis. When the values for pH, HCO_3^-, and P_{CO_2} are plotted on the nomogram, however, the convergence point falls out of the range for a simple metabolic acidosis, suggesting the possibility of a superimposed respiratory acidosis. To delineate this further, one can estimate the expected compensation (i.e., a respiratory alkalosis) based on the values presented in Table 92.4 or, alternatively, the Winters formula. With a decrease in serum HCO_3^- from 22 mEq/L to 12 mEq/L, P_{CO_2} should decrease by 12.5 mm Hg. The estimated compensation would result in a P_{CO_2} of 27 mm Hg. Similarly, the Winters formula predicts a compensatory P_{CO_2} of 24-28 mm Hg. The higher-than-expected P_{CO_2} confirms the presence of a superimposed primary respiratory acidosis.

Basic Principles of Therapy

Metabolic Acidosis

Metabolic acidosis is a common problem in critically ill neonates that results from either excess acid production or increased loss of base. Box 92.1 lists common causes of metabolic acidosis in neonates. Calculation of the anion gap allows differentiation into two groups. Increased anion gap metabolic acidosis is caused by the addition of exogenous acids (e.g., salicylates) or increased production of endogenous acids (e.g., lactic acid). In neonates, an increased anion gap is usually caused by increased production of endogenous acids, such as lactic acidosis in patients with sepsis or toxic metabolites in patients with inborn errors of metabolism. Increased anion gap metabolic acidosis is associated with a normal serum chloride.

In contrast, a normal anion gap metabolic acidosis is attributable to either bicarbonate loss in the urine (proximal renal tubular acidosis [RTA]) or the stool, or the inability to excrete acid because of a defect in distal nephron function (distal RTA). In this disorder, the serum chloride is elevated. Correction of the underlying cause is the most important therapeutic measure in the management of metabolic acidosis. The dose of alkali required to treat metabolic acidosis in newborns ranges from 1 mEq/kg per day for mild base deficits to 5-8 mEq/kg per day for more severe base deficits, such as seen in proximal RTA. Dialysis may be required

• BOX 92.1 Common Causes of Metabolic Acidosis in Neonates

Increased Anion Gap

Lactic Acidosis

- Hypoxemia, shock, sepsis
- Inborn errors of carbohydrate or pyruvate metabolism
- Pyruvate dehydrogenase deficiency
- Pyruvate carboxylase deficiency
- Mitochondrial respiratory chain defects
- Chronic kidney disease

Ketoacidosis

- Glycogen storage disease (type I)
- Inborn errors of amino acid or organic acid metabolism

Normal Anion Gap

- Bicarbonate loss: acute diarrhea; drainage from small bowel, biliary, or pancreatic tube; fistula drainage; bowel augmentation cystoplasty; ureteral diversion with bowel
- Renal tubular acidosis
- Mineralocorticoid deficiency
- Administration of Cl-containing compounds: arginine HCl, HCl, $CaCl_2$, $MgCl_2$, NH_4Cl parenteral alimentation, high-protein formula
- Carbonic anhydrase inhibitors
- Dilution of extracellular fluid compartment

Adapted from Brewer E. Disorders of acid-base balance. *Pediatr Clin North Am*. 1990;37:429.

when acid production is severe, such as in lactic acidosis, acute kidney injury, or severe inborn errors of metabolism.

Administration of alkali, such as bicarbonate, has several potential adverse effects, including volume overload, hypernatremia, decreased oxygen delivery to the brain secondary to shifts in the hemoglobin dissociation curve, increased P_{CO_2}, and a paradoxical intracellular acidosis as CO_2 diffuses into cells.[48] Bicarbonate administration should be used with caution in most neonates.[4] The notable exception is cases of suspected RTA (primary or secondary to chronic kidney disease), in which bicarbonate supplementation has an important role in growth and maintenance of bone health and lean muscle mass.[19]

Metabolic Alkalosis

Metabolic alkalosis is generated by one of three general mechanisms: (1) loss of acid, such as hydrochloric acid loss with vomiting; (2) ingestion of base, such as sodium bicarbonate administration during resuscitation; or (3) contraction of the extracellular volume, with loss of fluid containing more chloride than bicarbonate. Box 92.2 lists common causes of metabolic alkalosis in neonates.[10]

Although the kidney is usually very effective in excreting excess alkali, several conditions maintain metabolic alkalosis when it is generated. Extracellular volume depletion limits bicarbonate excretion by several mechanisms. The decrease in GFR reduces the filtered load of bicarbonate, and the bicarbonate that is filtered is rapidly reabsorbed in

• BOX 92.2 Common Causes of Metabolic Alkalosis in Neonates

- Acid loss: vomiting (e.g., pyloric stenosis), nasogastric suction
- Diuretics
- Chloride deficiency: chronic chloride-losing diarrhea, Bartter syndrome, low-chloride formula, loss via skin secondary to cystic fibrosis
- Administration of alkali: bicarbonate, lactate, acetate, citrate

the proximal tubule as a result of avid sodium reabsorption. Volume depletion also stimulates renin-angiotensin system-mediated release of aldosterone, which leads to an increase in distal renal tubular absorption of sodium and excretion of H^+ and potassium. Other states of hyperaldosteronism, such as excess production of endogenous mineralocorticoids or administration of exogenous steroids, lead to enhanced distal renal tubular excretion of H^+ and potassium. Potassium depletion also maintains metabolic alkalosis by stimulating renal ammoniagenesis and inhibiting movement of H^+ out of the cell. Chloride depletion or respiratory acidosis, as evidenced by an elevated P_{CO_2}, can also maintain metabolic alkalosis.

Therapy for metabolic alkalosis consists of correction of the underlying disorder. Alkalosis resulting from volume depletion typically improves with saline administration and potassium repletion. Use of agents such as ammonium hydrochloride may be associated with life-threatening complications such as severe acidosis or a paradoxical intracellular alkalosis and is not supported by the literature. Acetazolamide has been used safely in patients with chronic contraction alkalosis associated with congenital heart disease.[41] However, no randomized studies have addressed the use of this agent in neonates or infants with chronic lung disease or other disorders requiring long-term diuretic therapy. As an alternative, aggressive repletion of potassium and chloride alone may facilitate correction of the hypokalemic metabolic alkalosis. Both oral and intravenous potassium supplementation may be required to correct significant total body potassium deficits. Although the long-term complications of chronic metabolic alkalosis are unknown, prolonged pH greater than 7.6 may increase the risk for sensorineural hearing loss.[32]

Respiratory Acidosis and Alkalosis

Respiratory acidosis results from any disorder with decreased alveolar ventilation, resulting in retention of CO_2. In neonates, this condition is usually caused by respiratory distress syndrome, meconium aspiration syndrome, pulmonary infections, or congenital diaphragmatic hernia. Correction of the underlying cause of respiratory acidosis is essential and frequently requires the use of assisted ventilation to increase excretion of volatile acid (CO_2). Administration of alkali to correct acidemia caused by a primary respiratory acidosis is generally inappropriate. The resultant increase

in serum bicarbonate levels (and serum pH) promotes hypoventilation and a further increase in P_{CO_2}, exacerbating the respiratory acidosis. In instances in which a mixed acid–base disorder is present (i.e., a primary respiratory acidosis and a primary metabolic acidosis), bicarbonate administration should be used with caution, and assisted ventilation is typically required.

Respiratory alkalosis is rare in neonates; however, it may occur during excessive assisted ventilation or during central hyperventilation secondary to serious central nervous system disease. Patients with respiratory alkalosis who are dependent on ventilators are treated easily by adjusting the assisted ventilation settings. A search for underlying causes of central hyperventilation is necessary in other patients.

Specific Acid–Base Disorders That May Manifest in the Neonatal Period

Renal Tubular Acidosis

Renal tubular acidosis is a disorder characterized by a normal anion gap metabolic acidosis and is the sequela of either impaired reabsorption of bicarbonate or impaired urinary acidification/H^+ ion excretion. It may be the result of an inherited defect in the renal handling of H^+ ion or bicarbonate.[50]

More commonly, it is secondary to tubular damage from various causes, such as medications or obstructive uropathy. There are three main forms of RTA: type I (distal), type II (proximal), and type IV (hyperkalemic) (Box 92.3). Each form of RTA has a distinct pathophysiology and characteristic serum and urinary laboratory findings.

Type I (distal) RTA results from diminished distal H^+ secretion. Patients with distal RTA often present in the newborn period or during early infancy with lethargy, polyuria, vomiting, dehydration, and failure to thrive. Distal RTA is usually accompanied by hypokalemia, because potassium is secreted in lieu of H^+ to maintain electronegativity. Concomitant hypercalciuria and hypocitraturia predispose patients to the development of nephrocalcinosis and nephrolithiasis.

Distal RTA can occur as a sporadic form, although several well-characterized inherited forms have been described. In each instance, the genetic defect results in impairment of a specific component of the distal acidification mechanisms (see Fig. 92.5). Autosomal recessive and autosomal dominant forms have been described.[50] Acquired forms of type I RTA also can occur as the result of tubular injury. Certain medications cause damage to the distal nephron and result in backleak of H^+ from the lumen. Amphotericin toxicity is a classic example of this "gradient defect" form of acquired distal RTA. In addition, congenital lesions, most notably obstructive uropathies, may cause secondary RTA because of tubular damage from obstruction or infections.

The diagnosis of suspected distal RTA should be considered in any infant with a urinary pH that is greater than 6.5 in the presence of a nonanion gap metabolic acidosis.

• BOX 92.3 Classification of Renal Tubular Acidosis

Type I (Distal)

- Primary (autosomal dominant or recessive; sporadic)
- Secondary, associated with other renal disorders
  - Obstructive uropathy
  - Hypercalciuria/nephrocalcinosis
- Secondary, associated with acquired or other hereditary diseases
  - Osteopetrosis
  - Sickle cell anemia
  - Hereditary elliptocytosis
  - Marfan syndrome
  - Primary biliary cirrhosis
- Secondary, associated with drugs or toxins (e.g., amphotericin B)

Type II (Proximal)

- Primary (familial or sporadic)
  - Fanconi syndrome
- Primary
  - Cystinosis
  - Tyrosinemia
  - Oculocerebral renal syndrome (Lowe syndrome)
  - Hereditary fructose intolerance
  - Wilson disease

Type IV (Hyperkalemic)

- Pseudohypoaldosteronism
- Renal immaturity
- Obstructive uropathy
- Potassium-sparing diuretics
- Chloride shunt
- Hyporenin hypoaldosteronism
- Medications (e.g., cyclosporine)

Adapted from Brewer E. Disorders of acid-base balance. *Pediatr Clin North Am*. 1990;37:429.

Conversely, a urine pH of 5.5 or less indicates that distal acidification mechanisms are intact and effectively rules out distal RTA. The urine anion gap ($= Na^+ + K^+ - Cl^-$) indirectly assesses the amount of urine ammonium and can be helpful in distinguishing distal and proximal RTA. A positive value suggests a defect in urine ammonium excretion and deficient urinary acidification consistent with a distal RTA.[29]

Although primary distal RTA is a permanent defect, the prognosis for growth and the prevention of renal insufficiency is satisfactory when the condition is correctly treated. Therapy for distal RTA in infancy consists of the administration of alkali, usually in the form of an alkali-containing liquid such as Bicitra. The typical dose is 2-3 mEq/kg per day. Maintenance of normal blood pH and serum bicarbonate maximizes the opportunity for normal growth.

Type II (proximal) RTA is caused by a decrease in the threshold tubular maximum for HCO_3^- reabsorption in the proximal tubule, resulting in HCO_3^- wastage. The tubular maximum is decreased to approximately 15 mEq/L,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

so reabsorption of bicarbonate does not occur until the serum levels decrease to less than this value. The loss of HCO_3^- is often large because 60%-80% of the filtered HCO_3^- is normally reabsorbed in the proximal tubule. Distal urinary acidification is normal, and patients can appropriately acidify the urine (pH ≤5.5) when plasma HCO_3^- levels are less than 14-15 mEq/L. An increase in plasma HCO_3^- beyond the capacity of the proximal tubule results in HCO_3^- wastage and an alkaline urine pH of 7.6 or greater. Isolated inherited forms of proximal RTA occur rarely and can be inherited as an autosomal recessive (with ocular abnormalities) or autosomal dominant trait.[50] More commonly, proximal RTA is a component of Fanconi syndrome, a disorder of global proximal tubule dysfunction. In addition to bicarbonate wasting, patients with Fanconi syndrome exhibit tubular wasting of sodium, potassium, glucose, phosphorus, and amino acids. Fanconi syndrome is seen in many inherited metabolic disorders, including Lowe syndrome, galactosemia, tyrosinemia, and hereditary fructose intolerance. Patients with proximal RTA typically require larger amounts of bicarbonate supplementation than patients with distal RTA. Dosages of 10 mEq/kg or more per day may be required because of excessive HCO_3^- wastage.

As previously discussed, neonates display a mild degree of proximal RTA because of an altered threshold for proximal tubular HCO_3^- reabsorption, with maintenance of plasma HCO_3^- in the range of 15-21 mEq/L. Over the first year of life, the tubular maximum for HCO_3^- increases to adult levels as the proximal tubule elongates and transport function matures. Type IV (hyperkalemic) RTA is characterized by impaired ammoniagenesis as the result of hyperkalemia. Hyperkalemia results from abnormalities in aldosterone production or from altered tubular sensitivity to aldosterone. Disorders associated with abnormalities in mineralocorticoid production (e.g., congenital adrenal hyperplasia) or responsiveness (i.e., inherited or acquired pseudohypoaldosteronism) have been discussed earlier in this chapter. The symptoms of type IV RTA in infancy include dehydration and symptoms related to hyperkalemia. Laboratory abnormalities include a nonanion gap metabolic acidosis, hyperkalemia, elevated urine sodium, and diminished urine potassium. Therapy for type IV RTA consists of mineralocorticoid supplementation in conditions characterized by a deficiency of aldosterone. Treatment of hyperkalemia may reverse many of the abnormalities; however, alkali supplementation is generally required in patients with end-organ resistance to aldosterone, such as those with congenital obstructive uropathies. The need for such supplementation may decrease in the first few years of life, likely related to further maturation of the kidney.

Neonatal Bartter Syndrome

Bartter syndrome is a heterogeneous group of inherited tubular disorders characterized by hypokalemia, hypochloremia, and metabolic alkalosis. Typically, it is manifest as obligate and uncontrolled renal losses of sodium, potassium, and chloride. In the past, three clinically and genetically distinct variants of this syndrome were recognized: antenatal Bartter syndrome, "classic" Bartter syndrome, and Gitelman syndrome. However, in recent years, mutations in other tubular transporter-associated genes have been identified in patients with "Bartter-like" or "pseudo-Bartter" phenotypes, including antenatal presentations.[14,55]

The antenatal variant is typically the most severe form and manifests in the neonatal period with polyuria (leading to dehydration, hyponatremia, and hypokalemia). Urinary sodium and potassium losses can be massive. A history of polyhydramnios is also typical. Some patients will manifest characteristic dysmorphic facies, including triangular facies, protruding ears, strabismus, and a drooping mouth, but this is not invariant. Additional laboratory findings include markedly elevated plasma renin levels, normal serum magnesium levels, and elevated urine calcium excretion. Nephrocalcinosis may be evident on ultrasonography. This form of Bartter syndrome is inherited as an autosomal recessive trait and is often associated with mutations in genes encoding the rectifying potassium channel or the Na^+-K^+-2 Cl^- cotransporter both important for sodium and chloride reabsorption in the Loop of Henle. Treatment includes the use of indomethacin to inhibit prostaglandin and aldosterone production, sodium and potassium supplementation, and maintenance of adequate intravascular volume.

Key Points

- Neonates, especially premature neonates, are at increased risk of developing fluid, electrolyte, and acid–base disorders because of developmental differences in body water compensation and tubular immaturity compared with children and adults.
- Fluid and electrolyte therapy need to be tailored to the individual patient's clinical situation, taking into account gestational age, volume status, respiratory status, hemodynamic stability, and the presence of additional conditions, such as perinatal asphyxia, or mechanical devices, such as ventilators or phototherapy devices.
- Total body sodium determines overall volume status. Serum sodium is a reflection of the relationship between sodium and water but is generally not a reliable indicator of hyper- or hypovolemia.
- Hyponatremia is the result of an inability to excrete a water (fluid) load or renal tubular sodium wasting, which have different treatments. Assessment of overall volume status is an important consideration when assessing hyponatremia. Administration of sodium to treat hyponatremia in a patient suspected of having hypervolemia should be avoided.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

- Premature neonates have impaired urinary acidification mechanisms including impaired bicarbonate reabsorption, ammoniagenesis, and hydrogen ion secretion, all of which may contribute to development or persistence of acidosis, especially in the face of increased acid load.
- Rare inherited tubular disorders may present in the neonatal period with abnormalities in serum sodium, potassium, and/or bicarbonate and should be considered in the differential diagnosis of neonates with persistent electrolyte or acid–base disorders without a clear etiology.

The Kidney and Urinary Tract of the Neonate

BETH A. VOGT AND TAMAR SPRINGEL

In the past 25 years, the field of clinical neonatal nephrology has expanded significantly in concert with major advances and changes in the care and survival of neonates, particularly premature neonates. The widespread use of invasive vascular catheters, for example, has resulted in a new set of complications, including acute kidney injury (AKI) and renovascular hypertension related to thromboembolic disease. The improved survival of infants with extremely low birth weight and bronchopulmonary dysplasia has led to the relatively new complication of neonatal nephrocalcinosis. The increased use of prenatal ultrasonography has created new paradigms for the prenatal management of urinary tract anomalies (see Chapter 11).

The goals of this chapter are to review the anatomic and functional development of the kidney, outline the recommended approach to the evaluation of the neonate with suspected renal disease, and provide an overview of the common nephrologic and urologic problems seen in preterm and term neonates.

Kidney and Urinary Tract Development

Kidney and urinary tract development is a complex process involving interactions between genes involved in the formation and maturation of the glomeruli, tubules, renal blood vessels, extracellular matrix, and uroepithelium. This carefully coordinated process involves the regulated activation and inactivation of hundreds of genes that encode transcription factors, growth factors and receptors, structural proteins, adhesion molecules, and other regulatory proteins.[63] Since the mid-1990s, the rapidly expanding field of molecular genetics has provided important new insights into the mechanisms involved in renal and urinary tract development. A detailed review of the genes and signaling pathways involved in renal development is beyond the scope of this chapter; therefore, the reader is referred to two detailed reviews of the subject.[22,40] This section highlights some of the important pathways involved in these processes and provides examples of human kidney diseases resulting from abnormalities in normal development.

Development of the Kidney

Kidney embryogenesis involves successive formation of three different kidneys: the pronephros, mesonephros, and metanephros. The formation of these structures during intrauterine development is illustrated in Fig. 93.1. The pronephros, a vestigial structure of 7-10 solid or tubular cell groups called nephrotomes, develops in the cervical region and disappears by the end of the fourth week of gestation. As the pronephros regresses, the mesonephros appears and is characterized by excretory tubules that form an S-shaped loop, with a glomerulus and Bowman capsule at the proximal end. At the distal portion, the tubule enters the collecting duct (also referred to as the mesonephric or Wolffian duct), which does not drain into the coelomic cavity. During the second month of gestation, the urogenital ridge, which is the forerunner of the gonads, develops. By the end of the second month of gestation, most portions of the mesonephros disappear. However, a few caudal tubules remain in close proximity to the testis and ovaries, developing into the vas deferens in males and remaining as remnant tissue in females.

The metanephric, or definitive, kidney is derived solely from intermediate mesoderm and begins forming at 5 weeks of gestation, when a portion of the Wolffian duct swells to form the ureteric bud (UB). The UB, composed of epithelium, then invades the nearby metanephric mesenchyme. The outgrowth and subsequent branching of the ureteric bud is dependent on interaction between glial cell–derived neurotrophic factor (GDNF) expressed by the metanephric mesenchyme and Ret receptors present on the UB. The GDNF-Ret interaction leads to patterned, progressive divisions of the UB (called "branching morphogenesis") that form the collecting ducts of the kidney as well as the major and minor caliceal system of the renal pelvis. At the tip of the branches, the mesenchymal cells of the metanephric blastema are induced by the advancing ureteric bud to differentiate into the epithelial cells that eventually become the glomeruli and renal tubules. The branching UB cells are dependent on the support of extracellular matrix

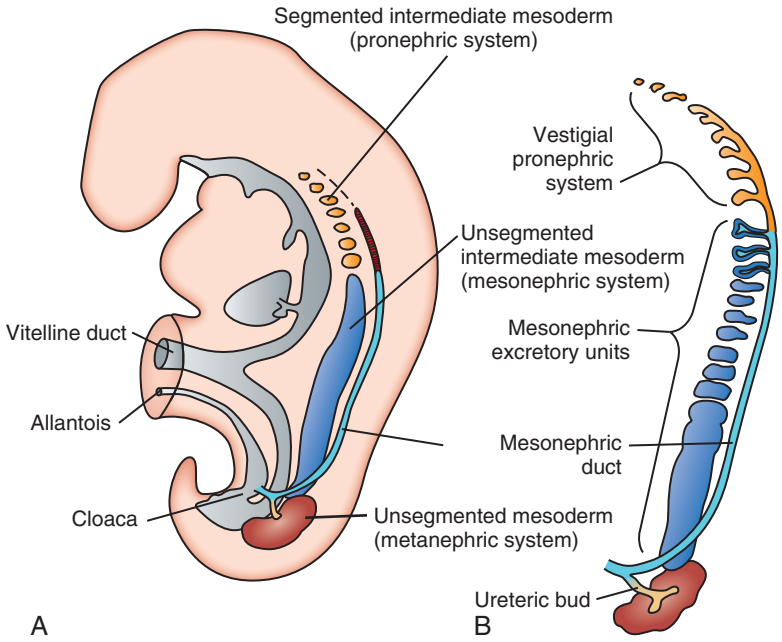
Abstract



In the past 25 years, the field of clinical neonatal nephrology has expanded significantly in concert with major advances and changes in the care and survival of neonates, particularly premature neonates. The widespread use of invasive vascular catheters, for example, has resulted in a new set of complications, including acute kidney injury (AKI) and renovascular hypertension related to thromboembolic disease. The improved survival of infants with extremely low birth weight and bronchopulmonary dysplasia has led to the relatively new complication of neonatal nephrocalcinosis. The increased use of prenatal ultrasonography has created new paradigms for the prenatal management of urinary tract anomalies (see Chapter 11).

The goals of this chapter are to review the anatomic and functional development of the kidney, outline the recommended approach to the evaluation of the neonate with suspected renal disease, and provide an overview of the common nephrologic and urologic problems seen in preterm and term neonates.

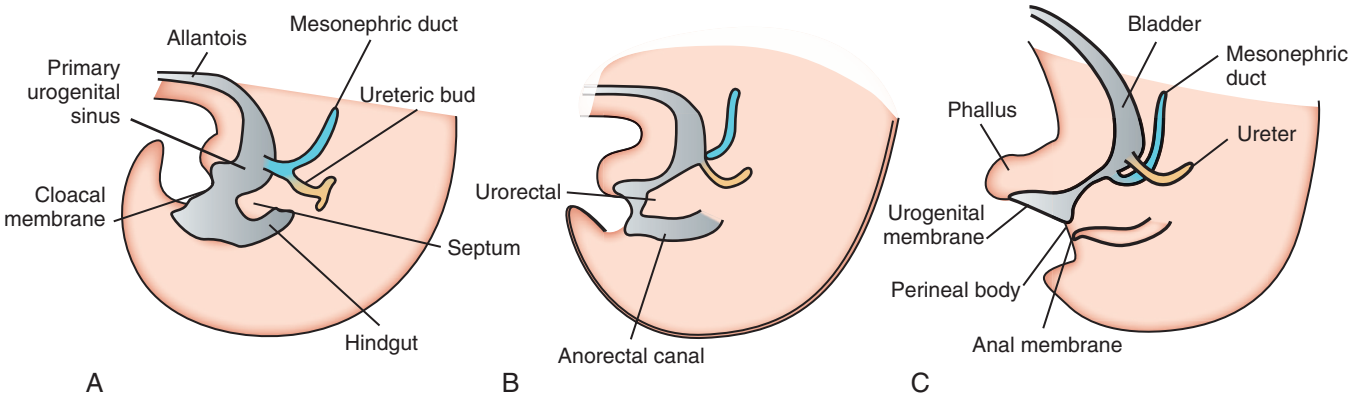
• **Fig. 93.1** Development of the early embryonic kidney. **A,** Schematic diagram showing the relation of the intermediate mesoderm of the pronephric, mesonephric, and metanephric systems. In the cervical and upper thoracic regions, the intermediate mesoderm is segmented; in the lower thoracic, lumbar, and sacral regions, it forms a solid, unsegmented mass of tissue known as the nephrogenic cord. Note the longitudinal collecting duct, initially formed by the pronephros but later taken over by the mesonephros. **B,** Schematic representation of the excretory tubules of the pronephric and mesonephric systems in a 5-week-old embryo. The ureteric bud penetrates the metanephric tissue. Note the remnant of the pronephric excretory tubules and longitudinal collecting duct. (From Langman J, ed. *Medical embryology.* 3rd ed. Baltimore: Williams & Wilkins; 1975:162.)

components such as laminins and integrins. Foci of the metanephric blastema become condensed adjacent to the branching ureteric bud to form comma-shaped bodies that then elongate to form S-shaped bodies. The lower portion of the S-shaped body becomes associated with a tuft of capillaries to form the glomerulus, because the upper portion forms the tubular elements of the nephron.

The metanephric kidney ascends from the pelvic to the thoracolumbar region. This process is thought to occur as the result of a decrease in body curvature and body growth of the lumbar and sacral regions. In the pelvis, the metanephric kidney receives its blood supply from a pelvic branch of the aorta. During ascent, the metanephric kidney receives its blood supply from arterial branches at higher levels of the aorta. Although the pelvic vessels usually degenerate, persistence of these early embryonic vessels can lead to supernumerary renal arteries. The metanephric kidney becomes functional during the second half of pregnancy. Nephrogenesis, which is the formation of new nephron units, is complete at 34 weeks of gestation, when each kidney contains its definitive complement of approximately 800,000 to 1.2 million nephrons.[3]



Development of the Bladder and Urethra

The bladder and urethra are formed during the second and third months of gestation, which is illustrated in Fig. 93.2. During the fourth to seventh week of development, the cloaca, which is located at the proximal end of the allantois and is the precursor to the urinary bladder and urethra, is divided by the urorectal septum into the primitive urogenital sinus (anterior portion) and the anorectal canal (posterior portion). The primitive urogenital sinus develops into the bladder (upper portion), prostatic and membranous urethra (pelvic portion) in males, and the penile urethra (males) or urethra and vestibule (females). As the cloaca develops, the caudal portion of the mesonephric ducts is absorbed into the bladder wall. Similarly, the caudal portions of the ureters, which originate from the mesonephric ducts, enter the bladder. During these processes, the ureteral orifices move cranially and the mesonephric ducts move closer together to enter the prostatic urethra, forming the trigone of the bladder. At the end of the third month of gestation, the epithelial proliferation of the prostatic urethra forms outbuddings that constitute the prostate gland in males. In females, the cranial portion of the urethra forms buds that develop into the urethral and paraurethral glands.[70]

Genetic and Prenatal Factors Affecting Renal Development

Studies in animal models have highlighted the important role of multiple proteins and signaling mechanisms in nephrogenesis, including growth factors such as fibroblast

TABLE 93.1 Genes Associated With CAKUT in Humans[63,66]

Type of Malformation	Renal Phenotype	Gene	Cause
Renal agenesis	Absence of the ureter and kidney	*RET, GDNF, FGF20, FRAS1, FREM2*	Lack of interaction between the ureteric bud and MM
Renal hypoplasia	Reduced number of ureteric bud branches and nephrons, small kidney size, often associated with dysplasia	*Pax2, Sall1, Six2, BMP4, HNF1B, UMOD*	Aberrant interaction between ureteric bud and MM
Renal dysplasia	Reduced number of ureteric bud branches and nephrons, undifferentiated stromal and mesenchymal cells, cysts, or cartilage	*PAX2, HNF1B, UMOD, Nphp1 BMP4, Six2, XPNPEP3*	Aberrant interaction between ureteric bud and MM
MCDK	Absent glomeruli and tubules	*HNF1B, UPIIIA, PEX26, ELN, HNF1B, ALG12, FRG1, FRG2, CYP4A11*	Aberrant interaction between ureteric bud and MM
Duplex ureters	Duplex ureters and kidneys or duplex ureters and collecting systems	*Robo2, FoxC1, FoxC2, BMP4*	Supernumerary ureteric bud budding from the MD
Horseshoe kidney	Kidneys are fused at inferior lobes and located lower than usual	*HNF1B*	Defects in renal capsule
VUR	Urine refluxes to various degrees from bladder up into the collecting system	*PAX2, ROBO2, SIX1, SIX5, SOX17, TNXB, CHD1L, TRAP1*	Aberrant insertion of ureter into bladder wall
Renal tubular dysgenesis	Absence of or incomplete differentiation of proximal tubule	*ACE, AGT, AGTR1, REN*	Impaired tubular growth and differentiation

CAKUT, Congenital anomalies of the kidney and urinary tract; MD; mesonephric duct; MCDK, multicystic dysplastic kidney; MM, metanephric mesenchyme

growth factor (FGF), adhesion molecules such as integrin alpha 8, the transcription factor WT-1, the canonical Wnt/beta catenin signaling pathway, and the GDNF/Ret tyrosine kinase signaling pathway.[22,40] Alterations in the actions of one or more of these proteins/pathways can result in renal or urogenital anomalies such as renal agenesis, renal dysplasia, cystic kidneys, and glomerulosclerosis.

A number of genes have been associated with congenital anomalies of the kidney and urinary tract (CAKUT) and often present with similar renal phenotypes (Table 93.1).[66] Genetic mutations associated with CAKUT may be inherited in an autosomal dominant or recessive pattern, but most often occur as sporadic, *de novo* mutations. In addition to monogenic causes, copy number variation (CNV) has

been found in 10%-16% of patients with CAKUT, specifically in patients with posterior urethral valves or multicystic dysplastic kidneys.[17] However, identified genetic mutations do not account for all patients with CAKUT, and the majority of patients with anomalies do not have a known mutation identified.

Certain prenatal factors have been associated with increased risk of CAKUT. Maternal diabetes mellitus, older maternal age, gestational hypertension, and BMI greater than 25 were associated with higher likelihood of having renal dysplasia or obstructive uropathy in the infant.[30] Teratogenic effects of several drugs have been documented, most notably angiotensin converting enzyme inhibitors (ACE-I) and angiotensin II receptor blockers (ARB). ACE-I fetopathy presents with renal tubular dysgenesis, neonatal anuria, pulmonary hypoplasia, and occasional central nervous system abnormalities, most often after exposure to ACE-I or ARB during the second trimester of pregnancy.[51] Animal studies have demonstrated nephrotoxic effects of nonsteroidal, anti-inflammatory drugs; immunosuppressive medications, such as corticosteroids, cyclosporine, and tacrolimus; and antibacterial medications, such as aminoglycosides and beta-lactams.[48] These drugs are mostly associated with reduced nephron mass, but their effects in humans are still uncertain. Finally, heavy metal exposure can potentially damage fetal kidney development, and there may be other unidentified environmental toxins that may cause developmental abnormalities of kidneys.[48]

Physiology of the Developing Kidney

During intrauterine life, the kidneys play only a minor role in regulating fetal salt and water balance, because this function is maintained primarily by the placenta. The most important functions of the prenatal kidneys are the formation and excretion of urine to maintain an adequate amount of amniotic fluid. After birth, there is a progressive maturation in renal function, which appears to parallel the needs of the neonate for growth and development (Table 93.2).

Renal Blood Flow

Absolute renal blood flow (RBF) and the percentage of cardiac output directed to the kidneys increase steadily with advancing gestational age. The kidneys of a human fetus weighing more than 150 g receive approximately 4% of the cardiac output, compared with approximately 6% in the term infant. The relatively low RBF of the fetus is related to high renovascular resistance caused by the increased activity of the renin-angiotensin-aldosterone and sympathetic nervous systems. The RBF dramatically increases postnatally, reaching 8%-10% of the cardiac output at 1 week of life, and achieves adult values of 20%-25% of the cardiac output by 2 years of age. This rise in RBF is caused primarily by decreasing renovascular resistance and increasing cardiac output and perfusion pressure.

Glomerular Filtration

The glomerular filtration rate (GFR) in the fetal kidney increases steadily with advancing gestational age. By 32-34 weeks' gestation, a GFR of 14 mL/min per 1.73 m^2 is achieved, which further increases to 21 mL/min per 1.73 m^2 at term. The GFR continues to increase postnatally, achieving adult values of approximately 120 mL/min per 1.73 m^2 by the age of 2 years. The achievement of adult GFR may be delayed in preterm infants, especially those with very low birth weights.[1,5] The progressive increase in GFR during the initial weeks of postnatal life primarily results from an increase in glomerular perfusion pressure. Subsequent increases in GFR during the first 2 years of life are caused primarily by increases in RBF and the maturation of superficial cortical nephrons, which lead to an increase in the glomerular capillary surface area.

Concentration and Dilution of Urine

Newborn infants have a limited capacity to concentrate their urine, with maximal urinary osmolality of 800 mOsm/kg in a term infant compared to that of a 2 year old, which approximates adult values of 1400 mOsm/kg. In contrast, the term newborn infant has full ability to maximally dilute its urine in response to a water load, achieving adult values of 50 mOsm/kg. Preterm infants are unable to fully dilute their urine but can achieve urine osmolality of 70 mOsm/kg. However, the response of premature infants to an acute water load may be limited because of their low GFR and the decreased activity of sodium transporters in the diluting segment of the nephron. The excessive administration of water may place the newborn infant at a high risk for dilutional hyponatremia and hypervolemia. Urinary diluting and concentrating capacity in term and preterm infants is discussed in more detail in Chapter 92.

Evaluation of the Neonate With Renal Disease

History

The antenatal history should be reviewed thoroughly, with particular attention devoted to medications, toxins, and unusual environmental exposures during the pregnancy. Exposure to angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs), particularly in the second and third trimesters, can result in oligohydramnios, renal failure caused by renal tubular dysgenesis, limb deformities, prolonged hypotension, pulmonary hypoplasia, and hypocalvaria.[51] Structural and functional alterations of the newborn kidney have also been described in infants with antenatal exposure to nonsteroidal anti-inflammatory drugs; selective COX-2 inhibitors; mycophenolate mofetil; certain antiepileptic medications; and chemotherapeutic agents, such as doxorubicin and cyclophosphamide.[48] A review of the family medical history is important, including any prior fetal or neonatal deaths. Certain congenital abnormalities of the kidney and urinary tract (CAKUT) (renal hypoplasia/dysplasia, multicystic dysplastic kidney, and vesicoureteral reflux) may have familial clustering. In other disorders, including polycystic kidney disease and congenital nephrotic syndrome, a clear genetic basis has been established. The results of prenatal ultrasonography should be carefully reviewed, with particular attention devoted to kidney size, echogenicity, structural malformations, amniotic fluid volume, and bladder size and shape (Box 93.1). Although the bladder may be identified and its volume discerned at 15 weeks of gestation, the kidneys are not visualized until after the 16th-17th week of gestation in most fetuses. The presence of small or enlarged kidneys, renal cysts, hydronephrosis, bladder enlargement, or oligohydramnios suggests significant renal or urologic pathology.

• BOX 93.1 Prenatal Ultrasonography as a Diagnostic Tool for Abnormalities of the Urinary Tract

Kidneys

- Dilated renal pelvis/hydronephrosis: physiologic, vesicoureteral reflux, obstruction
- Cystic kidney: MCDK, cystic dysplasia, ADPKD, severe obstruction
- Echogenic kidney: renal dysplasia, ARPKD
- Structural abnormalities: renal duplication, fusion abnormalities (e.g., horseshoe, crossed fused ectopia), ectopic kidneys (pelvic, thoracic)
- Lack of visualization: renal agenesis, hypoplasia, ectopic
- Enlarged kidneys: ARPKD, obstruction, overgrowth syndromes (Simpson-Golabi-Behmel, Perlman, Beckwith-Wiedemann)
- Renal mass

Ureter

- Hydroureter

Bladder

- Dilation
- Ureterocele
- With thickened wall: posterior urethral valves
- Without thickened wall: megacystis-megaureter syndrome, neurogenic bladder, EBS
- Bladder exstrophy, cloacal exstrophy
- Lack of visualization: minimal or absent fetal urine production; obstructive uropathy

Ascites

- Urinary ascites (typically associated with thickened bladder wall and/or abnormal kidneys)

Hydrops Fetalis

- Most often due to nonrenal causes; occasionally caused by bilateral renal cystic disease, urinary tract obstruction, congenital nephrotic syndrome

Oligohydramnios

- Bilateral renal dysplasia, urinary tract obstruction, ARPKD
- Rupture of membranes, postmaturity, subacute fetal distress

Polyhydramnios

- Renal tubular disorder with urinary concentrating defect (NDI, Bartter syndrome)
- Multiple gestation, upper gastrointestinal tract obstruction, neurologic disorders, maternal diabetes, fetal hydrops

Placental Edema

- Congenital nephrotic syndrome

ADPKD, Autosomal dominant polycystic kidney disease; ARPKD, autosomal recessive polycystic kidney disease; EBS, Eagle Barrett syndrome; MCDK, multicystic dysplastic kidney; NDI, nephrogenic diabetes insipidus.

Physical Examination

The evaluation of blood pressure and volume status is critical in the newborn with suspected renal disease. Hypertension may be present in infants with polycystic kidney disease, acute kidney injury (AKI), renovascular or aortic

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

thrombosis, or obstructive uropathy. Hypotension may be present in infants with volume depletion, hemorrhage, or sepsis, any of which may lead to AKI. Edema may occur in infants with AKI, hydrops fetalis, or congenital nephrotic syndrome. Ascites may be present in infants with urinary tract obstruction, congenital nephrotic syndrome, or volume overload. Special attention should be paid to the abdominal examination. In the neonate, the lower pole of each kidney is easily palpable because of the neonate's reduced abdominal muscle tone. The presence of an abdominal mass in a newborn should be assumed to involve the urinary tract until proved otherwise, because two-thirds of neonatal abdominal masses are genitourinary in origin. The most common renal cause of an abdominal mass is hydronephrosis, followed by a multicystic dysplastic kidney. Less common renal causes of an abdominal mass include polycystic kidney disease, renal vein thrombosis, ectopic or fused kidneys, and renal tumors. The abdomen should be examined for the absence of or laxity in the abdominal muscles, which may suggest Eagle-Barrett ("prune-belly") syndrome. Distention of the newborn bladder may suggest lower urinary tract obstruction or an occult spinal cord lesion.

A number of anomalies should alert the physician to the possibility of underlying renal defects, including abnormal external ears, aniridia, microcephaly, meningomyelocele, hemihypertrophy, persistent urachus, bladder or cloacal exstrophy, an abnormality of the external genitalia, cryptorchidism, imperforate anus, and limb deformities. Although screening renal ultrasonography of infants with a single umbilical artery had previously been recommended, in the era of routine prenatal ultrasonography, this practice is no longer recommended.

A constellation of physical findings designated the oligohydramnios (Potter) sequence may be seen in infants with severe neonatal kidney disease, including bilateral renal dysplasia, bilateral urinary tract obstruction, or autosomal recessive polycystic kidney disease. Marked reduction of fetal kidney function results in oligohydramnios or anhydramnios, which causes fetal deformation by compression of the uterine wall. The characteristic facial features include wide-set eyes; depressed nasal bridge; beaked nose; receding chin; and posteriorly rotated, low-set ears (Fig. 93.3). Other associated anomalies include a small, compressed chest wall; arthrogryposis; hip dislocation; and clubfoot. Such patients often have respiratory failure caused by pulmonary hypoplasia; complications include spontaneous pneumothorax and/or pneumomediastinum resulting from their requirement for high ventilator pressures.

• **Fig. 93.3** Potter facies. Photomicrograph demonstrates the characteristic findings, including epicanthal folds, hypertelorism, low-set ears, a crease below lower lip, and a receding chin.

Laboratory Evaluation

Urinalysis

The examination of a freshly voided urine specimen provides immediate, valuable information about the condition of the kidneys. A urine specimen collected by cleaning the perineum and applying a sterile adhesive plastic bag is useful for obtaining urine for urinalysis but is not recommended for urine culture, as it may be associated with a false-positive result caused by fecal contamination. Bladder catheterization is a more reliable method for collecting a sample for culture but may be technically difficult in preterm infants. Suprapubic bladder aspiration is an alternative urinary collection method in preterm infants without intra-abdominal pathology or bleeding disorders.

Analysis of the urine should include inspection, urinary dipstick assessment, and microscopic analysis. The newborn urine is usually clear and nearly colorless. Cloudiness may represent a urinary tract infection or the presence of crystals. A yellow-brown to deep olive-green color may represent large amounts of conjugated bilirubin. Porphyrins, certain drugs such as phenytoin, bacteria, and urate crystals may stain the diaper pink and be confused with bleeding. Brown urine may suggest AKI, hemoglobinuria, or myoglobinuria.

The specific gravity of neonatal urine is usually very low (<1.004) but may be factitiously elevated by high-molecular-weight solutes such as contrast agents, glucose or other reducing substances, or large amounts of protein. Urinary osmolality may be a more reliable measurement of the concentrating and diluting capacity of the kidney. Urinary dipstick evaluation can detect the presence of heme-containing compounds (i.e., red blood cells, myoglobin, and hemoglobin), protein, and glucose. White blood cell products such as leukocyte esterase and nitrite may also be detected on urinary dipstick evaluation and should raise the suspicion of urinary tract infection, mandating collection of a urine culture. The microscopic examination of urinary sediment may detect the presence of red blood cells, white blood cells, bacteria, casts, or crystals.

Assessment of Renal Function

Although 98% of term infants void during the first 30 hours of life,[20] a delay in urination for up to 48 hours should

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

not be a cause for immediate concern in the absence of a palpable bladder, abdominal mass, or other signs or symptoms of renal disease. A failure to void for longer than 48 hours may suggest impairment of renal function and should prompt further investigation. The serum creatinine level is the simplest and most commonly used indicator of neonatal kidney function. Immediately after birth, the serum creatinine concentration reflects the maternal creatinine concentration. In term infants, the serum creatinine level gradually decreases from a range of 0.6-1 mg/dL (depending on the mother's serum creatinine) at birth to a mean value of 0.4 mg/dL within the first 2 weeks of life (Table 93.2). In preterm infants, the decline in serum creatinine level is slower and may not reach nadir for 1-2 months. In very preterm infants, the creatinine may actually rise transiently because of low GFR and tubular reabsorption of creatinine before falling to reach a nadir value at 2 months of age (Table 93.3).[11] Failure of the serum creatinine level to fall or a persistent increase in serum creatinine suggests impairment of renal function. Estimation of GFR is difficult in neonates, because formulas used in children have not been validated in infants less than 1 year of age. Measurement of serum cystatin C, a low molecular weight protein produced in all cells and filtered through the glomerulus, may offer more accurate estimation of neonatal kidney function but is not yet widely available for use.[27]

Radiologic Evaluation

Ultrasonography is the most common method of imaging the neonatal urinary tract, as it is a readily available, noninvasive test that does not involve exposure to contrast agents or radiation. Ultrasonography is indicated in infants with a history of an abnormal antenatal ultrasound, as well as in infants with an abdominal mass, AKI, hypertension, hematuria, or congenital malformations or genetic syndromes with increased risk of urinary tract anomalies. Ultrasonography can identify hydronephrosis, cystic kidney disease, and abnormalities of kidney size and position. It also may be used as a screening tool in preterm infants at increased risk of developing nephrocalcinosis due to chronic lung disease and long-term loop diuretic therapy. A Doppler flow study of the renal arteries and aorta may be helpful in the evaluation of infants with suspected renovascular hypertension, renal arterial or venous thrombosis, or AKI.

Importantly, nonurgent postnatal ultrasounds, such as those performed to follow up mild to moderate antenatal hydronephrosis, should be delayed until at least 48 hours after birth. Ultrasounds performed in the first 24-48 hours of life may not show hydronephrosis because of the low urine output of the neonate in the first few days of life.

Voiding cystourethrography (VCUG) should be considered an important part of the radiologic examination in infants with significant hydronephrosis, hydroureter, or documented urinary tract infection. Voiding cystourethrography involves the instillation of a radiopaque contrast agent into the bladder by urinary catheterization. This study is the procedure of choice to evaluate the urethra and bladder and ascertain the presence or absence of vesicoureteral reflux and posterior urethral valves. Other radiologic tests may occasionally be used for diagnostic purposes in the neonate (see

Chapter 38). Radioisotopic renal scanning may be of value in locating anomalous kidneys and identifying obstruction or renal scarring. Radioisotopic scans also provide information about the contribution of each kidney to overall renal function but may be difficult to interpret in the first few weeks of life because of the relatively low GFR in newborns. Abdominal computed tomography is useful in the diagnosis of renal tumors, renal abscesses, and nephrolithiasis.

Clinical Problems

Hematuria

Hematuria can be broadly classified into two categories: microscopic and macroscopic (gross). Microscopic hematuria is defined as ≥5 red blood cells on high-powered examination of the urine without visible discoloration of the urine. Macroscopic hematuria is defined as visibly discolored (red or brown) urine with ≥5 red blood cells on high-powered examination of the urine. When a neonate is suspected as having macroscopic hematuria, it is important to confirm that the discolored urine is caused by hematuria and not caused by a condition mimicking hematuria. Urate crystals, bile pigments, and porphyrins may discolor the urine and mimic hematuria, but in these conditions the urinary dipstick test is negative for blood and the microscopic examination reveals no red blood cells. Infants with myoglobinuria caused by inherited metabolic myopathy, infectious myositis, or rhabdomyolysis may have red or brown urine and test dipstick positive for blood, but the microscopic examination of the urine reveals no red blood cells. Similarly, infants with hemoglobinuria caused by hemolysis from ABO incompatibility or other forms of hemolytic disease will have a positive urinary dipstick for blood but no red blood cells present on microscopic examination. Vaginal bleeding or skin breakdown from diaper dermatitis can also mimic gross hematuria.

Once it is determined that an infant has macroscopic hematuria, there is a broad differential diagnosis.[38] Urinary tract infection should be ruled out with urine culture. Acute tubular necrosis (ATN) or cortical necrosis should be considered in infants with a history of perinatal asphyxia. Renal venous thrombosis must be considered in infants with risk factors, including birth to a diabetic mother, cyanotic congenital heart disease, volume depletion, or an indwelling umbilical venous catheter. Coagulopathy related to hemorrhagic disease of the newborn should be considered in at-risk infants who have not received vitamin K prophylaxis. Urolithiasis or nephrocalcinosis should be suspected in at-risk infants with a history of chronic lung disease and loop diuretic use. Other causes include trauma from bladder catheterization or suprapubic aspiration, obstructive uropathy, and tumors.

Evaluation of the neonate with macroscopic hematuria includes formal urinalysis with microscopic examination, catheter urine culture, complete blood count, serum electrolytes, creatinine, and kidney/bladder ultrasound. Further evaluation may include coagulation profile, urine calcium-to-creatinine ratio, abdominal computerized tomography scan, or urologic evaluation.

Proteinuria

Proteinuria is defined as a urinary dipstick value of at least 1+ (30 mg/dL), with a specific gravity of 1.015 or less, or a urinary dipstick value of at least 2+ (100 mg/ dL), with a specific gravity of more than 1.015. Normal urinary protein-to-creatinine ratio is less than 0.5 mg/mg in infants and toddlers younger than 2 years of age. Nearly any form of renal injury can result in a transient increase in urinary protein excretion, including ATN, fever, dehydration, cardiac failure, high doses of penicillin, and the administration of a contrast agent. Persistent heavy proteinuria, edema, and hypoalbuminemia in a neonate should prompt the consideration of congenital nephrotic syndrome, an autosomal recessive disorder characterized by massive proteinuria, failure to thrive, a large placenta, and chronic kidney disease (see section later in chapter). Proteinuria associated with glucosuria, phosphaturia, and metabolic acidosis raises concern for Fanconi syndrome, a rare condition characterized by generalized proximal tubular dysfunction; possible causes include cystinosis, Lowe syndrome, and mitochondrial disorders. False positive urinary dipstick values for protein may be the result of highly concentrated urine, alkaline urine, infection, and detergents.

Glycosuria

The diagnosis of glycosuria is established by the presence of glucose on a urinary dipstick. Glycosuria frequently occurs in infants with hyperglycemia, a condition in which the serum glucose exceeds the renal threshold for reabsorption. Common causes of hyperglycemia and resultant glycosuria in the NICU include sepsis or the administration of total parenteral nutrition. It is important to measure the serum glucose concentration in neonates with glycosuria on urinary dipstick evaluation. Correction of hyperglycemia normalizes the urinary dipstick findings. Isolated glycosuria with a normal serum glucose concentration raises concern for renal glycosuria, a benign inherited condition caused by an abnormality in the proximal tubular transport of glucose. No therapy is necessary other than the recognition of the condition, avoidance of confusion with diabetes mellitus, and provision of a normal intake of carbohydrates.

If glycosuria is accompanied by other evidence of renal tubular dysfunction, such as an excessive urinary loss of potassium, phosphorus, and amino acids, a generalized proximal tubulopathy (e.g., Fanconi syndrome) should be considered. Glycosuria may also be seen in infants with congenital renal diseases such as renal dysplasia, in which there is significant tubular dysfunction. Glycosuria in an infant with severe, watery diarrhea should raise the suspicion of congenital intestinal glucose-galactose malabsorption syndrome.

Acute Kidney Injury

Acute kidney injury (AKI) is a common condition in the NICU, ranging from mild renal dysfunction to complete anuric kidney failure. AKI is characterized by a sudden decline in kidney function over hours to days, resulting in derangements in fluid, electrolyte, and acid–base balance. There has been difficulty in establishing a standardized definition of AKI in neonates because of a number of factors, including maturational difference in kidney function at different gestational ages, the overall low GFR of neonates, and the fact that serum Cr reflects maternal Cr for days to a week after birth. A consensus definition for neonatal AKI was recently established and termed the neonatal modified KDIGO (Kidney Disease: Improving Global Outcomes) criteria.[60] These criteria define neonatal AKI in infants under 120 days of age as an increase in serum Cr ≥0.3 mg/dL or 50% or more from the previous lowest value and/or urine output <0.5 mL/kg/hr. Three stages of neonatal AKI are defined by relative changes in serum Cr from baseline (Table 93.4). Biomarkers including neutrophil gelatinase-associated lipocalin (NGAL), urinary interleukin-18, and cystatin C may show promise in the earlier detection of neonatal AKI, potentially identifying earlier stages of kidney injury, which occur prior to the elevation of serum creatinine.[43,50]

Neonatal AKI is a common occurrence, occurring in 30% of critically ill neonates recently evaluated in a large multicenter retrospective cohort study.[37] The incidence of AKI varied by gestational age group, occurring in 48% of infants 22-29 weeks' gestation, 18% of infants 29-36 weeks' gestation, and 37% of infants ≥36 weeks' gestation.[37]

Neonates are at particularly high risk of developing AKI because of their intrinsically low GFR in the first week of life, immaturity of renal tubules, increased susceptibility of the kidney to impaired perfusion, high exposure to nephrotoxic agents including indomethacin and aminoglycosides, and frequent use of umbilical access catheters with potential for thrombosis.[60] Within the general NICU population, certain groups at heightened risk of developing AKI include term and near-term neonates with perinatal asphyxia, very low birth weight and extremely low birth weight infants, and infants requiring cardiac surgery or ECMO support.

Clinical signs of AKI may include oliguria, systemic hypertension, cardiac arrhythmia, evidence of fluid overload or volume depletion, decreased activity, seizure, vomiting, and anorexia. Laboratory findings may include elevated serum creatinine and blood urea nitrogen, hyperkalemia, metabolic acidosis, hypocalcemia, hyperphosphatemia, and a prolonged half-life for medications excreted by the kidney (e.g., aminoglycosides, vancomycin, theophylline). The causes of neonatal AKI are multiple and can be divided into prerenal, renal, and postrenal categories (Box 93.2).

Prerenal Azotemia

Prerenal azotemia is the most common type of AKI in the neonate and may account for up to 85% of all cases. Prerenal azotemia is characterized by inadequate renal perfusion, which if promptly treated, is followed by improvements in renal function and urine output. The most common causes of prerenal azotemia are hypotension, volume depletion, hemorrhage, septic shock, necrotizing enterocolitis, patent ductus arteriosus, and congestive heart failure. The administration of medications that reduce renal blood flow, such as indomethacin or ibuprofen, ACE inhibitors, and phenylephrine eye drops, can result in prerenal azotemia.

TABLE 93.4 Neonatal Modified KDIGO Criteria for Acute Kidney Injury

Stage	SCr (Serum Creatinine)	Urine Output
0	No change in SCr or rise <0.3 mg/dL	≥0.5 mL/kg/h
1	SCr rise ≥0.3 mg/dL within 48 h or SCr rise ≥1.5-1.9 x reference SCr within 7 days	<0.5 mL/kg/h for 6-12 hr
2	SCr rise ≥2.0-2.9 x reference SCr	<0.5 mL/kg/h for ≥12 hr
3	SCr rise >3.0-2.9 x reference SCr or SCr >2.5 mg/dL or receipt of dialysis	<0.3 mL/kg/h for ≥24 h or anuria for ≥12 hr

Intrinsic (Renal) Acute Kidney Injury

The most common cause of intrinsic AKI in neonates is acute tubular necrosis (ATN). Risk factors for ATN include a prolonged prerenal state, perinatal asphyxia, sepsis, neonatal cardiac surgery, need for ECMO support, and nephrotoxic drug administration (acyclovir, aminoglycoside antibiotics, amphotericin B, ACE inhibitors, NSAIDs, radiocontrast agents, and vancomycin). The pathophysiology of ATN is complex and appears to involve interrelationships among renal tubular cellular injury, hypoxia, and altered glomerular filtration and hemodynamics. Other causes of intrinsic AKI in the newborn include renal dysplasia, autosomal recessive polycystic kidney disease, and renal arterial or venous thrombosis. Glomerulonephritis, although a common cause of AKI in older children and adolescents, is very uncommon in the neonatal population.

Obstructive (Postrenal) Acute Kidney Injury

Obstructive AKI in the neonate may be related to a variety of congenital urinary tract conditions, including posterior urethral valves, bilateral ureteropelvic or ureterovesical junction obstruction, obstructive urolithiasis, and neurogenic bladder. Rarer causes of obstructive AKI include extrinsic compression of the ureters or bladder by a congenital tumor such as a sacrococcygeal teratoma or intrinsic obstruction by renal calculi or fungus balls. Although relief of the urinary tract obstruction may yield improvement in urine output and GFR, many infants will develop chronic kidney disease because of variable degrees of associated renal dysplasia.

Evaluation

A careful history should focus on prenatal ultrasound abnormalities, perinatal asphyxia, the pre- or postnatal administration of potentially nephrotoxic drugs, and a family history of renal disease. The physical examination should focus on signs of volume depletion or volume overload, the abdomen, genitalia, and a search for other congenital anomalies or signs of the oligohydramnios (Potter) sequence. Levels of electrolytes, blood urea nitrogen, creatinine (Cr), calcium, phosphorus, albumin, and uric acid should be monitored at least daily or more frequently if significant metabolic abnormalities are present. Urine should be sent for urinalysis, urine culture, and urine sodium and creatinine determination. The fractional excretion of sodium (FE_{Na}), as well as other diagnostic indexes, may be useful in differentiating prerenal from intrinsic AKI (Table 93.5).

$$FE_{Na}\ (\%) = (UNa \times PCr)/(PNa \times UCr) \times 100\%$$

where U = urinary, P = plasma

Neonates with a FE_{Na} value of more than 3.0% generally have intrinsic AKI, whereas those with a FE_{Na} value of less than 2.5% have prerenal AKI. Baseline normal FE_{Na} values in preterm neonates may be as high as 6% at birth,[65] so the FE_{Na} measurement may be less helpful in distinguishing intrinsic versus prerenal AKI in that population. Renal ultrasound is helpful in the identification of congenital renal disease and urinary tract obstruction.

TABLE 93.5 Diagnostic Indexes in Acute Kidney Injury

Test	Prerenal AKI	Intrinsic AKI
BUN/Cr ratio (mg/mg)	>30	<20
FE_{Na} (%)	≤2.5	≥3.0
Urinary Na (mEq/L)	≤20	≥50
Urinary Osm (mOsm/kg)	≥350	≤300
Urinary specific gravity	>1.012	<1.014
Ultrasonography	Normal	May be abnormal
Response to volume challenge	Urine output >2 mL/kg/h	No increase in urinary output

AKI, Acute kidney injury; BUN, blood urea nitrogen; Cr, creatinine; FE_{Na}, fractional excretion of sodium; Osm, osmolality.

Prevention of AKI

The prevention of AKI in newborn infants requires maintenance of an adequate circulatory volume, careful fluid and electrolyte management, and prompt diagnosis and treatment of hemodynamic or respiratory abnormalities. Nephrotoxic medications such as acyclovir, aminoglycoside antibiotics, amphotericin B, ACE inhibitors, NSAIDs, radiocontrast agents, and vancomycin should be avoided if possible in neonates at high risk for AKI. Prophylactic theophylline (5 mg/kg IV) given within the first hour of life has been recommended to reduce the incidence of AKI in asphyxiated neonates, although its use must be weighed against potentially harmful neurologic side effects.[39] Therapeutic hypothermia protocols currently used for treatment of infants with perinatal asphyxia may have a beneficial effect in reducing the incidence of neonatal AKI.[61]

Medical Management

In the case of established oliguric AKI, a urinary catheter should be placed to exclude lower urinary tract obstruction. If there is no improvement in urine output after bladder drainage is established, a fluid challenge of 10-20 mL/kg should be administered over 1-2 hours to exclude prerenal AKI. Consideration should be given to use of vasopressor support such as dopamine to ensure that the infant has a mean arterial pressure adequate to provide renal perfusion. A lack of improvement in urine output and serum creatinine following adequate bladder drainage, fluid resuscitation, and establishment of an adequate mean arterial pressure suggests intrinsic AKI.

The goal of medical management of intrinsic AKI is to provide supportive care until there is spontaneous improvement in renal function. After adequate resuscitation, intake

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

should be restricted to insensible losses (500 mL/m^2 per day, or 30 mL/kg per day) plus urine output and other measured losses (see Chapter 92) to prevent symptomatic fluid overload. Daily to twice daily weights and careful intake and output measurements are essential to follow volume status. Nephrotoxic drugs should be discontinued to reduce the risk of additional renal injury. Medications should be adjusted by dose, interval, or both according to the degree of renal dysfunction. Potassium and phosphorus should be restricted in those neonates with hyperkalemia, hyperphosphatemia, oliguria, and/or rapidly worsening renal function. Metabolic acidosis may require treatment with intravenous or oral sodium bicarbonate. Loop diuretics may prove helpful in augmenting the urinary flow rate but should be withheld if there is no response or in the case of anuria.

Renal Replacement Therapy

Renal replacement therapy is rarely needed in neonates with AKI but should be considered if maximum medical management fails to maintain acceptable fluid and electrolyte levels. The indications for the initiation of renal replacement therapy include hyperkalemia, hyponatremia with symptomatic volume overload, acidosis, hypocalcemia, hyperphosphatemia, uremic symptoms, and an inability to provide adequate nutrition because of the need for fluid restriction in the face of oliguria (Box 93.3). The two purposes of renal replacement therapy are ultrafiltration (removal of water) and dialysis (removal of solutes). In general, only neonates greater than 1.5-2 kg in size may be considered for renal replacement therapies because of limited ability to place and maintain dialysis access in smaller infants.

Peritoneal dialysis is the most commonly used renal replacement modality in the neonatal population, because it is technically less difficult and does not require vascular access or anticoagulation. For this procedure, hyperosmolar dialysate is repeatedly infused into and drained out of the peritoneal cavity through a surgically placed catheter, accomplishing ultrafiltration and dialysis. Cycle length, volume of dialysate infused ("dwell volume"), and the osmolar concentration of the dialysate can be varied to accomplish the goals of therapy. Contraindications to peritoneal dialysis include recent abdominal surgery, necrotizing enterocolitis, pleuroperitoneal leakage, and ventriculoperitoneal shunting.

• BOX 93.3 Indications for Dialysis

- Hyperkalemia
- Hyponatremia
- Acidosis
- Hypocalcemia
- Hyperphosphatemia
- Volume overload
- Uremic symptoms
- Inability to provide adequate nutrition

Continuous renal replacement therapy (CRRT) is becoming a more frequently used therapeutic modality in neonates and infants with AKI.[9] For this procedure, the patient's blood is continuously circulated through a pump-driven extracorporeal circuit containing a highly permeable hemofilter. In continuous venovenous hemofiltration (CVVH), an ultrafiltrate of plasma is removed, a portion of which is returned to the patient in the form of a physiologic replacement fluid. In continuous venovenous hemodialysis (CVVH-D), countercurrent dialysate is used rather than replacement fluid to achieve solute removal. CRRT can be employed in conjunction with extracorporeal membrane oxygenation (ECMO) by putting the CRRT circuit in line with the ECMO circuit. The chief advantage of CRRT is the ability to carefully control fluid removal, which makes this modality especially useful in the neonate with hemodynamic instability. The main disadvantages are the need to achieve and maintain central vascular access and the need for continuous anticoagulation.

Intermittent hemodialysis is a less commonly used but technically feasible mode of renal replacement therapy in the neonatal population. Hemodialysis involves intermittent 3- to 4-hour treatments in which fluid and solutes are rapidly removed from the infant using an extracorporeal dialyzer, with clearance achieved by the use of countercurrent dialysate. The chief advantage of hemodialysis is the ability to rapidly remove solutes and fluid, a characteristic that makes this modality the therapy of choice in neonatal hyperammonemia. The main disadvantages are the requirement for central vascular access, usually a double lumen 7 French catheter, and the hemodynamic instability and osmolar shifts that may occur with rapid solute and fluid shifts.

Providing adequate renal replacement therapy may be limited by the challenges in placing and/or maintaining intravascular or peritoneal dialysis access in the very small premature neonate. If dialysis access cannot be established, care of the infant with AKI is limited to maximal supportive medical management, with meticulous attention to fluid, electrolyte, and acid–base balance.

Prognosis

Research has demonstrated that AKI is not just a marker of severity of illness in neonates but is also independently associated with poor outcomes. A recent large multicenter retrospective study demonstrated that the presence of AKI was independently associated with increased mortality in neonates (10% vs 1%), as well as increased length of hospital stay (median 23 vs 19 days).[37] Infants with higher stages of AKI had higher mortality rates and lengths of hospitalization when compared to infants with lower stages of AKI.

In the past, AKI was felt to be a completely reversible syndrome in neonates, with the idea that kidney function returning to baseline indicated no further renal risk. However, observational studies have demonstrated high rates of chronic kidney disease (CKD) in survivors of neonatal AKI.[18] The risk of CKD in survivors of neonatal

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

AKI may be compounded by the risks of prematurity and low birth weight, both of which are associated with CKD because of associated inadequate nephron development.[2] Long-term nephrology follow-up care is important to monitor for evidence of CKD over time. All neonates with an identified episode of AKI should be referred to nephrology for outpatient follow-up to assess for microalbuminuria, proteinuria, hypertension, and rise in serum creatinine over time indicative of CKD. Special attention should be given to those infants with a history of AKI stages 2 and 3 or treatment with dialysis, significant prematurity, IUGR, or underlying renal anomalies. Early identification of CKD allows implementation of strategies to slow the loss of kidney function, including healthy lifestyle, careful management of BP, reduction of proteinuria, hydration, and avoidance of nephrotoxin exposure.

Hypertension

Incidence and Definition

The incidence of hypertension in neonates is estimated to be approximately 1%-2%.[24] Hypertension is most often seen in infants with a concurrent condition such as chronic lung disease, renal disease, or a history of umbilical arterial catheterization. The definition of neonatal hypertension is sustained blood pressure above the 95th percentile for infants of similar size, gestational age, and postnatal age. Identification of elevated blood pressure in neonates can be difficult because of variations in blood pressure measurement techniques, normal changes in blood pressure with gestational age and weight, and other factors that affect blood pressure readings, including level of wakefulness, feeding, crying, and pain.

Useful data on normal infant blood pressures were published by Zubrow and colleagues, who prospectively measured blood pressure in nearly 700 infants, showing that blood pressure increased with gestational age, postconceptual age, and birth weight.[74] Based on these data and synthesis of several other studies, a practical table of systolic, diastolic, and mean arterial blood pressure values was created and may be useful in defining normal and elevated blood pressures in neonates greater than 2 weeks of age from 26-44 weeks' postconceptual age (Table 93.6).[24]

Causes

The causes of neonatal hypertension are varied and are outlined in Box 93.4. Renovascular hypertension is the most frequent cause of neonatal hypertension and accounts for up to 80%-90% of all cases. The most common cause of renovascular hypertension is renal arterial thromboembolism related to umbilical artery catheterization. Risk factors for complications from umbilical artery catheters include maternal diabetes, sepsis, dehydration, birth trauma, perinatal asphyxia, patent ductus arteriosus, and cocaine exposure.

• BOX 93.4 Causes of Neonatal Hypertension

- Renovascular Disease
  - Renal arterial thrombosis
  - Renal arterial stenosis
  - Renal venous thrombosis
- Obstructive Uropathy
  - Hydronephrosis
- Renal Parenchymal Disease/Malformations
  - Acute tubular necrosis
  - Polycystic kidney disease
  - Renal dysplasia
- Coarctation of the Aorta
- Neurologic Disorders
  - Pain
  - Seizures
  - Intracranial hypertension
  - Drug withdrawal
- Miscellaneous Causes
  - Bronchopulmonary dysplasia
  - Drug exposure (e.g., corticosteroids, catecholamines)
  - Abdominal wall closure
  - Extracorporeal membrane oxygenation

Less common causes of neonatal renovascular hypertension include congenital renal artery stenosis, fibromuscular dysplasia, midaortic coarctation, and renovascular compression by tumors.

Other causes of neonatal hypertension include renal disorders such as AKI, autosomal recessive polycystic kidney disease, and obstructive uropathy. The most significant nonrenal cause of neonatal hypertension is bronchopulmonary dysplasia (BPD). Although the mechanism by which BPD is associated with hypertension is not clearly defined, the severity of the blood pressure elevation appears to correlate with the severity of the lung disease.[4] Less common causes of neonatal hypertension include endocrine disorders, coarctation of the aorta, intraventricular hemorrhage, history of abdominal wall closure, tumors, treatment with ECMO, seizures, pain, and drug withdrawal. Medications such as corticosteroids, vasopressors, caffeine, theophylline, and bronchodilators have been associated with elevated blood pressures in neonates.

Clinical Presentation

The majority of neonates with hypertension are asymptomatic, as elevated blood pressures are typically noted on routine monitoring. If present, symptoms of neonatal hypertension are often nonspecific, including poor feeding, irritability, and lethargy. Marked blood pressure elevation may lead to cardiopulmonary symptoms, including tachypnea, cyanosis, apnea, impaired perfusion, vasomotor instability, congestive heart failure, and hepatosplenomegaly. Neurologic symptoms such as tremors, hypertonicity, hypotonicity, opisthotonos, asymmetric reflexes, hemiparesis, seizures, apnea, or coma may also occur. The renal effects of hypertension may include AKI and sodium wasting related to pressure natriuresis.

• BOX 93.5 Standardized Protocol for Blood Pressure Measurement in Neonates

- Measured by oscillometric device
- 1.5 hours after a feed or medical intervention
- Infant lying prone or supine
- Appropriately sized blood pressure cuff
- Right upper arm
- After cuff placement, infant is left undisturbed for 15 minutes
- Infant asleep or in quiet awake state
- Three successive blood pressure readings at 2-minute intervals

Reprinted from Dionne JM, Abitbol CL, Flynn JT. Hypertension in infancy: diagnosis, management and outcome. *Pediatr Nephrol*. 2012;27:17, with permission.[24]

Evaluation

The first step is to determine whether the elevated blood pressure persists when the infant is quiet and relaxed. A standardized protocol for accurate blood pressure measurement in neonates is shown in Box 93.5.[24] Blood pressures are preferably measured in the upper arm, as leg blood pressure measurements tend to overestimate the true blood pressure. History should focus on prenatal medication exposures, presence or history of an umbilical artery catheter, and treatment with medications that raise blood pressure. Blood pressure trends since birth should be reviewed to establish the onset and severity of hypertension. A complete physical examination is imperative, including four-extremity blood pressure measurements to diagnose or rule out aortic coarctation. The infant should be examined carefully for signs of volume overload, including peripheral edema, cardiac gallop, or rales. The abdomen should be carefully inspected for presence of abdominal or flank masses or renal bruits. Ambiguous genitalia in a hypertensive infant should raise the suspicion of congenital adrenal hyperplasia. Initial laboratory studies should include a urinalysis and determinations of serum electrolytes, blood urea nitrogen, serum creatinine, and serum calcium. Other diagnostic studies, including renin, aldosterone, cortisol, thyroid function tests, and catecholamines, can be considered based on the clinical scenario and results of screening studies.

Ultrasonography of the kidneys with a Doppler flow study of the aorta and renal arteries should be performed to exclude a renal arterial or aortic thrombus or structural anomalies of the urinary tract. Absence of a defined thrombus does not, however, rule out renovascular hypertension as the majority of thrombi are very small and not detectable by ultrasonography. Computed tomography, magnetic resonance angiography, and angiography may be considered in more difficult cases, although their use may be limited in the very small infant. Echocardiography should be performed to exclude aortic coarctation and evaluate the left ventricular mass.

Treatment

The first approach to the treatment of neonatal hypertension is to correct all iatrogenic causes of blood pressure elevation, including improper measurement technique, vasopressor administration, volume overload, narcotic withdrawal, or inadequately controlled pain. If blood pressures remain elevated above the 99th percentile, experts advocate antihypertensive treatment with an intravenous or oral antihypertensive agent to prevent adverse effects on the kidneys, heart, and central nervous system (Tables 93.7 and 93.8).

Neonates with signs and symptoms of a hypertensive emergency such as cardiopulmonary failure, acute neurologic dysfunction, and AKI are best treated with a continuous intravenous infusion of an antihypertensive agent such as nicardipine, esmolol, or labetalol. Careful monitoring using an arterial line is recommended. The chief advantage of a continuous infusion is the ability to quickly increase or decrease the rate of infusion to achieve the desired blood pressure. The goal of therapy is a gradual decrease in blood pressure to minimize injury to the brain, heart, and kidneys. Blood pressure should not be lowered below the 95th percentile for at least 24-48 hours to avoid the possibility of cerebral and optic disc ischemia.

Oral antihypertensive agents are best used in infants with less severe hypertension or in those whose acute hypertension has been controlled with intravenous infusions and who are ready to switch to chronic oral therapy. Calcium channel blockers, such as isradipine and amlodipine, are first-choice agents. ACE inhibitors such as captopril may be useful but are not recommended for infants less than 44 weeks' postconceptional age, because they may impair the final stages of renal maturation. If ACE inhibitors are used, careful attention to urine output and the levels of serum creatinine and potassium is recommended, as neonates may be extremely sensitive to the reduction in renal blood flow associated with the administration of these agents. Diuretics such as chlorothiazide may be useful agents in infants with chronic lung disease. Intermittent administration of intravenous agents, such as hydralazine or labetalol, may be considered in hypertensive infants with mild to moderate hypertension in whom oral agents cannot be used because of gastrointestinal dysfunction.

In infants with suspected renovascular hypertension, the umbilical artery catheter should be removed as soon as

TABLE 93.7 Intravenous Antihypertensive Medications

Drug	Dose	Interval	Action
Esmolol	100-500 mcg/kg/min	Continuous infusion	Beta blocker
Hydralazine	0.15-0.6 mg/kg/dose	Every 4-6 hr	Vasodilator
Labetalol	0.2-1.0 mg/kg/dose 0.25-3.0 mg/kg/hr	Every 4-6 hr Continuous infusion	Alpha and beta blocker
Nicardipine	1-4 mcg/kg/min	Continuous infusion	Calcium channel blocker
Sodium nitroprusside	0.5-10.0 mcg/kg/min	Continuous infusion	Vasodilator

TABLE 93.8 Oral Antihypertensive Medications

Drug	Dose	Interval	Class
Amlodipine	0.05-0.3 mg/kg/dose	Daily to BID	Calcium channel blocker
Captopril	0.01-0.5 mg/kg/dose	TID	Angiotensin-converting enzyme inhibitor
Chlorothiazide	5-15 mg/kg/dose	BID	Distal tubule diuretic
Clonidine	5-10 mcg/kg/day (in 3 divided doses)	TID	Alpha-agonist
Enalapril	0.04-0.3 mg/kg/dose	Daily to BID	Angiotensin-converting enzyme inhibitor
Furosemide	1-2 mg/kg/dose	Daily to TID	Loop diuretic
Isradipine	0.05-0.15 mg/kg/dose	QID	Calcium channel blocker
Labetalol	0.05-1.0 mg/kg/dose	BID to TID	Alpha and beta blocker
Propranolol	0.5-1.0 mg/kg/dose	TID	Beta blocker

BID, Twice daily; QID, four times daily; TID, three times daily.

possible. If a large thrombus is identified, systemic heparinization may be considered to prevent extension of the clot. If the hypertension cannot be controlled medically or massive aortic thrombosis results in major complications, thrombolysis with urokinase, streptokinase, or tissue plasminogen activator may be considered. If severe hypertension persists, surgical thrombectomy or nephrectomy may be contemplated.

Prognosis

Most neonates with hypertension presumed to be caused by umbilical artery catheters or bronchopulmonary dysplasia experience improvement in their blood pressures and do not typically require antihypertensive medications beyond 12 months of age. Infants may require periodic increases in their antihypertensive medications following discharge from the hospital because of rapid growth, but over time antihypertensive agents may be weaned by maintaining a stable medication dose as the infant grows in size. On the other hand, infants with hypertension related to renal disease or another secondary cause will most likely have hypertension that persists into childhood.

Long-term studies of children and adolescents with a history of neonatal hypertension are needed. There is growing evidence that neonates born prior to completion of nephrogenesis at 34-36 weeks' gestation may be at increased risk for development of hypertension and chronic kidney disease in adolescence or adulthood.[2]

Nephrocalcinosis

Nephrocalcinosis, defined as calcium salt deposition in the renal interstitium, is a well-known complication in the neonatal population, occurring in 7%-41% of hospitalized premature infants.[59] Infants at highest risk appear to be those with lower gestational age and birth weight, often in combination with severe respiratory disease. Nephrocalcinosis is usually discovered incidentally on abdominal imaging studies, although infants with nephrocalcinosis may present with microscopic or gross hematuria, granular material in the diaper, or urinary tract infection.

Neonatal nephrocalcinosis is multifactorial in etiology and develops as the consequence of an imbalance between stone-promoting and stone-inhibiting factors.[59] The immature renal tubular cells of the preterm infant are more susceptible to crystal formation and aggregation. Furthermore, the low GFR of the preterm infant results in a low tubular fluid flow rate that promotes crystal formation. Hypercalciuria (excessive urinary calcium excretion) is a common risk factor and may result from chronic treatment with loop diuretics, increased calcium intake from TPN, or vitamin D supplementation. Subcutaneous fat necrosis following birth trauma is a rare but serious cause of hypercalciuria. Other risk factors for nephrocalcinosis include hypocitraturia (low urinary citrate excretion); this is a common finding in patients with persistent metabolic acidosis, which often occurs in ill preterm infants. Less common genetic conditions in which there is an increased risk of nephrocalcinosis include primary hyperoxaluria, distal renal tubular acidosis, Bartter syndrome, Williams syndrome, and idiopathic infantile hypercalcemia.

Routine ultrasonographic screening should be considered for all infants who receive long-term loop diuretics for chronic lung or heart disease. In those with documented nephrocalcinosis, loop diuretics should be discontinued, if possible. Thiazide diuretics, such as chlorothiazide, may be substituted as they tend to reduce urinary calcium excretion, although serum calcium must be monitored closely to avoid hypercalcemia. Agents that may increase urinary calcium excretion, including glucocorticoids, xanthine derivatives, and any sodium-containing supplements should be minimized or discontinued if possible. Administration of calcium and phosphorus in TPN as well as vitamin D supplementation should be reduced if excessive. A high urinary flow rate should be maintained to reduce the probability of urinary crystallization. Metabolic acidosis, if present, should be treated with potassium citrate. The goal of therapy should be the maintenance of the spot urinary calcium-to-creatinine ratio at less than 0.8 for infants less than 7 months of age.[59]

The usual outcome for infants with neonatal nephrocalcinosis without an underlying genetic defect is spontaneous resolution over the first 2 years of life. Serial renal ultrasonography is needed to confirm resolution of nephrocalcinosis. There is concern that neonatal nephrocalcinosis may increase risk for impairment in kidney function later in life, particularly in premature infants who are inherently at increased risk of chronic kidney disease. Although results are conflicting whether nephrocalcinosis affects renal growth and function, one case series demonstrated evidence of tubular dysfunction and shorter kidney length in the first year of life of infants with nephrocalcinosis.[29] Long-term nephrology follow-up care of premature infants with nephrocalcinosis is recommended.

Renal Vascular Thrombosis

Thromboembolic complications are rare but serious events in the NICU. The neonatal kidney is particularly vulnerable to thrombosis because of its relatively low blood flow, small vessel diameter, enhanced renal vasoconstriction, and intervening events including hypoxia, volume depletion, hypotension, and infection that disturb the delicate balance between procoagulant and anticoagulant factors. Both venous and arterial thrombosis may occur in the neonate, although renal venous thromboses (RVT) are more common. Risk factors for RVT include prematurity, maternal diabetes mellitus, congenital heart disease, polycythemia, hypertonic dehydration, acute blood loss, perinatal asphyxia, in utero death of a twin, sepsis, RDS, and prolonged central venous cannulation.[58] A subset of neonates with RVT have an inherited thrombophilia, including deficiencies of protein C, protein S or antithrombin, Factor V Leiden mutation, or the prothrombin gene mutation.

Thrombosis begins in the small renal veins and propagates toward the main renal vein, ultimately reaching the inferior vena cava. Thrombosis is usually unilateral (70%) but may be bilateral or extend into the inferior vena cava and is associated with adrenal infarction in a minority of patients.

The classic clinical triad of symptoms in RVT includes a flank mass, macroscopic hematuria, and thrombocytopenia, although all elements of the triad are present in fewer than 25% of infants with RVT. Additional signs may include oliguric AKI, hypertension, vomiting, lethargy, anorexia, fever, and shock. Ultrasonography in the acute phase reveals enlarged and echogenic kidneys with loss of corticomedullary differentiation. A Doppler study may reveal resistance or absence of blood flow in the main renal vein and collateral vessels. Uptake may be absent or severely diminished on a radionuclide scan. Ultrasonography following the acute phase may show gradual decrease in kidney size with renal atrophy.

Initial evaluation after identification of a thrombosis should include baseline testing, including a CBC, prothrombin time, activated partial thromboplastin time (aPTT), and fibrinogen concentration. Maternal blood may be tested for lupus anticoagulant and anticardiolipin antibody. Testing for an inherited prothrombotic state should be conducted in neonates with thrombosis, which is clinically significant, recurrent, or spontaneous. Testing is best deferred until after resolution of the acute event.

There are no evidence-based guidelines for management of neonatal RVT, although expert opinion guidelines suggest the need for a multidisciplinary team including neonatology, nephrology, radiology, and hematology. If the thrombosis appears to be catheter-associated, the catheter should be removed. Supportive medical treatment consists of correction of fluid and electrolyte imbalances as well as supportive treatment of AKI, possibly including dialysis. Anticoagulation (unfractionated heparin or low molecular weight heparin) may be employed to prevent the extension of thrombosis, although the benefits of anticoagulation should be weighed against the risks of hemorrhagic events, including intraventricular hemorrhage. Thrombolytic therapies such as recombinant tissue plasminogen activator or urokinase should be reserved for cases of critical compromise of kidney function, as seen in bilateral renal vein thrombosis. Surgical thrombectomy is considered in patients with thrombosis of the inferior vena cava, and nephrectomy may be necessary in infants with severe refractory hypertension.

Although the perinatal mortality rate in infants with RVT has decreased progressively during the past decades, the prognosis for the affected kidney is poor, with progressive atrophy in up to 70% of kidneys.[58] Long-term complications include hypertension in 20% of patients, chronic kidney disease, and end-stage kidney disease in the minority of patients with a history of bilateral thrombosis.

Congenital Anomalies of Kidneys and Urinary Tract

Many of the disorders of the kidney and urinary tract that present in utero or in the neonatal period are the result of congenital malformations or inherited disorders (Box 93.6; see also Table 93.1). Most of the congenital abnormalities of the kidney and urinary tract disorders occur sporadically, and the pathogenesis is not well defined. As mentioned above, studies have begun to elucidate the genetic basis for some of these disorders, such as Eagle-Barrett ("prune belly") syndrome, renal hypoplasia, and renal dysplasia.[63,70] The following section will review some of the more common congenital renal anomalies that present in neonates and infants. Because of the rapidly changing nature of molecular genetics, it is suggested that the reader consult the OMIM (Online Mendelian Inheritance in

• BOX 93.6 Overview of Congenital and Inherited Disorders of the Kidney and Urinary Tract that Present in Infancy

Urologic Anomalies

- Ureteropelvic junction or ureterovesical junction obstruction
- Posterior urethral valves
- Eagle-Barrett syndrome
- Vesicoureteral reflux

Cystic and Dysplastic Disorders

- Renal hypoplasia
- Renal dysplasia (including multicystic dysplastic kidney)
- Unilateral or bilateral renal agenesis
- Polycystic kidney disease
- Autosomal recessive polycystic kidney disease
- Autosomal dominant polycystic kidney disease
- Glomerulocystic kidney disease
- Other cystic disorders
- Infantile nephronophthisis
- Diffuse cystic dysplasia associated with congenital abnormalities

Tubular Transport Disorders

- Renal tubular acidosis
- Fanconi syndrome
- Bartter syndrome
- Nephrogenic diabetes insipidus
- Tubular disorders associated with syndromes (e.g. Lowe syndrome, cystinosis, and galactosemia)
- Pseudohypoaldosteronism

Miscellaneous Disorders

- Congenital nephrotic syndrome
- Teratogen fetopathies (e.g., ACEIs, ARBs, mycophenolate mofetil)
- Tumors (e.g., Wilms tumor, neuroblastoma, congenital mesoblastic nephroma)

ACEIs, Angiotensin-converting enzyme inhibitors; ARBs, angiotensin-receptor blockers.

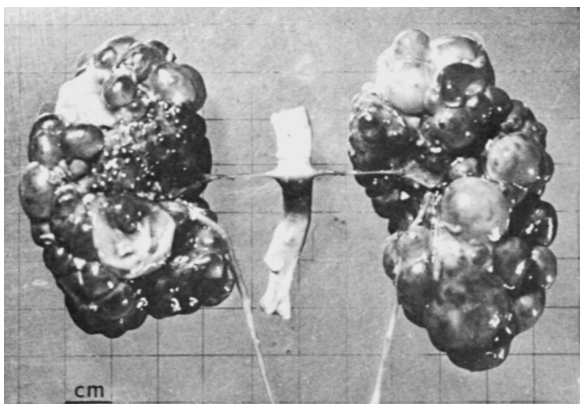
Man) database at http://www.omim.org (accessed March 4, 2019) for the most up-to-date information about the genetic basis for these disorders.

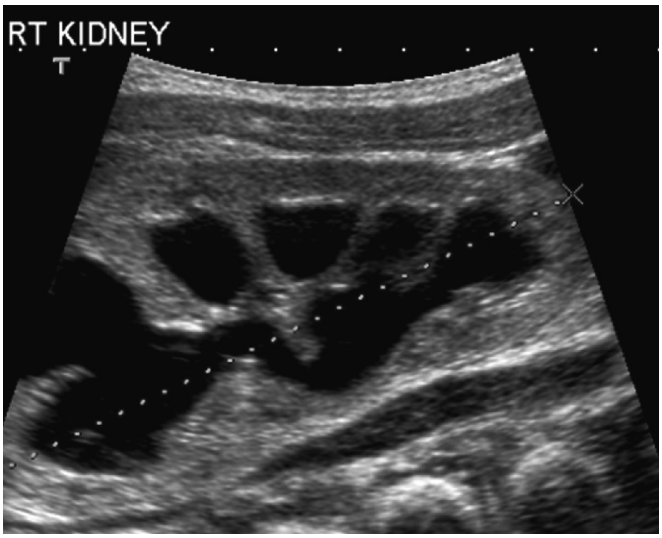
Renal Agenesis



Unilateral renal agenesis (URA; congenital absence of the kidney) occurs in 1 of 2000-2500 births, and bilateral renal agenesis occurs in 1 of 4,000-10,000.[42,68] Renal agenesis occurs when the ureteric bud fails to induce proper differentiation of the metanephric blastema, an event that may be related to both genetic and environmental factors. In a review of birth registry data, about 30% of infants with URA had extra-renal anomalies, cardiac in 60% and skeletal in 30%, and only 7% had contralateral CAKUT.[42] Syndromic URA may be seen in infants with the VACTERL association (i.e., *v*ertebral abnormalities, *a*nal atresia, *c*ardiac abnormalities, *t*racheoesophageal fistula or *e*sophageal atresia, *r*enal agenesis and dysplasia, and *l*imb defects), caudal regression syndrome, branchio-oto-renal syndrome, and multiple chromosomal defects, but it may also occur in otherwise healthy infants. In isolated renal agenesis, compensatory hypertrophy of the remaining solitary kidney is usually evident in utero and may begin as early as 20 weeks' gestation, with the contralateral kidney growing at about the 97th percentile for gestational age.[55] The presence of hypertrophy in a solitary kidney is an important clinical indicator in terms of prognosis for good long-term renal function. VCUG may be considered for neonates with unilateral renal agenesis who have hydronephrosis, bladder abnormality, or small or echogenic solitary kidney. Unilateral renal agenesis is also associated with developmental defects of the Müllerian ducts in about 10% of females,[68] such as Mayer-Rokitansky or Herlyn-Werner-Wunderlich syndromes.[35] These disorders, however, may not be clinically evident until adolescence, when patients present with amenorrhea or dysmenorrhea. In males, cases of congenital absence of the vas deferens along with URA have been reported.[41]

Renal Dysplasia

Renal dysplasia is characterized by abnormal renal development in the fetus, leading to replacement of the renal parenchyma by cartilage and disorganized epithelial structures. The pathogenesis of renal dysplasia may involve mutations in developmental genes (Table 93.1), urinary tract obstruction, or in utero toxin/medication exposure.[19,48] Renal dysplasia occurs frequently in infants with obstructive uropathy and a variety of congenital disorders, such as VACTERL association; CHARGE syndrome; brachio-oto-renal syndrome; Jeune syndrome; and trisomies 13, 18, and 21. Most forms of "polycystic kidneys" that are reported in association with syndromes, in fact, represent bilateral cystic dysplasia. Renal dysplasia may also occur as an isolated finding. The function of dysplastic kidneys is quite variable, and infants with bilateral dysplasia may exhibit signs of renal insufficiency as early as the first few days of life. Concentration and acidification defects may also be present, but hematuria, proteinuria, and hypertension are unusual findings. Children with bilateral renal dysplasia generally develop progressive renal insufficiency during childhood and adolescence.



Multicystic Dysplastic Kidney

Multicystic dysplastic kidney (MCDK) represents the most severe form of renal dysplasia and is characterized by a nonfunctioning kidney that is devoid of normal renal architecture and composed of multiple large cysts that resemble a cluster of grapes (Fig. 93.4).[69] In a recent review of European registry data, the incidence of MCDK was 1 in 2400 total births and 1 in 3200 live births.[69] MCDK is slightly more prevalent in males and occurs twice as often on the left side as the right side. The pathogenesis is poorly understood but may involve failure of the ureteric bud to integrate and branch appropriately into the metanephros.[32] Multiple different genetic abnormalities may be linked to MCDK (Table 93.1), and 4% of infants will have an abnormal karyotype while 17% have pathogenic copy number variation.[28] With the widespread use of prenatal ultrasonography, 90% of cases of MCDK are identified in utero.[69] Eighty-four percent of infants with unilateral MCDK will have an isolated renal anomaly and overall, these infants do well in the perinatal period.[69] Bilateral MCDK is usually fatal and associated with extra-renal anomalies in about half of cases. About 20% of children with unilateral MCDK will have vesicoureteral reflux into the contralateral kidney, which is grades I-III in 96%.[26] Historically, a full evaluation of the urinary tract, including a VCUG, was advised for all infants with MCDK to rule out abnormalities of the contralateral urinary tract, including vesicoureteral reflux (VUR). However, contralateral abnormalities are uncommon and most VUR in children with MCDK is insignificant, so most infants can be managed conservatively with watchful waiting.[26] The majority of MCDKs undergo partial or

• **Fig. 93.4** Bilateral multicystic dysplastic kidneys in a newborn infant. Gross pathology demonstrates enlarged, irregularly cystic kidneys; the usual reniform configuration is barely apparent. Both ureters are atretic, and the renal arteries are extremely small. This condition results in total absence of renal function and is one of the multiple causes of oligohydramnios sequence (Potter syndrome).

• **Fig. 93.5** Neonatal hydronephrosis. Sonogram of the right kidney in a 1-day-old neonate with a history of prenatal hydronephrosis demonstrates severe dilation of the collecting system.

complete spontaneous involution over time, with close to 60% involution by 10 years.[26] The contralateral kidney, if unaffected by other urologic malformations, generally shows compensatory hypertrophy, allowing the child to maintain normal renal function. It is common practice to follow patients with MCDKs using serial ultrasonography to ensure involution and appropriate compensatory growth of the contralateral kidney over time. Hypertension does not appear to occur at increased frequency in isolated MCDK, and the risk for malignancy is extremely low and may not be higher than the general population. Surgical removal, therefore, is reserved for children in whom the MCDK grows larger over time.[26]

Hydronephrosis

Hydronephrosis, defined as significant dilation of the upper urinary tract (Fig. 93.5), is one of the most common congenital conditions detected by prenatal ultrasonography.[71] The differential diagnosis of hydronephrosis (in order of frequency) includes physiologic hydronephrosis (50%-70% of cases), ureteropelvic junction obstruction (10%-30%), vesicoureteral reflux (10%-40%), ureterovesical junction obstruction (5%-15%), multicystic dysplastic kidney (2%-5%), posterior urethral valves (1%-5%), ureterocele (1%-3%), and Eagle-Barrett syndrome (<1%).[71] The grading system for prenatal and postnatal hydronephrosis proposed by the Society of Fetal Urology has become widely accepted.[52] This system is dependent on the measurement of anterior–posterior renal pelvis dilation (APRPD) taken at the maximal diameter of intrarenal pelvis dilation. Normal APRPD is less than 4 mm at 16-28 weeks' gestation, less than 7 mm after 28 weeks, and less than 10 mm at 2 days of life.[52] In addition, the parenchymal thickness, echogenicity, and differentiation of the kidneys should be delineated, and the ureters and bladder should be examined for abnormalities. Finally, the presence or absence of oligohydramnios should be commented on prenatally. The APRPD on prenatal US can inform diagnosis and postnatal outcomes and, therefore, the postnatal management.[15]

Physiologic Hydronephrosis

At least 80% of all prenatally detected mild hydronephrosis (APRPD 7-10 mm at 30 weeks' gestational age) resolves spontaneously and is not associated with an anatomic abnormality of the urinary tract. Hydronephrosis, which improves or resolves during the pregnancy, is unlikely to have any postnatal implications.[53] Physiologic hydronephrosis may be caused by a delay in the maturation of the ureter, which leads to transient urinary flow obstruction. The hydronephrosis in these patients generally resolves within the first 2 years of life.[15]

Ureteropelvic Junction Obstruction

Ureteropelvic junction (UPJ) obstruction is the most common cause of moderate to severe congenital hydronephrosis and may be the result of incomplete recanalization of the proximal ureter, abnormal development of the ureteral musculature, abnormal peristalsis, or polyps. UPJ obstruction is more common in boys and may be associated with other congenital anomalies (including other genitourinary malformations) or syndromes. The diagnosis is confirmed by an obstructive pattern observed on a diuretic-enhanced radionuclide scan, which is typically deferred until several weeks of age owing to limitation in testing related to low newborn GFRs. Many clinicians advocate antibiotic prophylaxis to prevent urinary tract infection, which was shown to be effective in preventing infection in patients with high-grade hydronephrosis.[16,72,73] Temporary relief of obstruction may be necessary and is often achieved by placement of a percutaneous nephrostomy drain. Definitive treatment often involves surgical repair. The indication for surgery varies by center and provider, and children with more severe hydronephrosis are more likely to receive intervention. About 20%-25% of children with UPJ obstruction will have surgery for decreased renal function or progression of hydronephrosis.[53] Early consultation with an experienced pediatric urologist is recommended.

Ureterovesical Junction Obstruction

Ureterovesical junction (UVJ) obstruction is another cause of congenital hydronephrosis and is characterized by hydronephrosis with associated ureteral dilatation. This disorder may be related to the deficient development of the distal ureter or the presence of a ureterocele and is likely to spontaneously resolve in 70% of patients.[53] The diagnosis is confirmed by a radionuclide scan and VCUG. UVJ obstruction is usually not associated with other congenital malformations. A ureteral dilation greater than 1 cm is associated with higher risk of urinary tract infection so antibiotic prophylaxis may be indicated.[34] Temporary or permanent surgical interventions may be required, based on the clinical situation.

Vesicoureteral Reflux

Vesicoureteral reflux (VUR) accounts for 10%-40% of neonatal hydronephrosis. It is defined as the retrograde propulsion of urine into the upper urinary tract during bladder contraction. The underlying cause of VUR is believed to be ectopic insertion of the ureter into the bladder wall, resulting in a shorter intravesicular ureter, which acts as an incompetent valve during urination. Vesicoureteral reflux is graded from I to V, with grade I indicating the lowest and grade V the highest. In infants and children evaluated for their first urinary tract infection, at least one-third have VUR identified on a VCUG. Although the exact genetic basis of this condition has not been determined, there appears to be a genetic component, because the incidence of VUR is approximately 30% in first-degree relatives, including siblings.[66] Table 93.1 lists a number of mutations, which have been associated with VUR.

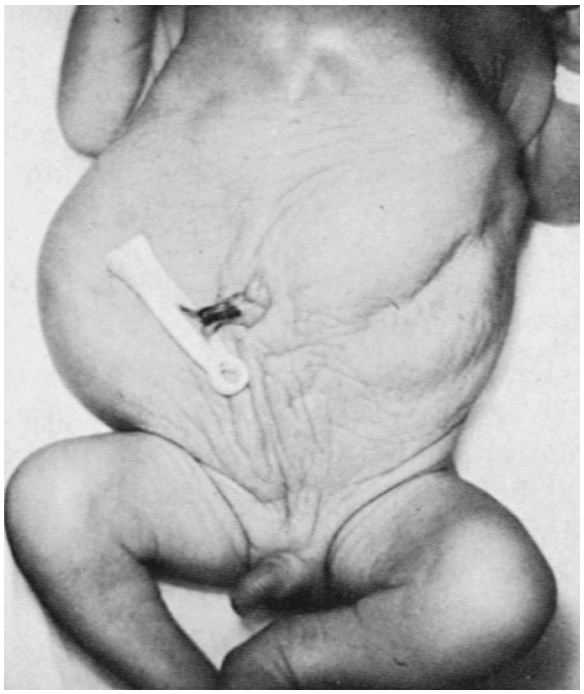
Primary VUR tends to resolve over time as the intravesical segment of the ureter elongates with growth. VUR itself is not thought to cause renal damage. Instead, VUR may be associated with CKD if there is either primary renal dysplasia or with secondary scarring acquired as the result of febrile urinary tract infection.[56] Clinicians should be aware that ultrasonography is a poor screening tool for VUR, even in young children with documented urinary tract infection and high-grade reflux.[46]

Management of VUR depends on its extent and severity as well as the presence or absence of associated renal parenchymal abnormalities (e.g., renal dysplasia). In the past, antibiotic prophylaxis was recommended for patients with all grades of VUR. This practice is also the subject of controversy, and patients with low grade (I–II) VUR probably do not require prophylaxis. Antibiotic prophylaxis does appear to decrease the rate of urinary tract infections in patients with high-grade VUR.[34] Surgical repair is considered in children with high-grade VUR or breakthrough urinary tract infections despite antibiotic prophylaxis. Long-term complications of VUR in conjunction with infections include hypertension, renal scarring, and chronic kidney disease ("reflux nephropathy").

Posterior Urethral Valves

Posterior urethral valves (PUV) represent the most common cause of lower urinary tract obstruction, with an incidence of 1 in 5000-8000 live male births. A posterior urethral valve is composed of a congenital membrane that obstructs or partially obstructs the posterior urethra and is formed when the mesonephric duct fails to adequately regress. Findings on prenatal ultrasound may include hydronephrosis; dilated ureters; a thickened, trabeculated bladder; dilated proximal urethra; and oligohydramnios. The antenatal presentation may include a palpable, distended bladder, poor urinary stream, and signs and symptoms of renal and pulmonary insufficiency. The VCUG is diagnostic for PUV and reveals associated VUR in 30% of patients.

Prenatal therapy with laser valve ablation or insertion of vesico-amniotic shunt has been attempted, but the benefits of prenatal intervention for postnatal and long-term outcomes are still unclear.[45,49] Postnatal treatment is centered on securing adequate drainage of the urinary tract, initially by placement of a urinary catheter and later by primary ablation of the valves. Vesicostomy may be required in infants who show persistent obstruction and impaired urinary drainage despite ablation. Upper tract diversion is less commonly required but may be attempted in patients with markedly dilated, tortuous ureters and worsening renal function despite placement of a bladder catheter. The long-term outcome for infants with PUV depends on the degree of associated renal dysplasia, as postnatal correction of the obstruction often does not result in normalization of renal function.[21,54] Approximately 15%-20% of boys with PUV who present in infancy will progress to end-stage renal disease by adolescence.[6,7] Reported risk factors for progression to end-stage renal disease include a nadir serum creatinine of greater than 1 mg/dL, bladder dysfunction, and urinary tract infections.[6,7] A more recent analysis, however, demonstrated that while a creatinine greater than 1 mg/dL has good specificity for the development of chronic kidney insufficiency in infants with PUV, it has poor sensitivity,[21] so infants should be referred to a pediatric nephrologist for ongoing care.



Eagle-Barrett Syndrome

Eagle-Barrett ("prune belly") syndrome (EBS) is characterized by a triad of genitourinary abnormalities (markedly enlarged bladder with poor contractility without urethral obstruction, megaureters, and renal dysplasia), deficiency of abdominal wall musculature, and cryptorchidism (Fig. 93.6). Not all patients display all three components, and the severity of findings may be variable. The estimated incidence is 1 in 35,000-50,000 live births, with more than 95% of the cases occurring in boys. Although most cases occur sporadically, several reports of familial inheritance led to the identification of at least two potential causative genes, CHRM3/acetylcholine receptor and ACTA2/alpha-smooth muscle actin2, and whole gene deletion of HNF1-ß as well as trisomy 21 have also been associated with EBS.[70] Cardiac, pulmonary, gastrointestinal, and orthopedic anomalies are present in a large percentage of EBS patients, some of which may be attributable to oligohydramnios sequence. Treatment in the neonatal period involves optimization of urinary tract drainage, management of renal insufficiency, and antibiotic prophylaxis. Management later in childhood may include the surgical repair of reflux, orchiopexy, reconstruction of the abdominal wall, and dialysis and/or renal transplantation.

Bladder Exstrophy-Epispadias Complex

The bladder exstrophy-epispadias complex includes a spectrum of malformations that ranges from the mildest form, epispadias, through classic bladder exstrophy, to the most severe form, cloacal exstrophy, which may encompass

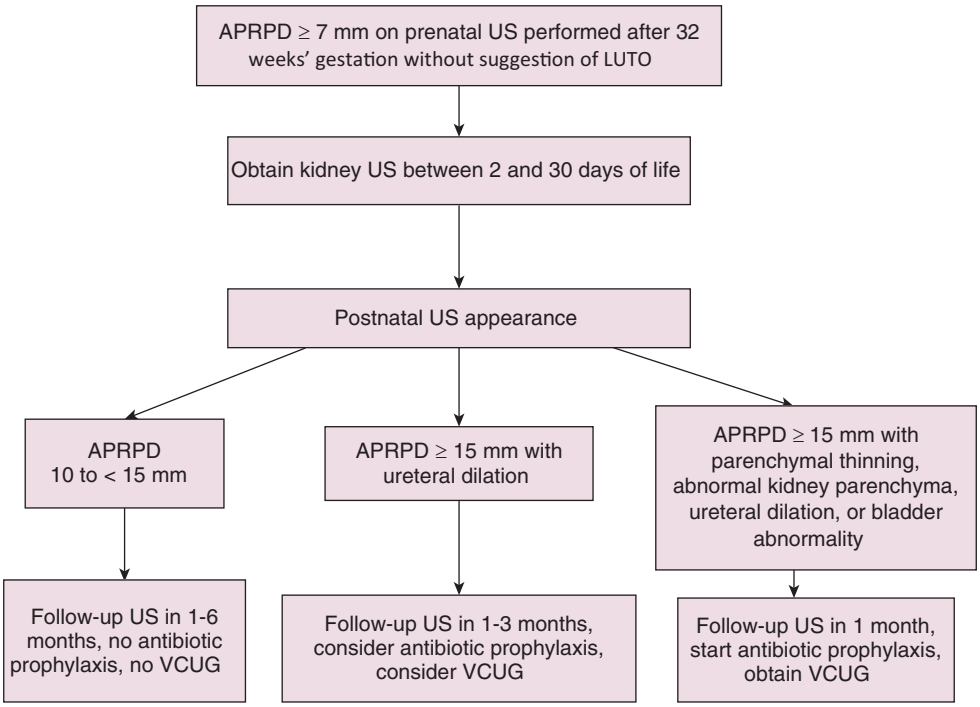
• **Fig. 93.6** Eagle-Barrett ("prune-belly") syndrome. Photomicrograph illustrates the characteristic appearance of a wrinkled abdomen, indicative of absent or deficient abdominal musculature.

omphalocele, bladder exstrophy, imperforate anus, and spinal defects.[70] The incidence of bladder exstrophy-epispadias complex is estimated at 1 in 10,000 births with a male predisposition.[70]

Enlargement or mechanical disruption of the cloacal membrane (the bladder portion of the cloaca and the overlying ectoderm) prevents the invasion of mesodermal cells along the infraumbilical midline, resulting in exstrophy. The nature of the specific abnormality is dependent, in large part, on the timing of the rupture of the cloacal membrane. If rupture occurs before the fourth week of gestation, cloacal exstrophy develops, whereas if rupture occurs after 6 weeks of gestation, epispadias or classic bladder exstrophy occurs. As with other congenital structural urogenital anomalies, many cases of bladder exstrophy-epispadias complex are sporadic. However, there are some reports of occurrence within families, suggesting a genetic component for this multifactorial disorder.[44]

The clinical presentation of classic bladder exstrophy is characterized by an evaginated bladder plate with urine dripping from the ureteric orifices on the bladder surface. Bilateral inguinal hernias are usually present as well. Pubic bones can be felt on both sides of the bladder. The penis appears shorter and the epispadic urethra covers the dorsum of the penis. Testes are usually descended. In females, the clitoris is completely split next to the open urethra.[25] Epispadias is categorized by three degrees of severity, with severe forms involving the entire urethra and bladder.[25] Cloacal exstrophy is the more severe form and can easily involve different organs that require immediate surgical attention.



A renal sonogram is mandatory for every infant with bladder exstrophy-epispadias complex to obtain a baseline examination of both kidneys before repair. Spine ultrasound and radiographs are required to define individual abnormalities. Hip radiographs and possibly magnetic resonance imaging of the pelvis help estimate the symphysis gap and hip localization.[25] Treatment is surgical, and patients require long-term follow-up and a multidisciplinary team that includes a pediatric urologist, pediatric orthopedic surgeon, pediatric nephrologist (if renal dysplasia is present), and appropriate support team.[25]

Management of Antenatal Hydronephrosis

The postnatal management of infants with history of antenatal hydronephrosis is dependent on the degree of dilation seen on third-trimester ultrasound and on the suspicion for lower urinary tract obstruction. A thick-walled bladder, usually defined as wall thickness of 5 mm or greater, that fails to empty and a dilated urethra, with or without bilateral hydronephrosis, should raise the suspicion of lower tract obstruction, and those infants should be evaluated by a pediatric urologist and/or nephrologist in the immediate postnatal period.[53] In the presence of oligohydramnios, the infant should be delivered in a setting capable of providing high acuity care, and immediate respiratory support as these infants are more likely to have significant renal dysfunction.[53]

Several grading systems for antenatal hydronephrosis have been recommended, but the most commonly cited is the one proposed by the Society of Fetal Urology.[52] This system has shown some ability to predict which infants will go on to need surgical intervention versus which ones can be monitored because their degree of hydronephrosis is likely to self-resolve. Grading of antenatal hydronephrosis is based on the anterior–posterior renal pelvis dilation (APRPD) of the renal pelvis when it is visualized in the transverse plane. In the third trimester, an APRPD less than 7 mm is considered normal, while mild, moderate, and severe hydronephrosis are defined as APRPD 7-9 mm, 10-15 mm, and greater than 15 mm respectively.[53] Mild hydronephrosis (APRPD 7 to <10 mm) is more likely to be a transient dilation that will self-resolve. Only about 3% of these infants will have VUR or develop urinary tract infections, and most will not require surgical intervention.[62] Therefore, they do not require antibiotic prophylaxis, and the first postnatal ultrasound may be delayed for 1-2 weeks. Of infants with severe hydronephrosis, about 20% will have VUR and 10%-35% will develop UTIs mostly in the first year of life.[73] Even in the absence of VUR, children with severe hydronephrosis are at high risk of urinary tract infection, especially in the setting of ureteral obstruction or dilation. There is mixed evidence for the benefit of antibiotic prophylaxis for infants with moderate to severe hydronephrosis; however, many practitioners will recommend prophylactic antibiotics, as some studies have shown a decreased risk for infection with prophylactic antibiotics.[14,34,72,73] The need for VCUG in these patients is controversial and may be

• **Fig. 93.7** Suggested postnatal management of antenatal hydronephrosis.[49] APRPD, anterior posterior renal pelvic dilation; LUTO, lower urinary tract obstruction; US, ultrasound; VCUG, voiding cystourethrogram.

dependent on provider preference.[53] Fig. 93.7 demonstrates one suggested approach to the management of antenatal hydronephrosis.

Oligohydramnios of Renal Origin

Severe congenital renal malformation (see also Chapters 13 and 24) may lead to oligohydramnios of renal origin with resultant pulmonary hypoplasia and Potter sequence. In general, oligohydramnios of renal origin portends a poor prognosis, especially when diagnosed during the second trimester.[47] Renal anomalies or obstruction of both kidneys may lead to low amniotic fluid. Cases of serial amnioinfusion with successful delivery of live infants who survived with subsequent dialysis have been reported.[12] Randomized trials testing the effectiveness of vesico-amniotic shunting have failed to show benefit but were also underpowered.[64] Therefore, to date, no prenatal intervention for oligohydramnios of renal origin is considered standard of care, although it may be attempted depending on center expertise or in research settings.

Inherited Renal Disorders

Inherited renal disorders include a spectrum of abnormalities involving the glomeruli or renal tubules. Monogenic diseases (those with single gene defects) that may present in the newborn period include congenital nephrotic syndrome, polycystic kidney diseases, and several disorders of tubular transport.

Congenital Nephrotic Syndrome

Congenital nephrotic syndrome (CNS) is a rare condition that is defined as the development of nephrotic syndrome within the first 3 months of life. As in other forms of nephrotic syndrome, the clinical characteristics include heavy proteinuria, hypoalbuminemia, hyperlipidemia, and edema.[36] Most of the cases of primary CNS occur in infants with Finnish ancestry (CNF). CNF is a well-characterized autosomal recessive disorder with an estimated incidence of 1 in 8200 live births in the Finnish population.[67] However, primary CNS has also been described in infants of non-Finnish ancestry and in infants with other genetic defects that affect the structure or function of the glomerular slit diaphragm (e.g., Denys-Drash or Pierson syndromes). Secondary CNS can occur in infants with congenital infections or a history of maternal systemic lupus erythematosis.[67]

A prenatal diagnosis of CNS should be suspected in mothers with a high serum or amniotic fluid alpha-fetoprotein concentration, which results from massive fetal urinary protein losses. The ultrasonographic detection of placental edema, ascites, or fetal hydrops should also raise the suspicion of this disorder.

Infants with CNF typically have full-blown nephrotic syndrome at birth, with massive proteinuria, profound hypoalbuminemia, hyperlipidemia, and edema. Forty-two percent of the infants with CNF are delivered prematurely; the mean gestational age is 36.6 weeks. Many

infants, particularly those born after 37 weeks, are small for their gestational age. The placenta is always large, weighing greater than 25% of the infant's birth weight.

CNF, also called CNS type I, is caused by mutations in *NPHS1*, located on chromosome 19. *NPHS1* encodes nephrin, a key component of the glomerular slit diaphragm. Alterations in nephrin cause disruption of the filtration barrier, leading to massive urinary protein loss and the clinical characteristics of nephrotic syndrome. The renal histopathology of CNF includes mesangial hypercellularity, tubular microcysts, and variably sized glomeruli with a characteristic fetal appearance, demonstrating prominent cuboidal epithelial cells. Although *NPHS1* mutations account for the majority of patients with CNS, other genetic forms of CNS have been identified, including disorders associated with mutations in *NPHS2* (podocin), *WT-1* (Wilms tumor suppressor gene), and *LAMB2* (laminin beta-2 gene).[67]

The treatment of congenital nephrotic syndrome is complex.[36] The clinician should first exclude congenital infections such as syphilis, HIV, CMV, hepatitis B, rubella, and toxoplasmosis, all of which have been associated with treatable forms of nephrotic syndrome in neonates. Unlike other forms of nephrotic syndrome occurring later in life, primary CNS is resistant to therapy with corticosteroids and immunosuppressive agents. Current treatment includes intravenous albumin infusions, aggressive nutritional support, correction of associated hypothyroidism, and prompt treatment of infectious and thromboembolic complications. Bilateral nephrectomy is typically required for the management of massive protein loss, followed by peritoneal dialysis support and early renal transplantation.

Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease (ARPKD) is an inherited disorder characterized by polycystic kidneys and a developmental bile duct disorder called congenital hepatic fibrosis. ARPKD is rare and is estimated to occur in approximately 1 in 40,000 live births.[33] The majority of patients with ARPKD present in the newborn period, although rare presentations in later childhood are described. Prenatal ultrasonography shows enlarged, echogenic kidneys. Although the amniotic fluid volume is initially normal, oligohydramnios is often noted in the late second trimester. The newborn infant with ARPKD may present with palpable abdominal masses, severe hypertension, and renal insufficiency. Respiratory failure related to pulmonary hypoplasia and marked abdominal distention from the massively enlarged kidneys is common in neonates with ARPKD.

ARPKD is caused by mutations in *PKHD1*, located on chromosome 6p21. *PKHD1* encodes fibrocystin, a very large, novel protein with receptor-like properties for which the exact function is unknown. Renal histopathology reveals that the principal site of subsequent cyst formation in ARPKD is the collecting tubule. Progressive interstitial fibrosis is an additional histopathologic feature of ARPKD. In addition, although virtually all infants with ARPKD have histologic evidence of congenital hepatic fibrosis at birth, clinical evidence of hepatic involvement is present in only 40% of affected newborns.

The diagnosis of ARPKD is typically made based on characteristic clinical features, including enlarged echogenic kidneys, oligohydramnios, and hypertension. However, other cystic disorders, including diffuse cystic dysplasia and ADPKD, can be clinically indistinguishable from ARPKD in the newborn period. Although initial management is similar for all of the disorders, establishing a definitive diagnosis may be helpful for future family planning, and consultation with a geneticist is recommended. Genetic testing, through direct sequencing, is available for ARPKD but may detect only 80% of cases.[31]

The management of the neonate with ARPKD is largely supportive. Ventilatory support is critical in neonates with pulmonary hypoplasia or respiratory embarrassment. Hypertension is often a primary concern and may require the administration of continuous intravenous infusions of several antihypertensive agents. Patients may require correction of electrolyte imbalances, notably hyponatremia. Optimizing nutrition may be challenging owing to massively enlarged kidneys causing feeding difficulties. Unilateral nephrectomies have not been shown to improve the respiratory status but may improve feeding issues. Hepatic complications, such as portal hypertension, are typically absent in the newborn period, and synthetic function is intact.

In the era of modern neonatal care, survival in the neonatal period is estimated to be about 70%. Most mortality is the result of respiratory distress caused by severe pulmonary hypoplasia and inability to achieve adequate oxygenation and ventilation despite aggressive ventilator support. With improved care of pediatric chronic kidney disease, long-term survival has improved as well. Approximately 80% of neonatal survivors are alive at 10 years of life. Morbidity is significant, however, and complications include chronic kidney disease, growth failure, hepatic complications (portal hypertension, bleeding varices, and ascending cholangitis), and chronic lung disease.[31] Progression to end-stage renal disease occurs in 50% of patients in the first decade of life. With the long-term survival afforded by dialysis and renal transplantation, the hepatic complications have emerged as an important cause of morbidity and mortality, particularly as patients enter adulthood.

The clinical presentation of neonatal autosomal dominant polycystic kidney disease (ADPKD) is similar to that of ARPKD, ranging from asymptomatic cysts seen on renal ultrasonography to severe neonatal manifestations.[23] Because the two conditions can be very similar, renal ultrasonography of the patient's parents is important in establishing the correct diagnosis. Historically, the prognosis for an infant with ADPKD presenting in the neonatal period was thought to be poor. Data, however, suggest that over 90% of these patients maintain intact renal function during childhood.[23] Although ADPKD is a systemic disease that can affect the liver, gastrointestinal tract, aorta,

and cerebral vessels, extra-renal manifestations in children are rare.

Neonatal Bartter Syndrome

Neonatal Bartter syndrome is one of the inherited hypokalemic tubulopathies that also include classic Bartter syndrome and Gitelman syndrome. Bartter syndrome is inherited as an autosomal recessive trait; the incidence of neonatal Bartter syndrome is 1 in 50,000-100,000 live births. Newborn infants with neonatal Bartter syndrome typically present with profound salt wasting, polyuria, hypokalemia, and hypercalciuria (see also Chapter 92).

Renal Tubular Acidosis

Renal tubular acidosis (RTA) is caused by a defect in the reabsorption of bicarbonate or in the secretion of hydrogen ions that is not related to a decrease in GFR. RTA should be suspected in infants with persistent hyperchloremic (i.e., nonanion gap) metabolic acidosis. There are three forms of RTA: proximal (type II), distal (type I), and hyperkalemic (type IV). RTA may be sporadic or inherited as a classic Mendelian trait. RTA is discussed in detail in Chapter 92.

Tumors of the Kidney

Renal tumors in the newborn infant are uncommon. Interestingly, despite the widespread use of antenatal ultrasound, only 15% are detected prenatally.[57] The more typical clinical presentation of renal tumors in the neonatal period is abdominal swelling or a palpable mass. Other symptoms may include hypertension, hematuria, fever, and feeding intolerance.

The more common types of neonatal renal tumors include congenital mesoblastic nephroma, multilocular cystic nephroma, and Wilms tumor (nephroblastoma).[57] Malignant rhabdoid tumor is a very rare but aggressive renal malignancy that presents in newborns and young infants and carries an extremely poor prognosis. Other renal neoplasms, such as renal cell carcinoma or lymphoma, are exceedingly rare in neonates.

Congenital mesoblastic nephroma is the most common renal neoplasm in the first year of life.[57] Approximately 60% of all congenital mesoblastic nephromas are diagnosed before 6 months of age; the clinical presentation is an abdominal mass. Congestive heart failure and hypertension are less common manifestations. Nephrectomy is curative, with the exception of infrequent local recurrences and rare pulmonary metastases.

Multilocular cystic nephroma is a benign renal tumor that consists of large cysts separated by fibrous septae. This tumor arises from metanephric blastema and has features of immature blastema, tubules, and skeletal muscle on histopathologic examination. The prognosis is excellent with surgical removal alone.

Wilms tumor accounts for 90% of all renal tumors diagnosed in the pediatric population. However, 80% of Wilms tumors are diagnosed in patients between the ages of 1 and 5 years, making its appearance uncommon in the first year of life and rare in the neonatal period. Most Wilms tumors occur sporadically, but 15% are associated with congenital anomalies or syndromes, including congenital aniridia, hemihypertrophy, WAGR (Wilms, aniridia, genitourinary anomalies, mental retardation) syndrome, Denys-Drash syndrome, and Beckwith-Wiedemann syndrome.[57]

Definitive therapy for a localized renal mass begins with surgical exploration, and in most cases the primary treatment is nephrectomy. Infants with multilocular cystic nephromas or congenital mesoblastic nephromas require no postoperative therapy. Infants with malignant tumors such as Wilms tumor are treated according to well-established oncologic protocols. The prognosis for most infants with neonatal renal tumors is good, although an infant with aggressive Wilms tumor, atypical congenital mesoblastic nephroma, malignant rhabdoid, or renal sarcoma may have a poor prognosis.

Key Points

- Acute kidney injury (AKI) occurs in 30% of critically ill neonates and is independently associated with increased mortality and length of hospital stay.
- Providers should monitor for chronic kidney disease (CKD) in survivors of neonatal AKI, as well as neonates with a history of nephrocalcinosis, prematurity, and/or low birth weight.
- Hypertension occurs in 1%-2% of neonates and is most commonly associated with renovascular thromboembolism related to umbilical arterial catheterization.
- Neonatal nephrocalcinosis is multifactorial in origin and usually resolves spontaneously within the first 2 years of life.
- If mild, antenatal hydronephrosis is most likely to be physiologic and benign, resolving spontaneously over time. Moderate to severe hydronephrosis, especially if associated with oligohydramnios, or small/echogenic/cystic kidneys, is more likely to represent significant urinary tract pathology.
- Congenital anomalies of the kidney and urinary tract (CAKUT) encompass a wide spectrum of conditions associated with genetic and/or environmental risk factors. CAKUT includes disorders such as renal dysplasia, posterior urethral valves, UPJ obstruction, renal agenesis, and multicystic dysplastic kidney.

The Skin of the Neonate

VIVEK NARENDRAN

This chapter provides an overview of the principles of newborn skin care followed by a summary of the many diseases of the newborn presenting with primary or secondary cutaneous manifestations. A basic understanding of the structural development of the skin as well as the multiple functions subserved by the skin during transition to extrauterine life will be highlighted. The caregiver will be able to distinguish benign and transient lesions of newborn skin, such as erythema toxicum, from potential life-threatening diseases such as herpes simplex neonatorum. In addition, the chapter highlights the fact that many common cutaneous findings in the newborn, such as sebaceous gland hyperplasia and neonatal pustular melanosis, have an intrauterine etiology. The advantage of the accessibility of the skin to physical examination is counterbalanced by the extreme structural and functional diversity of this organ.

The skin is a critical interface between the body and environment. This layer differentiates between "self" and "nonself." At birth, the first response in resuscitation includes drying the baby to prevent heat loss and an assessment of skin color, perfusion, and integrity. Pathologic processes visible on the skin surface range from general signs of systemic dysfunction (cyanosis, pallor, jaundice) to clinical evidence of specific diseases (vesicles, petechiae). Cutaneous characteristics are routinely used as determinants of gestational age (breast buds, plantar creases, desquamation). The definitive organ of mammals, the mammary gland, similar to the epidermis, is an ectodermally derived cutaneous structure.[51] Maternal–infant bonding is, in large part, a complex dynamic interaction between skin surfaces.

At birth, the skin of the term infant must perform multiple functions critical for survival in an extrauterine environment (Box 94.1).[11] Many of these functions depend on structural development of the skin during the last trimester of pregnancy. The development of a competent epidermal barrier, for example, is essential for temperature regulation, maintenance of fluid homeostasis, infection control, and prevention of penetration of environmental toxins and drugs. Similarly, the acquisition of the skin microbiome is important in regulating keratinocyte homeostasis to locally produce hormones, neurotransmitters, and cytokines, which in turn maintain epidermal integrity, enhance innate immunity, and inhibit pathogenic bacteria.[54]

The epidermal permeability barrier primarily resides in the outermost layer of the epidermis, the stratum corneum. This layer, approximately one-fourth the thickness of a sheet of paper, develops in utero during the third trimester of pregnancy in conjunction with a protective mantle of vernix caseosa. Extremely low birth weight preterm infants (<1000 g birth weight) lack a well-developed stratum corneum, which poses special problems for newborn care. The stratum corneum is necessary for the adherence of thermistors, cardiorespiratory monitors, and endotracheal tubes, and forms the primary environmental interface with caregivers and parents. Box 94.2 gives a summary and consensus of general principles of skin care.[11]

The Structural Biology of Fetal and Neonatal Skin

Development of the Epidermis

Human skin has two distinct but interdependent components—the epidermis and the dermis (Fig. 94.1). The epidermis has marked regional variations in thickness, color, permeability, and surface chemical components. It consists of a highly ordered, compact layering of keratinocytes and melanocytes. Traditionally, the epidermis is segmented into distinct structural and functional compartments called the stratum germinativum (basale), stratum spinosum, stratum granulosum, and stratum corneum (see Fig. 94.1). Intermixed is a third distinct cell type, the Langerhans cell, which is derived from bone marrow precursors and migrates into the primitive epidermis.

The process of cutaneous morphogenesis can be divided into embryonic and fetal periods (Fig. 94.2).[30] This transition, which occurs at approximately 2 months, is an important time in skin development, because many critical morphogenetic events occur during this transitional period. Between 30 and 40 days of development, the embryonic skin consists of a two-layered epidermis: the basal layer, associated with the basal lamina, and the periderm, which serves as a cover and a presumptive nutritional interface with

Abstract

This chapter provides an overview of the importance of newborn skin in neonatal adaptation and reviews common neonatal skin conditions. The anatomy and function of the skin along with fetal skin development is discussed in depth. The basic primary and secondary skin lesions are characterized and associated with common skin diagnosis to facilitate clinical diagnosis. Common benign and transient skin conditions are differentiated from the pathologic skin lesions. The immaturity of the preterm epidermal barrier and its consequences are highlighted. The role of vernix caseosa, a cheesy material that coats the fetus and serves multiple functions in the newborn, is detailed.

Keywords

epidermal barrier
vernix caseosa

• BOX 94.1 Multiple Physiologic Roles of the Skin at Birth

- Barrier to water loss
- Thermoregulation
- Infection control
- Immunosurveillance
- Acid mantle formation
- Antioxidant function
- Ultraviolet light photoprotection
- Barrier to chemicals
- Tactile discrimination
- Attraction to caregiver

• BOX 94.2 Principles of Newborn Skin Care

Delivery Room

- Provide immediate drying and tactile stimulation.
- Remove blood and meconium.
- Leave vernix intact and spread to allow absorption.

Bathing

- Limit frequency.
- Use neutral pH cleansers.
- Use only water for infants weighing less than 1000 g.
- Avoid antibacterial soaps.

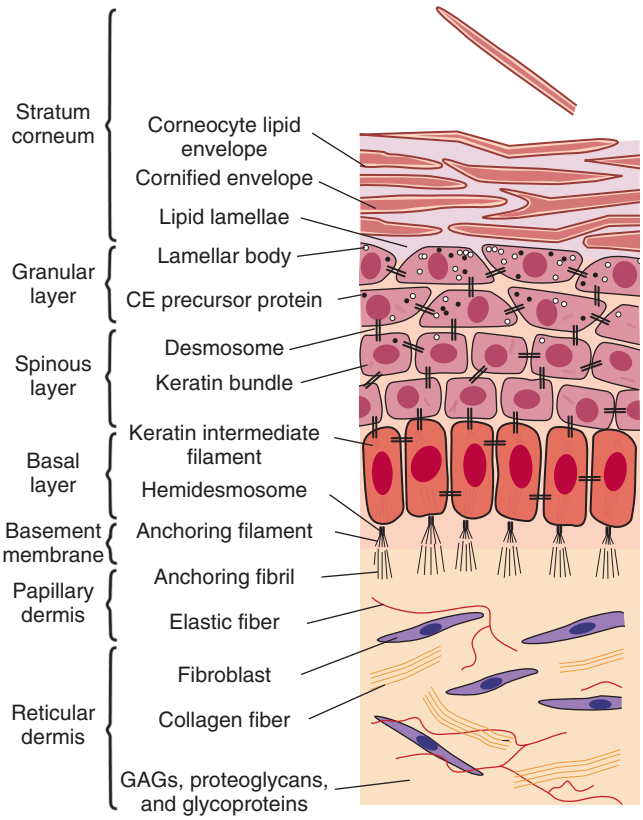
Emollients

- Avoid petrolatum-based ointments in infants with very low birth weight during the first week of life.
- Use emollients as needed for dryness in older infants.

Disinfectants

- Use chlorhexidine, and remove excess after procedure.
- Use of isopropyl alcohol and alcohol-based disinfectants is discouraged in infants with very low birth weight until the stratum corneum has formed.

Adhesives



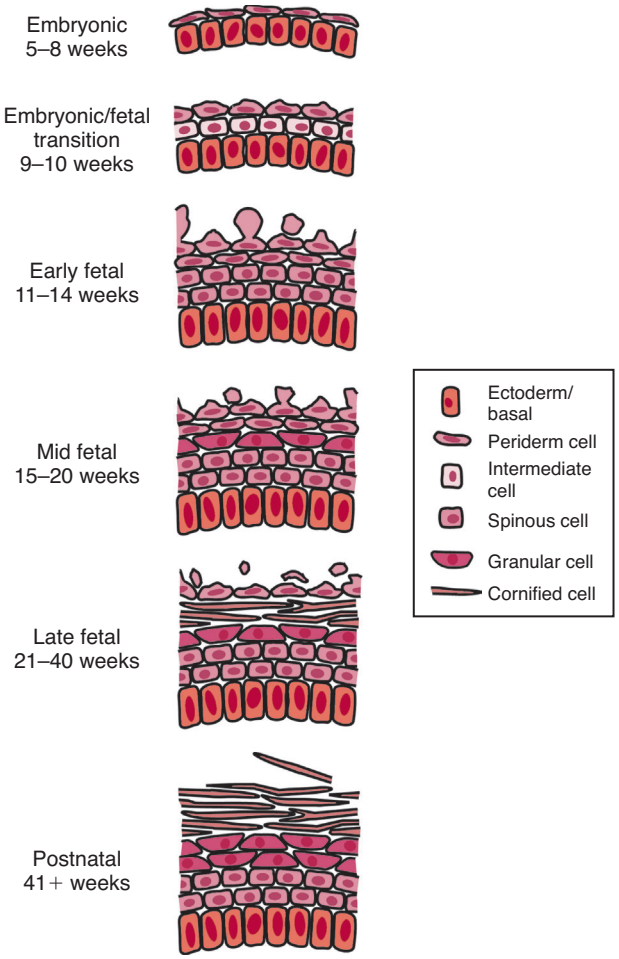
- Minimize use of adhesives.
- Use hydrogel electrodes.
- Avoid solvents and bonding agents.
- Counsel patience during tape removal.

Transepidermal Water Loss

- For infants younger than 30 weeks' gestation, select high incubator humidity (>60%) and transparent, semipermeable dressings to reduce evaporative water and heat loss.
- Use incubators and supplemental conductive heat to avoid drying effects of radiant warmers.
- Measure humidity routinely.

Cord Care

- Allow natural drying.
- Avoid the routine use of isopropyl alcohol.



• **Fig. 94.1** Structure of skin. The normal term infant's skin is composed of three separate layers: dermis, basement membrane, and epidermis. The epidermis can be subdivided into four further strata (basal, spinous, granular, corneum), each representing a specific stage in terminal differentiation. (From Hardman MJ, Byrne C. Skin structural development. In: Hoath SB, Maibach HI, eds. *Neonatal skin: structure and function.* New York: Marcel Dekker; 2003:1-19.)

the amniotic fluid. The basal layer includes cells that give rise to the future definitive epidermis, whereas the periderm is a transient layer that covers the embryo and fetus until the epidermis keratinizes at the end of the second trimester. Basal cells join with each other and peridermal cells by a relatively few desmosomes but do not yet form hemidesmosomes with the basement membrane. Small numbers of keratin intermediate filaments are associated with these junctions. Matrix adhesion of the embryonic epidermis is likely mediated by actin-associated α6β4 integrin.[30]

Langerhans cells and melanocytes migrate into the embryonic epidermis and are identifiable at 40 and 50 days of gestation, respectively. At this stage, the Langerhans cells do not express CD1 antigen on their cell surfaces, nor are Langerhans cell granules identifiable. Likewise, at this time, the melanocyte lacks the characteristic cytoplasmic organelle, the melanosome. A third immigrant cell, the Merkel cell, does not appear to be present in embryonic epidermis and may differentiate at a later stage from keratinocytes in situ.

At the time of embryonic–fetal transition (60 days' gestation), the epidermis begins to stratify, forming an intermediate layer of cells. These young keratinocytes still contain a high volume of glycogen in their cytoplasm and produce large amounts of intermediate filaments in association with the desmosomes. At this time, new keratins are identifiable as markers of differentiation, as is the pemphigus antigen, which is detectable on the cell surface. These cells, unlike

• **Fig. 94.2** Schematic diagram of the six key stages of epidermal differentiation and development. The epidermis develops from a single layer of undifferentiated ectoderm (5-8 weeks) to a multilayered, stratified, differentiated epithelium with a competent epidermal barrier (40 weeks). The periderm undergoes intense proliferation (11-14 weeks) and forms characteristic blebs and microvilli thought to be functionally important. Regression and disaggregation of the periderm occur concomitant with formation of the vernix caseosa (not shown). (From Hardman MJ, Byrne C. Skin structural development. In: Hoath SB, Maibach HI, eds. *Neonatal skin: structure and function.* New York: Marcel Dekker; 2003:1-19.)

adult spinous cells, remain proliferative and continue to express epidermal growth factor receptors on their surfaces. Two to three additional layers of intermediate cells are added during the second trimester. These cells show a progressive increase in the number of keratin filaments but do not further differentiate until the onset of keratinization in the interappendageal epidermis around 22-24 weeks' gestation.

The Langerhans cells in the embryonic epidermis begin to express CD1 antigen and contain Langerhans granules after the embryonic–fetal transition.[12] The numbers of Langerhans cells increase significantly during the third trimester; however, the function of these cells in fetal skin remains unknown. Between 80 and 90 days' gestation, melanocytes also increase in density at a time when keratinocytes in the epidermis are forming appendages, and melanin synthesis begins at the end of the first trimester. Transfer of melanosomes to keratinocytes occurs in the 5th month of gestation.

Melanin production is low in the newborn, who is not as pigmented as the older child and is more sensitive to sunlight, but there is no significant difference in the number of melanocytes in light, medium, or deeply pigmented skin or in infant or adult skin. Difference in color is the result of the shape, size, chemical structure, and distribution of melanosomes and the activity of individual melanocytes.

Development of the Appendages

The appendages derive from embryonic invaginations of epidermal germinative buds into the dermis. They include hair, sebaceous glands, apocrine glands, eccrine glands, and nails. The arrector pili muscle is attached to the hair follicle. Lanugo (i.e., fine, soft, immature hair) frequently covers the scalp and brow of the premature infant. The scalp line may be poorly demarcated, and lanugo also may cover the face. Scalp hair is usually somewhat coarser and matures earlier in dark-haired infants.

The growth phases of the hair follicle are usually synchronous at birth. Eighty percent of the follicles are in the resting state.[58] During the first few months of life, the synchrony between hair loss and regrowth is altered so that 20% of scalp hairs are growing in the same phase at the same time. Hair may become coarse and thick, acquiring an adult distribution, or there may be temporary alopecia.

There are sex differences in hair growth; boys' hair grows faster than girls' hair. In both sexes, scalp hair growth is slower at the crown. The normal pattern of hair growth is disturbed in many chromosomal disorders. Evidence supports a genetic link between the formation of clockwise posterior parietal hair whorls and specific (right) handedness of the individual. This finding supports an unexpected association between gene-based hair patterning and human brain development that warrants further substantiation. Supporting the significance of the skin–brain connection, evidence has shown the human hair follicle can synthesize cortisol de novo and is a functional equivalent of the hypothalamic-pituitary-adrenal axis.

The eccrine sweat glands are coiled structures that form during the first trimester as a downgrowth from epidermal cellular clones. No new glands are formed after birth. They are distributed over the entire body surface and are innervated by sympathetic cholinergic nerves. During the first 24 hours of life, term infants usually do not sweat; on approximately the 3rd day, sweating begins on the face. Palmar sweating begins later. Thermal sweating as a function of body or environmental temperature should be distinguished from emotional sweating associated with crying or pain. The latter is best assessed on the palms and soles.

The sebaceous glands differentiate primarily from the epithelial portion of the hair follicle at approximately 13-15 weeks of life and almost immediately produce sebum in all hairy areas. The glands develop as solid outpouchings from the upper third of the hair follicle. These solid buds become filled with liquid centrally where the cells disintegrate; acini

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

and ducts develop, opening most frequently into the canals between the hair follicle wall and hair shaft.[50] Ectopic glands occur occasionally on the lips, buccal mucosa, esophagus, and vagina.

Surprisingly little is known about the regulation of the rapid growth and activity of sebaceous glands up to and immediately after birth. Hypothetically, secretion by the fetal adrenal gland of weak androgens such as dehydroepiandrosterone (DHEA) is followed by intra-sebocyte conversion to testosterone and production of products of the pilosebaceous unit such as vernix caseosa. This hypothesis remains to be fully tested, but it has the singular advantage of functionally integrating two disparate and unexplained facts; that is, the mutual hyperplasia of the sebaceous gland and the adrenal cortex during the latter half of gestation in the human fetus. Androgens are the only hormones that unequivocally have a stimulating effect on the sebaceous glands; estrogens depress their growth. Between 2 months and 2 years, the sebaceous glands of the normal infant begin a period of quiescence that lasts until puberty.

The apocrine glands are relatively large organs that originate from and empty into a hair follicle. Embryologically, they develop somewhat later than the eccrine glands. Apocrine development is advanced by 7 or 8 fetal months, when the glands begin to produce a milky-white fluid containing water, lipids, protein, reducing sugars, ferric iron, and ammonia. In the newborn, the acini are well formed. The biologic function of the gland is unknown in infants, but it is related to pheromone production in other animal species.

Vernix Biology

Vernix caseosa, a unique material that coats the fetal skin surface during the last trimester of pregnancy, contains lipids of sebaceous origin as well as numerous water-laden fetal corneocytes. A growing body of evidence supports the hypothesis that vernix caseosa participates in regionally "waterproofing" the skin surface, thereby allowing cornification to occur, initially around the hair follicles and then over the interfollicular skin.[71] A better understanding of vernix caseosa and fetal sebaceous gland physiology is biologically relevant and may be applicable to care of the very low birth weight infant and to clinical situations in which the epidermal surface is inadequately developed, burned, or traumatized.

Physiologically, vernix is a hydrophobic material containing wax esters, cholesterol, ceramides, and squalene in addition to other minor lipid components. Vernix has high water content (≈80%), with the water primarily distributed within flat, polygonal, cornified squames. As term approaches, vernix detaches from the fetal skin surface under the influence of pulmonary surfactant and is swallowed by the fetus. In close analogy to breast milk, vernix contains multiple molecules associated with the innate immune system, including lysozyme, lactoferrin, and defensins, as well as antioxidants such as alpha tocopherol.[28] Vernix possesses both emollient (moisturizing) and cleansing functions. Thus, at birth, the human infant is covered with a complex material possessing endogenous anti-infective, antioxidative, moisturizing, and cleansing capabilities. Extreme prematurity, as well as postmaturity, is associated with diminished vernix on the skin surface at birth.

Development of the Dermis

The fetal dermis acquires some of the characteristics of adult dermis around 20 weeks' gestation. However, it is only in the more mature fetus that the true structural and biochemical qualities of the newborn dermis are detectable. The dermis contains three identifiable zones: the region adjacent to the basement membrane, the papillary dermis, and the reticular dermis (see Fig. 94.1). The superficial dermis has finer collagen fibers and is biochemically more active than the deeper zone. The papillary dermis also is more susceptible to light injury and elastic tissue degeneration than the reticular dermis. The dermis has a symbiotic relationship with, and may exert a controlling influence on, the epidermis. It is a metabolically active tissue that contains fibrous elements, amorphous ground substance, free cells, nerves, blood vessels, and lymphatics.

The fibrous elements are collagen and elastic tissue. Collagen types I, III, V, and VI comprise the dermal collagens, whereas type IV is present in the basement membrane of the dermal–epidermal junction and dermal vessels, and type VII occurs in anchoring fibrils and basal keratinocytes. With increasing age, collagen becomes progressively less soluble, and thicker bundles predominate. The morphologic characteristics and chemical properties of cutaneous elastic fibers differ from those of collagen. Elastic fibers are first detectable in the skin by histochemical means and electron microscopy at around 20 weeks' gestation.

The fibroblasts are the most numerous cells in the dermis. They produce collagen and the glycosaminoglycans of the ground substance. Mast cells (which produce heparin and histamine), histiocytes, macrophages, lymphocytes, neutrophils, and an occasional plasma cell and eosinophil are also present in the dermis. The major glycosaminoglycans in the ground substance of skin are hyaluronic acid and dermatan sulfate (i.e., chondroitin sulfate B). An increase in age brings a shift from hyaluronic acid toward dermatan sulfate and a decrease in water content of the dermis.

Blood and Lymphatic Vessel Development

The vascular network supplying the skin develops in early embryonic life from the mesoderm. In 60- to 70-day-old fetuses, there are two vascular networks: a superficial one that appears to correspond to the subpapillary plexus of adult skin and a deeper network that represents the deep reticular vascular network of adult skin. New capillary beds organize to supply the developing epidermal appendages from the 5th month of gestation. These two networks persist into the newborn period; however, the arrangement of vessels remains unstable for the first year of

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

life, and further organization of the vascular network occurs postnatally.

Vasomotor tone is controlled by a delicate and complex series of neural and pharmacologic mechanisms that involve the sympathetic nervous system, norepinephrine, acetylcholine, and histamine, and may involve serotonin, vasoactive polypeptides, corticosteroids, and prostaglandins. The physiologic requirements of skin vary considerably; skin blood flow ranges from 0.1-150 mL/mm^2 of tissue per minute.

Development of Cutaneous Innervation

The nerve networks in the dermis develop at a very early embryologic age and appear to be distributed in a random fashion. The most superficial nerves have the smallest diameter and are the least myelinated. In addition to the dermal nerve network, which may show considerable regional variation, nerve fibers may serve particular regions or structures such as hair follicles, eccrine glands, arrector pili muscles, and the subepidermal zone. Superficial nerves conduct mechanosensory stimuli from the specialized Merkel cells within the epidermis. The sebaceous glands are not innervated.

Special neurologic structures include a dense perifollicular nerve network with exquisite tactile sensory properties and mucocutaneous end organs highly concentrated in erogenous zones. Meissner tactile organs are found in newborn skin as undeveloped structures that mature after birth. Merkel corpuscles probably govern two-point tactile discrimination on palms and fingertips; they are disk-shaped terminals that are seen during the 28th week of fetal life. After birth, these receptors undergo little alteration. Vater-Pacini corpuscles are found around the digits, palms, and genitals; they are fully formed and numerous at birth.[29]

The arrector pili muscles are innervated by sympathetic nerves, and norepinephrine acts as the neurotransmitter. The eccrine glands are innervated by sympathetic fibers, but acetylcholine acts as the neurotransmitter. Parasympathetic fibers may accompany the sensory nerves in the vessel walls and cause vasodilation. The axon reflex is poorly developed in the newborn; in the neonate of low birth weight, axon reflex sweating may be difficult to elicit.

Disorders and Diseases of Fetal and Neonatal Skin

This section provides a cursory synopsis of normal and abnormal aspects of newborn skin. An accurate description of primary and secondary skin lesions forms the basis for the diagnosis of skin pathology. Tables 94.1 and 94.2 describe the basic lesional morphology of infant skin with specific examples. More definitive treatises on normal skin

TABLE 94.1 Primary Cutaneous Lesions*

Type	Description	Clinical Examples
Macule	A circumscribed, flat lesion with color change, up to 1 cm in size; by definition, they are not palpable	Ash leaf macules, café-au-lait spots, capillary ectasias
Patch	Same as macule but >1 cm in size	Nevus depigmentosus, nevus simplex, mongolian spots
Papule	A circumscribed, elevated, solid lesion, up to 1 cm in size; elevation may be accentuated with oblique lighting	Verrucae, milia, juvenile xanthogranuloma
Plaque	A circumscribed, elevated, plateau-like, solid lesion, >1 cm in size	Mastocytoma, nevus sebaceous
Nodule	A circumscribed, elevated, solid lesion with depth, up to 2 cm in size	Dermoid cysts, neuroblastoma
Tumor	Same as a nodule but >2 cm in size	Hemangioma, lipoma, rhabdomyosarcoma
Vesicle	A circumscribed, elevated, fluid-filled lesion up to 1 cm in size	Herpes simplex, varicella, miliaria crystalline
Bulla	Same as a vesicle but >1 cm in size	Sucking blisters, epidermolysis bullosa, bullous impetigo
Wheal	A circumscribed, elevated, edematous, often evanescent lesion, caused by accumulation of fluid within the dermis	Urticaria, bite reactions, drug eruptions
Pustule	A circumscribed, elevated lesion filled within purulent fluid, <1 cm in size	Neonatal pustular melanosis, erythema toxicum neonatorum, infantile acropustulosis
Abscess	Same as a pustule but >1 cm in size	Pyodermas

*Lesions arise de novo and are therefore most characteristic of the disease process.
Modified from Yan AC, et al. Lesional morphology and assessment. In: Eichenfeld LF, et al., eds. *Neonatal and infant dermatology.* 3rd ed. Philadelphia: Elsevier Saunders; 2015 [chapter 3].

TABLE 94.2 Secondary Cutaneous Lesions*

Type	Description	Clinical Examples
Crust	Results from dried exudates overlying an impaired epidermis. Can be composed of serum, blood, or pus.	Epidermolysis bullosa, impetigo
Scale	Results from increased shedding or accumulation of stratum corneum as a result of abnormal keratinization and exfoliation. Can be subdivided further into pityriasiform (branny, delicate), psoriasiform (thick, white, and adherent), and ichthyosiform (fish scalelike).	Ichthyoses, postmaturity desquamation, seborrheic dermatitis
Erosion	Intraepithelial loss of epidermis. Heals without scarring.	Herpes simplex, certain types of epidermolysis bullosa
Ulcer	Full thickness loss of the epidermis with damage into the dermis. Will heal with scarring.	Ulcerated hemangiomas, aplasia cutis congenita
Fissure	Linear, often painful break within the skin surface, as a result of excessive xerosis.	Inherited keratodermas, hand and foot eczema
Lichenification	Thickening of the epidermis with exaggeration of normal skin markings caused by chronic scratching or rubbing.	Sucking callus, atopic dermatitis
Atrophy	Localized diminution of skin. *Epidermal atrophy* results in a translucent epidermis with increased wrinkling, whereas *dermal atrophy* results in depression of the skin with retained skin markings. Use of topical steroids can result in epidermal atrophy, whereas intralesional steroids may result in dermal atrophy.	Aplasia cutis congenita, intrauterine scarring, and focal dermal hypoplasia
Scar	Permanent fibrotic skin changes that develop as a consequence of tissue injury. In utero scarring can occur as a result of certain infections or amniocentesis or postnatally from a variety of external factors.	Congenital varicella, aplasia cutis congenita

*Lesions arise as characteristic modifications of primary lesions through environmental interaction (e.g., drying) or subject interaction (e.g., scratching).
Modified from Yan AC, et al. Lesional morphology and assessment. In: Eichenfeld LF, et al., eds. *Neonatal and infant dermatology*. 3rd ed. Philadelphia: Elsevier Saunders; 2015 [chapter 3].

structure, function, development, and specific disease states are available.[49] The remainder of this chapter delineates specific conditions of newborn skin ranging from transient lesions to definitive cutaneous diseases and diagnostic categories.

Transient Cutaneous Lesions

A number of benign and transient lesions of the skin are commonly observed in a normal nursery population.[34] It is important for the infant caregiver to distinguish such ephemeral lesions from significant life-threatening diseases with cutaneous manifestations.

Sebaceous Gland Hyperplasia and Milia

Approximately 8% of infants have multiple, white, 1-mm cysts (i.e., milia) scattered over the cheeks, forehead, nose, and nasolabial folds. These milia may be few or numerous, but they frequently occur in clusters. Milia are often confused with the more common condition of sebaceous gland hyperplasia (43% of infants), which manifests as smaller, flatter, more yellow dots seen on the midface as well (Fig. 94.3). Histologically, milia are keratogenous cysts similar to Epstein pearls, which are distributed along the midpalatal raphe. Bohn nodules are cysts that occur on the palate and the buccal and lingual aspects of the dental ridges and represent remnants of mucous gland tissue. Intraoral lesions are found in 75%-80% of newborns. Because all these cysts exfoliate or involute spontaneously within the first few weeks of life, no treatment is required.

Pigmentary Lesions

The most frequently encountered pigmented lesion is the mongolian spot (dermal melanosis), which occurs frequently in African-American, Asian, and Native-American infants and infrequently in white infants. Although most of these lesions are found in the lumbosacral area, occurrence at other sites is not uncommon. The pigmentation is macular and gray-blue, lacks a sharp border, and may cover an area 10 cm or larger in diameter. Pigmentary lesions result from delayed disappearance of dermal melanocytes.

Most of these lesions gradually disappear during the first few years of life, but aberrant lesions in unusual sites are more likely to persist. Because of their distinctive color and morphology, mongolian spots are not easily confused with congenital pigmented melanocytic nevi or café au lait spots,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

which often have their onset later in infancy or in early childhood, although they may be present at birth.

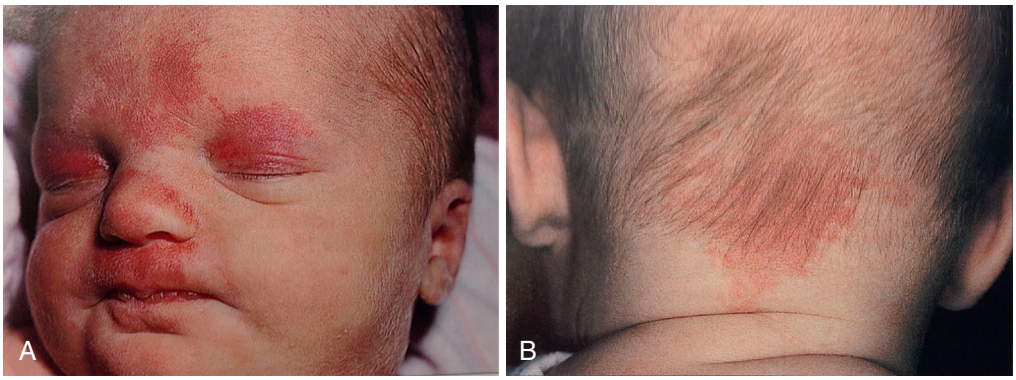
Rarely, extensive mongolian spots may be associated with inborn errors of metabolism (Hurler syndrome, GM1 gangliosidosis, mucolipidosis) and neurocristopathies.[24]

Nevus Simplex or Salmon Patch

The nevus simplex is the most common neonatal cutaneous lesion and is present in up to 80% of normal newborns (Fig. 94.4).[34] These lesions blanch when compressed and are usually centrally located and symmetric, appearing on the nape, the eyelids, and the glabella. In a prospective study of affected infants, most of the facial lesions had faded by 1 year of age, but those on the neck were more persistent. Surveys of adult populations confirm the persistence of the nuchal lesions in approximately one-fourth of the population.

Harlequin Color Change

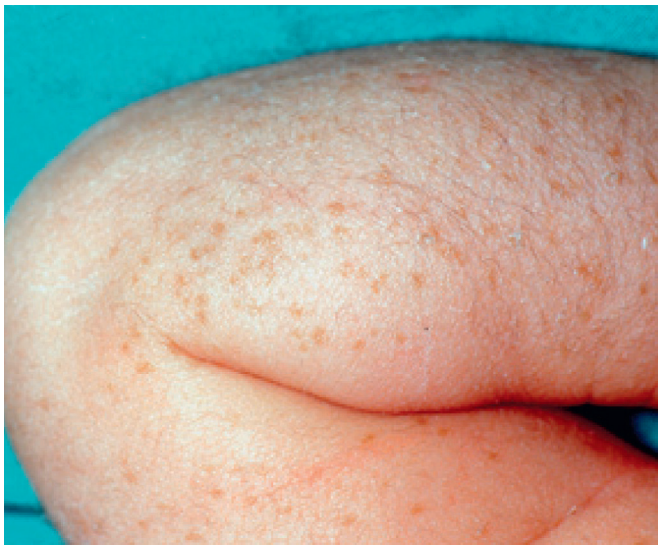
Harlequin color change is a transient phenomenon observed in the immediate neonatal period and common in the low birth weight infant. The dependent side of the body becomes intensely red, and the upper side pales, with a sharp midline demarcation. The peak frequency of attacks in one series occurred on the 2nd, 3rd, and 4th days, but episodes were observed during the first 3 weeks of life. These episodes are of no pathologic significance. They have been attributed to a temporary imbalance in the autonomic regulatory mechanism of the cutaneous vessels; there are no accompanying vital sign changes.



• **Fig. 94.3** Sebaceous gland hyperplasia is manifested by tiny yellow-white follicular papules without inflammation over the nose and surrounding area. (From Lucky AW. Transient benign cutaneous lesions in the newborn. In: Eichenfield LF, et al., eds. *Neonatal and infant dermatology.* 3rd ed. Philadelphia: Elsevier Saunders; 2015, Chapter 7.)

Erythema Toxicum

Erythema toxicum is a benign and self-limited eruption that usually develops at 24-72 hours of age, but new lesions may appear until 2-3 weeks of age.[46] The disorder is more common in term than premature infants, which suggests that it may represent an inflammatory reaction requiring mature skin. These lesions may vary considerably in character and number; they may be firm, 1-3 mm, pale yellow to white papules or pustules on an erythematous base resembling flea bites or erythematous macules as large as 3 cm in diameter. Individual lesions are evanescent, often lasting only a matter of hours. They may be found on any area of the body but occur only rarely on the palms and soles. They are asymptomatic with no related systemic involvement and the cause is unknown, although a variety of specific cytokines have been implicated in the pathogenesis. A microscopic examination of a Wright- or Giemsa-stained smear of the pustule contents demonstrates numerous eosinophils; Gram stains are negative for bacteria and cultures are sterile. No treatment is necessary because spontaneous resolution occurs in 6 days to 2 weeks.



Transient Neonatal Pustular Melanosis

Transient neonatal pustular melanosis is a distinctive eruption that heals with brown pigmented macules. It consists of three types of lesions: first-stage lesions are small superficial vesiculopustules with little or no surrounding erythema. These rapidly progress to the second stage, which consists of collarettes of scale or scale crust surrounding a

• **Fig. 94.4** Capillary ectasias or transient macular stains (salmon patches). **A,** Also called a nevus simplex, these lesions appear on the glabella, eyelids, nose, and upper lip. **B**, The most common location for a nevus simplex is the nape of the neck. (From Lucky AW. Transient benign cutaneous lesions in the newborn. In: Eichenfield LF, et al, eds. *Neonatal and infant dermatology.* 3rd ed. Philadelphia: Elsevier Saunders; 2015 [chapter 7].)

• **Fig. 94.5** Transient neonatal pustular melanosis begins in utero with superficial pustules, followed by rupture, leaving a collarette of scale and subsequent postinflammatory hyperpigmentation. (From O'Connor NR, McLaughlin MR, Ham P. Newborn skin: part I. Common rashes. *Am Fam Physician*. 2008;77:47-52.)

• **Fig. 94.6** Miliaria crystallina. (From Antaya RJ, Robinson DM. Blisters and pustules in the newborn. *Pediatr Ann*. 2010;39:635-645.)

hyperpigmented macule (third stage) (Fig. 94.5). All three types of lesions may be present at birth, but the macules are observed more frequently. The lesions may be profuse or sparse and occur on any body surface, including the palms, soles, and scalp. Sites of predilection are the forehead, submental area and anterior neck, and lower back. When intact pustules rupture, a pigmented macule often is discernible central to the collarette of scale, which represents the margin of the unroofed pustule. Presumably, the macules result from postinflammatory hyperpigmentation, and those present at birth may be the sequelae of in utero pustular lesions.

Pustular melanosis may be confused with erythema toxicum, congenital cutaneous candidiasis, or staphylococcal pyoderma. Cultures and Gram stains of smears prepared from intact pustules are devoid of organisms; Wright stains of intralesional contents demonstrate cellular debris, polymorphonuclear leukocytes, and a few or no eosinophils, in contrast to those of erythema toxicum. Although the pustules disappear in 48 hours, the hyperpigmented macules may persist for as long as 3 months. These lesions require no therapy as the disorder is benign and transient.

Miliaria

Miliaria is an eruption characterized by crops of superficial vesicles resulting from eccrine sweat gland duct obstruction leading to sweat retention. The three types of lesions are superficial thin-walled vesicles without inflammation (i.e., miliaria crystallina, Fig. 94.6); small, erythematous, grouped papules (i.e., miliaria rubra); and nonerythematous pustules (i.e., miliaria pustulosis or profunda). The eruption most frequently develops in the intertriginous areas and over the face and scalp. It is exacerbated by exposure to a warm and humid environment. Miliaria sometimes can be confused with erythema toxicum; rapid resolution of the lesions when the infant is placed in a cooler environment differentiates them from other causes of infectious pustulosis. A Wright-stained smear of vesicular lesions demonstrates only sparse squamous cells or lymphocytes, permitting exclusion of infectious vesicular eruptions. No topical therapy is indicated.

Neonatal Acne and Infantile Acne

Neonatal acne occurs in up to 20% of newborns and is more commonly seen in boys. Increased sebaceous secretions secondary to maternal and neonatal androgens and colonization of the sebaceous glands by the yeast *Malassezia furfur* are implicated in its pathogenesis[20] and are characterized by small red papules and pustules on the face during the first weeks of life. Unlike in adolescents, comedones and cysts are usually absent. The lesions are asymptomatic and resolve spontaneously without scarring over several weeks. The clinical significance lies in differentiating this rash from infections, excluding virilization as its underlying cause and potential implication of severe acne in adolescence.

Infantile Acropustulosis

Infantile acropustulosis is characterized by recurrent crops of pruritic, sterile vesiculopustules with a predilection for the palms and soles. The lesions appear in crops every 2-3 weeks and last 7-10 days. They involve the hands and feet primarily, but occasionally may involve the limbs as well. Because of the distribution, it is often confused with scabies. It is more common in African-American and male infants. The condition resolves spontaneously. A subcorneal pustule filled with neutrophils is seen on skin biopsy. Traditional therapy consists of topical steroids and antihistamines, although one report indicates successful treatment with topical maxacalcitol, an active form of vitamin D3.[37] A recessive mutation in the gene coding interleukin 1 receptor antagonist has been described in a case of infantile pustulosis treated successfully with recombinant human interleukin 1 receptor antagonist anakinra.[44]

Disorders of Cornification: The Scaly Baby

The most common and benign causes of excessive scaling are due to physiologic desquamation (normal term infants) and dysmaturity (post-mature and small for gestational age infants), neither of which have long-term sequelae. Less common causes include the congenital ichthyoses and the ectodermal dysplasias (particularly hypohidrotic ectodermal dysplasia), all of which are chronic, heritable disorders.[13,19]

Physiologic Desquamation and Dysmaturity

The gestational age of a newborn with accentuated physiologic desquamation usually is 40-42 weeks; peak shedding occurs near the 8th day of life. These infants are otherwise normal in physical appearance and behavior. In contrast, the dysmature infant (see Chapter 22) has distinctive characteristics. The body is lean with thin extremities and decreased subcutaneous fat. The ponderal index is low with diminished body weight in relation to length. The skin is often scaly with parchment-like desquamation, especially of the distal extremities. There is often meconium staining of the skin as well as the nails and umbilical cord. The hair is abundant and the nails are abnormally long. In the normal infant with accentuated physiologic scaling and the dysmature infant, desquamation is a transient phenomenon, and the integument continues to serve its intended protective function. In contrast, the infant with congenital ichthyosis may have serious difficulties early in life because of impaired barrier function and the subsequent risks of secondary infection.

Ichthyoses

The term *ichthyosis* derives from the similarity of the skin condition to the scales of a fish. It refers to a complex and often confusing plethora of conditions characterized by disorders of cornification with or without systemic symptoms.[13,19] In 2010, a consensus conference of experts developed a new classification that was clinically based and easily comprehensible by clinicians.[52] It was broadly divided into nonsyndromic (restricted to skin) and syndromic (skin plus other organs). Ichthyosis in the newborn period may manifest as scaling only, scaling and erythroderma, a collodion membrane, or the thickened plates of harlequin ichthyosis. Although rare, it is important for the neonatal caregiver to recognize the patient with ichthyosis as the barrier function of the skin is often compromised. Prompt management and diagnosis can be lifesaving. Selected conditions with particular relevance to the newborn are highlighted below, followed by a general overview of treatment strategies. Table 94.3 lists the major clinical phenotypes of the ichthyoses in the newborn period.

X-Linked Ichthyosis

X-linked ichthyosis is the most common form of ichthyosis in the newborn period, affecting approximately 1 in 2500 male babies. Genetic mutations of the *STS* gene lead to deficiency of steroid sulfatase. Female carriers of the gene for X-linked ichthyosis, when pregnant with an affected male fetus, have a deficiency of placental steroid sulfatase reflected by low maternal urinary estriol excretion and a difficult or prolonged labor that often requires intervention. Clinical manifestations of X-linked ichthyosis in males include alterations in the skin, eye, and testes of affected infants. Most patients have cutaneous findings at birth, and 80%-90% show scaling by 3 months of age. Rarely, a collodion membrane may be present. The hyperkeratosis is variable, but the scales typically are large, thick, and dark and are prominent over the scalp, neck, anterior trunk, and extensor extremities. Sparing of palms and soles and partial sparing of the flexures are helpful diagnostic features. Systemic manifestations are generally absent, and complications are rare. Skin biopsy is helpful (although the histologic pattern resembles that of lamellar ichthyosis), showing hyperkeratosis, a well-developed granular layer, hypertrophic epidermis, and a perivascular lymphocytic infiltrate. This form of ichthyosis is clinically apparent in affected

TABLE 94.3 Clinical Presentation of Ichthyoses in the Newborn

Phenotype	Type of Ichthyosis
Erythroderma	Netherton syndrome, KID syndrome, CIE Also consider: Omenn syndrome, SCID, ectodermal dysplasia, erythrodermic psoriasis
Generalized scaling	XLI, Netherton syndrome, Sjögren-Larsson syndrome, trichothiodystrophy, neutral lipid storage disease
Collodion baby	Lamellar ichthyosis, CIE, self-healing collodion baby, harlequin ichthyosis (mild), Sjögren-Larsson syndrome, trichothiodystrophy, neutral lipid storage disease Also consider: ectodermal dysplasias, Gaucher disease
Vernix-like hyperkeratosis	Harlequin ichthyosis, KID syndrome
Constrictive scales with deformities	Harlequin ichthyosis
Blisters/erosions	Epidermolytic ichthyosis, ichthyosis bullosa of Siemens Also consider: epidermolysis bullosa, TEN, SSSS, immunobullous disease, mastocytosis

CIE, Congenital ichthyosiform erythroderma; KID, keratitis-ichthyosis-deafness; SCID, severe combined immunodeficiency; SSSS, staphylococcal scalded skin syndrome; TEN, toxic epidermal necrolysis; XLI, X-linked ichthyosis.
Different clinical presentations of ichthyosis in the newborn and the most likely underlying clinical conditions.

homozygous males and not in heterozygous females. Cryptorchidism is seen in approximately 25% of affected males; these patients may be at increased risk for testicular cancer. Deep stromal corneal opacities have also been found in about 50% of male infants with the disorder and in a smaller percentage of female carriers, but they do not affect vision.

Harlequin Ichthyosis

Harlequin ichthyosis and harlequin fetus are rare, very severe disorders of keratinization inherited as an autosomal recessive trait in most families owing to mutations in the *ABCA12* gene. The skin of affected infants is markedly thickened, hard (armor-like), and hyperkeratotic, with deep crevices running transversely and vertically. The fissures are most prominent over areas of flexion. Rigidity of the skin around the eyes results in marked ectropion, although the globe is usually normal. The ears and nose are underdeveloped, flattened, and distorted, and the lips are everted and gaping, producing a "fish-mouth" deformity. The nails and hair may be hypoplastic or absent. Extreme inelasticity of the skin is associated with flexion deformity of all joints. The hands and feet are ischemic, hard, and waxy in appearance, with poorly developed distal digits.

Most harlequin fetuses are born prematurely, usually between 32 and 36 weeks' gestation, adding to their morbidity and mortality. Complications relate to an impaired skin barrier with associated hypernatremic dehydration, altered thermoregulation, increased metabolic demands, and increased risk of respiratory failure and sepsis. Although the disease still has a high mortality, therapeutic trials of oral retinoids combined with multidisciplinary intensive care have resulted in dramatic survival of several of these infants.[21] All surviving infants develop chronic, severe ichthyosis.

Collodion Baby

The collodion baby is less severely affected than the infant with harlequin ichthyosis and may represent a phenotypic expression of several genotypes. The infant is covered with a cellophane-like membrane, which by its tautness may distort the facial features and the digits. The membrane is shiny and brownish yellow, resembling an envelope of collodion or oiled parchment, and may be perforated by hair. This condition eventuates in lamellar ichthyosis or congenital ichthyosiform erythroderma in approximately 60% of patients. Sjögren-Larsson syndrome, Conradi-Hünermann syndrome, trichothiodystrophy, dominant lamellar ichthyosis, and neonatal Gaucher disease account for the remainder of the infants born with a collodion membrane. Rarely, shedding of the collodion membrane results in a normal underlying integument (i.e., lamellar exfoliation of the newborn). Collodion babies often are born prematurely. The presence of ectropion, eclabium, and crumpled ears causes these infants to resemble one another for the first few days of life. Fissuring and peeling begin shortly after birth, and large sheets may desquamate, revealing erythema of variable intensity. These infants have an abnormal epidermal barrier, which leads to complications such as dehydration, electrolyte imbalance, temperature instability, and cutaneous and systemic infection. Complete shedding of the collodion membrane may take several weeks. Pedigree information and histopathologic examination of a skin biopsy are additional aids in the delineation of the specific type of ichthyosis.

Management of Ichthyosis

Management of ichthyotic patients in the newborn period varies from managing mild cosmetic problems with excessive dryness and scaling to treatment of potentially life-threatening illness because of deficits in the epidermal barrier and subsequent infection. Table 94.4 lists the primary complications that form the primary targets of therapy for ichthyosis. Severely affected infants require aggressive topical care, oral systemic retinoids (Acitretin), liberal use of bland emollients, and careful monitoring of electrolyte needs. The infant should be placed in an environment with increased humidity and every effort taken to prevent infections. Keratolytic agents if necessary can be used with caution in the neonatal period. The long-term goal of ichthyotic therapy is to eliminate scaling owing to excessive cornification and reduce dryness (xerosis) of the skin without inducing irritation. Although the stratum corneum is often thick and scaly, the barrier is compromised, and there are significant risks of systemic absorption of potentially toxic substances applied topically. Avoidance of corneal desiccation and ulceration is critical if ectropion is present.

Future Prospects

At present, there is no definitive cure for ichthyosis, and current therapies are generally palliative. Over the past decade, however, the molecular basis of many of these predominantly monogenetic disorders has been elucidated.[13,19] Identification of the affected genes opens the door for prenatal diagnosis and genetic counseling for these potentially lethal conditions. Rapid progress in this field is anticipated, including the possibility of cutaneous gene therapy. Parents are referred to an extensive online support group for families of infants with cornification disorders, the Foundation for Ichthyosis and Related Skin Types (FIRST) (www.firstskinfoundation.org).

Vesicobullous Eruptions

Blistering eruptions in the neonatal period are relatively common (Table 94.5) and may be caused by infections, congenital diseases, or infiltrative processes or may be of unknown origin.[1,22,32] The management of such infants depends on knowledge of the cause of the disease or, when this is not possible, on an understanding of the pathogenesis of the type of blister encountered. Establishing the pathogenesis often depends on determining at which level (plane) within the skin the blister has occurred.

TABLE 94.4 Clinical Complications of Ichthyosis and Therapeutic Management

Complications with Ichthyosis	Therapeutic Management Strategies
Restricted chest movement, contractures of limbs and soft tissues, sucking and feeding problems, compartment syndromes	Respiratory support, nasogastric feeding, liberal emollients with daily bathing and/or retinoids to thin and remove scale, monitor tissue perfusion and compartment pressure, orthopedic and plastic surgery evaluation of contractures, ophthalmology consult for ectropion and avoidance of corneal desiccation
Risk for bacterial infections and sepsis caused by impaired epidermal barrier	Watch for clinical signs of localized infection and/or sepsis with institution of aggressive culturing and treatment, topical antibiotics to fissures, reverse isolation
Risk of dehydration and electrolyte imbalance	Monitor fluid balance and electrolytes, humidified incubator to decrease evaporative water loss, intravenous hydration and/or alimentation
Fragile, easily traumatized skin; risk of absorption of topical preparations	Minimal handling; avoid aggressive adhesives; use self-adherent wraps or gauze; use bland emollients; avoid silver sulfadiazine, lactic acid, and salicylic acid preparations; antibacterial soaps

TABLE 94.5 Clinical Conditions of the Newborn Presenting with Cutaneous Vesicles, Bullae, Pustules, and Erosions

Differential Category	Specific Conditions
Noninfectious transient conditions	Sucking blister, superficial trauma, miliaria, neonatal acne, erythema toxicum neonatorum, transient neonatal pustular melanosis, eosinophilic pustular folliculitis, acropustulosis of infancy
Nontransient bullous dermatoses	Epidermolysis bullosa, Langerhans cell histiocytosis, incontinentia pigmenti, epidermolytic hyperkeratosis, pemphigus vulgaris, mastocytosis, hyper-IgE syndrome, herpes gestationis
Infectious vesiculopustular dermatoses	Viral infections: Herpes simplex, varicella, cytomegalovirus; Bacterial infection: Group B streptococcus, Group A streptococcus, *Haemophilus influenza* type B, *Staphylococcus aureus*, Listeria, *Pseudomonas*; Other: *Treponema pallidum*, *scabies*, *Candida*, *Aspergillus*

Adapted from Antaya RJ, Robinson DM. Blisters and pustules in the newborn. *Pediatr Ann.* 2010;39:635-645; Avram MM, Gobel V, Sepehr A. Case records of the Massachusetts General Hospital. Case 30-2007. A newborn girl with skin lesions. *N Engl J Med.* 2007;357:1327-1335.

Blister sites may be intraepidermal or subepidermal. In the epidermis, the blister can be very high (subcorneal), midepidermal, or basal. The midepidermal blister may be formed by primary separation of intercellular contacts (e.g., acantholysis), by secondary edematous disruption of intercellular contacts (e.g., spongiosis), or by intracellular injury as seen in patients with viral infections. The diagnosis of a blistering disease usually requires a family history, an immediate past history of the infant and mother, laboratory studies to exclude infectious agents, evaluation of the infant's general state of health, consideration of the morphologic characteristics of the eruption, and often a biopsy of the involved skin. The biopsy should be obtained from a fresh, typical, small lesion and should include some surrounding skin.

Sepsis

Bacterial sepsis in the neonate can present with vesicles, pustules, or bullae. The most common cause of sepsis presenting with pustules is *S. aureus.* Group B *Streptococcus* (GBS) *agalactiae* is a leading cause of neonatal sepsis, pneumonia, and meningitis, but it rarely manifests in the neonate at birth with vesicles, pustules, or bullae. Other occasional causes of pustules and sepsis in neonates include *Listeria monocytogenes*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae.*

Staphylococcal Infection and Impetigo

Superficial skin infections caused by *Staphylococcus aureus* range from localized bullous impetigo to generalized cutaneous involvement with systemic illness.[4] In contrast to congenital blistering diseases, which are often present at birth, skin infections with *S. aureus* usually develop after the first few days of life. They may be bullous, crusted, or pustular. Typical lesions are small vesicles or pustules or large, fragile bullae filled with clear, turbid, or purulent fluid. They rupture easily, leaving red, moist, denuded areas often with a superficial varnish-like crust. Although they may develop anywhere on the body, the blisters and pustules commonly occur on the diaper area, axillae, and periumbilical skin. The diagnosis is made by Gram stain and culture of the blister fluid, which can distinguish this eruption from streptococcal impetigo and other bullous disorders of the neonatal period. Blood cultures should be obtained from affected infants before initiating systemic antibiotic therapy,

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

even if the infants are usually otherwise well. Contacts and nursery personnel should be investigated for a source of the infectious organism. The infant should be placed in isolation and observed carefully for early signs of sepsis. A high index of suspicion during examination of other infants in the nursery is the most effective means of preventing epidemic spread of this infection.

Compresses of physiologic saline solution and systemic antibiotics to cover the principal etiologic possibilities are indicated until culture results are available. Fluid and electrolyte replacement therapy may be required if the disease is extensive. Recovery is usually complete in several days with no residual scarring.

Staphylococcal Scalded Skin Syndrome

The staphylococcal scalded skin syndrome is a severe bullous eruption heralded by a bright erythema that resembles a scald. The erythema begins on the face and gradually spreads downward to involve the remainder of the skin, with accentuation in the flexural areas. The level of cleavage is superficial, occurring in the granular layer of the epidermis, and the bullae, therefore, are flaccid, easily ruptured, and rapidly progress into areas of denudation. The infant is febrile, irritable, and has marked cutaneous tenderness. The face, neck, and flexural areas are the first to be eroded. The entire upper epidermis may be shed from the limb like a glove. Crusting around the mouth and eyes results in a typical facies. Conjunctivitis is common, as is hyperemia of the mucous membranes, but oral ulcerations do not occur. Infants with a milder form of the disease display a scarlatiniform eruption with perioral and flexural desquamation but without bullae or denudation. Like staphylococcal pyoderma, staphylococcal scalded skin syndrome is rarely seen at birth, with most neonatal cases presenting between 3 and 7 days of life.

The infecting organism in scalded skin syndrome is *S. aureus*, usually a group 2 phage type, although other phage types occasionally have been incriminated. These organisms produce an exotoxin (i.e., exfoliatin) that has proteolytic activity on desmoglein-1, a molecule found within the desmosomes of keratinocytes that is responsible for the cutaneous manifestations.[26] Two major serotypes of the toxin, A and B, cause bullous impetigo and scalded skin syndrome. In cases of the former, the toxin produces exfoliation and blisters locally, whereas in the latter, the toxin circulates systemically with widespread epidermal necrolysis. Histologic examination of the skin demonstrates separation at the level of the granular layer with cell death and acantholysis; there is a striking absence of inflammatory infiltrate. Because intact bullae are sterile, cultures should be obtained from the nasopharynx, conjunctival sac, umbilicus, abnormal skin, blood, urine, and any other suspected focus of infection that might have provided a portal of entry for the organism.

Treatment consists of prompt systemic administration of penicillinase-resistant semisynthetic penicillin and pain management. Fluid and electrolyte replacement is warranted if necessary, and reports indicate successful use of skin-substitute dressings. Flaky desquamation occurs during the healing phase. Scarring never occurs because the blister cleavage plane is intraepidermal.

Streptococcal Infection

Infection with group B beta-hemolytic streptococci rarely produces skin lesions, but vesicles, bullae, and erosions have been reported. Epidemics of group A streptococcal infection may occur primarily as omphalitis or rarely as isolated pustules. These infants should be treated aggressively with parenteral antibiotics, because sepsis, cellulitis, meningitis, and pneumonia have been documented.

Miscellaneous Bacterial and Spirochete Infections

Listeria and *Haemophilus* may also be the cause of cutaneous vesicles or pustules in the newborn. *Pseudomonas aeruginosa* may cause large hemorrhagic bullae in the neonatal period. This is usually a nosocomial infection seen primarily in infants with low birth weights. The skin lesions result from septicemia and hematogenous spread to the skin. In older children, the pustules and bullae are in the perineal region, but in the newborn, they may occur anywhere. The lesions rapidly ulcerate, leaving "punched-out" erosions. Diagnosis can be made by performing a Gram stain or culture of the bullae or the base of the ulcer. Parenteral antibiotics should be administered immediately, and the prognosis is usually poor. Although previously rare, congenital syphilis is increasing in incidence and mirrors the increase in pregnant women.[69] Sixty percent of infants with congenital syphilis are asymptomatic at birth. Vesicles or bullae with erythema on a polished base may form on the palms and soles and are pathognomonic. (Fig. 94.7).[1] This rash is accompanied by hepatosplenomegaly, periostitis of long bones, snuffles, and iritis. The diagnosis is made by using a combination of nontreponemal and treponemal antibody tests as recommended by the CDC. More recently, the reverse syphilis testing algorithm has outperformed the traditional testing and has been widely accepted.[67] The main stay of treatment remains systemic procaine and benzathine penicillin.

Viral Lesions

One of the most important causes of vesicular rash in the neonatal period is herpes simplex infection.[32] Frequently, an inconspicuous cutaneous lesion heralds severe systemic infection. The infection may be acquired in utero or perinatally. Intrauterine herpes simplex infection typically presents with vesicles at birth or within 24 hours. The vesicular eruption may be widespread or even bullous, resembling epidermolysis bullosa. Rarely, congenital scars may be present when infection was early in gestation, in which case additional findings may include low birth weight, microcephaly, chorioretinitis, and neurologic changes. Perinatally acquired herpes simplex may be limited to the skin, eyes, and mouth or may be disseminated with multiple organ involvement. The cutaneous lesions usually develop in the second week

• **Fig. 94.7 A,** Congenital syphilis with erythema and widespread plantar desquamation of the foot. **B,** Erythematous rash on palmar surface. (From Ferreira ST, et al. Skin rash: a manifestation of early congenital syphilis. *BMJ Case Rep.* Published online: doi: 10.1136/bcr-2016-216148).

of life, concurrent with or after nonspecific systemic signs and symptoms. Typically the lesions are 1- to 3-mm vesicles, usually occurring on the scalp or face. Vesicles may be present on the torso or buttocks, especially in a breech delivery. Rarely, pustules, erosions, or oral ulcerations may be the only cutaneous findings. In infants with cutaneous lesions suggestive of herpes simplex infection, antiviral therapy should be administered immediately, and the diagnosis can be confirmed by PCR of HSV antigens in blood or CSF. Isolation of HSV by culture of vesicle scrapings or "surface" culture of mouth, nasopharynx, rectum, or conjunctivae is the traditional diagnostic method.[36] Current recommendations for prevention of herpes simplex infections include cesarean section for women with active lesions or prodromal symptoms consistent with herpes. Vaccines against HSV2 have been of low efficacy. High-dose, prolonged acyclovir therapy remains the treatment of choice for neonatal herpes simplex infections.

Primary varicella may occur in the newborn if the mother has a primary varicella infection in the last 3 weeks of pregnancy. The onset of this diffuse vesicular disease is 5-10 days of age, and the lesions may be numerous and monomorphic given the infant's impaired ability to mount an immune response. Varicella zoster has also been reported in the neonatal period in infants of mothers who have had primary varicella during pregnancy. These vesicles are unilateral and occur in a dermatomal distribution. The vesicles of varicella, herpes zoster, and herpes simplex have a similar histologic pattern, with cleavage in the mid-epidermis. Acantholysis and marked destruction of individual cells result in the ballooning type of degeneration characteristic of viral vesicles.

Candidiasis

See Chapter 49. *Candida* species are commensal organisms commonly found in the gastrointestinal and female genital tracts. Roughly one-third of health care workers in neonatal intensive care units test positive for candida on routine surveillance cultures, and up to 40% of women are culture positive for *Candida* at the time of delivery. Candidiasis in the first 4 weeks of life is usually benign and is localized most often to the oral cavity (thrush) or the diaper area. If maternal vaginal organisms are acquired during the birth process, the infant may manifest symptomatic mouth lesions or become an intestinal carrier. Fecal contamination is the usual source of the organism in candidal dermatitis. Paronychial lesions also may occur, particularly in thumb-sucking infants. The lesions of thrush are detectable as creamy white patches of friable material on the buccal mucosa, gums, palate, and tongue. Early cutaneous lesions consist of erythematous papules and vesicopustules that become confluent, forming a moist, erosive, scaly dermatitis surrounded by satellite pustules.

Rarely, cutaneous candidiasis may be congenital as a result of ascending infection from a vaginal or cervical focus. Risk factors for this type of candidiasis include a foreign body in the uterus or cervix, premature birth, and a history of vaginal candidiasis. Affected infants usually have a widespread eruption with pustules on the palms and soles, and occasionally, nail dystrophy. In contrast to acquired cutaneous candidiasis, congenital candidiasis has lesions at nonflexural sites.[9] Distinctive yellow-white papules on the umbilical cord and placenta represent *Candida* granulomas. *C. albicans* may be demonstrable on histologic examination

of these tissues and may be cultured from the amniotic fluid.

Although candidal infection is usually localized to skin, infants who weigh less than 1500 g are also at risk for systemic infections. In addition to birth weight less than 1500 g, risk factors for disseminated candidiasis include central line placement, being on a ventilator, broad spectrum antibiotic use, and parenteral nutrition.

In the chronic mucocutaneous or granulomatous forms of candidiasis (rare in the neonatal period), the scalp, lips, hands, and nails may be sites of chronically scaling, heaped-up lesions. These two forms of infection often are associated with a defect in the immune response, multiple endocrinopathies, or both.

The diagnosis is usually clinical or aided by identification of budding yeast spores on Gram stain or of spores and pseudohyphae on a potassium hydroxide preparation. Growth of the organism is rapid on Sabouraud dextrose or Mycosel agar.

Treatment depends on the extent of involvement. Topical antifungal agents from the imidazole group are the most effective for disease limited to the skin. Systemic administration of amphotericin B, 5-fluorocytosine, or an imidazole should be reserved for patients with evidence of disseminated disease.[66] Fluconazole or itraconazole for disseminated candidiasis in the very low birth weight infant has been used for prophylaxis or an alternative to systemic amphotericin B and 5-fluorocytosine. Recent clinical trials have shown that probiotics reduce oral, vaginal, and enteric colonization of Candida and may reduce the incidence of invasive candidiasis.[42]

Hereditary Blistering Diseases

Epidermolysis Bullosa

Epidermolysis bullosa (EB) refers to a group of heterogeneous diseases that are characterized by simplex (intraepidermal), junctional (lucidolytic), or dystrophic (subepidermal) subtypes with blisters produced by minor degrees of trauma and heat.[6] These disorders are the result of a variety of inherited defects of the proteins that maintain skin integrity. In 2008, EB was reclassified into four major subtypes based on the region within the skin that the defective or missing protein is expressed and at what depth the resultant blister occurs.[17] Table 94.6 lists the major clinical EB subtypes, the ultrastructural features (i.e., depth of blister), the affected proteins, and the inheritance patterns. Recent advances have made molecular analysis of the defect available as well. At present, 14 distinct structural genes representing more than 1000 different mutations are linked etiologically to EB subtypes.[6,18] First trimester prenatal diagnosis is available and preimplantation genetic testing is possible in select centers.

The clinical features may be quite variable in the newborn period, making it difficult to identify the specific subtype of EB and the expected prognosis. Some subtypes of EB are severe, life-threatening diseases, and others are mild and do not manifest until adolescence. In all forms of EB, blisters may be readily elicited (Nikolsky sign) by gentle rubbing (Fig. 94.8). If there is friction in utero, the baby may be

• **Fig. 94.8** Denudation and erosion as a result of blistering in an infant with epidermolysis bullosa. (From Antaya RJ, Robinson DM. Blisters and pustules in the newborn. *Pediatr Ann.* 2010;39:635-645.)

TABLE 94.6 Epidermolysis Bullosa: Major Subtypes with Corresponding Level of Skin Cleavage, Affected Proteins, and Mode of Inheritance in the Newborn

	EB Simplex (Epidermolytic)	Junctional EB (Lucidolytic)	Dystrophic EB (Dermolytic)	Mixed EB Type
Level of skin cleavage	Within the epidermis	Within the lamina lucida (basement membrane)	Within the dermis	Multiple cleavage points
Affected proteins	Keratins 5 and 14, plectin, dystonin, plakophillin-1, desmoplakin	Laminin-332, collagen XVII, α6β64 integrin	Collagen VII	Kindlin-1
Inheritance pattern	Most are autosomal dominant except for suprabasilar types and forms with muscular dystrophy or pyloric atresia	Autosomal recessive	Both autosomal dominant and recessive	Autosomal recessive (Kindler syndrome)

EB, Epidermolysis bullosa.

born with large areas of denuded skin. In the past, this was referred to as Bart syndrome, but further delineation of the molecular defects has shown that several subtypes of EB can result in this clinical picture (Table 94.6). More frequently, the birth process or minor perinatal trauma causes blistering of the skin. The more severe, dystrophic, recessive forms of EB are associated with low birth weight.

Junctional EB is further subtyped into generalized severe (Herlitz type) and generalized intermediate (non-Herlitz type) based on the absence or decrease of laminin-332 respectively. JEB deserves special mention because it is almost always present at birth and is a very severe form of EB. The mean age of death in the generalized severe form is 5 months secondary to sepsis, respiratory failure, or failure to thrive. The epidermis loosens after minimal trauma, and bullae of various sizes are formed anywhere on the body. The nails are frequently involved. Oral and anal lesions also occur. Many lesions heal spontaneously, but large bullae may fail to heal and result in moist, chronic vegetative lesions consisting of exuberant granulation tissue. There may be significant loss of electrolytes and protein through these erosions.

Blisters and erosions may also be severe and widespread in the epidermolytic subtype of EB simplex. This subtype may be distinguished clinically by the characteristic grouping of the blisters and the formation of milia. In all forms of EB, blisters may be readily elicited by gentle rubbing (Nikolsky sign). Mild trauma can result in a blister within a few minutes to hours, and the resulting fresh lesions may be used for histopathologic examination. Treatment is aimed at protecting the skin from trauma and secondary infection.

Scarring or dystrophic EB has recessive and dominant forms. In contrast to the simplex and junctional groups (except the Dowling-Meara type), milia may mark the site of healed blisters. In the severe form of recessive dystrophic EB, hemorrhagic erosions and blisters may be present at birth, especially on the feet. The toe and finger lesions may heal with fusion of digits and loss of nails, resulting in a characteristic mitten-like envelope of the hands. As the fingers fuse (this usually takes several years), the hands and arms become fixed in a flexed position and contractures develop. Repeated episodes of blistering, infection, and scar formation lead to severe deformities, loss of hair, mucosal scarring, dysphagia, anemia, and retarded physical and sexual development. Visceral amyloidosis, hyperglobulinemic purpura, clotting abnormalities, and squamous cell carcinoma are associated with this severe, life-limiting disease.

The dominant forms of scarring EB usually are less severe than the major recessive type. Lesions may be generalized or localized at birth, or they may appear later and may be limited to the elbows, knees, hands, feet, and sacrum. Oral involvement is common but is usually not severe. Nails may be lost, but deforming scars and contractures occur infrequently. Red plaques rather than blisters may result from injury. The lesions heal with soft, wrinkled scars. Pigmentary change and milia may be formed at old blister sites. General health is usually unimpaired.

The initial diagnosis of EB is a clinical one, and other disorders that cause blistering, particularly infections, should be excluded. Clinical differentiation of EB subtypes is difficult or impossible; for this reason, all infants with the diagnosis should undergo skin biopsy to obtain a more precise diagnosis. Light microscopy may be helpful in determining the level of cleavage, but results can often be difficult to interpret. Immunofluorescence mapping of biopsied EB skin specimens is the currently recommended primary laboratory method of diagnosing EB subtypes.[17] If available, electron microscopy, immunofluorescence mapping, and DNA mutational analysis are used simultaneously to confirm the diagnosis.

Unfortunately, there is no effective treatment for infants with EB. Treatment is aimed at protecting the skin from trauma, providing wound healing dressings, maximizing nutrition, and preventing secondary infection. Management strategies for treating neonatal EB are given in Box 94.3. Gene and cell-based molecular therapies hold hope for future approaches that may cure or ameliorate specific EB subtypes.

Incontinentia Pigmenti

Incontinentia pigmenti (IP) is a rare, X-linked, dominant genodermatosis that affects the skin, skeletal system, eyes, and central nervous system (CNS). Incontinentia pigmenti results from mutations in the *IKBKG* (formerly known as *NEMO*) gene on chromosome Xq28 that inhibits expression of NF-kappa B, an essential modulator. The common IP deletion is at exons 4 through 10, found in 80% of known cases. This protein is required for activation of a transcription factor important in apoptotic, inflammatory, and immune pathways. Molecular analysis of the *IKBKG* gene is commercially available; however, the diagnosis of IP is typically based on characteristic clinical findings.[23] Almost all patients are female, but affected male patients have been reported and are thought to represent genetic mosaicism or Klinefelter syndrome.

The cutaneous lesions usually are present at birth and have four morphologic stages. Stage 1 is known as vesicular or inflammatory stage, characterized by vesicles and pustules distributed in a linear pattern, along Blaschko lines on the extremities and less often on the head, trunk, and face (Fig. 94.9). In the majority the lesions are either present at birth or appear within the first 2 weeks. Stage 2 is the verrucous stage, wherein warty papules or plaques are distributed in a linear fashion along the Blaschko lines, not necessarily along the same lines occupied by the vesicular lesions. This occurs between 2-6 weeks and may overlap with stage 1. In stage 3, linear or whorled lesions with a brownish pigmentation develop along Blaschko lines during early infancy and disappear during adolescence. Stage 4 is the hypopigmented or atrophic stage, where hypopigmented lesions occur along Blaschko lines mainly in the

• BOX 94.3 Management of Epidermolysis Bullosa in the Neonatal Period

Minimize Trauma to Skin and Promote Comfort

- Use gentle handling and reduce friction.
- When possible, use wrapping or suturing instead of taping when applying instruments or monitors; if taping is necessary, leave probes in place.
- Use oral sucrose with dressing changes.
- Administer acetaminophen or opiate agonist for extreme discomfort.

Provide Ideal (Moist) Wound-Healing Environment

- Open and drain tense vesicles with sterile needle.
- Perform gentle daily debridement of crust in bathtub.
- Apply emollients and nonstick primary dressing.
- Protect wound and secure primary dressing with secondary dressing such as gauze wrap and stockinette or Coban tape.
- Tape dressing to itself and not to skin.

Prevent Sepsis and Bacterial Superinfection of Wounds

- Observe wounds for purulence and foul smell.
- Monitor colonization with weekly surveillance cultures.
- Apply topical antibiotics combined with emollient on open erosions to control colonization.
- Cover Gram-positive organisms with intravenous antibiotics if there are signs or symptoms of sepsis.

Maximize Nutrition with Minimal Trauma for Optimal Wound Healing and Growth

- Breastfeed if there is mild oral involvement and the infant can feed through pain.
- If not, have mother pump breast milk and bottle feed with high-flow nipple or drip feeds.
- Add breast milk fortifier to maximize caloric intake.
- For formula-fed baby, use high-calorie formulas.
- Obtain dietary consultation and follow up to ascertain energy needs and how to meet them.

Monitor for Extracutaneous Complications

- Eye: Request ophthalmology consultation for redness or photophobia.
- Gastrointestinal: If oral involvement, watch for feeding intolerance.
- Genitourinary: Look for gross hematuria, meatal narrowing in boys; consider urinary source if infant is febrile.
- Polyhydramnios: Look for pyloric atresia.
- Respiratory: Monitor airway for hoarse cry or stridor as a sign of laryngeal involvement.

Provide Psychosocial Support

- Provide counseling regarding prognosis once diagnosis is known. Emphasize unpredictability of course even when subtype is known.
- Discuss usual short-term complications in general terms.
- Provide access to peer counseling through Internet sites and local chapters of national patient advocacy groups.

Expanded from Bruckner AL, et al. Inherited and Acquired Blistering Diseases. In: Eichenfield LF, et al., eds. *Neonatal and infant dermatology*. 3rd ed. Philadelphia: Elsevier Saunders; 2015 [chapter 7].

lower extremities. This develops during adolescence and persists into adulthood.[23] Nail hypoplasia, areas of alopecia, and ocular and skeletal abnormalities also may be detected. There is often peripheral eosinophilia during the vesicular phase of the disease. The diagnosis should be considered when inflammatory vesicles arranged in lines are seen in a newborn female infant. Delayed dentition, partial anodontia, and abnormalities of the CNS can occur but may not be apparent during the neonatal period. Biopsy of a small blister demonstrates a subcorneal vesicle filled with eosinophils. The differential diagnosis includes herpes simplex infection and other blistering diseases. The clinical evolution of the cutaneous process, the demonstration of a large number of eosinophils in the skin lesions and peripheral blood, and the presence of pigment-laden macrophages in the upper dermis of end-stage lesions establish the diagnosis. No specific therapy is required for the skin lesions; if inflammation becomes excessive during the vesicular phase, treatment with cold compresses, oatmeal baths, and topical steroids may be helpful. Ophthalmologic and neurologic examinations are indicated for all infants with this disorder. Parents can be directed to the IP International Foundation (www.ipif.org) for information on latest research articles and treatment protocols.

Zinc Deficiency

Zinc deficiency occurs in the genetic disorder acrodermatitis enteropathica (AE) and is an acquired condition attributable to inadequate zinc intake. Acrodermatitis enteropathica, a rare disorder, is inherited as an autosomal recessive trait. The AE gene (*SLC39A4*) has been localized to chromosomal region 8q24.3 and encodes for a member of the ZIP family of metal transporters.[38] Alopecia, dermatitis, and diarrhea form the clinical triad of AE. Cutaneous manifestations are typically flexural, anogenital, and periorifacial. There is typical sparing of upper lip, resulting in a "horseshoe-shaped" lesion (Fig. 94.10). Secondary infection with *C. albicans* is a common complication. The onset may be as early as the 3rd week of life, but more frequently it occurs later in infancy. The disease is caused by a defect in zinc absorption or transport, and plasma zinc levels should be checked when the diagnosis of AE is suspected. Low levels of alkaline phosphatase, a zinc-dependent enzyme, may aid in diagnosis. The clinical presentation is later in breastfed infants because of higher bioavailability of zinc in breast milk. Oral zinc sulfate (3 mg/kg per day) is the treatment of choice. Maternal blood and breast milk zinc levels should be assessed to support maternal supplementation and continuation of exclusive breastfeeding.

• **Fig. 94.9** Incontinentia pigmenti. Erythematous vesicopapular lesions following the lines of Blaschko in a V-shaped configuration over the dorsal skin. Lesions typically evolve through verrucous, hyperpigmented stages to finally manifest hypopigmentation and dermal atrophy. (Courtesy of Dr. Taeun Chang.)

• **Fig. 94.10** Recalcitrant perioral eruption caused by zinc deficiency in an infant with acrodermatitis enteropathica. Note the "horseshoe-like" involvement with relative sparing of the upper lip.

A similar eruption has been observed in premature infants maintained on total parenteral nutrition inadequately supplemented with zinc. These infants suffer from relative zinc deficiency caused by high metabolic demands. Premature and term infants receiving breast milk with low levels of zinc and infants with malabsorption syndrome or cystic fibrosis also have developed symptomatic zinc deficiency. Maternal zinc deficiency in pregnancy may result in fetal malformation, growth restriction, prematurity, postmaturity, and perinatal death.

Pigmentary Abnormalities

The melanocyte system of the newborn skin is not mature at birth. As a result, all babies regardless of racial pigmentation may look lighter than their parents at birth. Within the first few weeks, pigmentation becomes more evident because melanin production has been stimulated by exposure to the postnatal environment.

Diffuse Hyperpigmentation

The intensity of pigmentation must be considered in light of the infant's genetic and racial background. Diffuse hyperpigmentation in the newborn is unusual. It may be caused by a gene whose main effect is on the melanocyte, by a hereditary disease that has secondary pigmentary consequences, by endocrinopathy, by a nutritional disorder, or by hepatic disease. Although in such cases, hyperpigmentation may be described as diffuse; it may be accentuated in certain areas such as the face, over bony prominences, or in the flexural creases.

Localized Hyperpigmentation

Cafe au Lait Macules

Café au lait spots are flat, pigmented macules with distinct borders that may be present in the newborn infant and are light brown in whites and dark brown in blacks.[60] Whereas lesions are seen in 24%-36% of older children, most commonly on the trunk, they are present in 0.3%-18% of newborns, usually over the buttocks.[55] Lesions vary with ethnicity and race; they are seen over the buttocks in newborns. Lesions that are larger than 0.5 cm in diameter and more than six in number, especially when accompanied by "freckling" in the flexures, strongly suggest neurofibromatosis. The axillary freckles really represent tiny café au lait macules. Café au lait spots are usually the first cutaneous lesions to appear in a patient with neurofibromatosis, but additional genetic and clinical investigations may be required to establish a diagnosis. For example, small, pigmented spots (i.e., Lisch nodules) may be detected on the iris by slit-lamp examination in most patients older than 6 years with classic neurofibromatosis. Patients with tuberous sclerosis also may have café au lait spots that are identical in appearance to those of neurofibromatosis, but they are usually accompanied by white macules, which are called ash leaf macules.

McCune-Albright Syndrome

In a patient with McCune-Albright syndrome (i.e., polyostotic bone dysplasia, café au lait spots, and multiple endocrine disorders), the pigmented patches may be solitary or multiple, unilateral, elongated, and large (>10 cm), and often have a ragged, irregular border. These manifestations are caused by somatic activating mutations in the *GNAS* gene, which codes for the alpha subunit of the stimulatory G-protein (protein Gsα) that is involved in intracellular cyclic adenosinemonophosphate (cAMP) production.[39]

Congenital Melanocytic Nevi

Congenital nevi represent nested proliferations of melanocytes that are present at birth or appear in the first months of life. Small nevi (<1.5 cm) are seen in 1%-2% of newborns, intermediate nevi (1.5-20 cm) in 0.6%, and large nevi in less than 0.02%.[55] Small lesions (as opposed to giant pigmented nevi) are flat and light to dark brown, often with variegated color or speckling and an accentuated epidermal surface ridge pattern. These lesions vary in site, size, and number, but most often are solitary. Histologically, they are characterized by the presence of nevus cells in the dermis, and most have nevus cells extending into the deeper dermis; fat; and perivascular, periappendageal, and perineural sites. There is no clear-cut evidence that the small congenital nevus is a premalignant lesion, and conservative management consisting of serial observation with photographic documentation may be appropriate.[55] Individualized approaches about surgical excision include the location and appearance of the lesion, ease of excision, and expected cosmetic result. Laser treatment may lighten small nevi but does not completely remove the melanocytes, and its use for this indication is controversial.

Large Congenital Melanocytic Nevi

The giant (>20 cm) nevus (Fig. 94.11) is the most important of the congenital melanocytic (pigmented) nevi (CMN). A somatic mutation in codon 61 of the tyrosine kinase gene *NRAS* accounts for 80% of large CMN. The lifetime risk of malignant transformation and melanoma is estimated to be 6%-8%.[55] The onset of melanoma in utero has been reported. These nevi may occupy 15%-35% of the body surface, most commonly involving the trunk. The pigmentation often is variegated from light brown to black. The affected skin may be smooth, nodular, or leathery in consistency. Prominent hypertrichosis is often present. Almost invariably, numerous satellite nevi coexist elsewhere on the body. Leptomeningeal melanocytosis has been documented in some of these patients, and this complication may manifest as seizures.

• **Fig. 94.11** Giant congenital melanocytic nevus involving the bathing trunk area with sparing of the genitalia. Note the thickening of the skin and hypertrichosis. This infant had a similar lesion on the scalp.

Because of the significant incidence of malignant transformation, the hideous deformity, and the intense pruritus that may accompany them, it is desirable, when feasible, to excise these lesions surgically as soon as possible. Lasers, dermabrasion, and tissue expansion techniques have been used in conjunction with surgical excision for removal and cosmesis of large lesions. Recently, NRAS inhibitor trametinib has been used to treat large CMN in patients with *NRAS* gene mutations.[65]

Peutz-Jeghers Syndrome

The cutaneous lesions of the Peutz-Jeghers syndrome may be present at birth or develop soon thereafter. They consist of brown to blue-black macules, somewhat darker than freckles, which develop around the nose and mouth. The lips and oral mucosa often are involved, as are the hands, fingertips, and toes. Macular hyperpigmentation is the only visible sign of this autosomal dominant disorder until adolescence, when the patient begins to suffer from attacks of intussusception, bleeding, and subsequent anemia secondary to coexisting small bowel polyposis.

Xeroderma Pigmentosum

Xeroderma pigmentosum is transmitted by an autosomal recessive gene and results in marked hypersensitivity to ultraviolet light. The skin is normal at birth but changes develop soon thereafter depending on the degree of UV exposure. The infant develops erythema, speckled hyperpigmentation, atrophy, actinic keratoses, and all known types of cutaneous premalignant and malignant lesions. The outcome is often fatal by the second decade of life as a result of metastatic disease. The underlying abnormality in most cases is a deficiency in an endonuclease that is responsible for the repair of DNA damaged by ultraviolet light. Approximately 20% of patients have neurologic problems. Protection from ultraviolet light exposure is mandatory to prevent skin damage and tumor development. Prenatal diagnosis of xeroderma pigmentosum is possible using PCR-based genetic diagnosis combined with measurement of DNA repair of amniotic fluid cells or chorionic villi fibroblasts.[47]

Postinflammatory Hyperpigmentation

Hyperpigmentation may result secondarily from any inflammatory process in the skin and may have many causes, including primary irritant dermatitis, infectious processes, panniculitis, and hereditary diseases such as EB. The hyperpigmentation may result from enhanced melanosome production, larger melanin deposits in basal cells, greater numbers of keratinocytes, an increase in the thickness of the stratum corneum, or deposits of melanin in dermal melanophages. Hyperpigmentation usually fades gradually over weeks to months without treatment, although a low-potency topical steroid may decrease residual inflammation.

Blue Nevus

Occasionally, a blue nevus (so called because of its Prussian blue color), or dermal melanocytoma, may be present at birth. It usually is a 1- to 3-cm, oval, dome-shaped, black-blue tumor found on the upper half of the body. It grows very slowly and has little tendency to become malignant but may be difficult to differentiate clinically from vascular tumors. Excisional biopsy is diagnostic and curative.

Hypopigmentation

Diffuse or localized reduction or absence of cutaneous pigment in the neonate may be caused by a heritable or developmental disorder or may result from a nutritional disease or postinflammatory change.[8] Decrease in cutaneous melanin may be caused by an absence or destruction of melanocytes or by a defect in one of four biologic processes: formation of melanosomes, formation of melanin, transfer of melanosomes to keratinocytes, and transport of melanosomes by keratinocytes.

Albinism

Albinism (e.g., complete albinism, oculocutaneous albinism), which occurs in all races, has an incidence of 1 case per 17,000 persons in the United States; the phenotypic picture is caused by an autosomal recessive gene. Several forms of this disorder have been delineated. The affected infant usually has markedly reduced skin pigment, yellow or white hair, pink pupils, gray irides, photophobia, and cutaneous photosensitivity. Melanocytic nevi can be present in patients with albinism, and the nevi may or may not be pigmented. In blacks, the skin may be tan, the hair may have a yellow or orange color, and freckles can appear on exposure to light. The usual eye findings are photophobia, nystagmus, and a central scotoma with reduced visual acuity. Other associated abnormalities reported in certain types of albinism are small stature and coagulation disorders.

The biochemical defect responsible for oculocutaneous albinism type 1 is a deficiency of tyrosinase, the enzyme responsible for converting tyrosine to dopa, an early step in the formation of melanin. The range of tyrosinase deficiency correlates well with the spectrum of color seen in affected individuals. Structurally, the melanosomes appear to be normal. In oculocutaneous albinism type 2, however, mutations in the *P* gene affect function of a melanosomal protein. Molecular analyses of the tyrosinase and *P* genes are necessary for precise diagnosis. Treatment in all cases is aimed at protection from ultraviolet light, because early actinic keratoses and squamous cell carcinoma are common occurrences in these patients.

Partial Albinism (Piebaldism)

Partial albinism is an inherited disease caused by mutations of the autosomal dominant *KIT* gene coding for the tyrosine kinase transmembrane cellular receptor for mast/stem cell growth factor, a critical factor for melanoblast migration and function. This leads to defective cell proliferation and melanocyte migration during embryogenesis.[8] This condition is present at birth but may not be evident in fair-skinned infants because of a lack of contrast in skin color. In piebaldism, the hair and skin are affected. The amelanotic areas usually involve the midline frontal scalp (i.e., widow's peak), resulting in the characteristic white forelock, forehead to the base of the nose, chin, thorax, trunk, back midarm, and midleg. There are normal islands of pigment within the amelanotic areas, and the distribution pattern is fairly constant. Examination of an affected area by electron microscopy shows an absence of melanocytes or melanocytes with markedly deformed melanosomes. Repigmentation does not take place. The differential diagnosis may include vitiligo, achromic nevus, nevus anemicus, and the hypomelanotic macules of tuberous sclerosis. A combination of dermabrasion and grafting of pigmented skin into depigmented areas, with or without phototherapy, has been tried with variable results.

Phenylketonuria

Phenylketonuria, caused by an absence of phenylalanine hydroxylase, results in a variety of neurologic and cutaneous abnormalities, which include mental retardation, seizures, diffuse hypopigmentation, eczema, and photosensitivity (see Chapter 90).

Chédiak-Higashi Syndrome

The Chédiak-Higashi syndrome is a rare, fatal disorder resulting from mutations in the autosomal recessive lysosomal trafficking regulator (*LYST*) gene. Clinical features include diffuse to moderate reduction in cutaneous and ocular pigment; photophobia; hepatosplenomegaly; and recalcitrant, recurrent infections. Seizures and progressive neurologic deficits have occurred in some patients in early childhood. The leukocytes and other cells contain the pathognomonic giant azurophilic granules, and this finding has its parallel in the melanocyte, which produces giant melanosomes. These abnormal granules are unable to discharge their lysosomal and peroxidative enzymes into phagocytic vacuoles. The diagnosis can be made by the characteristic family history, physical findings, laboratory demonstration of abnormal leukocytes and melanosomes, and the usual course, which leads to death in childhood. Death results from a lymphoma-like process (accelerated phase or hemophagocytic lymphohistiocytosis) or infection. Treatment is palliative, but bone marrow transplantation has been used successfully to reverse the immunologic defects.[40]

Waardenburg Syndrome

Waardenburg syndrome is an auditory-pigmentary syndrome inherited as an autosomal dominant condition secondary to mutations in the *PAX3* gene controlling neural crest differentiation.[8] The most constant features are lateral displacement of the inner canthi, a prominently broad nasal root, confluent eyebrows, variegation of pigment in the iris (i.e., heterochromia iridis) and fundus, congenital deafness, a white forelock, and cutaneous hypochromia. The

clinical picture is quite striking, and the diagnosis usually is not difficult. Although usually limited to small areas, the hypopigmentation may be severe and extensive enough to resemble that of piebaldism.

Nevus Anemicus

Nevus anemicus is a congenital vascular anomaly that appears as a permanently pale, mottled lesion that occurs most often on the trunk. The lesions appear hypopigmented but contain normal amounts of pigment. The nevus is best characterized as a pharmacologic abnormality rather than an anatomic one. Pallor results from increased local reactivity to catecholamines, which results in vasoconstriction and subsequent pallor. When rubbed, the lesion does not redden like the surrounding skin. There is no effective treatment.

Nevus Achromicus

Present at birth but often not visible until 1-2 years of age, nevus achromicus is usually a unilateral, hypopigmented, irregularly shaped lesion. The hypopigmented area is quite uniform in color, and in contrast to nevus anemicus, the vessels within it react normally to rubbing. The melanocytes in the affected epidermis seem to function poorly or not at all.

White Macules in Tuberous Sclerosis

Tuberous sclerosis is a condition with multisystem involvement characterized by hamartomas, often in association with mental retardation and seizures. Mutations in the tumor suppressor gene *TSC1* (hamartin) or more commonly *TSC2* (tuberin) are implicated in the pathogenesis of tuberous sclerosis. Between 50% and 90% of infants with tuberous sclerosis have white macules that become apparent at birth or soon thereafter. These hypomelanotic macules are referred to as "ash leaf" macules, as they resemble the leaf of an ash tree. More commonly, these lesions are polygonal thumbprint-like and smaller than the ash leaf macules. In fair-skinned infants, the hypopigmented areas may be demonstrated more easily by examining the skin with a Wood lamp. These lesions are often leaflet shaped, are variable in number, and occur more frequently on the trunk and buttocks. The melanocytes within areas of macular hypopigmentation contain poorly pigmented melanosomes. A single, hypopigmented macule in an infant without other features of tuberous sclerosis does not warrant extensive investigation. These macules in general do not require treatment. Severe forms of cutaneous manifestations of tuberous sclerosis have been successfully treated with either systemic or topical sirolimus (rapamycin) or everolimus.[7]

Vascular Anomalies: Vascular Malformations and Vascular Tumors

Vascular anomalies are a common problem in the neonate.[25,41,57] They were divided into two major categories—vascular malformations and vascular tumors—by the International Society for the Study of Vascular Anomalies (ISSVA) in 1997 and were updated in 2014 to be more clinically relevant and incorporate new knowledge.[72] The updated increasing list of genetic causes associated with vascular anomalies is freely available on ISSVA website (www.issva.org). The vascular tumors are subdivided into benign, locally aggressive, and malignant. Similarly, the malformations are categorized further as simple, combined, involving major named vessels, and associated with other anomalies. Malformations are developmental defects derived from the capillary, venous, arterial, or lymphatic vessels. These lesions remain relatively static, and growth is commensurate with growth of the child. Hemangiomas are benign tumors of the vascular endothelium characterized by a proliferative and an involutional phase.

Simple Malformations: Capillary

See Nevus Simplex or Salmon Patch. Port-wine stains (i.e., nevus flammeus) are capillary malformations that are almost always present at birth and should be considered permanent developmental defects.[41] These lesions may be only a few millimeters in diameter or may cover extensive areas with facial lesions being the most common. They do not proliferate after birth but may appear to increase in size with the growth of the child. Port-wine stains usually are sharply demarcated and flat in infancy but with time develop a pebbly or slightly thickened surface. Color ranges from pale pink to purple.

The most successful treatment modality is the pulsed dye laser, which is effective in fading these lesions, although only 15%-20% will clear completely.[53] Some studies report treatment is more effective if undertaken in infancy, whereas others have found no difference.

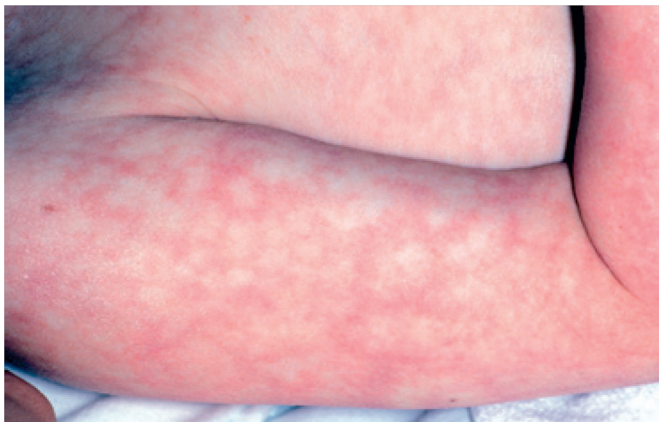
Most port-wine stains occur as isolated defects and do not indicate involvement of other organs, but they occasionally may be a clue to the presence of defects in the eye or certain vascular malformation syndromes. Children with facial port-wine stains involving skin innervated by the V1 or V2 branches of the trigeminal nerve should have a thorough ophthalmologic examination in infancy.

Simple Malformations: Venous and Common Associated Syndromes

Venous malformations are typically composed of ectatic venous channels with slow blood flow. They present as soft, compressible masses that tend to increase in volume with an increase in venous pressure during exercise or when the affected segment is dependent. They tend to persist and often dilate with secondary venous congestion, pain, and thrombosis.

Sturge-Weber syndrome (i.e., encephalofacial angiomatosis) consists of a facial port-wine stain, usually in the cutaneous distribution of the first branch of the trigeminal nerve, a leptomeningeal venous malformation, mental retardation, seizures, hemiparesis contralateral to the facial lesions, and ipsilateral intracortical calcification.[41] Ocular manifestations are frequent and include buphthalmos, glaucoma, angioma of the choroid, hemianoptic defects, and optic atrophy. Roentgenograms of the skull of the older child show pathognomonic "tramline," double-contoured calcifications in the

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.



cerebral cortex on the same side as the port-wine stain. Magnetic resonance imaging is the diagnostic modality of choice. Electroencephalography may demonstrate unilateral depression of cortical activity, with or without spike discharges. The prognosis depends on the extent of cerebral involvement, rapidity of progression, and response to treatment. Anticonvulsant therapy and neurosurgical procedures have been of value in treating some patients.

Klippel-Trénaunay-Weber syndrome is characterized by a cutaneous vascular malformation (usually a port-wine stain), venous varicosities, and overgrowth of the bony structures and soft tissues of the involved part.[41] The vascular lesions are apparent at birth. Some of these patients also have venous malformations, lymphatic anomalies, and arteriovenous shunts. Complications include severe edema, phlebitis, thrombosis, ulceration of the affected area, and vascular malformations involving the viscera. The prognosis depends on the extent of involvement, which can be assessed by peripheral vascular studies and scans. Management includes careful orthopedic assessment of limb growth. Surgery may be effective in treating severe limb hypertrophy in some patients. Compressive clothing (Jobst garments) may be helpful, but proper fitting is difficult in infants with rapid growth.

Port-wine stains also occur with moderate frequency in Beckwith-Wiedemann syndrome (i.e., macroglossia, omphalocele, macrosomia, and cytomegaly of the fetal adrenal gland) (see Chapter 86), Robert syndrome, and Cobb syndrome (i.e., cutaneomeningospinal angiomatosis).

The blue-rubber bleb nevus syndrome is a rare disorder consisting of multiple venous malformations of the skin and bowel.[41] Cutaneous lesions sometimes are present at birth, and their appearance is characteristic as the descriptive name of this syndrome suggests. The lesions are blue to purple, rubbery, compressible protuberances that vary from a few millimeters to 3-4 cm in diameter. They are diffusely distributed over the body surface and may be sparse or number in the hundreds. Gastrointestinal lesions are common in the small bowel but also may involve the colon. Occasionally, lesions in the liver, spleen, and central nervous system have been observed. Severe anemia may result from recurrent episodes of gastrointestinal bleeding. Neither the skin nor the bowel lesions regress spontaneously. Surgery is sometimes palliative, but it is frequently impossible to resect the entire affected bowel.

Vascular malformations also have been reported as a congenital feature of Bannayan-Riley-Ruvalcaba syndrome. Maffucci syndrome (i.e., vascular malformations and dyschondroplasia) and Gorham disease (i.e., vascular malformations and disappearing bones) usually are not apparent in the neonatal period. Cutis marmorata telangiectatica congenita is a vascular malformation that may persist for years in large, well-defined patches. This lesion should not be confused with the more common and transient lesion of cutis marmorata caused by cutaneous vasomotor instability that is seen commonly in premature infants in response to cold exposure (Fig. 94.12).

• **Fig. 94.12** Cutis marmorata on the upper arm showing normal reticulated mottling of the skin. (From O'Connor NR, McLaughlin MR, Ham P. Newborn skin: part I. Common rashes. *Am Fam Physician.* 2008;77:47-52.)

Malformations: Lymphatic

Lymphangiomas are hamartomatous malformations composed of dilated lymph channels that are lined by normal lymphatic endothelium.[41] They may be superficial or deep and often are associated with anomalies of the regional lymphatic vessels. In addition to surgery, trials using intralesional injection of sclerosing agents have proven effective.

Milroy primary congenital lymphedema is present at birth and often affects the dorsal aspects of the feet. This autosomal dominant condition arises from a congenital dysgenesis of the lymphatic microvessels secondary to mutation in the *FLT4* (VEGFR3) gene. This condition is rarely associated with significant complications.

Lymphangioma circumscriptum is probably the most common type of lymphangioma and may be present at birth or may appear in early childhood. Areas of predilection are the oral mucosa, the proximal limbs, and the flexures. This malformation consists of clustered, small, thick-walled vesicles resembling frog spawn; it is often skin colored but may have a red or purple cast because of the presence of blood mixed with lymph in the vesicles. Treatment is excision, with attention to removal of the deep component of the lesion. Large lesions may require full-thickness skin grafting. Recurrence has been observed even with full-thickness grafts.

Simple lymphangioma appears in infancy as a solitary, skin-colored, dermal, or subcutaneous nodule. After trauma, it may exude serous fluid. Occasionally it has been associated with more extensive lymphatic involvement. Uncomplicated lesions can be removed by simple excision.

Deep lymphangiomas are more diffuse and consist of large, cystic dilations of lymphatics in the dermis, subcutaneous tissue, and intermuscular septa. Surgery is impractical in most cases.

Cystic hygroma is a benign, multilocular tumor usually found in the neck region. The tumors tend to increase in size and should be treated by surgical excision.

Simple Malformations: Arteriovenous

Arteriovenous malformations (AVMs) are more aggressive types of simple malformations. They are composed of malformed arteries, veins, and capillaries, with direct arteriovenous communications resulting in arteriovenous shunting.[72] They may be misdiagnosed and mimic other vascular lesions such as an involuting hemangioma or other simple malformations. They present as an enlarging red, warm, painful lesion with pulsation, thrill, or bruit. Rarely, it can present as an ulcerated and bleeding lesion or in high output congestive cardiac failure. Arteriovenous malformations may remain quiescent for years followed by sudden growth at puberty or following local trauma. Arteriovenous malformations are the most difficult vascular anomaly to manage and exhibit high recurrence rates following treatment. Magnetic resonance imaging and angiographic imaging are essential to delimit the lesions. Treatment of AVMs may consist of surgical excision and/or embolization.

Vascular Tumors: Hemangiomas

Hemangiomas are the most common soft tissue tumors of infancy, occurring in approximately 1%-3% of newborns and up to 12% in infants. They are clinically heterogeneous and present as solitary cutaneous lesions, with their appearance dictated by the depth, location, and stage of evolution. Infantile hemangiomas (IHs) are characterized by a growth phase, marked by endothelial proliferation and hypercellularity followed by an involutional phase. As the tumor proliferates, it assumes its most recognizable form, a bright red, slightly elevated, noncompressible plaque (Fig. 94.13). IHs are subclassified as focal, multifocal, segmental, and indeterminate depending on their morphology, extent, or distribution.[72] The endothelial cells contain a unique immunohistochemical marker called glucose transporter 1 (GLUT1), which is used for diagnosis. A negative GLUT1 renders a diagnosis of IH unlikely.[70]

Hemangiomas that lie deeper in the skin are soft, warm masses with a slightly bluish discoloration. Frequently IHs have superficial and deep components. Female gender, prematurity, and multiple gestation pregnancy have been documented to increase the incidence of IHs. They range from a few millimeters to several centimeters in diameter and usually are solitary, but up to 20% of infants have multiple lesions. Increased numbers of superficial IHs have an increased likelihood of visceral involvement (diffuse neonatal hemangiomatosis). Generally, superficial hemangiomas have reached their maximal size by 6-8 months, but deep hemangiomas may proliferate for 12-14 months or, rarely, up to 2 years.

Despite the benign nature of most cutaneous hemangiomas, a significant number cause functional compromise or permanent disfigurement. Approximately 20%-40% of patients have residual skin changes; nasal tip, lip, and parotid hemangiomas are notorious for slow involution, and very large superficial facial hemangiomas often leave disfiguring scarring. Ulceration, the most frequent complication, can be excruciatingly painful and carries the risk of infection, hemorrhage, and scarring. Occasionally, hemangiomas manifest as congenital ulcerations with only a very small rim of the typical hemangioma, making the diagnosis difficult.

• **Fig. 94.13** **A**, Infant with midfacial hemangioma. **B**, Same infant after treatment with oral propranolol. (From: Blei F, Guarini A. Current workup and therapy of infantile hemangiomas. *Clin Dermatol* 2014:32;459-470.)

Periorbital hemangiomas and hemangiomas that involve the ear pose considerable risk to vision, hearing, and speech. Multiple cutaneous (i.e., diffuse hemangiomatosis) and large facial hemangiomas may be associated with visceral hemangiomas. Subglottic hemangiomas manifest with hoarseness and stridor, and progression to respiratory failure may be rapid. Approximately 50% of these infants have associated cutaneous hemangiomas, and "noisy breathing" by an infant with a cutaneous hemangioma involving the chin,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

lips, mandibular region, and neck warrants direct visualization of the airway. Sixty percent of young infants with extensive facial hemangiomas in the "beard" distribution develop symptomatic airway hemangiomas.

Extensive cervicofacial hemangiomas may be associated with multiple anomalies, including vascular malformations (i.e., PHACE [*p*osterior fossa, *h*emangioma, *a*rterial lesions, *c*ardiac abnormalities, *e*ye abnormalities] syndrome). This syndrome has a marked female predominance (9:1) and is thought to represent a developmental field defect that occurs during the 8th-10th weeks of gestation. Lumbosacral hemangiomas may be markers for occult spinal dysraphism and anorectal and urogenital anomalies. Imaging of the spine is indicated in all patients with midline hemangiomas in this region.

Congenital hemangiomas are relatively uncommon, present fully grown at birth, and either undergo rapid involution (RICH: rapidly involuting congenital hemangioma) or persist into adulthood (NICH: noninvoluting congenital hemangioma). Cellular proliferation in both RICH and NICH occurs prenatally with no further growth after birth. The endothelial cells do not express GLUT1. Congenital hemangiomas that resolve rapidly often leave pronounced atrophic skin changes in their wake (Fig. 94.14).

Most hemangiomas require "active nonintervention" coupled with a careful discussion of the natural history of the lesions and photographic documentation of involution.[5,10,41] Studies have shown, however, that up to 40% of children develop complications requiring intervention. Ulceration is the most common complication, but other problems include bleeding, airway or visual axis obstruction, cosmetic disfigurement, and high-output cardiac failure. Since 2008, propranolol has become the first-line treatment, eclipsing systemic steroids and interventional radiology. A list of medical and surgical treatment options along with their safety concerns are given in Table 94.7.

Kaposiform hemangioendothelioma (Kasabach-Merritt phenomenon), a complication of a rapidly enlarging vascular lesion, is characterized by hemolytic anemia, thrombocytopenia, and coagulopathy. These massive tumors are usually a deep red-blue color, are firm, grow rapidly, have no sex predilection, tend to proliferate for a longer period (2-5 years), and have a different histologic pattern. These lesions express lymphatic endothelial markers (podoplanin, prox-1) but do not express GLUT1. Most patients with Kasabach-Merritt phenomenon do not have typical hemangiomas but rather have other proliferative vascular tumors, usually kaposiform hemangioendotheliomas or tufted angiomas.[41] The Kasabach-Merritt phenomenon requires aggressive, often multimodality treatment such as transcutaneous arterial embolization and carries a significant mortality rate.

• **Fig. 94.14** **A**, Rapidly involuting congenital hemangioma, a large bulky lesion on scalp at birth. **B**, Same lesion at age 9 months with no treatment. (From Wassef M, et al. Vascular anomalies classification: recommendations from the International Society for the Study of Vascular Anomalies. *Pediatrics* 2015:136(1);e203. Copyright © 2015 by the AAP.)

Epidermal Nevi

Epidermal nevi are a group of lesions that are found commonly in the neonatal period. Most of them consist of an overgrowth of keratinocytes and often have an identifiable differentiation toward one of the appendages normally found in skin. They vary considerably in their size, clinical appearance, histologic characteristics, and evolution, depending on their topographic location. Lesions occurring in sites normally rich in sebaceous glands (e.g., the scalp) may look like sebaceous nevi, whereas others found in areas where the epidermis is thick (e.g., the elbow) look primarily warty.

TABLE 94.7 Management Options for Infantile Hemangiomas

Clinical Strategy	Dosage	Safety Concerns
Active nonintervention	Adjust scheduled visits based on rapidity of growth and family concern	Monitor for functional or life-threatening complications during proliferative phase
Systemic Treatment		
• Propranolol	1-3 mg/kg per day after meals*	Hypotension, hypoglycemia, bronchial hyperreactivity, seizure, restless sleep, constipation, cold extremities
• Corticosteroids	1-3 mg/kg per day	High blood pressure, increased appetite, stomach irritation, cardiomyopathy, growth suppression, increased risk of systemic infection, aseptic necrosis of bones
• Vincristine†	Recommended dosages vary	Strong vesicant; irritates vessels, mixed sensory-motor neurotoxicity, loss of deep tendon reflexes, constipation
• Interferon†	Recommended dosages vary	Flulike reactions, transammonitis, neutropenia, skin necrosis, spastic diplegia (up to 20%)
Topical Treatment		
• Timolol 0.5% gel	1 drop twice daily	Theoretical risks similar to those for propranolol but not yet well documented in patients treated with timolol for infantile hemangiomas
• Laser	Standard: pulsed dye laser 585-595 nm; use every 2-4 weeks as needed; particularly useful for ulcerating lesions, residual erythema, telangiectasia	May lead to ulceration in some patients, particularly in lip area
	Refractory lesions: ND:Yag or alexandrite laser Residual scar: fractionated CO_2 laser	ND:Yag, alexandrite, and CO_2 lasers—higher risk of scarring
• Topical corticosteroids	Applied twice daily	Cutaneous atrophy and telangiectasia

ND:Yag, Neodymium-doped yttrium aluminum garnet.
*Dosing guidelines have not been fully elucidated.
†Dosing recommendations vary; consult those with experience in administering these agents.
Adapted from Chen TS, Eichenfield LF, Friedlander SF. Infantile hemangiomas: an update on pathogenesis and therapy. *Pediatrics.* 2013;131:99-108.

The most common type of epidermal nevus in the newborn infant is the sebaceous nevus, a hairless, papillomatous, yellow or pink, slightly elevated plaque on the scalp, forehead, or face. These lesions have a characteristic oval or lancet shape. Because there is a slight increase in malignant transformation (basal cell carcinoma) in these lesions after puberty, prophylactic surgical excision is recommended.[33]

The treatment of large, verrucous epidermal nevi is generally unsatisfactory. The only effective treatment is removal of the lesion together with its underlying dermis. This is only possible in localized lesions, and treatment should be delayed beyond the neonatal period, because these lesions may extend over a period of years.

Patients with epidermal nevi may have associated abnormalities, but there are three well-defined entities: Proteus syndrome, CHILD syndrome (i.e., congenital hemidysplasia with ichthyosiform nevus and limb defects), and nevus sebaceous syndrome.

Inflammatory Diseases of the Skin

Several inflammatory skin conditions may occur in the neonate. Irritant contact dermatitis, atopic dermatitis, and seborrheic dermatitis are the most frequently encountered. They may be difficult to distinguish because their clinical features have a significant degree of overlap. There are four phases of cutaneous inflammation, any one of which may persist as the dominant feature depending on the age of the patient, the local physiologic characteristics of the skin involved, and the persistence of the underlying cause. The initial stage is erythema, which proceeds to microvesicle formation, weeping, or oozing. The epidermal response to the injurious process then causes a burst of rapid epidermal mitotic activity that leads to scaling. Lichenification (i.e., thickening of the skin) and pigmentary disturbances supervene. In the young infant, the first three stages predominate; lichenification, which results from scratching or rubbing, is not seen. The enumeration of the complex cellular and

• **Fig. 94.15** Neonate with irritant diaper dermatitis. (From Atherton D. Understanding irritant napkin dermatitis. *Int J Dermatol.* 2016;55(1);7-9.)

molecular components of the inflammatory network in the skin has led to better understanding of the different symptomatology and offers potential targets for therapy.[64]

Irritant Contact Dermatitis

Primary irritant contact dermatitis (as opposed to allergic contact dermatitis) is probably the most common exogenous cause of dermatitis in the newborn. The distribution of the eruption varies somewhat, depending on the precipitating agent. Saliva may be irritating to the face and fecal excretions to the buttocks (diaper dermatitis). Detergent bubble bath, antiseptic proprietary agents, and soap zealously used to clean the perianal area may cause acute eczematous diaper dermatitis, which may become generalized (Fig. 94.15). Obtaining precise information about what has been applied to the skin and how it has been applied is imperative in making an accurate diagnosis. The principal irritants in diaper dermatitis are fecal enzymes, skin maceration, friction, high pH, and prolonged contact with urine and feces.[2] Its proper management should include obtaining a culture for bacteria and yeast, the discontinuance of all ointments containing irritants, the use of barrier cream, and conservative treatment for 1 or 2 weeks. If no improvement follows, a skin biopsy may be indicated.

Seborrheic Dermatitis

Seborrheic dermatitis is characterized by greasy, non-pruritic scaling associated with patchy redness, fissuring, and occasional weeping, usually involving the scalp, ears, axillary, and perineal folds. There is controversy about whether seborrheic dermatitis is a distinct entity or presages the advent of atopic dermatitis. Some infants never progress beyond the seborrheic phase of the dermatitis, which in its classic form rarely is seen in the first month. Cradle cap is a minor variant of seborrheic dermatitis. Treatment of seborrheic dermatitis consists of a mild shampoo containing selenium zinc with gentle brushing to remove scales. A low-potency topical corticosteroid or antifungal shampoo such as ketoconazole may be efficacious. The usual course of seborrheic dermatitis is one of rapid regression after 1 or 2 weeks of therapy. Occasionally, a seborrheic-like process may involve the entire body, resulting in full-blown exfoliative dermatitis, which has been called Leiner disease when associated with failure to thrive and chronic diarrhea.

Atopic Dermatitis

Atopic dermatitis generally does not present in the newborn period; however, 90% of cases present before 4 years of age.[15] Atopic dermatitis is characterized by red, scaling patches and plaques on the face, particularly the cheeks and on the extensor surfaces of the extremities. Like seborrheic dermatitis, the eruption may be generalized. These infants are often agitated because of the severe pruritus. Clear diagnostic criteria have been established for the diagnosis of atopic dermatitis and include pruritus, chronicity, typical family history, and distribution. Skin barrier dysfunction is prominent in atopic dermatitis, with an abnormal stratum corneum, increased turnover time, and elevated transepidermal water loss with immune dysregulation of both innate and adaptive immune systems. Increased levels of IgE correlate with increased atopic symptoms during early childhood.[59] Several studies have demonstrated that certain dietary and environmental interventions in the first months of life may decrease the incidence of atopic dermatitis in babies at risk for the disease. These include elimination of house dust mites and passive smoking, probiotics/prebiotics supplementation, exclusive breastfeeding for 3 months, and delayed weaning beyond 6 months.

Dermatitis resembling atopic dermatitis may be a feature of a number of systemic conditions, including ataxia-telangiectasia, X-linked agammaglobulinemia, phenylketonuria, gluten-sensitive enteropathy, and long-arm 18 deletion syndrome.[68] Many patients with hypohidrotic ectodermal dysplasia have an eczematous eruption identical to that of atopic dermatitis. Purpura is a frequent additional component of eczema, particularly in Langerhans cell histiocytosis and Wiskott-Aldrich syndrome.

Children with atopic dermatitis have a much higher prevalence of staphylococcal colonization and substantial loss of biodiversity than nonatopic children.[73] Staphylococcal exoproteins and superantigens evoke inflammatory reactions in the host. When bacterial or fungal infection exists, appropriate antibacterial or antifungal therapy is indicated based on the results of culture and sensitivity studies. Weeping lesions should be treated with compresses or bathing in tepid water, protective ointments such as simple zinc oxide paste should be applied after each diaper change, and soiled ointments and pastes should be removed with mineral oil. A more extensive eruption may be treated for short periods with a 1%-2.5% hydrocortisone ointment. A scaly eruption in the scalp may be treated by frequent shampooing with a zinc pyrithione- or salicylic acid–containing shampoo. Bathing should be done in tepid water containing water-dispersible oil. Infants with diffuse dermatitis lose heat readily and are intolerant of even mild changes in environmental temperature or humidity. Humidification of

the bedroom in winter and air conditioning in summer is desirable. The efficacy of dietary management and probiotic supplementation for atopic eczema in older children remains controversial.

Subcutaneous and Infiltrative Dermatoses

Juvenile Xanthogranuloma

Juvenile xanthogranuloma (JXG) is a benign, non-Langerhans cell histiocytosis characterized by solitary or multiple yellow-red cutaneous papules that may enlarge to become nodules or plaques (Fig. 94.16).[35] One-fifth of infants with JXG are affected at birth, and two-thirds have onset of lesions before 6 months of age. There is no predilection for race or sex, and no familial predisposition has been observed for this self-limited disorder, which usually remains confined to the skin. The skin lesions often are restricted to the head, neck, and upper trunk. Involution occasionally leaves a flat atrophic pigmented scar. Serum lipid levels are normal, but histologically, the lesions result from an infiltrate of fat-laden histiocytes, giant cells, and mixed inflammatory cells. Ocular lesions are the most frequent complication (although involvement of other organs may occur rarely) and may result in tumors, unilateral glaucoma, hyphema, uveitis, heterochromia iridis, and proptosis. Ophthalmologic consultation is required for management of the ocular lesions, but the best treatment for the skin lesions is expectant observation.

Several unusual variants may occur, such as giant juvenile xanthogranuloma or bony involvement. There is an increased incidence of juvenile xanthogranulomas among patients with neurofibromatosis type I in which they may be markers for acute granulocytic leukemia.

Mastocytosis

Mast cell disease refers to a spectrum of conditions characterized by mast cell infiltration of the skin or other organs.[56] Pediatric mastocytosis presents before 2 years in 90% of cases and includes three forms: a disseminated maculopapular or nodular eruption (formerly urticaria pigmentosa, 75%), a solitary mast cell tumor (mastocytoma, 20%), and diffuse cutaneous mastocytosis (5%).[43] The diagnosis is usually clinical, but demonstration of excessive numbers of mast cells on skin biopsy is definitive.

The most common form seen at birth is the firm, solitary mast cell tumor (mastocytoma, Fig. 94.17). These tumors usually are ovoid, are pink or tan, and rarely exceed 6 cm in diameter. The lesions are conspicuous by their tendency to form wheals when rubbed (Darier sign) and, in the newborn, to develop overlying blisters. Solitary lesions involute spontaneously within months to years. Maculopapular mastocytosis manifests as numerous pink-brown, 1-2 cm oval macules and papules. The lesions are usually located centrally and often develop later in infancy. Treatment is usually unnecessary, but in symptomatic patients, distressing cutaneous symptoms such as dermatographism and pruritus may be helped with oral antihistamines. Hot water bathing and vigorous toweling must be avoided, as must histamine releasers such as codeine, morphine and its derivatives, aspirin, alcohol-containing elixirs, and certain anesthetics. The patient support website http://www.mastokids.org includes a comprehensive list of degranulating triggers and practical tips for parents. Pediatric mastocytosis was previously considered to be benign and a spontaneously regressing disease; however, recent systematic review suggests that clinical regression (partial or complete) occurs in 67% of cases, stabilization in 27%, and fatality in 2.9%.[43] The genetics of this condition are unclear. Roughly one-third of the cases have *KIT* D816V mutations.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH) is a rare nonmalignant proliferative disorder with skin involvement. The Reclassification Working Group of the Histiocytic Society stratified

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

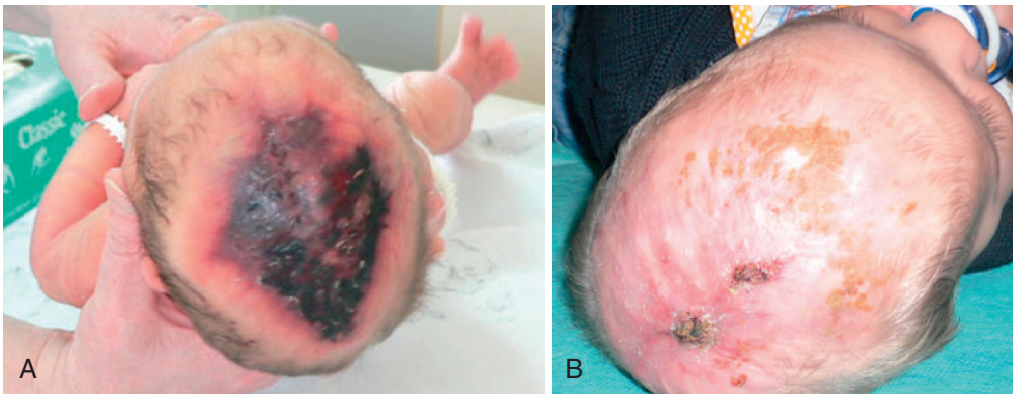
LCH into (a) single system (S-S-LCH) and (b) multisystem (M-S-LCH) to differentiate involvement of one organ versus two-or-more organ dysfunction. Skin manifestations are seen in 12% of single system LCH, while more than 50% have cutaneous involvement in multisystem LCH.[48] Langerhans cell histiocytosis is characterized by accumulation of clonal dendritic cells immunologically resembling normal epidermal Langerhans cells.[45] Langerhans cell histiocytosis can present at any time from birth to adulthood. Unlike normal Langerhans cells, LCH cells can infiltrate almost any body site accompanied by lymphocytes, neutrophils, eosinophils, and multinucleated giant cells forming characteristic granulomas. Commonly involved areas include the scalp, followed by the skin flexures, including the perineum. The appearance of skin LCH is very diverse, with crusted or scaly papules, vesicles, nodules, eroded nodules, and purple plaques.[62] The majority of infants with LCH show multisystem involvement. Single or multifocal bone lesions with lymph node involvement are common, and intracranial disease may present with exophthalmos or diabetes insipidus. Definitive diagnosis is made on skin biopsy. CD1a-positive Langerhans cells are seen infiltrating the skin. Langerhans granules (Birbeck granules) within the cells on electron microscopy are also a common finding. Langerhans cell histiocytosis with multisystem organ involvement is most often a rapidly fatal disease. The somatic BRAF (V600E) mutation in children with LCH is associated with severe features, permanent injury, and poor short-term response to chemotherapy.[27] Various chemotherapeutic regimens and systemic corticosteroids have been used for treatment.

In 1973, Hashimoto and Pritzker described a pure cutaneous form of LCH, which occurs only in the neonate or infant. The characteristic features of this congenital, self-healing reticulosis are skin lesions in an otherwise well infant, a histopathology demonstrating Langerhans cell infiltrate, and spontaneous involution of the skin lesions. The pathology is said to be typical with histiocytic infiltration limited to the dermis, sparing of the epidermis, and so-called myelin-dense bodies seen on electron microscopy. This entity is considered a mild form of LCH, as progression to severe LCH has now been reported in children who initially met the above criteria. The diagnosis of purely cutaneous LCH should be made only after several years of follow-up.

Sclerema Neonatorum, Scleredema, and Subcutaneous Fat Necrosis

Sclerema neonatorum, scleredema, and subcutaneous fat necrosis (SFN) are disorders of the subcutaneous tissues that are commonly seen in the first 1-2 weeks of life. Of the three conditions, sclerema neonatorum has the worst prognosis and usually affects the severely ill preterm or debilitated newborn. It manifests by diffuse hardening of the subcutaneous tissue, resulting in a tight, smooth skin that feels bound to the underlying structures. The skin is nonpitting, cold, and waxy hard. The joints become immobile and the face masklike. Histologically, the epidermis and dermis are normal, the subcutaneous tissue may exhibit a sparse inflammatory infiltrate without fat necrosis, and there may be radially arranged needle-shaped crystals with adipocytes. The etiology is unclear, presumed to be an underlying fulminant sepsis. Management includes broad-spectrum antibiotics, intravenous immunoglobulin, exchange transfusion, and systemic steroids.[61] Prognosis remains poor despite aggressive interventions. Scleredema is often confused with sclerema neonatorum and typically is seen in premature infants in the first week of life. Unlike sclerema, this condition manifests a pitting edema that is firm and often most prominent in the lower extremities. Histologically, there is often lobular panniculitis without vasculitis associated with marked skin edema. Infections and hypothermic injury have been linked to scleredema, but the exact etiology remains unclear. Treatment is supportive, and the condition often heals spontaneously as the infant improves clinically.

The lesions of subcutaneous fat necrosis, in contrast to the previous conditions, are more common in postmature infants and typically manifest in a localized and sharply circumscribed form. They appear 1-4 weeks after delivery as small nodules or large plaques and are found on the cheeks, buttocks, back, arms, and thighs. The affected fat is firm, and the overlying skin may appear reddish or violaceous and occasionally has the texture of orange peel. Histologically, there is a granulomatous reaction in the fat, with formation of needle-shaped crystals, foreign body giant cells, fibroblasts, lymphocytes, and histiocytes. Resolution of the lesion results in fibrosis. Possible precipitating causes of fat necrosis include cold exposure, trauma, asphyxia, therapeutic hypothermia, and peripheral circulatory collapse. The lesions usually resolve in several weeks or months without complications. Hypercalcemia has been associated in 60% of patients in a 20-year retrospective cohort study of 30 newborns.[14]



Miscellaneous Congenital Diseases Affecting the Skin

A multitude of hereditary diseases affect the skin. Some of the congenital diseases with prominent cutaneous findings are reviewed here.

Aplasia Cutis Congenita

Aplasia cutis congenita (ACC) is a rare group of disorders of varying etiology characterized by the focal absence of skin at birth.[16] Most frequently, the lesions are on the scalp in the midline, but other areas of the body may be affected, including the trunk and extremities (Fig. 94.18). Approximately 80% of patients have the defect confined to the skin and often less than 2 cm in diameter; however, some patients present large cutaneous defects along with aplasia of the underlying skull. Several theories have been proposed to explain the pathogenesis of this disorder, but a single unifying mechanism seems unlikely. Possible etiologies include

• **Fig. 94.18** Aplasia cutis congenita. The large full-thickness scalp defect in this 3-day-old infant (**A**) was accompanied by a bony defect in the cranium. Conservative management without surgery led to complete bony recovery of the skull at 8 months of age (**B**) with residual scar alopecia and epithelialization of the skin defect. (From Starcevic M, Sepec MP, Zah V. A case of extensive aplasia cutis congenita: a conservative approach. *Pediatr Dermatol.* 2010;27:540-542.)

incomplete closure of the neural tube, localized vascular insufficiency, amniotic membrane adhesions, teratogenic agents, and intrauterine infections. Large scalp defects are associated with trisomy 13. The diagnosis is usually based on clinical findings. Increased levels of acetylcholinesterase and α-fetoprotein have been reported in the amniotic fluid of mothers with children with aplasia cutis. Prognosis and management should be individualized based on the size, location, and presence or absence of ulceration or underlying bony defect. Management strategies include simple observation, prevention of infection in the case of ulceration, and surgical excision or skin grafting in the case of large defects.

Cutis Laxa

Cutis laxa (i.e., generalized elastolysis) is a heterogeneous group of congenital and acquired disorders and is a feature of several malformation syndromes.[16] There are three major forms of congenital cutis laxa, one inherited as an autosomal dominant trait, and two inherited in an autosomal recessive fashion. In all forms of the disease, affected infants have diminished resilience of the skin, which hangs in folds, resulting in a bloodhound appearance. The joints are not hypermobile, and there is no tendency to increased bruising as in Ehlers-Danlos syndrome. Elastic tissue may be greatly diminished in the dermis and is of poor quality. The collagen has normal tensile properties. In the autosomal dominant form, there are few complications, and the life span is usually normal. In the generalized recessive type of cutis laxa, elastic fibers elsewhere in the body are defective, resulting in inguinal, diaphragmatic, and ventral hernias; rectal prolapse; diverticula of the gastrointestinal and genitourinary tracts; pulmonary emphysema; and aortic aneurysms. Cardiorespiratory complications may cause death during childhood. The other recessive form of cutis laxa, with retarded growth and skeletal dysplasia, is typified by intrauterine growth restriction, congenital dislocation of the hips, and a peculiar facies with frontal bossing, antimongoloid slanting of the palpebral fissures, and widening of the fontanelles. Unlike other loose-skin syndromes, persons with cutis laxa have almost normal wound healing. These children are good candidates for cosmetic plastic surgery and its attendant psychological benefits.[16]

Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome (EDS) is a group of inherited connective tissue disorders with the common features of hyperextensible skin, joint laxity, and soft tissue fragility.[63] Bleeding episodes and cardiovascular complications are characteristic of some forms of the disorder. The skin of patients with EDS is hyperextensible when stretched but snaps back with normal resiliency, in contrast to the skin of patients with cutis laxa, which hangs in redundant folds. In some forms of EDS, the skin also is excessively fragile. Associated findings may include short stature, scoliosis, soft tissue contractures, multiple dislocations, periodontosis, and eye defects. Involvement of the gastrointestinal tract may lead to episodes of acute blood loss or megacolon. Aortic aneurysms also may develop. The underlying genetic defect is unique to different subtypes. This led to the widely used Villefranche classification of EDS, which has six subtypes.[63] Identified gene mutations include various collagens; collagen-processing genes; and tenascin-X, a connective tissue protein. Forty percent of newborns with EDS are delivered prematurely.[62]

Ectodermal Dysplasias

The term ectodermal dysplasias describes a group of more than 100 rare congenital disorders with abnormal development of two or more structures derived from embryonic ectoderm. Such structures include nails, teeth, hair, the lens of the eye, and sweat glands. Information on specific syndromes, clinical management, and the availability of support programs can be found through the National Foundation for Ectodermal Dysplasia (www.nfed.org).

The most commonly encountered form of ectodermal dysplasia is the hypohidrotic type.[62] Diminution or absence of sweating, hypotrichosis, and defective dentition are the most striking features of hypohidrotic ectodermal dysplasia, which is inherited in an X-linked recessive (*EDA* gene) fashion in two-thirds of the cases. The facies are distinctive because of frontal bossing and depression of the bridge of the nose. Eyebrows and lashes are absent or sparse. The skin around the eyes is wrinkled and frequently hyperpigmented. The skin elsewhere is thin, dry, peeling (like postmature babies), and hypopigmented, and the cutaneous vasculature is more visible. The scalp and body hair is sparse and the ears and chin prominent. The lips are thick and everted and may show pseudo rhagades. Dental anomalies range from total anodontia to hypodontia with peg-shaped teeth.

The most striking physiologic abnormality is the diminution or absence of sweating. Sweat pores usually are decreased to absent on the fingertips. Absence or hypoplasia of eccrine glands can be confirmed by skin biopsy. Other glandular structures also may be absent or hypoplastic. Less constant ancillary findings include conductive hearing loss, gonadal abnormalities, stenotic lacrimal puncta, corneal dysplasia, and cataracts. Mental development is normal. Marked heat intolerance is caused by an inability to regulate the body temperature adequately by sweating. Because the respiratory mucosa also may be deficient in mucus-secreting glands, viral respiratory tract infections in these patients tend to linger and become complicated by secondary bacterial infections in the bronchial tree. It is imperative to diagnose these children in infancy.

Every effort should be made to moderate extreme environmental temperatures by using air conditioning. Deficient lacrimation can be palliated by the regular use of artificial tears. The nasal mucosa also must be protected by intermittent saline solution irrigations and application of petrolatum. It is imperative that these children have a thorough dental evaluation during the first years of life, and dental prostheses should be provided even for toddlers so that adequate nutrition is maintained. Reconstructive procedures can be performed later in life to improve the facial configuration. A wig may be required for patients with scant scalp hair.

The incidence of atopic diseases—asthma, allergic rhinitis, and atopic dermatitis—is increased significantly among patients with anhidrotic ectodermal dysplasia. Atopic manifestations should be managed as they would be in otherwise healthy infants and children. Accurate carrier detection and early neonatal and prenatal diagnoses are feasible using molecular genetic testing.

Numerous other types of ectodermal dysplasia have been defined, including hidrotic ectodermal dysplasia, ectrodactyly ectodermal dysplasia cleft palate (EEC) syndrome, ankyloblepharon ectodermal dysplasia cleft palate (AEC) syndrome, ectodermal dysplasia cleft palate midfacial hypoplasia (Rapp-Hodgkin) syndrome, and chondroectodermal dysplasia (Ellis-van Creveld) syndrome. Some of these conditions may manifest with scalp erosions or impetiginous lesions in the neonate. Isolated lack of sweat glands occurs in congenital familial anhidrosis.

Porphyrias

The inherited porphyrias are a diverse group of inborn errors of heme biosynthesis, resulting from the deficient activity of a specific enzyme in the pathway. They are classified as hepatic or erythropoietic according to the organ site in which the underlying heme synthetic defect is predominantly expressed. The erythropoietic porphyrias include congenital erythropoietic porphyria (CEP) and erythropoietic protoporphyria (EPP). The erythropoietic porphyrias present at birth, infancy, or early childhood, whereas the hepatic porphyrias present after puberty or in adulthood.

Erythropoietic protoporphyria is the most common childhood porphyria, caused by a deficient activity of ferrochelatase (<30% of normal), and usually presents by age 2 years. EPP is inherited as an autosomal recessive condition. Clinical diagnosis is made with a history of crying or skin pain following sun exposure. Some patients are photosensitive to fluorescent lighting. Hemolytic anemia is absent. The diagnosis is made by the markedly elevated levels of protoporphyrin in erythrocytes and/or by the identification of biallelic pathogenic variants in FECH (ferrochelatase) on molecular genetic testing. The treatment includes sun avoidance; oral administration of β-carotene, cysteine, and antihistamines to increase tolerance to sunlight; vitamin D supplementation; and liver transplantation. Recently, Afamelanotide (Scenesse®), a synthetic melanocyte stimulating hormone analog, has been approved in Europe to improve quality of life by its ability to increase pain-free sun exposure.[3]

Congenital erythropoietic porphyria, also called Gunther disease, is a rare autosomal recessive disorder caused by deficient activity of uroporphyrinogen III synthase. The *CEP* gene has been mapped to chromosome 10, allowing prenatal diagnosis to be made with chorionic villus sampling. Diagnosis is also suspected when a reddish-brown amniotic fluid is noticed at amniocentesis. Clinical presentation includes severe photosensitivity from birth or early infancy with formation of vesicles and bullae on areas exposed to sun, phototherapy, or fluorescent lighting. There is also marked skin fragility. Diagnosis is made by elevated levels of uroporphyrin I in urine and erythrocytes and increased levels of coproporphyrin I in feces. Treatment modalities include oral superactivated charcoal, hypertransfusion, splenectomy, and bone marrow transplantation.

Transient porphyrinemias have been described in newborns with hemolytic disease with unclear etiology. These infants present with erythema, violaceous discoloration, purpura, erosions, and blisters on areas exposed to phototherapy. The elevated levels of porphyrins normalize spontaneously after the first few months.

Neonatal Lupus Erythematosus

Neonatal lupus erythematosus (NLE) is an acquired autoimmune disease caused by transplacental passage of

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

• **Fig. 94.19** Cutaneous neonatal lupus erythematosus. Note the "raccoon" eye over the right periorbital area and the typical erythematous annular plaques over the glabella with central atrophy. (From Jaka A, et al. Cutaneous neonatal lupus erythematosus. *Indian J Dermatol Venereol Leprol.* 2012;78:775.)

maternal autoantibodies. It occurs in 1 of every 20,000 live births in the United States.[31] Pregnant women whose sera contain antibodies against Ro/SSA or La/SSB are at risk of having a child with NLE. Permanent congenital heart block and transient skin lesions are the hallmark of this condition. Mean age at the onset of skin rash is 6 weeks but may be present at birth.

Clinically, the skin lesions are primarily annular and papulosquamous and are widespread, but most commonly seen on the face and scalp, predominantly affecting the periorbital and malar areas, and often cause a "raccoon eyes" appearance (Fig. 94.19). Sun exposure precipitates or aggravates these lesions. Telangiectasia may be a presenting sign and a more permanent sequela. Between 30% and 50% of mothers of infants with NLE have a connective tissue disease, most commonly SLE or Sjögren syndrome. The presence of anti-SSA/Ro antibodies, with or without anti-La, rather than the type of maternal autoimmune disease, is the risk factor for the development of neonatal lupus.[74]

Many questions regarding pathogenesis remain unanswered. Serologic studies for autoantibodies are confirmatory for diagnosis. It is unclear why less than 5% of mothers with anti-Ro and anti-La antibodies give birth to affected children and why mothers of affected infants are often asymptomatic despite having the same antibodies. Approximately 40%-60% of mothers with NLE infants are asymptomatic.[31] Diagnosis of NLE in the infant, therefore, may lead to diagnosis of lupus in the mother. Treatment of skin lesions is primarily aimed at sun protection along with topical steroids. A triple therapy combining plasmapheresis, IVIG, and glucocorticoids may potentially stop the evolution of fetal cardiac disease in positive anti-SSA/Ro antibody patients. Development of rheumatic disease later in childhood can occur and warrants long-term follow-up. The risk of a subsequent child having any manifestation of NLE is roughly 25%.

Principles of Newborn Skin Care

It is reported that nearly 80% of normal newborns develop a skin problem, for example, a "rash," during the first month of life. Despite the desire of parents and caregivers to promote good skin care and the ubiquity of skin problems, particularly in the preterm infant, there is a surprising lack of evidence upon which to base infant skin care recommendations. Common skin care practices are still based on tradition, experience, and cultural factors. Ideal skin care guidelines should preserve skin integrity, allow physiologic adaptation to a changing environment, prevent toxicity, and avoid potential sensitivity from topical medications. Basic principles of skin care were cited earlier in Box 94.2.

The gross appearance of the skin at birth is related in part to the maturity of the infant. The premature infant's skin may be readily distinguished from the term infant's skin. At birth, it is more transparent and gelatinous and tends to be free of wrinkles. The premature infant may be covered with fine lanugo hair. Sexual hormonal effects are less conspicuous in the premature infant; the scrotum is less rugose and pigmented, the labia majora are less prominent and not approximated, the nipples and areolas are less pigmented, and breast tissue is less palpable.

The extremely premature infant (<750 g) is at particular risk secondary to a poorly developed epidermal permeability barrier. The stratum corneum becomes multilayered during the third trimester. Transepidermal water losses (TEWL) may be 10- to 15-fold higher in extremely low birth weight preterm infants compared with term infants. At 23 weeks' gestation, the stratum corneum is nearly absent with transepidermal water loss of ~75 g/m^2/hour; at 26 weeks the TEWL is ~45 g/m^2/hour. By 29 weeks, the TEWL is ~17 g/m^2/hour and remains higher than the values of 4-6 observed in full-term infants.[71] Around weeks 34 and 35, the barrier is relatively well formed. Each milliliter of water lost via

evaporation expends 0.58 kilocalories. Epidermal permeability is highest in the premature infant immediately after birth. Heat and water loss can be a significant source of morbidity in the preterm infant and should be prevented beginning in the delivery room. The difference between cutaneous permeability in premature infants and term infants decreases with each postnatal day. At 2 weeks after birth, however, the epidermal barrier of the very low birth weight infant still has markedly increased transepidermal water loss compared to infants born at the same corrected gestational age.

An immature permeability barrier can lead to increased absorption of environmental toxins and infections (Table 94.8). The normal acid mantle of the skin develops more slowly in preterm infants, and the expression of cationic antimicrobial peptides, such as those associated with the protective coating of vernix caseosa at birth, may be diminished. The dermis is deficient in structural proteins leading to poor mechanical properties and easy tearing of the skin.

Strategies for improving epidermal barrier function in VLBW preterm infants are listed in Box 94.4. Studies have shown that postnatal massage of moderately preterm infants with traditional oils reduces infection and mortality. As might be expected from an organ situated at the body surface, there is a continuing and complicated interplay between genotype and environment in their effects upon skin condition. This interaction is illustrated in the etiology of common skin disorders such as diaper dermatitis. It is anticipated that increasing understanding of the molecular basis of the skin disorders and diseases covered in this chapter will shed new light on the mechanisms of more common and less serious skin problems in the newborn.

• BOX 94.4 Strategies to Improve Epidermal Barrier Function in Preterm Infants

- Topical application of one or more nonphysiologic lipids (e.g., petrolatum)
- Topical application of natural oils (e.g., sunflower oil) or mixtures of physiologic lipids (ceramides, cholesterol, free fatty acids)
- Topical dressings
- Vapor-permeable: allow metabolic (repair) processes to continue in the underlying epidermis
- Vapor-impermeable (occlusive): delay metabolic responses in the underlying epidermis
- Xeric stress: postnatal transition to low-humidity (~60%) environment accelerates barrier development

TABLE 94.8 Potential Untoward Effects from Application of Topical Products in Neonates

Compound	Function	Toxicity
Adhesive remover solvents	Skin preparations to aid in adhesive removal	Epidermal injury, hemorrhage, and necrosis
Alcohols	Skin antiseptic	Cutaneous hemorrhagic necrosis, elevated blood alcohol levels
Aluminum	Metal containers for topical ointments	Neurotoxicity
Ammonium lactate	Keratolytic emollient	Possible lactic acidosis
Aniline	Dye used as a laundry marker	Methemoglobinemia
Benzethonium chloride	Skin cleansers	Poisoning by ingestion, carcinogenesis
Benzocaine	Mucosal anesthetic (teething products)	Methemoglobinemia
Benzyl benzoate	Scabicide	Neurotoxicity
Bicarbonate	Baking soda for diaper dermatitis	Metabolic alkalosis
Boric acid	Baby powder, diaper paste	Vomiting, diarrhea, erythroderma, seizures, death
Calcipotriol	Topical vitamin D3 analogue	Hypercalcemia, hypercalcemic crisis
Camphor	Topical antipruritic and camphorated oils	Gastrointestinal toxin and neurotoxicity
Chlorhexidine	Topical antiseptic	Systemic absorption but no toxic effects
Coal tar	Shampoos, anti-inflammatory ointment	Excessive use of polycyclic aromatic hydrocarbons is associated with an increased risk of cancer

TABLE 94.8 Potential Untoward Effects from Application of Topical Products in Neonates—cont'd

Compound	Function	Toxicity
Corticosteroids	Topical anti-inflammatory	Skin atrophy, striae, adrenal suppression
Diphenhydramine	Topical antipruritic	Central anticholinergic syndrome
Gentian violet	Antimicrobial	Possibly carcinogenic
Glycerin	Emollients, cleansing agents (Aquanil)	Hyperosmolality, seizures
Hexachlorophene	Antiseptic soaps	Neurotoxicity
Imidazoles	Topical antifungals	Drug interactions secondary to p450 inhibition
Iodochlorhydroxyquin	Topical antibiotic	Optical neuritis
Isopropyl alcohol	Topical antiseptic	Skin necrosis and neurotoxicity
Lactic acid	Topical keratolytics	Metabolic acidosis
Lidocaine	Topical anesthetic	Petechiae, seizures
Lindane	Scabicide (Kwell)	Neurotoxicity
Mercuric chloride	Diaper rinses, teething powders	Acrodynia, hypotonia
Methylene blue	Amniotic fluid leak diagnosis	Methemoglobinemia
Neomycin	Topical antibiotic (Neosporin)	Neural deafness
N,N-dimethyl-m-toluamide (DEET)	Insect repellant	Neurotoxicity
Nystatin	Topical antifungal	Nephrotoxicity
Phenolic compounds (pentachlorophenol, hexachlorophene, resorcinol)	Laundry disinfectant, topical antiseptic (PHisoHex)	Neurotoxicity, tachycardia, metabolic acidosis, methemoglobinemia, death
Phenylephrine	Ophthalmic drops	Vasoconstriction, periorbital pallor
Povidone-iodine	Topical antiseptic (Betadine)	Hypothyroidism
Prilocaine	Topical anesthetic (EMLA)	Methemoglobinemia
Propylene glycol	Topical vehicles, emollients, cleansing agents (Cetaphil)	Hyperosmolality, neurotoxicity, seizures
Resorcinol	Topical antiseptic	Methemoglobinemia
Salicylic acid	Keratolytic emollient	Metabolic acidosis, salicylism
Silver sulfadiazine	Topical antibiotic (Silvadene)	Kernicterus (sulfa component), agranulocytosis, argyria (silver component)
Sulfur	Scabicide	Paralysis, death
Tacrolimus	Topical immunomodulator	Elevated blood levels of immunosuppressive drugs
Triclosan	Deodorant and antibacterial soaps	Toxicities seen with other phenolic products
Triple dye (brilliant green, gentian violet, proflavine hemisulfate)	Topical antiseptic for umbilical cord	Ulceration of mucous membranes, skin necrosis, vomiting, diarrhea
Urea	Keratolytic emollient	Uremia

Key Points

- The skin of the term infant serves multiple functions critical for survival in an extrauterine environment.
- An accurate description of primary and secondary skin lesions forms the basis for the diagnosis of skin pathology.
- There are benign and transient neonatal skin lesions that need to be differentiated from pathologic lesions.
- Vernix caseosa provides a hydrophobic barrier to the developing skin and contains multiple anti-infective peptides that are associated with the innate immune system.
- Preterm infants have an immature epidermal barrier leading to heat and water loss and increased absorption of environmental toxins, which predisposes them to infections.
- Etiology of skin pathology varies widely from an intrauterine origin, infection, allergic reaction, malformation, and tumors, to being genetically inherited.
- Identification of affected genes is leading to prenatal diagnosis, genetic counseling, and potential gene replacement therapies in certain skin conditions.

Examination and Common Problems in the Neonatal Eye

FARUK H. ÖRGE

"The eye is the light of the body; therefore, if the eye is good, then the whole body will be full of light, but if the eye is bad, then the whole body will be full of darkness."

Clinicians should develop the ability to recognize the signs and symptoms of serious eye diseases or complications of diseases early in their course to prevent visual loss and, in some cases, preserve life. For example, early detection and treatment of congenital cataracts and congenital glaucoma are critical for visual rehabilitation. Malignant orbital tumors and intraocular tumors such as retinoblastoma are life threatening.

Ocular findings can also assist in the diagnosis of a systemic illness such as type 1 neurofibromatosis (NF1) and CHARGE syndrome (*c*oloboma, *h*eart anomaly, *a*tresia choanae, *r*etardation, *g*enital anomaly, *e*ar anomaly).[97]

The visual system is not completely developed at birth but progressively matures during the neonatal period.[27] The neonatologist must recognize normal ocular findings during different stages of the infant's growth to understand what is abnormal. Some ocular and visual milestones are shown in Table 95.1.

A screening eye examination should be performed during the newborn physical examination and during routine well-baby checkups.[4] The screening examination should include the assessments[24] listed in Box 95.1. Fortunately, the screening examination identifies most problems such as glaucoma, cataract, infection, or tumor. However, if abnormalities are suspected because of the history, presence of systemic anomalies, or abnormal result of the screening examination, a more detailed ocular evaluation is mandatory, preferably by a pediatric ophthalmologist.[34]

Neonatal Eye Examination

A screening ocular examination begins with a careful history, especially of ocular diseases in the family.[24] For example, a family history of retinoblastoma necessitates a comprehensive ocular examination of the fundus shortly after birth. Information about maternal diseases (e.g., rubella), injuries, medications, or use of drugs or alcohol during the prenatal period should be obtained. It is also important to document the duration and abnormalities of pregnancy, labor, and delivery. Premature birth suggests potential retinopathy of prematurity (ROP), and difficult delivery with obstetric forceps can result in direct ocular trauma.

The examination should be done under comfortable circumstances and with the proper equipment (Fig. 95.1). Much can be learned if the examiner takes a few moments initially to observe the infant for facial anomalies, the external ocular appearance, and ocular motility while taking the history. The examination is most easily performed with the baby in a parent's arms; the more difficult parts of an examination often can be accomplished while a baby is nursing or sucking on a bottle or pacifier. It is well documented that an oral sucrose solution can calm the baby significantly for them to allow easier examination. The screening eye examination should include an evaluation of visual function, preferably one eye at a time. For infants less than 4-6 weeks of age, visual function is assessed by withdrawal or blinking to light, or pupil constriction to light.[24]

Maintenance of the eyes on an object is called fixation. The infant's ability to fixate and follow a target can be an approximate guide to the amount of visual function present. Beyond 4-6 weeks of age, visual function is assessed in terms of the quality of the fixation and following. By experience, the clinician must develop an age-appropriate scale that assesses this quality of fixation and following, paying attention to the intensiveness, steadiness, and maintenance of the fixation and the smoothness and duration of the following.

Visual acuity refers to the subjective response from the patient of the ability to discern images of set sizes, such as the tumbling "E" or Snellen letters. Most normally developing children can participate in some form of visual acuity testing by the age of 30 months. If additional information regarding visual function is desired, some ancillary visual tests are available and used in indicated situations. (1) Optokinetic nystagmus describes a reflex ocular response to a moving target. As a target moves across the visual field, a pursuit motion occurs, followed by a rapid return motion in

Abstract

Clinicians should develop the ability to recognize the signs and symptoms of serious eye diseases or complications of diseases early in their course to prevent visual loss and, in some cases, preserve life. For example, early detection and treatment of congenital cataracts and congenital glaucoma are critical for visual rehabilitation. Malignant orbital tumors and intraocular tumors such as retinoblastoma are life threatening. Ocular findings can also assist in the diagnosis of a systemic illness such as type 1 neurofibromatosis (NF1) and CHARGE syndrome (coloboma, heart anomaly, choanal atresia, retardation, genital anomaly, ear anomaly). The visual system is not completely developed at birth but progressively matures during the neonatal period. The neonatologist must recognize normal ocular findings during different stages of the infant's growth to understand what is abnormal. A screening eye examination should be performed during the newborn physical examination and during routine well-baby checkups. Fortunately, the screening examination identifies most problems such as glaucoma, cataract, infection, or tumor. However, if abnormalities are suspected because of the history, presence of systemic anomalies, or abnormal result of the screening examination, a more detailed ocular evaluation is mandatory, preferably by a pediatric ophthalmologist.

TABLE 95.1 Visual System Milestones

Description	Age
Pupillary light reaction present	30 weeks' gestation
Pupillary light reaction well developed	1 month
Lid closure in response to bright light	30 weeks' gestation
Blink response to visual threat	2-5 months
Visual fixation present	Birth
Fixation well developed	2 months
Visual following well developed	3 months
Accommodation well developed	4 months
Visual evoked potential acuity at adult level	6 months
Grating acuity preferential looking at adult level	2 years
Snellen letter acuity at adult level	2 years
Color vision present	2 months
Color vision at adult level	6 months
Stereopsis developed	6 months
Stereoacuity at adult level	7 years
End of critical period for monocular visual deprivation	10 years
Conjugate horizontal gaze well developed	Birth
Conjugate vertical gaze well developed	2 months
Vestibular (doll's eye) rotations well developed	34 weeks' gestation
Optokinetic nystagmus well developed	Birth
Ocular alignment stable	4 months
Fusional convergence well developed	6 months
Eyeball 70% of adult diameter	Birth
Eyeball 95% of adult diameter	3 years
Cornea 80% of adult diameter	Birth
Cornea 95% of adult diameter	1 year
Differentiation of fovea completed	4 months
Myelination of optic nerve completed	7 months-2 years
Iris stromal pigmentation well developed	6 months

• **Fig. 95.1** Basic equipment for ocular examination: Various types of eyelid specula to keep the eyelids open, scleral depressor to gently move the eye around, cyclomydril eye drops for dilation (1.25% phenylephrine [ophthalmic], 0.25% cyclopentolate [ophthalmic]), and a 20 or 28 diopter magnifying lens.

the opposite direction to regain fixation. We experience this response when telephone poles or fence posts are watched from a fast-moving vehicle. With an optokinetic drum, which consists of black and white stripes on a spinning cylinder, if the examiner can elicit optokinetic nystagmus in the infant, this establishes that the child has enough visual function to discern the stripes. The stripe widths can be calibrated so as to yield a visual acuity equivalent. Optokinetic nystagmus can be evident in term newborns.[73] (2) Another quantitative technique to measure a visual acuity equivalent in the infant older than 3 months is forced preferential looking.[108] An infant prefers to look at black and white stripes instead of a uniformly gray target. For the

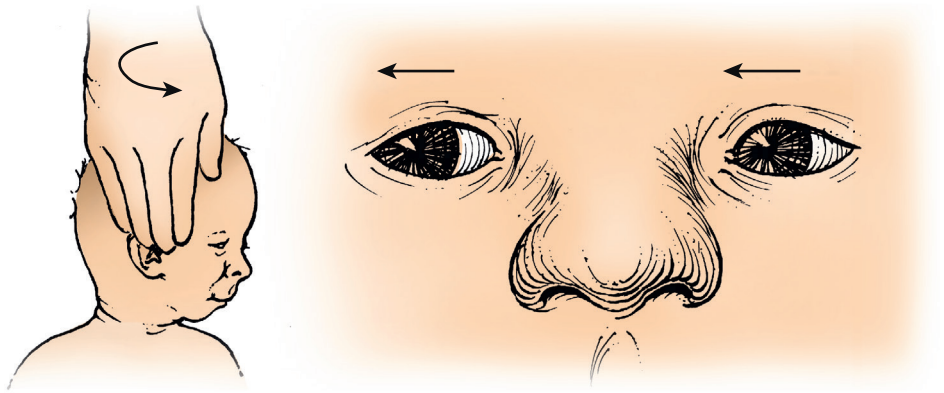
• **Fig. 95.2** Marcus Gunn jaw wink phenomenon: Left upper lid ptosis seen in the first picture while the left lid raises up as patient sucks from the bottle.

test, infants are quickly shown a card that has stripes on one end and a gray target on the opposite end. The examiner watches the infant's eyes to see whether the baby looks right or left to find the stripes. If the infant's visual function is high enough to distinguish the stripes from the gray target, the infant will look consistently toward the stripes. If the infant's visual function is less than the ability to distinguish the stripes from the gray target, the infant will look randomly right or left. By varying the size of the stripes, the examiner can grade the visual acuity equivalent. The disadvantages of this procedure include the number of people necessary to administer the test, the time involved, and the need for the cooperation of an alert infant. (3) Unfortunately, most estimations of an acuity equivalent in the infant rely heavily on adequate motor responses as part of the visual evaluation. Immature or underdeveloped motor systems can reduce or interfere with eye or head movements and decrease the estimation of the visual acuity equivalent. Visual evoked potentials, which measure the electrical cortical responses to a visual stimulus, eliminate the need for patient cooperation or motor control.[35] Electrodes are placed over the occipital cortex to monitor activity in the brain as the eyes are visually stimulated with graded stripes or checkerboard patterns, and a computer-averaged tracing is made.

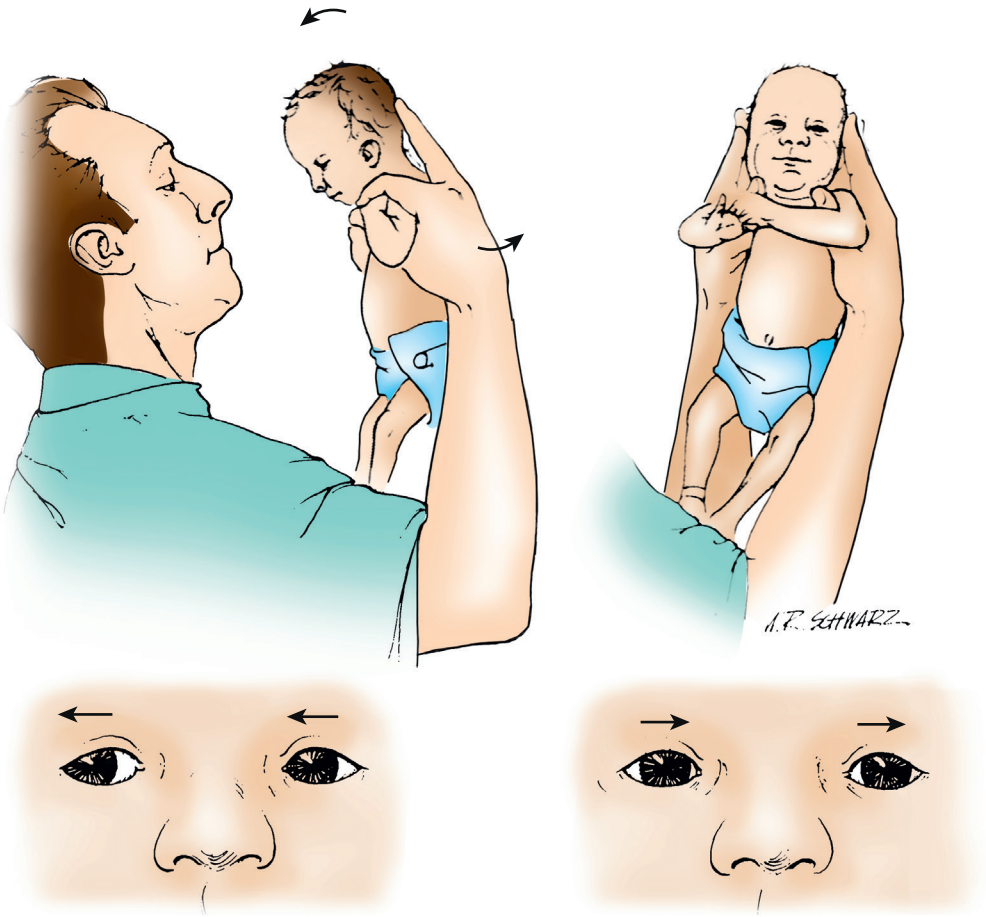
Continuing with the screening eye examination, the general facial configuration and the structure of the orbits are inspected next. Note any facial dysmorphism that could affect ocular health or be part of an ocular syndrome, such as clefts or abnormal head shape. The orbits should be proportional and symmetric compared with the overall craniofacial configuration. Palpation is performed to examine the orbital margin, the contents of the upper and lower lids, and the round contour of the globes. The orbital rims should be sharply outlined. In the newborn infant, the rims are initially round and increase in vertical diameter with normal growth. The area of the lacrimal sac is palpated for abnormal masses or increased size by pressing the sac against the bones of the nose and medial orbital wall. Mucopurulent material expressed from the lacrimal puncta is a symptom of obstruction of the nasolacrimal system. The eyelids are examined grossly and are compared for symmetry of horizontal and vertical placement. Spontaneous opening and closing of the lids should be observed. The lid margins should be inspected for regularity of contour, apposition to the globe, and the presence of lacrimal puncta. The punctum, the proximal opening into the nasolacrimal drainage system, is a minute hole in each lid margin a short distance from the inner corner of the eye. A rapid up-and-down movement of the lid during nursing indicates a jaw-winking phenomenon[61] (Fig. 95.2).

The examiner should view the lashes, which normally are directed outward in an orderly row. Abnormalities include distichiasis and trichiasis and are discussed later in this chapter. Lid position abnormalities should be checked (i.e., epiblepharon).



The ocular motor system is evaluated with a motility examination. This includes ocular alignment, conjugate ocular movements, and range of movement. Infants younger than 4 months may show small physiologic misalignments of the eyes. Misaligned eyes beyond the age of 4 months should be considered pathologic.[34]

Alignment is tested with the corneal reflex test (Hirschberg test). The examiner shines a well-focused light at the patient's eyes and notes the spot on the cornea where the light is reflected back. If the patient is properly fixating, the light reflex should appear in the same location on each cornea, slightly nasal to the anatomic center of the cornea. If the light reflex is centered in one eye and deviated laterally in the fellow eye, esotropia is present. If the light reflex is centered in one eye and deviated nasally in the fellow eye, exotropia is present.



A positive cover-uncover test will support the impression of strabismus. If the patient does not appear to move the eyes well enough into the periphery, either spontaneously or by following an object, these movements can be driven by the doll's head maneuver (vestibulo-ocular reflex [VOR]). The reflex is tested by turning the infant's head to one shoulder, producing an opposite movement of the eyes (Fig. 95.3). The eyes appear stationary as the head turns. This reflex may be reduced in severely brain damaged infants but normal in blind infants.[19]

Another rotational reflex is elicited by holding the infant vertically and rotating the infant in an arc around the

• **Fig. 95.3** Doll's head rotation: As the head is turned toward the shoulder, a tonic neck muscle reflex produces corresponding ocular rotation in the opposite direction as though the eyes were remaining in their original position as the head moves.

• **Fig. 95.4** Rotational nystagmus: The infant's head is inclined slightly forward with eyes open. With rotation, the eyes move in the opposite direction as in a doll's eye rotation. When rotation stops, the recovery movement occurs in the reverse direction.

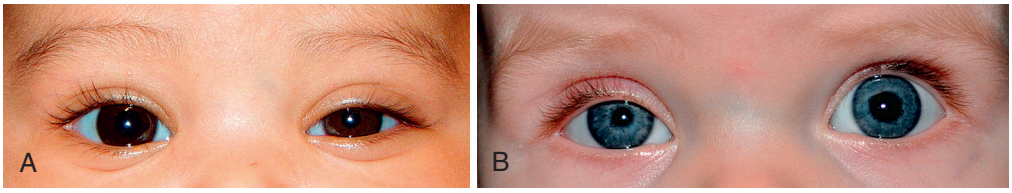
examiner (Fig. 95.4). The infant's eyes will then tonically rotate in the direction of the spin, with short quick movements (saccades) in the direction opposite the spin. This ocular reflex may be a form of optokinetic nystagmus and is reduced in infants with major defects of the vestibular system, lower motor pathways to the extraocular muscles, visual system, or central nervous system.[19]

Examination of the globes may be difficult owing to the inability of the examiner to open the neonates' eyelids sufficiently. Various pediatric eye speculums, such as an Alfonso speculum (Bausch and Lomb, STORZ, San Dimas, CA), can be used to maintain the lids open and allow for adequate inspection of the ocular surface, anterior segment, or posterior segment. Before placing the eye speculum, topical

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

ocular anesthesia can be achieved with a drop of tetracaine 0.5% eye drops. Oral sucrose can also relieve some of the discomfort of an ocular speculum.[36] The conjunctiva is inspected after the lids are separated, with the use of a pediatric ocular speculum or fingers. The bulbar and palpebral conjunctivae are normally moist and pinkish. Redness or exudate is abnormal and can indicate infection. The conjunctivae of the lids overlying the tarsal plates should be examined after the lids are everted. Eversion is usually simple to perform with the examiner's fingers, particularly if the infant is attempting to squeeze the lids shut. The normally white sclera is evaluated for changes of color. A bluish coloration, however, is present in premature infants and in other small babies because of their very thin sclera.

The cornea is inspected with a penlight, paying attention to corneal size, shape, clarity, and luster. Magnification with loupes or an ophthalmoscope with the 20-diopter lens in place may be used. During the first few days of life, premature and term infants might demonstrate a slightly hazy cornea, which is thought to be the result of corneal edema. Thereafter, the surface of the cornea should have good luster and be absolutely transparent even to the extreme periphery. Any opacity or translucency is abnormal after the first few days of life, and referral to an ophthalmologist is indicated. Changes in transparency or opacification in the peripheral cornea may be associated with a local mesenchymal abnormality or glaucoma (Fig. 95.5).



The irides are usually similar in appearance. Although normally incomplete for the first 6 months of life, pigmentation of both irides develop simultaneously. In a normal infant, the iris is often blue or blue-gray for the first few weeks or months of life. However, darkly pigmented babies can show pigmentation at birth or within the first week. Heterochromia (dissimilarity in pigmentation between the two eyes or within one eye) can indicate a normal hereditary pattern, congenital Horner syndrome (Fig. 95.6*A, B*), or one of several syndromes (e.g., Waardenburg) discussed later in this chapter. These syndromes might not become apparent until the end of the neonatal period or even later in life when the iris is fully pigmented.

• **Fig. 95.5** Congenital glaucoma: Left eye larger than the right eye with grayish discoloration secondary to corneal edema in the left eye.

The pupils should be central, round, and equal in diameter. The pupillary space should be uniformly black. Any amount of a white reflection is abnormal and could indicate an abnormality within the lens, vitreous, or retina. The neonate's pupils are typically miotic in ambient light, perhaps related to prolonged sleep.[55] A penlight or a transilluminator is used to shine a light at each pupil. Beyond a corrected gestational age of 30 weeks, pupils should constrict to both direct and contralateral stimulation.[55] First, the reaction of the illuminated pupil is observed. It should constrict briskly (although the response in the neonate may be slower than in an older child) and should remain constricted as long as the illumination is maintained. If a poor response is observed, the contralateral pupil's reaction is studied. If the contralateral pupil constricts, the directly illuminated eye must have intact photoreceptors and optic nerve pathways. Failure of constriction in the directly illuminated eye in this instance could result from abnormalities in the iris. If neither pupil constricts on direct illumination to one eye, the first eye may be severely deficient in vision. The swinging flashlight test is used to check for a relative afferent pupillary defect. Normally, if the light is quickly shifted from one eye to the other, the newly illuminated eye's pupil should show an initial small constriction movement. If illumination is maintained on the eye, small rhythmic constriction and dilation movements may follow—called hippus, a normal phenomenon. If, however, the shift of light is followed by dilation of the newly stimulated eye, a Marcus Gunn (or relative afferent pupillary defect) is present. This result indicates decreased vision in the eye that inappropriately dilated. Pupillary reflexes should be completely normal in patients with central (cortical) visual impairment.

The red reflex test is an essential part of the infant screening eye examination.[3,111] Examination starts with a "0" diopter setting in the direct ophthalmoscope, and the child is examined at arm's length, with both pupils illuminated (Fig. 95.7). The red reflex of each eye should be clearly

• **Fig. 95.6** **A,** Congenital Horner syndrome affecting the left side: Note the smaller left pupil, the mild left upper lid ptosis, the left lower lid reverse ptosis and heterochromia (left eye lighter brown while right eye dark brown). **B,** Horner syndrome affecting right side: Note right pupil smaller than the left and mildly droopy right upper lid.

• **Fig. 95.7** Red reflex: Normal red reflex in the left eye and a white reflex in the right eye. This patient was later diagnosed with retinoblastoma in the right eye.

distinct, with no shadows or alterations. Look for any asymmetry of the intensity of the red reflex within each pupil and between the two pupils. If a red reflex cannot be seen, the pupils can be dilated with cyclomydril eye drops[89] (Alcon Laboratories), and if a clear and equal red reflex is still not seen, the baby should be referred to an ophthalmologist.[34] Precise viewing of the anterior chamber and crystalline lens requires a slit-lamp examination, instrumentation that is usually not available to the neonatologist or primary care physician. An indirect assessment of the clarity of the cornea, anterior chamber, lens, and vitreous is performed during the red reflex test, which measures the ability of light to enter the eye and reflect back out of the eye off the retina. Similarly, the red reflex test indirectly assesses the intactness of the retina. The adventurous neonatologist or primary care physician can attempt direct viewing of the infant's retina with a direct ophthalmoscope or a panoptic (Fig. 95.8). Viewing the retina of the infant's undilated eye with a direct ophthalmoscope is a challenge, even to the pediatric ophthalmologist, but a panfundoscope can provide adequate examination with more ease. If a view of the retina is required, such as for retinopathy of prematurity screening, the consulting ophthalmologist would dilate the infant's eyes and use more sophisticated examination instrumentation such as the indirect ophthalmoscope.

Certainly, the use of the direct ophthalmoscope to directly view the retina is not considered part of the screening eye examination in the infant.[81] However, if a direct ophthalmoscope examination is attempted, attention should be directed to the clarity of the vitreous cavity and the appearance of the optic disc, major retinal vessels, the macula, and the surrounding retina.

Normal Ocular Findings

The eye of the newborn infant differs from the adult eye primarily in function, although structural differences also exist. The growth of the eye, which parallels that of the brain, continues at a rapid rate for the first 3 years of life, especially during the first year. The anteroposterior dimension of the eye at birth is about 16.5 mm and grows to about 23 mm in adulthood. Normal values in the neonate fall within a very wide range. Suspected abnormalities in size often are substantiated only by comparison with measured values

• **Fig. 95.8** Panoptic, indirect, and direct ophthalmoscope.

in the fellow eye or by ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI). The horizontal and vertical diameters of the cornea of the newborn are about 9-10 mm. Enlarged corneas suggest the diagnosis of congenital glaucoma.

The lid fissures of the term infant are usually narrow and often widely separated horizontally by prominent epicanthal folds. Normal horizontal measurement of the lid fissures in the newborn can range from 17-27 mm (Table 95.2). These measurements should be symmetric. The term telecanthus indicates a disproportionate increase in the distance between the medial canthal angles. It is particularly noticeable in fetal alcohol syndrome and Waardenburg syndrome. Measurements between the two medial canthi in the term newborn vary from 18-22 mm. Hypertelorism is defined as an increase in distance between the orbits, observed clinically as a large interpupillary distance, which is often seen in many craniofacial syndromes. A secondary telecanthus is observed in patients with hypertelorism.

Reflex tearing to irritants is evident shortly after birth. However, emotional tearing begins at about 3 weeks of age and is developed at 2-3 months. The newborn infant

*Neonates weighing 1000-1300 g.

possesses a strong blink reflex in response to light and to stimulation of the lids, lashes, or cornea. The reflex response to a threatening gesture does not appear until 7 or 8 weeks of age in the term infant. Repetitive eye opening is evident at birth.[45]

After birth, the eyes should appear straight for the most part, although erratic, purposeless, and independent movements can be observed during the first few months of life. Any constant strabismus beyond the age of 4 months requires further evaluation.[6] Conjugate horizontal gaze should be evident in the newborn; vertical conjugate gaze develops by 2 months of age. Convergence spasms are a normal transient phenomenon of infancy.

The ability to maintain a steady gaze or to fixate and follow an object is only weakly initiated at 4-6 weeks of age. At first, the eyes pursue a moving visual stimulus with short saccades. By 3 months of age, the infant can fixate and follow in both vertical and horizontal directions. At about 4 months of age, central fixation is associated with the motor activity of grasping. Binocular vision is present at about 6 months of age.

Prematurity

The ocular findings of the premature infant differ from those of the term neonate. At 28 weeks of gestation, the globe is only 10-14 mm in diameter. The anterior and posterior hyaloid vascular systems are usually present to some degree, although their involution continues for the next several months. Remnants of this system may be seen in the form of persistent blood vessels or fibrous strands anterior and posterior to the lens. The main hyaloid artery coursing from the optic disc to the posterior lens surface may be patent or appears as a white strand in the vitreous. A moderate amount of vitreous haze is often present at this time, interfering with visualization of the fundus. Vascularization of the retina begins with the ophthalmic artery entering the eye through the posterior edge of the eye's embryonic fissure at 4 months of gestation. Retinal vessels then grow anteriorly to vascularize the peripheral retina, a process that is not complete until near term. Thus premature infants have incomplete retinal vascularization, creating the basis for retinopathy of prematurity (see also Chapter 96).

Pupil constriction to light is not seen until 30 weeks of gestational age.[55] Lack of pupil response to light should not be considered abnormal until at least 32 weeks after conception. Premature infants have a higher incidence of myopia, amblyopia, and strabismus in childhood. Careful follow-up of all children born prematurely is advisable to ensure early detection of these ocular conditions.

Requesting Ophthalmologic Consultations

Routine ophthalmologic consultation for all infants in the nursery is not warranted.[34] Pathologic ocular findings in normal neonates are sufficiently unusual that evaluation should be requested only after a screening ocular examination indicates the presence of an abnormality or for patients who for some reason are at increased risk for ocular problems. Indications for ophthalmologic consultation include a family history of congenital cataracts, retinoblastoma, congenital glaucoma, or other serious ocular diseases. Intrauterine infectious disease such as rubella, toxoplasmosis, or cytomegalovirus necessitates a thorough eye evaluation. For preterm infants, ophthalmologic consultation is necessary to exclude retinopathy of prematurity.

Orbital Abnormalities

The contents of the orbit are confined to a conical shape by its bony walls. At the posterior apex of the orbit, the extraocular muscles originate, and the vascular and nerve structures enter the orbit. The bone structures of the lateral wall do not protect the orbital contents as far anteriorly as do the remaining sides of the orbit, which leaves the eye more susceptible to trauma on its lateral side. In the neonate, the orbital rims form a circular outline at the anterior base of the cone.

Box 95.2 lists systemic syndromes associated with abnormal orbits.

The terms proptosis, exophthalmos, and exorbitism are often used interchangeably to describe forwardly displaced eyes. In the strictest sense, proptosis results from an increase in orbital contents within a normal bony orbit, exophthalmos from Graves disease, and exorbitism from shallow bony orbits.

Proptosis

The diagnosis of proptosis can be confirmed if the examiner observes the infant's eyes and lids from above, over the prominence of the eyebrows. A more anterior protrusion of the orbital content is observed in comparison with the opposite side. In proptosis, the eye frequently also has a widened palpebral fissure.

• BOX 95.2 Syndromes Associated With Abnormal Orbits

Hypotelorism

- Cebocephaly
- Oculodentodigital dysplasia
- Trisomy 13
- Scaphocephaly

Hypertelorism

- Cerebral gigantism
- Cerebrohepatorenal syndrome
- Chromosome deletions
- Craniosynostosis
- Frontonasal dysplasia and median cleft face syndrome
- Infantile hypercalcemia
- Smith-Lemli-Opitz syndrome
- Isolated finding

Masses within the orbital cavity can expand most easily anteriorly, producing proptosis. Those located within the cone of extraocular muscles produce a symmetric anterior displacement, whereas tumors located outside the cone of extraocular muscles displace the eye outward and away from the area of origin of the tumor. A tumor in the inferior portion of the orbit displaces the eye upward and forward, whereas one located medially displaces the eye laterally and forward. A diffuse, extensive tumor can produce sufficient changes to affect the eye's movement, whereas a localized tumor often does not interfere with rotation of the eye. If a tumor is located anterior to the equator of the globe, it can extend anteriorly into the lids without producing proptosis.

An orbital encephalocele or meningocele producing proptosis may be evident at birth or may be delayed until later years. This abnormality results from a defect in the wall between the cranial cavity and the orbit, usually located at the suture lines. Pressure within the cranium causes herniation of brain tissue, meninges, or both into the orbit, most often at the inner angle of the orbit at the root of the nose.

Diagnosis is made by identifying the bone defect in association with the area of the orbital cyst. Clinically, an encephalocele is suggested by the presence of a pulsating, fluctuant cyst that can be reduced somewhat with digital pressure or that increases with coughing or crying. Excessive manipulation of the encephalocele can cause pulse and respirations to slow or can cause convulsions. Neurosurgical consultation and intervention are necessary.

Proptosis also can occur from venous engorgement of the orbital cavity such as that produced by a carotid-cavernous fistula. A cephalic bruit is often heard in the infant but is not pathognomonic of a carotid-cavernous sinus fistula. A false diagnosis of proptosis might be made when there is a slight ptosis of one eye, which gives the opposite, normal eye an appearance of a wide palpebral fissure. Marked enlargement of the eye, as in congenital glaucoma or high myopia, makes the eye appear proptotic because of the increased size of the globe. Facial abnormalities that produce shallow orbits, as in Crouzon disease, simulate proptosis because the normal amount of orbital structure appears to protrude in an abnormally shallow orbit.

Hyperthyroid Exophthalmos

Hyperthyroid exophthalmos, a rare neonatal sequela of hyperthyroidism, can occur as the result of maternal Graves disease during the last trimester of pregnancy. The infant is born with classic hyperthyroidism, including exophthalmos, upper lid retraction, and extraocular muscle involvement. Symptoms usually subside during the first 2 months of life.[41]

Enophthalmos

Enophthalmos refers to eyes that look sunken into the orbit. Causes in infants include orbital asymmetry, microphthalmos, trauma resulting in an orbital blow-out fracture, congenital fibrosis of the extraocular muscles, and congenital Horner syndrome.[23] Numerous syndromes, and many infants with unclassifiable facial dysmorphisms, feature deep-set eyes, such as Lowe syndrome, Cockayne syndrome, and Cornelia de Lange syndrome.

Ocular Hypotelorism or Hypertelorism

Abnormal spatial relationships between the two orbits create excessively wide or excessively narrow intraorbital distances.[71] These abnormalities are caused by a variety of related cranial abnormalities involving the disproportionate growth or lack of development of the body and lesser wing of the sphenoid and ethmoid sinuses and of the maxillary processes. Hypotelorism (narrowing of the intraorbital distance) may be associated with central nervous system malformation.

Ocular hypertelorism is a term indicating increased separation between the bony orbits, usually greater than two standard deviations above the mean. It is an anatomic description rather than a diagnostic entity and is noted with varying severity in many syndromes such as the craniosynostosis syndromes. One condition with marked hypertelorism is frontonasal dysplasia (median facial cleft syndrome), which may be the result of morphokinetic arrest during embryogenesis.

Characteristic findings of frontonasal dysplasia are medial cleft nose, lip, and palate; widow's peak; and cranium bifidum occultum. Common other ocular abnormalities include exotropia, dacryostenosis, epibulbar dermoids, palpebral fissure changes, and optic atrophy.[95] A phenotypically similar but probably distinct clinical entity within the frontonasal dysplasia spectrum has been reported with the features of facial midline defects, basal encephalocele, callosal agenesis, endocrine dwarfism, and morning glory disc anomaly.[93]

Eyelid Abnormalities

Colobomas

Colobomas of the lids are partial-thickness or complete defects that can range from a small notching of the lid borders to involvement of the entire length of the lid. Most lid colobomas occur in the medial aspect of the upper lid. When the lower lid is involved, the defect is more often in its lateral aspects. The cause of lid colobomas is often unknown unless associated with a craniofacial syndrome. It has been suggested that these isolated colobomas arise from the localized failure of adhesion of the lid folds that results in a lag of growth or from mechanical effects of amniotic bands. Syndromes with associated lower lid colobomas are mandibulofacial dysostosis (Treacher Collins syndrome), Goldenhar syndrome (more often upper lid), amniotic band syndrome, and Burn-McKeown syndrome.[123]

The treatment of lid colobomas is important when the lid defect prevents adequate lid closure and allows exposure of the cornea. Subsequent thickening, opacification, infection, ulceration, or perforation of the unprotected cornea can occur. Vision can be degraded by the amblyopia that develops. Early surgical correction is often required when the coloboma is greater than one-third of the eyelid margin.[100]

Congenital Blepharophimosis

The term blepharophimosis describes eyelids that are too narrow horizontally and vertically. There is usually an associated ptosis, and strabismus is frequently present. Lid fissure measurements commonly are reduced to about two-thirds of normal, whereas the space between the medial canthi is considerably widened. Surgical repair to widen the medial and lateral canthal angles, elevate the upper lid, and correct the strabismus is available.

Blepharophimosis can occur in isolation, as a feature of BPES (blepharophimosis, ptosis, and epicanthus inversus syndrome), or in multiple systemic syndromes such as fetal alcohol syndrome, Saethre-Chotzen syndrome, and van den Ende-Gupta syndrome. BPES has been mapped to the FOXL2 gene encoding a fork head transcription factor. BPES is divided into type 1 and type 2, with and without premature ovarian failure, respectively.[11]

Epicanthus

Epicanthus is the most commonly encountered lid abnormality. A skinfold originating in the upper lid extends over the medial end of the upper lid, the medial canthus, and the caruncle, and ends in the skin of the lower lid. It gradually disappears with the growth of the bridge of the nose as the child loses its baby face. Epicanthal folds can give a false appearance of crossed eyes (pseudostrabismus). Epicanthus inversus is similar except that the predominance of the skinfold arises in the lower lid and runs diagonally upward toward the root of the nose to overlie the medial canthus. These folds are benign and generally do not require treatment.

Congenital Ectropion, Entropion, and Epiblepharon

Congenital ectropion is an eversion of the lid margin, most commonly of the lower lid. It may be associated with other eye abnormalities or syndromes such as Duane syndrome. If the ectropion is mild, no treatment is necessary. A more severely everted lid might require surgical correction. The integrity of the cornea requires monitoring and will determine the treatment.

Often associated with other lid or ocular abnormalities, congenital entropion is an in-turning of the lid margin, most often of the lower lid. If the lashes on the lid margin rub the cornea and cause corneal abrasions, surgery is necessary.

Epiblepharon is an extra fold of skin along the lower lid that can cause lashes to turn inward. This condition usually requires no treatment and is most often seen in infants of Asian ancestry. This condition usually improves spontaneously during the first 2 years of life, but if it persists, consideration should be given to surgical correction. As the lashes are soft when the child is younger, lashes rubbing against the cornea tend not to produce symptoms. But beyond age one, as the lashes get thicker and harder, corneal irritation leading to abrasion and even ulceration not controlled with simple lubrication with ointments warrants earlier surgical intervention.[151]

Blepharoptosis

Ptosis is asymmetry in upper lid height or symmetrical lowering of both upper lids. Although both upper and lower eyelids may be ptotic, the terms blepharoptosis or ptosis generally refer to the upper lids unless otherwise specified (Fig. 95.9). The condition could be idiopathic or inherited, unilateral or bilateral, congenital or acquired. When looking straight ahead, the normal lid should elevate to a point at least midway between the pupil and the upper margin of the cornea. Neonates may have a transient self-limited droopy or closed lid as a result of facial edema or lid trauma during normal vaginal delivery. A temporary, simulated ptosis (protective ptosis or guarding) can result from irritation or infection of the cornea or conjunctiva.

• **Fig. 95.9** Congenital ptosis of the left upper lid.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Congenital ptosis most often results from the dysfunction of the levator palpebrae muscle, mostly seen as an idiopathic or familial disorder. Although occlusion of the pupil is rare, the ptotic lid can induce a corneal astigmatism and refractive amblyopia. Occlusive patching and glasses may be needed. Mild, unilateral ptosis should prompt a comparison of pupil size to evaluate for Horner syndrome. Congenital Horner syndrome (ipsilateral ptosis, miosis, anhydrosis [see Fig. 95.6*A, B*]) is often a result of trauma at birth, although it may be associated with mediastinal disease or neuroblastoma. The involved iris may be hypopigmented.

Ptosis also may be associated with a Marcus-Gunn jaw-winking phenomenon. This syndrome is caused by anomalous motor innervation of the levator palpebrae muscle from nerve twigs to the pterygoid, masseter, or lingual muscles. The affected patient has an up-and-down rhythmic movement of the upper lid during nursing activity (see Fig. 95.2). The jaw-winking portion of the syndrome is thought to decrease or disappear in early adulthood, but the ptosis remains. Many surgical procedures have been designed to mitigate the ptosis.

Two forms of myasthenia gravis can produce ptosis in the neonatal period. In about 15% of neonates born to mothers with myasthenia gravis, a transient form of myasthenia occurs shortly after birth.[44] Affected children have a weak cry and poor suck and can develop weakness in all muscle groups. Ocular symptoms are rare and most commonly involve ptosis. A variety of congenital myasthenia syndromes linked to genetic disorders of the neuromuscular junction or acetylcholine production can display ptosis and ophthalmoparesis, which are often variable and related to the level of fatigue. Pseudoptosis, or false ptosis, may be apparent when the globes are of different sizes or if enophthalmos or proptosis is present.

Microphthalmia (small eye) is a common congenital defect that can be mildly expressed. In such situations, the lid will look drooped even if it is functioning properly (Fig. 95.10). A unilateral large globe caused by monocular myopia can produce a relative ptosis in the contralateral normal eye.

• **Fig. 95.10** Microphthalmus: Patient with microphthalmic right eye also has significant choroidal coloboma in the same eye.

• **Fig. 95.11** Ankyloblepharon: Persistent adhesion between upper and lower lid.

Ankyloblepharon

The upper and the lower lids may be fused at birth or through an inflammatory process (Fig. 95.11). The term ankyloblepharon is used to designate this condition, which may be dominantly inherited. Simple excision of the bridging tissues between the eyelids is all that is required to separate the lids.

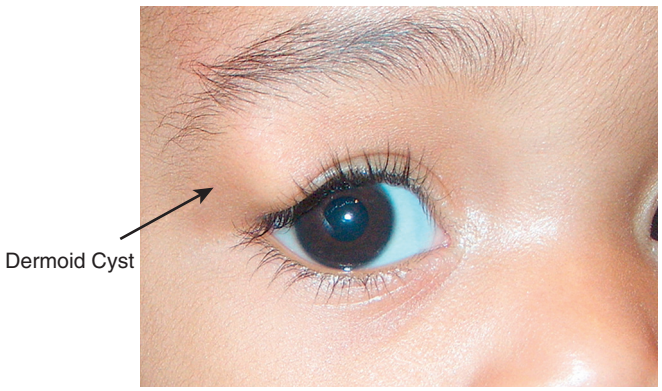
Eyelid Lesions

Nevi

Nevi may occur anywhere on the lid margin, skin, or conjunctiva. Often a congenital nevus will not be noticed until puberty, when pigment begins to accumulate and the lesion is thought to be growing (Fig. 95.12). Observation for change in size, shape, depth, or pigmentation is recommended.

Dermoid Cysts

Dermoid cysts are tumors that appear at the suture lines, most commonly at the superotemporal brow or in the superior medial central area of the brow (Fig. 95.13). Occasionally they appear to be free in the orbit or lid without demonstrable direct connection to a suture line. They are benign choristomata that grow slowly but will thin out the adjacent bone. They should be removed surgically without rupturing the cyst (Fig. 95.14). If a dermoid cyst is ruptured by accidental trauma or surgery, severe local inflammation can result if the extruded contents are not irrigated from the wound.



Hemangioma

Hemangiomata are quite common and occur in up to 10% of newborns.[118] They may virtually occur in any body location including the upper or lower lids and orbit. In infants, the hemangioma usually is not well encapsulated and frequently periorbital, and orbital lesions will occur in association with similar lesions elsewhere on the body.

• **Fig. 95.12** Nevus of Ota: Hyper-pigmented nevus affecting the left temple, forehead, and periorbital; also associated with scleral melanosis.

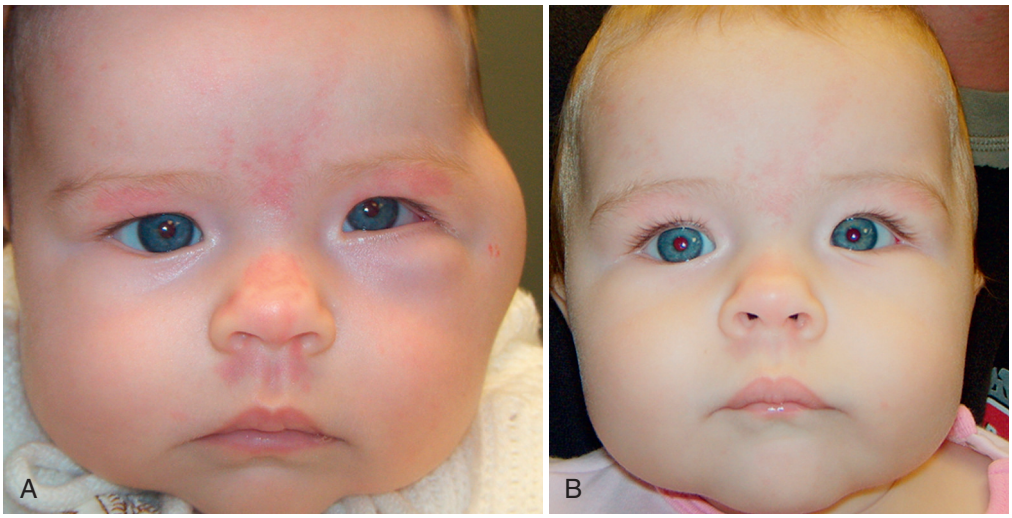
• **Fig. 95.13** Dermoid cyst in right temporal anterior orbit: Firm, non-tender, oval mass palpated.

Although observation of lid involvement assists in making the diagnosis, a biopsy might be required to exclude other orbital tumors if the hemangioma lacks a superficial component. Crying or straining by the infant often causes the mass to increase in size and assume a bluish coloration. Digital pressure on the superficial portion of the tumor is rapidly reversed, demonstrating the high flow of capillary hemangioma. When a hemangioma involves the eyelids, amblyopia can develop. Amblyopia may be secondary to the hemangioma's obstruction of the visual axis or from pressure on the cornea that subsequently induces astigmatism and anisometropic amblyopia.

Congenital capillary hemangiomata are inconsequential at birth but grow rapidly during the first 6 months of life.

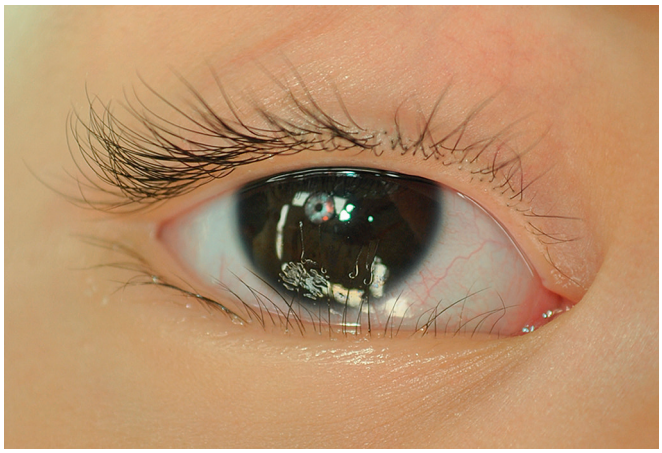
• **Fig. 95.14** Dermoid cyst removed in total; pathology confirmed diagnosis of dermoid cyst.

Spontaneous involution occurs at about age 2-4 years. The natural history of hemangiomas is that they will regress over several years even without treatment, but local soft tissue and occasional bone deformities may remain and are common around the eye.



When threatening the sight via amblyopiogenic properties, treatment is warranted. Until recently, treatment was oral use or intralesional injections of steroids, subcutaneous interferon, or excision of the lesion. Although these modalities are still valid, they are not free of side effects. Oral propranolol or topical timolol are effective ways of treating these tumors[22,67] (Figs. 95.15*A*, *B*). In the past, treatment involved systemic, injectable, or topical corticosteroids with potential side effects over months of treatment. Central artery occlusion is a rare but well-described complication of steroid injection with permanent vision loss.[104] Occasionally, surgery is indicated for well-defined, easily accessible tumors to avoid side effects of medical treatment.[109] Oral use of propranolol (2 mg/kg/day) is found to be very effective in the hemangioma treatment. However, its use, although relatively uncommon, necessitates that side effects such as hypotension and hypoglycemia have to be monitored closely. Also, an MRI of the brain to rule out associated intracranial vascular abnormalities will prevent cerebrovascular injuries secondary to the blood flow and tension changes caused by this medication.

Other eyelid lesions include, but are not limited to, plexiform neuromas secondary to neurofibromatosis type-1, amyloid depositions, and juvenile xanthogranuloma.



Eyelash Abnormalities

Lashes may be redundant, absent, misdirected, or discolored. The condition may be inherited or acquired through mucous membrane diseases of the conjunctival sacs, infectious process, or trauma. *Trichiasis* is a lash that grows from

• **Fig. 95.15 A,** Diffuse capillary hemangioma affecting the left side of the face and orbit. **B,** Resolved hemangioma with oral propranolol treatment.

• **Fig. 95.16** Epiblepharon: Right lower lid lashes turned in toward the cornea, abrading the front surface of the eye.

a normal location but is misdirected toward the ocular surface. *Congenital trichiasis* patients should be examined for Down syndrome or signs of ectodermal dysplasia. If a second row of lashes is present in the area of the meibomian glands (metaplasia), the condition is referred as *distichiasis*. This condition usually results in contact of the lashes with the cornea, producing corneal irritation and abrasions. True distichiasis is rare but can easily be distinguished from trichiasis, entropion, and epiblepharon (Fig. 95.16), all of which may be seen together. Excessive eyelash growth can result as a side effect from multiple medications, including topical prostaglandin analogues and epidermal growth factor receptor inhibitors.[29]

Hypertrichosis

Excessive hair on the lids and forehead can occur as a dominant characteristic in male infants and, on occasion, may be extreme. Hypertrichosis involving the eyebrows, forehead, and upper lid appears in *Cornelia de Lange syndrome*, a pathologic dwarfism associated with multiple congenital anomalies. Hypertrichosis lanuginosa is transmitted as an autosomal dominant condition. The fetal lanugo persists into adult life, creating an abundant covering of hair on the eyebrows, forehead, eyelids, and other areas of the body.

Lacrimal Abnormalities

Watery Eye

Epiphora (excess tearing) usually does not occur until after the first 3 weeks of life, when the major portion of the lacrimal gland has become functional. Although the usual cause of epiphora is a blockage of the nasolacrimal ducts (dacryostenosis), the possibility of congenital glaucoma is the most important consideration in the differential diagnosis. Less commonly, tearing can result from an obstruction of the common canaliculus, from congenital absence of the lid puncta, or from dacryocystitis. Congenital absence of the entire lacrimal drainage apparatus is extremely rare. Reflex tearing may be produced by any stimulation of the fifth cranial nerve. Epiphora can occur as the result of corneal abrasion, corneal foreign body, or nasal and facial lesions that irritate the fifth cranial nerve. Chronic nasal congestion also may produce epiphora by mechanically blocking the nasolacrimal duct. Dacryostenosis may be present in up to 7% of neonates and creates a stagnant pooling of tears in the lacrimal sac that contributes to chronic or recurrent dacryocystitis. The inflammation is marked by a purulent exudate in the medial canthal area of the conjunctiva. Severe dacryocystitis can produce swelling and induration of the lacrimal sac medial and inferior to the medial canthus. Treatment of mild nasolacrimal infection consists of topical antibiotic drops or ointment. If surrounding cellulitis is suspected, systemic administration of medication and locally applied

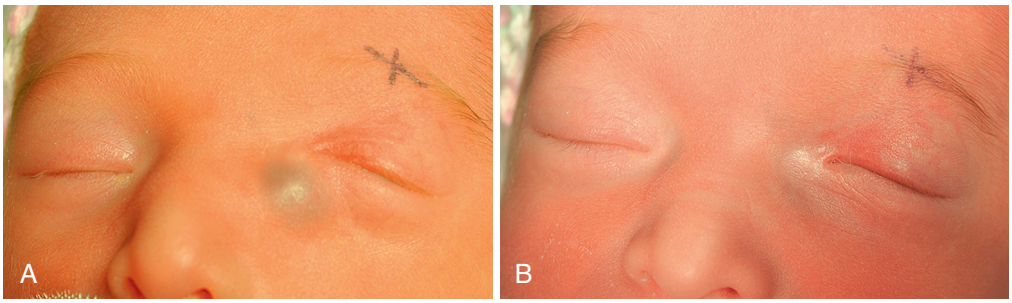
Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

heat may be required. Repeated massage of the lacrimal sac at the medial canthal area serves to flush out the stagnant tears, decrease the risk for infection, and "pop" open the nasolacrimal obstruction. If the epiphora continues, a lacrimal probe passed through the nasolacrimal duct to the nose usually creates an adequate opening. Probing between 6 and 12 months of age is sometimes performed in an office setting under topical anesthesia with the baby swaddled in a sheet. In more than 90% of children with congenital dacryostenosis, the obstructions spontaneously correct during the first year of life. If persistent, treatment is then offered but requires general anesthesia because these children are too large to swaddle for an office probing. Surgical options include simple probing, silicone tube intubation, or balloon dilation of the lacrimal system.[70]

Dacryocystocele

A congenital dacryocystocele presents within the first week of life as a bluish mass adjacent to but lower than the medial canthus. Similar lesions found higher than the medial canthus should be suspected to be encephalocele. The distended lacrimal sac is filled with clear fluid, feels firm or fluctuant to palpation, and does not pulsate like a frontal encephalocele.[125] Initiating oral antibiotics is recommended as soon as a dacryocystocele is identified to prevent infection of the dacryocystocele, which can occur in up to two-thirds of these patients. If the patient presents with signs of a dacryocele infection, admission to a pediatric intensive care unit for intravenous antibiotics is required. Surgical treatment with a nasolacrimal probing should be considered within the next 2-4 days (Figs. 95.17*A, B*).

Dry Eye



The normal newborn will have moist eyes from basal secretion of tears. Reflex tearing from ocular irritation or psychogenic (emotional) tearing may not develop for weeks to months after birth. Infants do not usually have symptoms from dry eyes unless in rare conditions such as *alacrima* from a congenital lack of tear glands or Riley-Day syndrome. Recognition of alacrima in the infant is important in preventing corneal abrasions, infections, and perforations, the inevitable sequelae of dry eye. During the first month of life, an infant with alacrima from any cause might not appear different from the normal infant, because tear production is minimal during this period. The usual time of discovery is at 6-12 months of age after the lack of tears has produced changes such as scarring or ulceration of the cornea. At 1-2 months of age, early symptoms of dry eye are conjunctival hyperemia and photophobia. Instead of the ample tears expected with conjunctival irritation, a sticky mucoid secretion is produced, and the cornea shows punctuate staining with fluorescein solution application. Treatment includes frequent use of artificial tears (as often as every 15-30 minutes), punctal occlusion, or tarsorrhaphy (partial or complete temporary or permanent suturing of the upper and the lower lid together to decrease the exposed ocular surface area).

Isolated congenital lack of tears, usually bilateral, is a rare anomaly. The cause is unknown, but it has been suggested to result from hypoplasia of the lacrimal gland or from an absence of innervation of the lacrimal gland structures. The ocular findings in familial dysautonomia (Riley-Day syndrome) are characteristic and can produce the initial criteria for diagnosis. They include alacrima and corneal anesthesia. These ocular changes and constriction of the pupil by instillation of 0.125% pilocarpine should establish the diagnosis. The onset of major systemic symptoms occurs when the child is about 2 years old. An abnormal swallowing mechanism, inappropriate blood pressure and respiratory control, decreased sensitivity to pain, deficient taste perception, and abnormal ocular findings in this syndrome are the result of sympathetic, parasympathetic, and sensory neuronal abnormalities. Additional ocular findings are myopia, anisometropia (significantly different refractive error in the two eyes), exotropia, tortuosity of the retinal vessels, and occasionally ptosis. Familial dysautonomia results from a mutation in the *IKBKAP* gene encoding elongation protein 1, resulting in defective splicing.[84]

Globe Abnormalities

Anophthalmia

Anophthalmia is a rare sporadic phenomenon in which there is total absence or a minute rudiment of the globe, and it can present either unilaterally or bilaterally (Fig. 95.18).

• **Fig. 95.17 A,** Dacryocystocele: Bluish-colored, firm, nonmobile cyst seen below the medial canthal tendon. **B,** Dacryocystocele: After decompression with tear duct probing.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

• **Fig. 95.18** Anophthalmia: Goldenhar syndrome, with maldeveloped right side of the face and anophthalmia.

It occurs as a developmental failure of the optic vesicle. It is often accompanied by other congenital anomalies, such as central nervous system defects and mental retardation, and has been observed in isolation, in genetic defects (e.g., *SOX2*, *STRA6*, *PAX6* genes), and in chromosomal syndromes (e.g., trisomy 13).[119] Because lid formation does not depend on ocular formation, the lids are fully formed. However, the lids remain closed and can be partially fused, and they are smaller and sunken without the support of the eye. Treatment involves reconstruction of the orbit to improve the appearance of the face. Plastic molds of the conjunctival sac of gradually enlarging sizes are used to stretch the lids and sac sufficiently to hold an ocular prosthesis. In unilateral situations, orbital reconstruction using tissue expanders can dramatically improve the overall facial appearance.

Cryptophthalmia

In cryptophthalmia, the eyelids fail to cleave, and uninterrupted skin runs from the forehead to the malar area. The eyelids and eyelashes usually are absent; however, the eye can be palpated beneath the skin and might even be observed to move with the stimulation of a strong light.

The anterior segment of the eye is invariably disorganized into fibrovascular tissue adherent to the subcuticular tissue of the lids. Because the conjunctival sac is absent or small, attempts to separate the lids from the ocular structures are usually unsuccessful, and surgical correction is not advisable in most circumstances. Although a globe is present, only rarely is vision obtainable.

Cryptophthalmia is frequently associated with systemic abnormalities such as urogenital malformations (Fraser syndrome) linked to defects of the *FRAS1* and *FREM2* genes, and a thorough genetic evaluation is indicated.[54,118]

Microphthalmia

Microphthalmia describes a variety of conditions in which the axial length of the neonatal eye is less than two-thirds of the normal 16 mm. Causes include familial, syndromic, and chromosomal abnormalities and environmental influences during gestation. Simple microphthalmia is a condition in which there is an abnormally small eye but with intact internal organization. It may be associated with other ocular features of importance: a high degree of hypermetropia, retinal folds, a tendency for choroidal effusions, and the late occurrence of glaucoma.[122]

Complex microphthalmia describes small eyes with internal disorganization, such as anterior segment dysgenesis, cataract, coloboma, or persistent fetal vasculature.[121] Colobomatous microphthalmia occurs when the embryonic cleft of the optic vesicle fails to close. Typically, this form is associated with other ocular anomalies such as colobomas of the iris, ciliary body, fundus, or optic nerve, or colobomatous orbital cysts (see Fig. 95.21).

Microphthalmia can also be associated with other ocular and systemic syndromes, including intrauterine infections such as rubella and cytomegalovirus, craniofacial anomalies, anterior segment dysgenesis syndromes, or chromosomal abnormalities. Because of the heterogenicity of associated findings, infants with microphthalmia should be evaluated by both an ophthalmologist and geneticist.

Large Eye

An abnormally enlarged eye in the neonatal period is rare but is extremely important to recognize. An apparently enlarged eye may be caused by colobomatous microphthalmia with an associated large cyst, congenital megalocornea (see later), or congenital glaucoma (see later). Colobomatous microphthalmia results when the embryonic optic vesicle fails to close. Tissue that originally should have become intraocular is encased in a cystic structure outside the eye in the orbit. If the cyst becomes sufficiently large that proptosis occurs, the microphthalmic eye simulates an enlarged eye.

Scleral Abnormalities

The normal term neonate has a glistening white sclera. The overlying conjunctiva and the conjunctival vessels superimpose a filmy, vascular pattern. A generalized bluish discoloration of the underdeveloped sclera is normal in premature infants. Rarely, a congenital weakness in a small area of the sclera produces a bluish bulge called a staphyloma. The light blue color is caused by thinness of the sclera that transmits the darker color of the underlying uveal tissue. Osteogenesis imperfecta may be associated with a similar bluish discoloration of the sclera in the term neonate because of inadequately developed scleral collagen. Blue sclera may also be seen in other systemic diseases such as Marfan syndrome, Ehlers-Danlos syndrome, and Crouzon syndrome.

Pigmentation of the conjunctiva and sclera is common in darkly pigmented people. Intrascleral nerve loops appear as darkly pigmented dots about 3-4 mm from the limbus. Congenital ocular melanosis and oculodermal melanosis (nevus of Ota [see Fig. 95.12]) occur as a unilateral slate-blue pigmentation in infancy.

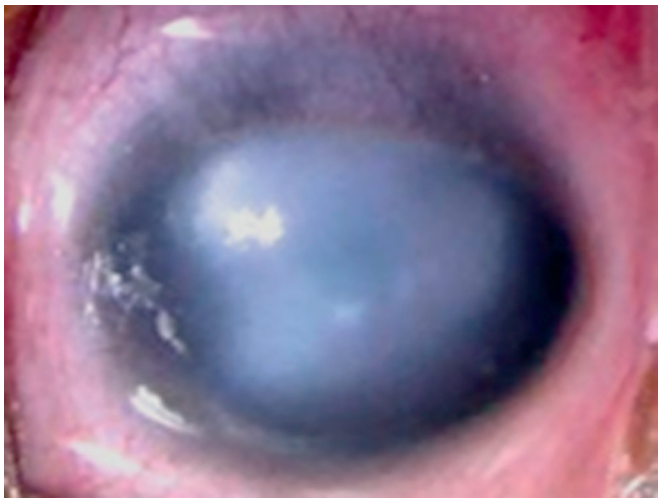
Corneal Abnormalities

Cloudy Cornea

The normal premature infant might have a slightly hazy cornea for the first few weeks of life, caused by temporary excess hydration of the cornea. In the normal term infant, a similar appearance may be seen for the first 48 hours after delivery.



A persistently hazy or cloudy cornea suggests congenital glaucoma or birth injury. Anterior segment dysgenesis syndromes, corneal dystrophies, infection, or systemic disease should also be considered (Fig. 95.19).

Enlarged Cornea

Most newborn infants have a corneal diameter of about 9-10 mm. If this measurement exceeds 12 mm, congenital glaucoma must be considered, especially if corneal haze, tearing, and photophobia are present. Megalocornea is an enlarged cornea exceeding 13 mm in diameter. The cornea is usually clear, with distinct margins and thin iris stroma. There are no other features of congenital glaucoma, such as elevated intraocular pressure, tearing, photophobia, or conjunctival injection. Megalocornea as an isolated finding is usually inherited in an autosomal dominant manner. Megalophthalmia, which is commonly inherited as an X-linked recessive trait, is characterized by deep anterior chambers, subluxation of the lens, hypoplastic iris, and cataract formation in early adult life. A corneal diameter of less than 10 mm may be an isolated finding or may be associated with other ocular anomalies. Cases of autosomal dominant and recessive inheritance of microcornea have been described.

Anterior Segment Dysgenesis Syndromes

A wide spectrum of clinical findings is observed in the anterior segment dysgenesis syndromes, including abnormalities of the cornea, anterior chamber, iris, and lens. Corneal opacities, adhesions of the iris, and glaucoma can occur. Although a continuous spectrum of findings can be evident in a family pedigree, or between the two eyes of one patient, eyes are often assigned into the distinct subgroups of posterior embryotoxon, Axenfeld anomaly, Rieger anomaly, or Peter anomaly.

• **Fig. 95.19** Cloudy cornea: This patient is a 30-week-gestation premature child with Peters anomaly.

Corneal Dystrophies

Most corneal dystrophies become apparent in adolescence or early adult life. However, congenital hereditary endothelial dystrophy may be present at birth. This condition is characterized by bilateral cloudy corneas, normal corneal diameter, and normal intraocular pressure. Early cornea transplantation may be helpful, but the prognosis is guarded.

Corneal Manifestations of Systemic Disease

Corneal opacities and haze can occur because of inborn errors of metabolism. Most are not associated with corneal opacities in the neonatal period. Systemic diseases that cause corneal opacities include the mucopolysaccharidoses, mucolipidoses, Fabry disease, hypophosphatasia, cystinosis, and Wilson disease.

Congenital Glaucoma

Although congenital glaucoma is uncommon, the devastating effects of uncontrolled ocular pressure are sufficiently important to keep this disease uppermost in the mind of the examining physician. The classic symptoms of congenital glaucoma include tearing, light sensitivity, and blepharospasm. As the disease progresses, the increased intraocular pressure produces stretching of the eye, creating an increased corneal diameter greater than 12 mm (buphthalmos, Fig. 95.5), cloudy cornea, progressive myopia, and loss of vision. Symptoms can be apparent at birth or weeks to months later.

Congenital glaucoma can occur as a primary disease or secondary to numerous other ocular conditions or systemic syndromes. A list of diseases associated with congenital glaucoma is shown in Box 95.3. In addition to visual impairment from glaucomatous damage, amblyopia from visual deprivation or anisometropia can prevent a successful visual outcome. The prognosis depends on the age of onset, time to diagnosis, and associated ocular and systemic conditions. Unlike the glaucoma in adults, the treatment is surgical in vast majority of cases, and medical management is only used for temporizing the condition or better visualization for various surgical procedures.

Iris Abnormalities

Aniridia

Aniridia (absence of the iris) is a rare congenital anomaly, usually bilateral, that is almost invariably associated with

• BOX 95.3 Conditions Associated With Glaucoma

Seen in Isolated (Congenital) Conditions

- Aniridia
- Rubella syndrome
- Hallermann-Streiff syndrome
- Lowe syndrome
- Axenfeld or Rieger syndrome
- Sturge-Weber syndrome

Uncommonly Seen in These Conditions

- Chromosome abnormalities
- Down syndrome
- Homocystinuria
- Marfan syndrome
- Neurofibromatosis
- Ocular-dental-digital syndrome
- Persistent hyperplastic primary vitreous
- Rubinstein-Taybi syndrome
- Weill-Marchesani syndrome

• Fig. 95.20 Aniridia: This patient has a remnant of the iris tissue that appears like a significantly dilated pupil. Sometimes the iris remnant cannot be visualized with direct observation.

poor vision and nystagmus. A small rudimentary cuff of peripheral iris can be observed grossly or microscopically (Fig. 95.20). Associated ocular findings include glaucoma, corneal pannus, cataract, abnormal optic discs, and foveal hypoplasia. Because the fovea sub serves our best vision, its maldevelopment causes the nystagmus and poor visual acuity.

Aniridia is caused by a defect in the *PAX6* gene on chromosome 11 at 11p13.[47] WAGR syndrome, a contiguous gene syndrome, results from a larger deletion in the area that involves the Wilms tumor gene (*WT1*) and includes Wilms tumor, aniridia, genitourinary abnormalities, and mental retardation.[31] All infants with nonfamilial aniridia should undergo chromosomal analysis to detect small deletions; if a deletion exists, the infant should be carefully monitored for early detection of Wilms tumor.[68]

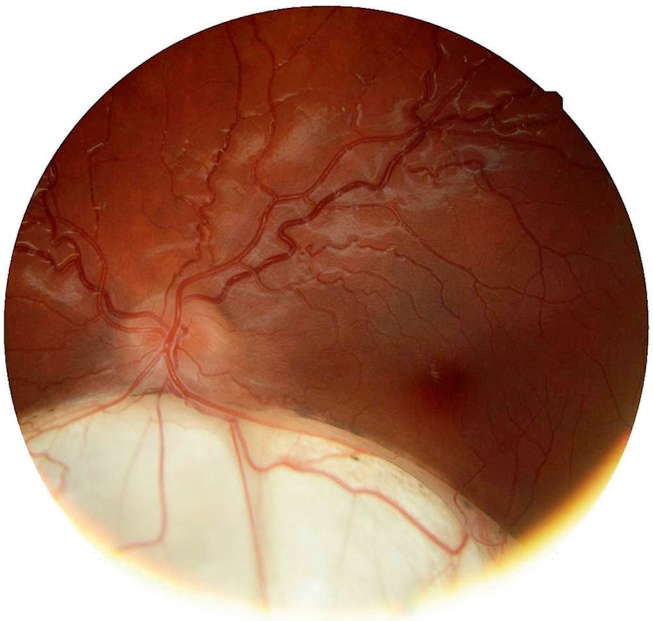
• BOX 95.4 Syndromes Associated With Iris Colobomas

- Congenital colobomatous microphthalmia
- CHARGE association
- Trisomy 13
- Trisomy 18
- Rieger syndrome
- Iris coloboma and anal atresia syndrome
- Lowe syndrome (infrequent)
- Rubinstein-Taybi syndrome (uncommon)
- Multiple chromosome anomalies

CHARGE, *c*oloboma, *h*eart anomaly, choanal *a*tresia, *r*etardation, *g*enital anomaly, *e*ar anomaly.

Coloboma

Iris coloboma is one of the most common congenital abnormalities of the eye. It can occur as a single ocular finding, have a Mendelian mode of inheritance, be associated with a chromosomal abnormality, or be associated with other malformation syndromes (Box 95.4). Typical colobomas occur in the inferonasal quadrant, where the embryonic fissure closes. Because typical iris colobomas result from an abnormal closure of the embryonic fissure, they also may be associated with a coloboma of the ciliary body, fundus, or optic nerve. Associated microphthalmia is common. When the optic nerve or macula is involved in the coloboma, visual difficulty occurs. It is always wise to evaluate the fundus for a pathologic condition when an iris coloboma is detected. Atypical iris colobomas occur away from the inferonasal quadrant. Atypical colobomas, which vary from a small notch in the pupil to the absence of an entire segment of the iris, are not usually associated with visual difficulties. Coloboma of the iris, uvea, or retina, with or without microphthalmia, is a feature of CHARGE association (Fig. 95.21).



Persistent Pupillary Membrane

Persistent pupillary membranes are common in the neonate, particularly in the premature infant. The membranes are remnants of the anterior fetal vascular supply of the lens that failed to atrophy in the 7th month of gestation. If these persistent vessels adhere to the lens, a localized cataract can form.

Iris Heterochromia

Heterochromia indicates a difference in pigmentation in the irides. For example, one eye may have a blue iris, and the other iris may be brown; or one iris may have a wedge of lighter or darker pigmentation. The heterochromia itself

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• **Fig. 95.21** Choroidal coloboma.

does not affect ocular health or vision but may secondarily result from other pathologic ocular conditions, such as trauma or inflammations. Heterochromia can occur as an isolated autosomal dominant trait. It also is associated with several syndromes such as Waardenburg syndrome. Congenital Horner syndrome produces heterochromia, usually after the neonatal period, resulting from the failure of normal pigmentation to develop in the iris on the sympathetically denervated side. Aganglionic megacolon (Hirschsprung disease) can also be associated with iris heterochromia.

Abnormal Red Reflex

This is one of the most important abnormalities that requires immediate evaluation. The term leukocoria is used to describe a white pupil seen by the naked eye or during the red reflex test. Leukocoria is not a diagnosis but rather a description of an observation. Because the infant sleeps much of the time and because the pupils are small, a white pupil often is not noticed until the infant becomes more alert and active. False positive red reflex test results are commonly due to small pupils, shifting gaze, limited patient cooperation, poor illumination from the ophthalmoscope, and examiner inexperience. Regardless, these patients should be over-referred to the ophthalmologist to ascertain the true-positive results.

Causes of leukocoria in infants include opacities of the cornea, lens, and vitreous, as well as retinal diseases such as retinoblastoma, chorioretinal coloboma, persistent hyperplastic primary vitreous, endophthalmitis, Coats disease, congenital retinal fold, retinoschisis, or scarring from ROP. Abnormal red reflexes can also result from misaligned eye or from high or asymmetric refractive errors.

Lens Abnormalities

Cataract

The lens helps images focus on the retina and is designed to be transparent. The lens grows continuously during life, laying down new lens fibers on its external surface much as an onion does. The lens is preserved in capsules (anterior and posterior) and has a nuclear core and surrounding cortical portion. Any opacity or abnormality within these structures is defined as cataract. Childhood cataracts can be classified as congenital, infantile, or juvenile depending on the age of onset. Congenital cataracts are present at birth but may go unnoticed until an effect on the child's visual function is noticed or a white pupil reflex develops. Congenital and infantile cataracts are responsible for about 10% of all blindness worldwide.[7]

It is important to consider the origin of a cataract. The etiology of pediatric cataracts can be broadly classified and summarized as hereditary, metabolic (galactosemia, Fabry disease, hemolytic jaundice, etc.), traumatic, secondary (maternal infection, inflammation, steroid use, etc.), seen with chromosomal abnormalities (Lowe, Alport, Marfan, Hallerman Strieff, and other syndromes), iatrogenic, and idiopathic. Furthermore, cataracts can be classified according to their morphology as diffuse/total, anterior polar, lamellar, nuclear, posterior polar, posterior lentiglobus, posterior (and anterior) subcapsular, persistent hyperplastic primary vitreous, and traumatic.

The size and shape of a cataract depends on the area of the lens that is being formed at the time the damage or developmental defects occur. Damage that occurs in the early embryonic period produces opacifications in the center of the lens. Such nuclear cataracts have clear layers in the periphery of the lens. Later periods of damage produce ringlike opacifications surrounded by central and peripheral clear areas (zonular cataracts). Recent damage produces peripheral opacifications near the surface of the lens (cortical cataracts). Dense opacities near the central axis cause greater visual disturbance, especially if they are located in the central visual axis.

However, most congenital cataracts are genetic or isolated and idiopathic. A list of causes of neonatal cataracts is shown in Table 95.3.

Genetically determined cataracts often are isolated abnormalities and bilateral. Many genetic loci have been mapped.[99] The primary mode of transmission is autosomal dominant. Recessive transmission and X-linked transmission have been recorded. Because there is variable expressivity, parents should be examined for mild cataracts.

The rubella embryopathy syndrome is rare in the era of rubella vaccination but is still seen in developing countries. The syndrome comprises multiple congenital anomalies that result from maternal viremia during the first trimester of pregnancy. Cataracts are present in about 20% of children with the congenital rubella syndrome (Fig. 95.22). The rubella virus may remain dormant in lens material in the

Modified from Arkin M, Azar D, Fraioli A. Infantile cataracts. *Int Ophthalmol Clin.* 1992;32(1):110-111.

offspring for as long as several years. Microphthalmia, pupil abnormalities, congenital glaucoma, and anterior uveitis also may result. A cloudy, edematous, or white cornea may be found with normal intraocular pressure as part of the rubella embryopathy. Rubella retinopathy is a pigmentary disturbance of the retina without demonstrable effect on visual function. A TORCH (*t*oxoplasmosis, *o*ther agents, *r*ubella, *c*ytomegalovirus, *h*erpes simplex) titer should be obtained from all infants with nongenetic congenital cataracts.

Galactosemia is a hereditary inborn error of metabolism with deficiency of the enzymes responsible for galactose metabolism: galactose-1-phosphate uridyltransferase, galactokinase, or uridine diphosphategalactose-4-epimerase. The affected neonate may appear normal at birth. Cataracts usually develop during the first 2 months of life. The cataracts may be zonular or may appear as vacuoles (classically described as "drop of oil") in the center of the lens owing to an accumulation of galactose and galactitol. Early diagnosis and a regimen of a galactose-free diet

• **Fig. 95.22** Infantile cataract: White opacification seen in the center of the visual axis. This is a posterior lenticonus type cataract.

can prevent development or further progression of cataracts. All congenital forms of infantile cataracts require a prompt evaluation by an ophthalmologist. Dense cataracts are treated surgically to prevent irreversible amblyopia and strabismus. Removal of the lens, followed by optical correction and amblyopia therapy, provides the best hope of restoring vision.

The prognosis for vision is poorer in the involved eye when the cataract is monocular. Intraocular lens implantation, especially in older infants, is often used to restore the focusing ability of the eye.[106] Long-term follow-up is necessary to monitor vision development, treat strabismus and amblyopia, and detect glaucoma.

Subluxed Lens

The discovery of a subluxed lens (ectopia lentis) in an eye helps in identifying systemic disease processes associated with this abnormality. Although lens dislocation may be present during the neonatal period, it typically develops in the first or second decade of life. Therefore, other causes such as blunt trauma should be suspected, especially if it is seen with other signs of ocular, peri-ocular, and/or systemic signs of trauma (i.e., shaken baby syndrome). Marfan syndrome is the most common cause, but homocystinuria, sulfite oxidase deficiency, hyperlysinemia, Ehlers-Danlos syndrome, Weill-Marchesani syndrome, and trauma can also produce this finding. There is also an isolated genetic form. The dislocation results from a laxity, absence, or defect of the zonular attachments that suspend the lens from the ciliary body. A subluxed lens usually is not treated during the neonatal period unless there is the complication of cataract formation or glaucoma.

By dilating the pupil, the examiner can visualize the edge of a dislocated lens in the pupillary space. Ectopia lentis may also be suggested by iridodonesis (shaking of the iris), which occurs when the posterior surface of the iris lacks the normal support of the lens. A dislocated lens is one of the toughest surgical problems in pediatric ophthalmology.

Retina and Vitreus Diseases

During the neonatal period, nonvascular structures of the fundus are nearly transparent because uveal pigmentation is not fully developed. The neonatal retina does have sheen to its inner surface, but the macular region appears flattened. Retinal transparency is disturbed when abnormalities are present. The retina resembles a pale, ghostlike sheet when it is detached. Retinal edema gives a slightly raised, opalescent appearance. Infection obscures the underlying structures with a fuzzy, white thickening of the retinal tissue. In pathologic processes characterized by a lack or an excess of pigment, retinal abnormalities may become evident only after the first few months of life. The choroid is the deepest layer normally visible with the ophthalmoscope. Pathologic processes that prevent its development or that destroy areas of choroid expose areas of bare sclera, which appear glistening white.

Retinal Dysplasia

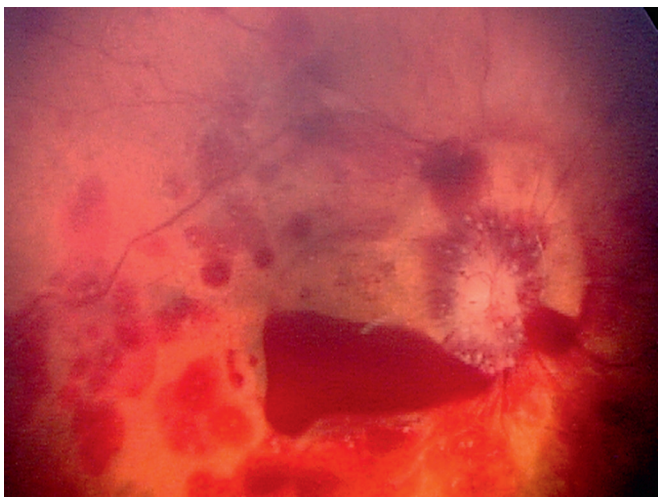
Many of the heritable retinal disorders tend to be noticed far beyond the neonatal period. Although these are genetic problems obviously present at birth, it takes years or sometimes decades to manifest its affects and debilitating visual effects. Retinal dysplasia is rare and is a usually bilateral, congenital anomaly of term infants showing congenital retinal folds and retinal detachments. Histopathologically, the retina shows disorganization and dysplasia. The retinal detachments may clinically resemble a mass and should be considered in the differential diagnosis of retinoblastoma. Rather than a distinct clinical entity, retinal dysplasia may represent a common final pathway of many different developmental disorders of retinal differentiation and organization. Retinal dysplasia can occur as part of a group of congenital anomalies—including defects of the central nervous system, cardiovascular system, and skeletal system—that are sufficiently severe to produce early death of the infant. Specific conditions that result in retinal dysplasia include trisomy 13, Norrie disease, and Walker-Warburg syndrome.

Norrie Disease

A rare genetic disorder transmitted as an X-linked recessive trait, Norrie disease is characterized by the presence of bilateral total retinal detachments that result in a white pupil. Organization of the retinal detachment can disrupt the lens, producing cataract, or can affect the anterior chamber angle, producing congenital glaucoma. The usual result is atrophy of the globe. Norrie disease maps to the *NDP* gene on chromosome Xp11.4, most commonly caused by mutations of the cysteine-knot motif.[127] Patients with Norrie disease may also develop progressive mental disorders often with psychotic features, and about one-third of patients develop sensorineural deafness.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

Mutations of the *NDP* gene away from the cysteine-knot motif often result not in Norrie disease but in a clinically distinct entity termed familial exudative vitreoretinopathy (FEVR). FEVR is characterized by avascularity of the peripheral retina, abnormal retinal neovascularization, retinal traction, and detachment.[28] FEVR is actually a genetically diverse disorder, having been also mapped to the *FZD4* and *LRP5* genes, both of which encode for receptors for the *NDP* gene product.[12]



X-Linked Juvenile Retinoschisis

Juvenile X-linked retinoschisis is transmitted as an X-linked recessive trait, occurring almost exclusively in males, and invariably bilateral. It is a progressive, degenerative disorder. Although relatively rare worldwide, it is the most common X chromosome disorder in Finland. Retinoschisis is a splitting of the nerve fiber layer (the most superficial layer of the retina) with ballooning of the inner layer into the vitreus. This splitting creates a veil like appearance in front of the retina. Visual function is absent in the affected tissue. Macular changes and vitreous hemorrhages can occur as associated findings. Both lead to loss of vision. Early diagnosis offers a better chance in improving prognosis. It has no known systemic manifestations.

Retinoschisis can also be seen in trauma, and especially is pathognomonic for shaken baby syndrome when seen with retinal hemorrhages affecting multiple layers of the retina (Fig. 95.23).

Leber Congenital Amaurosis (LCA)

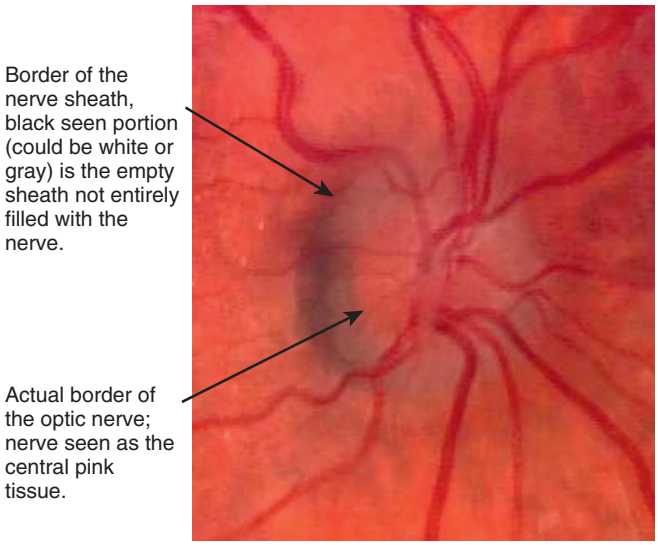
LCA, first described by Theodore Leber in 1869, is an autosomal recessive condition that presents before age 1 year with severely affected vision (majority light perception), nystagmus, and poor papillary reactions. Although retinal examination can be normal, nonrecordable electroretinography (ERG)—a diagnostic test that measures the electrical responses of the photoreceptors to light stimulation—is associated with this condition. Children with this disorder sometimes rub or poke their eyes excessively, called "blindism behavior." Nystagmus usually appears after a few months. LCA that has no other associated systemic manifestations is termed uncomplicated LCA. Today, LCA is recognized as a heterogeneous group of disorders that together are estimated to account for approximately 5% of all retinal dystrophies and approximately 10%-18% of all cases of congenital blindness. To date, seven genes have been implicated in the pathophysiology of LCA and together account for almost 40% of patients presenting with this condition. Ground-breaking gene therapy work has made significant advancement in potential cure of these diseases.[43]

• **Fig. 95.23** Shaken baby syndrome.

Albinism

Albinism refers to the absence or reduction in the amount of melanin in the skin, eye, or both. Diseases featuring albinism are genetically determined and involve defects of melanogenesis. Ocular albinism is X-linked recessive. It is the leading cause of nystagmus in male infants and children. The diagnosis of albinism in the neonatal period is difficult to substantiate, because the uveal pigment is underdeveloped during this period. The diagnosis may be suggested when pigmentation of the skin, hair, and irises fails to progress during the first several months in comparison with that of parents and siblings. Lack of pigmentation is more apparent earlier in darker races. The fundus remains blonde, and choroidal vessels are prominent. Photophobia, nystagmus, and abnormal transillumination of the irides are characteristic features of albinism. Moderately to severely reduced vision is characteristic as a result of foveal hypoplasia and the consequent nystagmus.

Abnormal Macula



Several of the lysosomal storage diseases alter the appearance of the macula, a fact that may be useful in detecting these disorders (Table 95.4). The stored material accumulates in the ganglion cells of the retina, which decreases the transparency of the retina except at the very center of the macula, where no ganglion cells exist. The center of the macula retains its normal cherry-red appearance, in sharp contrast to the surrounding grayish involved fundus.

Sphingolipidoses that may produce a cherry-red spot are Tay-Sachs disease, in which a cherry-red spot may be present shortly after birth or may develop during the first year, and Niemann-Pick disease (infantile), in which about 50% of patients have a cherry-red spot in the macula during the neonatal period. Of the lipidoses, Farber disease shows a grayish discoloration of the macula at 6-8 weeks of age, and GM1-gangliosidosis demonstrates a cherry-red spot in the macula in about 30% of patients before 2 months of

age. The mucopolysaccharidoses are characterized by the abnormal deposition of mucopolysaccharides in the cornea, but the macula appears normal.

Congenital Disc Anomalies

Optic Nerve Hypoplasia

Optic nerve hypoplasia is the most common congenital disc anomaly and is a common cause of congenital blindness. It can be associated with alcohol and drug abuse of the mother. It may be unilateral or bilateral, and may occur with or without any associated neurologic or ocular abnormalities.[65]

It is an abnormally small optic nerve head that may appear gray or pale because of a decreased number of optic nerve axons with normal glial tissue. A yellowish peripapillary ring of sclera and an outer concentric ring of hyper- or hypopigmentation, known as the "double ring" sign, surround the optic disc. The surrounding large retinal veins are usually tortuous[49,112] (Fig. 95.24).

The diagnosis of optic nerve hypoplasia is based upon small optic discs, decreased or normal vision, and visual field defects with corresponding nerve fiber bundle defects. Visual acuity ranges from 20/20 to no light perception. Localized defects with peripheral constriction are common. Visual acuity is determined mainly by the integrity of the papillomacular bundle and does not correlate with the size of the optic disc.[37,90]

Unilateral or bilateral optic nerve hypoplasia may be associated with central nervous system malformations,[13] especially forebrain malformations and endocrinologic abnormalities,[52] as in septo-optic dysplasia (de Morsier syndrome). Focal thinning or absence of the side of the chiasm corresponding to the hypoplastic optic disc can be seen on magnetic resonance imaging (MRI). In bilateral optic nerve hypoplasia, the optic chiasm is atrophied. The prechiasmatic intracranial optic nerve corresponding to the hypoplastic disc is thinned. The diagnosis of optic nerve hypoplasia may be presumed based upon diminished intracranial optic nerves with other neuroradiologic features of septo-optic dysplasia.[14]

Other CNS malformations associated with optic nerve hypoplasia include abnormalities in the cerebral hemispheres and the pituitary infundibulum.[13,37,49,52,65,90,112] Hemispheric migration abnormalities, such as schizencephaly and cortical heterotopia, and hemispheric injury, such as periventricular leukomalacia and encephalomalacia, may occur in 45% of patients with optic nerve hypoplasia.[52] Fifteen percent of patients with optic nerve hypoplasia may have perinatal injury of the pituitary infundibulum leading to necrosis. This brain abnormality is seen as posterior pituitary ectopia on MRI. This is associated with antidiuretic hormone deficiency. Growth hormone deficiency is most often associated with optic nerve hypoplasia. Hypothyroidism, hypocortisolism, panhypopituitarism, diabetes insipidus, and hyperprolactinemia may also occur.[8] Cerebral hemispheric abnormalities that are often associated with thinning or agenesis of the corpus collosum are predictive of neurodevelopmental defects.[13]

Optic Disc Atrophy

Optic atrophy indicates loss of nerve fiber layers forming the optic disc. Clinically it is subjectively graded on the scale of 1-4 (grade 1 atrophy mild pallor of the disc, grade 4 severe atrophy as the optic nerve appears white), but newer technology such as optical coherence tomography allows to objectively quantify the actual nerve fiber amount and consecutive loss. Causes of childhood optic atrophy are listed in Box 95.5.

- DIDMOAD (diabetes insipidis, diabetes mellitus, optic atrophy, deafness) (Wolfram) optic atrophy

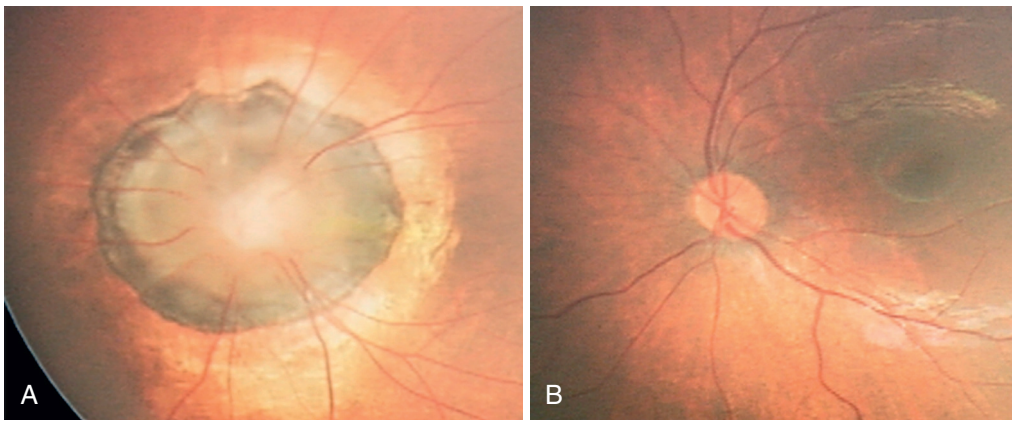
Toxic or nutritional optic neuropathy
Hypoxia
Trauma
Postoptic neuritis
Radiation optic neuropathy
Paraneoplastic syndromes
Neurodegenerative disorders with optic atrophy
- Krabbe disease
- Canavan disease
- Leigh disease
- Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like (MELAS) episodes
- Neonatal adrenoleukodystrophy
- Metachromic leukodystrophy
- Riley-Day syndrome
- Lactic acidosis
- Spinocerebellar degeneration
- Mucopolysaccharidosis

Ocular disorders
- Glaucoma
- Retinal disease
- Vascular disease
- Uveitis
- Optic nerve hypoplasia

Segmental Optic Nerve Hypoplasia

Superior segmental optic nerve hypoplasia may occur in children of insulin-dependent diabetic mothers. These children have no other systemic anomalies and may be found via incidental inferior visual field defects.[59,90]

Megalopapilla



Megalopapilla refers to an enlarged optic disc with no other structural abnormalities. More commonly, it is bilateral. Visual acuity is generally normal. Differential diagnosis should include glaucoma, optic disc coloboma, and orbital optic glioma.[40]

Morning Glory Disc Anomaly

This condition consists of an optic nerve coloboma associated with retinal vascular abnormalities, glial proliferation, metaplasia, and pigment changes around the head of the nerve. The embryologic origin and hereditary factors are unclear. It usually occurs unilaterally in females and rarely in African Americans.[91]

The enlarged optic disc is orange-pink and is located centrally within a funnel-shaped excavation around the nerve head. White glial proliferative tissue lies over the center. Anomalous blood vessels emanate radially from the disc (Figs. 95.25*A, B*). The macula may occasionally be incorporated into the excavation.[91]

Visual acuity is often poor, ranging from 20/200 to a finger counting. The most common complication is retinal detachment, which can lead to further vision loss.[113] Systemically, it can be associated with transphenoidal encephalocele, hypoplasia of the ipsilateral intracranial vasculature, Moyamoya syndrome,[74] and PHACES (*p*osterior fossa malformations, large facial *h*emangioma, *a*rterial anomalies, *c*ardiac anomalies and aortic *c*oarctation; *e*ye anomalies; and *s*ternal abnormalities). MRI and MR angiography should be performed to rule out these conditions.

• Fig. 95.25 A, Morning glory disc anomaly: The defect looks like a fully opened morning glory flower. **B,** Normal appearance of scaled fundus photography.

Optic Disc and Choroidal Coloboma

Coloboma may occur in one or both eyes with equal frequency. The inheritance pattern may be sporadic or autosomal dominant.[32] It has been linked to a mutation of the *PAX6* gene.

A coloboma of the fundus is visible as a defect in the retinal and choroidal layers through which the underlying sclera is visible (see Fig. 95.21). Leukocoria may result. Typical coloboma occur inferonasally, which is the site of the closure of the embryonic fissure. The fissure usually begins to close at the globe's equator and then extends posteriorly toward the optic disc and anteriorly toward the periphery. Any part or this entire region may be involved in the colobomatous defect. The visual prognosis depends on how much of the macula or optic disc is involved. If the defect extends inferiorly to involve the adjacent retina and choroid, then microphthalmia and iris and ciliary colobomas may form.[32]

Colobomas may be associated with other multisystemic congenital syndromes such as CHARGE, Walker-Warburg syndrome, Goltz focal dermal hypoplasia, Aicardi syndrome, Goldenhar syndrome, and linear sebaceous nevus syndrome.[82] Orbital cysts may also be rarely seen with optic disc colobomas.[97] Table 95.5 lists systemic abnormalities that may be associated with optic disc changes.

In CHARGE syndrome, at least three of the following features must be present for the condition: heart defect, choanal atresia, restricted growth, genital anomalies, and ear anomalies or deafness.

TABLE 95.5 Systemic Abnormalities That May Be Associated With Optic Disc Changes

With CNS Abnormalities

Dandy Walker cyst
Arhinencephaly
Anencephaly
Agenesis of corpus callosum
Sphenoidal encephalocele

With Chromosomal Abnormalities

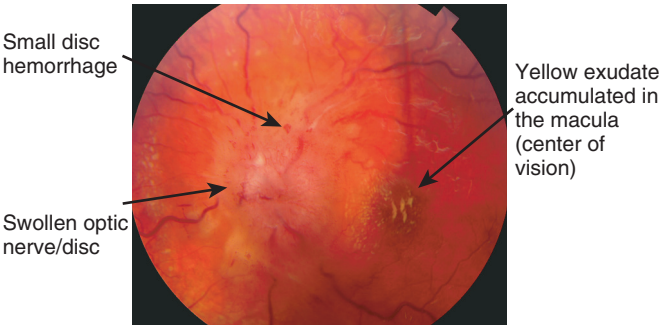
Trisomy 13 (Patau syndrome)
Trisomy 18 (Edward syndrome)

With Congenital Syndromes

Meckel-Gruber syndrome (autosomal recessive)
Goltz syndrome (X-linked dominant)
Lenz microphthalmia syndrome (X-linked recessive)

CHARGE Association: With at Least Three of the Following Features

Coloboma
Heart defects
Atresia of the choanae
Retardation of growth and development
Genital hypoplasia
Ear abnormalities and/or hearing loss



Optic Disc Pit

Optic disc pit is a congenital oval or round depression in the optic nerve head. Its incidence is 1 in 11,000, and it usually occurs sporadically. Most occur unilaterally. In unilateral cases, the affected disc is slightly larger than the normal one. Optic pits may appear gray, white, or yellowish. They average about 0.3 disc-diameters in width and are often located temporally. Visual acuity is usually normal, but approximately 50% of patients with optic disc pits have visual field defects. This condition may lead to retinal detachment and macular edema or hole.[16,38]

Optic Disc Drusen

Drusen are an accumulation of substances (calcium, mucopolysaccarides, amino acid, ribonucleic acids, deoxyribonucleic acid, and iron)[101] buried within the optic disc, causing disc elevation. It is important to distinguish this relatively common (3.4-24/1000 population) condition from other causes of disc elevation, primarily papilledema (Fig. 95.26). The vast majority is seen bilaterally. It is inherited as an irregularly autosomal dominant disorder. Most are asymptomatic. Although very rare, significant visual field defects and visual acuity decrease may be seen.[10] These changes are generally slowly progressive.

The accumulated substances can be buried in the disc (the most common appearance in newborns), or may be visible when they are superficial. Therefore, direct visualization could be diagnostic, but when in doubt, B-scan ultrasonography is the most reliable method to detect the calcium in the drusen. Although visual evoked potential (VEP) is also abnormal in 41%-97% of patients, it is not a reliable diagnostic modality for drusen.[63] Treatment is often not needed, but monitoring for elevated intraocular pressure and vascular complications along with other possible associated disorders (retinitis pigmentosa, pseudoxanthoma elasticum)[20] is recommended.

• **Fig. 95.26** Papilledema: Left optic nerve significantly swollen with no visible distinct disc margins, tortuous veins, macular exudate accumulation, and small hemorrhages at disc margins.

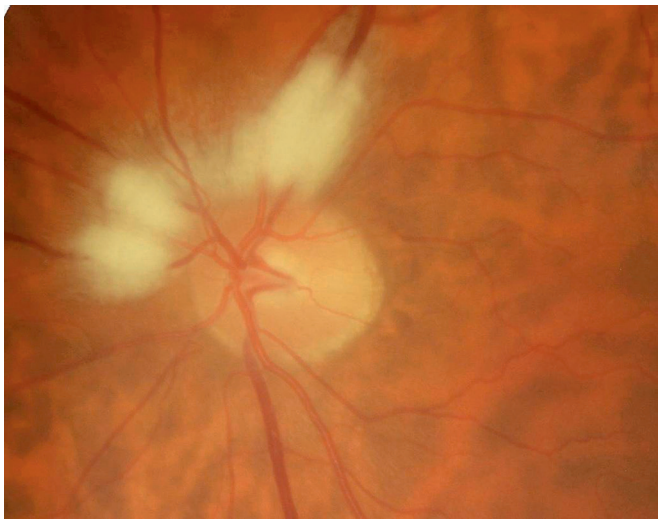
Hyaloid System Remnants



The hyaloid vascular system and the glial sheath of Bergmeister should normally atrophy spontaneously by the end of the gestation. The embryonic vitreous system develops as a complex network of vessels that grows anteriorly from the disc to surround the developing lens and normally involutes during the third trimester. The persistence and proliferation of these normally transient vessels of the primary vitreus, especially the posterior tunica vasculosa lentis (vascular remnant behind the lens), leads to the formation of persistent hyperplastic primary vitreus (PHPV), also known as primary fetal vasculature (PFV). PFV causes a white pupillary reflex that must be distinguished from retinoblastoma. Disc abnormalities are determined by the extent of persistence of glial and/or vascular components.

At birth, PFV may appear as a strand or plaque of white tissue immediately behind a clear lens. Vessels are frequently seen to radiate from the plaque's center, and the retrolental mass may, therefore, be pinkish white. When the pupil is dilated, the ciliary processes are often drawn centrally along the posterior surface of the lens toward the central mass. Almost always unilateral, PFV occurs in term infants without a history of oxygen therapy. The involved eye is commonly microphthalmic. PFV should be suspected in the neonate with a rapidly progressive unilateral cataract. Differentiation of PFV from ROP is usually possible because of the unilateral involvement and occurrence of PFV in a term infant. Differentiation from retinoblastoma is important. The absence of calcification within the eye, as occurs in retinoblastoma, is a critical finding. A persistent embryonic iris vessel or one that notches the pupil suggests the presence of PFV, even when an opaque lens obscures its presence. Ophthalmic ultrasonography can help in the diagnosis of difficult cases. Surgical removal of the lens and vitreous with optical correction and amblyopia treatment must be attempted very early to achieve any degree of success in recovering vision.

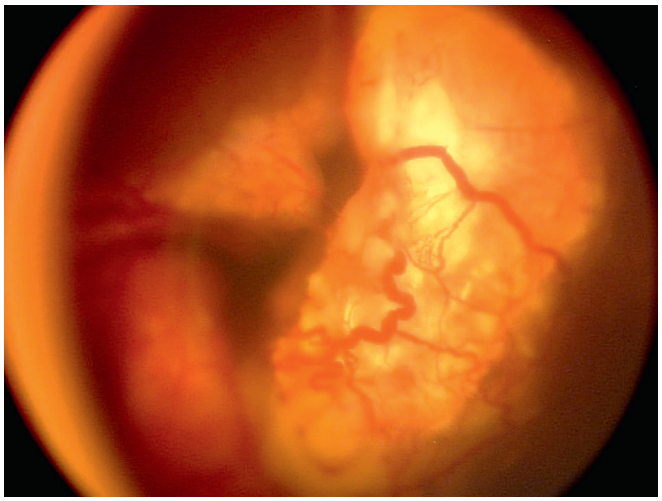
Myelinated Nerve Fibers

During fetal development at 5 months' gestation, myelination progresses from the lateral geniculate body to the optic tracts, then the optic chiasm, and last to the optic nerve by 8 months of gestation.[72] Anomalous myelinated nerve fibers occur when myelination extends beyond the posterior portion and into the disc and peripapillary areas. The myelinated areas have a whitish, feathery appearance and are usually continuous with the disc at the upper or lower poles (Fig. 95.27). The process may progress after birth but does not usually extend into the macula. Visual acuity is not affected.

In the general population, it is seen at a frequency of 0.3%-1%.[72] It is inherited as an autosomal dominant disorder and occurs unilaterally in 80% of patients.[72] It may be associated with systemic disorders such Gorlin syndrome[25] (multiple basal cell nevi), which is an autosomal dominant disorder that may present in children with cutaneous lesions (small pits in the hands and feet, jaw cysts, and other bony abnormalities).

• **Fig. 95.27** Myelinated nerve fiber layer: Just above and nasal to the optic nerve head, the white, feathery appearance of the myelinated nerve fibers is seen. These myelinations will be above the vessels. These are benign findings and rarely progress.

Intraocular Tumors



Retinoblastoma

Retinoblastoma is the most frequent malignant intraocular tumor in the pediatric population, including neonates. The tumor arises sporadically or may be hereditary. Retinoblastoma occurs in about 1 in 15,000-18,000 live births, with no predilection for sex. The predilection for race is yet to be defined. Up to 30% of cases are bilateral. Bilateral cases are transmitted in an autosomal dominant manner with incomplete penetrance. Only 10%-15% of unilateral cases are hereditary. The average age of presentation in bilateral cases is about 10 months, and 21 months in unilateral cases.[103] About 75% of cases of retinoblastoma include calcium deposits, which can be detected with B-scan ultrasonography and computerized tomography. Magnetic resonance imaging of the brain may detect a pinealoblastoma[46] (trilateral disease).

In the United States, clinical presentation is leukocoria in 60% or strabismus in 20% with other presentations (red eye, glaucoma, and screening by pediatrician or ophthalmologist) in the minority (Fig. 95.28). Leukocoria is detected more often by a parent or family member (80%) than a medical professional despite the routine screening with red reflex.[124] The eye with leukocoria has relatively advanced disease. Screening the red reflex after dilation might be a way to detect retinoblastoma in an early stage with improved visual prognosis and ocular survival.

The genetic basis for retinoblastoma has been widely studied. The gene, located on the q14 band of chromosome

• **Fig. 95.28** Retinoblastoma: White calcific retinoblastoma filling the eye, the retinal vessels seen over the lesion; the retina has detached completely secondary to the tumor.

13, is a tumor suppressor gene. Mutation or inactivation of both alleles in a vulnerable retina cell results in transformation of the cell into retinoblastoma.[21] The tumor originates in the retina and grows anteriorly into the vitreous or posteriorly into the choroid. If the tumor disrupts vision, a sensory strabismus may result. Hence, all infants with strabismus require a fundus examination with dilated pupils to exclude retinoblastoma. With further enlargement, the tumor produces secondary glaucoma, which may be associated with pain and photophobia or symptoms identical to those of congenital glaucoma. With extension into the anterior chamber, an opaque layer of leukocytes (pseudohypopyon) or spontaneous bleeding (hyphema) can occur. With exophytic growth, retinal detachment can be the presenting sign. Proptosis is a late finding. Massive necrosis of the tumor can cause a picture mistaken for orbital cellulitis. Hence, a fundus examination should be part of any work-up of orbital cellulitis. The diagnosis of retinoblastoma is made noninvasively by exam under anesthesia with ophthalmoscopy, orbital ultrasound, and fluorescein angiography. Calcification identified within the eye on CT scan, ultrasound, and MRI findings helps to confirm the diagnosis.[103] The differential diagnosis may be exceedingly difficult if the tumor is advanced or atypical, and enucleation may be required for histologic study and positive identification. Other lesions that rarely can simulate retinoblastoma in neonates are coloboma of the fundus, congenital retinal fold, retinal dysplasia, persistent hyperplastic primary vitreous, retinoschisis, retinal detachment, organized vitreous hemorrhage, or scarring from ROP.

The treatment of retinoblastoma is determined by its size and location. Treatment of retinoblastoma involves a team approach between pediatric oncologists, radiologists, and ophthalmologists. The most significant factor in the prognosis is the stage of disease when treatment is instituted. When retinoblastoma is limited to the eye, 98% of patients can expect a 5-year, disease-free survival.[2] If the retinoblastoma remains in the optic nerve anterior to the lamina scleralis, the prognosis is good. Hematogenous spread to the bone and liver,[80] along with direct spread to the brain, indicates very poor prognosis.

Local treatment modalities for early, small tumors include photocoagulation, plaque radiotherapy, trans-pupillary thermotherapy, and cryotherapy. For more advanced tumors, primary systemic chemotherapy is followed by local consolidation with the same treatment modalities as above (photocoagulation, etc.). Enucleation continues to be a treatment modality that is often used in unilateral advanced retinoblastoma in order to avoid chemotherapy. Selective intra-arterial chemotherapy is also being investigated as an enucleation-sparing procedure.[1,102] With extension beyond the globe, the cure rate is reduced. Chemotherapy is used in this case to prevent metastatic disease. Patients with the familial form of retinoblastoma also are at risk for developing secondary malignancies.[80] The most common secondary malignancy is osteogenic sarcoma, usually occurring in the teen years. Pinealoblastoma forms the third part of what is called trilateral retinoblastoma. This malignancy usually occurs during the first 4 years of life.

Astrocytic Hamartoma

Astrocytic hamartoma can be found infiltrating the optic nerve or in the retina. They occur bilaterally in 50% of patients with tuberous sclerosis complex.[64] The most common type appears as a smooth, flat, salmon-colored lesion that is either round or oval shaped. It is semitransparent and located in the superficial posterior pole of the retina. Astrocytic hamartomas consist of astrocyets, calcium, and amorphous material. They may demonstrate auto-fluorescence in angiography. Visual function is often normal unless the optic disc or the macula is affected. As they typically do not grow or affect vision, treatment is not needed. It may be an isolated phenomenon in 30% of cases. Calcified hamartomas may be seen in the basal ganglia and ventricles on MRI. Larger tubers may be seen in the cortical gray matter. The diagnosis of tuberous sclerosis is based on clinical criteria and can be confirmed with molecular gene testing for chromosome 9q34 and chromosome 16p13.[96] Astrocytic hamartomas can also be associated with neurofibromatosis type 1.[94]

Racemose Hemangioma

Racemose hemangiomas are rare arteriovenous anastomoses consisting of engorged retinal vessels entering the optic disc, then into the peripheral retina, and finally out of the optic disc. They are thought to be congenital abnormalities, but remodeling may occur over the years.[5] About one-third are associated with Wyburn-Mason syndrome (arteriovenous malformations in the midbrain that are ipsilateral to a separate retinal lesion). Growth into the orbit can cause diplopia, proptosis that is usually nonpulsatile, orbital bruit, and conjunctival vascular dilatation[128]. They are usually stable.

• **Fig. 95.29** Exotropia. The patient is fixing with the left eye while the right eye is drifting outward. It can also be easily identified via the corneal reflex, which is seen in the center of the pupil in the left eye while also seen in the nasal aspect of the iris in the right eye.

Neuromuscular Abnormalities

Strabismus

Strabismus or misalignment of the eyes is approached based on etiology.[51,126] Horizontal deviations are the most frequent type of strabismus and can be further classified in esodeviations, eye deviated inward, and exodeviations (Fig. 95.29), eye deviated outward. Vertical deviations are rare in infancy similar to other stages of life. Both horizontal and vertical deviations could be comitant or incomitant. Comitant strabismus has the same amount of deviation in all gazes. In infancy, infantile exotropia and early intermittent exotropia are the most frequent types of comitant exodeviation. Congenital/infantile esotropia, early accommodative esotropia, esotropia associated with neurologic conditions or prematurity, and sensory esotropia are frequent forms of comitant esodeviation in infancy. Accommodative esotropia is secondary to exaggerated accommodative efforts in significant hyperopia or with vision directed at a near target. Sensory strabismus can occur because the oculomotor system requires a certain level of vision in both eyes to maintain ocular alignment. If vision is lost in one or both eyes, an ocular misalignment may follow. Unilateral vision loss results more often in esodeviation, unlike older ages when it results more in exodeviation. It is paramount, therefore, to visualize macula in evaluation of esotropia in infants. Retinoblastoma can manifest with sensory esotropia.

Incomitant deviations are variable on various gaze positions and result from impairment of the globe movements secondary to muscular restrictions or muscular weaknesses. Fractures with entrapment of muscles or orbital tumors can cause restrictive strabismus. Cranial nerve palsies and congenital myasthenia gravis are the main causes for nonrestrictive incomitant strabismus in infants. In 4th cranial nerve palsy, compensatory head position to the opposite side along with incomitant vertical strabismus can be noticed as early as a few months of life. This condition needs to be differentiated from more common muscular torticollis, as strabismus surgery done in timely fashion is the correct treatment in 4th cranial nerve palsy and resolves compensatory head tilt. Other forms of incomitant strabismus—alphabet patterns, Duane syndrome, or Brown syndrome—are likely present at this age group but hard to diagnose given the low degree of cooperation.

To further complicate the evaluation of strabismus in infancy, there are two conditions that can be confused with true strabismus. Early in infancy, there could be small angle misalignments of variable magnitude before the establishment of firm foveal fixation. This condition resolves with development of foveal fixation and binocularity and establishment of firm control of the eye movements; this type of misalignment leaves no long-term consequences. Another condition is pseudostrabismus that can present in two types: pseudoesotropia and pseudoexotropia. In pseudoesotropia, the large nasal bridge, prominent epicanthal folds, or other configurations of face in the infant can create an appearance of inward deviation of one or both eyes. Symmetric red reflexes and corneal light reflexes with no eye shift at the cover–uncover test differentiate pseudoesotropia from true esotropia. It is important to remember that epicanthal folds may exist with true esotropia, and if there is an intermittent esotropia, the eye may be straight on one examination. Infants with severe ROP causing a dragging of the macula may appear to have strabismus when the dystopic maculae are aligned. Again, there is no shift with cover–uncover tests.

Treatment of strabismus is done by pediatric ophthalmologist specialist after a complete eye examination, including careful cycloplegic refraction and dilated fundus exam. Surgery is the main treatment in infantile esotropia and is performed after correction of significant refractive errors and treatment of associated amblyopia. This approach maximizes the chance of stable surgical alignments of the eye. Surgery should be undertaken early to increase chance of binocular cooperation (between 4 and 6 months in healthy infants).

Nystagmus

Nystagmus consists of rhythmic oscillations of the eyes. Nystagmus can be unilateral or bilateral; it can be horizontal, vertical, torsional, or a combination of the above. Jerk nystagmus has one direction faster; pendular nystagmus has both directions of equal speed. Nystagmus is said to be infantile (infantile nystagmus syndrome, INS) if onset is before 6 months of age and acquired after that. Documenting the direction (horizontal, vertical, and torsional), frequency (mild, moderate, or fast), amplitude (small, moderate, or large), laterality (one or both eyes), associated head positioning is useful to help guide the possible underlying cause of the nystagmus. In infancy, nystagmus can be divided into nystagmus secondary to poor vision, nystagmus associated with neurologic anomalies, and various types of congenital/infantile nystagmus. Optic nerve atrophy, hypoplasia, or severe optic nerve anomalies along with early-onset retinal dystrophies or macular scars are the main causes for nystagmus associated with poor

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

vision in infancy and generally pendular type nystagmus is seen with these conditions. Electroretinography or brain imaging using MRI are required for further characterization of these conditions. Brain imaging is also necessary in nystagmus associated with neurologic findings. Infantile nystagmus syndrome (INS) is diagnosed based on clinical characteristics, seemingly unaffected vision, and absence of other neurologic signs. No brain imaging is necessary if diagnosis of INS is established. However, in spasmus nutans (triad of unilateral nystagmus, head nodding, and torticollis) brain imaging is mandatory. Fine and rapid, asymmetric nystagmus seen in spasmus nutans can resemble nystagmus seen in chiasmal glioma. Hence, the benign nature of spasmus nutans can be demonstrated only retrospectively after disappearance (usually within 2 years).[17]

Opsoclonus

Opsoclonus is a striking ocular motility disorder characterized by involuntary, chaotic bursts of multidirectional, high-amplitude saccades without an inter-saccadic interval. When the oscillations are clinically horizontal, they are termed ocular flutter. Hoyt et al. have reported that opsoclonus may occur as a transient phenomenon in healthy neonates.[50] In this case, this phenomenon disappears by 6 months of age.

The major diagnostic consideration for opsoclonus in the first several years of life is a neural crest tumor such as neuroblastoma. Neuroblastoma is found in approximately half of cases with opsoclonus in this age range.[117] Opsoclonus also occurs commonly as a part of a "benign" encephalitis (Kinsbourne myoclonic encephalopathy, dancing eyes, and dancing feet).[62]

Amblyopia

Amblyopia represents an uncorrectable-with-glasses decrease in vision in one or both eyes with no apparent structural abnormality of the eye to explain it. It is a consequence of various organic processes that interfere with development of vision during a critical young age. Amblyopia can develop at any time during the "sensitive period" of visual development, usually during the first 7 years in humans, and can be treated if discovered within this same time frame of plasticity. When a diagnosis of amblyopia is made, other organic causes need to be excluded. Even if organic causes are present, the amblyopia might still be partially responsive for the decrease in vision and is important to treat in a timely manner for a better success rate. The main causes are strabismus, refraction, occlusion, and visual deprivation.

Strabismic amblyopia occurs in children who first develop strabismus and then favor one eye. The constantly deviated eye will then develop amblyopia; hence, strabismic amblyopia is always unilateral. Refractive amblyopia results from large refractive errors that create significant blurry vision. This can be a bilateral or unilateral process.

Deprivation amblyopia is caused by opacities in the visual axes, such as cataracts or corneal scars or macular and optic nerve conditions. If the visual obstruction is not cleared by 3 or 4 months of age, the amblyopia becomes very dense and unresponsive to treatment—hence the urgency to identify and treat congenital cataracts.

Treatment of underlying causes of amblyopia is important for the success of therapy. Various methods of visual penalization are applied to the good-seeing eye in the treatment of monocular amblyopia. Patching is the oldest and most often used method in all forms of monocular amblyopia. Atropine daily can be used as first-line therapy in monocular moderate amblyopia or as a second line in patch failure. Other methods of penalization are described and available. If bilateral amblyopia is present because of high refractive error, glasses are prescribed.

The Blind Infant

The definitions of blindness that are used in literate children (legal blindness: Snellen visual acuity less than 20/200 or visual field less than 20 degrees) are not applicable to infants. Also, vision in this age is normally very low and changing rapidly. The majority of tests used to estimate vision in infants give, at the most, 20/400 vision at birth and vision less than 20/40 by 1 year of age. For these reasons, a more appropriate term at this age is apparent blindness. This is suggested by history and examination clues: absence of any light reaction including no pupillary reaction, absent eye movements, nystagmus early in life, searching eye movements, oculodigital sign, paradoxical pupillary reaction (dilation with light), staring at bright lights, and waving of hands between the eyes and a light source. Important medical history details include history of prematurity, perinatal hypoxia, and family history of blindness at young age. Three major causes for blindness at this young age are: obvious eye malformations, anterior visual pathways disease (retina, optic nerve, chiasm) that can be subtle, and cerebral visual impairment. An external abnormal eye is occasionally a quick diagnosis when microphthalmos, bilateral white cataract, corneal opacities, advanced ROP, persistent fetal vasculature, or retinoblastoma are present. For the subtler cases of anterior visual pathway disease versus cerebral visual impairment, nystagmus can be the distinguishing factor, as it is normally present in the former and absent in the latter. Optic nerve conditions require further MRI of the brain to characterize. Nystagmus and no optic nerve pathology indicate electroretinogram (ERG) to demonstrate the presence of retinal dystrophy. The possibility of cerebral visual impairment suggested by normal structure of the eye and no nystagmus can be confirmed with normal vestibulo-ocular response (VOR) with prolonged "after" nystagmus. History of prematurity in this scenario suggests a form of cerebral visual impairment, namely periventricular leukomalacia that can be confirmed with MRI of the brain. Absence of VOR and nystagmus suggests the presence of congenital motor apraxia, bilateral Duane syndrome, or Möbius syndrome,

when the baby cannot move the eye but vision may still be good. Likewise, after a generalized seizure, the movements of the eye or reaction to visual stimuli can be suppressed and simulate blindness with recovery after the postictal period.[15]

Eye Findings in Chromosomal Syndromes

Chromosomal anomalies involve significant alteration of genetic materials with multiple genes being affected simultaneously. However, genes that control the development and function of the eye are spread on multiple chromosomes. Therefore, it is not surprising that the majority of chromosomal anomalies involve the eye in some form. Following is a selection of eye features that are important, given the frequency or severity.

Trisomy 21

Ocular findings associated with Down syndrome are extensive. Because of this, children with Down syndrome should be examined by an ophthalmologist during infancy and periodically after that. From front to back, the eye findings are as follows: significant refractive errors, amblyopia, nystagmus, strabismus, nasolacrimal duct obstruction, epicanthus, telecanthus, upward slant of palpebral fissures, blepharitis, keratoconus, glaucoma, iris nodules (Brushfield spots), cataract, and optic nerve swelling. Caution should be exercised when using dilating drops in these children, as they can have an exaggerated systemic reaction to atropine, and atlanto-axial instability can induce a risk in case of neck hyperextension.

Trisomy 13

Ocular findings are present in 90% of Patau syndrome subjects.[105] Intraocular cartilage found at histopathology is virtually pathognomonic for trisomy 13.[56] Typical inferonasal iris coloboma with sectoral cataract in the same location is highly suggestive of this syndrome. Other eye features in this syndrome are microphthalmia, cyclopia, short/slanted palpebral fissures, ptosis, hypertelorism, corneal opacities, luxation of the lens, coloboma of the lens, persistent tunica vasculosalentis, persistent fetal vasculature (formerly known as persistent hyperplastic primary vitreous), typical coloboma of the choroid, and retinal dysplasia.[56,105]

Trisomy 18

The most common eye anomalies in Edwards syndrome include epicanthus, hypertelorism, and hypoplastic supraorbital ridges. Ankyloblepharon filiforme adnatum (strands joining the upper and lower lids together) is very suggestive of trisomy 18. Less frequently, strabismus, cyclopia, colobomatous microphthalmia, microcornea, corneal opacities, congenital glaucoma, posterior subcapsular cataract, and retinal depigmentation are present in this syndrome.

11p Abnormalities

Infants with a deletion of the short arm of chromosome 11 involving the *PAX6* gene and the adjacent *WT1* gene on the 11p13 band have the WAGR syndrome of aniridia, genito-urinary abnormalities, and mental retardation.[31] Wilms tumor has been diagnosed in a significant percentage of children with this chromosomal deletion and must be evaluated with periodic ultrasounds of the abdomen for a number of years.

13q Abnormalities

The most important possible finding that requires a comprehensive retinal examination is retinoblastoma. The retinoblastoma gene is a tumor suppressor gene that is lost in 13q deletion. That creates a situation when cells throughout the body have only one copy of the tumor suppressor gene and are vulnerable to lose that copy and start developing tumors, among them retinoblastoma, which tends to be bilateral and start at a young age. Other ocular abnormalities are almost always present and severe, including microphthalmia, iris and choroidal colobomas, ptosis, cataracts, and down-slanting palpebral apertures and epicanthus.

Turner Syndrome

Strabismus, ptosis, congenital cataracts, and occasionally corneal nebulae and blue sclerae in the neonatal period have been described as being associated with Turner syndrome.

Eye Findings in Craniofacial Syndromes

Eye abnormalities can be associated with congenital anomalies of the face, skull, or head in both craniosynostotic and nonsynostotic forms.

Craniosynostosis Syndromes

There is well-defined eye involvement in craniosynostosis syndromes that requires careful follow-up and management. Proptosis is secondary to maldeveloped, small orbits and can further be complicated by lagophthalmos, exposure keratopathy, or globe subluxation. Globe subluxation, when the globe protrudes anteriorly to the eyelids, is an ocular emergency that needs to be treated by the caregiver or medical personnel immediately in order to avoid optic nerve ischemic damage with permanent vision loss. One approach for globe subluxation is to place a finger on the visible conjunctiva in the interpalpebral area and apply firm pressure until the globe is behind the eyelids. This approach avoids damage of the cornea. Lagophthalmos with exposure keratopathy and possible corneal scar is another cause of vision loss requiring an aggressive approach consisting of frequent lubrication, moist chamber, taping the eyelids

closed at night, and tarsorrhaphy. The definitive treatment of lagophthalmos is orbital expansion. The optic nerve can develop edema or atrophy. Edema is secondary to increased intracranial pressure, secondary to difficult expansion of the cranium, and less often due to compressive optic neuropathy in a tight optic canal. Optic atrophy is the end result of longstanding optic nerve edema. Strabismus is a common occurrence in craniosynostosis with V pattern exotropia and inferior oblique overaction seen as characteristic types.

Because of comparable cranial and orbital anomalies, eye findings can be similar in the other craniosynostosis syndromes such as Crouzon syndrome, Apert syndrome,[58] Saethre-Chotzen syndrome, and Pfeiffer syndrome.

Hemifacial Microsomia

Ocular manifestations can range from clinical anophthalmia to minor fissure asymmetry. Goldenhar syndrome is probably a variant of this group, with characteristic limbal dermoids and orbital lipodermoids. Limbal dermoids are reported more frequently than lipodermoids and are occasionally bilateral. Another common finding is an upper eyelid coloboma, almost always on the more affected side. Less frequent findings are Duane syndrome and microphthalmia.[114]

Terminal Transverse Defects With Orofacial Malformations and Oromandibular-Limb Hypogenesis

These are a heterogeneous collection of syndromes with a wide variety of facial and limb anomalies; they include Möbius syndrome. The minimal findings of this syndrome are abduction weakness (cranial nerve 6 palsy) and facial nerve palsy, with frequent limb and tongue anomalies.

Pierre Robin Sequence

The Pierre Robin sequence is characterized by micrognathia, glossoptosis, and cleft palate. Pierre Robin sequence can occur in isolation or be part of a syndrome. About 10% of patients with Pierre Robin sequence have Stickler syndrome as well, with the additional features of high myopia, propensity for retinal detachment, cataracts, deafness, and arthritis.[30]

Waardenburg Syndrome

Waardenburg syndrome is transmitted as an autosomal dominant trait and has been divided into four types based on clinical attributes. The most common is Waardenburg syndrome type 1. It is associated with lateral displacement of the medial canthi (i.e., telecanthus), abnormal position of the lacrimal puncta, coalescing of eyebrows (i.e., synophrys), white forelock, heterochromia irides, retinal pigmentary changes, and sensorineural deafness.

Cornelia de Lange Syndrome

The typical facial appearance in infants with Cornelia de Lange syndrome is a low hairline, synophrys, long eyelashes, and a small upturned nose. Eye disorders, which are less frequently encountered, include hypertelorism and downslanting palpebral fissures, dacryostenosis, strabismus, nystagmus, ptosis, severe myopia, and pupillary abnormalities.[83]

CHARGE Association

This heterogeneous group of anomalies (colobomas, heart defects, choanal atresia, restricted growth, genital hypoplasia, and ear malformations) presents with typical coloboma of the optic nerve, choroid, or iris in the inferior nasal direction. Other eye involvements have been described: microphthalmia, refractive errors, and vertical strabismus.[76]

Deformation Syndromes

Congenital deformations resulting from intrauterine restraints are common and may involve craniofacial structures. Congenital torticollis is one of the deformation syndromes that can have ophthalmic implications, as it may be confused with superior oblique palsy with compensatory head posture.[15]

Eye Findings in Neurocutaneous Disorders (Phakomatoses)

Eye findings are important manifestations in phakomatoses, which are a group of disorders featuring discrete hamartomas in multiple organ systems including the skin and the brain. Four disorders have been designated as classic phakomatoses with other conditions sometime included as well. From the four classic phakomatoses—neurofibromatosis, tuberous sclerosis, encephalotrigeminal angiomatosis, and retinal angiomatosis—only the first three are active in infancy or early childhood.

Neurofibromatosis

Neurofibromatosis (NF) is described in two types. Both NF type 1 and 2 are autosomal dominant genetic conditions with high penetrance and high spontaneous mutation rates. NF1 (von Recklinghausen disease) is characterized by melanocytic and glial cell lesions distributed in the brain, skin, and eye. The occurrence of these lesions is highly age dependent with some features present early in life with stabilization or regression while other features start late with subsequent progression throughout life. Overall NF1 is rarely diagnosed in neonates. Early ophthalmic manifestations of NF1 are plexiform neurofibroma of the upper eyelid, glaucoma, optic nerve glioma, and sphenoid

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

dysplasia. Neuroimaging should be obtained in patients with ocular pulsations, neurofibromas of the eyelid, afferent pupillary defect, or optic nerve swelling. Plexiform neurofibroma in the area suggests a 50% risk for glaucoma. Progressive enlargement of the globe or buphthalmos is seen if glaucoma with high intraocular pressure is present before 2 years of life. Optic nerve glioma, although rare with a rate of up to 5%, is an important cause of morbidity and mortality in NF1. Iris Lisch nodules that are often sought to help in early diagnosis are rarely seen in infant and in only a 25% minority by 2 years with presence in 90% by puberty.[86] Despite this, Lisch nodules are valuable features as they have a tendency to be present before the hallmark lesion of NF1, nodular neurofibromas of the skin. NF2 is less common than NF1 and has the hallmark lesion of bilateral eighth nerve tumors, hence the name of central NF. Early-onset posterior subcapsular or wedge-shape cataracts have been described in NF2.

Encephalofacial Angiomatosis (Sturge-Weber Syndrome)

As the name implies, this condition encompasses angiomas of the facial skin with ipsilateral leptomeningeal vascular malformation. There is no apparent hereditary pattern. Ocular complications of Sturge-Weber syndrome include glaucoma and chorioretinal angioma. Glaucoma can present in two types, one of them resembling congenital glaucoma with enlargement of the globe, high myopia, and amblyopia. The associated choroidal angioma is usually indistinct and difficult to visualize without indirect ophthalmoscopy. If present, it may lead to macular edema and decreased visual acuity.

Tuberous Sclerosis (Bourneville Disease)

Hamartomas of the brain that cause seizures and mental retardation associated with hamartomas in the eyes, kidney, heart, lungs, and skin are the hallmarks of this autosomal condition. The spontaneous rate of mutation is very high, similar to that with NF. Retinal lesions, called astrocytic hamartomas (or phakomas) have one of two distinct appearances. Phakoma type 1 is seen at very young age and has the appearance of gray-white nodules with smooth, flat surface and indistinct borders. Consequently, these lesions are difficult to visualize and special techniques are employed on indirect ophthalmoscopy in order to avoid missing the early lesions.

Ocular Trauma

Two types of eye trauma are seen only in this age group: birth trauma and shaken baby syndrome. Regular contusions and lacerations happen at this age also but with decreased frequency compared with late ages owing to decreased mobility in infants.

Birth Trauma

Birth trauma to the eyes is associated with the duration of labor and difficulty of delivery.[92] Lid petechiae and hemorrhages, observed more often with face presentations than with vertex presentations, usually resolve rapidly without treatment. Subconjunctival hemorrhages are also common and require no treatment. Such findings, however, should increase the suspicion of associated intraocular injuries.

Retinal hemorrhages are common after delivery, occurring in 78% of newborns after vacuum delivery, 30% after normal vaginal delivery or with forceps assists, and only 8% after cesarean delivery.[53] These retinal hemorrhages are usually small, multiple, and scattered throughout the retina; they may persist for months and must be considered in the differential diagnosis of suspected nonaccidental trauma (shaken baby syndrome).[53] Bleeding into the orbital contents (retrobulbar hemorrhage) can result from birth trauma. This bleeding produces a unilateral proptosis that tends to increase gradually in size during the first 3 or 4 hours after birth. Ecchymosis of the lids can be associated findings immediately or 1-2 days later. The differential diagnosis includes dermoid cysts, teratomas, and other congenital tumors of the orbit. The hematoma usually absorbs spontaneously over 1-2 weeks. It is important during this time to ensure that the cornea is not dry from exposure or abraded and that the retinal circulation is not compromised. A detailed fundoscopic exam is indicated, and if it shows impairment of arterial or venous circulation, immediate surgical decompression of the orbit is required. Forceps deliveries, particularly when associated with improper application, can produce bruises and lacerations of the lid or globe.[48] A forceps mark or lid laceration requires a careful and complete examination of the orbit and globe for associated injuries.[75] Forceps application can produce a rupture in the cornea's endothelial basement membrane (Descemet membrane). Seen with magnification, these ruptures appear as vertical lines in the posterior portion of the cornea. They can lead to rapid corneal edema (hydrops) due to compromised water pump mechanism of the endothelium, with a cloudy appearance that must be differentiated from other congenital corneal opacities. Children with Descemet membrane ruptures can develop astigmatism and dense amblyopia. Traumatic forceps delivery has been known to cause a variety of other ocular injuries, including Purtscher retinopathy, choroid ruptures, and traumatic optic neuropathy.[57] Ocular injury in the newborn has also been reported as a result of fetal monitors,[66,79] surgical instruments,[110] phototherapy lights,[88] prenatal maternal injury, and amniocentesis.[85]

Shaken Baby Syndrome

Forceful, repeated back and forth movement of the head can result in devastating and blinding ocular injuries. Characteristic hemorrhages involve preretinal, intraretinal, and

subretinal spaces; are numerous; and extend in the far periphery of the fundus.

Dome-shaped hemorrhagic lesions with white borders represent hemorrhagic retinoschisis and when associated with characteristic hemorrhages are said to be diagnostic of shaken baby syndrome. The retina can even be folded in a circumferential manner along the vascular arcades surrounding the macula, another finding highly suggestive of shaken baby syndrome. Retinal hemorrhages may resolve without sequelae, but involvement of the optic nerve, macula, or occipital cortex can produce profound lifelong visual loss.[60] The extent and type of retinal hemorrhages that occur in shaken baby syndrome can be pathognomonic of the syndrome and may support the legal prosecution of the offender[116] (see Fig. 95.23). Accidental head trauma and cardiopulmonary resuscitation in infants do not result in the type and extent of retinal hemorrhage seen in shaken baby syndrome.[87,115]

Neonatal Ocular Infections

Neonatal Conjunctivitis (Ophthalmia Neonatorum)

Neonatal conjunctivitis represents inflammation or infection of the conjunctiva in the neonatal period. What makes an otherwise benign condition a public health concern requiring prophylaxis at birth in all neonates is the possibility of long-term vision loss and systemic associated conditions. Neonatal conjunctivitis is the most common infection in the first month of life with incidence from 1%-24%.[33] The four categories of neonatal conjunctivitis are chemical, bacterial, chlamydial, and viral. Conjunctival injection, chemosis, discharge, and eyelid edema can occur with all subtypes of neonatal conjunctivitis. Clinical history, most importantly prenatal history, and clinical elements such as character of the discharge, presence of chemosis and membranes, or skin vesicles can suggest the specific etiology and direct laboratory testing.

Chemical conjunctivitis occurs 1-2 days after instillation of silver nitrate 1% or other antibiotics for prophylaxis at birth. Typical chemical conjunctivitis is bilateral and has a low amount of purulence; the Gram stain shows no organisms, and it resolves spontaneously within 2 days. Alternative treatments for neonatal prophylaxis other than silver nitrate 1% include erythromycin ointment 0.5%, povidone iodine 2.5%, and tetracycline ointment 1%.

Chlamydial conjunctivitis is now a common infection in the neonatal period with higher rates in absent prenatal care. The infection is typically acquired from the mother as the child passes through the birth canal, although it can occur after cesarean section. This type of conjunctivitis develops typically in the 2nd week of life with unilateral or bilateral mucopurulent discharge with possible pseudomembranes. Evolution is chronic with disappearance of discharge after weeks or months, but with the possibility of scarring of the conjunctiva or cornea and possibility of systemic spread and complications. The usual cultures and Gram staining are unhelpful in the diagnosis of chlamydia. Cell culture is the gold standard because of high specificity but is expensive. Diagnosis can be made more conveniently by Giemsa staining of a conjunctival scraping or by a variety of commercially available antibody or PCR tests. Chlamydial conjunctivitis is treated with erythromycin ointment three times a day for 2-3 weeks. Systemic antibiotics are necessary because chlamydia can cause pneumonia, otitis, or nasal congestion.[98]

Neisseria gonorrhoeae is an acute, severe, purulent conjunctivitis with an incubation period of 2-5 days. If *N. gonorrhoeae* is the cause of the conjunctivitis, immediate treatment with systemic and topical antibiotics is necessary. In cases of infection with organisms resistant to penicillin, a third-generation cephalosporin is indicated.

Ophthalmia neonatorum also can result from other common pathogens such as staphylococci, pneumococci, streptococci, or Gram-negative bacteria. These bacterial infections usually appear several days after birth. Most respond well to topical antibiotics or ointment.

Older infants with chronic or recurrent mucous or purulent discharge usually have a blocked nasolacrimal duct as the underlying cause. The duct frequently opens spontaneously during the first year of life. Treatment with topical antibiotics and massage of the lacrimal sac can help resolve the problem.

Ocular Manifestations of Intrauterine Infections

A number of intrauterine infections have important ophthalmic manifestations. These congenital infections are known by the acronym TORCH. These infections include *t*oxoplasmosis, "*o*ther infections", *r*ubella, *c*ytomegalovirus, and *h*erpes simplex. The "other" designation is used for syphilis and varicella, as well as lymphocytic choriomeningitis virus. Some infections result from maternal infections that either cross the placental barrier or are transmitted during passage through the birth canal. Congenital toxoplasmosis manifests with necrotizing retinochoroiditis with associated vitritis and retinal vasculitis. These lesions result in chorioretinal scars characterized by white areas of exposed sclera circumscribed by well-defined darkly pigmented borders. Retinochoroiditis in toxoplasmosis is a recurrent condition; new lesions develop topically at the border of a scar, although it can develop in areas devoid of scar or in the other eye. Serologic confirmation of congenital infection is done by elevated IgM and IgA titers.[77] Syphilis can affect most structures of the eye ranging from eyelid skin rash, orbital inflammation, interstitial keratitis, and various types of intraocular inflammation to cranial nerve involvement and central visual pathway involvement, including optic nerve atrophy and pupillomotor disturbances. The interstitial keratitis associated with congenital syphilis is

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

a late finding, not apparent until after the age of 5 years. Treatment with penicillin in the neonatal period does not prevent later development of interstitial keratitis.[69] The most common eye finding in lymphocytic choriomeningitis virus infection is generalized chorioretinal scars.[77] Neonatal herpes infection is most often acquired during passage through the birth canal and can cause typical herpetic eye disease such as blepharoconjunctivitis, keratitis, iritis, or chorioretinitis. Ocular involvement with either congenital cytomegalovirus disease or varicella is unusual but can result in chorioretinitis, keratitis, or cataract. Ocular involvement in congenital rubella is common, including microphthalmia, corneal haze, cataract, glaucoma, uveitis, and retinopathy. The characteristic "salt and pepper" retinopathy is the most common occurrence but cataract is responsible for the greatest visual loss.[120] The incidence of children with congenital human immunodeficiency virus (HIV) is decreasing dramatically with the advent of new drugs. Chorioretinitis secondary to various other infectious agents including herpes, CMV, and toxoplasma were described in this population.[9,26]

Preseptal and Orbital Cellulitis

The diagnosis of infective orbital cellulitis requires urgent evaluation and treatment in order to prevent rapid worsening with cavernous sinus thrombosis, cerebral abscess, osteomyelitis, and septicemia. Orbital cellulitis is the most common cause of proptosis in older children but is fortunately rare in neonates. Bacterial spread from paranasal sinuses is the main etiology with hematogenous or direct inoculation very infrequent at this age. The disease is characterized by the rapid onset of progressive proptosis, often with erythema of the lids, chemosis of the conjunctiva, limited motility, and systemic signs of toxicity and hyperpyrexia. Rapid loss of vision caused by compression of the orbital structures can occur and persists as a sequela if compression is not reversed in a timely manner. Afferent pupillary defect is a sign of compression in this setting. Diagnosis is made by clinical appearance and radiologic evaluation of the orbits and sinuses. Treatment includes admission to a hospital, CT scan of the orbits, intravenous administration of antibiotics, application of warm compresses, and surgical drainage of persistent orbital abscesses if necessary.[129] At this early age, the subperiosteal fluid collection in the orbit has high likelihood of being devoid of bacteria and resolves with intravenous antibiotics only.[129]

In preseptal cellulitis, the infection is limited to the lids and does not extend past the orbital septum to involve the orbital contents. It is usually caused by streptococcal and staphylococcal bacteria. In older children, it can be treated on an outpatient basis with oral antibiotics, but in infants, admission to the hospital for intravenous antibiotics is indicated. Widespread vaccination has dramatically decreased Haemophilus-associated orbital and preseptal cellulitis.[107]

Ocular Tumors in Infants

Hemangioma

Discussed in Eyelid Lesions.

Lymphatic Malformation (Lymphangioma)

Lymphatic malformations are slowly progressive, diffuse, soft tumors composed of thin-walled vascular channels that can involve the orbit, conjunctiva, and lids. They may be present at birth or develop during the first several years of life and cease growing by early adulthood. An upper respiratory tract infection and spontaneous hemorrhage may increase the size of the lesion and cause rapid proptosis. The tumors can also cause ptosis, strabismus, or anisometropia. Amblyopia is common and must be aggressively treated. MRI can be exceedingly helpful in diagnosing a lymphatic malformation. The lesion itself is difficult to treat, because it does not regress spontaneously or respond to radiation or corticosteroid therapy. Surgery is rarely used, as results are not always satisfactory. Reports on using percutaneous sclerotherapy using interventional radiology techniques show promise in this difficult-to-treat tumor.[18]

Dermoid Cysts

Dermoid cysts are thought to arise from a congenital rest of primitive ectoderm at the site of closure of a fetal cleft. They usually contain connective tissue, sebaceous glands, and hair follicles. Cysts are often located near the orbital rim, where they are attached to bone at suture sites. The most frequent location is in the lateral third of the brow or upper lid. The skin overlying the soft cyst is freely movable, although the cyst remains attached to the periosteum at the site of the embryonic cleft. Cysts located within the orbit produce proptosis and vertical or horizontal displacement of the globe. Radiographic examination might document bone erosion where the cyst is attached. Local trauma can produce a hemorrhage into a dermoid cyst or cyst rupture, leading to a clinical picture resembling cellulitis. Surgical excision is recommended and is usually curative, especially for the dermoids external to the orbit (see Figs. 95.13 and 95.14).

Teratoma

Teratoma is a primary orbital tumor composed of the three embryonic cell layers. It can differentiate into a variety of tissues containing cartilage, connective tissue, skin, hair, and sebaceous glands, or into endodermal epithelium. Bone is a common component and can be identified by CT. Orbital teratomas that are present at birth produce a striking massive proptosis. Treatment is early excision of the teratoma. Malignant transformation can occur but is rare in the orbit.

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common malignant tumor of the orbit in children although is rare in infants. Rhabdomyosarcoma develops in the orbit more often than elsewhere in the body. Orbital involvement produces proptosis that develops over a few weeks. Diagnosis is made by biopsy. Treatment involves chemotherapy and radiation therapy.

Retinoblastoma

See Intraocular Tumors.

Ocular Manifestations of Maternal Substance Abuse

An increasing number of infants are born bearing the physical, mental, and social consequences of maternal drug and alcohol abuse. Miller and colleagues described many of the ocular findings of fetal alcohol syndrome, including refractive errors, strabismus, anterior segment abnormalities, cataract, ptosis, long eyelashes, telecanthus, and optic nerve hypoplasia.[78]

Maternal ingestion of cocaine can result in optic nerve abnormalities, delayed visual maturation, and prolonged eyelid edema.[39]

Maternal cigarette smoking has been identified as a risk factor for strabismus.[42] As more information is gathered, additional evidence of the teratogenicity of various illicit drugs may be obtained.

Key Points

- Ocular problems are very common in the neonatal period, so a thorough examination with at least a simple pen light should be performed in every child.
- Ocular findings can be the precursor of systemic findings, and some specific ocular findings can lead to definitive diagnosis for many vague systemic findings. Ophthalmology consultation should be initiated for such guidance and possible ocular involvement.
- Nystagmus, copious discharge that is refractory to broad spectrum topical antibiotics, poor red reflex, cloudy corneas, droopy eyelids, constant large misalignment of the eyes, and frank anatomic abnormalities of the eyes and the orbit require prompt pediatric ophthalmology consultation.

Retinopathy of Prematurity

YE SUN, ANN HELLSTRÖM, AND LOIS E. H. SMITH

Introduction

Retinopathy of prematurity (ROP) was first described ~70 years ago as *retrolental fibroplasia*. The introduction of closed incubators with the use of high levels of supplemental oxygen caused inhibition of the growth of retinal vessels in premature infants, followed by vasoproliferation and traction eventually resulting in a complete retinal detachment behind the lens. Supplemental oxygen increased the risk of blindness but also improved survival.[62] When oxygen use was curtailed in the 1950s, ROP incidence decreased but mortality and morbidity increased.[62] Optimal oxygenation saturation levels balancing ROP risk against improved survival at each gestational age are still undefined. Large multicenter studies suggest that oxygen saturation target ranges of 85%-89% versus 91%-95% decrease the incidence of severe ROP but increase mortality.[59,67] The results from several separate randomized controlled trials that found that the frequency of death before 18-24 months was reduced when SpO_2 targets were raised to 91%-95%, compared to when targets were 85%-89%.[65] However, Manja et al. performed a systematic review and meta-analysis of those results and found that the quality of evidence was moderate or low for the outcomes of mortality rates.[48]

Although oxygen is now much better controlled, ROP still persists because of increased survival of infants with extremely low gestational age and birth weight[35] and very immature retinas at high risk for ROP. The lack of factors normally provided in utero such as insulin-like growth factor 1 (IGF-1) also significantly impact the risk of ROP.[10,43] Without the necessary growth factors normally provided in utero, it is more likely that the immature state will persist, predisposing the eye to hypoxia, which then precipitates retinal neovascularization.

Incidence

Worldwide, approximately 10% of births occur preterm (before 37 completed weeks' gestational age).[5] In countries with advanced neonatal intensive care units (NICUs), most cases of ROP now occur among extremely low gestational age newborns (born <28 weeks' gestational age). Determining the current incidence of ROP in population-based studies, even among more developed countries, is challenging because there is considerable variability in study design and in gestational age of included premature infants, as well as in survival rates.[73] Taken as a whole, reports suggest that there has not been a significant change in ROP incidence over time,[20,68] perhaps explained by an increase in survival rates among very immature infants at high risk for ROP balanced against improved NICU care, which lowers ROP risk. Worldwide, the incidence of ROP is also influenced by the fact that even more mature infants at no risk for ROP with more advanced NICU care are at risk in regions with uncontrolled oxygen delivery and less intensive neonatal care.[13] The overall incidence of ROP of any severity was reported by gestational age as shown in Fig. 96.1.

Pathogenesis

Retinopathy of prematurity is initiated as an arrest of normal retinal neuronal and vascular development in the preterm infant. The lower the gestational age at birth, the less complete the retinal development. Vascular growth may resume normally, but when it does not, there can be a pathologic aberrant vascularization of the retina. ROP is usually classified in two postnatal phases[10]—phase 1: cessation of normal vascular growth (as well as obliteration of immature vessels with high oxygen use), and phase 2: pathologic vessel growth (Fig. 96.2).

Phase 1 ROP

Relative hyperoxia is an important driver for the arrest of vascular growth in phase 1 in both animal models and human studies.[18,66] In 1952, Patz first demonstrated the clinical association between oxygen and ROP.[52] In 1954, Ashton established the concepts of oxygen toxicity (phase 1) followed by hypoxia-mediated vasoproliferation (phase 2) in ROP in a kitten model.[3]

As the intrauterine environment has a mean partial pressure of oxygen (PO_2) below 50 mm Hg, unregulated supplemental oxygen given to premature infants with respiratory distress can drive oxygen saturations to abnormally high levels. Hyperoxia suppresses oxygen-regulated angiogenic growth factors such as erythropoietin[9,7] and vascular

Abstract

Retinopathy of prematurity (ROP) was first described around 70 years ago as retrolental fibroplasia. The introduction of closed incubators with the use of high levels of supplemental oxygen caused inhibition of the growth of retinal vessels in premature infants, eventually resulting in a complete retinal detachment behind the lens. Supplemental oxygen increased the risk of blindness but also improved survival. When oxygen use was curtailed in the 1950s, ROP incidence decreased but mortality and morbidity increased. Optimal oxygenation saturation levels balancing ROP risk against improved survival are still unknown. Although oxygen is now much better controlled, ROP still persists because of increased survival of infants with extremely low gestational age and birth weight and very immature retinas at high risk for ROP. The lack of factors normally provided in utero such as insulin-like growth factor 1 (IGF-1) also significantly impacts the risk of ROP. Without the necessary growth factors normally provided in utero, it is more likely that the immature state will persist, predisposing the eye to hypoxia in phase 1 of ROP, which then precipitates retinal neovascularization.

endothelial growth factor (VEGF).[54] Phase 1 is partially reversed in a mouse model with replacement of VEGF and erythropoietin, proving that dysregulation of these particular oxygen-regulated factors contributes to phase I of ROP.[7,9,54]

Besides oxygen, another important driver of vascular growth arrest is loss of growth factors normally present at optimal levels in utero, such as insulin-like growth factor 1 (IGF-1).[32] IGF-1 is critical for normal growth and development of many tissues including brain and blood vessels. Other factors provided by the maternal–fetal interaction often lost after preterm birth are omega long-chain polyunsaturated fatty acids (omega LCPUFA), which are also crucial to retinal development. Loss of omega 3 and 6 LCPUFAs in particular appears to play a role in ROP pathogenesis,[12] and replacement might prove clinically helpful.[53]

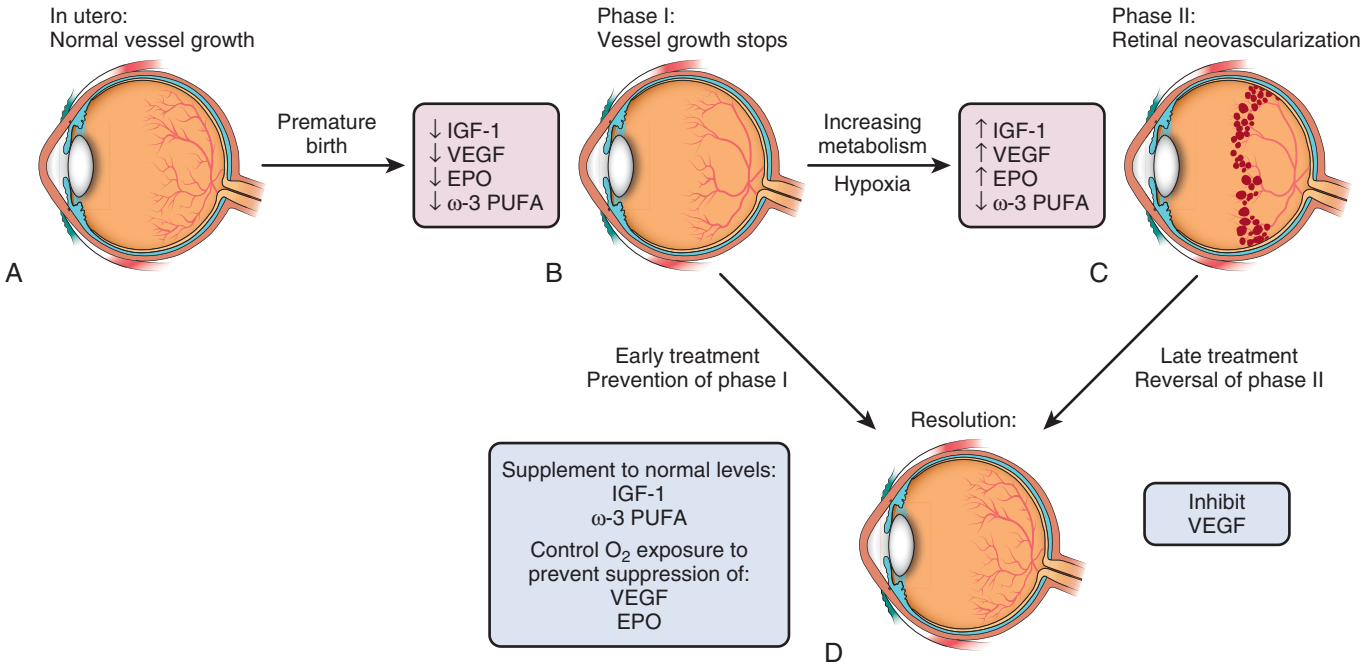
Phase 2 ROP

Phase 2 of ROP is characterized by proliferation of blood vessels in response to markedly elevated increases in VEGF and erythropoietin and other factors (as opposed to suppression in phase 1).[2,70] In severe ROP, phase 2 characteristically begins when the increasingly metabolically active yet poorly vascularized retina (owing to the initial suppression of vessel growth in phase 1) becomes hypoxic. The neovessels (induced by growth factor overshoot) poorly perfuse the retina and are leaky, leading to fibrous scar formation and retinal detachment. In most preterm babies, the retina revascularizes relatively normally and ROP regresses spontaneously, although neural deficits (loss of photoreceptor function) may remain even in cases of mild ROP.[21] The transition between phase 1 and phase 2 usually occurs independent of chronologic age at postmenstrual age 32-37 weeks (peaking at postmenstrual age 34-36 weeks).

Risk Factors

Oxygen and ROP

It is clear that unmonitored high oxygen supplementation contributes to ROP, but the optimum level balancing the risk of ROP with high oxygen saturation versus morbidity that occurs with insufficient oxygenation is not known. After the first epidemic of ROP when the use of 100% oxygen made mildly premature babies blind, oxygen was restricted to 50% of inspired oxygen, which resulted in about 16 deaths per case of blindness prevented.[6]



Theoretically, oxygen in phase 2 of ROP could suppress high levels of oxygen-sensitive growth factors such as VEGF that cause proliferative disease. This premise has been examined in several studies. The Benefits of Oxygen Saturation Targeting trial was a multicenter, double-blind, randomized controlled trial in Australia on 358 babies with gestational age less than 30 weeks who were dependent on oxygen supplementation at 32 weeks, thus investigating the effect of oxygen targets during a time corresponding to the second phase of ROP. No benefit was seen with higher targets in phase 2. The Supplemental Therapeutic Oxygen for Prethreshold Retinopathy of Prematurity study found no change in progression of prethreshold ROP to proliferative disease by increasing oxygen saturation to 96%-99% from conventional 89%-94% for at least 2 weeks. However, increased target oxygen was associated with more pulmonary complications.[69]

Individually, these studies did not show a benefit from higher oxygen in phase 2. Chen et al. performed a meta-analysis of 10 publications to assess at different phases of ROP the association between severe ROP and high or low target oxygen saturation. They found that low oxygen saturation (70%-96%) in the first several postnatal weeks was associated with reduced risk and that high oxygen saturation (94%-99%) at or after 32 weeks' postmenstrual age was associated with decreased risk for progression to severe ROP,[11] and that the control of oxygen in the first phase was more important than the higher oxygen saturation in the second phase. Oxygen level fluctuations during the first few weeks of life are also associated with increased ROP risk,[29] as is frequent intermittent hypoxia during the first 8 weeks of life.[14]

Gestational Age and Birth Weight

Low gestational age and low birth weight, which reflect the degree of immaturity of retinal neural and vascular development at birth and, therefore, the degree of retinal vulnerability to insult are major risk factors for ROP.[47] Loss of growth factors normally found in utero is also a major risk factor for the disease. The lower the gestational age and birth weight, the more profound is the loss of factors provided by the intrauterine environment.

• **Fig. 96.2** Progression of retinopathy of prematurity. **A,** Oxygen tension is low in utero. **B,** Phase 1: After birth until ≈30 weeks' postmenstrual age, retinal vascularization is inhibited because of hyperoxia and loss of the nutrients and growth factors provided at the maternal–fetal interface. Blood-vessel growth stops and as the retina matures and metabolic demand increases, hypoxia results. **C,** Phase 2: The hypoxic retina stimulates expression of the oxygen-regulated factors such as erythropoietin (EPO) and vascular endothelial growth factor (VEGF), which stimulates retinal neovascularization. Insulin-like growth factor 1 (IGF-1) concentrations increase slowly from low concentrations after preterm birth to concentrations high enough to allow effects on the concentration of VEGF pathways. **D,** Resolution of retinopathy might be achieved through prevention of phase 1 by increasing IGF-1 to in utero concentrations and by limiting oxygen to prevent suppression of VEGF; alternatively, VEGF can be suppressed in phase 2 after neovascularization with laser therapy or an antibody. EPO, Erythropoietin; ω-3 PUFA, ω-3 polyunsaturated fatty acids. (Adapted from Smith LE. Through the eyes of a child: understanding retinopathy through ROP: the Friedenwald lecture. *Invest Ophthalmol Vis Sci.* 2008;49:5177-5182, by permission of the Association for Research in Vision and Ophthalmology.)

Low IGF-1

In babies born preterm, there is a strong association between early postnatal low serum IGF-1 concentrations and later ROP as well as other prematurity-related morbidities.[32] In utero, plasma levels of IGF-1 increase with gestational age, particularly during the third trimester of pregnancy, and decrease after preterm birth.[42,45] Most infants born before 33 weeks' gestational age have a very slow increase in IGF-1 production after birth until 40 weeks' postmenstrual age. Full-term infants by comparison have a rapid increase in serum IGF-1 levels postnatally.[45] Postnatal IGF-1 levels are nutrition-dependent in older preterm infants and are reduced with starvation, infection, and stress.[41]

IGF-1-deficient mice have retinal vessel growth suppression, suggesting that low IGF-1 levels contribute to vascular growth suppression in ROP.[31] In preterm infants, low IGF-1 serum levels, as well as directly correlating with the severity of ROP, also correlate with poor brain growth as measured by head circumference and MRI at term.[24] IGF-1 acts as a permissive factor for VEGF-dependent vascular endothelial cell growth and survival.[31,63,64] Increased levels of the major IGF-1 binding protein found in serum, insulin-like growth factor binding protein 3 (IGFBP3), also improve vessel survival in a mouse model of oxygen-induced retinopathy. Importantly, IGFBP3 levels are significantly diminished in infants with ROP.[46]

Hyperglycemia and Insulin Use

Elevated neonatal glucose levels are a risk factor for ROP.[1,51] In a study of 372 infants born after 30 weeks' gestational age,[39] increased nutrition alone (without IGF-1 supplementation) caused increased hyperglycemia, precipitating increased insulin use. Both hyperglycemia and insulin use were associated with an increase in ROP. These studies underline the importance of an integrated approach to ROP prevention.

Increasing nutrition alone also does not influence weight gain (normalized for gestational age)[22] or IGF-1 levels in extremely low birth weight infants, who appear to be unable to either increase IGF-1 levels with increased calories or to use calories for growth with low IGF-1 levels.[22] Exogenous IGF-1 can improve growth in experimental states of undernutrition. In rats fed half of needed calories, exogenous IGF-1 improved weight gain.[17] As postnatal weight gain

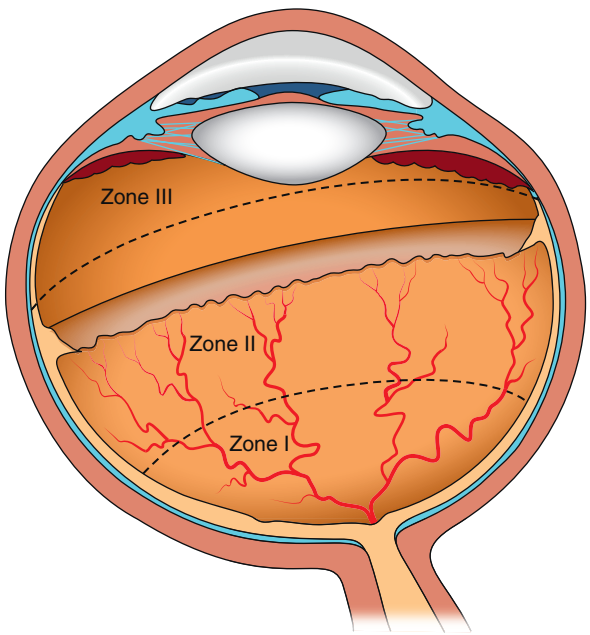
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.



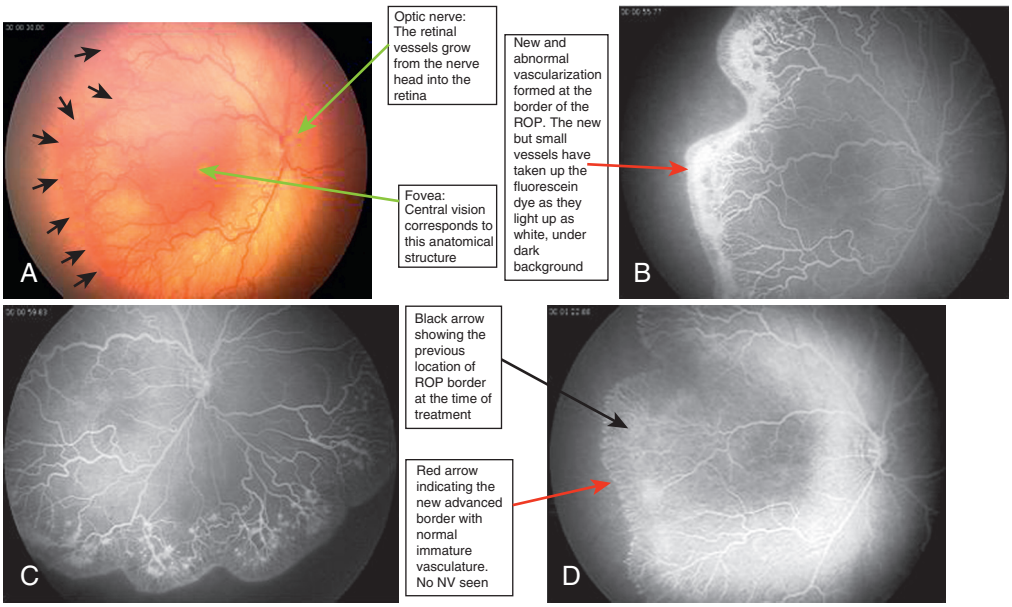
predicts ROP risk,[4] this suggests that both increased nutrition and adequate IGF-1 levels are required for postnatal growth and for a reduction in ROP risk.

Additional attention must also be paid to nutritional components such as adequate protein and appropriate fats, as well as appropriate use of glucose and other carbohydrates. In particular, it has been shown in animal studies that lack of omega 3 polyunsaturated fatty acids increases susceptibility for retinopathy.[12] Given that total parenteral nutrition (TPN) rarely contains any omega 3 or 6 LCPUFAs, it is likely that adding these essential lipids to nutrients would be beneficial.[53] It is noteworthy that in a study of ≈2000 infants with ROP in North America, those with extended total parenteral nutrition use were at high risk for ROP, independent of weight gain.[72]

Classification

The International Classification of Retinopathy of Prematurity was developed in 1984 and 1987 to clearly define stages of ROP for physicians and investigators. It was published in two parts throughout the world[36,37] and was revisited in 2005.[38]

The retina is divided into three zones (Fig. 96.3). ROP located in the most immature zone I has a much worse prognosis. Second, the extent of the disease is described by the number of clock hours involved within the zone. Therefore, one can describe how many clock hours of retina are affected by which severity in detail by using this description method (e.g., stage 3 seen between 7 and 10 o'clock as well as 2-5 o'clock and the remaining clock hours were stage 2 in zone II). Third, the change in posterior pole venous dilation and arterial tortuosity that occurs in aggressive disease is identified as "plus disease" (or "preplus disease" if it is not normal but does not meet criteria for plus disease). As in previous classifications, the degree of vasculopathy at the vascular-avascular transition is divided into stages 1 through 5. Stages 1 through 3 are increasing degrees of abnormal blood vessel growth (neovascularization) with vessels growing into the vitreous in stage 3. Stage 4 is partial retinal detachment, and stage 5 is complete retinal detachment, both of which carry a poor prognosis for normal vision. Stages 1 and 2 are mild and likely to regress spontaneously. In stage 3, extraretinal neovascularization may become severe enough to cause total retinal detachment (stage 5), which most often leads to blindness. The Early Treatment for Retinopathy of Prematurity (ETROP) Study[15] reclassified ROP into type 1 (requiring treatment) and type 2 (to be followed) to include a more virulent form of retinopathy in extremely low birth weight babies (aggressive, posterior ROP), which involves very central neovascularization with plus disease.[37]



• **Fig. 96.3** Artist's rendering of half of the eye with zone II, stage 3 retinopathy of prematurity with plus disease. The view is from the top of the head, with the temporal side of the retina to the reader's left, and the nasal side to the right. Zones I, II, and III are drawn onto the retina to assist in visualizing their positions within the eye.

Clinical Course

Infants at risk for severe ROP are examined according to national guidelines, usually starting at about 31 weeks' postmenstrual age to detect those needing treatment. The sequential development of the stages of ROP is monitored until "threshold," or "type 1" disease, a point when the ROP is equally likely to regress or to progress to advanced disease, at the time-point ROP is treated. If no ROP is seen by 36-42 weeks' postmenstrual age, the risk of developing disease is very low.[70] However, if ROP is treated with anti-VEGF therapy, incomplete retinal vascularization with the risk of further ROP is extended. Rates of progression are variable, and the worst prognosis is associated with onset of severe disease in zone I (most immature) that can rapidly progress to type 1 disease with high risk of retinal detachment. Onset in zone II, or a slower evolution of the disorder, leads more often to complete resolution. ROP with an onset in zone III has a good prognosis for full recovery.[58] Infants who develop only mild ROP (i.e., stage 1 or 2 without plus disease) usually heal without a residual cicatrix and have only a slightly increased incidence of myopia/hyperopia, strabismus, and amblyopia compared with term infants.[6] However, for those infants who develop type 1 ROP and receive laser ablation, severe myopia, glaucoma, and associated sequelae are common.[34] The infants who have a residual cicatrix without retinal detachment are also more likely to have any of these problems and are at risk for retinal detachment and acuity loss in later decades.[56,29] Therefore, physicians must refer these high-risk infants to early intervention programs and support their families. Retinal fluorescein angiography can be used to visualize the pathology better, because sometimes it could be difficult to see the extent and the severity of the pathology with simple direct visualization (Fig. 96.4).

• **Fig. 96.4** A single patient with zone I, stage 3 ROP with plus disease. **A,** Small arrows indicate the border where the vascular zone ends and the avascular (part of retina that does not have any vessels to bring oxygen and nutrition) zone starts. Along that border, the red thick line indicates significant neovascularization (NV) at that border. Also note dilation of veins and tortuosity of the arteries. It is still somewhat difficult to see the detail because of the underlying pinkish hue that masks the contrast. **B,** Fluorescein angiography documents retinal vascular anatomy in much better detail, as the fluorescein dye lights up only the retinal vasculature and every other structure is dark. Bright white structures at the border are all significant neovascularization. **C,** Fluorescein angiography shows the inferior retina. The border is visible again with less but present neovascularization seen as light bulbs on a tree. **D,** Fluorescein angiography performed 1 month after treatment with anti-VEGF therapy. Note that the normal retinal vasculature has grown, and neovascularization has completely disappeared. Plus disease has also regressed with no tortuosity seen in the arteries.

Therapy

The only completely effective prophylaxis for ROP is the prevention of premature deliveries or the development of treatment that normalizes factors missing after preterm birth and avoids factors not found in utero (e.g., hyperoxia). Meticulous oxygen monitoring is necessary to reduce the incidence of ROP, but it does not eliminate the disease.[29] Other factors must also be matched with the prenatal environment, adjusted for the adaptation to the postnatal environment.

The question also remains of the balance between lower oxygen supplementation in the early postnatal period to prevent blood vessel loss versus higher oxygen in the later postnatal period to support oxygenation of the retina in phase 2 of ROP.

After ROP has developed to a point in phase 2 that is as likely to regress as progress to retinal detachment (defined as type 1 by the ETROP study), the standard treatment is laser therapy to ablate the entire peripheral avascular retina, which is overproducing angiogenic factors and driving the blood vessels to grow abnormally (Fig. 96.5). Although this treatment does not always succeed in preventing retinal detachment, it reduced the incidence of poor retinal outcomes for type 1 ROP at 2 years in treated versus controls from 15.4% to 9.1%.[19] At 15 years' follow-up, the benefit of ablative therapy persists, with respect to preventing poor structural outcome (which is greater than the benefit for visual function).[56] The criteria for laser treatment established by the ETROP multicenter trial first published in 2003 are shown in Box 96.1. Ablative treatment of nonvascularized retina helps to prevent blindness but does not address the underlying cause of retinopathy of prematurity or other co-morbidities, which is the failure of normal neural and vascular growth. Furthermore, peripheral retina is destroyed to save central vision.

• **Fig. 96.5** Fundus photography taken 4 weeks after laser treatment. The laser spots/scars are seen as white/black areas beyond the border of ROP.

• BOX 96.1 Criteria for Peripheral Ablative Therapy for Retinopathy of Prematurity

Zone II: Plus disease with stage 2 or 3 ROP
Zone I: Plus disease with stage 1 or 2 ROP
Zone I: Stage 3 ROP

ROP, Retinopathy of prematurity.
Adapted from Early Treatment for Retinopathy of Prematurity Cooperative Group. Revised indications for the treatment of retinopathy of prematurity: results of the Early Treatment for Retinopathy of Prematurity Randomized Trial. *Arch Ophthalmol*. 2003;121:1684.

Treatment of proliferative retinopathy with humanized antibody fragments that block VEGF (by intravitreal injection) (see Fig. 96.4) has been reported in many small case series, for example, by Harder and colleagues.[28] In a trial of 150 infants randomly assigned to receive laser or intravitreal bevacizumab treatment, recurrence was slightly less likely in the bevacizumab group than in the laser-treated group at 54 weeks' postmenstrual age.[50] A significant treatment effect with bevacizumab was seen for retinopathy of prematurity in zone I but not zone II.[50] However, visual outcomes and adverse systemic effects were not reported. Bevacizumab injected into the eye leaks into systemic circulation and reduces systemic VEGF concentrations for at least several weeks to months[57] and might suppress systemic vascular growth or have other as-yet-unknown negative effects.[25] Additional studies to assess the best choice of an anti-VEGF drug, the optimum dose, the pharmacokinetics, and short-term and long-term safety are underway.[26] When total or subtotal retinal detachment occurs, the usual prognosis is that there will be little useful vision, even when attempts are made to reattach the retina.[55]

Candidate Interventions for Prevention and Treatment

Addressing the postnatal risk factors for retinopathy of prematurity might help to normalize postnatal growth and reduce risk. Increasing nutrition alone seems to be insufficient to increase IGF-1 and promote postnatal weight gain in the early postnatal period in the most immature babies,[23] and insufficient to decrease risk of retinopathy of prematurity.[71] Instead, hyperglycemia and insulin requirement are raised, both of which are associated with an increased risk.[40] Because persistently low serum IGF-1 concentrations in preterm infants are associated with ROP and other morbidities,[30] and because supplemental IGF-1 seems to improve food utilization in undernutrition,[17] supplementation with exogenous IGF-1 might improve early postnatal growth and outcome. A pharmacokinetic and dosing study[44] of intravenous IGF-1-IGFBP3 complex in preterm infants showed no adverse effects and an increase in serum IGF-1 to in utero concentrations. An IGF-1–IGFBP3 phase II replacement trial (NCT01096784) has been performed in 120 preterm infants and reported no effects on ROP outcome. However, significant reduction in bronchopulmonary dysplasia was seen as well as a significant tendency for a reduction in severe brain injury. A phase III study is now under way, with reduction in the severity of pulmonary disease as the primary endpoint and brain injury and ROP as secondary endpoints.

During the third trimester of pregnancy, a massive transfer of essential fatty acids (ω-3 and ω-6 long-chain polyunsaturated fatty acids) from the mother to the fetus takes place; these essential fatty acids [especially the ω-3 fatty acids: docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) and omega-6 fatty acid arachidonic acid (AA)] are not provided in parenteral solutions after preterm birth.[49] In a study in mice, adequate ω-3 long-chain polyunsaturated fatty acids reduced retinopathy by 50%,[12] which suggests that replacement of these fatty acids in infants would reduce the risk of retinopathy of prematurity.

The β blocker propranolol has been proposed as a potential treatment to reduce retinal neovascularization,[16] and clinical studies are underway in Israel and Italy. However, investigators of a 2012 study[8] report that propranolol does not reduce retinopathy in a mouse model of retinopathy of prematurity. Results of a meta-analysis suggest that the carbohydrate inositol can reduce the number of infants with stage 3 or higher cases of retinopathy of prematurity.[33] However, a randomized trial of inositol was stopped early for increased deaths without an impact on retinopathy of prematurity or BPD.[53a]

Recommendations for Examination Schedule

A trained clinician must examine at-risk premature infants with indirect ophthalmoscopy to detect ROP before it has reached well-established clinical criteria for the application of laser therapy (or cryotherapy) to prevent progression of the disease.[60-61] The ophthalmic and pediatric societies periodically publish recommendations for the screening guidelines, which may vary between countries (Box 96.2). Largely, infants at risk are suggested to be those weighing less than 1500 g or born at 30 weeks' gestation or less, and those more mature preterm infants with birth weight of 1500-2000 g who had an unstable medical course. These children should be examined initially by 31 weeks' postmenstrual age or 4 weeks' chronologic age until the retina is vascularized to the ora serrata. If there is normal vascularization into zone III, ROP is unlikely to develop or is likely to be mild, and repeated examinations are done at 2- to 4-week intervals until complete vascularization is noted. Infants with normal retinal vascularization into zone II should be followed at least every 2 weeks to observe for the development of ROP, which may require therapy. Infants with normal vascularization only into zone I are at greatest risk for severe ROP and should be followed closely on the

• BOX 96.2 Schedule for First Indirect Ophthalmoscopy in Premature Infants

Who

- All infants 30 weeks' gestation or less, or weighing less than 1500 g at birth
- Infants born at 1500 to 2000 g who have a medically unstable course

When

- By the later of 31 weeks' postmenstrual age* or 4 weeks after birth
- Recommend first examination before discharge from the hospital

*Postmenstrual age in weeks is equal to the gestational age at birth plus the chronologic age in weeks after birth.
Adapted from American Academy of Pediatrics, American Association for Pediatric Ophthalmology and Strabismus, and American Academy of Ophthalmology. Screening examination of premature infants for retinopathy of prematurity. *Pediatrics*. 2006;117:152 and 2006;118:1324.

basis of the presence, severity, and rate of progression of any ROP, particularly if vascular dilation (plus disease) is found.

Because fewer than 10% of children examined are found to need treatment, the use of an algorithm that predicts later development of ROP (WINROP) can be very helpful in adjusting the number of eye examinations based on predicted risk.[27] WINROP (winrop.com) is free for use. The algorithm is based on deviations of an infant's weight gain velocity from an established norm for infants who do not develop ROP and predicts on average the future development of ROP 2 months before treatment is needed. The algorithm must be used in conjunction with regular screening, but in Sweden it has reduced the number of eye examinations by up to 35%.

Neonatologists and ophthalmologists must work closely together to ensure an efficient tracking system for timely examination of these infants and to be certain that follow-up examinations occur at the best times both in the hospital and after discharge or transfer. Because ROP develops in the majority of infants born at less than 26 weeks' gestation, the index of suspicion must be high, and follow-up examinations must be frequent in these babies. At 26-28 weeks' gestational age at birth, the incidence drops, and at 29-30 weeks' gestational age at birth, few infants develop severe ROP requiring treatment. The goal is to ensure that infants who reach criteria for retinal ablation are treated to minimize vision loss.

After the acute process has resolved, continued follow-up is dictated by the worst degree of ROP that occurred in the acute course. For infants who have had laser or cryotherapy for ROP, close observation of the retina as well as assessment for refractive errors, strabismus, amblyopia, or late retinal detachments through childhood is also important.[34] Research must continue in order to learn about the basic mechanisms involved in the control of retinal vascular development and neovascularization. Such knowledge may permit prevention of ROP.

This work was supported in part by the: NIH/ NEI (EY022275, EY017017, R24EY024868), P01 HD18655, Research to Prevent Blindness Senior Investigator Award, Alcon Research Institute Award, Lowy Medical Foundation, V. Kann Rasmussen Foundation, Boston Children's Hospital Intellectual and Developmental Disabilities Research Center Grant 1U54-UD-090255 (LEHS), and Boston Children's Hospital's Office of Faculty Development, Basic and Translational Executive Committee, Clinical and Translational Research Executive Committee Faculty Career Development Grant (YS). The authors sincerely thank Dale L. Phelps, MD, for helping during the preparation of the manuscript, and all of the copyright holders for permission to reproduce the illustrations used in this chapter.

Key Points

- ROP incidence is reduced by improved neonatal care.
- Oxygen-regulated as well as non-oxygen-regulated growth factors are key in the pathogenesis of ROP.
- Oxygen, gestational age, birth weight, IGF1 level, hyperglycemia, and insulin use are risk factors for ROP.
- Candidate interventions for prevention and treatment.
- Recommended examination schedules should be followed to optimize available therapeutic interventions.

Musculoskeletal Disorders in Neonates

RAYMOND W. LIU AND GEORGE H. THOMPSON

Musculoskeletal abnormalities of the extremities, spine, and pelvis are common in the neonate. Some are pathologic and others physiologic in origin from normal in utero positioning. The congenital absence of all or part of a limb, deformities of the feet or hands, and abnormalities of the spine are rarely diagnostic problems, whereas others, such as developmental dysplasia of the hip (DDH), may escape diagnosis even after repeated screenings by experienced examiners. Bone and joint infections in the neonatal period produce few of the diagnostic signs and symptoms present in the older child and require a high index of suspicion and careful diagnostic evaluation. When an infection is diagnosed early and prompt treatment rendered, the growth potential of the neonate yields an excellent prognosis for normal development and function.

Normal Embryology

Because many neonatal musculoskeletal disorders are congenital in origin, it is important to understand the basic aspects of musculoskeletal embryology. Prenatal development is divided into two major stages: the embryonic period, consisting of the first trimester, and the fetal period, consisting of the middle and last trimesters of pregnancy. The components of the musculoskeletal system differentiate during the first trimester; the second and third trimesters are periods of further growth and development.[10,21] Abnormalities during the embryonic period produce congenital malformations, whereas the fetal period produces deformations and alterations in the configuration of essentially normal parts.

Embryonic Development

The early embryonic development of the musculoskeletal system is oriented around the notochord, a tubular column of cells running cranially and caudally along the long axis of the embryo. During the 3rd week of gestation, the neural crests develop dorsally and on either side of the notochord. These crests fold over and are joined dorsally to produce the neural tube, from which the spinal cord and associated spinal nerves develop. At the same time, paraxial collections of mesodermal tissue develop on either side of the notochord and segment in the cranial to caudal axis into 44 distinct condensations called *somites*. From the primitive mesodermal tissue comprising the somites, the skeletal tissues, muscle, and dermal elements of the body develop.

Extremities

The upper and lower extremities develop from the limb buds. They become recognizable during the 4th week of gestation. These buds grow and differentiate rapidly in a proximal to distal sequence during the next 4 weeks. The cells differentiate into three segments: the dermatomes, which become skin; the myotomes, which become muscle; and the sclerotomes, which become cartilage and bone. By the 5th week, the hand plate forms, and mesenchymal condensations occur in the limbs. By the 6th week, the digits become evident, and chondrification of the mesenchymal condensations occurs. Notches appear between the digit rays during the 7th week. The failure of the rays to separate at this time results in syndactyly. Also during the 7th week, the upper and lower limbs rotate in opposite directions. The lower limbs rotate internally to bring the toes to the midline, whereas the upper limbs rotate 90 degrees externally to the position of the thumb on the lateral side of the limb.

Spine

The differentiation of the spinal column begins during the 4th week of the embryonic period. The somites first appear in the occipital region of the embryo; further development occurs simultaneously in a cranial-to-caudal direction. Dorsal and anterolateral migrations of the mesodermal tissue derived from the somites give rise to the connective tissue elements of the trunk and limbs. Anteromedial extensions of the somatic mesoderm migrate to surround the notochord, separating it from the neural tube and forming the primitive anlage of the vertebral bodies. The differentiation of the neural and vascular elements of the spinal column occurs simultaneously to somite development.

Definitive formation of the spinal column occurs from the 4th through the 6th week of gestation. The somatic mesodermal tissue surrounding the notochord differentiates into a less cellular and dense upper portion and a more cellular and dense lower portion. The somites cleave together,

Abstract

Neonatal musculoskeletal abnormalities of the extremities, spine, and pelvis are common disorders. Some are pathologic while others are physiologic or acquired. The embryonic period constitutes the first trimester while the second and third trimesters are the fetal period. Abnormalities during the embryonic period produce congenital malformations while those occurring during the fetal period cause deformations and alterations in normal parts. Congenital malformations may include the spine (congenital scoliosis and kyphosis), extremity failure of formation and differentiation of parts, and other congenital abnormalities and teratogenic malformations. Fetal period disorders include those secondary to in utero positioning (tibial torsion, metatarsus adductus, developmental hip dysplasia), spinal injury, brachial plexus injuries, muscular torticollis, and fractures (clavicle, proximal humeral epiphyseal separation). It is important to be able to recognize these abnormalities and assess for related but less obvious abnormalities.

the lower portion of the superior somite joining with the upper portion of the inferior somite. The intervertebral disc develops at the site of the cleavage. The notochord, which is contained within the newly joined primitive vertebral bodies, degenerates, and those portions at the site of cleavage become the nucleus pulposus of the intervertebral disc. The neural arches and ribs develop from the dense portions of the somite, and the vertebral body develops from the less dense portions.

Chondrification begins in the primitive mesodermal vertebrae during the 6th week of pregnancy. It progresses rapidly to form cartilaginous models of the vertebral body by the end of the first trimester. Ossification of the cartilaginous models begins during the second trimester. The ossification of each side of the neural arch and of the body at each level proceeds separately. In the neonate, the ossified vertebral body and neural arches at each level are clearly visible radiographically, separated as they are by the nonossified synchondritic junctions. The ossification centers of the neural arches and body coalesce during the first 3 years of postnatal development.

The first and second cervical segments are embryologically and anatomically distinct from the remainder of the spinal column. The first cervical vertebra—the atlas—lacks the physical form characteristic of other vertebrae, having instead only a narrow anterior arch. This arch is not ossified at birth or during the neonatal period but is most often visible by 1 year of age.

The most striking feature of the second cervical vertebra—the axis—is the prominent odontoid process, derived from the caudal portion of the first cervical somite. The odontoid process joins with the remainder of the C2 body through synchondritic links with each neural arch and the vertebral body. The synchondrosis with the centrum lies below the level of the neural arches and may be radiographically confused with a fracture line; it closes by 3 years of age. The vertical synchondroses separating the centrum from the neural arches of C2 close by 7 years of age.

The radiographic evaluation of the neonatal spine requires experience. In the lateral view, the vertebral bodies are often notched at their waists and are trapezoidal rather than rectangular. In the anteroposterior view, the synchondritic links between the neural arches and vertebral bodies are not ossified and may give the false impression of a fracture. In the cervical region, the odontoid process may be confusing to those not familiar with the normal developmental anatomy of the region. Fortunately, fractures of the cervical spine are uncommon in the neonatal period and, when present, are usually associated with a suggestive history and other signs on physical examination.

Fetal Development

The appendicular and axial skeletons are preformed in cartilage. By the end of the first trimester, primary ossification centers are present in the long bones of the extremities. Further increases in length occur through endochondral growth at the ends of the long bones. This growth continues in the postnatal period until the end of adolescence, when growth plates close and the epiphyseal regions fuse with the remainder of the long bone.

Congenital Abnormalities

Teratogenic influences and genetic abnormalities occurring during the embryonic period can adversely affect the normal differentiation of the musculoskeletal system, resulting in malformations of the extremities or spine. Other organ systems differentiating at the same time are often concomitantly affected, such as the association of cardiac and genitourinary abnormalities with congenital spinal deformities (see Chapter 30).

Teratogenic Abnormalities

It has been estimated that 5% of all malformations are the result of the action of known teratogens on the developing embryo. Irradiation, industrial chemicals, therapeutic drugs, and certain maternal infections produce primary musculoskeletal malformations or secondarily affect the growth and development of the musculoskeletal system. Thalidomide is the best-known cause of musculoskeletal malformation, causing limb reduction deficits in addition to a variety of other congenital abnormalities. Rubella, cytomegalic inclusion disease, and congenital herpes produce lesions of the central nervous system that may secondarily affect the musculoskeletal system.

Genetic Disorders

Genetic disorders that affect the musculoskeletal system may be divided into three categories: Mendelian, chromosomal, and multifactorial.

Mendelian Disorders

Mendelian disorders are characterized by an abnormality in a single gene obeying the rules of Mendelian inheritance. Skeletal dysplasias such as achondroplasia and diastrophic dwarfism, Marfan syndrome, hemophilia, and rickets resistant to vitamin D are examples of Mendelian disorders. Skeletal dysplasias are often diagnosed in the neonate, whereas other entities do not become clinically recognizable until later in childhood.

Chromosomal Abnormalities

There are many varieties of chromosomal abnormalities. Aneuploidy is the presence of more or fewer chromosomes than normal and includes Down syndrome as well as Turner syndrome. Translocations are also changes that are detectable on ultrastructural analysis. Trisomies are common examples. Deletion and inversion can be more subtle and are discovered on specialized genetic testing. Although they are striking, the musculoskeletal manifestations of these conditions are frequently the least serious of the infant's problems in other organ systems.

Multifactorial Conditions

These conditions are determined by a combination of genetic predisposition and intrauterine environmental influences. Such conditions typically occur in families with a frequency that is greater than expected but do not follow the obvious rules of Mendelian inheritance. Talipes equinovarus (clubfoot) is such a disorder. The overall incidence of clubfoot is 1 case per 1000 live births, but the incidence of deformity among first-degree relatives is 20-30 times higher than that in the general population. Three percent of dizygous twins and 40% of monozygous twins share the deformity. An increased incidence of clubfoot occurs among breech and twin births.

Congenital Limb Malformations

Congenital limb malformations are relatively common among neonates. Some are grossly obvious, such as a congenital amputation, whereas others are subtle and perhaps unrecognizable for years, such as a congenital proximal radioulnar synostosis (fusion). Congenital limb malformations are classified according to the parts that have been primarily affected by embryologic failure. Swanson and colleagues developed a seven-group classification system.[24]

1. Failure of formation of parts (e.g., arrested development)
2. Failure of differentiation (e.g., separation) of parts
3. Duplication
4. Overgrowth (e.g., hyperplasia, gigantism)
5. Undergrowth (e.g., hypoplasia)
6. Congenital constriction band syndrome
7. Generalized skeletal abnormalities

These various malformations are caused by alterations in the organization of the limb mesenchyme; the time of the insult, the sequential development of the part, and the location of the destructive process determine the type of ensuing deformity. The presentation, diagnosis, and treatment of the more common congenital limb malformations are discussed in later sections.

Failure of Formation of Parts

This group is subdivided into transverse and longitudinal deficiencies. A transverse deficiency is manifested as an amputation type of stump that is classified by naming the level at which the remaining limb terminates. All elements distal to the level are absent. Longitudinal deficiencies represent all other skeletal limb deformities. These deficiencies are separated into preaxial and postaxial divisions of the limb and include longitudinal failure of the formation of an entire limb segment, such as phocomelia, or of the preaxial (i.e., radius, tibia), central, or postaxial (i.e., ulna, fibula) components of the limb. The more common deformities include phocomelia, a partially or completely absent radius (i.e., radial clubhand), and a partially or completely absent fibula (i.e., fibular hemimelia).[3,9,11]

Failure of Differentiation of Parts

In failure of the differentiation of parts, the basic units of the extremity developed, but the final form was not completed. The common disorders of this group include an undescended scapula (i.e., Sprengel deformity), proximal radioulnar synostosis, and syndactyly of the fingers and toes.

Duplication

Duplication occurs as the result of a particular insult to the limb bud at an early stage such that the splitting of the original embryonic part occurs. Polydactyly of the thumb, fingers, great toe, and lesser toes is the most common of the neonatal musculoskeletal disorders. Although a simple duplication is often an isolated finding, a complex toe duplication raises concern for associated tibial hemimelia (Fig. 97.1).

Overgrowth

Overgrowth disorders, such as congenital hemihypertrophy, can result from an excess of skeletal growth or soft tissues. The overgrowth frequently increases in size with development because of the asymmetric growth of the involved part.

• **Fig. 97.1** Complex polydactyly can be associated with tibial hemimelia. This child has an equinovarus position of the ankle that was resistive to casting. Eventual workup of this child demonstrated additional subtle signs of tibial hemimelia.

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

Undergrowth

Undergrowth, such as brachydactyly, usually represents the defective or incomplete development of parts. It can involve an entire extremity or only a portion of it. Overgrowth disorders are more common than undergrowth disorders.

Congenital Constriction Band Syndrome

Congenital constriction band syndrome may represent focal necrosis of the limb after the embryonic period or an acquired deformity owing to amniotic bands.

Generalized Skeletal Abnormalities

Generalized skeletal abnormalities manifest generalized disorders, some of which may be inherited. Examples include skeletal dysplasia and syndromes such as Marfan syndrome and neurofibromatosis.

Spinal Defects

Errors in the embryologic derivation of the spine cause a number of congenital defects of the spine and spinal cord. These errors range in severity from isolated hemivertebrae to the complex errors of vertebral formation and segmentation associated with massive defects of the neural tube or spinal cord. When such errors result in asymmetric vertebral formation or produce asymmetric vertebral growth potential, structural spinal curves such as congenital scoliosis or kyphosis develop. Partial or complete failure of the formation of a vertebra (i.e., hemivertebra) or errors in the normal pattern of vertebral segmentation and recombination (i.e., unsegmented bars and trapezoidal, butterfly, and block vertebrae) may occur as single anomalies or be associated with other malformations of the osseous, neural, and organ systems. When vertebral defects are unbalanced and have growth potential, striking spinal deformities may occur, such as with a unilateral unsegmented bar with a contralateral hemivertebrae. The nature of the deformity depends on the growth potential of the abnormal segments and their positions in the spinal column. For example, lateral abnormalities produce congenital scoliosis, and anterior or posterior midline defects result in congenital kyphotic or lordotic deformities.

Malformations of the head and neck, especially the internal and external auditory apparatuses, maxillae, and mandibles, occur frequently in patients with high thoracic and cervical curves. The association of a short neck, low posterior hairline, and restriction in neck motion caused by the congenital fusion of cervical vertebrae represents Klippel-Feil syndrome. Renal anomalies, the congenital elevation of the scapulae (i.e., Sprengel deformity), impaired hearing, and congenital heart disease are common associated anomalies in affected patients. The VACTERL syndrome (vertebral defects, imperforate anus, cardiac anomalies, tracheoesophageal fistula, renal dysplasia, and limb deficiencies often in the radius) underscores the complex nature of the relationships between the rapidly evolving organ systems and the musculoskeletal system during the first trimester of pregnancy. Any child with congenital scoliosis should be specifically screened for cardiac and renal defects, while other VACTERL components are generally more diagnostically obvious.

McMaster reported a high incidence of occult intraspinal abnormality in patients with congenital scoliosis.[19] Possible anomalies included intradural and extradural lipoma cysts, teratoma, spinal cord tethers, diplomyelia, and meningocele. In some instances, the spinal cord may be split by a bony, fibrous, or cartilaginous bar extending from the posterior aspect of the vertebral body to the vertebral arches. This condition, known as diastematomyelia, commonly occurs in association with defects at the thoracolumbar junction. Given this, children with spinal defects are typically evaluated with an MRI of the entire spine.

The association of vertebral anomalies with neural tube or spinal cord defects is to be expected, given the intimate relationships of their embryonic development. Spina bifida occulta is the most common and least serious and myelomeningocele the most severe of such anomalies. Not all anomalies are easily identified on physical or radiographic examination. Unless the spurs are ossified, they are not easily visualized by conventional radiographic techniques. The physical signs of underlying spinal dysraphism include hairy patches, midline dimpling, nevi, inequality in the length of the lower extremities or circumferential asymmetry, and asymmetry in foot size. Screening MRI of the spine is considered when there is a significant or draining defect, or if there are progressive changes in the neurologic exam (see Chapter 58).

In Utero Positioning

The imprint of in utero positioning is frequently seen in the neonate. It can produce joint and muscle contractures and torsional and angular variations in the long bones, especially those of the lower extremities. It can also produce craniofacial distortion and positional contracture of the neck. The upper extremities are usually less affected.

The expression of in utero positioning depends on fetal position and the amount of compressive force applied. Intrinsic and extrinsic factors contribute to these variables. The intrinsic factors include oligohydramnios, multiple fetuses, a large fetus, abnormal fetal positioning (e.g., breech and transverse), and abnormal fetal muscle tone. The extrinsic factors include a small maternal pelvis and uterine deformities (e.g., bicornuate). These factors can lead to increased uterine compression and secondary changes in the neonate. Some of the more common problems related to in utero positioning include developmental dysplasia of the hip, metatarsus adductus, calcaneovalgus foot, tibial bowing, internal and external tibial torsion, and hyperextended knees. Craniofacial abnormalities, which are much less common, may include plagiocephaly, mandibular

asymmetry, flattened facies, and crumpled ears. Therefore, most of these abnormalities are physiologic rather than pathologic in origin and resolve with normal growth and development. Others, such as developmental dysplasia of the hip, may not resolve and may cause significant disability unless they are recognized and appropriately managed. The speed of resolution depends on the severity of the deformity and the rate of growth of the involved area.

It is a common misconception that the bowed appearance of the neonate's lower extremities is an abnormality. All term neonates have 20- to 30-degree hip and knee flexion contractures that decrease to the neutral position by 4-6 months of age. The newborn hip is externally rotated in extension to 80-90 degrees and has a limitation of internal rotation of 0-10 degrees. Metatarsus adductus results from the tucked-under position, in which each foot is wrapped around the posterolateral aspect of the opposite thigh. The same position also produces lateral tibial bowing and inward (internal) rotation of the tibia. Tibial bowing and internal tibial torsion contribute to the bowed appearance of the lower extremity during the first year of life as well as a mild pigeon-toed or in-toed gait during the second year. However, this condition must be recognized as a normal variation resulting from the in utero position; it typically resolves with normal growth and development.

Trauma

See Chapter 29. Neonatal musculoskeletal injuries are frequently the result of a difficult or traumatic delivery. An abnormal intrauterine presentation and forcible extraction are associated with clavicular fractures, brachial plexus injuries, and occasionally long-bone fractures or epiphyseal separations (e.g., proximal humeral epiphysis) in otherwise healthy term infants. Prematurity, low birth weight, and underlying systemic disease may also predispose an infant to birth trauma and neonatal injury. These fractures are not usually associated with neurologic injury, and the prognosis for healing and subsequently normal function is excellent. Generally, these can be treated with minimal immobilization, such as pinning the arm sleeve to the body of the shirt. In contrast, fractures associated with neurologic injuries are more complex and have a more guarded prognosis.

Neonatal fractures resulting from abuse are uncommon but do unfortunately occur. Long-bone fractures in association with vague histories or suspicious causes must be investigated.

Spine

Neonatal spinal trauma may be classified as an injury directly to the spine (i.e., vertebrae, intervertebral discs, and supporting ligamentous structures) or indirectly to the surrounding structures. The latter includes injuries to the brachial plexus and the sternocleidomastoid muscle (e.g., muscular torticollis) of the neck.

Spinal Injury

Difficult delivery is the most frequent cause of neonatal spinal injury. Breech presentation, especially when associated with intrauterine neck hyperextension, traction during delivery, and forceps traction, puts the spine and enclosed neural elements at risk for injury. Injuries of the cervical spine are more common than those of the thoracic or lumbar spine; upper cervical injuries are more common than lower ones.

Spinal cord injury may occur with or without vertebral fracture. Excessive ligamentous laxity and the relative weakness of supporting musculature predispose the neonate to stretch injuries of the spinal cord without obvious skeletal damage. This stretch can produce spinal cord ischemia caused by vertebral artery or segmental vessel injuries and result in neurologic abnormality in some neonates. Extensive areas of vascular damage in the spinal cord have been reported in neonates who died as a result of obstetric trauma.

Fractures, dislocations, and subluxations of the occipitoatlantal, atlantoaxial, and second and third cervical articulations have been reported. The neonatal spine is incompletely ossified, and skeletal injury may be difficult to detect on routine radiography. Radioisotope scanning or magnetic resonance imaging may be useful for documenting injury in questionable cases.

Injuries of the brainstem and spinal cord may be fatal if the respiratory centers are compromised. For infants who survive, the goal of treatment is to improve function. When fracture or dislocation is documented, reduction and immobilization may be necessary to achieve segmental stability. Unfortunately, reduction rarely improves neurologic function.

Brachial Plexus Injury

See Chapter 29. Injuries of the brachial plexus have long been recognized as a consequence of difficult labor and delivery.[22] In 1877, Wilhelm Heinrich Erb described isolated upper plexus palsy and localized the site of damage to the junction of the C5 and C6 nerve roots, known thereafter as the *Erb point*. Erb's description remains an accurate assessment of the most common variety of plexus injury, with traction damage to spinal nerves C5, C6, and C7. The arm is held in a characteristic waiter's tip position, with the shoulder adducted and internal rotated, the elbow extended, the forearm pronated, and the wrist flexed.

Other patterns of brachial plexus injury are less common but well documented. Isolated injuries to the lower portion of the brachial plexus described by Klumpke are uncommon in infants. Wickstrom reported 11 such cases in his series of 87 patients.[29] Hoffer and associates observed four cases of posterior plexus damage in their series of 39 patients.[13] Total or mixed plexus involvement is reported to be the second most common pattern of injury after isolated upper plexus palsy.

The incidence of brachial plexus injury at birth is 0.1%-0.3% of live births. Risk factors include elevated birth

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

weight, prolonged labor, shoulder dystocia, and breech presentation, as well as high maternal body mass index and fetal asphyxia. Additionally, a humerus fracture is a risk factor for brachial plexus injury, whereas a clavicle fracture is not. Cesarean delivery does not fully protect children from birth palsy[1]; 10% of the affected patients have a history of cesarean delivery.

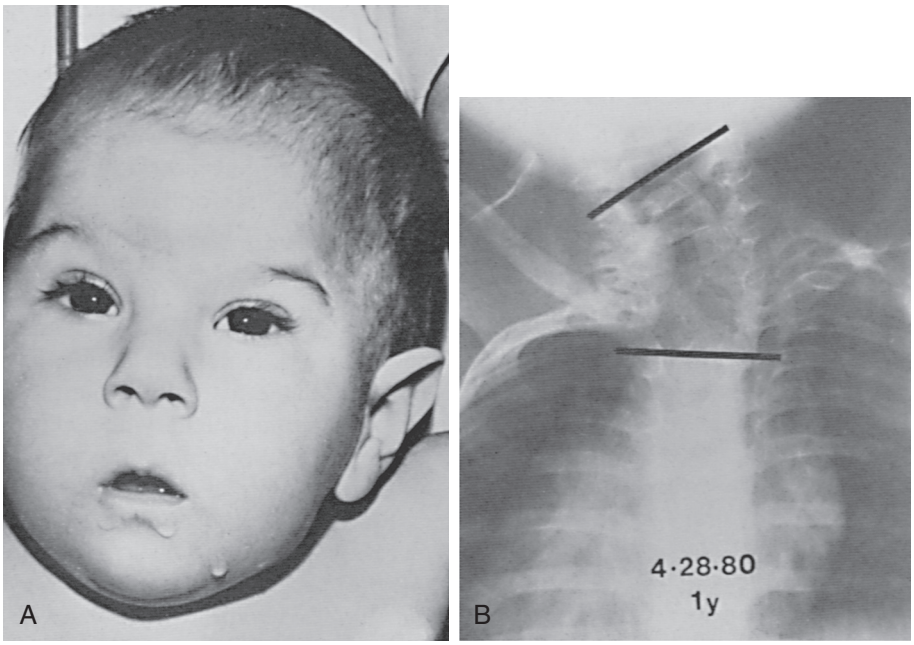
Traction damage of the plexus may occur at any level from the origins of the cervical nerve roots at the spinal cord to the terminal branches of the plexus and may range in severity from stretch with intact neural tissues to avulsion of nerve roots. The physical findings at birth reflect the degree of involvement. With lesions of the upper plexus, active wrist flexion and finger flexion may be present. In complete injuries, these motions are absent. An avulsion of the nerve root, or preganglionic lesion, is generally associated with the presence of Horner syndrome (sympathetic chain), elevated hemidiaphragm (phrenis nerve), or winged scapula (long thoracic nerve). The injury must be differentiated from other causes of decreased active motion in the neonatal period, such as fracture of the clavicle or upper humerus and septic arthritis or osteomyelitis. The diagnosis can usually be established from a history of difficult delivery, physical examination, and radiographic evaluation of the upper limb and trunk.

The prognosis varies with the extent of damage to neural tissues. Up to 90% of patients with incomplete lesions involving the upper plexus can expect full recovery with no treatment. In general, these children recover biceps function within 1 month of life and quickly become normal. Patients with complete injuries or injuries of the lower plexus do not fare as well. Most recovery occurs within the first 3 months of life, but continued slow improvement for up to 5 years after birth has been reported by Tada and colleagues for patients with complete injury.[25] Partial recovery occurs in most cases. Surgical repair of the brachial plexus has been recommended by Waters for children who have no return of biceps function by 6 months of age.[28] Compared with the natural history of the lesion, improved but not normal function is possible. Shoulder contracture and osseous deformity (nonspherical humeral heads and abnormal glenoids) are common in patients with birth palsies. They commonly occur in children who have incomplete recovery and are also seen in those who eventually have complete neurologic recovery if that recovery does not start within the first 3 weeks of life.[12]

Infants with nerve root avulsion have the worst prognosis; no motor recovery can be expected in such cases, although some sensory recovery may occur. Fortunately, avulsion injuries are uncommon. Surgical repair of infants without elbow flexion using ulnar and/or medial nerve fascicle transfers has demonstrated partial efficacy in infants with nerve root avulsion, late presentation, dissociative recovery, and failed nerve grafting.[8]

In most cases of neonatal brachial plexus palsy, no treatment is necessary. Abduction splinting of the limb in the first few months of life is unnecessary and may further complicate lower plexus injury. Gentle range-of-motion exercises may be used to prevent adduction and internal rotation contracture. Infants with incomplete recovery may require later reconstructive surgery to minimize deformity and functional disability. In young children without fixed contractures and secondary bony deformities, tendon transfers may be used to balance asymmetric forces.[13,27] In older children, humeral osteotomy is occasionally necessary to correct internal rotational deformity.[17]

Muscular Torticollis



Torticollis in the neonatal period is most commonly associated with abnormalities of the sternocleidomastoid muscle. Shortening of the sternocleidomastoid muscle results in tilting of the head toward the affected muscle and rotation of the chin toward the opposite side. Birth trauma, intrauterine malposition, muscle fibrosis, and venous abnormality within the muscle have all been implicated, but no single cause has been identified. Davids and associates demonstrated that the sternocleidomastoid muscle is contained within a separate fascial compartment.[6] They thought that a stretch or tear of the sternocleidomastoid muscle that caused bleeding could result in a compartment syndrome, leading to significant muscle damage and contracture. A palpable mass is sometimes present within the affected muscle during the first few weeks of life. Flattening of the head and slight facial asymmetry or plagiocephaly are usually present. If the deformity is not corrected, contractures of the soft tissues on the side of the affected muscle occur, and pronounced plagiocephaly may develop.

Torticollis is occasionally associated with developmental dysplasia of the hip (DDH) severe enough to require treatment; this varies between 3.7% and 10% of patients, depending on the study.[20,26] It is also seen in association with metatarsus adductus.[15] All of these conditions are often the consequence of tight in utero positioning.

Torticollis may also be the result of congenital cervicovertebral anomalies (Fig. 97.2). Ballock and colleagues reported that Klippel-Feil syndrome and congenital scoliosis were diagnosed in 5% of all torticollis patients referred to a large tertiary children's hospital.[2] The severity of the curvature and associated head deformity depend on the nature of the vertebral defect. Cervical hemivertebrae are sometimes less deforming than unsegmented, unilateral cervical bars. As in all cases of congenital spinal curvature, a careful search for other systemic anomalies, such as those involving the cardiac and genitourinary systems, must be made.

The cause of torticollis should be established before treatment is initiated. Careful radiographic examination of the cervical spine is recommended. Anteroposterior and lateral views of the neck should be obtained initially; computed tomography may be necessary in some cases. Particular attention should be given to the upper cervical spine, especially the occipitoatlantal (occiput-C1) and the atlantoaxial (C1-C2) regions. If no underlying skeletal abnormalities are identified, a program of stretching exercises is indicated to lengthen the contracted sternocleidomastoid muscle. The

• **Fig. 97.2** Congenital scoliosis may be manifested as torticollis. **A,** Clinical photograph of a 1-year-old child with congenital cervical scoliosis. The chin is tilted toward the right and the occiput toward the left. **B,** Radiographic views of the cervical spine in this patient show multiple hemivertebrae formation and an unsegmented congenital bar on the left side of the lower cervical spine. By convention, scoliosis films are viewed as if the examiner is facing the patient's back.

head is first tilted toward the opposite shoulder, and the chin is then rotated toward the affected side. Exercises should be performed gently, and the corrected position should be maintained for 5-10 seconds on each repetition. A program of 10-15 repetitions performed four times daily is sufficient in most cases. Stretching should begin early. This procedure seldom fails if begun during the first 3 months of life, but seldom succeeds if begun after 18 months of age.[7] Positioning the infant's crib with the normal side of the neck toward the wall sometimes stimulates an infant who lies prone to turn his head and stretch the sternocleidomastoid muscle. However, this is not always reliable and should not replace manual exercises.

The surgical release of sternocleidomastoid contracture is indicated if there is significant deformity after 6 months of vigorous therapy or for older children with untreated torticollis.[4] Early surgery provides the best outcome, although children can benefit from surgery up to 10 years of age.[5] Delayed treatment results in significant plagiocephaly, and surgery before 5 years of age was associated with more improvement in craniofacial curvature than surgery after 5 years, although both groups had improvement.[16] Recurring contracture is a problem in older children.

The treatment of torticollis resulting from congenital cervical scoliosis is difficult because the primary cause of torticollis in these patients is skeletal, and soft tissue stretching cannot provide lasting correction. Surgical fusion of the affected area may be necessary to halt progression. It may be impossible to reverse the facial asymmetry that has developed because of head tilting.

Fractures

See Chapter 29. Neonatal fractures usually involve the upper extremity, particularly the shoulder region, and are the result of a difficult delivery. Fractures of the lower extremity are less common and may be indicative of an underlying neuromuscular disorder, especially those that limit joint mobility, such as arthrogryposis multiplex congenita. Fractures may also result from a bone disorder, such as osteogenesis imperfecta.

Clavicle

Fractures of the clavicle are the most common type of fracture in neonates. The incidence of clavicular fractures ranges from 2-7 cases per 1000 live births. McBride and coworkers reported 9106 newborns prospectively screened for clavicular fracture.[18] In this study, the risk factors included high birth weight, shoulder dystocia, and mechanically assisted delivery. Breech positioning was a factor in previous decades but not in this study. The liberal use of cesarean delivery appears protective. Of the 9106 babies reviewed, 1789 were delivered by cesarean section for various indications, including breech positioning. There were no clavicular fractures in these patients, although other authors have reported clavicular fractures after cesarean delivery.[14]

Fractures may be complete or incomplete (e.g., greenstick fracture). Complete fractures are more likely to be accompanied by classic symptoms and signs. Irritability and pseudoparalysis (e.g., decreased motion because of pain) of

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

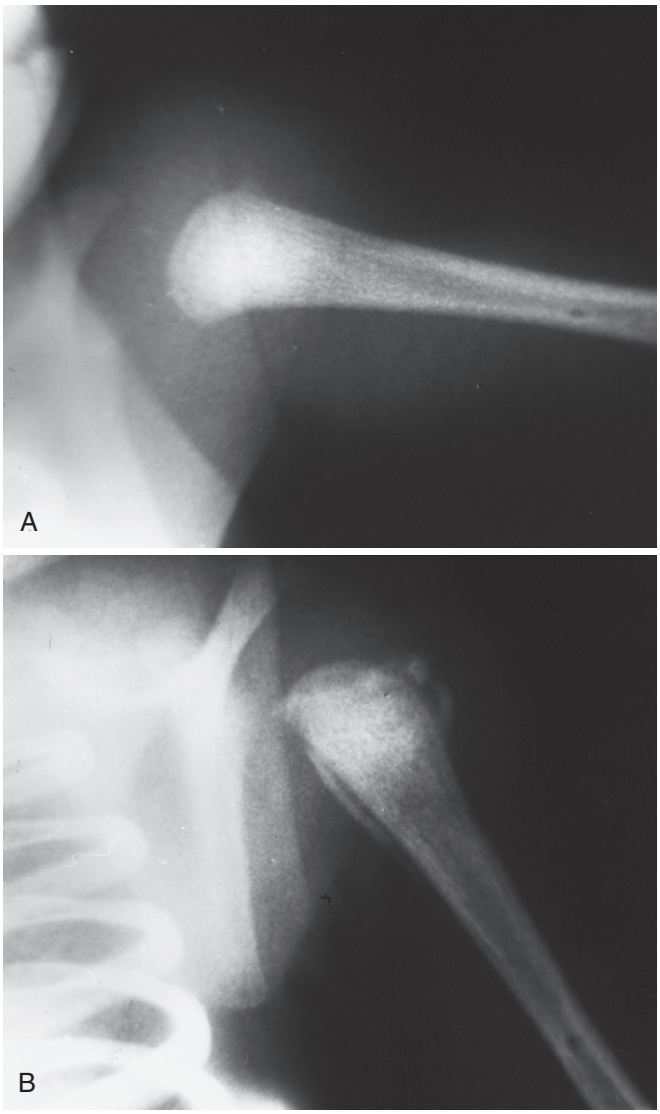
the involved limb are common. Discoloration, tenderness, and crepitation at the fracture site are common physical findings. Brachial plexus palsy, neonatal sepsis, traumatic separation of the proximal humeral epiphysis, humeral shaft fracture, and shoulder dislocation must be considered in the differential diagnosis.



The treatment of clavicular fracture is simple; asymptomatic patients with incomplete fractures need no immobilization. Symptomatic infants, usually those with complete fractures, should be treated. The treatment can include applying a figure-eight harness of gauze and tape or securing the affected arm to the chest with a bandage for 7-10 days. Pinning the sleeve of the infant's shirt to the front is often sufficient. An elastic bandage loosely applied around the chest and involved extremity after a cotton pad has been placed in the axilla can be considered for larger infants.

Congenital pseudarthrosis of the clavicle is a rare condition that is distinguished from a neonatal clavicle fracture by the lack of birth trauma and the lack of healing callus on follow-up images. Isolated right-sided involvement is most common, with bilateral involvement less common and isolated left-sided involvement generally seen only in the context of dextrocardia. It is postulated that compression from the subclavian artery may explain the predilection for right-sided disease, and cervical ribs may account for bilateral disease. Congenital pseudarthrosis of the clavicle is generally asymptomatic in infants, with operative repair delayed until early childhood.

Long-Bone Fractures

Fractures of other long bones are occasionally seen after a difficult delivery. Fractures or separations of the proximal humeral epiphysis may occur with the same force that produces clavicular fracture and brachial plexus injury. Symptoms and signs may be similar; pseudoparalysis, swelling, pain on passive motion, and crepitation with shoulder joint motion are usually present. In contrast to the clavicle, the proximal humeral epiphysis is not ossified at birth, and routine radiography cannot demonstrate fracture or epiphyseal separation (Fig. 97.3). Ultrasonography can be used to establish the diagnosis in some cases, but most often the diagnosis is not confirmed until healing callus formation is seen radiographically 7-14 days later. Arthrography and magnetic resonance imaging can also be used to establish the diagnosis. When the diagnosis is confirmed soon after injury, the affected limb can be immobilized in a Velpeau bandage, although simply pinning the shirt to restrict motion is often adequate. Treatment is unnecessary if the diagnosis is delayed until callus formation has occurred. Scaglietti pointed out that late contractures of the shoulder in patients with fractures or separations resulting from a severely displaced proximal humerus may be difficult to distinguish from contractures caused by brachial plexus injury.[22]

Fractures of the humeral and femoral shafts occasionally occur during delivery or with the routine management of a premature infant or an infant with a severe metabolic or neurologic disorder. Such injuries are the result of an underlying weakness of the bone rather than traumatic handling, and accompanying soft tissue injury is rarely severe. Such fractures can usually be treated successfully with the application of a simple plaster splint until radiographic callus formation occurs. Spica casts are often used for fractures of the femur shaft, although in the infant, a Pavlik harness may simplify care without any delay in healing or additional deformity.[23] The remodeling potential of the neonatal skeletal system is extraordinary, and long-term sequelae from long-bone fractures are not common.

• **Fig. 97.3** **A,** Normal-appearing radiograph of the humerus in a female newborn who had pseudoparalysis and appeared to have pain with passive motion of the left shoulder. **B,** Repeated radiograph 1 week later demonstrates subperiosteal new bone formation, indicating that there had been a traumatic separation of the proximal humeral epiphysis at delivery. The arm is now asymptomatic, and voluntary shoulder motion has returned.

Key Points

- Many neonatal musculoskeletal disorders are congenital in origin. The first trimester is the embryonic period producing congenital malformations, while the second and third trimester are the fetal period. This period produces deformations and alterations of essentially normal parts.
- Common embryonic period abnormalities include congenital spinal deformities, teratogenic limb and spinal malformations, and genetic disorders.
- Common fetal period abnormalities include in utero positioning problems (tibial torsion, metatarsus adductus, developmental dysplasia of the hip), trauma at birth producing spinal injuries, brachial plexus injuries, muscular torticollis, and fractures, especially of the clavicle and proximal humeral metaphysis.

Bone and Joint Infections in Neonates

ALLISON GILMORE AND GEORGE H. THOMPSON

Bacterial infections of the neonatal skeletal system are potentially disabling because of damage to the articular cartilage and epiphysis. Prompt diagnosis and treatment are imperative to prevent sequelae.[2,18] Unfortunately, neonates with skeletal infections do not usually have the classic symptoms or laboratory findings of sepsis early on because of their immature immune systems. Feeding intolerance, reduced movement, and/or irritability may be the only early signs of infection. Diagnosis requires a high index of suspicion and appropriate evaluation. When infections involve the bone, the disease process is called *osteomyelitis.* When the synovium (the membrane lining of the joint) is the primary site of infection, the process is called *septic arthritis* (see Part 9: The Immune System).[10]

Osteomyelitis

Pathology and Etiology

Bone infection, or osteomyelitis, occurs by three mechanisms: bacteremia or hematogenous spread; direct inoculation from a puncture wound, such as a heel or femoral vein stick; and a contiguous spread from an adjacent focus of infection. In neonates, as in infants and children, most bone infections are hematogenous in origin. The most common site of osteomyelitis is the metaphysis, the region of the bone immediately adjacent to the physis or growth plate. The anatomic arrangement of metaphyseal vessels and the dynamics of blood flow in this region permit bacteria to lodge and proliferate. The nutrient artery ascends to the metaphysis from a central location within the bone. When the arterioles reach the physis, they make 180-degree turns and empty into the venous sinusoids. This process creates an area of sluggish blood flow and an opportunity for bacteria to become trapped and proliferate. A separate set of vessels nourishes the epiphysis.

In childhood, there is no connection between the epiphyseal and metaphyseal blood supply. The physis creates a barrier that is seldom penetrated by the spread of infection from the metaphysis to the epiphysis or from the epiphysis to the metaphysis. However, during the first 12-18 months of life, this barrier to the spread of infection does not exist, because there are vessels passing through the physis that connect the epiphyseal and metaphyseal circulations.[2,3,17] These vessels allow infections to cross the physis, which may account for the increased incidence of physeal damage seen in neonatal osteomyelitis when compared with childhood osteomyelitis.[2,10,18] Peters and associates observed the late onset of growth disturbance after neonatal osteomyelitis and recommended that the affected neonates be followed to skeletal maturity to monitor for growth disturbances.[18]

When bacteria lodge in the metaphyseal vessels and begin to proliferate, inflammation followed by abscess formation occurs. The pressure from the purulent material causes extrusion of the pus through the haversian canals to the cortex and subsequently into the subperiosteal space. The continued subperiosteal accumulation of purulent material strips the periosteum from the bone. Because the periosteum supplies blood to the cortex, this stripping process interrupts cortical blood flow. As a result, large areas of cortical bone may become devascularized. This dead bone, or sequestrum, can serve as a site for chronic infection, which is isolated from limited neonatal defense mechanisms and antibiotics.[17] The elevated periosteum produces new bone in an attempt to repair the injured bone. This process in turn produces the involucrum, which surrounds the sequestrum.

Draining cutaneous sinuses may arise when pus ruptures through the periosteum, adjacent soft tissues, and skin. Infection may occasionally spread into an adjacent joint space, causing secondary septic arthritis. The destruction of the epiphysis may occur through the direct spread of infection into it. This process can result in subsequent shortening, angular deformity, or both, of the involved extremity.[18] In neonates, complete physeal closure can occur, resulting in shortening.[2] Damage to the articular surface of the joint may result in the loss of motion and ultimately degenerative osteoarthritis.

The etiologic organisms responsible for neonatal osteomyelitis are variable. *Staphylococcus aureus* has traditionally been the most common causative organism.[2] Methicillin-resistant *S. aureus* (MRSA) has been reported in neonates, which is especially destructive.[13] Group B streptococcus (*Streptococcus agalactiae*) and Gram-negative organisms (*E. coli* and *Klebsiella pneumonia*) are all seen in the neonatal

Abstract

Bacterial infections of the neonatal skeletal system are uncommon. Most will be hematogenous (blood borne) in origin. When bone is the primary focus it is termed osteomyelitis; if the synovial lining of a joint is the primary site it is septic arthritis. Limitation of motion, pain, joint effusion, and increased warmth are common findings. Involved neonates typically appear less ill because of the persistence of maternal antibodies. They have less fever, leukocytosis, and elevation of erythrocyte sedimentation rate and C-reactive protein. Plain radiographs can be helpful. Technetium bone scan and magnetic resonance imaging are frequently necessary in establishing the diagnosis and location. Early and accurate treatment is important. Antibiotics alone can be successful during the early inflammatory stage while surgery to drain an established septic arthritis, subperiosteal, or bone abscess in osteomyelitis is frequently necessary. Delaying adequate treatment can result in chronic osteomyelitis, bone and joint destruction, avascular necrosis, and other complications.

period.[5] *Candida albicans* can also cause osteomyelitis in those neonates at high risk for infection.

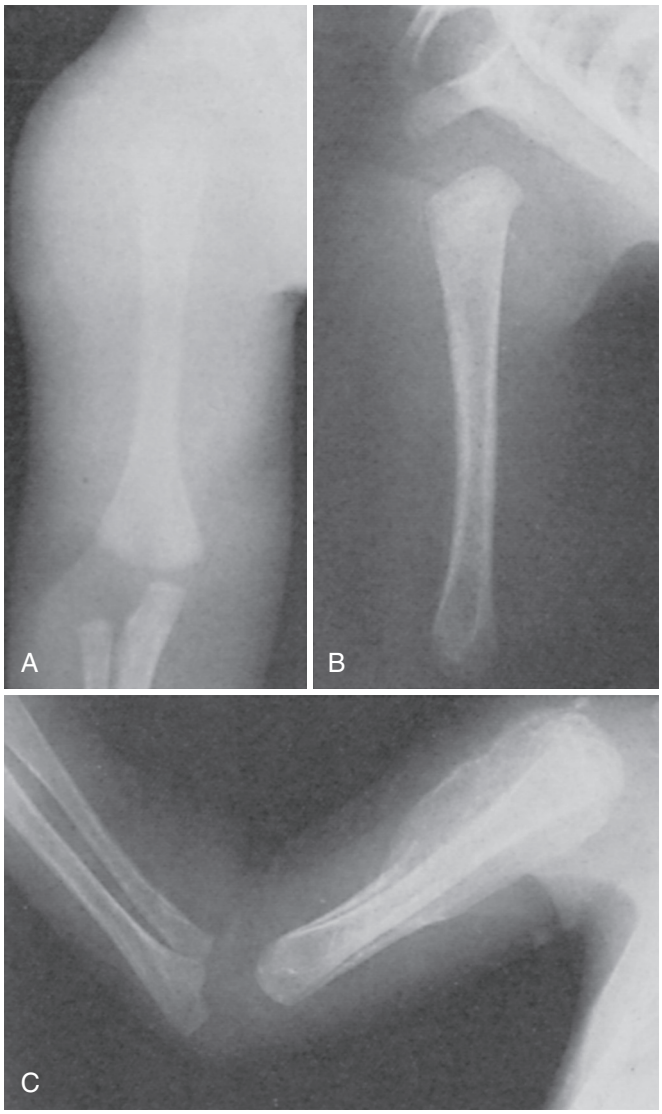
Diagnosis

The clinical manifestations of osteomyelitis in children vary with age. In previously healthy neonates, it usually occurs during the first 2 weeks of life. Limitation of spontaneous movement with pseudoparalysis of the involved extremity is the most common sign. Localized tenderness, erythema, increased warmth, and swelling may occur. Associated septic arthritis with accompanying joint effusion and increased warmth occurs in many cases. Term neonates usually appear less ill than would be expected because of the persistence of maternal antibodies. They have less fever, leukocytosis, and elevation of the C-reactive protein and erythrocyte sedimentation rate[2] than older children with similar infections. Less commonly, neonatal osteomyelitis presents as septicemia. The presentation and course of osteomyelitis are strongly correlated with the health of the infant before presentation. Infants with multiple sites of infection are usually ill before its onset and have an increased incidence of placement of umbilical catheters or other lines. They are also more ill than those neonates presenting with only one site of infection.[2]

Some neonates are at increased risk for osteomyelitis; they also have a more severe course of the disease. Bergdahl and colleagues identified the following risk factors in a study of 40 neonates with osteomyelitis: a birth weight of less than 2500 g or gestational age of less than 37 weeks, emergency cesarean delivery, a congenital malformation requiring neonatal surgery, respiratory distress syndrome, hyperbilirubinemia, large vessel (usually umbilical) catheterization, perinatal asphyxia, scalp laceration after vacuum extraction, and renal vein thrombosis.[2] Twenty-one neonates were found to have risk factors but 19 did not. Of the 21, most had multiple sites of infection; 13 of the 21 (62%) neonates with risk factors had serious skeletal sequelae. In the remaining 19 neonates, multiple sites of infection were uncommon, and serious skeletal sequelae occurred in less than 20%.

The early diagnosis of osteomyelitis is based on obtaining purulent material, blood, or both for cultures and antibiotic sensitivities. Early in the course of the disease, radiographs and bone scans may be normal.[1,3,6] Bone aspiration is usually positive. The cultures of subperiosteal metaphyseal pus yield a pathogen in about 70% of cases. The point of maximal swelling, bone tenderness, and fluctuation on physical examination is the most appropriate location for needle aspiration. The skin overlying the affected region should be prepared with an antiseptic solution and draped with sterile towels. After infiltration of the area with local anesthetic, an 18-gauge spinal needle, with the stylet in place, is passed through the skin to the bone. The subperiosteal space is aspirated first. If the tap is dry, the needle with the stylet should be gently twisted through the bone cortex into the metaphysis, which is then aspirated. The aspirated fluid or blood should be immediately Gram-stained and cultured. The organism may also be recovered from other sources. Blood cultures are positive in 60% of children with osteomyelitis. When osteomyelitis complicates meningitis, the organism may be recovered from cultures of the cerebrospinal fluid.

Imaging



See Chapter 38. A diagnosis cannot be easily made by bone aspiration during the inflammatory phase before abscess formation. At this point, imaging can be helpful. Plain radiographs of the suspected bone are often a valuable procedure. Within a few days of the onset of infection, deep edema, joint effusion, and sometimes bone destruction can be detected.[2] The edema is visible sooner in neonates than in children, because the neonate has very porous bones and a loosely attached periosteum (Fig. 98.1), which permits the earlier collection of subperiosteal abscesses in neonates than in children. This fact also accounts for the relatively favorable results of diagnostic aspiration in neonates.

If radiographs are unproductive, ultrasound can be useful in localizing the areas of deep edema (subperiosteal fluid collection or abscess) and joint effusion, as well as periosteal thickening or elevation.[15] Magnetic resonance imaging is very sensitive for early detection of osteomyelitis and will show details of bone involvement, abscess formation, and septic arthritis. Limitations include possible need for sedation and patient stability to transfer to the MRI unit.[9] Technetium bone scanning is currently used less often; however, it may be helpful in neonates with suspected multifocal infection.[11] There is some controversy over the merits of bone scanning in neonates because of their decreased inflammatory response and the large amount of isotope uptake from the very active adjacent epiphysis. In 1980, Ash and Gilday[1] concluded that it was very unreliable. However, Bressler and co-workers[3] and others[6] have suggested that technetium bone scans can be helpful. Bressler's group scanned 33 infants suspected of having osteomyelitis. Each of the 25 sites of proven osteomyelitis in 15 infants was demonstrated on bone scanning. Another 10 sites that were radiographically negative were also demonstrated to be positive on bone scanning. The bone scan, if negative, does not exclude osteomyelitis.

The results of indium and gallium scans for acute osteomyelitis in neonates have not been reported. A concern about gallium scans is related to the pathology of osteomyelitis. If there is extensive septic embolization of metaphyseal vessels, labeled blood cannot penetrate the metaphysis. If the periosteum is stripped off the cortex, devascularizing the cortical bone, there can be no blood flow in the cortex. Under these circumstances, the uptake by bone may be difficult to predict. However, Demopulos and associates recommended an indium scan if the technetium bone scan in the neonate is not highly suggestive of osteomyelitis.[6]

Another concern in the assessment of osteomyelitis is the determination of whether metaphyseal aspiration can

• **Fig. 98.1** Radiologic changes in neonatal osteomyelitis. **A,** Early proximal humeral osteomyelitis. Soft tissue has become swollen around the affected bone. **B,** Periosteal elevation is manifested by subperiosteal bone formation. **C,** Massive subperiosteal new bone formation. The humeral shaft has become surrounded by new bone.

produce a positive bone scan. Canale and colleagues[4] assessed the effects of bone, and joint aspiration on the bone scan results in healthy dogs. They used multiple aspiration techniques on the bones and joints of 15 dogs and scanned them between 5 hours and 10 days of aspiration. In no case did joint aspiration lead to a positive bone scan. Metaphyseal drilling and periosteal scraping with needles occasionally led to positive bone scans after a 2-day delay. Thus, bone aspiration does not initially affect a technetium bone scan.

Treatment

Treatment must not be delayed for neonates with suspected osteomyelitis. Antimicrobial therapy should be initiated, usually with a combination of agents, as soon as a presumptive diagnosis is made and appropriate material for cultures has been obtained. Treatment can later be appropriately altered according to culture results and antibiotic sensitivities. For neonates, optimal coverage is provided by penicillinase-resistant penicillin coupled with an aminoglycoside. The new third-generation cephalosporins have been successfully used in the treatment of a form of osteomyelitis caused by enteric bacilli. However, these agents should not be used alone as the initial treatment, because their activity against group B streptococci is inadequate. When these drugs are used as part of the initial therapeutic regimen, penicillinase-resistant penicillin should be used concomitant with them. After an organism is isolated, focused antibiotic treatment is possible. The duration of treatment should be at least 3 weeks and probably not more than 6 weeks for acute hematogenous osteomyelitis. Nelson suggests a clinical approach to antibiotic management.[16] After local inflammation subsides and measures of inflammation such as CRP and erythrocyte sedimentation rate return to normal, he recommends 14 more days of antibiotics for group A streptococci and encapsulated bacteria such as pneumococci and 21 more days for staphylococcal infection. Historically, neonates were treated solely with intravenous antibiotics. New literature may suggest treating neonates with osteomyelitis with sequential intravenous–oral antibiotic therapy. A Dutch neonatal ward successfully treated proven methicillin-susceptible *Staphylococcus aureus* osteomyelitis with 2-3 weeks of intravenous antibiotics followed by oral clindamycin for 3 weeks without relapse or sequelae. This theoretically could decrease morbidity from intravenous access as well as associated costs.[7]

Primary surgical treatment depends on the results of bone aspiration. If grossly purulent material is recovered from the subperiosteal space or the metaphysis, an abscess has formed. In these cases, surgical drainage is necessary to decompress the abscess. This procedure facilitates blood flow and the subsequent delivery of antibiotics. Surgical drainage also allows the removal of the bone sequestrum. When pus is not recovered at the time of initial aspiration, the patient's infection is in the cellulitic or inflammatory phase. The aspirated blood is used to obtain blood cultures, and antibiotic therapy is initiated. It is assumed that the bone blood flow is still adequate in the cellulitic phase to deliver antibiotics to the site of infection, because there is no pus under pressure. The affected limb should be immobilized with splints. Neonates must be carefully followed during the early phases of treatment. Surgical intervention may become necessary if an adequate clinical response is not obtained within 48 hours of initial antimicrobial therapy.[14] An inadequate response implies that an abscess is forming. Reassessment, including repeated aspiration, is indicated. If an abscess is identified, surgical drainage will be necessary.

La Mont and co-workers[14] reviewed 69 children (15 neonates) retrospectively and 44 children (4 neonates) prospectively, all with acute hematogenous osteomyelitis. They

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

concluded that surgery was seldom necessary because most of the prospective group improved clinically after 48 hours of appropriate intravenous antibiotics, and few of them had abscesses aspirated. In their study, surgery was infrequently used, and the results were excellent. It was their impression that the aspiration of pus from the bone was an indication for surgery but was seldom encountered. Drainage was also recommended for an extraosseous abscess.

It is believed that the surgical decompression of long bones such as the femur, tibia, humerus, radius, and ulna is necessary if pus is aspirated from bone or the subperiosteal space.[2] Decompression consists of drilling a hole in the metaphysis or removing a small cortical window. The wound is then closed loosely to allow it to drain. If a drain is placed, it is removed 24-48 hours later. Surgical decompression is also necessary if there is not a good clinical response to antibiotics within 48-72 hours, even if no pus is aspirated from the bone.

If osteomyelitis is localized to flat bones, such as the pelvis or vertebrae, the administration of antibiotics without surgical decompression is usually sufficient treatment. However, caution is necessary because Bergdahl and associates reported one death and one case of tetraparesis resulting from neonatal vertebral osteomyelitis.[2]

Septic Arthritis

Pathology and Etiology

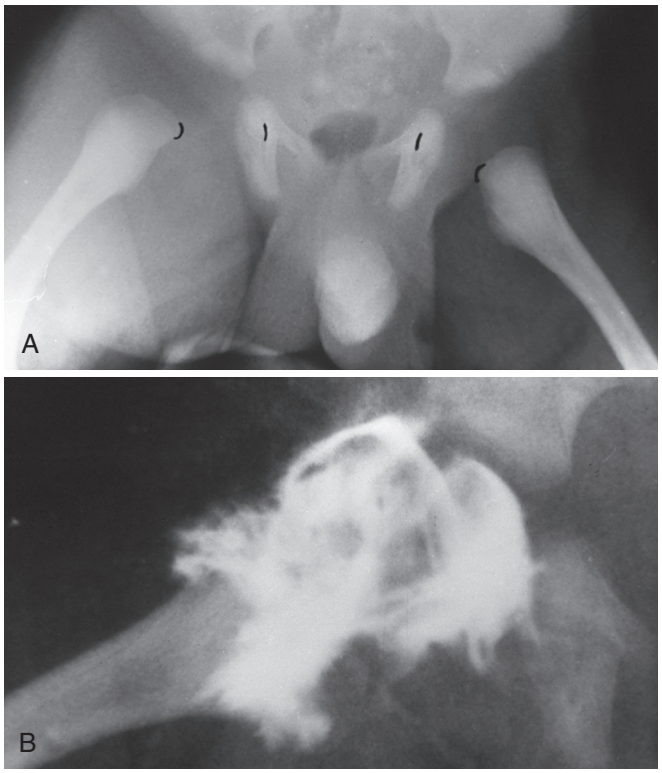
The mechanisms responsible for joint or synovial infections in neonates and children parallel those for osteomyelitis: septicemia, contiguous spread from an adjacent focus of infection, and traumatic penetration of the joint space. Osteomyelitis in the proximal femur (hip), proximal radius (elbow), proximal humerus (shoulder), and distal tibia (ankle) in neonates may progress to a septic joint, because the metaphyses of these bones are intra-articular. The risk factors include prematurity, umbilical catheterization, perinatal asphyxia, and a difficult birth.[12] Regardless of the source, the ensuing inflammatory response results in synovial hypertrophy and altered capillary permeability. Purulent material accumulates within the joint, and fibrinous clots may coat the joint surfaces. The diffusion of nutrients across the articular cartilage of the joint is interrupted, and the normal lubrication processes are altered. Lysosomal enzymes, which are released in neutrophil degeneration, attack the mucopolysaccharide components of articular cartilage. Hypertrophic granulation tissue forms a pannus that can erode articular cartilage and may allow the extension of infection to subchondral bone. Fibrous ankylosis of the joint may develop, with a permanent loss of motion.[19] Increased intra-articular pressure may occlude the vessels that supply the epiphyses and the physis, resulting in epiphyseal death or avascular necrosis. This process is especially applicable to the hip. The rupture of pus through the synovial membrane and into the surrounding tissues produces soft tissue abscesses that may later develop into draining sinuses.

Neonatal septic arthritis often results from osseous infection, and the bacterial agents responsible for the joint infections are similar to those previously described for neonatal osteomyelitis: *S. aureus*, streptococci, and enteric bacilli. Septic arthritis occurs less frequently as a primary entity; the Enterobacteriaceae family, the species of *Pseudomonas*, and *Neisseria gonorrhoeae* may be isolated in these cases. Fink and Nelson reported septic arthritis from *Haemophilus influenzae* in neonates as young as 3 days of age.[8] About 25% of the neonates with *H. influenzae* septic arthritis also have meningitis.

Diagnosis

The clinical presentation of neonatal septic arthritis is similar to that described for neonatal osteomyelitis. Joint effusion, increased warmth, and limited motion are often observed on physical examination. Often, early diagnosis is delayed because physical findings may be subtle.

The definitive diagnosis of septic arthritis requires aspiration of the affected joint. The causative agent can be recovered in about 60% of cases. The procedure should be performed under sterile conditions by an experienced physician, because repeated attempts to penetrate the joint may further damage the joint surface and the underlying bone. After culture and Gram staining of the fluid, determinations of the cellular count as well as glucose and protein concentrations should be obtained. Infected synovial fluid typically contains more than 50,000 white blood cells per cubic millimeter (primarily polymorphonuclear leukocytes); a glucose concentration of less than 40 mg/dL, or less than 30% of the serum concentration; and an elevated protein concentration. Blood cultures should also be obtained.



Imaging

Neonatal septic arthritis has the same recommendations as those for osteomyelitis (Fig. 98.2). Ultrasound is especially useful in neonatal hip infection. An ultrasound of both hips should be performed. Ultrasound, however, cannot differentiate between a septic and a sterile effusion. Magnetic resonance imaging may be difficult to obtain expeditiously, but can identify a joint effusion and subperiosteal abscess. Bone scans are used less often in neonates. Of special interest are the findings of Canale and colleagues that joint aspiration in dogs is never associated with a positive technetium bone scan.[4] Consequently, the aspiration of joints should never be discouraged on the basis of a belief that it may affect a later bone scan.

Treatment

Neonatal septic arthritis, like osteomyelitis, requires prompt treatment. Irreversible joint damage may occur unless

• **Fig. 98.2 A,** Anteroposterior pelvic radiograph of a 2-week-old boy who had been irritable during diaper changes for 1 week. There were no systemic symptoms, such as fever, although the child had been quite irritable and not feeding normally. The femoral heads are not visible, because they do not begin to ossify until 4-6 months of age. Observe the widening between the acetabulum and the ossified medial corner of the proximal femoral metaphysis, which indicates lateral displacement or subluxation of the femoral head. **B,** Arthrocentesis revealed only a small amount of purulent material. An attempted arthrogram revealed gross distortion of the hip joint caused by inspissated purulent material. At the time of hip arthrotomy, clotted, purulent material was removed. This child subsequently developed avascular necrosis as a consequence of septic arthritis with subluxation. Fortunately, he made a satisfactory recovery and regained essentially normal hip function.

intra-articular pus is evacuated and effective antimicrobial therapy initiated.[16,21] Neonates should be managed jointly by pediatricians and orthopedic surgeons.

Combinations of antibiotics are selected to cover the most likely pathogens. A penicillinase-resistant penicillin and an aminoglycoside or cephalosporin usually provide adequate coverage pending the results of the cultures and antibiotic sensitivities (see Part 9: The Immune System).

Joint decompression is an essential component of successful therapy for pyogenic arthritis. However, opinions vary on the most effective method, specifically surgical drainage compared with repeated aspiration. Primary decompression is usually accomplished at the time of initial joint aspiration and may be sufficient in peripheral joints such as the knee, ankle, and elbow, which are easily aspirated and in which blood flow to intra-articular epiphyses is not at risk. Needle aspiration is not sufficient for decompression of the hip because increased intra-articular pressure may occlude blood flow to the femoral head, resulting in avascular necrosis. Immediate surgical drainage is mandatory for septic arthritis of the hip.[20]

The repeated aspiration of joints other than that of the hip may be appropriate. The morbidity for careful aspirations is less than that for arthrotomy, but persistent infection after repeated aspiration is probably more harmful than the risk for primary arthrotomy. Poorly executed needle aspiration may damage the articular surfaces and inoculate underlying bone with purulent fluid.

Like the therapy for osteomyelitis, effective antimicrobial therapy for pyogenic arthritis is a function of the agent, route, and duration of drug administration. After the pathogen has been isolated and antibiotic sensitivities are known, a single agent may be used. Intra-articular antibiotic instillation is unnecessary, because adequate drug concentrations are achieved in synovial fluid by the intravenous and parenteral routes.

Joint infections caused by *H. influenzae* require 2-3 weeks of therapy, whereas infections caused by other agents or those complicated by osteomyelitis may require up to 6 weeks of therapy. The treatment of neonatal gonococcal arthritis differs significantly from that of arthritis caused by other pathogens. Penicillin G, ampicillin, amoxicillin, tetracycline, and erythromycin have all been used successfully in therapy for gonococcal arthritis in 7- to 10-day courses. Other than diagnostic arthrocentesis, no surgical intervention is necessary for this disease.

Acknowledgment

The author and editors acknowledge the important contributions of Daniel R. Cooperman to the previous editions of this chapter, portions of which remain unchanged.

Key Points

- Neonatal skeletal infections are uncommon, but early diagnosis and treatment is critically important to prevent complications.
- Most skeletal infections are hematogenous (blood borne) in origin. If bone is the primary focus, it is termed osteomyelitis; if the synovium of the joint is involved, it is septic arthritis.
- Evaluation and diagnosis are primarily clinical, although plain radiographs and specialized imaging studies can be useful. Hematologic studies other than bone/joint aspirates and blood cultures and sensitivities are less helpful.
- Treatment is either by antibiotics, surgical drainage of abscess, or both, depending on the location, radiographic findings, and initial response to antibiotic therapy alone.

Congenital Abnormalities of the Upper and Lower Extremities and Spine

JOCHEN P. SON-HING AND GEORGE H. THOMPSON

Upper Extremities

Congenital abnormalities of the upper extremities are those that occur during the embryonic period. Developmental deformities are those that occur primarily in the fetal or neonatal period. Because a developmental deformity may have a prenatal association, such as in utero positioning, it could be misinterpreted as a congenital abnormality. Congenital and developmental disorders of the upper extremities are less common than those affecting the lower extremities.

Shoulder

The failure of the scapula and the upper extremities to descend to their normal locations is called Sprengel deformity, which can vary from mild to severe. In this condition, the scapula is typically located abnormally elevated with respect to the child's neck and thorax, producing webbing of the skin at the base of the neck and a low posterior hairline. In the severe form, an accessory bone (the omovertebral bone) may connect the scapula to the spinous processes of the cervical spine and allow virtually no scapulothoracic motion. The severe forms are more likely than the mild forms to be diagnosed in the neonate. Associated muscle contractures that further limit the strength and stability of the shoulder girdle may also be present. In the mild form, the scapula is slightly elevated, with less than normal motion. There may be an association with congenital cervicovertebral abnormalities, particularly Klippel-Feil syndrome, and this association suggests the possibility of other congenital abnormalities, such as those in the cardiovascular and genitourinary systems. When Sprengel deformity is diagnosed, abnormalities in these other systems must be assessed.

Treatment is usually delayed until middle childhood and depends on the function of the child's shoulder and extremity. In severe forms, surgical repositioning and occasionally partial resection of the scapula may be necessary.

Elbow

Congenital radioulnar synostosis is an uncommon disorder that represents a failure of separation, or congenital fusion, between the proximal radius and ulna. It occurs from the 5th to the 8th week of gestation, when there is separation of the humerus, radius, and ulna from a common block of cartilage in the limb bud. This disorder is bilateral in approximately 50% of all patients and limits forearm pronation and supination. It is rarely recognized during the neonatal period, because there is no obvious deformity, only a loss of forearm rotation. In most cases, the forearm is in a physiologic position of 45-60 degrees of pronation. Only if there is extreme supination may the disorder be recognized in the neonatal period. The diagnosis of this disorder, which is confirmed radiographically, should be suspected in any neonate with restricted forearm pronation or supination.

Treatment is rarely indicated unless there is an abnormal position of the forearm that interferes with the function of the hand. The method of treatment, a rotational osteotomy through the synostosis, is usually delayed until middle childhood so that an adequate assessment of function can be determined. Attempts at restoring forearm pronation and supination by excising the synostosis have been unsuccessful.

Forearm and Wrist

Radial Hypoplasia and Clubhand

Hypoplasia of the radius is a commonly discussed and infrequently encountered entity, occurring in 1 in 100,000 live births. It is bilateral in 50% of cases. The deformity can vary from mild shortening of the radius to its complete absence (e.g., radial clubhand). As the radius shortens, the deformity becomes more apparent. In complete absence of the radius, the hand is radially angulated 90 degrees to the long axis of the forearm, the ulna is markedly bowed, and the ulna and humerus can be one-half the length of the opposite normal

Abstract

Congenital abnormalities of the upper and lower extremities and spine are common neonatal problems. These develop during the embryonic period. Those involving the upper extremities are much less common than those involving the lower extremities and spine. Upper extremity malformations include Sprengel deformity of the scapula; proximal radius and ulna synostosis; radial dysplasia and clubhand; constriction bands; congenital amputations and reduction anomalies; and syndactyly, polydactyly, and macrodactyly of the fingers. Congenital spinal deformities are predominantly scoliosis, kyphosis, or sacral agenesis. The common abnormalities of the lower extremities include congenital angular deformities of the tibia and fibula (posteromedial and anterolateral angulation); proximal femoral focal deficiency; subluxation/dislocation of the knee; congenital talipes equinovarus deformities (clubfeet); congenital vertical tali; amputations and reduction anomalies of the lower leg; and syndactyly, polydactyly and macrodactyly of toes. Deformities associated with syndromes include skeletal dysplasias, osteogenesis imperfecta, neurofibromatosis, arthrogryposis multiplex congenita, VACTERL, and others. Most will be recognizable on clinical examination and require radiographic confirmation. Appropriate referrals to specialists are important in their management.

side by maturity. As the deformity becomes profound, so does thumb involvement (e.g., an absent first ray, thumb hypoplasia) (Fig. 99.1).

The entire extremity may be involved, including the scapula and clavicle. The radially based muscles of the forearm are also hypoplastic or absent. There is hypoplasia or absence of the radial artery, leaving the ulnar artery as the main blood supply to the hand. There is no radial nerve innervation to the skin distal to the elbow, leaving the median and ulnar nerve to anastomose to provide dorsal sensation. Radial clubhand is not simply a bony defect.

The most frequently associated abnormalities are blood dyscrasias and heart defects. Fanconi syndrome is a pancytopenia seen in some children with radial clubhand (see Chapter 79). Thrombocytopenia with an absent radius (TAR) syndrome is also seen. Holt-Oram syndrome, in which the primary manifestation is an absent thumb with atrioseptal defects, has a well-recognized association with radial clubhand.

Radial hypoplasia alone is inherited sporadically. There is no definitively identifiable inheritance pattern; the careful scrutiny of relatives seldom yields another affected individual. However, radial hypoplasia as part of a syndrome frequently has a defined inheritance pattern. Holt-Oram syndrome is inherited in a dominant pattern and Fanconi syndrome is inherited in a recessive pattern.

Treatment comprises both operative and nonoperative options and is recommended for cosmetic and functional reasons. The treatment begins with stretching. During the first 6 months of life, casts and splints are used to stretch the radially deviated hand to conform to a more neutral alignment. If the deformity is corrected, the patient wears a splint full-time for the first 6 years of life and then only at night after that. If the deformity is not corrected, the hand is centralized onto the ulna. At surgery, the carpus is fused to the ulna after an osteotomy to straighten the ulna. If the patient has a nonfunctional thumb, the index finger occasionally undergoes pollicization—in essence, it is turned into a thumb. The surgery is frequently performed when the patient is between 6 months and 1 year of age. After surgery, bracing is maintained full-time for the first 6 years of life. In bilateral cases, the surgery is staged, with one hand operated on at 6 months and the other hand at about 3 years of age.

The contraindications to surgery are a serious blood dyscrasia, heart problems, and profound muscle imbalance. If the elbow flexors are overpowered by the elbow extensors such that a child cannot touch the hand to the face even after physical therapy, surgery is not likely to provide a functionally useful hand.

Constriction Bands

Congenital constriction bands or amniotic band syndrome, also known as Streeter dysplasia or annular bands, features defects of the skin that result in ringlike strictures about the limbs and occasionally the trunk (Fig. 99.2).[23] It is seen in 1 in 15,000 live births, and multiple extremities are usually involved. The upper extremities, especially the hands, are involved more frequently than the lower extremities. The cause appears to be early amniotic rupture followed by temporary oligohydramnios; this may result in intrauterine compression and the subsequent constriction of fetal appendages by cords or bands of torn amnion[71] (see Chapter 24).

Patterson developed diagnostic criteria for congenital constriction band syndrome.[50] These criteria include simple band constrictions; band constrictions accompanied by deformity of the distal part with or without lymphedema; band constrictions accompanied by fusions of distal parts ranging from fenestrated or terminal syndactyly (e.g., acrosyndactyly) to exogenous syndactyly; and intrauterine amputations. Other congenital abnormalities frequently occur, such as clubfoot (30%), pseudarthrosis, peripheral hand palsy, and lower extremity length discrepancies.[24]

Rigid clubfoot distal to deep constriction bands may be difficult to correct.[1] Treatment involves the surgical release of the bands if the distal aspect is swollen and has lymphedema. The surgery is usually performed in two stages, although Greene has demonstrated that a complete one-stage release can be performed safely.[26]

Thumb and Fingers of the Hand

Congenital Amputations

Congenital amputation is the best example of a failure of formation. In general, the greater the loss of length, the rarer is the lesion. For instance, a child with congenital amputation at the forearm level is encountered in 1 in 20,000 live births, and one with a missing arm is encountered in 1 in 270,000 live births.

• **Fig. 99.2** Clinical photographs of a newborn female with multiple annular bands. **A,** The right lower extremity demonstrates a band with complete transection of the skin and subcutaneous tissue. The associated talipes equinovarus (clubfoot) deformity has a duplication of the great toe. **B,** A similar lesion is present in the right upper extremity, with a significant amount of distal edema from lymphatic and venous obstruction. **C,** The left hand shows multiple bands with segmented edema and partial amputations.

When treating patients with congenital amputations of the upper extremities, it is necessary to define a goal for the patient. The arm serves as a positioning device for the hand. Consequently, treatment revolves around providing the patient with some sort of terminal device at the end of the usable arm. In the earlier stages, as the child achieves sitting balance, a soft terminal device is fitted. This device allows "two-handed" activities and is used to help pin objects against the normal hand. As the child reaches 2-3 years of age, prehension by means of a terminal device becomes possible. Early training allows children to become quite comfortable with these devices.

Syndactyly

Syndactyly is the most common form of congenital abnormality in the upper extremities and represents a failure of separation of two fingers (Fig. 99.3). This failure of separation occurs sometime between 5 and 8 weeks of gestational life and is seen in 1 in 2250 live births. The abnormality appears to be sporadic in 80% of cases; the other 20% are the result of genetic transmission. Because all forms of genetic transmission have been linked to syndactyly, genetic counseling is quite difficult. The classification of syndactyly

• **Fig. 99.3** Clinical photograph of a 3-month-old boy with complete syndactyly between the third and fourth fingers. There is hypoplasia of the distal phalanges of the index and small fingers.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

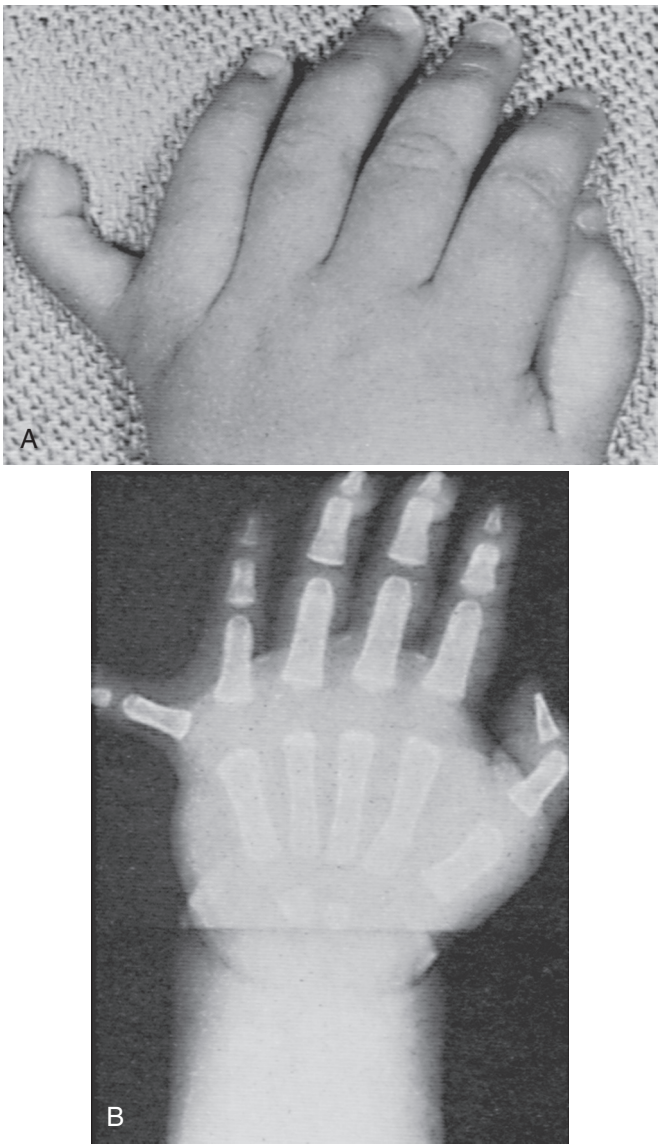
is defined by the degree of interconnection between the fingers. In complete syndactyly, the webbing extends to the tips of the fingers; in incomplete syndactyly, it does not. Simple syndactyly involves only the skin, whereas complex syndactyly involves bony fusion. Abnormalities of the blood vessels, nerves, and tendons are also seen.

Treatment is aimed at separating the digits to improve function. The affected digits are usually separated early, particularly when they are of unequal length. If the thumb and index finger are syndactylized, the longer digit becomes tethered and deformed by the shorter digit.[78] Surgery within the first year of life is suggested. When the digits are of nearly equal length, such as the long finger and the index finger, the surgery can wait until 2 or 3 years of age without difficulty.



Polydactyly

See Chapter 30. Polydactyly is a common duplication abnormality of the hand (Fig. 99.4). It is seen in 1 in 300 African-American and 1 in 3000 Caucasian live births in the United States. The incidence of thumb polydactyly is identical in African Americans and Caucasians (0.8 in 1000 live births). Little-finger polydactyly is common in African Americans, with 1 in 300 affected, and is usually seen without associated abnormalities. In Caucasian infants, little-finger polydactyly is infrequent and often associated with other skeletal abnormalities, including syndactyly, coalescence of carpal bones, radioulnar synostosis, hypoplasia and aplasia of the tibia and fibula, hemivertebrae, and dwarfism. Other disorders also seen are hydrocephalus, cleft lip, hypogonadism, kidney abnormalities, and imperforate anus.

The surgical approach to polydactyly is based on the vascular and bony anatomy of the digits, and it is individualized. The surgery is usually performed sometime after 6 months but before 18 months of age to minimize the anesthetic consequences.

Macrodactyly

Macrodactyly of the hand, also known as idiopathic local gigantism,[72] may involve one or more fingers and is bilateral in 5% of cases. All structures in the affected finger are enlarged, including the bone, blood vessels, nerves, and other soft tissues. True macrodactyly must be differentiated from other processes that create gigantism, because the treatment is different. Local enlargement of the hand occurs in neurofibromatosis, lymphedema, hemangioma, lymphangioma, arteriovenous fistulas, fibrous dysplasia, aneurysmal bone cysts, and lipomas. The treatment for these disorders is individualized to the process. In typical macrodactyly, the child is followed carefully until the affected digit(s) is about adult size, which usually happens between 7 and 8 years of age. At this point, growth arrests of all the bones in the affected digit(s) are performed and soft tissues are debulked. Occasionally, the growth is uncontrollable, and cosmesis is so poor that the parents and child prefer amputation. In contrast, ray resection with soft tissue reduction is the method of choice for managing macrodactyly of the foot, especially when it affects only the lesser toes.[8]

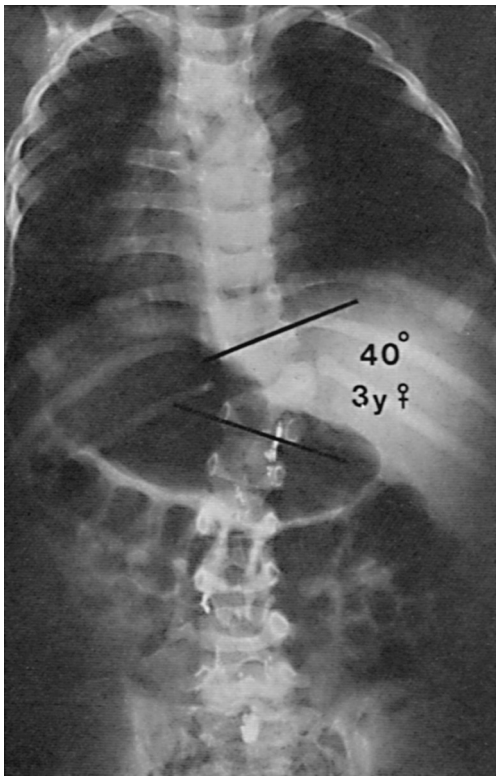
• **Fig. 99.4** Clinical photograph **(A)** and radiograph **(B)** show congenital polydactyly, the most common digit duplication, with complete bones, tendons, and nerves. The recommended treatment is early ablation by amputation.

Spine

Spinal disorders diagnosed during the neonatal period are uncommon.[49] Most of them are congenital in origin. Some of them, such as myelodysplasia and sacral agenesis, are obvious at birth, but others, such as congenital scoliosis and kyphosis, may not be recognized for months or years. Idiopathic spinal deformities can also occur but are rare.

Infantile Idiopathic Scoliosis

Scoliosis without a clearly identifiable cause is called idiopathic scoliosis. Idiopathic spinal deformities are classified



Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

as infantile, with the onset between birth and 3 years of age; juvenile, with the onset between 4 and 10 years of age; and adolescent, with the onset at 11 years of age or older. The adolescent type is the most common form of scoliosis and the infantile type is the least common. The infantile type is more common in the United Kingdom than in North America, although the reason for this is unknown.

When a neonate or infant is found to have a spinal deformity, a very careful physical examination and radiographic assessment are necessary to determine if an underlying cause is present. A diagnosis of idiopathic scoliosis is really a diagnosis of exclusion. Physical examination includes evaluation of the spine for mobility and areas of tenderness. The skin should be inspected for cutaneous lesions that may indicate underlying spinal dysraphism. The lower extremities need to be evaluated carefully for symmetry and neurologic function.

Plain radiographs usually determine whether there is a spinal deformity. However, additional studies, such as magnetic resonance imaging (MRI), may be necessary to evaluate the spinal canal and spinal cord for possible lesions.

The treatment of infantile scoliosis is variable. Some curves may be observed and even improve spontaneously with growth. However, others are progressive and require cast or orthotic management and possibly surgical intervention. It is important that all neonatal spinal abnormalities be referred to an orthopedic surgeon experienced in the management of pediatric spinal deformities.

• **Fig. 99.5** Radiograph of congenital scoliosis in a 3-year-old girl. A hemivertebra at T12 produces a 40-degree curve over a short segment of the spine. The mixed formation and segmentation defects in the upper thoracic spine are balanced and have not produced a significant curve.

Congenital Spinal Deformities

Abnormalities of vertebral formation can result in structural deformities of the spine that may be evident in the neonate or become more obvious during the first year of life. Deformities in the coronal plane produce congenital scoliosis, whereas those in the sagittal plane produce congenital kyphosis. The total or partial failure of formation of the sacrum is called *sacral agenesis,* typically associated with infants of diabetic mothers. If the lower lumbar spine is also absent, it is called *lumbosacral agenesis*.

Congenital Scoliosis

Congenital scoliosis is classified as failure of formation (e.g., hemivertebrae), failure of segmentation (e.g., unsegmented bars), or mixed (Fig. 99.5). A failure of formation or segmentation can be partial or complete and may occur as a single abnormality or in combination with other bone, soft tissue, or neurologic abnormalities of the axial or appendicular skeleton.[19] Congenital genitourinary malformations occur in 20% of children with congenital scoliosis. Unilateral renal agenesis is the most common abnormality. Most genitourinary abnormalities do not require treatment, but approximately 6% of the affected patients have a silent obstructive uropathy.[25] Renal ultrasound should be performed on all neonates with congenital scoliosis to search for possible genitourinary abnormalities. Congenital heart disease (10%-15%) and spinal dysraphism (20%) also occur in neonates with congenital scoliosis. Intraspinal abnormalities include tethered spinal cord, intradural lipoma, syringomyelia, and diastematomyelia (Fig. 99.6).[5,7,44,48,76] They are frequently associated with cutaneous lesions of the back, such as hairy patches, skin dimples, and hemangiomas, and with abnormalities of the feet and lower extremities, such as cavus feet, calf atrophy, asymmetric foot size, and neurologic changes. An ultrasound examination and MRI can be useful in the evaluation of spinal dysraphism in a neonate with congenital scoliosis. Congenital scoliosis may also occur in association with syndromes such as Klippel-Feil and VATERL and with spinal dysraphism, such as myelodysplasia.[77]

The risk for progression of congenital scoliosis depends on the growth potential of the malformed vertebrae.[75] Defects such as block vertebrae have little growth potential, whereas unilateral unsegmented bars invariably produce progressive deformities.[47] Approximately 75% of children with congenital scoliosis demonstrate some progression that typically continues until skeletal growth stops. Approximately 50% require treatment.[46] Rapid progression can be expected during periods of rapid growth, such as those between birth and 2 years of age and those after 10 years of age. Orthotic management is usually contraindicated, because it poorly mitigates such a growth disorder. When progression is aggressive, surgery is necessary. This may consist of

• **Fig. 99.6** Metrizamide myelogram demonstrates cartilaginous diastematomyelia at L2 in a 3-year-old boy. Observe the midline filling defect and the increased widening or interpedicular distance in the middle lumbar region.

combined anterior and posterior hemi-epiphysiodesis on the convex side or possibly posteriorly approached osteotomies to halt progression and allow for some correction from growth on the concavity of the curvature.

Congenital Kyphosis

Congenital kyphosis includes (1) failure of formation of all or part of the vertebral body with preservation of the posterior elements, and (2) failure of anterior segmentation of the spine (e.g., anterior unsegmented bar). The more severe deformities are usually recognized in the neonate, and they rapidly progress thereafter. The less obvious deformities may not appear until several years later. After progression begins, it does not cease until the end of growth. The most important factor regarding congenital kyphosis is the possibility that a progressive deformity in the thoracic spine can result in paraplegia.[45] This potential outcome is usually associated with failure of formation of the vertebral body. When necessary, the treatment of congenital kyphosis is operative.[37]

Sacral Agenesis

Sacral agenesis comprises a group of disorders with partial or complete absence of the sacrum. If the lower lumbar spine is also involved, it is called lumbosacral agenesis.[2,3,51] Motor function is typically lacking below the level of the remaining spine; however, sensation tends to be present at a much more caudal level. The disorder can be classified by the amount of sacrum remaining and the articulation between the spine and pelvis. It is a rare disorder, occurring in approximately 1 in 25,000 live births, and the exact cause is unknown. The incidence is increased among the children of diabetic mothers[27,57] (see Chapters 18 and 86).

The presentations of neonates with sacral agenesis can vary considerably. In severe forms, there is a small pelvis with pterygia anteriorly at the hips and posteriorly at the knees, as well as bilateral foot deformities, typically clubfoot. There may be spinopelvic instability. The neurologic examination tends to show no motor function below the last existing vertebra or sacral segment. However, sensation can be more variable. Children with sacral agenesis also have other visceral abnormalities similar to those seen in congenital scoliosis.

The treatment of sacral agenesis is variable. Those patients with only partial agenesis and a stable spinopelvic articulation can be observed. Those who are unstable may require a spinopelvic fusion in childhood for stabilization. This operation can enhance sitting balance and improve the function of the upper extremities. The problems associated with the lower extremities also require orthopedic intervention. If a child has the potential for ambulation, these problems need to be corrected to allow the child to assume an upright posture. Orthotics are usually necessary to support the extremities after they have been corrected.

Lower Extremities

The most common neonatal congenital and developmental abnormalities of the lower extremities include torsional and angular deformities; developmental dysplasia of the hip; proximal femoral focal deficiency (PFFD); congenital hyperextension, subluxation, and dislocation of the knee; clubfoot; metatarsus adductus; vertical talus; calcaneovalgus foot; and toe deformities, such as syndactyly and polydactyly.

Torsional and Angular Deformities

Physiologic Bowleg

The lower extremities of neonates commonly have mild to moderate bowing (i.e., genu varum) and internal rotation of the lower leg because of in utero positioning. The bowed appearance is actually a torsional combination of the external rotation of the hip (i.e., tight posterior hip capsule) and internal tibial torsion from in utero positioning. With the onset of standing and independent walking, the bowing and torsion are spontaneously corrected over a 6- to 12-month period. Significant improvement does not occur during the neonatal period or the first year of life. The typical neonate has 15 degrees of genu varum, which decreases to approximately 10 degrees by 1 year of age. By 2 years of age, most children have straight or neutrally aligned lower extremities.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Treatment is indicated for children older than 2-3 years of age who have had no documented improvement with growth.

Tibial Torsion

Torsional changes of the tibia may be internal or external, depending on in utero positioning. The degree of tibial torsion may be measured by the thigh-foot angle. With the child in the prone position, the knee is flexed to 90 degrees to neutralize the normal tibiofemoral rotation. The foot is placed in a neutral or simulated weight-bearing position. The long axis of the foot is compared with the long axis of the thigh. An inwardly rotated foot is assigned a negative value and represents internal tibial torsion. An outwardly rotated foot represents external tibial torsion and is given a positive value. It is important that the measurements be recorded on each visit to document the improvement. Radiographic evaluation is of no value in the assessment of tibial torsion.

Internal Tibial Torsion

Internal tibial torsion is the most common cause of pigeon-toed children from birth to 2 years of age. It is the major component of physiologic bowleg, or genu varum. Because this condition is physiologic, spontaneous resolution can be anticipated with normal growth and development. The persistence of internal tibial torsion in the older child or adolescent is uncommon.

External Tibial Torsion

External tibial torsion is a common deformity and is always associated with a calcaneovalgus foot. It is caused by a variation in the normal in utero position. The sole of the foot lies pressed against the wall of the uterus, forcing the limb into a hyperdorsiflexed, everted position. This physiologic configuration produces the calcaneovalgus foot and, secondarily, the external tibial torsion. When these two conditions are combined with a normally externally rotated hip from a tight posterior hip capsule, they produce a very externally rotated or out-toed position. Because they are also physiologic in origin, both undergo spontaneous resolution and follow a clinical course similar to that of internal tibial torsion.

Congenital Angular Deformities of the Tibia and Fibula

Congenital angular deformities of the tibia and fibula are uncommon neonatal problems. They are classified according to the direction of angulation—posteromedial or anterolateral. Posteromedial angulation is less common but is characterized by spontaneous resolution with growth and development. Anterolateral angulation is more common and is typically associated with other underlying congenital abnormalities, such as congenital absence of the fibula (e.g., fibular hemimelia), congenital absence of the tibia (e.g., tibial hemimelia), and congenital pseudarthrosis of the tibia (e.g., neurofibromatosis).

• **Fig. 99.7** **A,** A 1-month-old boy with posteromedial angulation of the left tibia. This condition resembles a calcaneovalgus foot, because the dorsum of the foot comes in contact with the lower leg. However, there is posterior angulation of the tibia in this case. **B,** The medial angulation is visible when viewed from the front.

Posteromedial Angulation

Posteromedial angulation has three associated clinical problems: angular deformity, the calcaneovalgus foot, and length discrepancy of the lower extremities. The angular deformity occurs at the junction of the middle and distal thirds of the shafts. The deformity is usually unilateral (Fig. 99.7). The neonates are normal and healthy, and there is no increased incidence of other congenital abnormalities. The degree of angulation varies between 25 and 65 degrees and is equal in both posterior and medial directions. The foot is hyperdorsiflexed and has a marked calcaneovalgus position. Radiographs are necessary to confirm the diagnosis. The cause of congenital posteromedial angulation in the tibia and fibula is unknown.

Posteromedial angulation resolves with growth, especially during the first 3 years of life. The posterior bowing tends to resolve more quickly than the medial bowing, which may not resolve until 5 years of age. However, the associated shortening of the tibia and fibula persists and progresses during growth. The fibula tends to be slightly shorter

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

than the tibia. The appearance of the foot also improves, although a pes planovalgus appearance may persist.

Nonoperative treatment is indicated in the neonatal period.[69] If the bowing does not resolve by 3 or 4 years of age, a tibial or fibular osteotomy may be necessary. The most common sequela of posteromedial angulation is a discrepancy in leg length. Most of these children have enough discrepancy to require equalization. An appropriately planned epiphysiodesis (physeal closure) of the longer limb is the most common procedure. Lengthening of the shorter limb may sometimes need to be considered.

Anterolateral Angulation

When anterolateral bowing is encountered, it is usually associated with a significant underlying pathologic disorder, such as congenital pseudarthrosis of the tibia or congenital longitudinal deficiencies of the tibia or fibula. Careful clinical and radiographic evaluation is necessary to establish the correct diagnosis. Congenital pseudarthrosis of the tibia is typically associated with neurofibromatosis.

Hip

The most common neonatal hip disorders include developmental dysplasia of the hip and septic arthritis and osteomyelitis. Septic arthritis and osteomyelitis are discussed in Chapter 98. Another congenital abnormality, although uncommon, is proximal femoral focal deficiency (PFFD).

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) is the most common neonatal hip disorder.[66,73] It was initially thought to be congenital in origin but is now recognized as developmental, hence the change in terminology from congenital dysplasia of the hip to DDH. At birth, an involved hip is rarely dislocated; instead, it is dislocatable. Whether the hip stabilizes, subluxates, or ultimately dislocates depends on postnatal factors. Most developmental dislocations are postnatal in origin; however, the exact time of their occurrence is controversial.

Neonatal hip dislocations are classified into two major groups: the typical, which is found in a neurologically normal infant, and the teratologic, which is found in an infant with an underlying neuromuscular disorder, such as myelodysplasia, arthrogryposis multiplex congenita, or a complex of syndromes. Teratologic dislocations occur in utero and are, therefore, truly congenital in origin. This section concentrates on typical DDH, because it is the more common form.

Pathology and Etiology

The pathogenesis and causes of typical DDH are multifactorial: genetic, physiologic, and mechanical factors are involved. The genetic factors include a positive family history (20%) and generalized ligamentous laxity, an inherited trait. The physiologic factors include female predominance (9 : 1) and maternal estrogen and other hormones associated with pelvic relaxation during labor and delivery. The mechanical factors include primigravida, breech presentation, and postnatal positioning. Positioning has a significant effect in determining which hip stabilizes and which may progress to dislocation.

The genetic and physiologic aspects are related etiologic factors. Most neonates with DDH have generalized ligamentous laxity, which can predispose to hip instability. The maternal estrogen and other hormones associated with pelvic relaxation at delivery cross the placenta and result in further, albeit temporary, relaxation of the newborn hip joint.

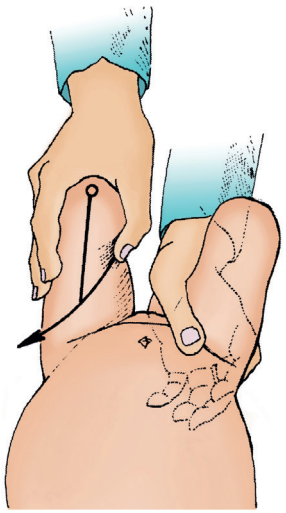
Approximately 60% of those children with typical DDH are first-born, and 30%-50% develop it as a result of the breech position. In this position, there is extreme hip flexion and a limitation of hip motion that results in the stretching of an already lax hip capsule and ligamentum teres and in the posterior uncovering of the femoral head. Decreased hip motion results in the lack of normal stimulation for the growth and development of the cartilaginous acetabulum.[54]

Congenital muscular torticollis and metatarsus adductus are associated with DDH. The presence of either of these conditions necessitates a careful examination of the hips.

Postnatal factors are important determinants in ultimate hip stability. Positioning an unstable hip in adduction and extension may lead to dislocation. These positions put the unstable hip under abnormal pressure as a result of the normal hip flexion and abduction contractures. Consequently, an unstable femoral head can be displaced from the acetabulum over several days or weeks.

Because the hips are not dislocated at birth, the components of the hip joints, excluding the hip capsule and ligamentum teres, are usually relatively normal. There may be some variation in the shape of the cartilaginous acetabulum. If a subluxation or dislocation is not recognized, it will lead to progressive acetabular dysplasia and maldirection, excessive femoral anteversion (e.g., torsion), and hip muscle contracture.[12] It is critical that an early diagnosis be made and appropriate treatment instituted. The longer a dislocation continues, the more complex the treatment becomes.

Diagnosis



The physical findings in neonates with DDH include a positive Barlow test (i.e., dislocatable hip) or positive Ortolani test (i.e., dislocated hip), asymmetric thigh skinfolds, uneven knee levels (i.e., Allis or Galeazzi sign), and the absence of normal knee flexion contractures.

The Barlow and Ortolani tests are the most sensitive for neonatal hip instability (Fig. 99.8). The Barlow[4] test is a provocative means of diagnosing an unstable hip and is the most important maneuver in examining the neonatal hip. With the infant supine, this test is performed by stabilizing the pelvis with one hand, flexing and adducting each hip separately, and applying a posterior force with the other hand (Fig. 99.9). If a hip is dislocatable, it is usually felt as a "clunk." After release of the posterior pressure, the hip usually spontaneously relocates. It has been estimated that

• **Fig. 99.8** Positioning of the hip in the newborn to perform two diagnostic tests. The Ortolani sign, or click of reduction, is elicited when abducting the hip in this manner. The reverse Ortolani, or Barlow, maneuver is performed by bringing the femur into adduction with flexion, causing a click of exit or dislocation.

• **Fig. 99.9** The Barlow test permits the early diagnosis of hip instability. It is a provocation test for dislocatability. The pelvis is steadied with one hand while the leg to be tested is grasped with the other. The thumb of the examiner's hand should lie over the lesser trochanter and the tip of the middle finger over the greater trochanter. With the hip and knee in flexion, gentle pressure is exerted with the thumb over the lesser trochanter. Dislocatability is manifested by a sudden shift of the proximal femur. Dislocation may be reduced with the Ortolani test.

• **Fig. 99.10** In the Ortolani test, the pelvis is held steady with one hand while the limb to be examined is grasped with the other. The hip and knee are flexed. While gently pulling the femur forward, the examiner abducts the limb under examination, using the greater trochanter as a fulcrum. Reduction of dislocation is manifested by a sudden shift in the position of the proximal femur, often accompanied by a palpable or audible clunk. There must be sufficient ligamentous laxity to permit relocation of the proximal femur into the acetabulum; therefore, the test is useful primarily in the neonatal period.

• **Fig. 99.11** Clinical photograph showing the limitation of abduction of the thighs when the hips are flexed at 90 degrees.

approximately 1 in 100 newborns has a clinically unstable hip (i.e., subluxatable or dislocatable) and that 1 in 800-1000 infants eventually develops a true dislocation.

The Ortolani test is a procedure to reduce a recently dislocated hip (Fig. 99.10). It is most likely to be positive in infants who are 1-2 months of age because adequate time must have passed for true dislocation to occur. This test is performed concomitant with the Barlow test. With the hip flexed, the thigh is abducted and the femoral head lifted anteriorly into the acetabulum. If a reduction occurs, it is felt as a "clunk." Clunks should not be confused with hip "clicks," which are common in neonates. A variety of normal factors produce a clicking sensation during examination of the hip, including the breaking of surface tension across the hip joint, the snapping of gluteal tendons, patellofemoral motion, and femorotibial (knee) rotation. These normal characteristics are commonly misinterpreted as a sign of instability. After 2 months of age, the Ortolani test usually becomes negative. It is no longer possible to relocate a dislocated hip because of the development of soft tissue contractures.

When the hip is dislocated, its abduction is limited by soft tissue contractures (Fig. 99.11). There are also an increased number of thigh skinfolds on the involved side owing to redundant soft tissues, the appearance of a shortened extremity, and a positive Allis or Galeazzi sign. The latter sign is demonstrated by placing the feet of the supine neonate together on the examining table and assessing the relative heights of the knees. An apparent shortening is observed on the involved side. With a proximal displacement of the femoral head, the quadriceps and hamstrings become relaxed. This effect can be demonstrated best by the

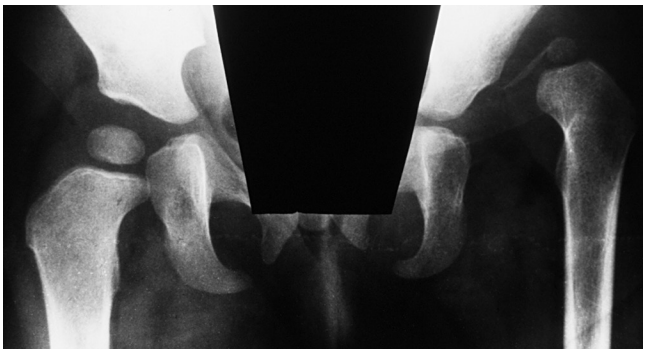
so-called "hamstring" test. Both hips are flexed and abducted with the knees flexed. Attempts to extend the knee are resisted on the normal side because of increased tightness in the hamstrings. If a dislocated hip is present, the knee can come into full extension because of the lack of proximal stability, which otherwise produces a fixed fulcrum for the hamstring muscles.



The presence of bilateral limitation of hip abduction in the young infant may be a normal variant and is an inaccurate clinical sign in the diagnosis of pathologic DDH. Limitation of hip abduction should be actively sought after 8 weeks of age and, if present, should be followed by a formal ultrasound or radiographic examination to confirm whether or not the hip is developing in a satisfactory manner.[9]

Imaging

The imaging of neonatal DDH is best accomplished with ultrasonography and plain radiographs. Ultrasonography[29] is becoming an increasingly popular method for the evaluation and assessment of the neonatal hip, because the femoral head does not ossify until 4-7 months of age. Hip stability and acetabular and femoral head development can be accurately assessed by an experienced ultrasonographer. Ultrasonography allows avoidance of the effects of ionizing radiation but is very user dependent and expensive. It is so sensitive that false-positive results are common. In large screening programs in which all births are screened, it is common to identify 7.5% of neonates with abnormal results.[10] This percentage decreases to a more appropriate level of 0.4% by 6 weeks, but the expense, anxiety, and administrative stress of retesting can be considerable. At present, there is no agreement about the efficacy of routine screening for all infants.[36,62] Some large centers suggest it,[43] although others claim that selective ultrasonography is as effective as universal screening when it is accompanied by a good clinical screening program.[20] Additionally, a stable, normal ultrasound does not assure normal hips after 6 months of age. Gwynne Jones has reported on seven developmental dislocations in five babies (age 6-22 months) in whom ultrasound demonstrated stable and reduced hips.[28] The Pediatric Orthopedic Society of North America warns that late-onset dislocation can be expected in 1 in 5000 infants who are clinically stable in the newborn period.[59] Anteroposterior and frog lateral radiographs of the pelvis may also be obtained. The limitation of plain radiographs is owing to the lack of ossification of the femoral head, which may be further delayed in DDH (Fig. 99.12). Line measurements are drawn to determine the development of the acetabulum and the relationship between the femoral head and acetabulum (see Chapters 28 and 38).

Treatment

The treatment of neonatal DDH is simple and effective. The most important factor in the treatment of this disorder is an accurate and early diagnosis. When an unstable or dislocatable hip (Barlow positive) is recognized at birth,

• **Fig. 99.12** Anteroposterior pelvic radiograph of a 9-month-old girl with a complete dislocation of the left hip. Observe the hypoplasia of the proximal femur and ossific nucleus of the femoral head. The right hip is normal.

• **Fig. 99.13** The Pavlik harness is a safe, reliable means of treating hip instability and dislocation in the neonate.

maintenance of the hip in the position of flexion and abduction, or the "human position," is usually sufficient. This position maintains reduction of the femoral head in the acetabulum and allows the progressive tightening of the ligamentous structures as the child grows. It also stimulates the normal growth and development of the acetabulum. The methods that can be used to maintain the hip in this position include double or triple diapers, the Pavlik harness, the Frejka pillow splint, and a variety of abduction orthoses. Double or triple diapers, although controversial, are commonly used in early infancy because the harness, pillow splint, and abduction orthoses usually do not fit satisfactorily. Treatment is continued until there is clinical stability of the hip and the ultrasonographic or radiographic results are normal, both of which usually take place within 3-4 months.

There may also be a true dislocation (Ortolani positive) during the neonatal period. As a consequence, treatment is directed toward the reduction of the femoral head in the true acetabulum.

The Pavlik harness is the major mode of treatment in this age group (Fig. 99.13). The harness places the hips in the human position by flexing them more than 90 degrees

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

(preferably 100-110 degrees) and maintaining relatively full but gentle abduction (50-70 degrees). This position redirects the femoral head toward the acetabulum. A spontaneous reduction usually occurs within 3-4 weeks. The Pavlik harness is approximately 95% successful for Barlow-positive hips and 80% successful for Ortolani-positive hips. If true dislocations are initially irreducible, treatment with the Pavlik harness may not be effective. Lerman and coworkers reported on 93 DDH patients treated with a Pavlik harness.[42] There were 82% who were successfully treated. Six patients had initially irreducible hips and less than 20% ultrasound coverage; all six failed treatment with the Pavlik harness. If the reduction of a dislocated hip is achieved, treatment is continued until ultrasonography or the radiographic parameters have returned to normal. If a spontaneous reduction does not occur, closed reduction by surgery will be necessary. This approach sometimes consists of preliminary skin traction for 1-3 weeks to stretch the existing soft tissue contractures, followed by an examination under anesthesia, percutaneous hip adductor muscle tenotomy, closed reduction, an arthrogram to assess the concentricity of the reduction, and the application of a hip spica cast in the human position. A post-reduction CT or MRI scan is obtained to confirm reduction. Treatment is continued until the radiographic parameters are within normal limits. The indications for an open reduction in the neonate up to the first 6 months of life are limited. Follow-up for at least 1 year is necessary, because dysplastic hips that improve with treatment can still subsequently deteriorate. If this deterioration occurs, further treatment is indicated.

The complications associated with treatment of neonatal DDH include failure of reduction and re-dislocation. Avascular necrosis of the capital femoral epiphysis, which is the most devastating complication of this disorder, develops in approximately 5% of infants, regardless of how careful initial management may have been.

Proximal Femoral Focal Deficiency

Proximal femoral focal deficiency (PFFD) is a congenital abnormality affecting the development of the proximal end of the femur and possibly the acetabulum. There is considerable variation, ranging from a mildly shortened femur to severe shortening with an absence of the femoral head and acetabulum. It may be bilateral or unilateral; bilateral cases tend to have more severe involvement. The cause of PFFD is unknown, but it results from embryologically abnormal formation of the hip that occurs during limb bud formation.

The clinical examination is usually diagnostic. The thigh is shortened, and the hip held in flexion, abduction, and external rotation (Fig. 99.14). There are usually hip- and knee-flexion contractures. Because of the proximity of the lower leg to the trunk, the entire extremity appears similar to a funnel. There may also be abnormalities of the lower leg. Approximately 50%-70% of affected neonates also have fibular hemimelia with or without the absence of the lateral portion of the foot.

• **Fig. 99.14** Clinical photograph of a newborn boy with significant shortening of the right thigh caused by proximal femoral focal deficiency.

Radiographs are necessary in the assessment of children with PFFD. However, the components may not be fully visualized because of the lack of ossification. If an acetabulum is present, there will usually be a femoral head. Magnetic resonance imaging scans can be helpful in difficult cases to determine the shape of the proximal femur and acetabulum.

The most important therapeutic component of the treatment of neonatal PFFD is observation. It is important that a careful evaluation be performed to search for other associated congenital abnormalities. The ultimate treatment depends on the length of the extremity, the stability of the hip, the presence or absence of a functional foot, and a determination of whether the disorder is unilateral or bilateral. Possible treatment options include prosthetic fitting; knee fusion, Syme amputation, and prosthesis; surgical reconstruction; and lengthening of the femur. The lengthening of the femur is considered only if the hip and knee are relatively normal and the degree of predicted shortening is less than 15 to 20 cm at skeletal maturity.

Knee

Hyperextension, Subluxation, and Dislocation of the Knee

The congenital abnormality comprising hyperextension, subluxation, and dislocation of the knee is uncommon. The tibia is displaced anterior to the femur, and the knee is hyperextended. The cause is multifactorial, with mechanical and genetic elements. Most cases are sporadic, with no particular predisposition; however, patients with inherited Larsen disease frequently demonstrate congenital subluxation and dislocation of the knee. Breech presentation is

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

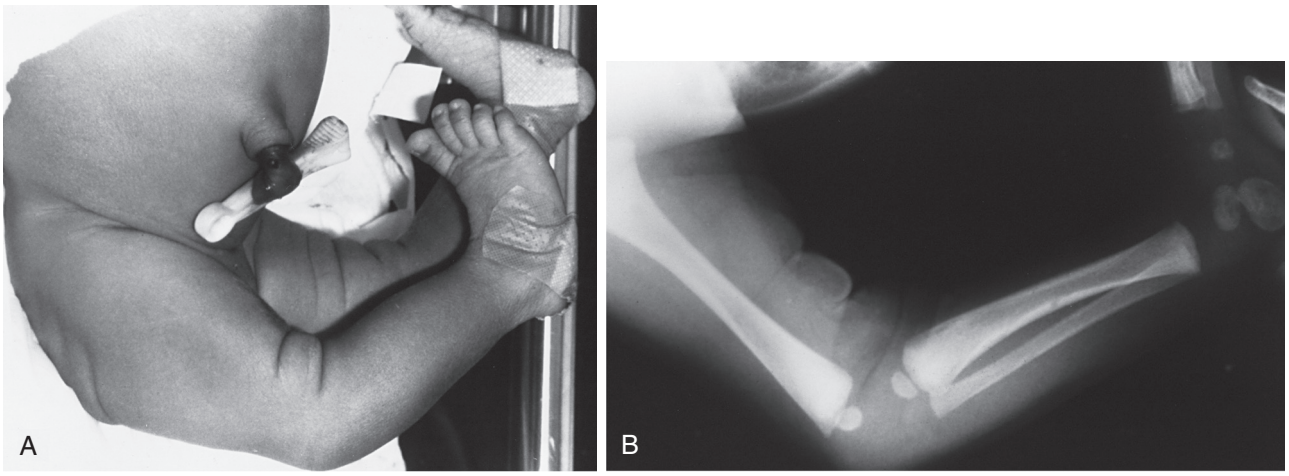
more frequently seen in children with congenital subluxation and dislocation of the knee, suggesting that mechanical factors are also important.

The pathologic picture is complex, and associated disorders are common. Curtis and Fisher reported on 11 patients, and in every case they noted congenital hip abnormalities.[15] Seven patients had clubfoot and seven were thought to have arthrogryposis multiplex congenita. Fibrosis of the quadriceps muscle was found in all surgical cases. The quadriceps muscle effectively runs from the anteroinferior iliac spine to the tibial tubercle, and progressive fibrosis would thereby provide pressure for anterior subluxation of the tibia and hip deformity, as well as a tendency to hyperextend the knee.

The diagnosis is made on physical examination. Hyperextension at the knee sometimes approaches 90 degrees (Fig. 99.15). A lateral radiograph can demonstrate that the tibia is anterior to the femur. A line is drawn down the long axis of the tibia and the long axis of the femur; it does not meet at the normal axis of the knee joint.

In benign hyperextension of the knee, hyperextension of 15-30 degrees is common. Flexion is frequently limited to a few degrees. In this "packing deformity," the radiographs demonstrate that the tibia is not anterior to the femur and that the center of rotation of the knee joint is normal, unlike congenital dislocation and subluxation of the knee. It is important to obtain the radiographs of knees that hyperextend considerably to determine whether an epiphyseal fracture is responsible for hyperextension of the knee. The results of treatment are very different when benign hyperextension of the knee is compared with congenital dislocation of the knee. In benign hyperextension of the knee and, to a certain extent, congenital subluxation of the knee, manipulation and serial casting provide an adequate result. Early manipulation and casting are often successful in uncomplicated congenital dislocation of the knee if treatment is begun during the first few weeks of life. The prognosis is much worse when the knee dislocation is associated with Larsen disease or arthrogryposis multiplex congenita.[39] Children with congenital dislocation of the knee who fail casting may benefit from traction delivered through skeletal pins in the tibia and femur. The goal of treatment is to achieve at least 100-110 degrees of knee flexion and full, stable knee extension before the child reaches walking age. If these objectives cannot be attained with casting, splinting, or traction, then surgery before the child reaches walking age is recommended.

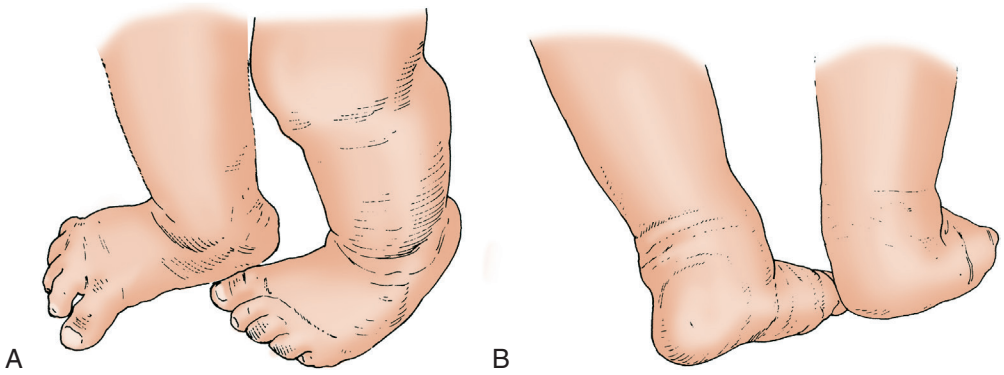
Foot and Toes



The most common foot and toe disorders include metatarsus adductus, the calcaneovalgus foot (pes calcaneovalgus), talipes equinovarus (clubfoot), congenital vertical talus, and syndactyly and polydactyly of the toes.

Metatarsus Adductus

Metatarsus adductus, or forefoot adduction, is probably the most common neonatal foot problem. It results from in utero positioning, occurring equally in boys and girls, and is bilateral in approximately 50% of neonates. The disorder has hereditary tendencies and is more common in the first-born than subsequent children because of an increased molding effect from the primigravid uterus and abdominal wall. It is also associated with hip dysplasia. Approximately 10% of children with metatarsus adductus have DDH; careful examination of the hips is necessary in any neonate with metatarsus adductus.[41]



Diagnosis

Clinically, the forefoot is adducted and occasionally supinated. The hindfoot and midfoot are normal. The lateral border of the foot is convex, and the base of the fifth metatarsal appears to be prominent (Fig. 99.16). The medial border of the foot is concave. There is usually an increased interval between the first and second toes, with the great toe being held in a greater varus position. Ankle dorsiflexion

• **Fig. 99.15** **A,** Clinical photograph of a newborn boy with bilateral congenital or developmental subluxation of the knees. The knees are hyperextended and have limited flexion. **B,** Lateral radiograph demonstrating the hyperextension or subluxation of the right knee.

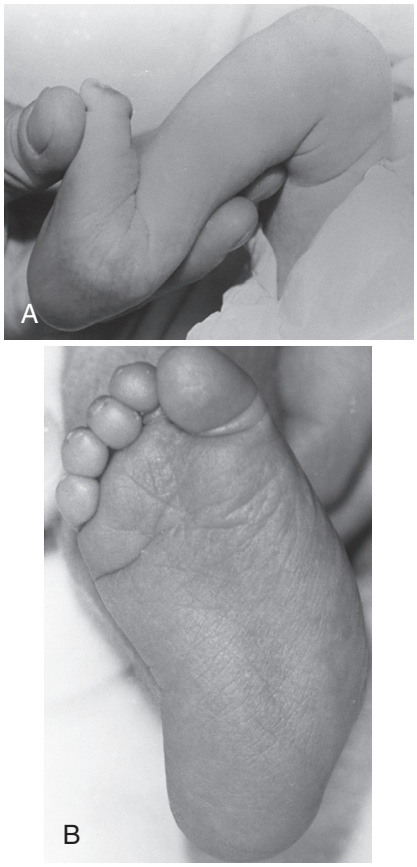
• **Fig. 99.16** Bilateral metatarsus adductus. **A,** Dorsomedial and dorsolateral views. The medial border of the foot is concave; the lateral border is convex. The medial arch may be accentuated. **B,** Posterior view. A slightly valgus hindfoot may be present in the standing position.



and plantar flexion are normal. These characteristics distinguish metatarsus adductus from a congenital clubfoot. Forefoot flexibility is variable. Passive flexibility is assessed by stabilizing the hindfoot in a neutral position with one hand and applying pressure over the first metatarsal head with the other. Active flexibility is assessed by gently stroking the lateral border of the involved foot. This approach induces reflex activity in the peroneal muscles along the lateral aspect of the calf. The forefoot is typically classified as flexible, moderately flexible, or rigid.[14] In flexible metatarsus adductus, the forefoot achieves an overcorrected position actively and passively. In moderately flexible metatarsus adductus, the forefoot can be corrected to the neutral position. In rigid metatarsus adductus, the forefoot cannot be corrected to the neutral position.

Imaging

Routine radiographs are unnecessary in the evaluation of metatarsus adductus. Radiographs do not demonstrate forefoot mobility; however, anteroposterior and lateral simulated weight-bearing radiographs of the foot are necessary to assist in the diagnosis of rigid deformities and those in which a diagnosis by other means is uncertain.

Treatment

Approximately 85% of neonatal metatarsus adductus deformities resolve spontaneously by 3 years of age,[53,56] and 95% resolve by 16 years of age.[74] Treatment is seldom recommended for metatarsus adductus, because most patients develop normal foot position and mobility without treatment, and even those with some residual deformity generally have normal function.

• **Fig. 99.17** **A,** A 3-month-old boy with a calcaneovalgus foot. The foot can be dorsiflexed to allow the dorsum to come in contact with the anterior aspect of the lower leg. **B,** There is abduction of the forefoot and increased valgus alignment of the hindfoot. This condition is always associated with external tibial torsion.

Calcaneovalgus Foot

The calcaneovalgus foot is a common physiologic variant.[68] It results from in utero positioning. This condition is manifested by a hyper-dorsiflexed foot, with an abducted forefoot and valgus hindfoot. It is usually associated with external tibial torsion. It typically occurs unilaterally but also occasionally occurs bilaterally. In utero, the plantar surface of the foot lies against the uterine wall, forcing it into a hyper-dorsiflexed, abducted, and externally rotated position (Fig. 99.17). This position produces the calcaneovalgus foot and external tibial torsion. When these two conditions are combined with the normal, increased external rotation of the hip (e.g., tight posterior hip capsule) in the neonate, the result is a lower extremity that appears excessively externally rotated.

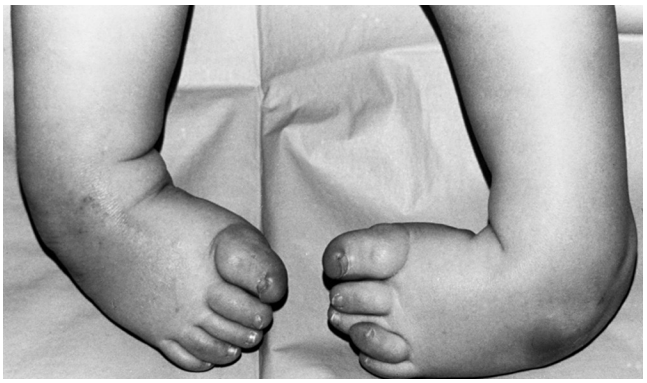
Diagnosis

The neonate typically presents with external rotation of the involved extremity and a calcaneovalgus foot. The forefoot is abducted, and the heel is in an everted (valgus) position. The foot can be hyper-dorsiflexed to bring its dorsal surface in contact with the anterior aspect of the lower leg. This condition should not be confused with the neonatal maturity classification of Dubowitz. External tibial torsion of 20-50 degrees is common. Ankle motion usually shows normal to nearly normal plantar flexion.

Three conditions must be distinguished from the benign calcaneovalgus foot: congenital vertical talus, posteromedial bowing of the tibia, and neuromuscular disorders that are associated with paralysis of the gastrocnemius muscles.[68] This differentiation can usually be established by clinical examination.

Imaging

Routine imaging of a benign calcaneovalgus foot is unnecessary; it is predominantly a clinical diagnosis. However, in severe deformities or in those with limited mobility, anteroposterior and lateral simulated weight-bearing radiographs of the foot and possibly the lower leg are necessary. These radiographs allow the recognition of a congenital vertical talus or posteromedial bowing of the tibia.



Treatment

The benign calcaneovalgus foot does not require treatment. This deformity usually resolves during the first 6 months of life. However, external tibial torsion follows the same natural history as that of internal tibial torsion. Spontaneous improvement does not take place until the child begins to pull to stand and walk independently. It takes 6-12 months thereafter to achieve complete correction. Most neonates presenting with a benign calcaneovalgus foot and external tibial torsion have a normally aligned foot and lower extremity by 2 years of age.

Talipes Equinovarus (Clubfoot)

A congenital clubfoot is one of the most common pathologic entities affecting the neonatal foot. It is a deformity of the foot and the entire lower leg. It is classified as congenital, teratologic, or positional. The congenital clubfoot is usually an isolated abnormality, whereas the teratologic form is associated with an underlying neuromuscular disorder, such as myelodysplasia or arthrogryposis multiplex congenita. Positional clubfoot refers to a normal foot that has been held in an equinovarus position in utero.

The cause of congenital clubfoot is unknown. There are hereditary factors and they are considered multifactorial, with a major influence from a single autosomal dominant gene. It develops more commonly in boys (2:1) and is bilateral in 50% of cases. The probability of the deformity occurring randomly is 1 in 1000 live births, but within affected families the probability is approximately 3% for subsequent siblings and 20%-30% for the offspring of affected parents. Muscle biopsies of the extrinsic muscles, electromyographic studies of these muscles, and histologic analysis of the associated connective tissue have indicated a probable neuromuscular etiology.[21,30] There are disproportionate fiber types and increased neuromuscular junctions within these muscles. These findings contrast with previous etiologic theories in which the deformity of the talus was thought to be the primary abnormality. These findings also suggest a reason as to why clubfoot is ubiquitous in syndromes and neuromuscular disorders; any child with a clubfoot deformity requires a careful musculoskeletal and neurologic evaluation to search for other abnormalities.

• **Fig. 99.18** Clinical photograph of a 9-month-old boy with bilateral talipes equinovarus (clubfoot) deformity.

Diagnosis

A congenital clubfoot is characterized by equinovarus deformity of the foot and ankle; variable rigidity of the deformity; mild calf atrophy; and mild hypoplasia of the tibia, fibula, and bones of the foot (Fig. 99.18).[67]

Imaging

Anteroposterior and lateral standing or simulated weight-bearing radiographs are used in the assessment of clubfoot. Multiple different radiographic measurements can be made. The navicular bone, which is the primary site of the deformity, does not ossify until 3 years of age in girls and 4 years of age in boys. Line measurements are required to determine the position of the unossified navicular bone and the overall alignment of the foot.

Treatment

Both nonoperative and operative methods are used in the treatment of clubfoot deformities. Nonoperative methods include taping, malleable splints, and serial plaster casts. Taping and malleable splints are particularly useful in premature infants until they attain an appropriate size for casting. Serial plaster casting is the major nonoperative method of treatment. For each cast change, the foot is gently manipulated toward the corrected position. Casts are changed at 1- to 2-week intervals to allow for progressive correction.

Complete clinical and radiographic correction should be achieved by 3 months of age. The failure to achieve

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

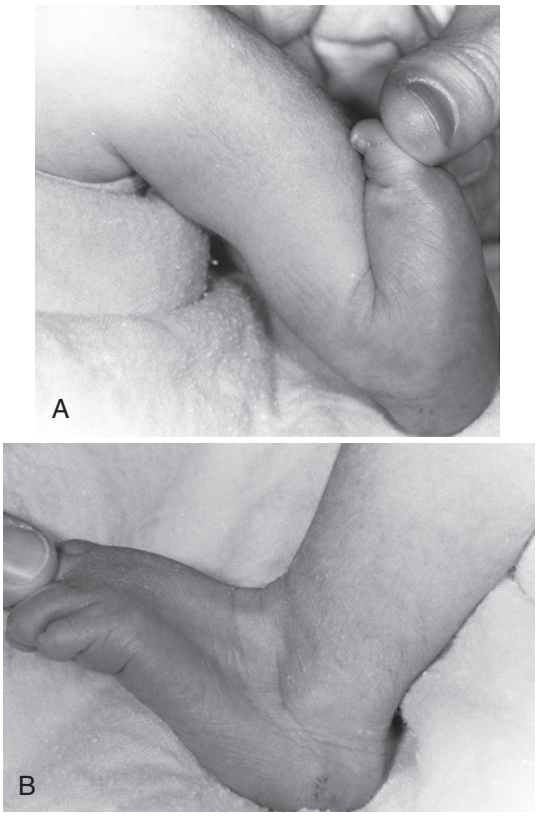
clinical and radiographic correction by 3 months of age is an indication for surgical treatment, because further attempts at casting may result in articular damage or a midfoot break (e.g., rocker-bottom deformity). Previously, primary operative treatment of congenital clubfoot often required a complete soft tissue release, usually performed between 6 and 12 months of age, and satisfactory long-term results were anticipated in 80%-90% of cases. However, over the last decade, the aforementioned Ponseti method of serial casting[53] (augmented with percutaneous tendo Achilles tenotomy when necessary) has become widely accepted. The Ponseti casting technique and tendo Achilles tenotomy are followed by a prolonged period of bracing, which lasts from 2-4 years. Strict adherence to the bracing protocol is mandatory for a positive outcome.[16]

Congenital Vertical Talus

Congenital vertical talus is an uncommon neonatal foot deformity, but its etiology is similar to that of clubfoot.[11,18] It must be distinguished from the benign calcaneovalgus foot, which is a much more common deformity. Congenital vertical talus typically presents as a rigid rocker-bottom deformity. Most of these deformities are associated with an underlying disorder such as teratologic malformation, myelodysplasia, arthrogryposis multiplex congenita, or a syndrome such as trisomy 18.

Diagnosis

The clinical characteristic of congenital vertical talus is a rocker-bottom foot (Fig. 99.19). There is an equinus hindfoot, a valgus hindfoot, a convex plantar surface, forefoot abduction and dorsiflexion, and rigidity. A careful musculoskeletal and neurologic examination must be performed on all neonates to search for associated disorders or syndromes.



Imaging

The radiographic evaluation of congenital vertical talus is similar to that of clubfoot. Anteroposterior and lateral simulated weight-bearing radiographs of the feet are obtained (Fig. 99.20) and typically reveal a vertically oriented talus, dorsal displacement of the midfoot on the hindfoot, and a valgus hindfoot.

Treatment

As in clubfoot, nonoperative treatment is the initial method of management. Dobbs has advocated a program of serial casting beginning at birth.[17] The forefoot is manipulated into an equinus position in an attempt to reduce the dorsally dislocated navicular bone onto the head of the talus. Once this is achieved, the talonavicular joint is pinned and a percutaneous tendo Achilles tenotomy then allows the ankle to be dorsiflexed without losing reduction at the joint. This technique has shown promise in decreasing the need for extensive initial soft tissue releases.

The goals for the treatment of congenital vertical talus are modest and include obtaining a plantigrade, painless foot on which a shoe can be worn. Orthotic management is frequently necessary postoperatively to maintain alignment and minimize the risk for recurrent deformity.[11]

• **Fig. 99.19 A,** A newborn girl with congenital vertical talus. The dorsum of the foot also comes in contact with the anterior aspect of the lower leg. The foot has a rocker-bottom appearance. **B,** An attempted plantar flexion shows the tightness of the anterior musculature and a persistent rocker-bottom appearance of the midfoot and hindfoot.

• **Fig. 99.20** Radiograph of a 9-month-old infant showing the vertical alignment of the talus, equinus hindfoot, and dorsal angulation of the midfoot and forefoot.

Syndactyly and Polydactyly of the Toes

Syndactyly and polydactyly are common disorders of the toes.[22,70] Syndactyly of the toes is almost always asymptomatic and rarely requires treatment but may be associated with a positive family history. Syndactyly may be classified

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

as zygodactyly (a complete or incomplete webbing usually involving the second and third toe) or polysyndactyly (polydactyly of the fifth toe and syndactyly between the duplicated toes).[70] Zygodactyly does not interfere with wearing shoes or normal function and does not require treatment; polysyndactyly usually requires treatment.

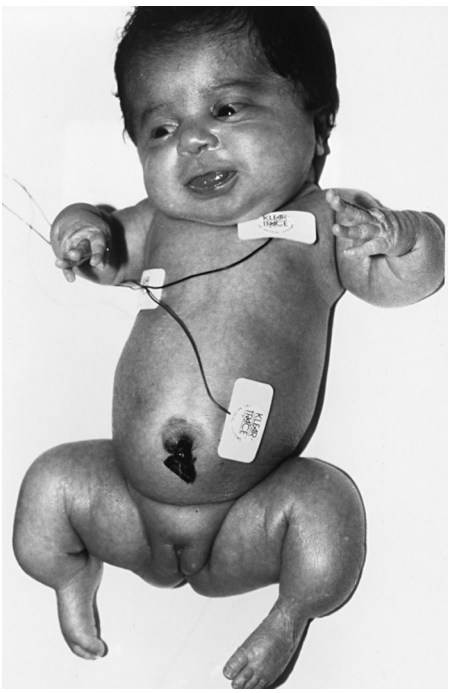
Polydactyly of the toes can be preaxial (i.e., great toe), central, or postaxial (i.e., fifth toe).[70] It occurs in approximately 2 of 1000 live births and is more common among African Americans than Caucasians. Postaxial deformities are the most common (80%) and can be subdivided into type A (articulated) and type B (rudimentary). Approximately 30% of neonates with polydactyly have a positive family history. It is usually an isolated disorder with autosomal dominant inheritance. Concomitant polydactyly of the hands and associated metatarsal deformities are common.

The goal of treatment is to restore a relatively normal contour to the forefoot to allow the appropriate fitting of shoes. Rudimentary digits can be ligated at birth, whereas articulated digits are removed at 9-12 months of age.[70] The more central of the involved digits are usually preserved and the more peripheral ones amputated.

Syndromes

Skeletal Dysplasias

See Chapter 30. Skeletal dysplasias constitute a group of disorders that produce short stature. Antenatal ultrasound diagnosis usually occurs or is suspected. Many of these disorders are recognizable at birth, whereas others are manifested during growth and development. The defects can occur in the epiphysis or physis (growth plate) or as abnormalities of bone remodeling that may affect the metaphysis or diaphysis. The most common skeletal dysplasia is achondroplasia, which produces short-limb dwarfism that is caused by a defect in a gene that encodes one of the fibroblast growth factor receptors. Diagnostic and prenatal testing is available. It is inherited as an autosomal dominant trait, but approximately 80% of cases are new mutations. It is caused by abnormal endochondral ossification of the physis. Achondroplasia produces a rhizomelic pattern of shortening, with the proximal segments (i.e., humerus and femur) more involved than the distal segments (i.e., radius and ulna or tibia and fibula). Periosteal and intramembranous ossification is normal.



The diagnosis is usually made at birth because of the characteristic features of the head, face, and short extremities. The head is typically enlarged; there are disproportionately short limbs and a normal trunk. Facial features include frontal bossing, flattening of the nasal bridge, midfacial hypoplasia, and prominence of the mandible. The trunk appears relatively normal but the abdomen is usually protuberant. The hands characteristically have a space between the long and ring fingers, producing a "trident" hand. The thoracolumbar spine may show an acute kyphotic deformity (gibbus) before the onset of walking. The lower extremities are usually bowed and the musculature appears enlarged. It is important to make an early diagnosis so that genetic counseling can be performed.

Treatment is usually not indicated in the neonatal period or during the first year. The one possible exception is the presence of a gibbus deformity of the thoracolumbar spine, which may benefit from orthotic management.

Osteogenesis Imperfecta

Osteogenesis imperfecta is an inherited disorder of connective tissues. It is caused by mutations in the *COL1A1* and *COL1A2* genes, which code for type I procollagen.[40] More than 150 separate mutations have been identified. Because type I collagen is the primary matrix protein for bone, dentin, sclerae, and ligaments, there is a heterogeneous mix of phenotypes. All children with osteogenesis imperfecta have increased bone fragility and susceptibility to fracture. Some children also present with blue sclerae, defective dentinogenesis, growth restriction, presenile hearing loss, scoliosis and kyphosis, and multiple angular deformities of bone (Fig. 99.21). Osteogenesis imperfecta is uncommon, occurring in fewer than 1 in 20,000 children. In its mildest form, children have a few fractures, normal teeth, sclerae with a slightly blue tinge, minimal hearing loss, and somewhat short stature. In its most severe form, perinatal death occurs. These children have blue sclerae and their bones collapse in utero.

Sillence and Danks and Sillence suggested a comprehensive classification scheme of osteogenesis imperfecta based

• **Fig. 99.21** Clinical photograph of a newborn girl with severe congenital osteogenesis imperfecta. The child had multiple fractures at birth. Observe the severe shortening of the extremities and darkened (blue) sclera.

on genetic inheritance and clinical manifestations.[63,64] In type I, patients have increased bone fragility, distinct blue sclerae, and presenile hearing loss. Some of these patients have defective dentinogenesis, although others do not. The inheritance pattern is autosomal dominant. In type II, the children are severely affected. Most of them die perinatally, because their bones collapse in utero. The inheritance pattern is autosomal recessive. At present, efforts to establish a relationship between genotype and phenotype are ongoing but complex. Bodian and co-workers analyzed 63 subjects with type II and found 61 distinct heterozygous mutations in type I collagen, of which 43 had not been previously seen. To say that osteogenesis imperfecta is heterogeneous would be an understatement.[6] In type III, the bone fragility is quite marked but compatible with survival. These children are born with multiple fractures and have progressive bowing of bones throughout life. Early on, their sclerae are quite blue but become less so as they mature; by adolescence, the sclerae are essentially normal in appearance. The inheritance pattern is autosomal recessive. In type IV, the bone fragility is modest. These patients usually have white sclerae; some have defective dentinogenesis, although others do not. They have modest bowing of bones. Some of these children may be difficult to differentiate from the normal population early in life.

The goal of orthopedic treatment in osteogenesis imperfecta is to maximize comfort and function. In modestly affected children, this approach frequently focuses on the closed treatment of fractures. The management of fractures in such children is not dissimilar to that in the average population. Children with increased bone fragility frequently benefit from orthotics, which are used to protect their bones as they are mobilized. Recently, intravenous pamidronate has shown promise for increasing bone density in children with moderate to severe osteogenesis imperfecta. Investigators also report reduced bone pain, a decreased incidence of fracture, and improved ambulation.[52,55,79] Children occasionally develop severe angular deformities from the poorly developed union of fractures or the insidious collapse of bones. As the deformities increase in magnitude, stress is concentrated at these angular deformities and children become increasingly susceptible to fracture. Osteotomies to straighten bones and intramedullary rods to maintain alignment may be helpful in assisting these children with their mobility. The rod provides internal support for the bone, and the elimination of angular deformities decreases stress within the bones.

Children with osteogenesis imperfecta do not necessarily have cognitive impairment. Every effort should be made to maximize their ability to attend school and interact with their peers.

Neurofibromatosis

Neurofibromatosis is a relatively common disorder that may or may not be diagnosable in the neonatal period. The presence of multiple café au lait spots or anterolateral bowing of the tibia suggests neurofibromatosis (Fig. 99.22). The café au lait spots frequently do not appear until the child is at least 2 years of age. The criteria for diagnosis have been outlined by Crawford[13] and include at least two of the following: multiple café au lait spots; a positive family history; a definitive biopsy; and characteristic bony lesions such as pseudarthrosis of the tibia, hemihypertrophy, or short and angulated spinal curvature. The café au lait spots are typically smooth; the presence of at least five spots larger than 0.5 cm in diameter is considered diagnostic.

• **Fig. 99.22** Clinical photograph of a 6-month-old boy with multiple café au lait spots resulting from neurofibromatosis.

Arthrogryposis Multiplex Congenita

Arthrogryposis multiplex congenita refers to a symptom complex (syndrome) characterized by multiple joint contractures that are present at birth. The involved muscles are replaced partially or completely by fat and fibrous tissue. However, it is not a single disease, because approximately 150 different syndromes are associated with multiple congenital contractures. The major form of arthrogryposis multiplex congenita is known as amyoplasia,[58,60] which refers to the classic syndrome in which the upper and lower extremities are involved. It accounts for approximately 40% of all children with multiple congenital contractures. Its cause is unknown. Children with this disorder have a decreased number of anterior horn cells in their spinal cords, suggesting a neuropathic origin. The clinical features include adduction, internal rotation, and contractures of the shoulders; fixed flexion or extension contractures of the elbows; rigid

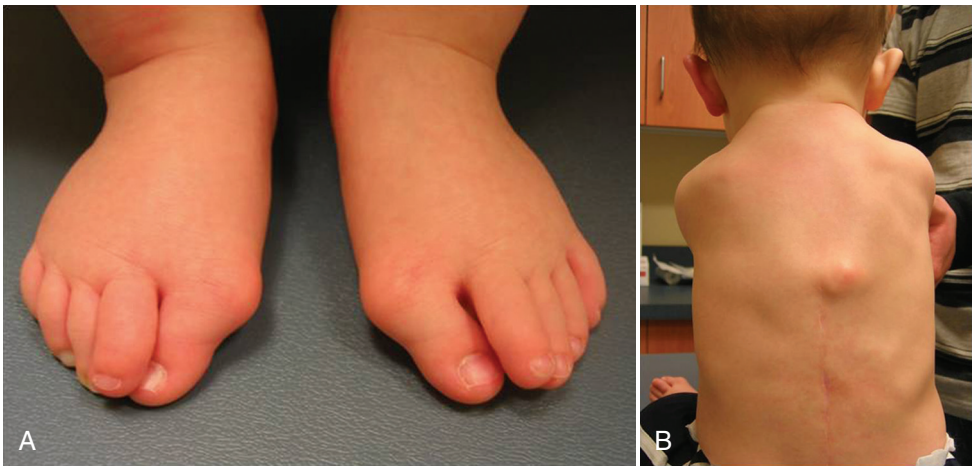
• **Fig. 99.23** **A,** A 1-month-old girl with arthrogryposis multiplex congenita involving the upper and lower extremities. The elbows are stiff in extension, whereas the wrist, fingers, and thumb are flexed. The hips are flexed and externally rotated. There are knee flexion contractures and bilateral talipes equinovarus clubfoot deformities. **B,** Serial casting is initiated at birth to improve the alignment of the lower extremities. Occupational therapy and splinting are used at a later time on the upper extremities.

volar flexion/ulnar deviation or dorsiflexion/radial deviation contractures of the wrists; thumb and palm deformities; rigid interphalangeal joints of the thumb and fingers; flexion, abduction, and external rotation contractures of the hips, with dislocation of one or both; fixed flexion or extension contractures of the knees; and severe, rigid, bilateral clubfeet (Fig. 99.23). Radiographs of all involved joints are obtained to assess their development; specialized studies are ordered as necessary.

Treatment modalities during the neonatal period consist of physical therapy and serial casting. Occasionally, orthotics and surgical intervention may be necessary; however, surgery is usually delayed until early childhood.[65]



Fibrodysplasia Ossificans Progressiva

Fibrodysplasia ossificans progressiva (FOP) is a rare genetic disease (incidence about 1 in 1.6 million) characterized by skeletal malformations and episodic heterotopic bone formation leading to progressive loss of mobility. Although FOP was first described in the seventeenth century, most individuals with FOP are initially misdiagnosed, and many suffer permanent disability from inappropriate diagnostic or therapeutic interventions. Two likely causes for these harmful diagnostic errors are the lack of teaching exposure to FOP in most medical schools and the lack of coverage of FOP in most medical textbooks.

The mode of inheritance of FOP is autosomal dominant with complete penetrance, but almost all cases result from a spontaneous activating mutation in the gene encoding activin receptor IA/activin like kinase-2 (ACVR1/ALK2), a bone morphogenetic protein type I receptor. Only seven small multigenerational families are known worldwide.[31-35,38,61]

The two classic findings in FOP are distinctive malformations of the great toes and episodic "flare-ups" characterized by soft tissue tumor-like swellings that often result in heterotopic ossification at the lesional site. The invariant malformations of the great toes are caused by hypoplasia or agenesis of the proximal phalanges that result in short great toes with a valgus deformity (Fig. 99.24*A*). The toe malformations are present at birth and may be the only congenital sign of FOP. Flare-ups, especially in the occipital region, may commence in the neonatal period and are often mistaken for cephalohematomas. However, flare-ups are usually recognized later in the first decade and typically appear on the head, neck, back, or shoulders (see Fig. 99.24*B*). The onset of a tender soft tissue swelling often appears overnight, triggered by soft tissue trauma or viral illnesses or may occur spontaneously. The soft tissue swellings

• **Fig. 99.24 A,** A photograph of the feet of an infant with fibrodysplasia ossificans progressiva (FOP) showing the characteristic findings of short great toes and hallux valgus. **B,** A photograph of the back of a very young child with a tumor-like swelling on his back that represents an early FOP flare-up. Note the surgical scar from an unnecessary biopsy that exacerbated the disease process.

may resolve completely but most often result in heterotopic bone formation.

Microscopically, perivascular lymphocytic, mast cell, and macrophage infiltration occurs in striated muscle, followed by widespread death of muscle cells. Subsequently, an angiogenic fibroproliferative lesion forms, evolving through a cartilage stage and finally into mature heterotopic bone through a characteristic endochondral mechanism. This process involves striated muscles, ligaments, tendons, and aponeuroses, but spares the diaphragm, tongue, extraocular muscles, and cardiac and smooth muscle.

Additional common findings may include short thumbs; short, broad femoral necks; proximal medial tibial osteochondromas; tall, narrow cervical vertebrae; and ankylosis of facet joints of the cervical spine. Findings later in life include hearing loss and atypical facies, which usually develops in the second decade of life and is caused by mandibular hypoplasia.[34]

Fibrodysplasia ossificans progressiva can be diagnosed clinically and with great accuracy when the clinician recognizes the pathognomonic combination of great toe malformations with the presence of rapidly appearing soft tissue tumors in characteristic anatomic locations. In most cases, the swellings are misdiagnosed, most commonly as cancer or aggressive fibromatosis, often because the physician is unfamiliar with FOP. In newborns, FOP should be suspected when the typical malformations of the great toes are present. For suspected cases, diagnostic genetic testing is readily available from a simple blood test.[31]

There is no effective treatment for FOP. The process of heterotopic ossification is often accelerated by trauma, including traumatic medical interventions. These include biopsies, intramuscular injections (including neonatal vitamin K), immunizations, and surgical procedures, all of which should be avoided. For flare-ups involving major joints or the airway, a brief (3- to 4-day) course of high-dose corticosteroids will reduce soft tissue swelling and may prevent ossification.

Episodic heterotopic bone formation in FOP leads to progressive immobilization of the joints and restrictive disease of the chest wall.[32] Malnutrition is common if there is ossification of the jaw muscles leading to restricted mouth opening and swallowing. Average life expectancy is 40 years (range, 3-77 years). Identification of the responsible gene provides hope for future effective treatment of FOP.

Key Points

- Upper extremity malformations are much less common than those involving the lower extremities or spine.
- Common upper extremity congenital malformations include Sprengel deformity of the scapula; proximal radius and ulna synostosis; radial dysplasia and club-hand; constriction bands; congenital amputations; and syndactyly, polydactyly, and macrodactyly of the fingers.
- Congenital spinal abnormalities are predominantly scoliosis, kyphosis, and sacral agenesis.
- Common lower extremity congenital malformations include congenital angular deformities of the tibia and fibula; proximal femoral focal deficiency; subluxation/dislocations of the knee; congenital talipes equinovarus deformities (clubfeet); congenital vertical tali; reduction anomalies and amputations of the lower leg; and syndactyly, polydactyly, and macrodactyly of the toes.
- Syndromes can also be associated with congenital musculoskeletal malformations, especially spinal deformities.

Appendix A

Therapeutic Agents

Jacquelyn D. McClary

Agent	Dosage	Comments
Anti-infective Agents		
Antibacterials		
Amikacin*	15-18 mg/kg/dose every 24-48 hr	Monitor serum concentrations if treating >48 hr
Ampicillin*	Meningitis: 100 mg/kg/dose IV every 6-12 hr Non-CNS infections: 25-50 mg/kg/dose IV, IM every 6-12 hr	
Azithromycin	Pertussis/ureaplasma infections: 10 mg/kg/dose PO, IV every 24 hr Chlamydial conjunctivitis: 20 mg/kg PO, IV every 24 hr x 3 days	IV dosing is not well-defined in neonates
Aztreonam*	30 mg/kg/dose IV, IM every 6-12 hr	
Cefazolin*	25 mg/kg/dose IV, IM every 6-12 hr	First-generation cephalosporin; commonly used for perioperative prophylaxis and treatment of urinary tract and soft tissue infections
Cefepime*	30-50 mg/kg/dose IV, IM every 12 hr	Fourth-generation cephalosporin; reserved for treatment of infections caused by multidrug-resistant organisms
Cefotaxime*	Sepsis or meningitis: 50 mg/kg/dose IV, IM every 6-12 hr Disseminated gonococcal infection: 25 mg/kg/dose IV, IM every 12 hr for 7 days if meningitis not present	Broad-spectrum, third-generation cephalosporin; may use to treat Gram-negative meningitis
Cefoxitin	30 mg/kg/dose IV, IM every 8 hr	Use limited to skin, intra-abdominal, and urinary tract infections
Ceftazidime*	30 mg/kg/dose IV, IM every 8-12 hr	Third-generation cephalosporin effective against *Pseudomonas* species
Ceftriaxone	Sepsis: 50 mg/kg/dose IV, IM every 24 hr Meningitis: 100 mg/kg/dose IV, IM every 24 hr Disseminated gonococcal infection: 25-50 mg/kg/dose IV, IM every 24 hr Gonococcal infection prophylaxis/ophthalmia: 25-50 mg/kg (max 125 mg) IV, IM single dose	Not recommended for infants with hyperbilirubinemia; do not administer in the same IV line with calcium-containing solutions
Clindamycin*	5-7.5 mg/kg/dose IV, PO every 6-12 hr	Do not use to treat meningitis; may cause pseudomembranous colitis
Erythromycin	10-12.5 mg/kg/dose PO every 6 hr Severe infection: 5-10 mg/kg IV every 6 hr	Higher dose used to treat chlamydial pneumonitis and conjunctivitis, and pertussis
Gentamicin*	4-5 mg/kg/dose IV, IM every 24-48 hr	Monitor serum concentrations if treating >48 hr

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Agent	Dosage	Comments
Imipenem/cilastatin	20-25 mg/kg/dose (imipenem component) IV every 8-12 hr	Restrict use to treatment of non-CNS infections; seizures occur frequently in patients with meningitis
Linezolid	10 mg/kg/dose IV, PO every 8 hr (premature infants <7 days of age: dose every 12 hr)	Use for Gram-positive infections refractory to conventional therapy
Meropenem*	20-40 mg/kg/dose IV every 8-12 hr	Reserve for infections caused by multidrug-resistant organisms; restrict use of 40 mg/kg doses to full-term infants with meningitis
Metronidazole*	Loading dose: 15 mg/kg/dose IV, PO Maintenance dose: 7.5 mg/kg/dose IV, PO every 8-48 hr	
Nafcillin*	Sepsis: 25 mg/kg/dose IV every 6-12 hr Meningitis: 50 mg/kg/dose IV every 6-12 hr	Greatest CSF penetration of antistaphylococcal penicillins; predominantly biliary excretion; irritating to veins
Oxacillin*	25-50 mg/kg/dose IV every 6-12 hr	Poor CSF penetration; irritating to veins
Penicillin G*	25,000-150,000 units/kg/dose IV, IM every 6-12 hr	Higher doses suggested for severe group B streptococcal infections
Piperacillin/tazobactam*	100 mg/kg/dose (as piperacillin component) IV every 8-12 hr	For non-CNS infections caused by susceptible β-lactamase-producing bacteria
Rifampin	PO: 10-20 mg/kg/dose every 24 hr IV: 5-10 mg/kg/dose every 12 hr Prophylaxis against meningococcal disease: 5 mg/kg/dose PO every 12 hr for 2 days Prophylaxis against *Haemophilus influenzae* type B disease: 10 mg/kg/dose PO every 24 hr for 4 days	Used in combination with vancomycin or aminoglycosides for treatment of persistent staphylococcal infections
Tobramycin*	4-5 mg/kg/dose every 24-48 hr	Monitor serum concentrations if treating >48 hr
Vancomycin*	10-15 mg/kg/dose every 6-18 hr	Target trough concentrations 10-15 μg/mL for most infections; 15-20 μg/mL may be necessary for meningitis, pneumonia, and other severe infections
Antifungals		
Amphotericin B	1-1.5 mg/kg/dose IV every 24 hr	Infuse over 2-6 hours; monitor serum creatinine and prolong dosing interval if creatinine increases >0.4 mg/dL from baseline
Amphotericin B liposome (Ambisome)	2.5-7 mg/kg/dose IV every 24 hr	Infuse over 2 hours; less nephrotoxic than amphotericin B
Amphotericin B lipid complex (Abelecet)	2.5-5 mg/kg/dose IV every 24 hr	Infuse over 2 hours; less nephrotoxic than amphotericin B
Caspofungin	25 mg/m^2/dose IV every 24 hr	Limited data in neonates—reserve for treatment of refractory candidemia or patients intolerant to amphotericin
Fluconazole*	Systemic infection: loading dose 12-25 mg/kg/dose IV, PO then 6-12 mg/kg/dose every 24-48 hr Prophylaxis: 3-6 mg/kg/dose IV, PO two times/week Thrush: 6 mg/kg/dose PO on day 1, then 3 mg/kg/dose PO every 24 hr	Higher doses used for severe infections; consider extended dosing interval if serum creatinine >1.3 mg/dL; may cause reversible elevations of transaminases; may interfere with metabolism of phenytoin, barbiturates, caffeine, and midazolam

Agent	Dosage	Comments
Flucytosine	12.5-37.5 mg/kg/dose PO every 6 hr	Use in conjunction with amphotericin B or fluconazole; increase dosing interval in presence of renal dysfunction
Micafungin	10 mg/kg/dose IV every 24 hr	Limited data in neonates—reserve for treatment of refractory candidemia or for patients intolerant to amphotericin
Nystatin	Topical: apply to affected area every 6 hr Thrush: 1 mL (premature) to 2 mL (full term) of 100,000 unit/mL suspension; swab inside mouth every 6 hr	Continue for 3 days after symptoms subside
Antivirals		
Acyclovir*	HSV treatment: 20 mg/kg/dose IV every 6-12 hr HSV chronic suppression: 300 mg/m^2/dose PO every 8 hr Varicella-zoster virus: 10-15 mg/kg/dose IV every 8 hr	Administer every 12-24 hours in patients with severe renal/hepatic impairment; neutropenia, phlebitis may occur
Ganciclovir	Treatment: 6 mg/kg/dose IV every 12 hr Chronic suppression: 30-40 mg/kg/dose PO every 8 hr	Significant neutropenia occurs in most patients; reduce dose by half for ANC <500 cells/mm^3
Lamivudine	2 mg/kg/dose PO every 12 hr	Refer to the Perinatal Guidelines at http://www.aidsinfo.nih.gov/ for the latest treatment information (accessed October 4, 2017)
Nevirapine	Birth weight 1.5-2 kg: 8 mg/dose PO for 3 doses Birth weight >2 kg: 12 mg/dose PO for 3 doses Dose 1: within 48 hr of birth Dose 2: 48 hr after dose 1 Dose 3: 96 hr after dose 2	Refer to the Perinatal Guidelines at http://www.aidsinfo.nih.gov/ for the latest treatment information
Oseltamivir*	1-3 mg/kg/dose PO every 12 hr for 5 days	Limited data available for preterm infants; may cause transient rise in transaminases
Valganciclovir	16 mg/kg/dose PO every 12 hr	Neutropenia occurs frequently; dose adjustment may be required
Zidovudine*	IV: 1.5-3 mg/kg/dose every 12 hr PO: 2-4 mg/kg/dose every 12 hr	Initiate therapy within 6-12 hours of birth; anemia and neutropenia may occur; refer to the Perinatal Guidelines at http://www.aidsinfo.nih.gov/ for the latest treatment information
Cardiovascular Drugs		
Antiarrhythmics		
Adenosine	Give 50 mcg/kg as a rapid IV bolus followed by a flush; increase dose in 50 mcg/kg increments every 2 minutes until response obtained (usual maximum dose of 250 mcg/kg)	May cause transient asystole or bradycardia prior to return of normal sinus rhythm
Amiodarone	Loading dose: 5 mg/kg IV over 20-60 minutes Continuous IV infusion: start at 7 mcg/kg/min, may increase to 15 mcg/kg/min PO: 5-10 mg/kg/dose every 12 hr	For treatment of refractory supraventricular arrhythmia; long elimination half-life; may cause hypothyroidism or hyperthyroidism, hepatitis, pulmonary fibrosis
Atropine	Bradycardia: 0.01-0.03 mg/kg/dose IV, IM, ET every 10-15 minutes up to total dose of 0.04 mg/kg Premedication for intubation: 0.02 mg/kg/dose IV	For reversal or prevention of sinus bradycardia

Agent	Dosage	Comments
Digoxin*	<37 weeks, loading dose: IV: 15-20 mcg/kg divided into 3 doses over 24 hr PO: 20-25 mcg/kg divided into 3 doses over 24 hr Maintenance dose: IV: 4-5 mcg/kg every 24 hr PO: 5-6 mcg/kg every 24 hr ≥37 weeks, loading dose: IV: 30-40 mcg/kg divided into 3 doses over 24 hr PO: 40-50 mcg/kg divided into 3 doses over 24 hr Maintenance dose: IV: 4-5 mcg/kg every 12 hr PO: 5-6 mcg/kg every 12 hr	Be aware of drug interactions; obtain periodic ECGs to assess for desired effects and signs of toxicity; hypokalemia, hypomagnesemia, hypermagnesemia, hypercalcemia, and renal impairment predispose patients to digoxin toxicity; target trough concentration of 0.8-2 ng/mL
Digoxin immune Fab	Chronic digoxin toxicity: Dose (in mg) = 40 mg × (serum digoxin concentration in ng/mL × weight in kg)/100 Acute ingestion: Dose (in vials) = (digoxin ingested in mg × bioavailability)/0.5 mg	Each vial contains 40 mg and will bind 0.5 mg digoxin; after administration, digoxin serum concentrations can no longer be determined accurately; bioavailability of digoxin solution = 0.85, tablets = 0.8
Flecainide	Begin at 2 mg/kg/dose PO every 12 hr; adjust based on response and serum concentrations to a maximum of 4 mg/kg/dose PO every 12 hr	Used for treatment of SVT not responsive to conventional therapies; can cause new or worsened arrhythmias
Lidocaine	Initial bolus: 0.5-1 mg/kg dose by slow IV push; may be repeated every 10 min up to total of 5 mg/kg Maintenance IV infusion: 10-50 mcg/kg/minute	Adverse effects include hypotension, seizures, respiratory depression, asystole
Procainamide	Initial bolus: 7-10 mg/kg/dose IV push Maintenance IV infusion: 20-80 mcg/kg/minute	Treatment of SVT refractory to vagal maneuvers and adenosine
Propranolol	PO: starting dose 0.25-1 mg/kg/dose every 6 hr; increase up to 3.5 mg/kg/dose every 6 hr IV: 0.01 mg/kg/dose IV every 6 hr; increase up to 0.15 mg/kg/dose every 6 hr	Adverse effects related to β receptor blockade include bradycardia, bronchospasm, and hypoglycemia
Sotalol	1 mg/kg/dose PO every 12 hr; increase to a maximum of 4 mg/kg/dose PO every 12 hr	For treatment of refractory ventricular and supraventricular tachyarrhythmias; has β blocking properties and prolongs cardiac action potential duration
Antihypertensive Agents		
Captopril	0.01-0.05 mg/kg/dose PO every 8-12 hr	Treatment of hypertension and CHF; monitor renal function and serum potassium; contraindicated in patients with bilateral renovascular disease
Enalapril (PO) Enalaprilat (IV)	PO: 40 mcg/kg PO every 24 hr; increase up to 150 mcg/kg PO every 6 hr IV: 10 mcg/kg IV every 24 hr; increase dose and interval based on response	Treatment of hypertension and CHF; monitor renal function and serum potassium; contraindicated in patients with bilateral renovascular disease
Hydralazine	IV: 0.1-0.5 mg/kg/dose every 6-8 hr; gradually increase to a maximum of 2 mg/kg/dose every 6 hr PO: 0.25-1 mg/kg/dose every 6-8 hr	Treatment of hypertension via vasodilation
Sodium nitroprusside	0.25-0.5 mcg/kg/min continuous IV infusion; increase dose every 20 min as needed Maintenance dose is usually <2 mcg/kg/min For hypertensive crisis, can use doses as high as 10 mcg/kg/min for ≤10 min	Must have continuous intra-arterial blood pressure monitoring; may produce profound hypotension, metabolic acidosis, thrombocytopenia, and/or CNS symptoms; cyanide toxicity can occur

Agent	Dosage	Comments
Hemodynamic Support Agents		
Dobutamine	2-25 mcg/kg/min continuous IV infusion	Typical starting dose is 5-10 mcg/kg/min, then titrate to effect; increases myocardial contractility and cardiac output; tachycardia may occur
Dopamine	2-20 mcg/kg/min continuous IV infusion	Typical starting dose is 5-10 mcg/kg/min, then titrate to effect; increases myocardial contractility and cardiac output and causes vasoconstriction; predominant effects vary with dose; tachycardia may occur
Epinephrine	Resuscitation: 0.01-0.03 mg/kg/dose IV push; 0.05-0.1 mg/kg/dose ET Continuous IV infusion: 0.05-1 mcg/kg/min	Increases blood pressure via direct myocardial stimulation, increased heart rate, and vasoconstriction; monitor for hyperglycemia and tachycardia
Isoproterenol	0.05-0.5 mcg/kg/min continuous IV infusion; titrate to maximum of 2 mcg/kg/min	Primarily acts by increasing heart rate; monitor for tachycardia
Milrinone	Loading dose: 75 mcg/kg IV over 60 min Maintenance infusion: 0.2-0.75 mcg/kg/min	Has both inotropic and vasodilatory properties; hypotension occurs frequently with bolus dose
Patent Ductus Arteriosus Agents		
Alprostadil	Initial dose: 0.05-0.1 mcg/kg/min continuous IV infusion Maintenance doses may be as low as 0.01 mcg/kg/min	Apnea occurs in 10%-12% of neonates
Ibuprofen lysine	First dose: 10 mg/kg IV Second and third doses: 5 mg/kg IV; administer at 24 hr intervals	Monitor urine output; can inhibit platelet aggregation
Indomethacin	Initial dose: 0.2 mg/kg IV Subsequent doses: If <2 days, 0.1 mg/kg/dose IV every 12-24 hr for 2 doses If 2-7 days, 0.2 mg/kg/dose IV every 12-24 hr for 2 doses If >7 days, 0.25 mg/kg dose IV every 12-24 hr for 2 doses	Monitor urine output; can cause platelet dysfunction; avoid concomitant steroid therapy to decrease risk of GI perforation
Central Nervous System Drugs		
Analgesics and Narcotics		
Acetaminophen*	PO: 10-15 mg/kg/dose every 6-12 hr Rectal: 15-20 mg/kg/dose every 6-12 hr IV: GA ≥32 weeks, 12.5 mg/kg every 6 hr	Dosing interval dependent on postmenstrual age
Fentanyl	Slow IV push: 1-4 mcg/kg/dose every 2-4 hr Continuous IV infusion: 0.5-5 mcg/kg/hr	Synthetic opioid; may cause chest wall rigidity with higher doses or with rapid infusion
Methadone	0.05-0.1 mg/kg/dose every 6-24 hr	Treatment of neonatal abstinence syndrome; adjust dose in 10%-20% increments based on signs and symptoms of withdrawal
Morphine	IV, IM, subcutaneous: 0.05-0.2 mg/kg/dose every 4 hr Continuous IV infusion: 10-20 mcg/kg/hr; increase based on response Neonatal abstinence syndrome: 0.02-0.2 mg/kg/dose PO every 3-4 hr; adjust dose based on abstinence scoring	May exacerbate hypotension and cause respiratory depression

Agent	Dosage	Comments
Anticonvulsants		
Fosphenytoin	Loading dose: 15-20 mg PE/kg IV, IM Maintenance dose: 4-8 mg PE/kg IV, IM every 24 hr	Fosphenytoin 1 mg PE = phenytoin 1 mg; monitor trough serum phenytoin concentrations; term infants >1 week of age may require more frequent dosing; use with caution in neonates with hyperbilirubinemia
Levetiracetam	10 mg/kg/dose IV, PO every 24 hr; increase dose as needed up to maximum of 30 mg/kg/dose every 12 hr	Treatment of seizures refractory to phenobarbital and other anticonvulsants
Lidocaine	Loading dose: 2 mg/kg IV over 10 minutes Maintenance infusion: 6 mg/kg/hr for 6 hr, then 4 mg/kg/hr for 12 hr, then 2 mg/kg/hr for 12 hr	Preterm newborns and newborns undergoing hypothermia treatment are at risk for drug accumulation; precise dosing in these infants is uncertain
Phenobarbital	Loading dose: 20 mg/kg slow IV push; additional 5-10 mg/kg doses may be given up to a total of 40 mg/kg Maintenance dose: 3-5 mg/kg/dose IV, IM, PO every 24 hr	Monitor serum concentrations and adjust dose to maintain concentrations at 15-40 mcg/mL
Phenytoin	Loading dose: 15-20 mg/kg IV over 30 minutes Maintenance dose: 4-8 mg/kg/dose IV, PO every 8-24 hr	Infants >1 week of age may require more frequent dosing
Neuromuscular Blockers[†]		
Pancuronium	0.1 mg/kg IV push every 1-2 hr as needed	Tachycardia, hypotension, and hypertension occur frequently
Rocuronium	0.3-1.2 mg/kg IV push, repeat as needed (every 30-60 min)	Short duration of action; use limited to premedication for procedures such as intubation
Vecuronium	0.1 mg/kg IV push, every 1-2 hr as needed Continuous IV infusion: 0.06-0.2 mg/kg/hr	Minimal cardiovascular side effects
Sedatives/Tranquilizers		
Clonidine	0.5-1 mcg/kg/dose PO every 4-6 hr	Adjunct treatment of neonatal abstinence syndrome; limited data available
Lorazepam	0.05-0.1 mg/kg/dose IV push	May cause respiratory depression; may be used acutely to stop seizures; some products contain benzyl alcohol
Midazolam	IV, IM: 0.05-0.15 mg/kg/dose every 2-4 hr Continuous IV infusion: 10-60 mcg/kg/hr; increase as needed Intranasal: 0.2-0.3 mg/kg/dose prior to procedure Oral: 0.25 mg/kg/dose every 4-6 hr	Dosage requirements are decreased by concurrent use of narcotics; monitor for respiratory depression and hypotension; may cause myoclonic seizure-like activity
Pentobarbital	2-6 mg/kg/dose IV push	Short-acting barbiturate for short-term use
Diuretics		
Bumetanide[*]	0.005-0.1 mg/kg/dose IV, IM, PO every 12-24 hr	May cause hyponatremia, hypokalemia, and hypochloremic alkalosis; may displace bilirubin from albumin-binding sites when given in high doses or for prolonged periods
Chlorothiazide	PO: 10-20 mg/kg/dose every 12 hr IV: 5-10 mg/kg/dose every 12 hr	May cause hypokalemia and alkalosis; effective in treatment of nephrocalcinosis secondary to loop diuretics

Agent	Dosage	Comments
Furosemide*	IV: 1-2 mg/kg/dose every 6-24 hr PO: 2-6 mg/kg/dose every 6-24 hr	Potentially ototoxic; may cause hypokalemia, hyponatremia, alkalosis, nephrocalcinosis; consider alternate-day therapy for long-term use
Hydrochlorothiazide	1-2 mg/kg/dose PO every 12 hr	May cause hypokalemia
Spironolactone	1-3 mg/kg/dose PO every 24 hr	Use in combination with other diuretics; may cause hyperkalemia
Endocrine Agents		
Dexamethasone	DART (Dexamethasone: A Randomized Trial) protocol: 0.075 mg/kg/dose IV, PO every 12 hr for 3 days then wean over 7 days (10-day course) Airway extubation: 0.25-0.5 mg/kg/dose IV, PO every 8 hours for 1-3 doses	Treat only those infants at highest risk of chronic lung disease; adverse effects include growth failure, hypertension, hyperglycemia, increased risk for cerebral palsy; do not use concurrently with indomethacin or ibuprofen because of risk for GI perforation
Diazoxide	2-5 mg/kg/dose PO every 8 hr	Reserved for treatment of severe, persistent hypoglycemia caused by hyperinsulinism; often causes sodium and fluid retention; may cause GI distention
Hydrocortisone	Physiologic dose: 7-9 mg/m^2/day IV, PO divided q 8-12 hr Stress dose: 20-50 mg/m^2/day IV divided every 8-12 hr	Adverse effects include hyperglycemia, hypertension, water and salt retention; there is an increased risk of GI perforation when treating concurrently with indomethacin/ibuprofen
Glucagon	0.2 mg/kg/dose IV, IM, or subcutaneous (maximum dose 1 mg)	Reserved for treatment of refractory hypoglycemia; watch for rebound hypoglycemia approximately 2 hours after dose
Insulin	Continuous IV infusion: 0.01-0.1 unit/kg/hr	Binds to plastic tubing—to saturate tubing binding sites fill tubing with insulin solution and wait at least 20 minutes prior to administration
Levothyroxine	PO: 10-14 mcg/kg/dose every 24 hr IV: 5-8 mcg/kg/dose every 24 hr	Adjust oral doses in 12.5 mcg increments, always round up; assess thyroid function 2 weeks after dosing change
Octreotide	Hyperinsulinemic hypoglycemia: 1 mcg/kg/dose IV, subcutaneous every 6 hr; titrate to desired effect; maximum dose is 10 mcg/kg/dose every 6 hr Chylothorax: 1 mcg/kg/hr, titrate up by 1 mcg/kg/hr every 24 hr; maximum dose is 10 mcg/kg/hr	May cause vomiting, diarrhea, abdominal distention; NEC has been reported in term neonates
Gastrointestinal Agents		
Cimetidine	2.5-5 mg/kg/dose PO, IV every 6-12 hr	Monitor for drug interactions; may increase risk for late-onset bacterial sepsis and fungal sepsis
Erythromycin	10 mg/kg/dose PO every 6 hr for 2 days, then 4 mg/kg/dose every 6 hr for 5 days	Treatment of feeding intolerance caused by GI dysmotility
Famotidine	IV: 0.25-0.5 mg/kg/dose every 24 hr PO: 0.5-1 mg/kg/dose every 24 hr	May increase risk for late-onset bacterial sepsis and fungal sepsis
Lansoprazole	0.73-1.66 mg/kg/dose PO every 24 hr	Limited data available in neonates
Metoclopramide	0.03-0.1 mg/kg/dose IV, PO every 8 hr	Facilitates gastric emptying and gastrointestinal motility; observe for dystonic reactions

Agent	Dosage	Comments
Nizatidine	2-5 mg/kg/dose PO every 12 hr	May increase risk for late-onset bacterial sepsis and fungal sepsis; limited data available in neonates
Omeprazole	0.5-1.5 mg/kg/dose PO every 24 hr	Limited data available in neonates
Ranitidine	PO: 2 mg/kg/dose every 8 hr IV preterm: 0.5 mg/kg/dose every 12 hr IV term: 1.5 mg/kg/dose every 8 hr Continuous IV infusion: 0.04-0.1 mg/kg/hr	May increase risk for late-onset bacterial sepsis and fungal sepsis
Ursodiol	10-15 mg/kg/dose PO every 12 hr	May cause vomiting, abdominal pain, constipation
Hematologic Agents		
Alteplase (t-PA)	Dissolution of intravascular thrombi: 200 mcg/kg/hr for 6-48 hr Restoration of patency for central venous catheter: instill a 1-mg/mL solution into the catheter and dwell up to 120 minutes; may repeat once if needed	Thrombi dose is a range of that used in case reports (20-500 mcg/kg/hr)
Enoxaparin	Term: 1.7 mg/kg/dose subcutaneous every 12 hr Preterm: 2 mg/kg/dose subcutaneous every 12 hr	Adjust dosage to maintain antifactor Xa level between 0.5 and 1 unit/mL
Epoetin alfa	200-400 units/kg/dose subcutaneous 3-5 times/week	Patient should be on supplemental iron therapy; higher doses under investigation for neuroprotective benefits
Heparin	Thrombosis: 75 units/kg IV, then 28 units/kg/hr Maintenance of central line patency: 0.5-1 unit/mL of IV fluid	For thrombosis, adjust dose based on aPTT or anti-factor Xa level
IVIG	400-1000 mg/kg/dose IV over 2-6 hr	If more than one dose needed, may repeat in 12-24 hr
Minerals/Vitamins		
Calcium carbonate	20-80 mg/kg/day elemental calcium PO every 6-12 hr	
Calcium gluconate 10%	Acute treatment: 100-200 mg/kg/dose IV (equivalent to 10-20 mg/kg elemental calcium) Maintenance treatment: 200-800 mg/kg/day by continuous IV infusion (20-80 mg/kg elemental calcium)	Monitor serum calcium and ionized calcium if possible
Ferrous sulfate	2-6 mg/kg/day elemental iron divided q12-24 hr	Higher dose for infants on epoetin therapy
Iron dextran	0.4-1 mg/kg/day continuous IV infusion in parenteral nutrition solution	For infants unable to tolerate oral iron therapy
Potassium chloride	Acute treatment of symptomatic hypokalemia: begin with 0.5-1 mEq/kg IV over 1 hr, then reassess Initial oral replacement: 0.5-1 mEq/kg/day PO divided and administered with feedings	Maximum concentrations: 40 mEq/L for peripheral, 80 mEq/L for central venous infusions
Pyridoxine (vitamin B_6)	Initial diagnostic dose: 50-100 mg IV, IM Maintenance dose: 50-100 mg PO every 24 hr	May cause bradycardia, apnea, hypotension
Sodium bicarbonate	1-2 mEq/kg/dose IV over at least 30 minutes	Maximum concentration 0.5 mEq/mL; treatment of normal anion gap metabolic acidosis caused by renal or GI losses; not a recommended therapy in neonatal resuscitation

Agent	Dosage	Comments
Vitamin D	Supplementation: 400 units PO every 24 hr Treatment of deficiency: 1000 units/day divided every 12-24 hr	Vitamin D_3 (cholecalciferol) has been shown to be more effective in raising 25(OH)-D levels when compared with vitamin D_2 (ergocalciferol)
Vitamin K_1	Prophylaxis: >32 weeks' gestational age: 0.5-1 mg IM at birth <32 weeks' gestational age: >1000 g birth weight: 0.5 mg IM <1000 g birth weight: 0.3 mg/kg IM Treatment of HDN: 1-10 mg IV	
Ophthalmic Agents		
Cyclopentolate	1-2 drops in the eye 10-30 minutes before funduscopy	Use solutions with concentrations of 0.5% or less in neonates; anticholinergic effects if absorbed systemically; apply pressure to lacrimal sac during and for 2 minutes after instillation
Phenylephrine	1 drop in eye 10-30 minutes before funduscopy	Use only the 2.5% solution in neonates; apply pressure to lacrimal sac during and for 2 minutes after instillation
Tropicamide	1 drop in eye 10-30 minutes before funduscopy	Use only the 0.5% solution in neonates; anticholinergic effects if absorbed systemically; apply pressure to lacrimal sac during and for 2 minutes after instillation
Pulmonary Agents		
Beractant (Survanta®)	4 mL/kg/dose intratracheally; may repeat every 6 hr up to a total of 4 doses	
Calfactant (Infasurf®)	3 mL/kg/dose intratracheally; may repeat every 12 hr up to a total of 3 doses	
Lucinactant (Surfaxin®)	5.8 mL/kg/dose intratracheally; may repeat every 6 hr up to a total of 4 doses	Only synthetic peptide-containing surfactant
Poractant alfa (Curosurf®)	2.5 mL/kg/dose intratracheally; may repeat dose of 1.25 mL/kg every 12 hr up to a total of 3 doses	
Albuterol	Nebulizer: 0.1-0.5 mg/kg/dose every 2-6 hr MDI: 1 puff every 2-6 hr	Selective β_2-agonist
Aminophylline	Loading dose: 8 mg/kg IV Maintenance dose: 1.5-3 mg/kg/dose IV every 8-12 hr	Follow serum trough concentrations—target 7-12 mcg/L
Theophylline	1.5-3 mg/kg/dose every 8-12 hr	IV aminophylline dose is equivalent to PO theophylline dose; follow serum trough concentrations—target 7-12 mcg/L
Caffeine citrate	Loading dose: 20-25 mg/kg IV, PO (equivalent to 10-12.5 mg/kg caffeine base) Maintenance dose: 5-10 mg/kg/dose IV, PO every 24 hr (equivalent to 2.5-5 mg/kg caffeine base)	Monitoring serum levels is not necessary if using recommended doses
Dornase alpha	1.25-2.5 mL via nebulizer or 0.2 mL/kg instilled directly into endotracheal tube every 12-24 hr	Desaturation and/or airway obstruction may occur, owing to rapid mobilization of secretions
Ipratropium bromide	MDI: 2-4 puffs every 6-8 hr Nebulizer: 75-175 mcg/dose every 6-8 hr	Precise dosing is uncertain, although therapeutic margin is wide

Agent	Dosage	Comments
Reversal Agents/Antidotes		
Flumazenil	IV: 5-10 mcg/kg/dose; repeat every 45 seconds up to maximum cumulative dose of 50 mcg/kg or 1 mg (whichever is smaller) Intranasal: 40 mcg/kg/dose divided between each nostril Rectal: 15-30 mcg/kg/dose; repeat after 15-20 minutes if needed	Reversal of sedative effect from benzodiazepines
Hyaluronidase	150 units subcutaneous as 5 separate injections around the site of extravasation	Initiate treatment as soon as possible after extravasation
Naloxone	0.1 mg/kg/dose IV every 2-3 minutes; may need to repeat doses in 20-60 minutes	Reversal of narcotic-induced respiratory/CNS depression; not recommended as part of delivery room resuscitation
Phentolamine	Inject 1-5 mL of a 0.5 mg/mL solution subcutaneous into the periphery of the affected area	Prevention of dermal necrosis caused by extravasation of vasoconstrictive agents
Protamine	0.25-1 mg per 100 units heparin received IV; maximum dose 50 mg	Heparin antagonist; exact dose depends on time in minutes since last heparin dose; may cause hypotension, pulmonary edema, and pulmonary hypertension

ANC, Absolute neutrophil count; CHF, congestive heart failure; CNS, central nervous system; CSF, cerebrospinal fluid; ECG, electrocardiogram; GA, gestational age; GI, gastrointestinal; HDN, hemolytic disease of the newborn; HSV, herpes simplex virus; IV, intravenous; IVIG, intravenous immunoglobulin; IM, intramuscular; MDI, metered-dose inhaler; NEC, necrotizing enterocolitis; PE, phenytoin equivalent; PO, per oral route; SVT, supraventricular tachycardia.
*Exact dose and dosing interval are dependent on postmenstrual and postnatal age.
†These agents must be used in conjunction with an effective sedative/analgesic agent. They do not provide any analgesia or amnesia.

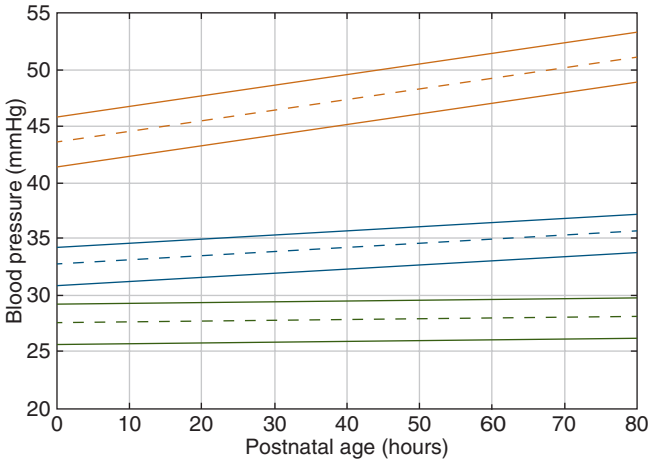
Appendix B

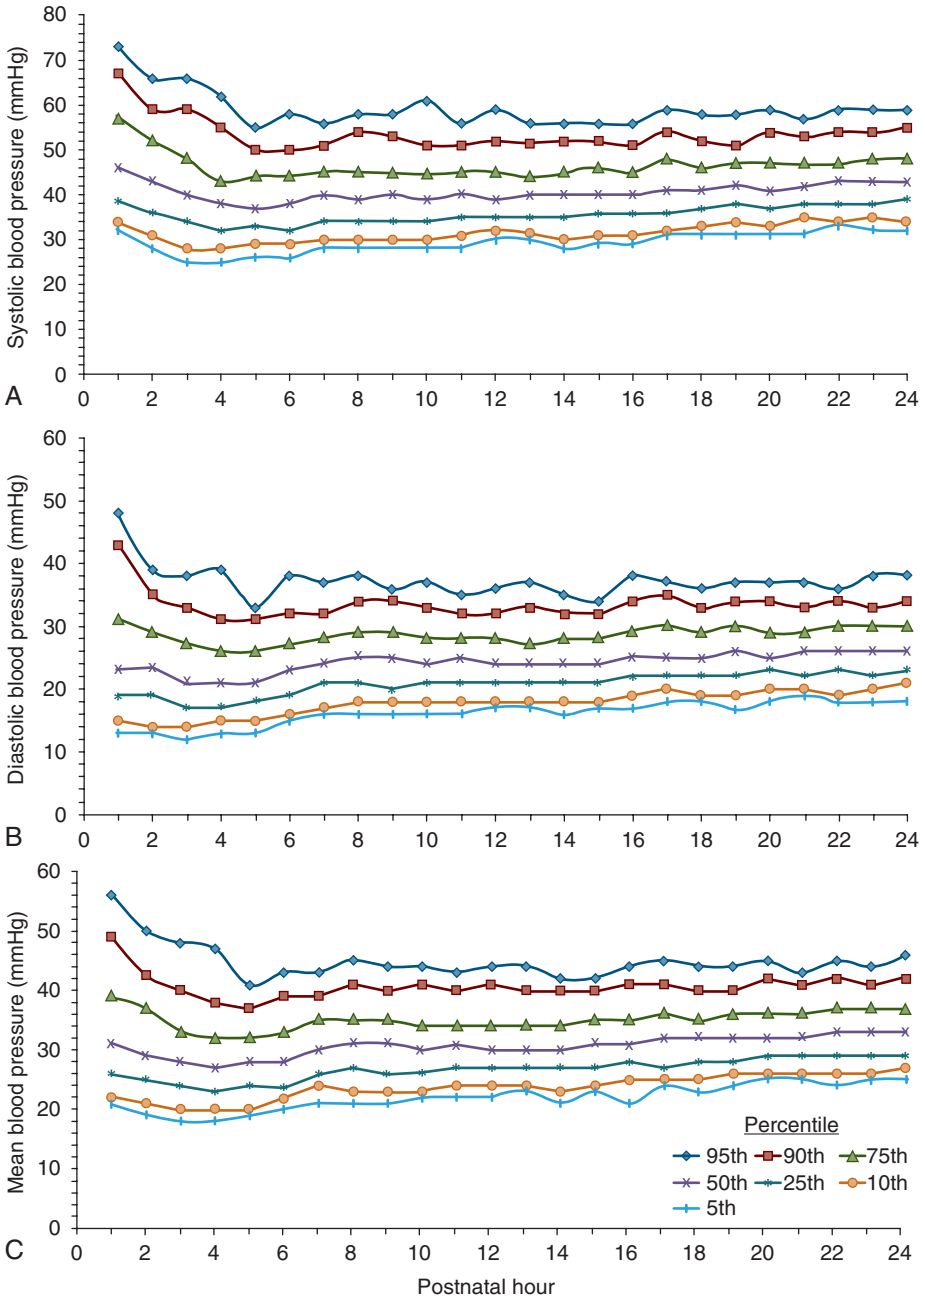
Tables of Normal Values



Mary L. Nock and Arielle L. Olicker

Physiologic Parameters

Blood Pressure



• **Fig. B.1** Systolic and diastolic blood pressures plotted for the first 5 days of life, with each day subdivided into 8-hour periods. Infants are categorized by gestational age into 4 groups: ≤28 weeks (n = 33), 29-32 weeks (n = 73), 33-36 weeks (n = 100), and ≥37 weeks (n = 110). (From Zubrow AB, et al. Determinants of blood pressure in infants admitted to neonatal intensive care units: a prospective multicenter study. Philadelphia Neonatal Blood Pressure Study Group. *J Perinatol*. 1995;15:470.)

• **Fig. B.2** Population estimate of blood pressure values by postnatal age in hours. Dashed line represents the blood pressure estimate, whereas the solid line represents the boundaries of the 95% confidence interval. Orange, SBP; blue, MABP; green, DBP. DBP, diastolic blood pressure; MABP, mean arterial blood pressure; SBP, systolic blood pressure. (From Vesoulis ZA, et al. Empirical estimation of the normative blood pressure in infants <28 weeks' gestation using a massive data approach. *J Perinatol*. 2016;36:291-295.)

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

• **Fig. B.3** Systolic **(A)**, diastolic **(B)**, and mean **(C)** arterial blood pressure curves over the first 25 hours for extremely preterm infants (n = 367). (From Batton B, et al. Evolving blood pressure dynamics for extremely preterm infants. *J Perinatol.* 2014;34(4):301-305.)

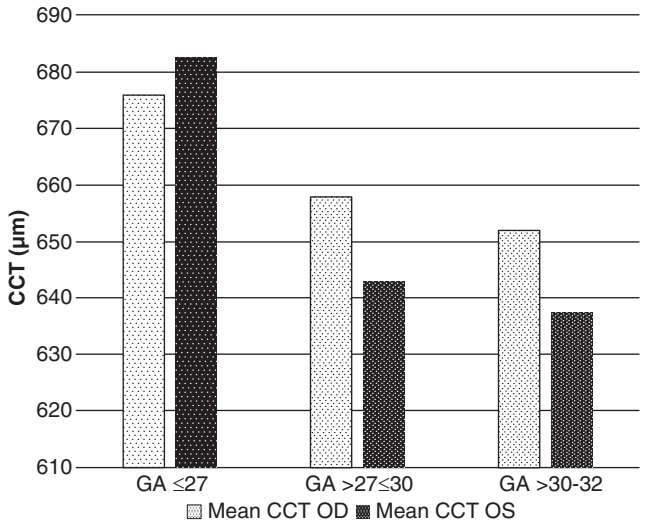
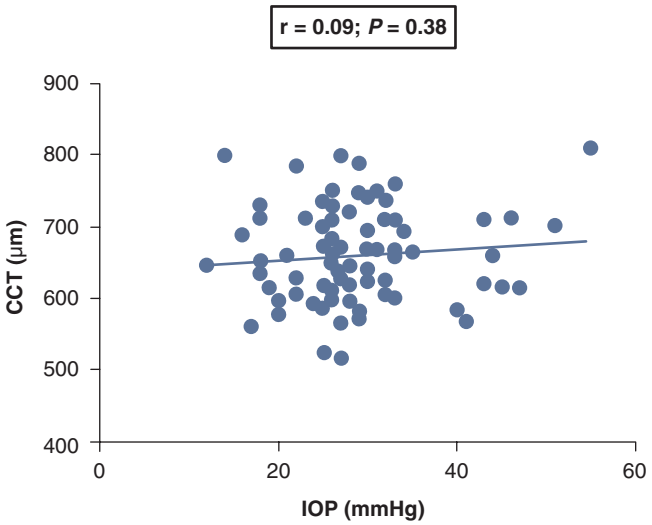
TABLE B.1 Blood Pressure Values in Neonatal Period after Two Weeks of Age, by Gestational Age



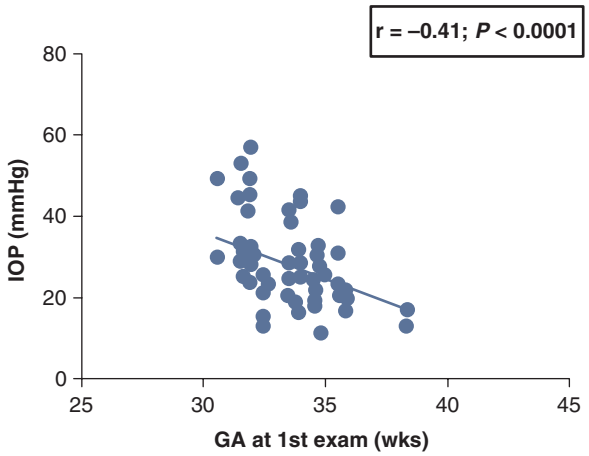
Gestational Age (weeks)	Percentile	Blood Pressure (mm Hg)		
		Systolic	Diastolic	Mean
26-28	50th	55-60	30-38	38-45
	95th	72-75	50-50	57-58
	99th	77-80	54-56	63-63
30-32	50th	65-68	40-40	48-48
	95th	80-83	55-55	63-64
	99th	85-88	60-60	68-69
34-36	50th	70-72	40-50	50-57
	95th	85-87	55-65	65-72
	99th	90-92	60-70	70-71
38-40	50th	77-80	50-50	59-60
	95th	92-95	65-65	74-75
	99th	97-100	70-70	79-80
42-44	50th	85-88	50-50	62-63
	95th	98-105	65-68	76-80
	99th	102-110	70-73	81-85

Modified from Nickavar A and Assadi F. Managing hypertension in newborn infants. *Int J Prev Med*. 2014;5(Suppl 1):S39-S43.

Intraocular Pressure



• **Fig. B.4** Intraocular pressure (IOP) measured at different gestational ages (GA) in weeks. OD, right eye; OS, left eye. (From Grover S, et al. Intraocular pressure in premature low birth weight infants. *J Pediatr Ophthamol Strabismus*. 2016;53(5):300-304.)



• **Fig. B.5** Changes in mean central corneal thickness (CCT) at different gestational ages (GA) in weeks. OD, right eye; OS, left eye. (From Grover S, et al. Intraocular pressure in premature low birth weight infants. *J Pediatr Ophthamol Strabismus*. 2016;53(5):300-304.)

32-34 wk								4.54	4.93	4.78	4.86	4.81				4.96	

Modified from Reading RF, et al. Plasma albumin and total protein in preterm babies from birth to eight weeks. *Early Human Dev*. 1990;22:81.

TABLE B.19 Cardiac Troponin T (cTnT) and Cardiac Troponin I (cTnI) Levels in 869 Healthy Term Newborns by Gender

	cTnT		cTnI	
	Male	Female	Male	Female
Mean	0.017	0.012	0.011	0.007
Median	0.01	0	0	0
Minimum	0	0	0	0
Maximum	1.26	0.58	0.71	0.98
99th percentile	0.093	0.101	0.206	0.094

Modified from Baum H, et al. Reference values for cardiac troponins T and I in healthy neonates. *Clin Biochem*. 2004;37:1080.
All values are µg/L.
Cardiac troponin T measured with Roche Elecsys® 2010 3rd generation assay; cardiac troponin I measured on a DadeBehering Dimension RxL assay.
Diagnostic cut-off value for adults with possible myocardial damage is at 99th percentile of apparently healthy reference population; same cut-off has been proposed for neonates.

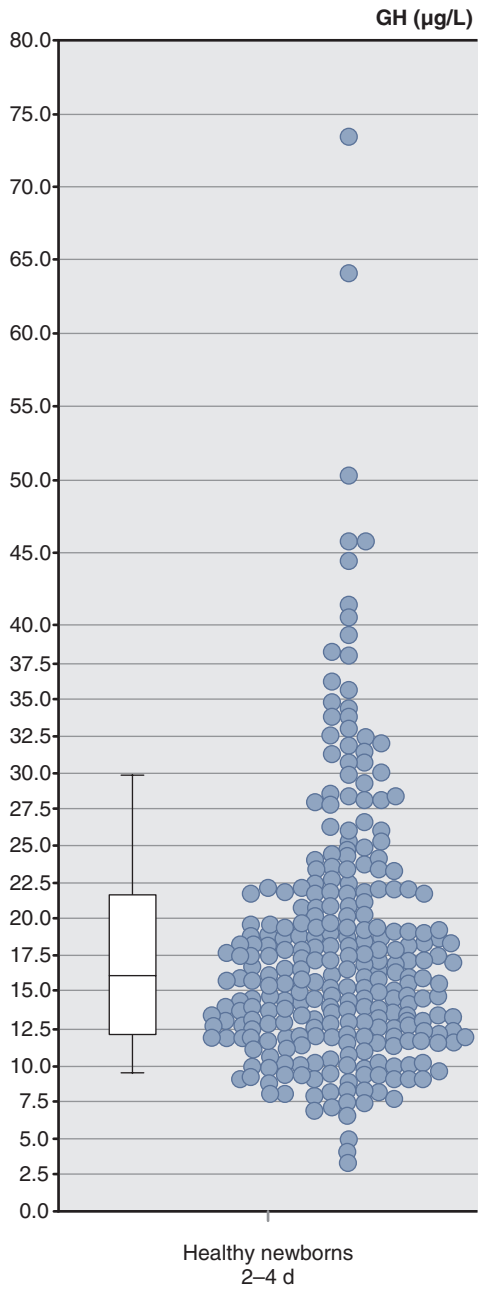

TABLE B.20 Longitudinal Serum Levels of Cystatin-C in Preterm Infants

	Weeks' Gestational Age								
	27-30		31-33		34-36		27-36		
Chronological Age	n	Cys-C (mg/L)	n	Cys-C (mg/L)	n	Cys-C (mg/L)	n	Median Cys-C (mg/L)	95% Reference interval
6-30 days	15	1.67 (1.325-2.275)	93	1.747 (0.912-2.275)	153	1.795 (1.325-2.237)	261	1.776	1.355-2.189
3-5 months	10	1.339 (0.979-1.632)	60	1.258 (0.538-1.747)	37	1.229 (0.95-1.594)	107	1.248	0.881-1.64
7-9 months	9	1.066 (0.902-1.296)	43	1.018 (0.528-1.469)	19	1.046 (0.797-1.344)	71	1.037	0.722-1.339
12-14 months	6	0.984 (0.739-1.546)	26	0.965 (0.749-1.2)	7	0.941 (0.893-1.104)	39	0.96	0.688-1.24

Modified from Nakashima T, et al. Longitudinal analysis of serum cystatin C for estimating the glomerular filtration rate in preterm infants. *Pediatr Nephrol*. 2016;31:983-989.

Hormone Levels

• **Fig. B.17** Growth hormone levels (µg/L) from 314 healthy newborns (blue circles). The box of the box plot indicates the mean and 50% confidence interval; the whiskers indicate the 80% confidence interval. (From Binder G, et al. Rational approach to the diagnosis of severe growth hormone deficiency in the newborn. *J Clin Endocrinol Metab*. 2010;95(5):2222.)

TABLE B.21 Serum Procalcitonin Levels According to Gestational Age (GA) and Postnatal Age (PNA)

			Serum Procalcitonin (ng/mL)		
GA (weeks)	PNA (days)	n	median	Range	95% Reference Interval
≤32	7-14	64	0.37	0.10-11	0-3.53
	14-30	90	0.25	0.08-4.17	0-1.66
	30-60	120	0.15	0.06-2.51	0.06-1.7
33-36	7-14	102	0.16	0.07-1.51	0-0.53
	14-30	119	0.12	0.07-6.6	0-0.56
	30-60	44	0.11	0.08-0.26	0.01-0.21
≥37	7-14	127	0.11	0.05-1.31	0.05-0.54
	14-30	153	0.11	0.03-2.67	0.06-0.9
	30-60	95	0.10	0.04-1.37	0-0.53

There were 914 samples from 425 infants enrolled in the study.
From Hahn W, et al. Reference intervals of serum procalcitonin are affected by postnatal age in very low birth weight infants during the first 60 days after birth. *Neonatology.* 2015;108:63. Copyright © 2015 Karger Publishers, Basel, Switzerland.

Estradiol# (pg/mL)	15 d to <1 y	NA	25	NA	22-38	NA	25	NA	22-38
Progesterone# (ng/dL)	4 d to <1 y	NA	132	NA	88-230	NA	66	NA	63-94
FSH# (mIU/mL)	30 d to <1 y	0.38	10.35	0.05-0.58	9.34-10.97	0.09	2.41	0.05-0.13	2.19-2.65
LH# (mIU/mL)	4 d to <3 m 3 m to <1 y	NA NA	2.41 1.19	NA NA	1.74-2.91 0.56-1.6	0.19 NA	3.81 2.89	0.07-0.4 NA	3.47-4 2.33-4.32
Prolactin# (ng/mL)	4 d to <30 d 30 d to <1 y	12.57 6.26	212.77 113.73	0.6-25.71 4.41-7.25	202.5-233.18 97.28-141.08	12.57 6.26	212.77 113.73	0.06-25.71 4.41-7.25	202.5-233.18 97.28-141.08

FSH, Follicle stimulating hormone; LH, luteinizing hormone; NA, not applicable; SHBG, sex hormone binding globulin; Te, testosterone.
Total Te lower limits calculated below the sensitivity of the assay are presented as ≤0.08 nmol/L.
When the lower limit of the reference interval was at the limit of detection, no value is given and the reference interval should be < upper limit.
*These data are from a cohort of healthy community children not studied in other CALIPER (Canadian Laboratory Initiative for Pediatric Reference Intervals) studies.
*Modified from Raizman JE, et al. Pediatric reference intervals for calculated free testosterone, bioavailable testosterone, and free androgen index in the CALIPER cohort. *Clin Chem Lab Med.* 2015;53(10):e240.
#These data from 1234 healthy children from a multiethnic population as part of the CALIPER study.
#Modified from Konforte D, et al. Complex biological pattern of fertility hormones in children and adolescents: a study of healthy children from the CALIPER cohort and establishment of pediatric reference intervals. *Clin Chem.* 2013;59(8):1219-20.

TABLE B.23 Hormone Reference Intervals in Healthy Children

	Age	Geometric Mean	Lower Limit	Lower Limit CI	Upper Limit	Upper Limit CI
Cortisol (µg/dL)	2 d to <15 d 15 d to <1 y	3.24 4.82	0.47 0.52	0.12-0.71 0.37-0.77	12.3 16.6	10.98-18.1 15.6-17.75
iPTH (pg/mL)	6 d to <1 y	26.79	6.42	3.96-8.58	88.58	74.81-146.04
25 (OH)D (ng/mL)	5 d to <15 d 15 d to <3 m 3 m to <1 yr	10.27 19.19 23.73	1.7 6.16 6.94	0.99-3.41 4.25-8.21 5.5-9.04	33.99 40.48 47.28	28.56-39.3 35.63-43.72 44.15-49.91

iPTH, intact parathyroid hormone; 25 (OH)D, 25(OH)vitamin D.
The CALIPER (Canadian Laboratory Initiative for Pediatric Reference Intervals) program used a total of 1482 samples from ethnically diverse healthy children ages 2 days to 18 years to establish pediatric reference intervals.
Modified from Bailey D, et al. Marked biological variance in endocrine and biochemical markers in childhood: establishment of pediatric reference intervals using healthy community children from the CALIPER cohort. *Clin Chem.* 2013;59(9):1395-1397.

TABLE B.28 Thyroid Hormones in Premature Neonates 26-32 Weeks' Gestational Age According to Postnatal Age

	1st Week of Life n = 196	2nd Week of Life n = 186	3rd-4th Weeks of Life n = 178
TT4 (nmol/L)	136.3 ± 85	143.9 ± 92	189.5 ± 98.1
FT4 (pmol/L)	16.9 ± 4.8	16.2 ± 4.4	16.2 ± 3.8
TT3 (nmol/L)	1.2 ± 0.7	1.5 ± 0.9	1.6 ± 0.9
FT3 (pmol/L)	3.7 ± 0.9	3.5 ± 0.9	3.6 ± 1
TSH (IU/L)	5.2 ± 5.1	5 ± 3	4.8 ± 3.8

Values are mean ± SD.
FT3, Free triiodothyronine; FT4, free thyroxine; TSH thyroid stimulating hormone; TT3, total triiodothyronine; TT4, total thyroxine.
From Dilli D, et al. Serum thyroid hormone levels in preterm infants born before 33 weeks of gestation and association of transient hypothyroxinemia with postnatal characteristics. *J Pediatr Endocrinol Metab*. 2010;23(9):899-912.

Cerebrospinal Fluid

TABLE B.29 Cerebrospinal Fluid Findings in Preterm and Term Infants Hospitalized in the Neonatal Intensive Care Unit

	Preterm Infants (<37 weeks)			Term Infants		
	All n = 148	≤7 Days n = 66	>7 Days n = 82	All n = 170	≤7 Days n = 130	>7 Days n = 40
CSF WBC, cells/μL						
All infants						
Median (IQR)	3 (1-6)	3 (1-7)	3 (1-4)	3 (1-6)	3 (1-6)	2 (1-4)
95th percentile	16	18	12	26	23	32
Antibiotic-unexposed						
95th percentile	11	17	10	32	31	53
CSF Protein, mg/dL						
All infants						
Median (IQR)	104 (79-131)	116 (93-138)	93 (69-122)	74 (54-96)	78 (60-100)	57 (42-77)
95th percentile	203	213	203	137	137	158
Antibiotic-unexposed						
95th percentile	195	195	136	136	136	284
CSF Glucose, mg/dL						
All infants						
Median (IQR)	49 (42-62)	53 (43-65)	47 (40-58)	51 (44-57)	50 (44-56)	52 (45-64)
5th percentile	33	33	33	36	35	38
Antibiotic-unexposed						
5th percentile	33	33	35	33	33	33

Studied infants were aged <6 months and underwent LP for evaluation for sepsis. Infants were excluded if there was culture-proven bacterial meningitis, unknown CSF culture results, positive CSF viral PCR, a ventriculoperitoneal shunt present, seizures, bacteremia, or CSF RBC >500 cells/μL.
Modified from Srinivasan L, et al. Cerebrospinal fluid reference ranges in term and preterm infants in the neonatal intensive care unit. *J Pediatr*. 2012;161:731.

Metric Units

TABLE B.38 Conversion Tables for Metric Units

A. Metric System Weights

1 kilogram (kg)	=	1000 grams (g)
1 milligram (mg)	=	0.001 gram (g)
1 microgram (μg)	=	10^{-6} g or μ
1 nanogram (ng)	=	10^{-9} g or mμ
1 picogram (pg)	=	10^{-12} g or μμ
1 femtogram (fg)	=	10^{-15} g or mμμ

B. Metric and Avoirdupois Systems of Volume (Fluid)

1 liter (L)	=	1000 milliliters (mL)
1 milliliter (mL)	=	1000 microliters (μL)
1 deciliter (dL)	=	100 mL

C. Standard Prefixes

Less than 1			More than 1		
atto	10^{-18}	A	deka	10^{1}	da
femto	10^{-15}	F	hector	10^{2}	h
pico	10^{-12}	P	Kilo	10^{3}	k
nano	10^{-9}	N	mega	10^{6}	M
micro	10^{-6}	M	Giga	10^{9}	G
milli	10^{-3}	M			
centi	10^{-2}	C			
deci	10^{-1}	D			

D. Conversion Factors

1 kg	=	2.2 pounds
1 pound	=	0.45 kilogram
1 ounce	=	28 grams
1 L	=	1.06 quarts
1 fluid ounce	=	30 mL
1 inch	=	2.54 cm
1 cm	=	0.394 inch
Degrees Celsius	=	(°F – 32) x 5/9
Degrees Fahrenheit	=	(°C x 9/5) + 32

Parts per million (ppm) to percent:

1 ppm	=	0.0001%
10 ppm	=	0.001%
100 ppm	=	0.01%
1000 ppm	=	0.1%

Atomic Weight and Valence

TABLE B.39 Atomic Weight and Valence for Common Elements

Element	Atomic Weight	Valence
Calcium	40	2
Sodium	23	1
Potassium	39	1
Chlorine	35.5	1
Magnesium	24.3	2
Phosphorus	31	*

Conversion of Common Elements from Milligrams (mg) to Milliequivalents (mEq)

To convert mg to mEq:

$$\frac{\text{mg} \times \text{valence}}{\text{atomic weight}} = \text{mEq}$$

To convert mEq to mg:

$$\frac{\text{mEq} \times \text{atomic weight}}{\text{valence}} = \text{mg}$$

*The valence of phosphorus varies. For nutritional purposes, it is convenient to express quantities in moles.

Appendix C

Schedule for Immunization of Preterm Infants

Jill E. Baley

All Preterm Infants[1]

- Vaccine doses should not be reduced for preterm infants.
- Use thimerosal-free vaccines.
- Intramuscular injections to preterm infants might require a shorter needle than the standard 5/8 to 1" needle.
- Immunizations may be given during corticosteroid administration.
- Palivizumab (synagis) should be given according to the respiratory syncytial virus policy.
- Preterm infants should receive a full dose of diphtheria and tetanus toxoids and acellular pertussis (DTaP), *Haemophilus influenza* type B (Hib) conjugate, inactivated poliovirus (IPV), hepatitis B (Hep B), and pneumococcal conjugate (PCV13) at 60 days' chronologic age, regardless of birth weight and gestational age, as long as they are medically stable and consistently gaining weight. These should be repeated in another 60 days.
- Immunizations for preterm infants may be given over 2 or 3 days to minimize the number of injections at a single time.
- Hospitalized infants with birth weight lower than 1000 g should be observed for apnea for 72 hours after the primary series of immunizations. The CBC may show a left shift and the CRP may be elevated.
- Breastfeeding by a mother who is positive for hepatitis B surface antigen (HBsAg) poses no additional risk for acquisition of hepatitis B virus (HBV) infection by the infant.
- Infants with chronic respiratory tract disease should receive the influenza inactivated trivalent or quadrivalent immunization annually, before or during the influenza season, when they are 6 months' postnatal age or older:
  - Infants who are 6 months to 8 years of age who have not previously received two doses of the influenza vaccine should receive two doses of vaccine at least 28 days apart.
  - Family and other caregivers should also receive the inactivated trivalent or quadrivalent influenza vaccine annually in the fall to protect the infant from exposure.
- The American Academy of Pediatrics recommends routine immunization of infants in the United States with rotavirus vaccine. There is no preference for either the live oral human-bovine reassortant vaccine (RV5) or the live oral, human attenuated rotavirus vaccine (RV1).
- Preterm infants who are clinically stable should be immunized for rotavirus on the same schedule and with the same precautions as term infants. The infant's postnatal age must be between 6 weeks and 14 weeks, 6 days postnatal age. Rotarix is a two-dose series, at 2 and 4 months of age. RotaTeq is a three-dose series, at 2, 4, and 6 months of age. If any dose is RotaTeq or an unknown product, three doses should be given.
- Preterm infants who are in the NICU or nursery may be immunized at the time of discharge if they are clinically stable and age-eligible for the vaccine. The AAP believes that the risk of shedding vaccine virus in the stool, and theoretically transmitting vaccine virus to another acutely ill or non-age-eligible infant, if the infant is readmitted, is less than the benefit of immunizing eligible infants.
- Any rotavirus vaccine-immunized infant who requires readmission to the NICU or nursery within 2 weeks of vaccination should remain under contact precautions for 2-3 weeks after vaccine administration.

Hepatitis B Vaccine at Birth[2]

1. Examine the original maternal lab report to verify the correct maternal serology for hepatitis B during this pregnancy.
2. Repeat the maternal hepatitis B serology at birth if the mother is high risk:
   a. Greater than one sexual partner in the last 6 months
   b. Evaluated or treated for a sexually transmitted disease
   c. Recent or current injection drug use
   d. HBsAg-positive partner
   e. Clinical hepatitis since last testing
3. Hepatitis B preventive measures depend on the maternal serology and the birth weight of the infant, as follows:

Hepatitis BsAg–Negative Mother

- Give the mother a hepatitis B vaccine information statement and obtain verbal consent prior to immunization.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

- If the infant is ≥2000 g birth weight, administer a single-antigen, pediatric, 0.5 mL, intramuscular vaccine into the anterolateral thigh within 24 hours of birth or at discharge, whichever is sooner.
- If the infant is <2000 g birth weight, administer the vaccine at 1 month of age or at hospital discharge, whichever is sooner.
- Document vaccine administration or refusal in the chart. Give the parent a record of the vaccination.

Hepatitis BsAg–Positive Mother

- Give the mother a hepatitis B vaccine information statement and obtain verbal consent prior to immunization.
- Notify Child Protective Services if the mother continues to refuse vaccination after discussion with the physician.
- Administer hepatitis B immune globulin (HBIG) 0.5 mL, IM, in the anterolateral thigh in the delivery room or as soon as possible within 12 hours of birth to all infants, regardless of the birth weight.
- Administer the single antigen hepatitis B vaccine, pediatric, 0.5 mL, into the opposite anterolateral thigh as soon as possible within 12 hours of birth to all infants, regardless of birth weight.
- Document both doses within the chart and give the parent a copy of the record.
- Notify the State Health Department of the positive maternal screen.
- Notify the primary care provider of the administration of HBIG and hepatitis B vaccine, and the need for additional, on-time doses. Infants with birth weights <2000 g need four doses of the vaccine as the birth dose is not counted.
- The infant should be tested for HBsAg and anti-HBs 1-2 months after completing the vaccine series, but no earlier than 8-12 months of age.
- The infant may breastfeed.

Hepatitis B Surface Antigen–Unknown Mother

- Give the mother a hepatitis B vaccine information statement and obtain verbal consent prior to immunization.
- Administer the single antigen hepatitis B vaccine, pediatric, 0.5 mL, IM, into the anterolateral thigh within 12 hours of birth, to all infants, regardless of birth weight.
- Administer hepatitis B immune globulin (HBIG), 0.5 mL, IM, within 12 hours of birth, if the infant weighs <2000 g at birth unless the maternal serology is confirmed to be negative by that time.
- Administer hepatitis B immune globulin (HBIG), 0.5 mL, IM, within 7 days of birth to all infants with a birth weight ≥2000 g if the maternal serology is confirmed to be negative. If the maternal serology remains unknown, administer HBIG by 7 days of life or at hospital discharge, whichever comes first.
- Document all doses in the chart and give the parent a copy of the immunizations.
- Notify the primary care provider of the immunizations and the need for follow-up.
