The *alveolar–arterial oxygen tension gradient* ($PAO_2 - PaO_2$ or $AaDO_2$) is expressed in mm Hg, increases with worsening oxygenation and can be obtained from the equation

$$P(A-a)O_2 = PiO_2 - PACO_2\left[FiO_2 + \left(\frac{1 - FiO_2}{R}\right)\right] - PaO_2$$

or

$$P(A-a)O_2 = PiO_2 - \frac{PaCO_2}{R} - PaO_2$$

The *oxygenation ratio* is expressed in mm Hg, decreases with worsening oxygenation, and can be obtained from the equation

$$\text{Oxygenation ratio} = \frac{PaO_2}{FiO_2}$$

The oxygenation ratio is less often used because it is subject to inaccurate assessment of the oxygenation derangement when $PaCO_2$ varies markedly. Often, it is necessary to correct the degree of oxygenation for the ventilatory support, because oxygenation is strongly influenced by mean airway pressure ($\bar{P}aw$) during assisted ventilation. The oxygenation index (OI) is useful under these circumstances. The OI, which increases with worsening oxygenation or increasing $\bar{P}aw$, has units of centimeters of water per mm Hg and can be obtained by the equation

$$OI = \frac{\bar{P}aw \times FiO_2}{PaO_2} \times 100$$

Partial Pressure of Arterial Carbon Dioxide

$PaCO_2$ is an important measure of pulmonary function in neonatal respiratory disease. Mechanisms responsible for impairment of pulmonary exchange of CO_2 include hypoventilation, $\dot{V}/\dot{Q}$ mismatch, and shunt. In addition, an increase in dead space, as occurs with alveolar overdistention or gas trapping, impairs CO_2 elimination. Because of the high solubility coefficient of CO_2, diffusion limitation rarely affects CO_2 exchange. As tissue levels of CO_2 increase above those of arterial blood, molecules diffuse into the capillaries and are transported in RBCs and plasma. Unlike the S-shaped dissociation curve for O_2, the relationship between CO_2 tension and content is almost linear over the physiologic range.

Noninvasive Blood Gas Measurements

See Chapter 37.

Carbon Dioxide

Noninvasive estimates of CO_2 by end-tidal or transcutaneous detectors provide a reasonable alternative to frequent blood gas sampling, allowing for continuous monitoring of CO_2 over prolonged periods of time. End-tidal CO_2 monitoring is a noninvasive technique that measures CO_2 concentration in the gas at the end of expiration. Quantitative measurements of end-tidal CO_2 have been shown to correlate well with arterial blood gases in term and preterm infants without pulmonary disease and can be useful for detection of rapid changes in exhaled CO_2 with data displayed on a breath-by-breath basis.[51] When there is minimal pulmonary disease, quantitative end-tidal CO_2 monitoring can assist in detection of hypercapnia and hypocapnia. However, with small tidal volumes and high respiratory rates it may underestimate the true alveolar gas in some neonates. Alternative designs, such as disposable colorimetric end-tidal CO_2 detectors, have a high diagnostic accuracy for confirmation of endotracheal tube placement.[76] A positive end-tidal CO_2 test confirms endotracheal tube placement, and a negative test strongly suggests esophageal intubation. However, many infants can have falsely negative results at birth.[62]

Transcutaneous CO_2 detectors have been shown to be superior to end-tidal CO_2 in ill neonates.[51] However, sensor preparation, taping, and the need for changes in sensor location may limit transcutaneous CO_2 usefulness. Despite the limitations of end-tidal and transcutaneous monitoring of CO_2, these methods provide critically important continuous information pertaining to changes in the respiratory system and minimize the need for blood gas analysis.

Several randomized controlled trials have evaluated allowing CO_2 to rise to reduce lung injury. Evidence from these randomized controlled trials and meta-analyses indicates that a strategy of permissive hypercapnia using noninvasive respiratory support with CPAP instead of a conventional ventilatory approach reduces death or bronchopulmonary dysplasia (risk difference −0.04; 95% confidence interval −0.08-0.00, number needed to treat 25).[61]

Oxygen

Maintenance of oxygenation in an acceptable range requires constant monitoring that is not possible with intermittent blood gas measurements. This has led to the widespread implementation of pulse oximetry as a means of continuous noninvasive O_2 monitoring (see Chapter 37). Pulse oximetry measures the amount of hemoglobin molecules that is bound with oxygen. It has a rapid response time and can be used as an estimate of Pao_2 for detecting short intermittent hypoxic episodes. However, as shown by the oxyhemoglobin dissociation curve (see Fig. 63.3), oxygen saturation levels should remain below 95% in infants requiring supplemental O_2, as hyperoxic values of Pao_2 cannot be distinguished beyond that range.

Pulse Oximetry: Optimal Oxygen Saturation Target Range

The ideal oxygen saturation target range is currently unknown. The avoidance of oxygen saturations greater than 95% in very preterm infants is generally accepted as this target range has been associated with both increased pulmonary complications[3] and retinopathy of prematurity. In an attempt to improve optimal oxygen saturation targets, saturation targeting below 95% has been tested. Five randomized trials of targeting oxygen saturations of 85%-89% versus 91%-95% included almost 5000 extremely preterm infants.[61,67,72] The trials were well designed and conducted. The meta-analysis shows that the lower oxygen saturation target group had a higher rate of death at 18-24 months' corrected age (risk difference [RD] 0.03, 95% CI 0.01-0.05; 4873 infants), a higher rate of necrotizing enterocolitis, and a lower rate of ROP-receiving treatment compared to the higher oxygen saturation target group.[2] An increased number of intermittent hypoxemic events were reported in the low (85%-89%) target group.[20] Despite the increased risk of retinopathy, blindness and other visual outcomes were not affected.[2] Death or major disability to 18-24 months' corrected age did not differ between the two oxygen saturation target groups. Other major outcomes including patent ductus arteriosus receiving treatment did not differ between the treatment groups. The revised American Academy of Pediatrics guidelines state that target oxygen saturations of 90%-95% may be safer than 85%-89%. The previous recommended target range of 85%-95% is no longer recommended. Guidelines by professional societies and others in many countries have been updated accordingly. Studies combining pulse oximetry with automated adjustments in Fio_2 show promise in maintaining oxygen levels within the desired range, mainly by reducing exposure to hypoxemia.[8]

Pulse Oximetry: Screening for Critical Congenital Heart Disease

About 25% of infants with critical congenital heart disease (those who require surgery or catheter intervention during the first year of life) may not be symptomatic and diagnosed until after initial discharge from the newborn nursery if oxygen saturation screening is not performed. Multiple cohort studies have shown a reasonable detection rate of critical congenital heart disease with oxygen saturation screenings. A sensitivity of around 70%-75% with a specificity and negative predictive value of about 99.9% have been reported using a cutoff oxygen saturation of usually less than 95% at greater than 24 hours after birth as abnormal.[44,71] The sensitivity is not higher because oximetry screening is less effective at identifying newborns with obstructive left heart lesions, including hypoplastic left heart syndrome, aortic stenosis, and coarctation of the aorta. Overall, pulse oximetry is highly specific for detection of critical congenital heart disease. Pulse oximetry newborn screening before hospital discharge is widely employed in the United States.

Pulse Oximetry: Perfusion Index

The perfusion index (PI), a noninvasive estimate of tissue perfusion, is obtained by comparing the pulsatile signal with the nonpulsatile signal of the oxygen saturation waveform.[58] A perfusion index of less than or equal to 1.24 has been shown to be predictive of high illness severity in newborn infants.[17]

Hyperoxia–Hyperventilation Test

The hyperoxia test aids in differentiating between primary lung disease and congenital heart disease with right-to-left shunting. The test is performed by placing the infant in 100% oxygen for 5-10 minutes followed by monitoring oxygenation by arterial blood gas or noninvasive measures (see Chapter 64). In patients with primary lung disease, oxygen should diffuse into the poorly ventilated areas and improve oxygenation by 5-10 minutes of oxygen exposure. Persistent hypoxemia after this time period would suggest the presence of right-to-left shunting.

A modification of the hyperoxia test combining hyperoxia with hyperventilation can be used to distinguish between structural congenital heart disease and primary (or persistent) pulmonary hypertension of the newborn (PPHN), both of which have right-to-left shunting. Inhalation of 100% oxygen improves oxygenation in some patients with PPHN. In response to hyperventilation with 100% oxygen ($PaCO_2$ 25-30 mm Hg), more infants with PPHN achieve PaO_2 levels higher than 100 mm Hg. In contrast, patients with anatomically fixed right-to-left shunting rarely generate a PaO_2 well above 40-50 mm Hg, even with inhalation of 100% oxygen and hyperventilation.

Evaluation of Shunting

Desaturated blood from the right side of the heart enters the main pulmonary artery and crosses the ductus arteriosus to the descending aorta when right-to-left ductal shunting occurs. Because the ductus arteriosus almost always enters the aorta after the origin of the right subclavian and carotid arteries, blood arriving at these two sites is well oxygenated, whereas blood from the aorta, and usually the left subclavian artery, is less oxygenated if there is a right-to-left ductal shunt. Thus preductal blood gases can be obtained from the right radial artery, whereas blood in the descending aorta, and usually the left radial artery, can include blood of postductal origin. Alternatively, placement of two pulse oximeters (one on the right hand and the other on the left hand or either foot) accomplishes the same effect in differentiating preductal and postductal Pao_2 or oxygen saturation.

Patients with PPHN sometimes have right-to-left shunting through the foramen ovale and the ductus arteriosus. Ductal shunting can be demonstrated by the presence of a simultaneous oxygenation gradient between preductal and postductal arterial blood, whereas foramen ovale shunting affects both preductal and postductal oxygenation. Echocardiography can be used to confirm foramen ovale and ductal shunts.

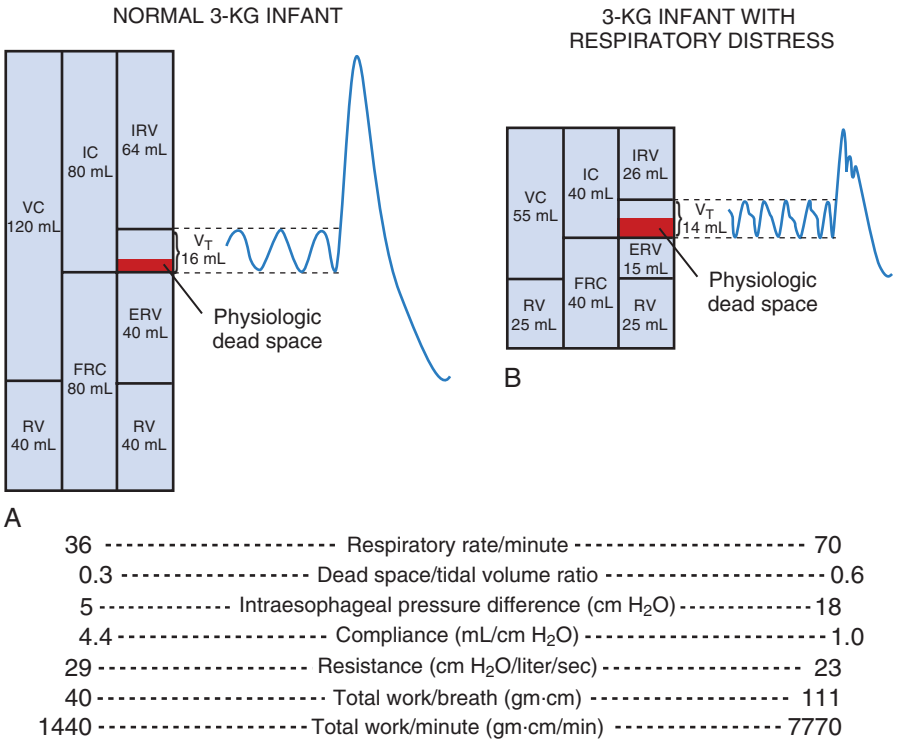
Respiratory Function

One of the principal functions of the first breaths is to transform the fluid-filled fetal lung from a gasless organ to one with an appropriate functional residual capacity (FRC) (see Chapter 31). The ability of the lungs to maintain a volume of gas at end-expiration depends on two factors. One is the chest wall, which acts as a support for the lungs, and the other is surfactant, which stabilizes the expanded alveoli. These two factors are not well developed in the premature infant.

The mechanisms responsible for initiation of breathing probably include both environmental and physiologic stimuli. After delivery, the infant is exposed to cold and tactile environment. In addition, interactions occur among pH, P_{O_2}, and P_{CO_2}, whose contributions to inducing breathing in the human neonate have yet to be determined. Once initiated, the negative intrathoracic pressure of the first breath must overcome the effects of viscosity of fluid in the airway, surface tension, and tissue resistance. Radiographic studies of the lung indicate that inflation with air occurs immediately with the first breath. Transient retention of lung fluid might underlie transient tachypnea of the newborn (see Chapter 66). Functional residual capacity is rapidly established, with little change throughout the first week of life.

Physiologic Measurements

Tests of cardiopulmonary function performed on sick neonates can assist in diagnosis and treatment. Radiographic evaluation of the chest is an integral part of the diagnostic evaluation of respiratory disorders and is discussed in Chapter 38. Measurements of central venous and pulmonary artery pressures could indirectly give useful information regarding pulmonary function but are rarely available in the clinical neonatal setting. Knowledge of pulmonary mechanics may be useful in identifying disease entities and in guiding treatments, whereas plots of airflow, volume, and pressure may provide additional information on a breath-by-breath basis.



Airflow

Many devices are available for estimating airflow in infants. Noninvasive devices can be used for extended periods, yielding qualitative measurements of airflow that are sufficient for cardiorespiratory monitoring. These include devices to estimate chest wall expansion using electrical impedance, strain gauges, or respiratory inductive plethysmography and devices to estimate airflow at the nose by application of a thermistor, nasal cannula, or end-tidal CO_2 detector. These devices can give approximations of tidal volume and information regarding the presence or absence of airflow and, used in conjunction, can distinguish central from obstructive apnea. Respiratory inductive plethysmography is a noninvasive method that can be used to determine respiratory rate, timing, and asynchrony as well as estimate airflow and lung volumes. Precise quantitative measurements of airflow needed for analysis of pulmonary mechanics require an alternative group of devices placed at the nose such as a pneumotachometer or hot-wire anemometer. The pneumotachometer is the gold standard for quantitative measurement of airflow. To accurately measure flow, all air must pass through the pneumotachometer. In a ventilated patient, the pneumotachometer can be attached to an endotracheal tube with leaks minimized by repositioning the infant, using a cuffed tube, or applying gentle pressure to the neck. In a spontaneously breathing infant, the pneumotachometer must be incorporated into a nasal or oral mask that is tightly sealed around the patient's nose and mouth. The hot-wire anemometer may also become an alternate choice in the measurement of pulmonary mechanics as improvements in hot-wire anemometer design continue in terms of accuracy and response time (see Chapter 37). After reliable measures of flow are acquired, the flow signal is integrated to calculate volume.

Lung Volume

The total volume of gas in the lungs and airways can be measured and subdivided into various volumes (Fig. 63.4). The size of the lung compartments is related to the height, weight, and surface area of the subjects. *Functional residual capacity* (FRC) is the volume of gas in the lungs that is in direct communication with the airways at the end of expiration. The volume of gas in the FRC serves as an oxygen storage compartment in the body and a buffer so that large changes in alveolar gas tension are reduced. Helium dilution and nitrogen washout techniques have been adapted to

• **Fig. 63.4** Partitioning of lung volumes and other measures of pulmonary function **(A)** in a normal infant and **(B)** in an infant with respiratory distress syndrome. ERV, Expiratory reserve volume; FRC, functional residual capacity; IC, inspiratory capacity; IRV, inspiratory reserve volume; RV, residual volume; VC, vital capacity; VT, tidal volume. (From Avery M, et al., eds. *The lung and its disorders in the newborn infant.* Philadelphia: Saunders; 1981, with permission.)

measure FRC in infants. The helium dilution technique uses the equilibration between a known volume and concentration of helium and the lung volume to be measured. After gas mixing and equilibration, FRC is calculated using the initial and final concentration of the helium and the initial volume of helium. Similarly, FRC can be estimated by measuring the volume of nitrogen washout from the lungs when nitrogen-free gas is inhaled.

Thoracic gas volume is the total volume of gas in the thorax at the end of expiration and, in contrast to FRC, includes gas that is not in communication with the airways (e.g., gas in pulmonary interstitial emphysema [PIE]). Thoracic gas volume is calculated by measuring pressure and volume changes during respiratory efforts against an occluded airway while the infant is inside a body plethysmograph. With an inspiratory effort, the gas in the lungs expands, the lung volume increases, and the pressure or volume in the box increases. Because the product of pressure and volume is constant, the pressure changes in the box can be used to determine the lung volume changes, which, when analyzed with the pressure changes in the airway, yield the thoracic gas volume.

Tidal volume, the volume of gas in and out of the lungs during a single breath, can be measured either with a pneumotachometer or a plethysmograph. *Vital capacity* (the total gas capacity of the lungs) cannot be measured in infants because of lack of cooperation, but crying vital capacity, the maximum volume of air expired in a single breath during crying, has been used as an alternative estimation.

Dead space, the portion of volume not involved in gas exchange, varies with the incidence of areas of high $\dot{V}/Q$. The dead space is divided into several compartments. *Anatomic dead space* is the airway volume not involved in gas exchange and is made up of the air passage from nares to terminal bronchioles. *Alveolar dead space* is the volume of gas in alveoli that are well ventilated but underperfused. *Physiologic dead space* is the sum of anatomic and alveolar dead space. In the normal newborn, physiologic dead space is 6-8 mL; smaller values are obtained in premature infants. The relationship of dead space to tidal volume (VT) is normally about 0.3. It is important to minimize the dead space added by apparatus for assisted ventilation or measurement of lung function to prevent rebreathing and inadvertent accumulation of carbon dioxide.

Pressure

Measurements of pressure that produce lung inflation are essential for pulmonary function testing. There are two ways to measure pressure, with the location of the measurement defining the system. Pressure can be determined by placing an esophageal balloon or catheter into the distal third of the esophagus. This measurement reflects pleural or alveolar pressure and is referred to as *transpulmonary pressure.* The accuracy of this measurement should be verified by demonstrating the absence of a pressure gradient between the airway and esophageal pressure tracings during airway occlusion.

In the case of mechanically ventilated patients, pressure can be measured at the airway opening. This reflects pressure of the entire respiratory system. This is equivalent to pleural or alveolar pressure plus the pressure component owing to the chest wall and is known as *transrespiratory pressure*. It is important to clarify the type of pressure measurement (transpulmonary versus transrespiratory) when

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

making comparisons of respiratory mechanics between studies. As transrespiratory pressure includes the additional pressure component due to the chest wall, measurements of transrespiratory resistance (described in the following section) will always be higher when compared to transpulmonary resistance.

Respiratory Mechanics

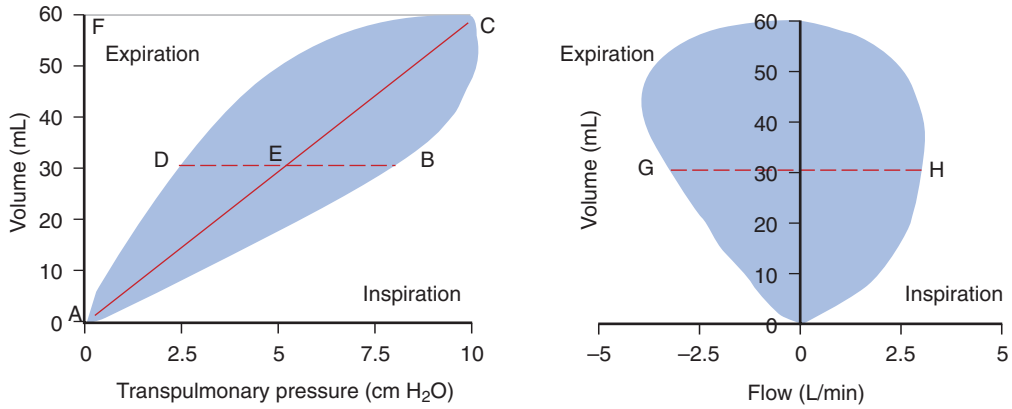
The challenge of utilizing measures of respiratory mechanics in preterm infants in a clinical setting includes the large intersubject and intrasubject variability. The magnitude of both resistance and compliance may also be dependent on the algorithm chosen. More detailed descriptions of models used in newborn infants are shown in the following section.

Compliance

Compliance is a measure of elasticity or distensibility (e.g., of the lungs, chest wall, or respiratory system) and is defined as

$$\text{Compliance} = \frac{\Delta\text{Volume}}{\Delta\text{Pressure}}$$

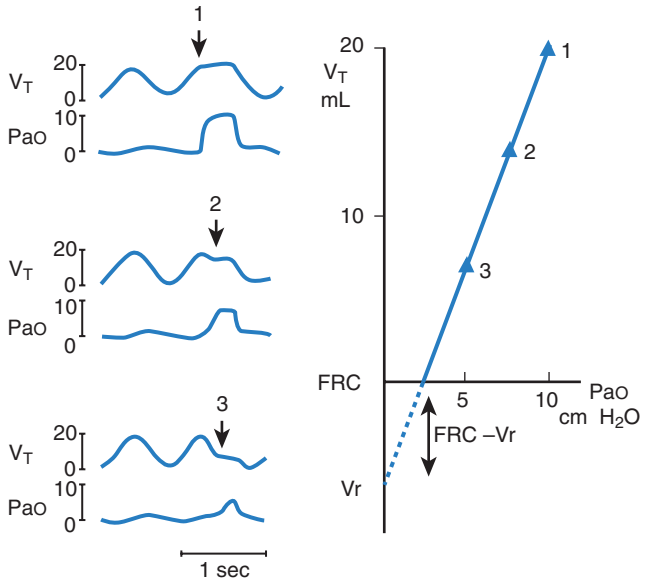
Elastance is the reciprocal of compliance.



Lung compliance is measured either dynamically or statically depending on the absence or presence of relaxation of the respiratory muscles. *Dynamic lung compliance* can be measured during spontaneous breathing using devices to measure VT and esophageal pressure as described earlier. With this method, dynamic lung compliance is calculated by dividing the change in VT by the corresponding change in esophageal pressure at points of no airflow (e.g., between end-inspiration and end-expiration). This is represented by the line drawn from point C to point A in Fig. 63.5. End-inspiration and end-expiration are used as quasi static points of reference for pressure equilibration. At high respiratory rates or increased levels of resistance, pressure does not equilibrate between these two points, resulting in an underestimation of the true compliance.

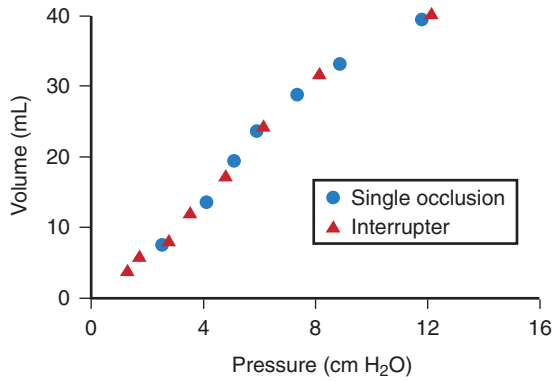
Alternatively, *static lung compliance* can be calculated between points of no flow when the respiratory muscles are relaxed by employing occlusion of the airway. This allows for complete equilibration of pressure throughout the system. During the occlusion, static respiratory system compliance can be calculated by dividing the total exhaled volume by the pressure change during the occlusion minus the pressure at end-expiration (Fig. 63.6). An important advantage of this technique is that it does not require an esophageal balloon to measure pressure.

Both dynamic and static compliance, using a single occlusion, assume that compliance is constant throughout the breath. This may not be the case during periods of lung disease or overdistention of the lung during mechanical ventilation. Under these conditions, dynamic compliance underestimates the true compliance. True changes in compliance throughout a breath can be determined by expanding the single occlusion technique to include multiple brief interruptions during the expiratory phase of a breath, also known as the *multiple-interruption technique* (Figs. 63.7 and 63.8).[63] Using this technique, a decrease in compliance can be seen with increasing pressure as the lung becomes overdistended. In mechanically ventilated infants, compliance measurements should be acquired at the same PEEP and peak inspiratory pressure (PIP) to obtain values at the same section of the pressure-volume curve.



Because lung elasticity depends on lung volume, changes in FRC can alter lung compliance. The degree of elasticity corrected for lung volume or patient size is called *specific compliance*. Whereas specific lung compliance in the normal neonate (1-2 mL/cm H_2O per kilogram) is comparable with that of the adult when corrected for unit body weight, compliance of the chest wall is relatively much higher in infants.

In addition to compliance, expiratory occlusion can also be used to determine the lung volume above the relaxation volume of the respiratory system (see Fig. 63.6). Expiratory volume clamping is a modification of the occlusion technique in which exhalation is prevented during several



• **Fig. 63.5** Dynamic lung compliance can be calculated as the Δ volume/Δ pressure as shown by the slope of line AC. Work of breathing is represented as the area inside the section drawn by ABCFA. Resistance (using the Mead-Whittenberger technique) can be calculated as the change in pressure, shown by the difference between points D and B, divided by the change in flow, shown by the difference between points G and H at the same midvolume points.

• **Fig. 63.6** Schematic representation (from actual records) of the changes in lung volume (V_T in milliliters) and airway pressure (Pao in cm H_2O) during one spontaneous breath and occlusion of the airways during the expiratory phase of the following breath in a ventilated infant. In the three examples shown, occlusion is performed (from top to bottom) at end-inspiration, in the first third of expiration, and in the last third of expiration. After the occlusions (indicated by *arrows*), Pao gradually rises to a plateau, corresponding to the recoil value of the respiratory system at that lung volume. *Right*, Plot of the changes in lung volume above the end-expiratory level (FRC) against the corresponding changes in Pao as obtained in the left panel. The slope of the function represents the compliance of the respiratory system, the intercept on the Pao axis represents the internal recoil of the respiratory system at FRC, and the intercept of the V_T axis represents the resting volume of the respiratory system (Vr). (From Mortola JP, et al. Measurements of respiratory mechanics in the newborn: a simple approach. *Pediatr Pulmonol.* 1987;3:123. With permission from Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.)

• **Fig. 63.7** A typical example of the volume-pressure relationships obtained with both the interrupter and single occlusion techniques. Each point represents the compliance at that particular volume within the breath.

breaths at increasing lung volumes. After plotting the corresponding volumes and pressures acquired during each occlusion, the slope of the function represents the compliance of the respiratory system. In addition, the intercept along the volume axis represents the resting volume of the respiratory system.

In neonates, lung compliance is the most important component, because the chest wall is very distensible. Lung compliance is low at the initiation of the first breath even in normal newborns. With the establishment of breathing and with gradual clearance of lung fluid during the first 3-6 hours after birth, FRC increases with concomitant improvement in lung compliance. Pathophysiologic factors that can increase the amount of fluid or impede the clearance of lung fluid could delay this improvement. The variability of compliance values in the first 2 hours after birth, in part the result of physiologic variation, could account for the frequent observations of higher respiratory rates in some infants during this period.

In distressed infants in whom lung compliance is markedly reduced, the compliant chest wall poses a disadvantage in that, as the infant attempts to increase negative intrathoracic pressure, the chest wall collapses (retracts). In addition, the more compliant neonatal airways could predispose the preterm infant to airway collapse during expiration and result in distal gas trapping.

Resistance

Pulmonary resistance is a measure of the friction encountered by gas flowing through the nasopharynx, trachea, and bronchi and by tissue moving against tissue. The basic definition of resistance states

$$\text{Resistance} = \frac{\Delta\text{Pressure}}{\Delta\text{Flow}}$$

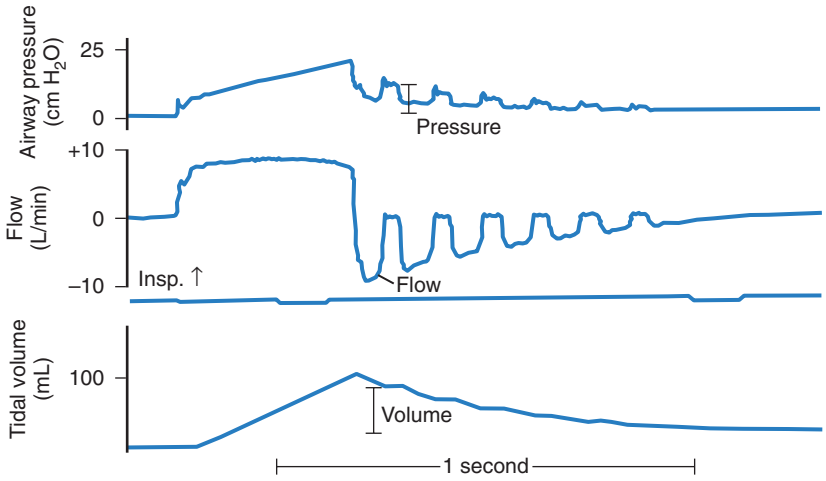
Conductance is the reciprocal of resistance. Both airway resistance (the resistance caused by the airways) and viscous resistance (the resistance caused by tissues) contribute to total pulmonary resistance.

The most commonly used algorithm to calculate resistance in commercial devices for infants is the multiple linear regression technique also known as the *equation of motion* or *Rohrer's equation*.

The *equation of motion* defines the relationship between pressure, flow, volume, and the elastic, resistive, and inertial components of the respiratory system. It is represented as

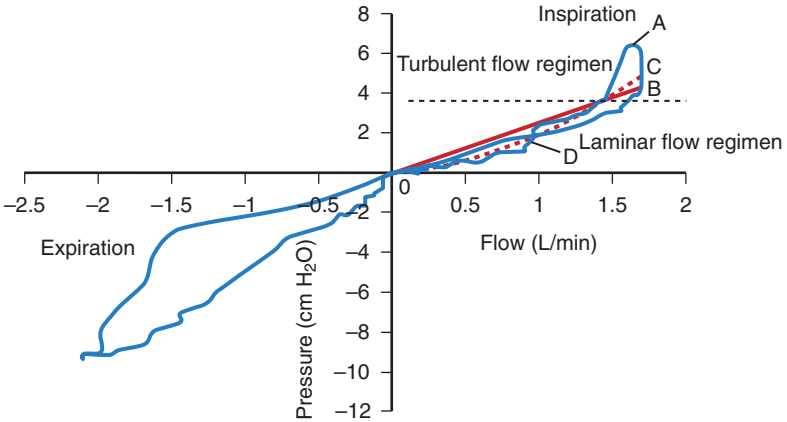
$$P = \frac{1}{C} \times V + R \times \dot{V} + I \times \ddot{V}$$

where P is the pressure that produces lung inflation, C is compliance, V is volume, R is resistance, $\dot{V}$ is flow, I is inertance, and $\ddot{V}$ is acceleration. Because the inertial component is considered negligible for clinical considerations, the equation of motion is further simplified with the inertial component often dropped from the equation. This equation assumes a linear relationship that is not usually the case in the preterm infant. Yet, although not optimal, as nonlinear models have not led to improvements in clinically applicable values for respiratory mechanics, the equation of motion continues to be the mode of choice in the clinical and research setting.



The *Mead-Whittenberger technique* uses the pressure-volume and flow-volume loops generated from pressure,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.



volume, and flow waveforms. By convention, resistance is calculated by dividing the change in pressure by the change in flow at the midvolume point of the breath (see Fig. 63.5). Resistance can be measured at additional volumes throughout the breath by using the *occlusion or multiple-interruption technique* as described earlier. In this case, resistance is calculated by dividing the pressure during the occlusion by the flow immediately preceding the occlusion (see Fig. 63.8). These points of pressure and flow can be plotted to represent resistance over a range of volumes throughout the breath. Furthermore, this technique can be used to partition the components of resistance into those due to airflow and those owing to viscous tissue resistance.

The model-dependent effects on resistance for a single breath are shown in Fig. 63.9. The Mead-Whittenberger technique gives the resistance at one point during the breath at midvolume, which approximates peak inspiratory flow. This will correspond to the highest value for resistance for a given breath. The equation of motion uses linear regression to acquire the best fit corresponding to an average overall resistance for the breath. The multiple-interrupter technique can be used to reveal changes in resistance within the breath by plotting multiple pressure and flow points for each breath (where Res = P/F at each point).

Possible conflicting values of resistance between multiple algorithms for the same breath are primarily owing to the presence or absence of a turbulent flow pattern. During periods of low pressure, the frictional contribution of the airway walls is minimized, the corresponding flow regimen is laminar, and the assumption that resistance is constant throughout the breath holds true (see Fig. 63.9). Under these conditions, the deviation among techniques is minimized. As the pressure increases further, the frictional contribution of the airway walls and the divergence of flow caused by branching of the smaller airways are no longer negligible. During this time the flow regimen changes from laminar to turbulent with a minimal increase in flow. In extreme cases, a point of flow limitation will occur where increasing pressure will be accompanied by no increase in flow. This is a common occurrence in both spontaneously breathing infants with lung disease and mechanically ventilated infants. During a turbulent flow regimen, resistance is no longer constant throughout the breath and is dependent on the technique used. Although discrepancies between algorithms have limited the application of resistance as a diagnostic tool in the clinical setting, useful information can be derived by using multiple techniques to compare breaths before and after an intervention. For example, a resistance measurement extrapolated from the linear portion of the pressure-flow curve will give information on changes in the mechanical structure of the airways (i.e., was there dilatation of the airway?). In contrast, resistance measurements

• **Fig. 63.8** Illustration of data collected with the interrupter technique. The top channel is airway pressure proximal to the interrupter valve. The middle and bottom channels represent flow and volume, respectively. Compliance is calculated by dividing the volume above the end-expiratory level by the pressure during the occlusion. Resistance is calculated by dividing this pressure by the flow that preceded the interruption.

• **Fig. 63.9** During a laminar flow regimen, resistance is constant throughout the breath and discrepancies between various techniques of measuring resistance are minimized. As the flow regimen changes from laminar to turbulent, resistance is no longer constant throughout the breath and becomes flow dependent. During this time, values of resistance between various techniques begin to diverge: **A,** Mead-Whittenberger (200 cm H_2O/L/sec); **B,** linear regression (152 cm H_2O/L/sec); **C,** nonlinear regression (32 cm H_2O/L/sec); and **D,** the linear portion of the curve (106 cm H_2O/L/sec). (From Di Fiore JM, et al. Respiratory function in infants. In: Haddad G, et al., eds. *Basic mechanisms of pediatric respiratory disease.* Toronto: Decker; 2002:165.)

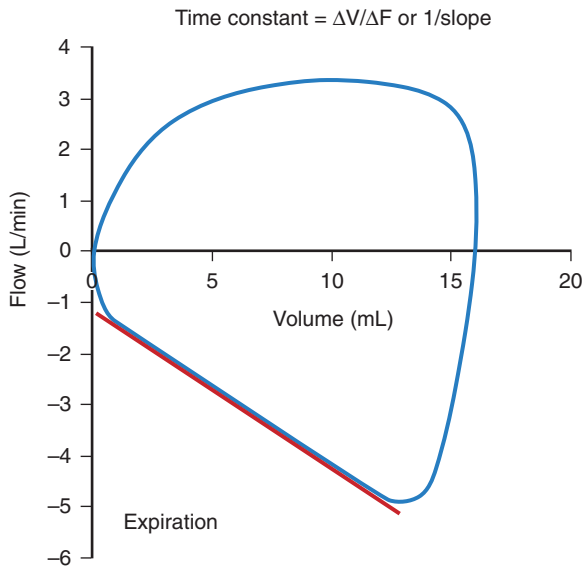
during the nonlinear portion of the pressure-flow curve will provide information on changes in resistance caused by dynamic flow patterns (i.e., did increasing PIP result in more turbulence in the airway?).

Time Constant



The *time constant* of the respiratory system is the duration (expressed in seconds) necessary for a step (e.g., pressure or volume) change to partially equilibrate throughout the lungs. A duration equivalent to one time constant allows for 63% of the equilibration of the change. Although one time constant is not a very useful parameter in the clinical environment, five time constants are equivalent to the amount of time needed for 99% equilibration of the system. This value can be useful in areas of patient care such as mechanical ventilation (see Chapter 65).

The time constant of the respiratory system can be calculated by using the relationship between the time constant, resistance, and compliance:

$$\text{Time Constant} = \text{Resistance} \times \text{Compliance}$$

Because both compliance and resistance are affected by different volumes and flows or by pulmonary disease, pulmonary mechanics change throughout the respiratory cycle, and a single time constant may not always accurately represent lung mechanics. However, for clinical purposes, linearity is assumed, and single values of compliance, resistance, and time constant usually suffice.

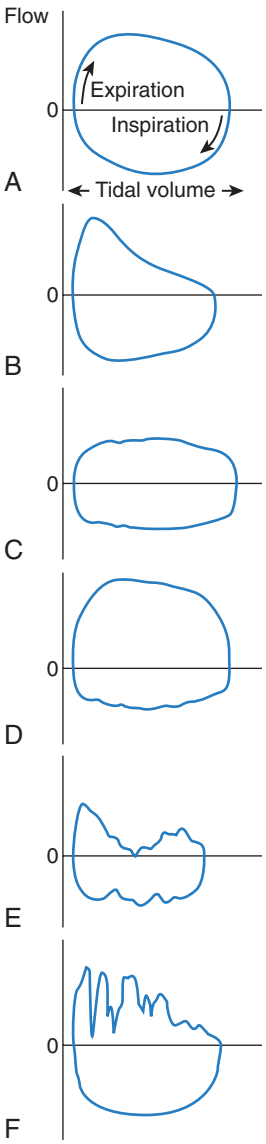
If resistance and compliance values are unknown, the time constant of the respiratory system can also be obtained from the flow-volume plot acquired during a passive exhalation. With this plot, 1/slope during the expiratory phase of the breath is equivalent to the time constant of the respiratory system (Fig. 63.10). Calculation of the time constant using the flow-volume curve assumes that the slope is linear

• **Fig. 63.10** The time constant of a breath can be represented by the change in volume divided by the change in flow during the expiratory phase of the breath.

throughout expiration. Flow limitation—as may occur with bronchoconstriction during expiration, postinspiratory activity of the respiratory muscles, or laryngeal adduction—can be identified by convexity toward the volume axis.[70] In this case, calculations of a single time constant are no longer valid. Although a numerical value for time constant cannot be accurately determined under these conditions, X-Y plots of flow and volume can be used to qualitatively characterize pulmonary function. Normal and abnormal flow-volume loops can be used to identify infants with airflow limitation patterns (Fig. 63.11).[13]

Forced Expiratory Maneuvers

There is increased interest in long-term airway reactivity and wheezing in preterm infants.[14] Measures of airway reactivity are most commonly quantified by the use of forced expiratory maneuvers. The maximal expiratory flow-volume relationship can be measured in uncooperative infants by using a respiratory jacket or cuff placed around the chest and abdomen that is suddenly inflated at the end of lung inflation to produce rapid thoracoabdominal compression and forced expiratory flow. Alternatively, sudden exposure of the inflated lung to a negative pressure at the airway opening can be used to produce a forced deflation. During this maneuver, peak expiratory flow, maximal flow at 1 sec (FEV_1) or at FRC, and the patterns of flow-volume curves can be measured using a pneumotachograph. Flow-volume curves can be used to evaluate intrathoracic airway abnormalities and can detect flow limitation missed by the passive expiratory techniques.[54]



Forced Oscillation Technique

The forced oscillation technique (FOT) has the advantage of assessing lung function in a noninvasive manner by applying external pressure or flow-based excitation superimposed on spontaneously breathing or mechanically ventilated infants under apneic conditions. The FOT presents a measure of respiratory system impedance (Z), encompassing a real (resistance) and imaginary (reactance) component, which together summarize the dissipative and energy-storing properties of the respiratory system. Limited FOT data are available in preterm and wheezy infants.[54]

Work of Breathing

The work of breathing is a measure of the energy expended in inflating the lungs and moving the chest wall. In general terms, work is the cumulative product of pressure and the volume of gas moved at each instant. In the normal infant, total pulmonary work has been determined to equal an average value of 1440 g/cm per minute. In an infant with respiratory distress, the total pulmonary work can increase as much as sixfold. This becomes most important when considered in terms of the oxygen cost of breathing. The neonate requires a higher caloric expenditure to breathe than does the adult, and the distressed infant requires an even higher caloric expenditure for this function. In the full-term infant, the work of breathing is minimal when

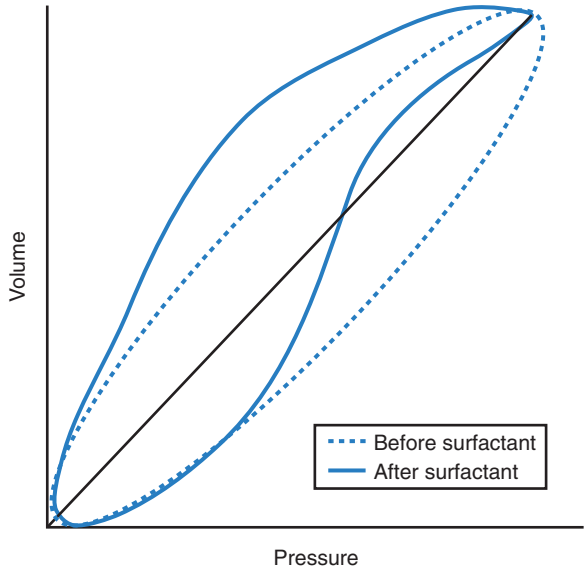
• **Fig. 63.11** Examples of the relationship between tidal flow and volume. **A,** Normal lemon-shaped loop; **B,** ski-slope loop observed with expiratory airflow limitation as seen in babies with bronchopulmonary dysplasia (BPD); **C,** cigar-shaped loops observed in babies with extrathoracic airway obstruction with inspiratory and expiratory airflow limitation as seen in babies with subglottic stenosis or narrow endotracheal tubes; **D,** bun-shaped loop observed in babies with intrathoracic inspiratory airflow limitation as seen in babies with intraluminal obstruction (close to the carina) or an aberrant vessel compressing the trachea; **E,** crumpled loop as observed in babies with unstable airways or tracheomalacia; and **F,** mountain-peaks loop is usually suggestive of an erratic airflow limitation as seen with airway secretions.

the infant has a respiratory rate of 30 breaths per minute. The pressure-volume loop can be used to calculate work of breathing as represented by the area inside the section drawn by ABCFA in Fig. 63.5.

Limitations



Before any measurements of pulmonary function can be made, a clear understanding of equipment performance is needed. Although beyond the scope of this chapter, a clear adherence to these guidelines is imperative to ensure that lung function measurements can be performed with an acceptable degree of safety, precision, and reproducibility.[28] Once data are acquired, there are a multitude of algorithms for measuring pulmonary mechanics available. As no algorithm is ideal, standards are available addressing a range of issues from equipment criteria[28,29] to testing procedures.[11,52,64,66] A review of the techniques for measuring pulmonary mechanics and function has been published by the American Thoracic Society and the European Respiratory Society.[1]

Because various algorithms yield different results for the same breath, a wide range of published values for any given patient population has resulted, making it extremely difficult to define ranges for comparison between normal and diseased states. Compounding the issue is the large intrasubject variability of compliance and resistance, which is minimized during mechanical ventilation. This is most likely caused by muscle relaxation and reduced fluctuations in respiratory rate and tidal volume compared with spontaneous respiration.

During mechanical ventilation, leaks around the endotracheal tube, a common occurrence in the neonatal intensive care unit setting, can result in overestimation of resistance and underestimation of elastance. This error is minimized during the expiratory phase of the breath. A leak of less than 10%-20% between the inspiratory and expiratory volume is generally considered acceptable to obtain reliable measurements of resistance and compliance.[41,45] Given these limitations, measurements of resistance and compliance during the expiratory phase of mechanical breaths with a leak of less than 10% should give the most precise and reproducible values.

Additional confounders that affect respiratory mechanics include sleep state,[56] posture,[12] endotracheal tube size,[47] FRC,[31] laryngeal braking,[33] gender,[67] race,[67] and respiratory patterns.[30] Errors in data calculation or interpretation can also occur if there are no compensatory modifications in mechanical ventilator settings in response to changes in lung function. This can occur because of overdistention of the lung as compliance improves in response to therapy if PIP is not decreased accordingly. As pressure-volume and flow-volume curves become more readily available on mechanical ventilators, they may become a useful tool, with or without measurements of respiratory mechanics, in distinguishing changes in pulmonary function. Fig. 63.12 shows a simulation of a pressure-volume curve for a mechanically ventilated infant before and after surfactant administration with no change in peak inspiratory pressure. A numerical representation for dynamic compliance would show no change in compliance in response to surfactant administration. In contrast, visualization of the graph reveals improvement in compliance at low pressures but overdistention of the lung at high pressures as the peak inspiratory pressure was not decreased.

• **Fig. 63.12** A representation of the change in compliance in response to surfactant administration. Note that dynamic compliance, as represented by the line, reflects no change. In contrast, visualization of the graph shows improvement in compliance at low volumes and overdistention of the lung after surfactant administration, indicating the need to decrease peak inspiratory pressure.

Clinical Applications

The goal of respiratory support is to optimize oxygenation and CO_2 elimination with the lowest possible ventilator settings to minimize lung injury. The use of pulmonary function testing can be a valuable tool in achieving this goal and reducing the incidence of barotrauma.[57] Visualization of pressure-volume curves and measurements of compliance can be used to assist in identification of excessive PIP or PEEP, leading to lung overdistention,[26] and to distinguish between alveolar collapse and overdistention to assist in determining the most advantageous PEEP.[10] High compliance and low resistance have also been shown to be associated with the likelihood of extubation success in infants recovering from RDS.[6]

Pulmonary function measurements have been used to assess mechanical effects of pharmacologic interventions. To optimize the response, changes in resistance have been used to compare treatment modalities, with the meter-dosed inhaler and ultrasonic nebulizer being shown as superior modes of bronchodilator administration.[27] Although surfactant results in rapid improvement of gas exchange, early beneficial effects on respiratory mechanics have been shown in some studies[16] but other studies report variable responses. There has been interest in the effect of nitric oxide (NO) on the incidence of chronic lung disease. Although beneficial effects of NO are dependent on dose, time of administration, and disease severity, there is currently no evidence that NO leads to improvement in baseline respiratory mechanics.[4,18] However, infants who received inhaled NO for PPHN had maximal expiratory flows comparable to those who were treated with extracorporeal membrane oxygenation (ECMO) but lower flows than control subjects.[38] Inhaled NO to prevent BPD has resulted in decreased need for bronchodilator therapy at 1 year of age.[37] Inhaled NO reduced death or need for extracorporeal membrane oxygenation in term and near-term infants but did not reduce BPD or death in preterm infants.[9,15] Both postnatal and antenatal steroids enhance lung function,[5,49] although there is a diminished response to antenatal steroids if delivery occurs more than 7 days after therapy.[50] Last, diuretic administration has been shown to enhance lung function.[23,39] Interestingly, improvements in resistance and compliance did not always correlate with better oxygenation.[23]

Respiratory mechanics have been employed in longitudinal studies to evaluate the clinical course of pulmonary diseases. The occurrence of meconium aspiration syndrome during infancy has been associated with alveolar hyperinflation and airway hyperreactivity to exercise at 7 ± 2 years of age.[22] Measurements of pulmonary mechanics at 1-year follow-up showed no difference between survivors in trials of high-frequency ventilation versus conventional ventilation.[72,73] However, during adolescence, former preterm infants who were randomized to high-frequency oscillatory ventilation had improved respiratory function in several measures, including FEV_1, forced vital capacity, peak expiratory flow, diffusing capacity, and impulse-oscillometric findings.[77] Hypoxemic respiratory failure has been linked with an increased risk for impaired pulmonary function, particularly in the presence of congenital diaphragmatic hernia or ECMO.[46] Decreases in FRC, compliance, and conductance have been shown to be predictive of BPD,[13,34,43] with gradual improvements in this cohort as the lungs grow.[32,59] Therapeutic agents in evolving or established BPD (i.e., diuretics, bronchodilators, and steroids) have been shown to have short-term benefits on resistance and compliance, but potential adverse side effects limit their use in neonates.[35] Because BPD is a manifestation of prolonged oxygen exposure or barotrauma, pulmonary function measurements and graphical displays may be most helpful in this area to minimize ventilator settings and duration of ventilatory support.

Evidence suggests that preterm birth alone may have long-term adverse effects on pulmonary function. For example, former preterm infants have deficits in FEV_1 at both 8 and 16 years of age,[74] and this impairment can occur even in those who do not develop BPD.[42] Pulmonary function testing in children with a history of BPD shows persistent abnormalities in clinical moderate expiratory flow obstruction.[25] About 25%-50% of very low birth weight infants and over 50% of children born at less than 26 weeks of gestation continue to have abnormal spirometry as preadolescents.[24,53] Many have asthma and respond to bronchodilators. Increased pulmonary arterial resistance is also common during infancy in infants who develop BPD. However, survivors of BPD have comparable right and left ventricular function at 8-12 years of age when

compared to preterm and term children without evidence of increased pulmonary arterial pressure even after hypoxic exposure.[68]

Even with the current limitations in methodology and confounders in the area of pulmonary function, diagnostic evaluations can be a useful tool in neonatal patient care. Ideally, clinical evaluation should include both numerical values for resistance and compliance in addition to visualization of flow-volume, pressure-volume, and pressure-flow curves. Application of these tools for pulmonary function measurements should complement clinical assessment in the care of infants with pulmonary disorders.

Key Points

- Methods developed to evaluate pulmonary function in neonates include physical signs, cardiovascular assessment, and physiologic measurements.
- Pulse oximetry and blood gas measurements are the most widely used clinical methods for assessing pulmonary function in neonates and form the basis for diagnosis and management of cardiorespiratory disease.
- Knowledge of pulmonary mechanics may be useful in identifying disease entities and in guiding treatments, whereas plots of airflow, volume, and pressure may provide additional information on a breath-by-breath basis.

Respiratory Distress Syndrome in the Neonate

MEGAN LAGOSKI, AARON HAMVAS, AND JENNIFER A. WAMBACH

Enormous strides have been made in understanding the pathophysiology of respiratory distress syndrome (RDS) and the role of surfactant in its cause and treatment (see Chapter 62). Nevertheless, RDS, formerly referred to as hyaline membrane disease, remains a dominant clinical problem despite the introduction of pharmacologic acceleration of pulmonary maturity using antenatal corticosteroids and the development of surfactant replacement therapy.[31,67]

Because more of the sickest, most immature infants are surviving,[90] the incidence of complications in the survivors of RDS remains significant. These include intracranial hemorrhage, patent ductus arteriosus (PDA), pulmonary hemorrhage, sepsis, and bronchopulmonary dysplasia (BPD) as discussed later. It is often impossible to determine whether these disorders are the sequelae of RDS, its treatment, or the underlying prematurity. In this section, the clinical features and evaluation of infants with RDS are discussed, and therapeutic approaches other than assisted ventilation (see Chapter 65) are outlined.

Incidence

Respiratory distress syndrome is one of the most common causes of morbidity and mortality in preterm neonates, although lack of a precise definition among infants with very low birth weight necessitates cautious interpretation of statistics regarding incidence, mortality, and outcome.[10,65] The diagnosis can be established pathologically or by biochemical documentation of surfactant deficiency; nonetheless, most series refer only to a combination of clinical and radiographic features. Without biochemical evidence of surfactant deficiency, it is difficult to clinically diagnose RDS in infants with extremely low birth weight. The term *respiratory insufficiency of prematurity* had been used in some centers for infants who require oxygen and ventilator support in the absence of typical radiographic evidence of RDS. More recently, the term *respiratory instability of prematurity* has been proposed to describe very low birth weight infants who require some respiratory support but may have additional contributing factors such as inconsistent central respiratory drive or poor inspiratory effort.[10]

Respiratory distress syndrome occurs throughout the world and has a slight male predominance.[4] The greatest risk factors appear to be young gestational age and low birth weight; however, European descent, late preterm delivery (35-36 weeks), or elective delivery in the absence of labor are also prominent risk factors.[4,73,118] Given the associated adverse respiratory outcomes of late preterm and early term births, initiatives to delay elective deliveries until 39 weeks' gestation have been successful in reducing pulmonary and nonpulmonary morbidity in these infants.[28,105] Other risk factors include maternal diabetes and perinatal hypoxia-ischemia.

The incidence of RDS is inversely proportional to gestational age: nearly all infants born at 22-24 weeks' gestation have RDS,[100] decreasing to approximately 25% in infants with birth weights between 1251 and 1500 g.[32,101] Even infants of 34 weeks' gestation and greater, especially males of European descent, have a discernible risk of RDS that decreases from ~10% at 34 weeks to less than 1% at 37 weeks (Fig. 64.1).[4]

Pathophysiology

The lungs of infants who succumb from RDS have a characteristic uniformly ruddy and airless appearance, macroscopically resembling hepatic tissue. On microscopic examination, the striking feature is diffuse atelectasis such that only a few widely dilated alveoli are readily distinguishable (Fig. 64.2). An eosinophilic membrane lines the visible airspaces that usually constitute terminal bronchioles and alveolar ducts. This characteristic membrane (from which the term *hyaline membrane disease* is derived) consists of a fibrinous matrix of materials derived from the blood and contains cellular debris derived from injured epithelium. The recovery phase is characterized by regeneration of alveolar cells, including the type II cells, with a resultant increase in surfactant activity. The development of RDS begins with impaired or delayed surfactant synthesis and

Abstract

Respiratory distress syndrome (RDS), formerly referred to as hyaline membrane disease, is one of the most common causes of morbidity and mortality among preterm infants. RDS results from a developmental deficiency of pulmonary surfactant production, and the incidence of RDS is inversely proportional to gestational age, affecting the majority of infants born less than 32 weeks' gestation. Late preterm status, male sex, European-descent ethnicity, maternal diabetes, cesarean section without labor, and genetic variants also contribute to disease risk. Infants with RDS typically present shortly after birth with clinical symptoms, including grunting respirations, tachypnea, chest retractions, nasal flaring, cyanosis, and increased oxygen requirement. Chest radiograph typically demonstrates a homogeneous, reticulogranular pattern with superimposed air bronchograms. Treatment includes delivery of positive pressure to maintain airway and alveolar expansion through invasive (intubation and mechanical ventilation) or noninvasive support (nasal continuous positive airway pressure), supplemental oxygen, exogenous surfactant therapy, and careful monitoring of gas exchange. Despite the use of pharmacologic acceleration of pulmonary maturity using antenatal corticosteroids, the development of exogenous surfactant replacement therapy, and invasive and noninvasive modes of respiratory support, RDS remains a dominant clinical problem in neonatology.

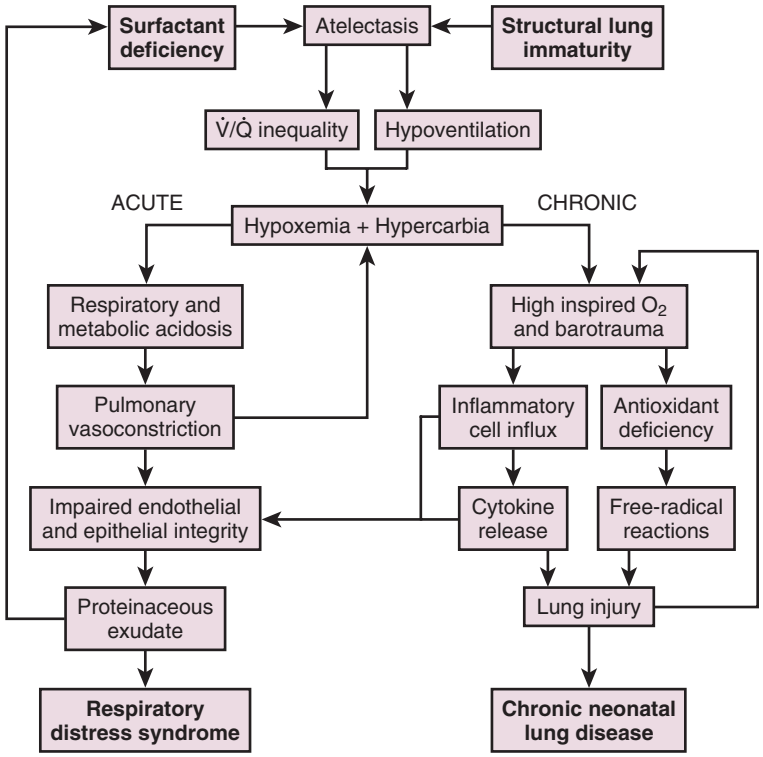
• **Fig. 64.1** Race and sex-specific risk of respiratory distress syndrome by gestational age (*circles*, left y-axis) and absolute difference in risk between sexes (*dashed line*, right y-axis) for infants born at 34 weeks and greater. White males have an increased risk of respiratory distress syndrome up to 38 weeks. (From Anadkat JS, Kuzniewicz MW, Chaudhari BP, et al. Increased risk for respiratory distress among white, male, late preterm and term infants. *J Perinatol*. 2012;32:780-785.)



• **Fig. 64.2** Histologic appearance of the lungs in an infant with respiratory distress syndrome. Note the marked atelectasis and so-called hyaline membranes lining the dilated alveolar ducts.

secretion followed by a series of events that may progressively increase the severity of the disease for several days in the absence of exogenous surfactant replacement (Fig. 64.3). Surfactant synthesis is a dynamic process that depends on factors such as pH, temperature, and perfusion and may be compromised by cold stress, hypovolemia, hypoxemia, and acidosis. Other unfavorable factors, such as exposure to high inspired oxygen concentration and the effects of barotrauma and volutrauma from assisted ventilation, can trigger the release of proinflammatory cytokines and chemokines and further damage the alveolar epithelial lining, resulting in reduced surfactant synthesis and function. The leakage of proteins such as fibrin in the intra-alveolar space further aggravates surfactant deficiency by promoting surfactant inactivation. Deficiency of surfactant and the accompanying decrease in lung compliance lead to alveolar hypoventilation and ventilation-perfusion (V/Q) imbalance.

Severe hypoxemia and systemic hypoperfusion result in decreased oxygen delivery with subsequent lactic acidosis secondary to anaerobic metabolism. Hypoxemia and acidosis also result in pulmonary hypoperfusion secondary to pulmonary vasoconstriction, and the result is a further aggravation of hypoxemia due to right-to-left shunting at the level of the ductus arteriosus, the foramen ovale, and within the lung itself.

The relative roles of surfactant deficiency and pulmonary hypoperfusion in the overall clinical picture of RDS vary somewhat with each patient. The natural history of RDS is now almost invariably altered by a combination of antenatal corticosteroid administration, exogenous surfactant

• **Fig. 64.3** Schematic representation of the complex series of acute and chronic events that lead to neonatal respiratory distress syndrome and the accompanying lung injury secondary to therapeutic intervention in these infants.

therapy, assisted ventilation, and in some cases, intrauterine inflammation.

Heritability of Respiratory Distress Syndrome

A genetic contribution to the risk of RDS has been suggested in twin studies where the concordance of RDS in monozygotic twins is greater than that in dizygotic twins and with isolated reports of recurrence in families.[69,81,94] With the application of molecular techniques, the contribution of genetic variations to the pathogenesis of respiratory disorders in newborns is rapidly emerging.[71,109]

Pathogenic mutations in genes encoding surfactant protein-B (SP-B, *SFTPB*), surfactant protein-C (SP-C, *SFTPC*), the ATP binding cassette subfamily A, member 3 (ABCA3, *ABCA3*), and the thyroid transcription factor (TTF-1, *NKX2-1*) represent rare monogenic causes of RDS.[49,83,84,95] Inherited SP-B deficiency is a recessive disorder that presents as severe respiratory failure in the immediate newborn period and is unresponsive to standard neonatal intensive care interventions. With a disease frequency of approximately 1 per million live births, the absence of SP-B, the presence of an incompletely processed proSP-C, and a generalized disruption of surfactant metabolism cause surfactant dysfunction and the clinical syndrome. Dominant mutations in *SFTPC* are present in significantly less than 0.1% of the population[42,109] and typically result in interstitial lung disease in infants older than 1 month of age, although an "RDS-like" presentation has been described.[17]

The accumulation of misfolded proSP-C within cellular secretory pathways results in activation of cell stress responses and apoptosis and impaired surfactant function.[80] Monoallelic, predicted deleterious variants in *ABCA3* are present in approximately 2%-4% of the population[109] and biallelic (recessive) mutations have been identified in association with progressive respiratory failure in newborns and with chronic respiratory insufficiency and interstitial lung disease in children.[26,95,108] Accumulating experience suggests that ABCA3 deficiency may be the most common of these disorders of surfactant homeostasis. Data from humans and mice suggest that ABCA3 mediates surfactant phospholipid transport (primarily phosphatidylcholine and phosphatidylglycerol) into lamellar bodies, and thus dysfunction of phospholipid transport into the lamellar body leads to reduced surfactant function.[36,41,45,75] Dominant mutations in *NKX2-1* were first identified in the context of benign hereditary chorea but since then have also been recognized in lethal and nonlethal neonatal RDS as well as interstitial lung disease in older children.[25,49,113] A triad of neurologic disease, characterized by hypotonia, developmental delay and movement disorders, congenital hypothyroidism, and RDS has been termed the *brain-thyroid-lung syndrome*, but any single organ presentation or combination thereof may be the initial and only manifestation of the syndrome.[49] Mutations in *NKX2-1* are rare, but the frequency of disease is unknown. Disruption in structural lung development and/or decreased expression of surfactant-associated genes are the postulated mechanisms of disease.

Large-scale cohort-based resequencing efforts have demonstrated an over-representation of monoallelic, predicted

deleterious variants in *ABCA3* in newborns 34 weeks and greater with RDS, suggesting that these mutations are modifiers for the risk or severity of respiratory disease in developmentally susceptible newborns.[42,82,109,114] These efforts have failed to identify an unequivocal contribution of rare or common variants in the surfactant protein-B or -C genes to RDS in newborns, suggesting that if these genes play a role in RDS, it is likely to be through interactions with variants in other lung-associated genes.[50,109] Exome and genome sequencing are becoming more accessible and will yield additional insights into candidate genes that account for the heritability of RDS.[61,71]

Prevention: Pharmacologic Acceleration of Pulmonary Maturation

In the early 1970s, Liggins, while studying the effects of steroids on premature labor in lambs, noticed the lack of RDS and increased survival in preterm animals prenatally exposed to steroids. The effects of various catecholamines as well as aminophylline and thyroid hormone have been studied; however, the most successful method to induce fetal lung maturation is prenatal corticosteroid administration (see Chapter 62).[72]

If premature delivery of any infant appears probable or necessary, lung maturity can be hastened pharmacologically. Accelerated lung maturation occurs with physiologic stress levels of corticosteroids via receptor-mediated induction of specific developmentally regulated proteins, including those associated with surfactant synthesis. Steroids, when administered to the mother at least 24-48 hours before delivery, decrease the incidence and severity of RDS.[87] Corticosteroids appear to be most effective before 34 weeks of gestation and when administered at least 24 hours and no longer than 7 days before delivery. Because corticosteroid therapy for less than 24 hours is still associated with significant reductions in neonatal mortality, RDS, and intraventricular hemorrhage (IVH), antenatal steroids should always be considered unless immediate delivery is anticipated.[21] While antenatal corticosteroids have routinely been administered to women at risk for preterm delivery before 34 weeks' gestation since the 1990s, recent data suggest that late preterm infants born at 34-36 weeks' gestation may also benefit.[47] Late preterm infants exposed to antenatal betamethasone are less likely to require respiratory support after birth; however, they require close monitoring for hypoglycemia.[47] While preterm infants as early as 23 weeks' gestation may benefit from antenatal corticosteroid exposure, their use before 23 weeks' gestation remains controversial.[18,110]

Less clear are the effects of repeated courses of antenatal corticosteroids on the short- and long-term outcomes of preterm infants. Decreased fetal growth and poorer neurodevelopmental outcomes have been reported with exposure to multiple courses of antenatal corticosteroids in retrospective clinical studies.[11,111] Prospective data suggest benefit for a single rescue course for women less than 34 weeks' gestation who are at risk for preterm delivery within 7 days and whose prior steroid course was greater than 14 days.[39]

Concern about the possibility of increased infection in mother or infant appears to be unfounded. Indeed, even when corticosteroids are administered to women with prolonged rupture of membranes, there is no evidence of increased risk of infection, and the neuroprotective effects of corticosteroids are still evident. However, the use of a rescue course of corticosteroids in the setting of premature rupture of membranes remains controversial.[21,46] Maternal steroids may induce an increase in total leukocyte and immature neutrophil counts in the infant, which should be considered if neonatal sepsis is suspected.[12]

There is proven benefit from the combined use of prenatal corticosteroids and postnatal surfactant therapy in preterm infants (see Surfactant Therapy). Their effects appear to be additive in improving lung function. Antenatal steroids induce structural maturation of the lung, as evidenced by physiologic and morphometric techniques, that is not secondary to increases in alveolar surfactant pool sizes.[55] These structural changes translate into improved physiologic properties of the lung, such as increased lung volume, increased lung compliance, and increased response to exogenous surfactant treatment.

Antenatal corticosteroids appear to reduce the incidence of other co-morbidities associated with prematurity, including intracranial hemorrhage, periventricular leukomalacia, and necrotizing enterocolitis.[19,70,112] The beneficial effect on intracranial hemorrhage does not correlate directly with improved pulmonary morbidity and may be secondary to stabilization of cerebral blood flow or a steroid-induced maturation of vascular integrity in the germinal matrix, or both.

In the 1990s, the observation that thyroid hormone could augment lung development and surfactant production *in vitro* prompted trials of antenatally administered thyrotropin releasing hormone (TRH). However, these trials failed to demonstrate a benefit and also raised concerns for adverse consequences on neurodevelopment, thereby significantly dampening enthusiasm for this therapy.[23]

Clinical Features

The classic clinical presentation of RDS includes grunting respirations, retractions, nasal flaring, cyanosis, and increased oxygen requirement, together with diagnostic radiographic findings and onset of symptoms shortly after birth. The respiratory rate is usually regular and increased well above the normal range of 30-60 breaths per minute. These infants usually show progression of respiratory symptoms and require supplemental oxygen. The presence of apneic episodes at this early stage is an ominous sign that could reflect thermal instability or sepsis but more often is a sign of hypoxemia and respiratory failure. This characteristic picture is modified in many infants with low birth weight as a result of the early administration of exogenous surfactant and immediate noninvasive or invasive assisted ventilation.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

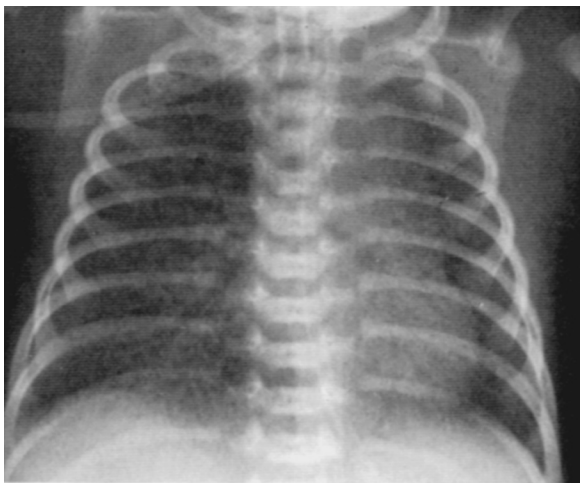
Retractions are prominent and are the result of the compliant rib cage collapsing on inspiration as the infant generates high negative intrathoracic pressures to expand the poorly compliant lungs. The typical expiratory grunt is an early feature and may subsequently disappear. Grunting results from partial closure of the glottis during expiration and in this way acts to trap alveolar air and maintain functional residual capacity (FRC). Although these signs are characteristic for neonatal RDS, they can result from a wide variety of nonpulmonary causes, such as hypothermia, hypoglycemia, anemia, polycythemia, or sepsis; furthermore, such nonpulmonary conditions can complicate the clinical course of RDS.

Cyanosis is a consequence of right-to-left shunting in RDS and is typically relieved by administering a higher concentration of oxygen and ventilatory support. Impaired cardiac output resulting from respiratory effort that is asynchronous with the ventilator may further impede oxygen delivery and lead to poor peripheral perfusion or cyanosis. The consistency of the arterial waveform with invasive blood pressure monitoring or the pulse signal with oxygen saturation monitoring can provide information about the effectiveness of cardiac output. Acrocyanosis of the hands and feet is a common finding in healthy infants and should not be confused with central cyanosis, which always must be investigated. Peripheral edema, often present in RDS, is of no particular prognostic significance unless it is associated with hydrops fetalis.

During auscultation of the chest, breath sounds are widely transmitted and cannot be relied upon to reflect pathologic conditions. Nonhomogeneous aeration plus elevated endogenously or exogenously generated intrathoracic pressures can cause pulmonary air leaks. Thus, unilaterally decreased breath sounds (with mediastinal shift to the opposite side) or bilaterally decreased air entry could indicate pneumothorax and immediate transillumination should be performed. Chest radiography is also needed to confirm endotracheal tube placement if air entry sounds are asymmetric. The murmur of a PDA is most often audible during the recovery phase of RDS, when pulmonary vascular resistance has fallen below systemic levels and there is left-to-right shunting. Distant, muffled heart sounds should alert one to the possibility of pneumopericardium. Percussion of the chest is of no diagnostic value in preterm infants.



A constant feature of RDS is the early onset of clinical signs of the disease. Most infants present with signs and symptoms either in the delivery room or within the first 6 hours after birth. Inadequate observation can lead to the impression of a symptom-free period of several hours. The uncomplicated clinical course is characterized by a progressive worsening of symptoms, with a peak severity by days 2-3 and onset of recovery by 72 hours. Surfactant therapy often shortens this course as it reconstitutes the surfactant pool and prevents atelectasis until endogenous surfactant production is sufficient. When the disease process is severe enough to require assisted ventilation or is complicated by the development of air leak, significant shunting through a PDA, concomitant infection, or early signs of BPD, recovery can be delayed for days, weeks, or months (see Fig. 64.3). In the most affected patients, the transition from the recovery phase of RDS to BPD is clinically imperceptible.

Radiographic Findings

The diagnosis of RDS is based on a combination of the previously described clinical features, evidence of prematurity, exclusion of other causes of respiratory distress, and characteristic radiographic appearance (see Chapter 38). The typical radiographic features consist of a diffuse reticulogranular pattern, giving the classic ground-glass appearance in both lung fields with superimposed air bronchograms (Fig. 64.4). Although the radiologic appearance of RDS is typically symmetric and homogeneous, asymmetry has also been described, especially if surfactant therapy has been administered preferentially to one side.

The reticulogranular pattern is primarily caused by alveolar atelectasis, although there may be some component of pulmonary edema. The prominent air bronchograms represent aerated bronchioles superimposed on a background of nonaerated alveoli. An area of localized air bronchograms may be normal in the left lower lobe overlying the cardiac silhouette, but in RDS they are widely distributed, particularly in the upper lobes. In the most severe cases, a complete opacification of the lungs can be observed, with total loss of the cardiac borders. Heart size is typically normal or slightly increased. Cardiomegaly may herald the development of congestive cardiac failure from a PDA. After the administration of exogenous surfactant therapy, the chest radiograph usually shows improved aeration of the lungs bilaterally; however, asymmetric clearing of the lungs may occur.

The radiographic appearance of RDS, typical or atypical, cannot be reliably differentiated from that of neonatal pneumonia, which is most commonly caused by group B streptococcal or Gram-negative (e.g., *E. coli*) infection. This

• **Fig. 64.4** Typical radiographic appearance of respiratory distress syndrome with reticulogranular infiltrates and air bronchograms.

problem has been the major reason for the widespread use of empiric antibiotics in the initial management of infants with RDS. Infants with RDS reportedly have a larger thymic silhouette than infants of comparable size without RDS. This supports the theory that patients with RDS have had reduced exposure to endogenous corticosteroids during fetal life.

Echocardiographic evaluation of selected infants with RDS may be of value in the diagnosis of a PDA to quantitate elevations in pulmonary artery pressure, to assess cardiac function, and to exclude congenital heart disease (e.g., obstructed total anomalous pulmonary venous return) (see Chapter 75).

Treatment

Therapy for RDS includes careful application of general supportive measures supplemented by respiratory support and selective use of surfactant therapy. Close and detailed supervision of small infants requires a dedicated, trained staff experienced and attuned to problems specific to the newborn and skillful in the unique technical procedures involved, such as CPAP administration, endotracheal intubation, titration of invasive and noninvasive respiratory support, and assessment of neonatal blood gases.

Positive-Pressure Ventilation

Delivery of distending pressure to maintain airway and alveolar expansion through invasive and noninvasive means is the mainstay of treatment for RDS (see Chapter 65). The most common approaches of invasive mechanical ventilation via an endotracheal tube utilize a time-cycled, pressure-limited mode, or volume-controlled mode with synchronized ventilated breaths. Alternatively, high-frequency jet ventilation or high-frequency oscillatory ventilation is utilized both as a primary means of ventilation and as rescue when conventional mechanical ventilation has failed.

There has been much enthusiasm for noninvasive methods of ventilation, especially nasal continuous positive airway pressure (nCPAP). The benefits of CPAP include maintenance of a constant airway opening pressure, establishment and maintenance of functional residual capacity, reduction of pharyngeal or laryngeal obstruction, improvement of oxygenation, and release of surfactant stores.[43,104] When compared to invasive mechanical ventilation, nCPAP reduces barotrauma, volutrauma, airway damage, and risk of secondary infections, and enhances mucociliary transport.[2,54,115]

Nasal CPAP used in combination with surfactant for the treatment of RDS among preterm infants is well established. Early studies demonstrated reduced need for mechanical ventilation among very preterm infants treated with surfactant and nCPAP.[107] Several randomized clinical trials have addressed the early-life respiratory management of extremely preterm infants (24-28 weeks) at risk for RDS. Taken together, these trials demonstrate that a subset of extremely preterm infants, especially those exposed to antenatal corticosteroids, can be stabilized with nCPAP shortly after birth and may avoid intubation, ventilation, and surfactant altogether.[30,79,103] Methods to identify this subset of infants before delivery or soon after birth remain an area of great interest.[37,88,96]

Although some extremely preterm infants can be treated with nCPAP, many infants fail this strategy because of persistent and severe apnea, desaturation, bradycardia, or respiratory acidosis. Noninvasive positive-pressure ventilation (NIPPV) combines nCPAP with intermittent ventilator breaths and can be administered through short binasal prongs. NIPPV increases tidal and minute volumes,[78] improves lung recruitment, decreases work of breathing,[1] may reduce apnea of prematurity,[68] and may reduce the need for mechanical ventilation among preterm infants.[86] NIPPV is superior to nCPAP in effectively weaning preterm infants with RDS from mechanical ventilation.[13,33,59,68,78] Caffeine also reduces risk of extubation failure for preterm infants.[33] However, despite increased use of less invasive ventilation strategies to avoid intubation and mechanical ventilation among extremely preterm infants, the frequency of need for supplemental oxygen at 36 weeks has not decreased, and pulmonary function during childhood has not significantly improved.[29]

Surfactant Therapy

First introduced in 1990, no intervention in the past 20 years has had more impact on the care of newborns with RDS than surfactant replacement therapy. A thorough history of the development of surfactant replacement therapy can be found in Chapter 62.[48] The discovery that surfactant deficiency was key in the pathophysiology of RDS led several investigators to administer artificial aerosolized phospholipids to infants with RDS. In these early studies, only limited therapeutic success was encountered. In contrast, animal models in which natural surfactant compounds were used yielded more promising results.

Because intact lung preparations were not available in Japan, Fujiwara and co-workers developed a mixture of both natural and synthetic surface-active lipids for use in humans.[38] Such a mixture might also afford alveolar stability with less potential risk for a reaction to foreign protein than would be the case with exclusively natural surfactant. When administered to an initial group of 10 preterm infants with severe RDS who were not improving despite artificial ventilation, a single 10-mL dose of surfactant instilled into the endotracheal tube resulted in a dramatic decrease in inspired oxygen and ventilator pressures. None of the infants in this uncontrolled series subsequently succumbed from RDS. Recovery, however, was complicated by clinical evidence of a PDA in nine of the infants, possibly the result of a prompt fall in pulmonary vascular resistance with the resultant left-to-right shunting after surfactant therapy.

Endotracheal administration of exogenous surfactant decreases complications of respiratory distress syndrome

among preterm infants.[53] Multiple studies have administered synthetic and mixed natural-synthetic surfactant preparations as part of prevention (delivery room administration), early treatment (within first few hours of life), and rescue (administration for established RDS) protocols.[5,9,53] The current synthetic-only preparation uses a bio-engineered peptide-mimic of surfactant-associated protein B, which assists as a spreading and stabilization agent for dipalmitoylphosphatidylcholine at the air-fluid-alveolar interface in a monolayer.[56,76] The mixed-surfactant preparations contain extracts of minced or lavaged bovine or porcine lungs. Despite differences in their chemical composition, manufacturing methods, dosage amount, and frequency of dosing (Table 64.1), both animal-derived surfactant extracts and protein-free synthetic extracts are effective treatments for respiratory distress syndrome (Box 64.1).[5] More strikingly, mortality from RDS, and even overall mortality of ventilated preterm infants, is significantly reduced.[92] While animal-derived surfactant extracts are associated with greater early improvement in need for ventilator support, fewer pneumothoraces, and decreased mortality, there is no difference in risk for bronchopulmonary dysplasia compared to protein-free synthetic surfactant preparations.[5] While some studies have shown decreased risk of death or bronchopulmonary dysplasia with higher initial dosing of porcine minced lung surfactant extract as compared to bovine minced lung surfactant extract, it is unclear whether these differences are caused by dosing regimen or source (porcine vs. bovine) because of lack of dose-equivalent, appropriately powered comparative trials.[97]

Early selective surfactant administration (within the first few hours after birth) given to infants with RDS requiring assisted ventilation leads to decreased risk of pneumothorax, pulmonary interstitial emphysema, chronic lung

TABLE 64.1 Surfactant Preparations Available in the United States[97]

Name of Surfactant	Derivation	Components and Concentration per mL	Dosage	Maximum Number of Doses	Frequency
Beractant (Survanta)	Bovine minced lung extract	25 mg/mL phospholipids (11-15.5 mg DPPC) <1 mg SP-B + SP-C	4 mL/kg	4	Every 6 hours
Calfactant (Infasurf)	Bovine lavage extract	35 mg/mL phospholipids (16 mg DPPC) 0.7 mg SP-B + SP-C	3 mL/kg	4	Every 6-12 hours
Poractant Alfa (Curosurf)	Porcine minced lung extract	76 mg/mL phospholipids (30 mg DPPC) 1 mg SP-B + SP-C	2.5 mL/kg (1st dose) 1.25 mL/kg (2nd/3rd doses)	3	Every 12 hours
Lucinactant (Surfaxin)	Synthetic	30 mg/mL phospholipids (22.5 mg DPPC) 0.862 mg SP-B analog	5.8 mL/kg	4	Every 6 hours

Information obtained from package inserts of products. All surfactant preparations are only FDA approved to be given intratracheally via an endotracheal tube.

• BOX 64.1 Surfactant Therapy for Respiratory Distress Syndrome

Resolved

- Improved mortality from respiratory distress syndrome (RDS).
- Greatest benefit when antenatal corticosteroids are also employed.
- Exogenous surfactant does not inhibit endogenous surfactant synthesis.
- Retreatment may be required in severe RDS.
- Major component for lowering surface tension: phosphatidylcholine.
- Endotracheal intubation required for administration of fluid suspension.
- Improvement in oxygenation, functional residual capacity, and lung compliance.
- Protein-containing preparations show a faster therapeutic response.
- Decrease in incidence of air leaks.
- Early use of CPAP with subsequent selective surfactant administration in extremely preterm infants.
- Early use of surfactant in infants who require endotracheal intubation and mechanical ventilation soon after birth.
- Efficacy of surfactant therapy, early extubation, noninvasive ventilation strategy.

Unresolved

- Role of surfactant in etiology and treatment of pulmonary hemorrhage.
- Optimal ventilatory strategy to maximize surfactant response.
- Effect on incidence and severity of bronchopulmonary dysplasia.
- Role of surfactant proteins as modulator of the immune system and inflammatory response.
- Role for recombinant surfactant protein-based preparations.
- Role for aerosolized surfactant preparations.
- Endotracheal administration via a narrow-bore catheter as an alternative to endotracheal intubation.
- Efficacy of synthetic peptide surfactant preparations.

disease, and mortality compared with delaying treatment until RDS is well established.[9] Given the increased use of antenatal corticosteroids and success of postdelivery stabilization on nCPAP, selective administration of surfactant to infants requiring intubation is now a preferred alternative to prophylactic surfactant administration.[89] In contrast with the impressive improvement in mortality, the incidence of BPD appears unaltered in most studies.[29,53] Although individual studies have shown a decreased incidence of BPD, these results have not been substantiated by meta-analysis of large randomized trials.[5] This could be a consequence of the enhanced survival caused by surfactant administration to infants who are very preterm but is more likely because BPD is unlikely to be a direct consequence of RDS as many infants who are preterm develop BPD without significant antecedent RDS.

Data from the early trials suggested slightly higher pulmonary hemorrhage rates in association with surfactant therapy in the smallest and most immature infants.[40] However, these findings have not been consistent throughout the literature, and controversy still exists. Generally, an acute deterioration in oxygenation and ventilation accompanied by variable degrees of cardiovascular compromise constitute the typical clinical findings. Several studies have reported an association of PDA and pulmonary hemorrhage among preterm infants.[35,60] One of the major hurdles encountered in defining the magnitude of the problem has been the lack of precise diagnostic criteria. In surfactant-treated infants, there tends to be extensive intra-alveolar hemorrhage, in contrast to infants not exposed to surfactant therapy, in whom hemorrhages occur as interstitial hemorrhage and localized hematomas. Although surfactant therapy has been proposed to contribute to pulmonary hemorrhage, the latter may inactivate surfactant and be an indication for its administration.[3]

Some infants do not exhibit the anticipated favorable response to surfactant therapy. The need for high oxygen concentration and ventilatory pressures during the early stages of RDS has been identified as a risk factor for an inadequate response. Animal studies have shown that even a few large tidal volume breaths in a surfactant-deficient lung are associated with alveolar accumulation of protein-rich edema fluid and decreased response to surfactant treatment.[52] Thus, it is unclear if lack of response is secondary to the initial severity of the disease or to the damage induced by short periods of aggressive ventilation before surfactant replacement. Furthermore, reactive oxygen species in preterm infants with poorly developed antioxidant defenses (e.g., superoxide dismutase, catalase, and reduced glutathione) may inactivate endogenous and exogenous surfactants. Finally, intrauterine inflammation or genetically determined factors may disrupt lung development or endogenous surfactant metabolism, thereby influencing response to surfactant therapy.

Data from large numbers of infants in the United States and Europe indicate no adverse effects of surfactant administration on physical growth, respiratory symptoms, or neurodevelopmental outcome. In a systematic review of randomized controlled trials, surfactant treatment was associated with a reduction in the combined outcomes of death or severe disability at 1 year of age.[98] Furthermore, this improvement in mortality and morbidity induced by surfactant therapy is accompanied by significant cost savings.[91]

Currently, all formulations of surfactant are approved solely for endotracheal administration. The most accepted method for this is via an endotracheal tube with assisted mechanical ventilation, although other methods have been attempted (Table 64.2). As mechanical ventilation is known to increase the risk of injury to the lungs, the INSURE technique (INtubate, SURfactant, Extubate) method gained popularity, as it has demonstrated a decreased need for reintubation and mechanical ventilation.[15] A more recently introduced method (less invasive surfactant administration or LISA) administers surfactant via a small catheter inserted into the trachea by direct laryngoscopy while the patient remains on nCPAP with a resultant decrease in need for intubation and mechanical ventilation.[24,44,62] Pilot studies of an aerosolized form of synthetic surfactant have shown similar results,[34,57] and a randomized clinical trial is currently underway (Clinicaltrials.gov, NCT02294630).[53]

Surfactant has also been used as a vehicle because of its lipid interface and ease at widespread distribution in the lungs. As postnatal steroids have been shown to reduce the incidence and severity of BPD, but are linked to neurodevelopmental impairment at higher doses, a combination of inhaled steroids and surfactant has been recently investigated[116,117] (NCT02907593). Early data suggest this combination is safe and decreases the risk of BPD or death at 36 weeks without affecting growth or neurodevelopment.[63]

Although no adverse immunologic consequences of foreign tissue protein administration have been reported in the recipients of natural surfactant therapy, concerns for transmitted disease prompt the desire to develop synthetic, non-animal-based products. Preparations that contain synthetic peptides that mimic the biophysical properties of SP-B or SP-C have been studied in newborns (SP-B) and adults (SP-C) but have not found their way into general use.[58,99] SP-A and SP-D, although not essential for surface-lowering activity, could play a significant role in the lung's innate immune response and modulation of inflammation. It is not yet known whether the use of purified SP-A or recombinant SP-D has a therapeutic role in neonatal lung disease. The combination of a new generation of surfactants along with a gentler ventilatory approach could hold the key to optimal pulmonary outcomes in the future.

Inhaled Nitric Oxide Therapy

Inhaled nitric oxide (iNO), currently approved for treatment of hypoxic respiratory failure in near-term and full-term infants, has been proposed as a potential intervention in preterm infants at risk for developing BPD or in RDS that is complicated by pulmonary hypertension (see Chapter 70). Although individual trials have exhibited variable results

TABLE 64.2 Modes of Surfactant Administration

Mode of Surfactant Administration	Level of Studies Completed	Brief Description	Advantages	Disadvantages
Intratracheal via endotracheal tube (ETT)	• FDA approved • Multiple phase 3 randomized control trials (RCTs)	Surfactant administered most commonly through 5F or 8F catheter threaded through ETT in bolus dosing with continuing mechanical ventilation or positive pressure ventilation	• Most evidence • Easiest way to ensure dose is administered • Uniform distribution	• Airway trauma • Requires appropriately positioned ETT to ensure uniform distribution • Difficult to maintain functional residual capacity (FRC) depending on method of instillation • Hemodynamic instability
Thin catheter/ less invasive surfactant administration (LISA)[24,44,62]	• Not FDA approved • 3 RCTs • 4 observational studies • 1 recruiting phase 4 RCT	5F catheter is threaded into trachea via forceps. Laryngoscope is removed and catheter remains in place during administration of surfactant.	• Decreased risk of airway trauma • May avoid mechanical ventilation and volutrauma/ barotrauma from aggressive positive pressure ventilation	• Accidental removal of catheter during laryngoscope removal • Slower instillation of surfactant • Increased incidence of reflux of surfactant • Dependent on adequate, spontaneous breathing
Aerosolized[34,57]	• Not FDA approved • 2 RCTs • One pilot study • One recruiting phase II study	Aerosolized surfactant is given while patient is receiving nasal CPAP. Dose and frequency varies.	Theoretical avoidance of intubation, mechanical ventilation, volutrauma/ barotrauma	• Small number of patients enrolled • No significant difference in number of infants progressing to intubation

in survival without BPD, meta-analyses and randomized clinical trials have failed to clearly demonstrate improved respiratory or neurodevelopmental outcomes associated with routine use of iNO in preterm infants.[20,27,51] However, there may be select cases in which iNO may be of benefit.[8] When pulmonary hypertension accompanies RDS, or with decreased vascular surface area and pulmonary hypoplasia resulting from oligohydramnios and prolonged rupture of membranes, early use of iNO may improve oxygenation and survival.[8]

Assessment of Blood Gas Status

The ability to accurately monitor gas exchange is essential in all cases of neonatal respiratory disease (see Chapter 37 and Chapter 63). In its most basic form, this involves intermittent arterial sampling, usually via an indwelling umbilical arterial catheter or, less commonly, a peripheral (e.g., radial) arterial line. Infants with acute respiratory distress requiring a significantly increased inspired oxygen concentration or assisted ventilation should have blood gases sampled as often as their clinical condition dictates. A strategy of "permissive hypercapnia" has been used in attempts to reduce lung injury in preterm infants.[74] In general, $Paco_2$ is maintained in the 45-55 mm Hg range with pH at least 7.25, although in the most immature infants these ranges have been relaxed to minimize the degree of ventilatory support in an effort to decrease ventilation-associated morbidity.[74,77]

Noninvasive Monitoring: Pulse Oximetry

Risk of infection and other complications has prompted early umbilical line removal and increased the reliance on noninvasive methods for measuring gas exchange. Pulse oximetry is a well-established technique for indirectly determining oxygenation in a noninvasive and continuous manner. For infants with mild respiratory distress, pulse oximetry is extremely valuable and could make an umbilical arterial catheter unnecessary, provided intermittent assessments of pH and PCO_2 are made. Generally, this is not the case in infants with moderate or severe respiratory disease in whom noninvasive measurement remains an important adjunct rather than a substitute for arterial blood gas sampling. One should bear in mind that a normal arterial oxygen tension or saturation does not ensure adequate tissue oxygen delivery, because oxygen delivery is dependent on cardiac output and oxygen content of the blood. Hence, interpretation of gas exchange should always be correlated with a thorough clinical assessment.

Continuous noninvasive measurement of arterial hemoglobin oxygen saturation (pulse oximetry) has gained

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

widespread acceptance. Pulse oximetry typically employs a microprocessor-based pulse oximeter consisting of a light-emitting probe attached to a distal extremity of the infant. Oxygen saturation is computed from the light absorption characteristics of the pulsatile flow (containing both oxygenated and nonoxygenated hemoglobin) as it passes beneath the probe. The monitor readings closely correlate with saturation measurements obtained from arterial samples.

The major disadvantage of pulse oximetry is that changes in saturation are small on the flat portion of the hemoglobin dissociation curve at PaO_2 values greater than about 60 mm Hg (depending on the fetal hemoglobin content and other factors affecting position of the hemoglobin dissociation curve). This is not a substantial problem in infants with BPD when oxygen saturation is generally maintained in the low to mid 90s and these infants are unlikely to be at risk for hyperoxemia. Significant decreases in severe forms of retinopathy of prematurity have been seen when oxygen saturation limits are constrained between 85% and 89%; however, more restricted oxygen supplementation may increase mortality.[7,102] Therefore, values of O_2 saturation persistently less than 90% should be avoided.[102] Significant variability in even resting oxygen saturations in some infants provides a significant challenge to administer the appropriate amount of oxygen to remain within these constraints.

Pulse oximeters are technically easy to use, do not require calibration or heating of the skin, and provide immediate data on arterial oxygenation. Unfortunately, this ease of use can allow misinterpretation of potentially erroneous measurements.[85] Placement must not be associated with excess pressure, and peripheral perfusion must be adequate, although pulse oximeters are less dependent on peripheral perfusion than the previously widely used transcutaneous PaO_2 probes. Pulse oximeters are quite sensitive to sudden changes in background signal such as those owing to body movements. It is, therefore, important to ensure that the pulsatile waveforms from which oxygen saturation is derived are not distorted. This is typically done by comparing pulse rate from the oximeter with heart rate obtained from a cardiorespiratory monitor; these values should be identical. Newer signal extraction technology has significantly improved the accuracy and reliability of pulse oximetry measurements.

A major effect of pulse oximetry has been the ability to rapidly optimize respiratory care and drastically reduce the time required to determine optimum inspired oxygen concentrations, levels of CPAP, and respirator settings. Other benefits include the ability to assess responses to all procedures, including surfactant instillation, as well as excessive handling. Complications such as pneumothorax, endotracheal tube dislodgement, disconnection from oxygen supply, or ventilator malfunction will be rapidly recognized so that immediate corrective treatment can be initiated. Episodes of hypoxemia or desaturation can occur spontaneously or accompany feeds and have complex etiologies, as discussed in Chapter 67. Noninvasive monitoring of oxygenation allows such episodes to be identified and their relationship to apnea and bradycardia recorded.

Noninvasive Carbon Dioxide Monitoring

Although not used as universally as pulse oximetry, noninvasive methods for monitoring carbon dioxide levels can also provide an important adjunct to blood gas monitoring (see Chapter 37). Capnography has become the standard of care in resuscitation situations for accurately and rapidly demonstrating that the endotracheal tube is in the airway. End tidal CO_2 monitoring, although routinely used during anesthesia, is useful for following trends but is not always reliable in very low birth weight infants. Transcutaneous PcO_2 monitoring is also very useful for monitoring trends, especially when trying to optimize the ventilatory settings when initiating conventional or high-frequency ventilation. The possible association of $PaCO_2$ levels of less than 30 mm Hg with periventricular leukomalacia in preterm newborns demonstrates the need for careful CO_2 monitoring.[93]

Arterial Sampling

Umbilical catheterization should be performed by an experienced operator and under strict surgical sterile technique. Once the umbilical arteries have been identified by their anatomic characteristics, one of the vessels is dilated with the use of an iris forceps. The catheter is then gently advanced to a predetermined length that will place its tip at a high (T6-T8) or at a low (L3-L4) position. Several methods have been developed to estimate the length of catheter to be inserted to achieve proper placement; however, radiologic confirmation of catheter position is still imperative.

Although umbilical artery catheters still form the basic means of arterial sampling in infants with RDS, the list of catheter-related complications is formidable. The most common visible problem from an umbilical or radial line is blanching or cyanosis of part or all of a distal extremity or the buttock area, resulting either from vasospasm or a thrombotic or embolic incident. This complication may be reduced in the case of an umbilical catheter by high placement, with the catheter tip at the level of T7 or T8 as opposed to lower placement at L3 or L4 just above the aortic bifurcation.

Tyson and associates observed thromboatheromatous complications resulting from umbilical artery catheters in 33 of 56 neonates at autopsy.[106] Small amounts of heparin added to the continuous infusion appear to reduce the risk of arterial thrombi. Hypertension can result if a renal artery is involved. A rare complication of indwelling arterial umbilical catheters is aneurysmal dilation with dissection of the abdominal aorta, which can be diagnosed by careful ultrasound examination. Retrograde blood flow into the proximal aorta can occur during flushing of radial and umbilical artery lines and result in transient blood pressure elevation; therefore, routine flushing should be performed with a small volume over a period of several seconds.

The risk of catheter-associated bloodstream infection increases significantly as the days in place increase; thus,

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

limiting the number of days these catheters remain in place reduces the risk of infection and catheter-associated thrombosis.[16] All these complications illustrate the importance of applying rigid criteria for the insertion and removal of indwelling arterial catheters and the need for less hazardous methods of monitoring blood gases.

If a peripheral arterial catheter is to be used, an Allen test should be performed before the insertion of a radial artery line to establish the presence of adequate collateral circulation to the fingers.

Acid–Base Therapy

A change in acid–base balance should prompt a rapid determination of the type of imbalance, respiratory or metabolic, and a thorough evaluation of the cause (see Chapter 92). Acidosis, respiratory or metabolic, especially when coupled with hypoxia, can cause pulmonary arterial vasoconstriction and ventilation-perfusion abnormalities, decreased cardiac output, or both. A metabolic acidosis out of proportion to the degree of respiratory distress might signify hypoperfusion, sepsis, or IVH. Although sodium bicarbonate was historically used to correct metabolic acidosis, its routine use has not been shown to improve neonatal morbidity or mortality among preterm infants[66] and may be associated with increased risk for adverse neonatal outcomes.[6] Treatment of metabolic acidosis depends on the underlying etiology (e.g., lactic acidosis, renal tubular acidosis), and therapy should be targeted accordingly.

Respiratory acidosis requires assisted ventilation, and serial blood gases should be performed to titrate respiratory support. Administration of sodium bicarbonate to infants with respiratory acidosis is not indicated and could further increase the P_{CO_2}.

Cardiovascular Management

Comprehensive management of patients with RDS includes a close evaluation and monitoring of the cardiovascular system. An in-depth understanding of the physical and physiologic interactions between the cardiovascular and pulmonary systems in the mechanically ventilated patient is paramount. For example, after surfactant administration, with the improvement in the mechanical properties of the lungs, an unrecognized overdistension of the lungs by excessive mechanical ventilation support can decrease systemic venous return to the heart and result in a decrease in cardiac output. Radiographically, a typical squeezed-heart silhouette and flattened diaphragm are found. A thorough clinical evaluation should include sequential assessment of vital signs, peripheral pulses, capillary refill, and urine output as surrogate markers of adequate cardiac output.

Myocardial dysfunction secondary to ischemia or hypoperfusion may be present and could lead to decreased peripheral perfusion with lactic acidemia and metabolic acidosis. Systemic hypotension is common in the early stages of RDS; thus, continuous monitoring of systemic blood pressure by means of an indwelling arterial catheter is of utmost importance in the moderately to severely ill infant. Noninvasive intermittent monitoring of systemic blood pressure should be reserved for the mildly affected neonate. Judicious use of crystalloids for intravascular expansion and vasopressor support are often indicated. In patients with persistent hypotension not responsive to fluid therapy or pressors (e.g., dopamine), serum cortisol levels should be measured and treatment with stress doses of hydrocortisone should be considered.

Failure of the ductus arteriosus to close is a common complication in infants with RDS and has been linked to worsening respiratory distress and acidosis. Clinically, the presence of a PDA is heralded by a widened pulse pressure, an active precordium, and bounding peripheral pulses. A heart murmur on the left subclavicular area and the back is often present. On the chest radiograph, cardiomegaly might signal the presence of a hemodynamically significant PDA with congestive heart failure. With clinical suspicion, a confirmatory echocardiogram, which should demonstrate evidence of pulmonary overcirculation such as left atrial enlargement, is usually obtained. The decision whether to proceed with pharmacologic closure of the ductus arteriosus with a prostaglandin synthesis inhibitor such as indomethacin or ibuprofen remains controversial.[14] Fluid restriction, vasopressors, and a loop diuretic (e.g., furosemide) may be indicated for the medical management of a hemodynamically significant PDA with congestive heart failure (see Chapter 74).

Antibiotics

Neonatal pneumonia (most commonly caused by group B streptococci or gram-negative organisms) can be indistinguishable from RDS both clinically and radiographically. Such infection usually is acquired around the time of delivery either through ascending infection or passage through a colonized genital tract. The potentially fulminant course of neonatal pneumonia, especially in preterm infants, and the difficulty in distinguishing it from RDS have led to the practice that infants with significant respiratory distress receive antibiotics after appropriate cultures.

Prenatal features suggestive of neonatal infection include maternal fever, prolonged rupture of membranes, and clinical evidence of chorioamnionitis. The suspicion for bacterial infection is raised by a history of maternal genital colonization with group B streptococcus in an inadequately treated mother.

In the newborn, persistent hypotension, metabolic acidosis, early onset of apnea, neutropenia, or neutrophilia accompanied by an increase in immature neutrophils (left shift) are clinical findings suggestive of systemic infection. Nonetheless, the absence of these features does not exclude the diagnosis of pneumonia. Penicillin combined with an aminoglycoside is the antibiotic regimen of choice and may be discontinued after 48 hours based on culture results and clinical course of the infant. However, for medically

indicated preterm deliveries in the absence of risk factors for infection, antibiotic use may not be necessary. Furthermore, longer treatment with antibiotics without a clear source of infection has been associated with increased risk of morbidity.[22,64]

Despite substantial improvements in the treatment of RDS, prevention of preterm birth is still the ultimate goal and will have significant impact on the prevention of RDS. In the meantime, understanding the interactions of the intrauterine environment and genetic determinants of lung development with the pathogenesis of RDS is essential to develop mechanism-specific interventions.

Key Points

- Antenatal corticosteroids enhance surfactant production and reduce co-morbidities such as intraventricular hemorrhage.
- RDS results from a developmental deficiency of pulmonary surfactant production that may be aggravated by maternal diabetes and perinatal hypoxia-ischemia.
- Respiratory distress syndrome (RDS) and its associated complications are one of the most common causes of morbidity among preterm infants.
- Various techniques of surfactant replacement, respiratory support including CPAP, and other supportive therapy are the mainstays of treatment.

Assisted Ventilation of the Neonate and Its Complications

STEVEN M. DONN AND MOHAMMAD A. ATTAR

Mechanical ventilation has been used to treat neonatal respiratory failure for more than a half century. The earliest applications began as modifications of adult ventilators, treating babies of modest size and prematurity by today's standards.[23] Most devices were time-cycled, pressure-limited ventilators. Landmark advances in respiratory care occurred in the 1970s. Antenatal corticosteroids were shown to enhance fetal lung maturity, and transcutaneous oxygen monitoring taught us much about the vulnerability of the preterm infant. The 1980s brought pulse oximetry and high-frequency ventilation, which greatly expanded the therapeutic armamentarium. The surfactant replacement era began in the 1990s and was accompanied contemporaneously by patient-triggered ventilation, real-time pulmonary graphics, and a host of pharmacologic agents. Finally, in the new millennium, the microprocessor was incorporated into neonatal ventilators to greatly expand capabilities, monitoring, safety, and efficacy. This technological revolution has extended survival to infants born extremely prematurely as well as those with severe pulmonary disease that was heretofore lethal.

Mechanical ventilation can now be provided in many permutations. Clinicians can alter target variables, waveforms, cycling mechanisms, and modes simply by adjusting a dial. This has led to the development of disease-specific strategies to deal with the wide spectrum of neonatal respiratory failure. Similar to the rapidity of change in the computer industry, advances have been rapid and are often introduced into clinical practice without much of an evidence base, causing further confusion and consternation. This chapter reviews the classification and principles of both noninvasive ventilation and mechanical ventilation, with an emphasis on nomenclature and terminology.

Continuous Positive Airway Pressure and Noninvasive Ventilation

Although mechanical ventilation had been the primary treatment for respiratory failure in most preterm babies, there continues to be a concern that it is a major contributor to lung injury. This has led to a growing interest in noninvasive forms of respiratory support in the belief that this will reduce the need for mechanical ventilation and its associated complications. The noninvasive neonatal respiratory support modalities fall into two broad groups: single-level pressure support, such as continuous positive airway pressure (CPAP), and high-flow nasal cannula (HFNC) support, or bilevel positive airway pressure in the form of nasal small pressure difference (bilevel CPAP [BiPAP] or synchronized bilevel CPAP [SiPAP]) and in the form of nasal intermittent positive-pressure ventilation (NIPPV). NIPPV uses a high pressure difference and can be either synchronized or nonsynchronized.

Physiology of CPAP

When used to treat respiratory distress syndrome (RDS), CPAP prevents collapse of the alveoli at end-expiration, maintaining some degree of alveolar inflation. It thus decreases the work of breathing in accordance with LaPlace's law, in which the pressure required to overcome the collapsing forces generated by surface tension is reduced, because the radius of curvature is greater when the alveolus is partially inflated. In this way, CPAP helps to maintain functional residual capacity and to facilitate gas exchange. In addition, CPAP helps to maintain upper airway stability by stenting the airway and decreasing obstruction. It may also augment stretch receptors and decrease diaphragmatic fatigue and thus be useful in treating apnea of prematurity.

Nasal Continuous Positive Airway Pressure

Continuous positive airway pressure is a form of continuous distending pressure (CDP), which is defined as the maintenance of increased transpulmonary pressure during the expiratory phase of respiration. When positive pressure is applied to the airways of spontaneously breathing infants, it is called continuous positive airway pressure

Abstract

Neonatal respiratory failure is the most common disease entity in the neonatal intensive care unit. Treatment options range from administration of supplemental oxygen to continuous distending pressure to assisted ventilation. This chapter addresses aspects of assisted ventilation and its complications. Principles of mechanical ventilation, monitoring of the infant, and short- and long-term outcomes are discussed.

• BOX 65.1 Clinical Indications for Continuous Positive Airway Pressure (CPAP)

- Delivery room resuscitation
- Management of respiratory distress syndrome (RDS)
- Postextubation support
- Apnea
- Mild upper airway obstruction

• BOX 65.2 Methods of Providing Continuous Positive Airway Pressure (CPAP)

- Ventilator-derived CPAP
- Flow-driven CPAP
- Bubble (underwater) CPAP
- High-flow nasal cannula CPAP

(CPAP), whereas distending pressure applied to a mechanically ventilated infant is called positive end expiratory pressure (PEEP). Thus, both CPAP and PEEP are types of CDP (although not technically a form of ventilation) that provide low-pressure distension of the lungs and prevent the collapse of alveoli at the end of expiration. Continuous distending pressure helps to maintain functional residual capacity (FRC) and thus facilitates gas exchange throughout the respiratory cycle. In addition, CPAP supports the breathing of premature infants in a number of other ways, including abolition of upper airway occlusion and decreasing upper airway resistance, enhancement of diaphragmatic tone and activity, improvement in lung compliance and decrease in lower airway resistance, increase in tidal volume delivery by improving pulmonary compliance, conservation of surfactant at the alveolar surface, and reduction in alveolar edema.[48]

CPAP may be administered invasively through an indwelling endotracheal tube, or it may be provided noninvasively using a variety of different nasal interfaces. This is referred to as nasal CPAP (NCPAP). Single nasal prongs are usually cut from endotracheal tubes and passed 1-2 cm into one nostril with about 3 cm residing externally. Resistance along the length of the cannula adds to the loss of pressure from the other nostril. Nasal masks are now used in the belief that they reduce trauma to the nostrils. However, it is often difficult to produce a good seal without undue pressure, which may still cause injury in the region between the nasal septum and the philtrum. Short binasal prongs are available in several designs; all have two short tubes that provide the least resistance of any other nasal interface. They may be more effective at maintaining extubation and preventing reintubation than single nasal prongs as shown in a recent meta-analysis of controlled studies.[2]

Clinical Indications for CPAP in Newborns

The clinical use of NCPAP in the neonate falls into one of several groups: (1) early use in resuscitation, (2) management of RDS, (3) postextubation care, (4) treatment of apnea, and (5) management of mild upper airway obstruction (Box 65.1).

Methods of Generating Continuous Positive Airway Pressure

The gas mixture delivered by CPAP is derived from either continuous or variable flow (Box 65.2). Continuous-flow CPAP consists of gas flow generated at a source and directed against the resistance of the expiratory limb of the circuit. Ventilator-derived CPAP and bubble or underwater CPAP are examples of continuous-flow devices, whereas infant flow drivers (flow-driven CPAP) and Benveniste valve CPAP are examples of variable-flow devices.

Flow-Driven CPAP

Flow-driven CPAP is a prototype of variable-flow CPAP. It uses a dedicated flow driver and gas generator with a fluidic-flip mechanism to deliver variable-flow CPAP. The principle is the Bernoulli effect, which directs gas flow toward each nostril, and the Coanda effect, which causes the inspiratory flow to flip and leave the generator chamber via the expiratory limb during exhalation. This assists spontaneous breathing and reduces the work of breathing by lowering expiratory resistance and maintaining stable airway pressure. Flow-driven CPAP can be delivered using binasal prongs or a nasal mask.

Bubble CPAP

Underwater bubble continuous positive airway pressure (BCPAP) is a continuous-flow system used since the early 1970s. In this method, the blended gas is heated and humidified and then delivered to the infant through a secured low-resistance nasal prong cannula. The distal end of the expiratory tubing is immersed in water, and the CPAP pressure generated is equal to the depth of immersion of the CPAP probe. It has also been proposed that chest vibrations produced by the bubbling may contribute to gas exchange. BCPAP is an effective and inexpensive option to provide respiratory support to premature babies.[48]

Ventilator-Derived CPAP

Ventilator-derived CPAP is another conventional way to administer continuous-flow CPAP. The CPAP is increased or decreased by varying the ventilator's expiratory orifice diameter. The exhalation valve works in conjunction with other controls, such as flow control and pressure transducers, to maintain the CPAP at the desired level.

Sustained Inflation at Neonatal Resuscitation

Sustained inflation (SI) uses pressures of 20-30 cm H_2O for 5-15 seconds during resuscitation to recruit lung airspaces immediately after delivery and to establish functional residual capacity. Thus far, studies have failed to demonstrate a benefit of presumed lung recruitment (and a decrease in the

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

rates of death or BPD). More randomized controlled studies are underway to evaluate the efficacy and safety of SI.[43,84]

CPAP Immediately After Birth

In a meta-analysis of randomized controlled trials comparing CPAP started in the immediate postnatal period in very low birth infants at risk for RDS, to support with mechanical ventilation (including 3123 babies), Subramaniam et al. found CPAP to decrease the need for mechanical ventilation and surfactant treatment and to reduce the incidence of BPD at 36 weeks and the incidence of death or BPD.[99]

High-Flow Nasal Cannula (HFNC)

Flow of gas in excess of 1 L/min, and up to 8 L/min, through a small nasal cannula might provide some degree of CPAP. The physiologic benefits of HFNC are attributed to washout of the nasopharyngeal dead space, possible reduction of the inspiratory resistance, and provision of a degree of CPAP.[19] However, a major problem is that the CPAP level is usually not measurable in clinical practice and has been shown to be highly variable depending on the leak at the nose and/or mouth. The cannula tips should not be more than 50% of the internal diameter of the nares to allow optimal washout of the dead space.[54] This leak around the nasal cannula affects the measured CPAP in an in vitro study.[95] In another study of preterm infants, a flow of 2 liters/minute generated 9.8 cm H_2O pressure (measured by an esophageal balloon) when a nasal cannula of certain diameter was used (0.3-cm outer diameter), emphasizing the potential risk of inappropriate size selection of the nasal cannula.[68] Utilization of this technique has increased in many units as a result of the simpler patient interface compared to CPAP, and because the use of HFNC appears to be associated with less nasal trauma.[63,70] HFNC in preterm infants has been used as a primary mode of support shortly after birth, postextubation, and for apnea. In general, HFNC was no worse than CPAP in a meta-analysis of controlled trials. However, there is a paucity of evidence in the extremely preterm infant.[63] In a large randomized, controlled, noninferiority trial, published subsequently, early (after birth) use of HFNC for primary support for RDS in infants older than 27 weeks was associated with more frequent treatment failures compared to CPAP.[82] Additional studies are needed to demonstrate safety and efficacy for HFNC under various clinical conditions.[19,116]

Noninvasive Nasal Ventilation

Methods of noninvasive ventilation include nasal intermittent positive-pressure ventilation (NIPPV), synchronized nasal intermittent positive-pressure ventilation (SNIPPV), and synchronized bilevel CPAP (SiPAP). In all of these modalities, ventilator inflations augment NCPAP while PEEP, peak inspiratory pressure (PIP), respiratory rate, and inspiratory time can all be manipulated. Terminology used to describe NIPPV is not standardized and may be confusing. SiPAP, a form of NIPPV, is also termed biphasic or bilevel nasal CPAP.

The mechanism of action of NIPPV remains unclear. It is not known whether mechanical inflations during NIPPV are transmitted to the lungs; clinical studies show contradictory results. Other trials also found no differences in tidal volume or minute volume when comparing NCPAP with SNIPPV. Similarly, there are conflicting reports on work of breathing, pulmonary mechanics, and thoracoabdominal synchrony during comparisons of NCPAP with SNIPPV.[78]

Clinical Indications for NIPPV

Several studies have compared nonsynchronized NIPPV with NCPAP for treatment of apnea in premature infants and showed no advantage of NIPPV. Trials have also compared SNIPPV with NCPAP following extubation and found a significant reduction in extubation failure using SNIPPV. Studies have also assessed NIPPV as a primary strategy to treat RDS to avoid intubation. Investigators reported improved carbon dioxide removal, reduced apnea, and shorter duration of ventilation in the NIPPV group. Nonetheless, these are small studies and used sufficiently different protocols that prevent generalizable conclusions. A large randomized controlled trial consisting of more than 1000 babies of less than 30 weeks' gestation and birth weight less than 1000 g did not show any advantage of NIPPV over CPAP either as a means of early respiratory support to treat RDS or to facilitate extubation.[72] This is now further supported by another large multicenter study.[61] Lemyre et al. reported a meta-analysis of randomized controlled trials comparing NIPPV to CPAP. NIPPV was associated with a reduction in the need for re-intubation, and that benefit was persistent in all the trials that synchronized NIPPV (although they used different methods of synchronization).[66] The authors cautioned that their data were not sufficiently robust to support the added benefits of synchronization.

New Modes of NIPPV

Other forms of NIPPV have been introduced to overcome the limited pneumatic synchrony (flow or pressure) from air leaks at the patient interface. The noninvasive neurally adjusted ventilator assist (NIV-NAVA) uses a trigger that incorporates electrical activity of the diaphragm (Edi) by placing a probe at the gastroesophageal junction to trigger and proportionally pressure-assist each breath depending on the level of the measured diaphragmatic activity. In preclinical studies of NIV-NAVA, mechanical breaths are synchronized to the initiation, size, and termination of each patient breath.[42,97] Data from clinical studies using NIV-NAVA are limited and report mainly about infant-ventilator synchrony.[42]

The use of high-frequency ventilators with a nasal interface (high-frequency nasal ventilation, HFNV) theoretically eliminates the need for synchrony by delivering

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

high-frequency, small tidal volume ventilation. Clinical reports of HFNV in human neonates are emerging,[42,115] but no recommendations can be made yet.

CPAP and Surfactant Administration

Intubation with surfactant administration, followed by extubation (INSURE), is a way for surfactant administration to premature infants supported with CPAP. Dani et al. described variation in the threshold for surfactant treatment in multiple studies using this technique of surfactant administration, with the lower threshold seemingly better.[20] Less invasive surfactant administration (LISA) describes administering surfactant to spontaneously breathing premature infants without traditional endotracheal intubation. LISA is used with the hope of decreasing exposure to mechanical ventilation and subsequently to decrease the risk for lung injury.[64] A meta-analysis of six randomized studies, enrolling 895 infants, demonstrated that LISA was associated with a lower need for mechanical ventilation and a reduction in the composite outcome of death or BPD.[1]

Practical Problems of NCPAP

Despite its widespread use, a number of problems still persist.[67] Nasal prongs rarely fit tightly into the nares, thus resulting in gas leak and inability to maintain a baseline pressure. The set CPAP level is rarely maintained in the pharynx. The best way to reduce nasal leak is to ensure that the prongs are of sufficient size to snugly fit the nostrils without making them blanch. A chin strap can be used to reduce leaks around the mouth, but it is not simple to use in practice.

Complications of CPAP

Nasal trauma is a common problem with NCPAP especially in very premature infants. Proposed interventions include alternating binasal prongs with a nasal mask and using a nasal barrier dressing.[53] Excessive CPAP may contribute to lung overinflation and increase the risk for air leaks. CPAP can increase intrathoracic pressure and decrease venous return and cardiac output. If set too high, CPAP may result in carbon dioxide retention and impaired gas exchange. Gastric distension is a commonly encountered problem and can be at least partially alleviated by placement of an orogastric tube.

Postextubation CPAP

Ferguson et al., in a meta-analysis of studies that evaluated rates of successful extubation, found that continuous positive pressure reduces extubation failure compared to headbox oxygen, NIPPV was superior to CPAP, and that HFNC had similar efficacy to CPAP.[41] Lemyre's meta-analysis did not find enough evidence to demonstrate superiority of synchronized over nonsynchronized NIPPV after extubation, although a postextubation benefit was consistently observed in studies using synchronized NIPPV.[66]

Discontinuing CPAP

There are several methods of discontinuing NCPAP, including transition to HFNC. A gradual decrease in CPAP before discontinuing it was associated with success in the initial trial off NCPAP in two randomized controlled studies of very low birth weight infants.[4,105]

Long-Term Outcomes

The use of CPAP immediately after birth and selective surfactant treatment has generally replaced the practice of prophylactic or early surfactant replacement in preterm infants. This change in practice was influenced by the evidence from multiple randomized trials that used CPAP for initial stabilization and demonstrated a decreased risk of death or BPD compared to prophylactic surfactant therapy. That change in practice also included using the INSURE strategy in surfactant administration in an attempt to decrease exposure to mechanical ventilation. There has been an increase in the use of noninvasive forms of pulmonary support over time in an attempt to decrease exposure to mechanical ventilation and to decrease the risk for lung injury and potentially decrease the risk of death or BPD. The temporal increase in the use of noninvasive ventilation was demonstrated in longitudinal studies using single-center and regional datasets. Vliegenthart et al., in a single center in the Netherlands, reported a decrease in the rate of intubation and a decrease in the duration of mechanical ventilation over two epochs spanning 2004-2011, but there was no significant decrease in BPD. However, the investigators reported a significant decrease in the rate of death or neurodevelopmental impairment at 24 months.[111]

A regional Australian evaluation that compared pulmonary support and outcomes in three periods, 1991-1992, 1997, and 2005, demonstrated a longitudinal increase in duration of noninvasive pulmonary support without a significant change in duration of endotracheal mechanical ventilation and no significant decrease in duration of oxygen therapy or in the rate of oxygen dependence at 36 weeks. In addition, survivors of that population born in the most recent time period had lower expiratory volumes, suggesting more airflow obstruction at their 8-year evaluation.[36] Although these longitudinal evaluations have many limitations, they are not showing the hoped-for pulmonary benefits of the increased use of noninvasive pulmonary support. It seems that more work needs to be done to identify better noninvasive pulmonary support practices and the ideal patient population.

Indications for Assisted Ventilation

Mechanical ventilation is intended to take over or assist the work of breathing in babies who are unable to support

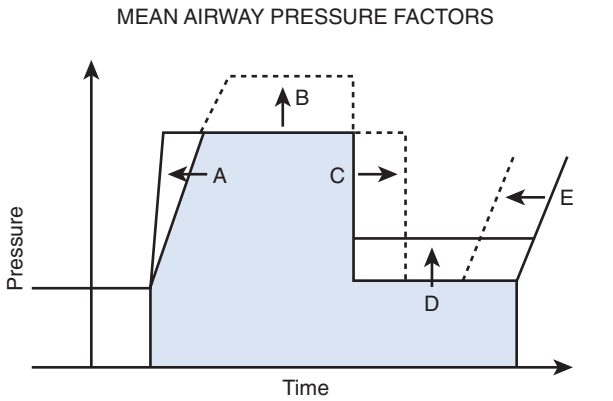
• BOX 65.3 Indications for Assisted Ventilation

Absolute Indications

- Failure to initiate or sustain spontaneous breathing
- Persistent bradycardia despite bag/mask ventilation
- Presence of major airway or pulmonary malformations
- Sudden respiratory or cardiac collapse with apnea/bradycardia

Relative Indications

- High likelihood of subsequent respiratory failure
- Surfactant administration
- Impaired pulmonary gas exchange
- Worsening apnea unresponsive to other measures
- Need to maintain airway patency
- Need to control carbon dioxide elimination
- Medication-induced respiratory depression



effective pulmonary gas exchange on their own. The causes for respiratory insufficiency may be pulmonary, such as respiratory distress syndrome or meconium aspiration syndrome; extrapulmonary, such as airway obstruction or compression; or neurologic, such as central apnea or neuromuscular disease. Respiratory failure may also accompany other systemic derangements, including sepsis or shock.

Indications for assisted ventilation may be thought of as absolute and relative (Box 65.3). Absolute indications include entities encountered in the delivery room, such as the failure to establish spontaneous breathing despite bag and mask ventilation, persistent bradycardia despite positive-pressure ventilation by mask, or the presence of major anomalies such as diaphragmatic hernia or severe hydrops fetalis, where there is a high likelihood of immediate respiratory failure. In the neonatal intensive care unit, sudden respiratory or cardiac collapse with apnea and bradycardia unresponsive to mask ventilation and massive pulmonary hemorrhage are two examples of absolute indications.[47]

Relative indications may be based on clinical judgment, such as intubating very preterm babies for prophylactic or early surfactant administration, or they may be based on an objective assessment of impaired gas exchange as evidenced by abnormal blood gases. Various recommendations exist to define respiratory failure severe enough to warrant assisted ventilation. In general, the easiest of these is the so-called "50-50 rule," whereby hypoxemia is defined as a failure to maintain an arterial oxygen tension of 50 mm Hg with a fraction of inspired oxygen of 0.5 or greater, and hypercapnia is defined as an arterial carbon dioxide tension greater than 50 mm Hg. Some have suggested that the arterial carbon dioxide tension criterion should be coupled with a pH value, such as less than 7.25. Additional relative indications for assisted ventilation include the stabilization of infants who are at risk for sudden deterioration, such as preterm infants with apnea unresponsive to CPAP or methylxanthines; severe systemic illness such as sepsis; the need to maintain airway patency, such as meconium aspiration syndrome or tracheobronchomalacia; the need to maintain

control of carbon dioxide elimination, such as persistent pulmonary hypertension; following severe hypoxic-ischemic brain injury; or for the management of drug-induced respiratory depression, such as maternal magnesium sulfate therapy, general anesthetics, or analgesics.

General Principles of Assisted Ventilation

Oxygenation

The two major factors that are responsible for oxygenating the blood are the fraction of inspired oxygen and the pressure to which the lung is exposed (Box 65.4). The role of inspired oxygen can be understood from the alveolar gas equation (see Chapter 63). Oxygenation is also proportional to mean airway pressure (mean Paw), which is the average pressure applied to the lungs during the respiratory cycle and is represented by the area under the curve for the pressure versus time waveform. Inflation of the lung recruits more airspaces and exposes more of the pulmonary surface area to alveolar gas. Thus, those factors that increase mean airway pressure will, up to a certain point, improve oxygenation (Fig. 65.1).[13]

The most direct impact comes from positive end expiratory pressure (PEEP), because it is applied throughout the respiratory cycle. PEEP is the baseline pressure, the lowest level to which airway pressure falls. It is used to take advantage of LaPlace's law by maintaining some degree

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

of alveolar inflation during expiration, thus reducing the pressure necessary to further inflate the alveolus during inspiration. There is a 1 : 1 relationship between PEEP and mean Paw; for every 1-cm H_2O increase in PEEP, there is a 1-cm H_2O increase in mean Paw. Excessive PEEP is potentially harmful. It may overdistend the alveoli, increasing the risk of air leaks; it may impede venous return and cardiac output; and it may decrease the amplitude, leading to carbon dioxide retention (see Complications of CPAP).[107]

Peak inspiratory pressure (PIP) will also increase the mean Paw, but this will be proportional to the inspiratory time (T_I) or duration of positive pressure. PIP is the driving pressure and also establishes the upper limit of the amplitude. Excessive PIP poses many of the same risks as excessive PEEP, including hyperinflation (overdistension) of the lung, leading to excessive stretch of the alveolar units (baro- or volutrauma); high intrathoracic pressure with decreased venous return and cardiac output; and air leaks. Additionally, if PIP and/or PEEP is/are inadequate, there may be alveolar atelectasis and resultant damage to the lung from cyclic opening and closing of lung units, a process referred to as atelectrauma.[17]

Mean Paw is also affected by T_I and the duration of positive pressure. As T_I increases, the mean Paw will also increase if all other parameters are held constant. Similarly, on machines wherein the inspiratory:expiratory (I:E) ratio is adjusted, mean Paw will increase as the inspiratory phase is lengthened or the expiratory phase is shortened. If the T_I is too long, however, there is an increased risk of gas trapping, inadvertent PEEP, and air leak. If it is too short, there may be inadequate lung expansion, air hunger, and patient-ventilator asynchrony, leading to inefficient gas exchange.

Changes in the ventilator rate will have a slight effect on mean Paw. At faster rates, the mean Paw will rise, because there are more breaths delivered per minute and the cumulative area under the curve per unit of time increases. Rapid rates may result in incomplete emptying of the lung, with gas trapping, inadvertent PEEP, and lung hyperinflation.

Finally, circuit gas flow will also impact mean Paw. If the T_I is held constant, more volume (and hence higher pressure) will be delivered as flow is increased. If the flow is set too high, turbulence, incomplete emptying of the lung, inadvertent PEEP, and hyperinflation may occur.[76] If the flow is set too low, air hunger and asynchrony will result. The injurious effects of improper airway flow have been referred to as *rheotrauma*.[32]

Ventilation

Ventilation refers to carbon dioxide removal. Its two primary determinants are tidal volume and frequency (Box 65.5).[106] Tidal volume is determined by the amplitude of the mechanical breath, or the difference between the peak (PIP) and baseline (PEEP) pressures. During conventional ventilation, carbon dioxide removal is the product of tidal volume and frequency. Clinically, this is usually expressed as the minute volume, or mL/kg/min, of exhaled gas. It is also important to consider the contribution of spontaneous breathing to minute ventilation (which is not always measured) and that pulmonary blood flow is also a key element in carbon dioxide removal, as well as oxygenation. During high-frequency ventilation, carbon dioxide removal is the product of frequency and the square of the tidal volume.[11] Thus, small changes in amplitude may have a profound effect on arterial carbon dioxide tension (see later).

• BOX 65.5 Determinants of Ventilation

Minute Volume

- Tidal volume
- Amplitude (PIP–PEEP)
- Frequency
- For conventional ventilation:
  Minute volume = frequency × tidal volume
- For high-frequency ventilation:
  Minute volume = frequency × (tidal volume)^2
- Expiratory time (or I : E ratio)

Control of ventilation during patient-triggered ventilation requires an understanding of the physiology of gas exchange. Most newborns will have intact chemoreceptors and will seek to maintain normocapnia. This is accomplished by adjustments in minute ventilation. Thus, if the amplitude is set too low, the baby will compensate by increasing the spontaneous (and hence, triggered) breathing rate. Conversely, if the amplitude is set too high, the infant's hypercapnic drive will be abolished, and the baby will "ride" the ventilator rate.[31]

Carbon dioxide tension is affected by minute ventilation, which in turn is the product of tidal volume and frequency during conventional mechanical (tidal) ventilation (CMV). Of these two parameters, adjustment in tidal volume (by adjusting the amplitude) has a more predictable effect on minute ventilation.[107]

Time Constant

Use of mechanical ventilators requires an understanding of the respiratory time constant. The respiratory time constant refers to the time required to allow pressure and volume equilibration of the lung. Mathematically, the time constant is the product of compliance and resistance. When the lung is stiff (low compliance) and has limited expansibility, such as occurs during RDS, it takes less time to fill and empty than it does at higher compliance. This pattern is clinically illustrated by observing the spontaneous breathing pattern of an infant with RDS not requiring assisted ventilation. Early on, when compliance is poor, the baby will breathe rapidly and take shallow breaths. As the disease process remits, compliance improves, and the baby breathes more slowly and takes deeper breaths.

If expiratory time is set at one time constant, approximately 63% of the change in pressure or volume will occur; if it is lengthened to three time constants, changeover will

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

increase to 95%; and at a five time constant-length, it will approach 99%. Thus, setting the expiratory time at less than 3-5 times the length of the time constant will increase the risk of gas trapping and potentially inadvertent PEEP and alveolar rupture.[12]

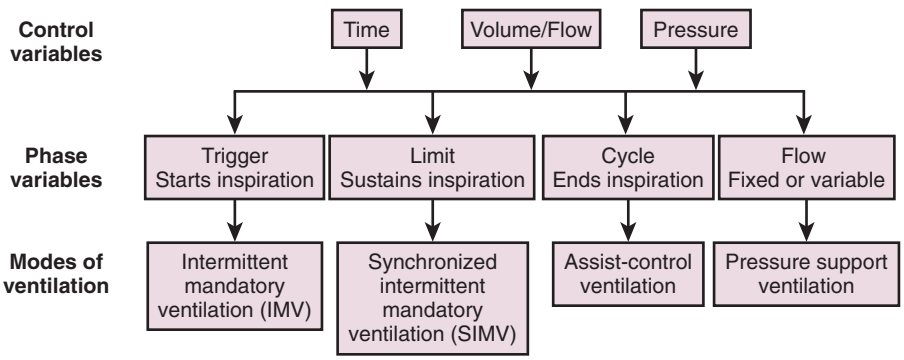
Classification of Mechanical Ventilators

Over the past decade, newer mechanical ventilation devices have been introduced into neonatal practice and devices that are based on sound physiologic principles. The proliferation of devices and techniques has caused confusion about nomenclature and classification, which are frequently device specific. In a general sense, mechanical ventilators can be divided into two groups: those that deliver physiologic tidal volumes, often referred to as conventional mechanical ventilators, and those that deliver tidal volumes that are less than physiologic dead space, referred to as high-frequency devices, which will be discussed later.

Among conventional mechanical ventilators, it is advisable to use a simple hierarchical classification to describe devices according to the variables they utilize (Fig. 65.2). These variables fall into two categories: those that control the type of ventilation (called *ventilatory modalities*) and those that determine the breath type (called *ventilatory modes*).[106] Recently, Chatburn, El-Khatib, and Mireles-Cabodevila proposed a taxonomy for mechanical ventilation. This system utilizes the defining of the control variable, breath sequence, targeting scheme, and mode classification to describe what is happening. This scheme, if adopted, could eliminate the widespread inconsistencies in nomenclature and terminology that presently exist among different devices and manufacturers.[14,15]

Control Variables (Ventilatory Modalities)

At any one time, the ventilator can control only a single variable—time, pressure, or volume. However, the same ventilatory device can operate using different control variables at different times. Ventilatory modalities can target either pressure or volume as the primary variable. Because volume is the integral of flow, volume- and flow-controlled ventilation are actually the same. When pressure is controlled, volume will fluctuate according to the compliance of the lungs, and conversely, when volume is controlled, pressure will fluctuate as a function of compliance.[14,106]



Phase Variables (Ventilatory Modes)

The mechanical breaths delivered by the ventilator have four phases, and more than one variable can be used to design the type of breath to suit the underlying lung mechanics and/or pathophysiology. The first of these is the variable that initiates or triggers inspiration (trigger). The second is the variable that is used to limit the inspiratory gas flow (limit). The third is the variable that changes inspiration to expiration and vice versa (cycle). The final is the variable that maintains the baseline pressure during expiration (PEEP).[106]

A number of variables can be used to trigger a breath. In the past, most neonatal ventilators used time to start inspiration. The clinician programmed either a set inspiratory time or ventilator rate and inspiratory:expiratory ratio, and the exhalation valve would open and close according to the lapse of time. More recently, other triggering variables have been introduced, allowing for the synchronization of the onset of mechanical breaths to spontaneous breathing. The clinician can set a threshold flow or pressure, above which the ventilator initiates a mechanical breath. These variables are used as a surrogate for spontaneous effort and include pressure or flow, with time as a backup. Most present ventilators use flow-triggering devices for newborns, because this requires less effort to trigger and is thus associated with less work of breathing.[33]

The limit variable restricts the inspiratory flow to a preset value. Traditionally, pressure has been used as a limit variable, but volume and flow are other variables that can limit inspiratory flow. True volume limitation is difficult to achieve, because cuffed endotracheal tubes are seldom used, and there is almost always some degree of volume loss around the endotracheal tube.

The cycling mechanism is the variable used to end inspiration. Most neonatal ventilators, including high-frequency ventilators, are time cycled, but changes in airway flow may also be used to end the inspiratory phase.[30] Termination of inspiration occurs when decelerating inspiratory flow has reached a preset percentage of peak inspiratory flow. At this point, the exhalation valve opens and expiration

• **Fig. 65.2** Hierarchical classification of conventional mechanical ventilators.

begins. Flow cycling more accurately mimics the physiologic breathing pattern and allows for the mechanical breath to be fully synchronized to the spontaneous breath during both inspiration and expiration. Changes in transthoracic electrical impedance that occur during spontaneous respiration can also be used to generate a trigger signal.[110] Thus, triggering during both active inspiration and active expiration can achieve total synchronous breathing between the baby and the ventilator.

A recent addition to neonatal ventilation has been Neurally Adjusted Ventilatory Assist. This modality uses the electrical activity of the diaphragm to trigger, cycle, and control the level of support.[9] Although there is a paucity of clinical data, the method appears promising but will require further investigation.

Modes of Ventilation

Using different phase variables, which are interchangeable, a variety of ventilatory modes can be generated that are applicable to both pressure- and volume-controlled modalities. The commonly used ventilatory modes are intermittent mandatory ventilation (IMV), synchronized intermittent mandatory ventilation (SIMV), assist/control (A/C) ventilation, and pressure support ventilation (PSV).[50] Fig. 65.3 is a graphic comparison of IMV and SIMV demonstrating the effects of asynchronous ventilation.

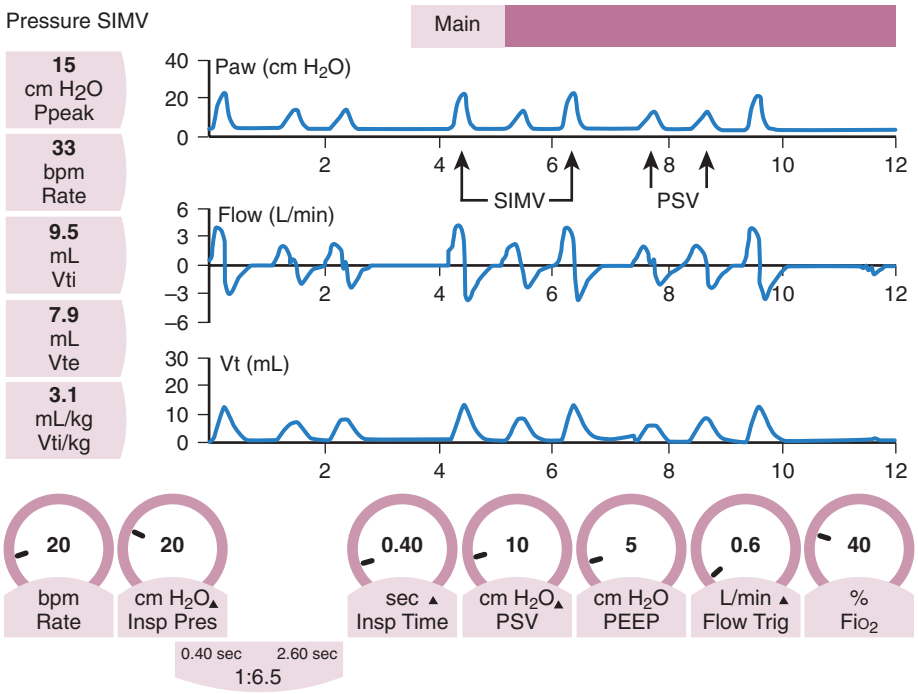
• **Fig. 65.3** Comparison of tidal volume delivery and flow during intermittent mandatory ventilation (IMV) and synchronized intermittent mandatory ventilation (SIMV). Note the tremendous variability in delivered tidal volume (*noted by asterisks*) during IMV breaths (*vertical arrows*) and SIMV breaths (*diagonal arrows*). Dyssynchronous breathing during IMV leads to inefficient gas exchange.

Intermittent Mandatory Ventilation

Intermittent mandatory ventilation delivers mechanical breaths at a rate set by the clinician. Inflations are provided at regular intervals and are not influenced by spontaneous breathing. The baby may breathe spontaneously with, between, or even against the mechanical breath, supported only by PEEP, and patient-ventilator asynchrony can be a major problem, resulting in a wide variability in delivered tidal volume. Efforts to reduce asynchrony include increasing the rate to override the spontaneous drive and "capture" the baby, generous use of sedatives, and in some instances, the administration of skeletal muscle relaxants. Virtually all forms of synchronized ventilation have been shown to be superior to IMV, and the latter should only be used when there is a complete cessation of spontaneous breathing.

Synchronized Intermittent Mandatory Ventilation

Synchronized intermittent mandatory ventilation is a mode in which the onset of mechanical breaths is synchronized to the onset of spontaneous breaths if the patient begins to breathe within a timing window. As a result, mechanical breaths are not delivered as regularly as in IMV but vary slightly according to the baby's own breathing pattern. In between the mechanical breaths, the baby may breathe spontaneously, but again, the spontaneous breaths are supported only by PEEP unless pressure support is utilized (see later). In time-cycled SIMV, synchrony between mechanical and spontaneous breath occurs only during inspiration, because the inspiratory time for both mechanical and spontaneous breaths may be different. This discrepancy can be offset by using flow cycling, where synchrony occurs during both inspiration and expiration.



Assist/Control Ventilation

In the A/C mode, the ventilator delivers a mechanical breath each time the patient's inspiratory effort exceeds the preset threshold criterion. When the patient triggers the ventilator to deliver a mechanical breath, the breath is said to be assisted. This mode also provides the safety of a guaranteed minimal mechanical breath rate (the control rate, set by the operator) in case no patient effort occurs or none is detected. A/C breaths can be time-cycled or flow-cycled. During A/C ventilation, as long as the baby breathes above the control rate, lowering the control rate will have no effect on the total respiratory rate, and thus the reduction of pressure should be the primary weaning strategy (see later).[86,91]

Pressure Support Ventilation

Pressure support ventilation (PSV) was developed to help intubated patients overcome the imposed work of breathing created by the narrow lumen (high-resistance) endotracheal tube, circuit dead space, and demand valve (if one is being used). It is, however, a *spontaneous* breath mode.

• **Fig. 65.4** Graphic representation of the combined use of synchronized intermittent mandatory ventilation (SIMV) and pressure support ventilation (PSV), where additional inspiratory pressure is applied to spontaneous breaths to help overcome the imposed work of breathing.

Spontaneous breaths that exceed the trigger threshold result in the delivery of additional inspiratory pressure to a limit set by the clinician. These breaths are flow-cycled, but for safety purposes they may be time limited. Most commonly, PSV is used in conjunction with SIMV to support spontaneous breathing between SIMV breaths with something more substantial than PEEP (Fig. 65.4). If the pressure limit of the PSV breath is adjusted to provide a full tidal volume breath, it is referred to as PS_{max}. If the pressure applied is just enough to overcome the imposed work of breathing, it is referred to as PS_{min}. PSV is a relatively new neonatal mode, but it is gaining acceptance.[77,79] It appears that it is most commonly used as a weaning strategy with low rate SIMV.[83]

Proportional Assist Ventilation

Proportional assist ventilation (PAV) is a fully adaptive modality, which attempts to provide a breath in total synchrony with the patient. The ventilator will also adapt the inspiratory flow to provide a breath waveform that matches what the patient is attempting to do. To achieve this, the ventilator continuously measures the respiratory effort of the baby, proportionally adjusting pressure and flow. Unfortunately, there is a paucity of clinical data.

Pressure-Targeted Modalities

Pressure-targeted modalities are characterized by limiting the amount of pressure that can be delivered during inspiration. The clinician sets the maximum pressure, and the ventilator will not exceed this level. The volume of gas delivered to the baby will vary according to lung compliance and the degree of synchronization between the baby and the ventilator. If compliance is low, less volume will be delivered than if compliance is high.[90,93,94] In IMV, tidal volume will fluctuate depending on whether the baby is breathing with the ventilator or against it.

There are three main pressure-targeted modalities: pressure-limited ventilation (PLV), pressure control ventilation (PCV), and pressure support ventilation (PSV), which is also a mode. All three are pressure limited. Some devices allow both PLV and PCV to be time or flow cycled. Traditional PSV is flow cycled but time limited. Inspiratory flow during PLV is continuous and is set by the clinician. During both PCV and PSV, inspiratory flow is variable and is related to lung mechanics and patient effort. It accelerates rapidly early in inspiration then decelerates quickly, producing a characteristic waveform.[26] Some devices allow modulation of the accelerating portion by offering an adjustable rise time. This enables "fine tuning" of flow to avoid pressure overshoot or flow starvation and helps to achieve optimal hysteresis of the pressure-volume loop.

Pressure-limited ventilation has been used to treat neonatal respiratory failure for a half century. It was developed from adult ventilators by adding continuous flow to the bias circuit to allow the baby to have a fresh source of gas from which to breathe between mechanical inflations. It is relatively easy to use and was presumed to be safe, because the delivered inspiratory pressure could be limited, thus reducing the risks associated with barotrauma. Although the inspiratory pressure is very consistent on a breath-to-breath basis, the delivered tidal volume will fluctuate, as noted above. In the postsurfactant era, lung compliance may vary considerably following the administration of surfactant, and

unless the clinician is vigilant, increasing tidal volume can lead to overexpansion and volutrauma.

Recently, PCV was introduced into neonatal ventilators. It differs from PLV primarily in the manner in which flow is regulated. PCV produces a waveform that accelerates rapidly then quickly decelerates. A rapid rise in flow early in inspiration leads to earlier pressurization of the ventilator circuit, and delivery of gas to the baby occurs early in inspiration. Intuitively, this should be beneficial in disease states characterized by homogeneity and the need for a higher opening pressure, such as early RDS. Variable flow should be advantageous when resistance is high, such as when a small endotracheal tube is used. The relative novelty of PCV has thus far precluded adequate comparison with PLV.

Both PLV and PCV are used as mandatory modes (IMV, SIMV, or A/C). PSV is a spontaneous mode; that is, it is applied only to spontaneous breaths the baby takes between mandatory mechanical inflations to support spontaneous breathing and overcome the imposed work of breathing created by the narrow lumen endotracheal tube, circuit dead space, and demand valve (if one is used). Because it is patient triggered and flow cycled, it is completely synchronized to the baby's own breathing, thus the baby controls the rate and the inspiratory time. The clinician sets the pressure level to augment spontaneous breathing. PSV can be used in conjunction with SIMV, or in patients with reliable respiratory drive, it may be used as a primary mode.[27] There is an evolving body of evidence that PSV is both safe and efficacious.[45,49,56,81,107] Still to be determined is the best way to apply PSV as a weaning tool. Table 65.1 compares the characteristics of pressure-targeted modalities.

Volume-Targeted Modalities

Broadly speaking, volume-targeted ventilation can be provided in several ways. Volume-controlled ventilation (VCV) targets a set tidal volume, which is delivered irrespective of lung compliance or the pressure required to deliver it (pressure may be limited for safety reasons). Hybrid ventilators are essentially pressure-targeted but aim to deliver the tidal volume within a set range using computer-controlled feedback mechanisms. Finally, standard pressure-targeted ventilation can function in a quasi–volume-targeted capacity if strict and vigilant attention is paid to volume delivery.[22]

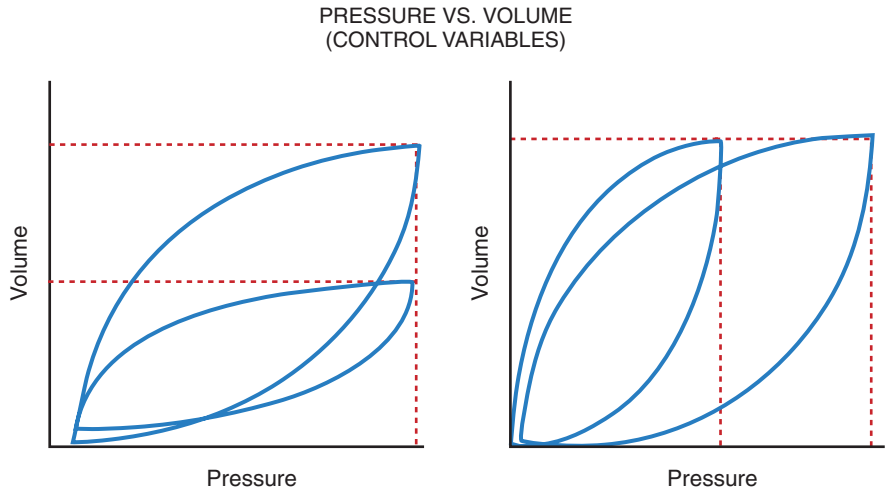
TABLE 65.1 Characteristics of Pressure-Targeted Modalities

Parameter	Pressure Limited	Pressure Control	Pressure Support
Limit variable	Pressure	Pressure	Pressure
Inspiratory flow	Fixed	Variable	Variable
Cycle mechanism	Time or flow*	Time or flow*	Flow (time limited)

*Device specific and not available on all machines.

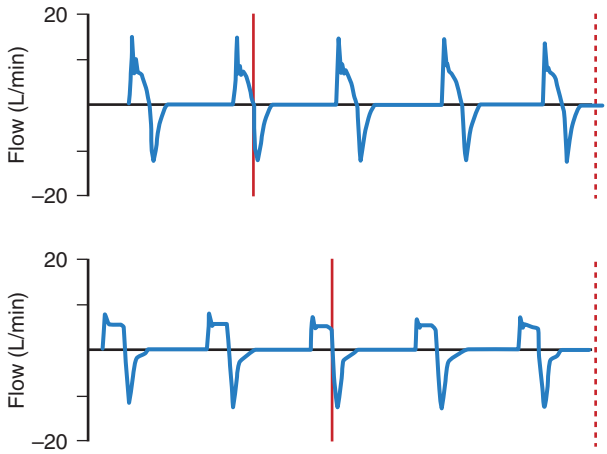
Volume-Controlled Ventilation

The first ventilator designed specifically for volume-targeted ventilation in infants was the Bourns LS 104-150, which was modified from an adult ventilator. Because of a multiplicity of problems, including a high trigger sensitivity, long response time, lack of continuous flow during spontaneous breathing, limited rate, poor circuit design, and the inability to measure small tidal volumes, this device (and VCV) fell out of favor in the early 1980s. Technologic advances in the 1990s enabled reintroduction of VCV to neonatal and pediatric patient populations. The new ventilators incorporate sophisticated devices to trigger, deliver, and accurately measure the tiny tidal volumes required by infants weighing as little as 500 g.



Volume-controlled ventilation for newborns differs from "adult" volume-cycled ventilation, where inspiration is terminated and the machine is cycled into expiration when the specific target tidal volume has been delivered. However, the use of uncuffed endotracheal tubes in newborns results in some degree of gas leak around the tube and precludes the ability to cycle based on a true delivered tidal volume. Thus, *volume cycling* is a misnomer in neonatal ventilation, and the terms *volume-controlled*, *volume-targeted*, or *volume-limited* better describe this modality. Many current ventilators provide the option of utilizing a leak compensation algorithm to at least partially offset this problem.

During VCV, there is also a discrepancy between the volume of gas leaving the ventilator and that reaching the proximal airway, which results from compression of gas within the ventilator circuit. This is referred to as *compressible volume loss*, which is greatest when pulmonary compliance is lowest. The use of semirigid circuits may help to offset this. Compressible volume is also affected by humidification. It is, therefore, critical that the delivered tidal volume is measured as close to the proximal airway as possible (i.e., at the patient wye piece).



The principal feature of VCV is that it delivers the set tidal volume irrespective of the underlying lung compliance by automatically adjusting the peak inspiratory pressure (Fig. 65.5). Another important feature of VCV that differentiates it from PLV is the way that gas is delivered during the inspiratory phase.[94,102] In traditional VCV, a square flow waveform is generated and peak volume and pressure delivery are achieved at the end of inspiration (Fig. 65.6). These may be thought of as "back end" loaded breaths. In comparison, in PLV the gas flow pattern accelerates rapidly, then decelerates, resulting in the achievement of peak pressure and volume delivery early in inspiration. This produces a "front end" loaded breath. Because these are very different, certain disease states might be more amenable to one form than the other.

Detractors of VCV have argued that unlike the limited pressure used in PLV, VCV may utilize a high inflation pressure to deliver the preset volume in cases of decreased compliance. This anxiety in the past arose because of the perceived risks of barotrauma and its consequences associated with high PIP. However, since it has become clear that

• **Fig. 65.5** Responses to changes in compliance in pressure- versus volume-targeted ventilation. In pressure-targeted, change in pulmonary compliance results in a change in delivered tidal volume while pressure remains constant (*left panel*). In volume-targeted ventilation, changes in compliance result in a change in pressure, while delivered tidal volume remains constant (*right panel*).

• **Fig. 65.6** Flow waveforms for pressure-targeted (*top*) and volume-targeted ventilation (*bottom*). Pressure-targeted produces a spiked waveform with rapid acceleration and deceleration of flow, producing peak pressure and volume delivery early in inspiration. Volume-targeted ventilation produces a characteristic "square wave," with constant or plateau flow. This results in peak pressure and volume delivery at the end of inspiration.

it is not necessarily the high pressure, but rather the excessive tidal volume (volutrauma) that causes lung injury,[37] attention to controlling tidal volume delivery has become an essential part of neonatal ventilation. It should also be realized that high peak pressure associated with fixed-flow delivery in VCV is a reflection of proximal airway pressure rather than alveolar pressure. When the compliance of the patient's lungs improves (increases), the ventilator generates less pressure to deliver the same tidal volume, thus leading to an automatic reduction of the PIP. It is also a misconception that pressure-limited ventilation of infants is superior to VCV, because it maintains a constant airway pressure in the presence of leaks around uncuffed endotracheal tubes. The reasoning seems to be that constant pressure implies that the delivered volume remains constant, but this is not true, because leaks around the uncuffed endotracheal tube also occur with PLV. Some VCV devices provide a way to compensate for leaks by adding additional flow to the circuit to automatically maintain a stable baseline pressure.

Like PLV, VCV can be provided as IMV, SIMV, and A/C ventilation. It may also be combined with PSV during SIMV and even A/C in some devices.[90]

Hybrid Volume-Targeted Ventilation

Some newer devices use a blended approach to volume targeting. They are primarily pressure-targeted ventilators but involve computerized servo-controlled ventilation, wherein a ventilator algorithm adjusts the rise and fall of pressure to produce tidal volume delivery within a set range. These include volume guarantee (VG), pressure-regulated volume control (PRVC), and volume-assured pressure support (VAPS). These hybrid forms try to achieve the same goal, the optimization of tidal volume delivery, although each has a different mechanism. Clinicians must familiarize themselves with the specific features of individual machines to maximize safety and efficacy.

Volume Guarantee Ventilation

Volume guarantee ventilation is a commonly used form of volume targeting.[58] It is a dual-loop, synchronized, pressure-targeted modality of ventilation with microprocessor-based adjustments in pressure to ensure adequate tidal volume delivery. The operator chooses a target tidal volume and selects a pressure limit up to which the inspiratory pressure (the working pressure) may be adjusted. The machine uses the exhaled tidal volume of the previous breath as a reference to adjust the working pressure up or down over the next breath to achieve the target volume. The auto feedback mechanism is an improvement in design but has some limitations. For example, if adjustments to PIP are made in small increments to avoid overcompensation and are based on the exhaled tidal volumes, the delivered tidal

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

volume may not compensate for large breath-to-breath fluctuations in the presence of large leaks. Moreover, if catch-up adjustments in pressures occur every few breaths, it may not work if the ventilator rate is set at low levels such as those used during weaning. In this context, the term *guarantee* is somewhat misleading.

On some devices, VG can only be used in conjunction with patient-triggered modes, that is, A/C, SIMV, and PSV, but newer devices also offer the use of VG with nontriggered continuous mandatory ventilation. The inspiratory pressure is set at the upper desired pressure limit. If this pressure is reached and the set tidal volume has not been delivered, an alarm will sound. Automatic pressure changes are made in increments to avoid overcompensation. No more than 130% of the target tidal volume is supposed to be delivered. The usual starting target is a tidal volume of 4-5 mL/kg. The pressure limit is set approximately 15%-20% above the peak pressure needed to constantly deliver the target tidal volume. Most infants can be extubated when they consistently maintain tidal volume at or above the target value with delivered PIP less than 10-12 cm H_2O and with good sustained respiratory effort.[62]

Pressure-Regulated Volume Control Ventilation

Pressure-regulated volume control ventilation is another modality of ventilation that attempts to combine the benefits of PLV and VCV.[9] It is a flow-cycled modality that offers the variable flow rate of pressure control ventilation with a targeted tidal volume. Like VG, PRVC is also a form of closed-loop ventilation in which pressure is adjusted according to the tidal volume delivered. The clinician selects a target tidal volume and the maximum permissible pressure to deliver the tidal volume. The microprocessor of the ventilator attempts to use the lowest possible pressure with a decelerating flow waveform to deliver the set tidal volume. The first breath is delivered at 10 cm H_2O above PEEP and is used as a test breath to enable the microprocessor to calculate the pressure needed to deliver the selected tidal volume based on the patient's compliance. The next three breaths are delivered at a pressure of 75% of the calculated pressure needed. If the targeted tidal volume is not achieved, the inspiratory pressure is increased by 3 cm H_2O for each breath until the desired tidal volume is reached. If targeted tidal volume is exceeded, the inspiratory pressure is decreased by 3 cm H_2O. Inspiratory pressure is regulated by the ventilator between the PEEP level and 5 cm H_2O below the clinician-set upper pressure limit. In PRVC, the pressure is adjusted based on the average of four breaths, so variations in delivered tidal volume still occur.

Volume-Assured Pressure Support Ventilation

Volume-assured pressure support ventilation is a hybrid modality of ventilation that optimizes two types of inspiratory flow patterns (VAPS = PSV + VCV), thus combining the advantages of both pressure and volume ventilation within a single breath and on a breath-to-breath basis.[24] It is best described as *variable flow volume ventilation*. VAPS can be used in either A/C or SIMV modes, or alone in babies with reliable respiratory drive. Spontaneous breaths begin as PSV breaths. The ventilator measures the gas volume delivered when the inspiratory flow has decelerated to the minimal set value. As long as the delivered volume exceeds the desired level (set by the clinician), the breath behaves like a pressure support breath and is flow cycled. If the preset tidal volume has not been achieved, the breath will transition to a volume-controlled breath; the set flow will persist and the inspiratory time will be prolonged (and pressure may increase slightly) until the desired volume has been reached. VAPS can be used both in the acute phase of respiratory illness, in which the patient requires a substantial level of ventilatory support, and when a patient is being weaned from the ventilator, especially in the face of unstable ventilatory drive. The optimal flow acceleration varies with patient dynamics, patient demand, and patient circuit characteristics. Pulmonary graphics are an essential tool for making the appropriate adjustments with VAPS.

Volume Support Ventilation

Volume support ventilation is another hybrid modality combining features of PSV and PRVC.[9] It is intended for patients who are breathing spontaneously with sufficient respiratory drive. Similar to PRVC, breath rate and tidal/minute volume are preselected by the clinician; however, inspiratory time is determined by the patient. Like PRVC, the ventilator algorithm increases or decreases the pressure limit by no more than 3 cm H_2O at a time. Adjustments are made in sequential breaths until the target tidal volume is achieved. The flow, pressure, and volume graphics for a volume-supported breath are similar to those of pressure-supported breaths; however, evidence for efficacy of volume support can only be assessed by evaluating sequential graphic presentations over time, as in PRVC. The tidal volume waveform will increase in a stepwise fashion until the targeted volume is reached.

Pressure Augmentation

This is also a hybrid modality, which offers the benefit of matching the patient's flow demand while guaranteeing a minimal tidal volume. Pressure augmentation differs from PRVC in the following ways: (1) the preset tidal volume is only a minimum, and the patient can breathe above this level; (2) the minimum tidal volume is guaranteed by adjustment in flow rather than pressure, which is fixed at preselected level; and (3) adjustment to flow is made within each breath rather than several sequential breaths. Pressure augmentation is interactive with the patient and is dependent upon the patient's flow demand and lung dynamics. Pressure augmentation can be utilized in either the A/C or SIMV modes, in which volume-controlled breaths are selected.

A meta-analysis of volume- versus pressure-targeted ventilation demonstrates a number of advantages of volume targeting. The duration of ventilation was shorter, the incidence of air leaks was significantly less, and there were

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

fewer severe neuroimaging abnormalities. There is also a statistically significant reduction in bronchopulmonary dysplasia in infants treated with volume targeting.[112] One study demonstrated better consistency and less variability in tidal volume delivery during volume targeting, which may explain some of these differences.[102]

Suggested Ventilatory Management Guidelines

Initiation of pressure-targeted ventilation is aimed at achieving adequate pulmonary gas exchange at the least possible pressure. Selection of pressure-limited or pressure control ventilation should be based on the pathophysiology of the respiratory failure. When the lungs are very stiff (poor compliance), such as in RDS, and there is a need for a high opening pressure, pressure control may be advantageous because of the rapid pressurization of the ventilator circuit and delivery of gas flow early in inspiration. If parenchymal disease is less heterogeneous, pressure-limited ventilation with slower inspiratory flow may be safer. Rapidly moving gas will preferentially ventilate the more compliant areas of the lung, perhaps contributing to ventilation-perfusion mismatch.

Pressure should be adequate enough to cause a visible rise in the chest wall during inspiration, and adequate breath sounds should be appreciated on auscultation. If measured, tidal volumes should be 4-6 mL/kg in preterm infants and 5-8 mL/kg in term infants.[69] Generally, PEEP is initiated at 4-6 cm H_2O, although higher levels are sometimes necessary. Remember that each baby is different and one setting does not fit all. The selection of a mode is usually based on personal preference, although A/C offers the most support. The rate should be adjusted to normalize minute ventilation and achieve normocapnia. It should not be too high, as this discourages spontaneous breathing.

The inspiratory time should be chosen according to the respiratory time constant. Small babies with stiff lungs generally require short inspiratory times, which tend to be proportional to birth weight.[86] Care must be taken to avoid gas trapping (see later).

The circuit (bias) flow rate should be adjusted to assure that it is adequate to meet the PIP within the allotted inspiratory time, but it should not be too high or it may cause turbulence, inefficient gas exchange, inadvertent PEEP, and lung overdistension.

Brief summaries of the clinical management protocol for VCV and VG are given in Table 65.2 and Box 65.6. In VCV (see Table 65.2), ventilation is generally initiated in the A/C mode using a desired inspiratory tidal volume of 4-6 mL/kg (measured at the proximal endotracheal tube) as the reference range to achieve the target blood gases. However, for monitoring and further adjustments in tidal volume delivery, expired (exhaled) tidal volume should be used as the reference, because it provides a more accurate measurement of the gas delivery to the lungs. To start weaning, a combination of low rate SIMV (6-20 breaths/minute) and PSV to augment spontaneous breathing seems best, because it compensates for the imposed work of breathing. In the beginning, the amount of pressure support should deliver a full tidal volume breath (PS_{max}), and with further improvement in spontaneous breathing, the PSV support can be reduced sequentially until a tidal volume of 3-4 mL/kg is

TABLE 65.2 Suggested Methods for Using Volume-Controlled Ventilation

Initial mode	Start in volume assist-control mode. Adjust volume at the machine to deliver 4-6 mL/kg (measured at proximal endotracheal tube).
Time limit (A/C)	Use flow to adjust inspiratory time to 0.2-0.4 seconds.
Target arterial blood gas range	pH: 7.25-7.4 P_{CO_2}: 40-60 mm Hg p_{O_2}: 50-80 mm Hg
Weaning	Wean by reducing volume as tolerated, but continue in A/C with control rate to assure normocapnia and tidal volume delivery at 3-4 mL/kg. Switch to SIMV/PS when control rate is <30 breaths/min. Load with a methylxanthine.
Weaning to extubation	Decrease SIMV rate to 10-20 breaths/min. Decrease pressure support to maintain tidal volume at 3-4 mL/kg.
Trial of extubation	Consider when pressure has been weaned to provide 3-4 mL/kg tidal volume and baby is breathing spontaneously at low rate SIMV.

A/C, Assist control; SIMV, synchronized intermittent mandatory ventilation.

• BOX 65.6 Suggested Methods for Using Volume Guarantee®

1. Press Vent Mode and select triggered mode of ventilation (SIMV, SIPPV = AC, PSV).
2. Set trigger sensitivity at most sensitive.
3. Set T_I, T_E (therefore, backup rate for apnea), FiO_2, P_{INSP}, PEEP, flow rate.
4. Press <VG>, preset V_T set by – and + buttons (starting value 4-6 mL/kg)
5. Connect infant to ventilator.
6. Select <Meas 1> or <VG> screen.
7. Check to see delivered V_T and PIP to delivery target V_T.
8. Adapt P_{INSP} (maximum allowed pressure) to actual peak inspiratory pressure.

reached (PS_{min}). Most babies can be extubated from this level of support if they are showing regular respiratory drive.

In VG, the initial ventilation is started in the synchronized intermittent positive-pressure ventilation (SIPPV) mode with a trigger sensitivity set at 1, the most sensitive setting (see Box 65.6). This may need subsequent adjustment to reduce the effect of leak-induced auto-triggering. The starting tidal volume reference range is 4-6 mL/kg, which can be adjusted based on blood gas analyses. It takes between six and eight breaths to reach the targeted tidal volume; the exact number depends upon the respiratory rate. If the PIP being used to deliver the desired tidal volume is several cm H_2O below P_{INSP} (where P_{INSP} is the maximum allowed pressure), then the set P_{INSP} may be left as is. This extra available peak pressure can be used by the ventilator if lung compliance decreases (or resistance increases, endotracheal tube leak increases, or respiratory effort decreases). If the PIP used by the ventilator is close to or equal to the set P_{INSP}, the set P_{INSP} should be increased by at least 4-5 cm H_2O. This will allow the ventilator some leeway to deliver the desired tidal volume in the event that compliance decreases. Once appropriate levels of tidal volume have been established, weaning should be an "automatic" process, with the amount of pressure deployed by the ventilator to provide the set tidal volume decreasing as the infant recovers. When the peak airway pressure used is very low, the infant may be ready for extubation.[58]

Weaning Infants From Assisted Ventilation

Weaning is the process in which the work of breathing is shifted from the ventilator to the patient (Box 65.7). Signs that an infant is ready to be weaned include improved gas exchange and pulmonary mechanics,[109] more spontaneous breathing,[113] and greater assumption of the work of breathing by the baby.[34] The most common reason for failure to wean is failure to wean.

There are physiologic requisites for weaning.[108] First, the baby must have adequate spontaneous drive to sustain alveolar ventilation. This can be assessed by observation (how easily the baby appears to be breathing), and measurement of tidal volume and frequency, and thus calculation (or measurement) of minute ventilation. Second, the baby must be able to overcome the respiratory system load, which can be defined as the forces necessary to overcome the elastic and resistive properties of the lungs and airways.[34] Additionally, there are defined elements of weaning (see Box 65.7). Tidal volume determinants include amplitude, inspiratory time, gas flow rate, and pulmonary compliance. Frequency determinants include chemoreceptor function and carbon dioxide production, as well as acid-base balance. Minute ventilation is determined by the product of tidal volume and frequency, and both spontaneous and mechanical components need to be evaluated. The work of breathing refers to the force or pressure necessary to overcome those forces that oppose gas flow and expansion of the lung during inspiration. It may be estimated by the product of pressure and volume, or graphically as the integral of the pressure-volume loop; it is thus proportional to compliance, but it may also be elevated if there is increased resistance. It is an indirect measurement of energy expenditure or oxygen consumption. Finally, there are nutritional aspects. Adequate calories need to be provided to fuel the work of breathing and avoid catabolism. However, an excess of non-nitrogen calories may increase carbon dioxide production and impede weaning.[34]

Clinicians should also recognize impediments to successful weaning (see Box 65.7). These should be avoided or treated, if present, to provide the best possible chance for the baby to be successfully weaned and extubated. Adjunctive therapies, including corticosteroids, diuretics, and bronchodilators, are often utilized to facilitate weaning, but only methylxanthines have sufficient evidence to be recommended.[8]

Weaning Strategies

Because infants are placed on assisted ventilation for differing reasons, and because different primary strategies are utilized for the different causes of respiratory failure, it is nearly impossible to design a "one size fits all" strategy. It has become even more confusing in the era of patient-triggered ventilation. In earlier times, when IMV was the only available mode, the usual strategy was to sequentially lower the rate and allow the baby to assume a greater burden of gas exchange by spontaneous breathing. During triggered ventilation, as long as the baby breathes above the control rate, lowering the ventilator rate has no effect on gas exchange.

In general, it is probably best to reduce the potentially most harmful parameter first. With the exception of HFOV, it is best to limit changes to one parameter at a time to

• BOX 65.7 Weaning From Assisted Ventilation

Physiologic Requisites

- Adequate spontaneous respiratory drive
- Overcome respiratory system load

Elements of Weaning

- Maintenance of alveolar ventilation
- Tidal volume
- Frequency
- Assumption of work of breathing
- Nutritional aspects

Impediments to Weaning

- Infection
- Neurologic/neuromuscular dysfunction
- Electrolyte imbalance
- Metabolic alkalosis
- Congestive heart failure
- Anemia
- Sedatives/analgesics
- Malnutrition (inadequate calories or excessive non-nitrogen calories)

better assess its impact on the baby's respiratory status. Avoid changes of a large magnitude, and be sure to document the baby's responses to changes so that subsequent care providers will be able to continue or adjust the plan.

Weaning and Ventilator Modes

For pressure-targeted A/C ventilation the primary strategy should be decreasing the PIP. It should be adjusted to keep tidal volume and P_{CO_2} in a reasonable range. If it is reduced too much, and alveolar ventilation is inadequate, it will be reflected by an increase in the spontaneous (and hence mechanical) ventilator rate. Increasing the assist sensitivity to increase the patient effort to trigger might be an alternative method, but there are no data to date to support this. Babies may be extubated directly from A/C, or they may be switched to SIMV or low-rate SIMV with PSV.

The goal of weaning in SIMV is to maintain minute ventilation while reducing the level of mechanical support. This can be accomplished by reductions in either the PIP or the SIMV rate, using the spontaneous rate as the monitored variable. As the SIMV rate is lowered, the baby may require additional support of spontaneous breathing to overcome the imposed work of breathing, either by increasing the PEEP, flow rate, or inspiratory time, or by adding PSV.

SIMV and PSV

The combined use of SIMV and PSV is analogous to A/C ventilation, except that changes can be made independently. Physiologic studies have demonstrated that if spontaneous breaths are fully supported with PSV (sufficient pressure to deliver a full tidal volume breath), lower SIMV rates can be used and weaning is faster.[49] In addition, the PSV breaths are fully synchronized, because they are patient triggered and flow cycled. If babies demonstrate reliable respiratory drive, PSV can even be used alone as a weaning strategy, with extubation occurring when the delivered tidal volumes are in the 3- to 5-mL/kg range.

Assessment for Extubation

In the past, predictive indices, such as blood gas or pulmonary mechanics testing, have not been adequately sensitive or specific in assessing readiness for extubation.[6,92] Part of the problem is not knowing what will happen to the airway once the endotracheal tube is removed, and obstructive apnea is common. Attention to spontaneous breathing while receiving only endotracheal CPAP has been shown to have a high positive predictive value for successful extubation. This can be accomplished by examining the relationship of spontaneous to mechanical ventilation[44,113] or simply by observing patient stability during a 10-minute period of CPAP.[55]

Postextubation Care

The care of the infant after extubation usually reflects clinician or institution preference. Most infants are extubated and placed on some form of continuous pressure provided by either nasal CPAP or nasal cannula, with or without supplemental oxygen. Most clinical trials support the use of CPAP to avoid postextubation failure.[21] Prone positioning has also been shown to improve gas exchange, perhaps by stabilizing the chest wall and allowing abdominal viscera to fall away from the diaphragm. Postextubation stridor is a relatively common occurrence from narrowing of the upper airway from swelling. It is usually transient, but it may require reintubation. Some affected infants will benefit from inhalational sympathomimetics or a short course of corticosteroids.

High-Frequency Ventilation

High-frequency ventilation (HFV) refers to a form of assisted ventilation in which the delivered gas volumes are less than the anatomic dead space volume and are provided to the patient at very rapid rates. During HFV, carbon dioxide removal is the product of frequency and approximately the square of the tidal volume, and thus the pressure required to set the amplitude can be considerably less than that used during conventional mechanical (tidal) ventilation (CMV). In addition, because the inspiratory times are much shorter, the duration of positive pressure is less and the alveoli are potentially exposed to less barotrauma. Because carbon dioxide removal can be achieved at lower amplitudes compared to conventional ventilation, HFV allows the clinician to use a higher PEEP with a wider margin of safety.[11] The two most commonly used forms of HFV are high-frequency jet ventilation (HFJV) and high-frequency oscillatory ventilation (HFOV)[16] (Table 65.3).

High-frequency ventilation has been used to treat lung conditions that have been challenging for CMV, including air leaks, refractory hypoxemia, and respiratory insufficiency after cardiac surgery. It also differs from CMV in not trying to mimic normal spontaneous breathing, and because of its unique flow characteristics, it provides a different pattern of gas distribution within the lungs, whereby airway resistance, and not compliance, is the major determinant of gas distribution. Because gas flow is more rapid during HFV than

TABLE 65.3 Characteristics of High-Frequency Ventilation

	HFJV	HFOV
Rate	360-450 bpm	480-900 bpm
T_I	20 msec	10-20 msec
Exhalation	Passive	Active
Tandem CMV	Yes	No
Gas delivery	High velocity injector	Piston

bpm, Breaths per minute; CMV, conventional mechanical (tidal) ventilation; HFJV, high-frequency jet ventilation; HFOV, high-frequency oscillatory ventilation.

during CMV, the gas-flow profile is more laminar or parabolic. Thus, inspiratory gas tends to remain in the center of the airways, enabling it to penetrate more deeply into the lung and to bypass airway disruptions, such as bronchopleural or tracheoesophageal fistulas,[35] or other thoracic air leaks, such as pneumothorax or pulmonary interstitial emphysema (PIE).[59]

Although the basic principles of mechanical ventilation are essentially the same for HFV as for CMV, HFV enables better uncoupling of oxygenation and ventilation. During CMV, adjustments made to improve oxygenation often adversely affect ventilation and vice versa. This phenomenon is much less apparent during HFV, particularly during oscillatory ventilation.

Although both HFJV and HFOV have been in use for more than 25 years, there is a relative paucity of evidence for either modality. A thorough review by Lampland and Mammel summarizes the clinical evidence.[65]

High-Frequency Jet Ventilation

This form of HFV involves pulses of high-velocity gas injected directly into the upper airway, either by a special endotracheal tube adapter (proximally) or a specialized triple-lumen endotracheal tube (distally). It is used in tandem with a conventional ventilator, which provides PEEP and can be used to deliver "sigh" breaths and maintain lung expansion.

High-frequency jet ventilation is similar to CMV in that inspiration is active and expiration is passive, meaning that exhaled gas flow results from the elastic recoil of the lungs. Theories of gas exchange during HFJV suggest that there may be some facilitation of expiratory gas flow by countercurrent energy imparted by the inspiratory flow. HFJV rates range from 240-660 breaths per minute; most commonly, rates of 360-450 are used in clinical practice. Inspiratory time is usually set at 0.02 seconds (20 msec). Gas volumes delivered during HFJV are considerably smaller than those delivered during CMV.[57]

Different strategies for using HFJV have been proposed for different diseases. A "low pressure" strategy is adopted for conditions in which air leak is the predominant pathophysiology. Here, the use of lower PIP allows for healing. If oxygenation is problematic, higher PEEP or more CMV support can be offered. The "optimal volume" strategy is used for conditions in which there is a tendency for the alveoli to collapse, such as RDS. HFJV is used to optimize the lung volume and improve ventilation/perfusion matching. Clinicians must be aware that because two ventilators are being used, there are usually two oxygen blenders, and both must be adjusted when a change in the fraction of inspired oxygen is made.

Clinical experience has demonstrated that HFJV is superior to rapid rate IMV in the management of preterm infants with pulmonary interstitial emphysema.[59] It has also been used to treat other types of intractable air leaks, such as esophageal atresia/tracheoesophageal fistula complicated by RDS.[35] One trial comparing HFJV to IMV for the early management of RDS showed less oxygen dependency at discharge when HFJV was used.[60]

High-Frequency Oscillatory Ventilation

This is another form of HFV. Its major distinguishing feature is the addition of active exhalation, whereby removal of exhaled gas is facilitated by negative pressure applied during expiration. Typical rates vary between 8 and 15 Hz (480-900 breaths per minute). Depending upon the nature of the device, I:E ratios vary from 1:1 to 1:2, and the clinical implication is that inspiratory times and tidal volumes are very short and small, respectively.

The general principles of mechanical ventilation also apply to the oscillator. Mean Paw is used to inflate the lung and recruit alveoli for oxygenation. This may be thought of as continuous distending pressure, because the lung remains inflated throughout the respiratory cycle. Ventilation is accomplished by adjusting the amplitude, which in turn regulates gas delivery during inspiration and gas removal during expiration.

High-frequency oscillatory ventilation has been used both as a primary strategy for the initial treatment of respiratory failure and as a rescue strategy for infants who fail to respond to CMV. Some centers prefer to wean and extubate directly from HFOV, whereas others prefer to transition to and wean from CMV. HFOV appears to be the best way to deliver inhaled nitric oxide because of its ability to recruit lung volume and match ventilation and perfusion.

The major drawback to HFOV is the inability to monitor the baby as closely as is possible with CMV. Proper settings are verified by blood gases, the degree of lung expansion on the chest radiograph, and by an assessment of chest wall movement during HFOV, referred to as the *chest wiggle factor*. Because intrathoracic pressure can be high, close attention needs to be paid to cardiac output and perfusion. In addition, care must be taken to avoid gas trapping in babies requiring a high amplitude for adequate ventilation, which can result in the collapse of the smaller airways, described as "choke points," during active exhalation.[17]

Monitoring of Ventilated Infants

Babies requiring assisted ventilation require close monitoring to assess underlying lung pathology, response to treatment, and surveillance for associated complications. Monitoring may be considered in five broad categories: (1) clinical evaluation; (2) assessment of gas exchange; (3) chest imaging; (4) pulmonary function and pulmonary mechanics testing; and (5) extrapulmonary monitoring, such as echocardiography and indicated imaging studies to screen for complications known to contribute to mortality and morbidity in ventilated infants.

Clinical Evaluation

Clinical examination of the cardiorespiratory system includes observations for general physical condition, chest

wall movement, equality of air entry, and the presence of abnormal sounds such as rales, rhonchi, or heart murmurs. The clinician must evaluate the interaction between positive-pressure ventilation and the baby's spontaneous breaths to detect asynchrony, which can interfere with gas exchange and lead to gas trapping and air leaks. Rapid, shallow breathing and the presence of subcostal/intercostal retractions in ventilated babies may suggest air hunger or increased work of breathing, which can be corrected by adjustments of ventilator parameters. A hyperactive precordium, tachycardia, easily felt peripheral pulses, and the presence of a cardiac murmur appearing on day two or three suggests a left-to-right shunt through a patent ductus arteriosus. In contrast, right-to-left shunting causing cyanosis (and desaturation on pulse oximetry) suggests persistent pulmonary hypertension of the newborn. Assessment of cardiac function, blood pressure, and tissue perfusion is an important part of evaluation, because they have a direct effect on the respiratory status. Blood pressure measurements should be interpreted in conjunction with other indices of tissue perfusion, such as capillary refill time, acid-base status, urinary output, and echocardiographic evaluation of myocardial contractility and cardiac output.[40] Bedside transillumination by a bright fiberoptic light source applied to the chest wall is a useful and effective way to detect pneumothorax, pneumomediastinum, and pneumopericardium, which may require urgent attention.[28] Other systemic clinical evaluation includes examination of abdomen for tenderness or distension and an assessment of the neurologic status by assessing the tone, posture, and movement.

Assessment of Gas Exchange

Blood Gases and Acid-Base Balance

Clinical interpretation of blood gases alone conveys relatively little information and must be interpreted in a clinical context, taking into account factors such as the work of breathing, recent trends, and the stage of illness. For example, a $Paco_2$ of 65 mm Hg is a genuine source of concern in an infant in the first few hours of life, but may be perfectly acceptable in an infant who is chronically ventilated for bronchopulmonary dysplasia (BPD). There is also a wide range of "normal" blood gas values, depending upon gestational age, postnatal age, source (arterial, venous, or capillary), and disease state. In most infants with respiratory disease, the goal is not to make blood gases entirely normal but to keep them within a target range appropriate for the clinical status.[25]

Analysis of gas exchange also requires an understanding of respiratory physiology. Oxygenation is dependent on ventilation-perfusion matching, whereas movement of CO_2 from the blood into the alveoli is dependent on alveolar ventilation (the product of alveolar tidal volume and respiratory rate). The pH of arterial blood is determined primarily by $PaCO_2$, lactic acid (produced by anaerobic metabolism), and buffering capacity, particularly serum or plasma bicarbonate and plasma hemoglobin concentration.

Arterial blood gases remain the gold standard for assessment, but analysis can only be performed intermittently. Moreover, arterial catheters are invasive, and intermittent arterial sampling requires skill and is painful for the patient. These limitations have led to increasing acceptance of noninvasive techniques, such as transcutaneous oxygen monitoring ($tcPO_2$) and oxygen saturation monitoring using pulse oximetry (see Chapter 37). There are no data to show that any one method is superior. A $tcPO_2$ value of more than 80 mm Hg is associated with a higher incidence of retinopathy of prematurity. A correlation between $tcPO_2$ and pulse oximetry (SpO_2) showed that oxygen saturation above 92% carries a risk of hyperoxia and thus an increased risk of retinopathy of prematurity (ROP) in preterm babies receiving supplemental oxygen.[103] One disadvantage of pulse oximetry is that it is not reliable in cases of severe hypotension or marked edema. Pulse oximeters measure either functional saturation or fractional saturation, which are device specific. Before interpreting an SpO_2 reading, the quality of signal should be assessed by observing the accompanying arterial pulse waveform. Interpretation also needs to take the signal averaging time into consideration. Long signal averaging times may result in the failure to detect brief periods of desaturation or the interpretation of a cluster of short events as a single, prolonged episode, overestimating the incidence of longer episodes.[104]

A recent technological advance has been closed-loop control of oxygen delivery to ventilated infants. This device controls the fraction of inspired oxygen based on a value derived from the pulse oximeter. If saturation falls, the device increases the oxygen concentration to bring the saturation back to the desired range. Conversely, if the saturation is too high, the oxygen concentration will be lowered to avoid hyperoxia. In a multicenter trial evaluating the short-term use of the device, with infants serving as their own controls, a greater proportion of time was spent in the desired range during automatic control. Importantly, there was a highly statistical reduction in the number of manual interventions required during the automated phase.[18] Although not yet approved for use in the United States, the device is gaining widespread acceptance in Europe.

The ventilatory parameters that affect oxygenation include FiO_2, PIP, PEEP, inspiratory time, tidal volume, and flow rate. Persistent hypoxemia despite appropriate adjustments in ventilatory parameters may indicate inadequate pulmonary blood flow or perfusion or right-to-left shunting. Another important factor that affects arterial oxygen tension is altitude, and this is relevant to air transport of sick babies.

Transcutaneous partial pressure of carbon dioxide ($tcPCO_2$) can be measured noninvasively and continuously using a special skin electrode. One of the factors influencing measurements is sensor temperature, which is optimal at 42°C. If $tcPCO_2$ is used in combination with a $tcPO_2$ sensor, a sensor temperature of 44°C can be used without jeopardizing the precision of the $tcPCO_2$ measurement. Measurements of $tcPCO_2$ are relatively independent of sensor site

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

and skin thickness. $tcPCO_2$ may be falsely high in severe shock, and precision may be affected if $PaCO_2$ is more than 45 mm Hg and/or arterial pH is less than 7.30, but there is no systemic over- or underestimation of $PaCO_2$ under these conditions. Sensitivity of $tcPCO_2$ in detecting hypercapnia and hypocapnia is 80%-90%.

Base Deficit

In the healthy term infant, the base deficit is usually 3-5 mEq/L. However, base deficit can vary significantly. In patients with a base deficit between 5 and 10 mEq/L, assuming reasonable tissue perfusion, no acute intervention is generally needed. However, a base deficit greater than 10 mEq/L should prompt a careful assessment of the infant for evidence of hypoperfusion. In most cases, correcting the underlying cause of metabolic acidosis is far more effective and less dangerous than administering sodium bicarbonate.

Capnometry or End-Tidal Carbon Dioxide Monitoring

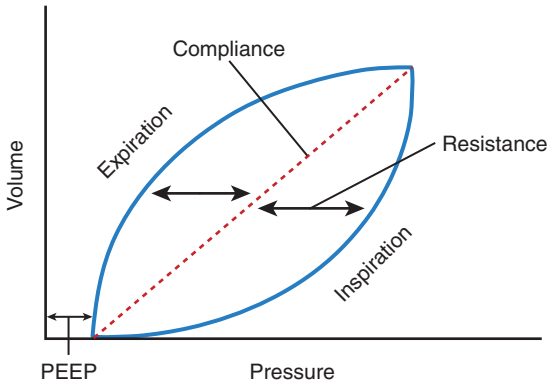
End-tidal carbon dioxide ($ETCO_2$) is an alternative method of measuring carbon dioxide and is called *capnometry*.[117] Depending on the gas-sampling techniques, devices are either mainstream or sidestream capnometers. Capnometry measurements are less reliable than $tcPCO_2$ monitoring, especially when the ventilation-perfusion relationship is not uniform within the lungs, as in infants with RDS or persistent pulmonary hypertension of the newborn.

Partial pressure of CO_2 is affected by minute ventilation, which in turn is the product of tidal volume and frequency during CMV. Of these two parameters, adjustment in tidal volume (by adjusting the amplitude) has a more predictable effect on minute ventilation changes.

Radiography and Other Chest Imaging

Chest radiography is the most commonly used imaging modality on neonatal intensive care units, both for diagnosing and following the course of a disease process. However, the specificity of chest radiography is poor and should always be interpreted in context with clinical information. The findings on chest radiographs are mostly suggestive of pathology and are not always diagnostic.

Ultrasound is a very popular imaging modality because of its portability and scope of repeated examination without any ionizing radiation. Although use of ultrasound for diagnosis of primary respiratory disorders is limited, it can be used to evaluate diaphragmatic excursion and position in suspected cases of phrenic nerve paresis or paralysis. It may also be useful in assessing lung fluid dynamics and differentiating pulmonary edema from atelectasis. Computerized tomography and magnetic resonance imaging have limited use in the neonatal intensive care unit because of practical difficulties but are helpful in certain conditions such as congenital pulmonary adenomatoid malformation, pulmonary sequestration, or complex congenital heart disease when there is insufficient information from echocardiography (e.g., total anomalous pulmonary venous return). Color Doppler echocardiography is now routinely used for assessment of cardiac function and hemodynamic assessment, which may impact the respiratory status in ventilated infants.



Real-Time Pulmonary Graphic Monitoring

Real-time graphic analysis of pulmonary mechanics in infants receiving assisted ventilation has emerged as a valuable tool to aid clinical decision making.[29] A working knowledge of pulmonary mechanics also improves understanding of pulmonary physiology and pathophysiology. Pulmonary mechanics monitoring consists of measurements of several parameters that define different aspects of lung function. Specifically, clinicians are interested in the *pressure* necessary to cause a *flow* of gas to enter the airway and increase the *volume* of the lungs. From these variables, several other measures of pulmonary mechanics can also be derived, such as pulmonary *compliance* (Fig. 65.7) and *resistance*, and resistive work of breathing (energetics). From this information, displayed as either numerical values or graphic representations, useful information can be obtained and used for diagnosing specific lung pathology, evaluating the disease progression, and determining the response to therapeutic interventions. Besides assessment of acute respiratory distress and evaluation of mechanical ventilation, other potential benefits of pulmonary graphics include assessment of suitability for weaning and the objective determination of the efficacy of pharmacologic treatments.

The two representations of pulmonary graphics most commonly used in clinical practice are waveforms and loops. Both patterns display the relationships between pressure, volume, and flow and time.

Volume and Pressure Waveforms

Measurement of tidal volume is becoming increasingly important in ventilatory management. The desired inspiratory tidal volume for a ventilated breath ranges from 4-7 mL/kg; for spontaneous breaths, a tidal volume of 3-4 mL/kg generally indicates suitability for weaning or

• **Fig. 65.7** Schematic representation of a pressure-volume loop denoting derivation of dynamic compliance and features of the relationship between pressure, volume, and time.

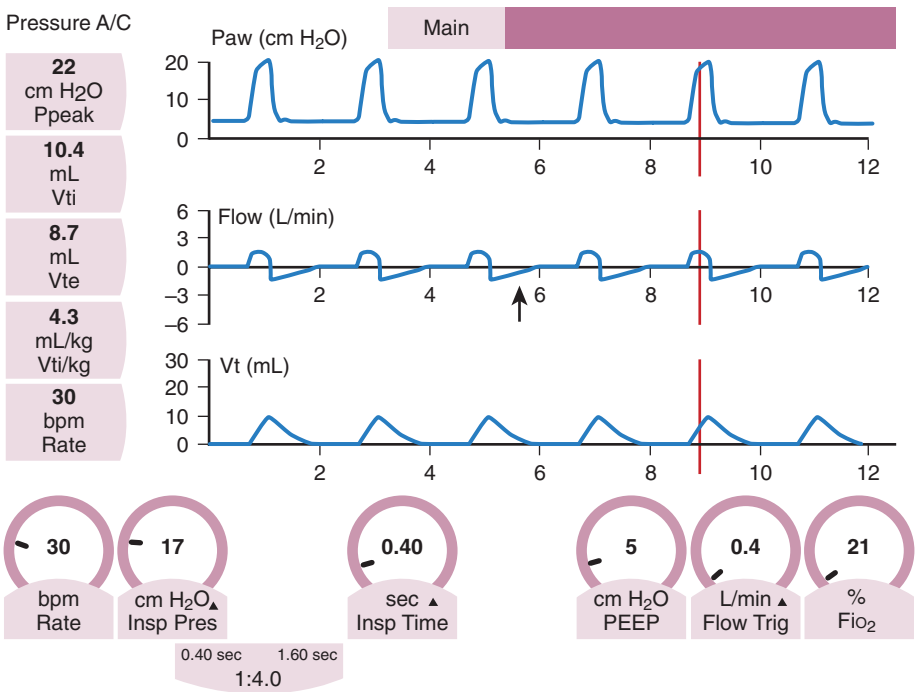
extubating. Minute ventilation (tidal volume × frequency) is another predictor of weaning, especially in small infants who have short inspiratory times and a higher frequency. Normal values are generally between 240 and 360 mL/kg/min. Breath-to-breath variability and longer-term trends are useful in selecting the mode and modality of ventilation and designing individualized strategies based on pulmonary pathophysiology.

Flow Waveform

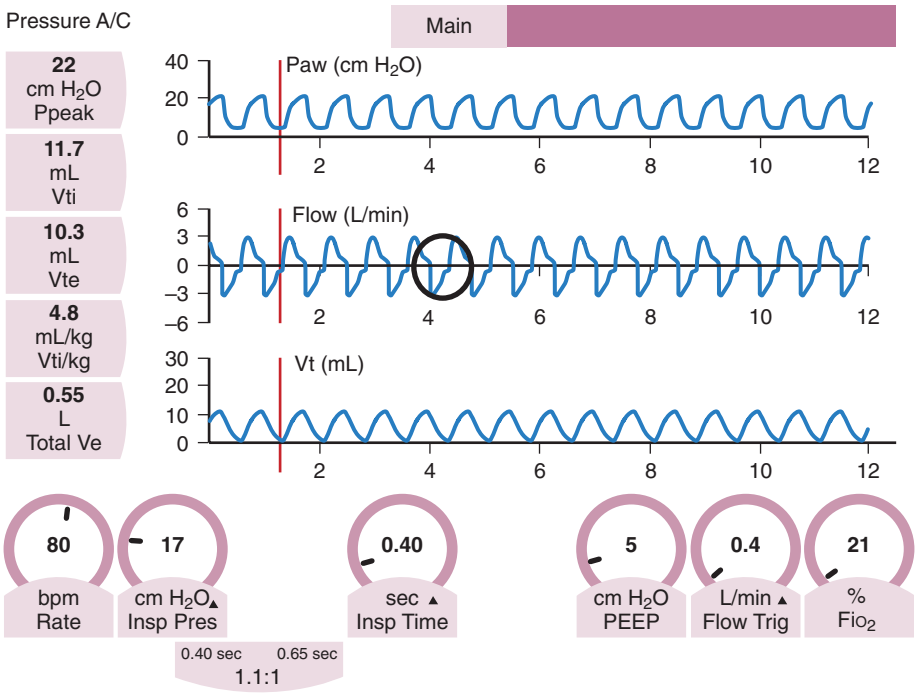
Flow is the volume of gas delivered per unit of time. Inspiratory flow is plotted above (positive) and expiratory flow is plotted below the abscissa (negative). The duration and shape of the inspiratory and expiratory flow waveforms are affected by many factors, including type of ventilation, I:E ratio, impedance and resistance to gas flow (Fig. 65.8), and the effect of therapeutic agents such as bronchodilators. The flow waveform can be used to determine if gas trapping is present (Fig. 65.9).



Pulmonary Mechanics (Loops)

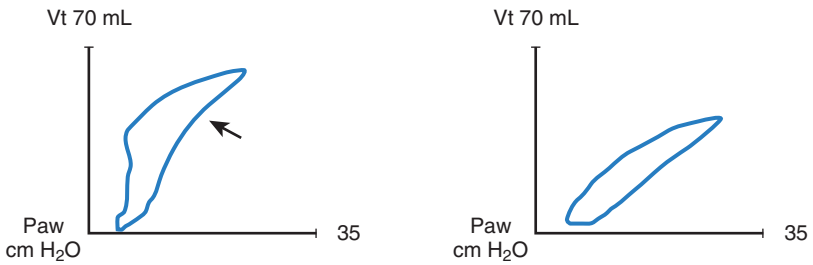
Loops are commonly used to demonstrate correlations between airway pressure and volume, and airflow and lung volume (see Chapter 63). Pressure-volume (P-V) loops graphically depict the correlation between the ventilator inspiratory pressure and the volume of gas entering the lungs on a breath-to-breath basis. A line connecting the points of zero flow (the changeover from expiration to inspiration) is the compliance axis, and the slope of this line reflects pulmonary compliance (a measure of the change in volume per unit of added pressure). An estimate of compliance can be made by looking at the slope of the compliance axis; a 45-degree slope indicates a compliance of 1.0. If this slope is more toward vertical, compliance is improving, and conversely, if the axis moves nearer to horizontal, compliance is decreasing. Be sure that the scale of each axis is equal.

Increased resistance, as is seen in conditions such as meconium aspiration syndrome and BPD, causes a bowing around the compliance line and is an indirect measure of the work of breathing, which can be estimated by the P-V loop and the area to its left, as measured from the highest point. The P-V loop may also be used to determine the optimal PEEP. Pressure-volume loops that appear "boxlike" indicate the need for a higher opening pressure, and the shape can be normalized by increasing the PEEP and PIP. Another potentially dangerous condition, lung hyperinflation, can also be detected graphically (Fig. 65.10).



Another valuable measurement is resistance. This can be assessed by observing the flow-volume (F-V) loop, which graphically displays the relation between change in volume and change in airflow (Fig. 65.11). A normal flow-volume loop should be rounded or oval and should appear symmetrical with respect to the abscissa. Identification and measurement of endotracheal tube leaks is possible with graphic monitoring. Increased resistance and turbulent gas flow from excessive condensation in the ventilator circuit or secretions in the airway can also be identified by the appearance of a noisy flow signal.

It should be realized that graphic monitoring is largely pattern recognition and should be used to trend data. Appropriate scaling of axes is crucial to proper interpretation. However, if properly calibrated, the real-time



• **Fig. 65.8** Flow waveform demonstrating increased expiratory resistance. Note the decreased peak expiratory flow and the prolonged time to return to baseline (*arrow*).

breath-to-breath view of pulmonary mechanics and respiratory waveforms allows the clinicians to fine-tune ventilator settings and provides constant surveillance for many potential complications such as gas trapping and lung overdistension before they become clinically apparent. Endotracheal tube leaks may also be detected graphically (Fig. 65.12).

Complications of Assisted Ventilation

Airway

Placement of an endotracheal tube into the airway can potentially damage the mucosal and submucosal tissues, causing injury that can obstruct gas exchange, lead to other functional disabilities, and create cosmetic deformities. Some of these are idiosyncratic, whereas others relate to the duration of ventilation, frequency of intubations, and associated complications such as infection. (Box 65.8 lists complications of assisted ventilation.)

Upper Airway

Procedural complications of endotracheal intubation are generally traumatic in nature and result from mechanical damage to structures in the naso- or oropharynx, trachea, and larynx. These injuries include superficial mucosal erosion, damage to the alveolar ridge (with subsequent dental problems),[75] perforation of the esophagus or trachea,[85,98] injury to the vocal cords,[114] and injury related to fixation devices such as tape. Long-term nasotracheal intubation may cause erosion of the nasal septum and nasal deformities.[46] Acquired palatal grooves[39] and even cleft palate[38] have been described after long-term orotracheal intubation.

Trachea

Less serious problems, which tend to resolve spontaneously over time, include tracheal and laryngeal mucosal metaplasia, subglottic cysts, tracheal enlargement, and tracheobronchomalacia. The latter is being increasingly recognized by the pediatric pulmonary follow-up of former preterm infants with lung injury.[52] Subglottic stenosis is a life-threatening condition generally requiring tracheostomy. Its etiology is still not completely understood, but associations have been demonstrated for duration of intubation, number of intubations, and the degree of prematurity.[87] Necrotizing tracheobronchitis was another highly lethal acquired entity.[10] This disorder was seen most commonly in the early days of HFJV and was felt to be related to the effects of insufficient humidification of inspired gas. It has all but disappeared since refinements in humidification systems.

Lungs

Ventilator-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is a disease entity defined as pneumonia characterized by the presence of new and persistent focal radiographic infiltrates in a ventilated infant appearing more than 48 hours after admission to the neonatal intensive care unit (see Chapters 48 through 50).

Ventilator-associated pneumonia is a commonly observed complication in babies requiring mechanical ventilation. It

• BOX 65.8 Complications of Assisted Ventilation

Airway

Upper Airway

- Trauma
- Abnormal dentition
- Esophageal perforation
- Nasal septal injury (nasotracheal tubes)
- Acquired palatal groove (orotracheal tubes)

Trachea

- Tracheal and laryngeal mucosal metaplasma
- Subglottic cysts
- Tracheal enlargement
- Tracheo-bronchomalacia
- Tracheal perforation
- Vocal cord paralysis/paresis
- Subglottic stenosis
- Necrotizing tracheobronchitis

Lungs

- Ventilator associated pneumonia (VAP)
- Air leaks
  - Pneumomediastinum
  - Pneumothorax
  - Pulmonary interstitial emphysema
  - Pneumopericardium
  - Pneumoperitoneum (trans-diaphragmatic)
- Ventilator induced lung injury (VILI)
- Bronchopulmonary dysplasia (chronic lung disease)

Miscellaneous

- Imposed work of breathing
- Patent ductus arteriosus

Neurologic

- Intraventricular hemorrhage (IVH)
- Periventricular leukomalacia (PVL)
- Retinopathy of prematurity (ROP)

results from either dissemination of micro-organisms from colonized mucosal sites or aspiration of gastric contents. Repeated and prolonged endotracheal intubation, as well as suctioning, can disrupt mucosal integrity and promote dissemination. Occasionally microorganisms may be transmitted from contaminated equipment. The reported incidence of VAP is 0.3-1.6 cases per 1000 ventilator days in Level 2 and 3 NICUs in the United States.[51] A number of risk factors and associations have been identified, including prematurity; use of corticosteroids, H2 blockers, antacids, and proton pump inhibitors; overcrowding; understaffing; and inadequate disinfection of equipment.

One should suspect VAP in a ventilated infant if there is deterioration in the respiratory status unexplained by other events or conditions. Blood cultures may or may not be positive in infants with VAP. Sepsis and/or pneumonia should also be considered when there is unexplained temperature instability, hyper- or hypoglycemia, acidosis, feeding intolerance, or abdominal distension. Radiographic findings are nonspecific and may be difficult to distinguish from chronic lung disease in the older baby. Bacterial and fungal pathogens are the most common agents. Tracheal aspirates for culture are not helpful in the diagnosis of pneumonia and may merely reflect colonization. Laboratory investigations such as abnormal blood counts and elevated acute phase reactants such as CRP suggest the diagnosis of sepsis/pneumonia.[51]

Management of VAP includes broad-spectrum antibacterial and/or antifungal agents, hemodynamic support, and provision of adequate nutrition. Respiratory support should be maintained as necessary. If hypoxemia is refractory despite maximal ventilatory support, consideration should be given to use of inhaled nitric oxide and/or extracorporeal membrane oxygenation for term and late-preterm infants, if they meet criteria. Benefit from the use of additional surfactant is unproved, but anecdotal reports suggest efficacy with preparations that contain surfactant proteins A and D. A study by Aly et al. suggests that more frequent positioning of babies on their sides, as opposed to supine, may decrease the incidence of VAP.[3]

Air Leaks

Thoracic air leaks are collections of pulmonary gas residing outside the pulmonary air spaces. They include pneumothorax, pneumomediastinum, pneumopericardium, pulmonary interstitial emphysema (PIE), pneumoperitoneum, and subcutaneous emphysema. Pneumothorax often results from high inspiratory pressure and unevenly distributed ventilation. The ventilator parameters that are contributory to the development of pneumothorax include: (1) a prolonged inspiratory time and/or an inversed I:E ratio, (2) high PIP or mean Paw, (3) high flow rates, and (4) patient-ventilator asynchrony. There is also higher incidence of pneumothorax in the presence of certain disease conditions, such as meconium and other aspiration syndromes, cystic fibrosis, and pulmonary hypoplasia, which are characterized by uneven lung compliance and alveolar overdistension.

Pneumothorax in patients receiving positive-pressure ventilation can manifest in three ways: (1) asymptomatic, where it is first detected on a routine chest radiograph without or with subtle clinical signs; (2) deterioration in laboratory or bedside monitoring findings, without an obvious change in the patient's clinical condition, but is suspected because of worsening blood gases and increasing ventilatory requirements; and (3) acute clinical deterioration with tension, which is the most common presentation in ventilated infants. Infants with tension pneumothorax present with agitation and increasing respiratory distress, hypotension, and other signs of cardiovascular collapse. Auscultation of the chest reveals diminished or absent breath sounds on the affected side, with a contralateral shift of heart sounds and the point of maximum impulse. Breath sounds on the contralateral side may also be decreased as tension worsens and compresses the unaffected lung. Arterial blood gases may show respiratory or mixed acidosis and hypoxemia. Transillumination will reveal increased

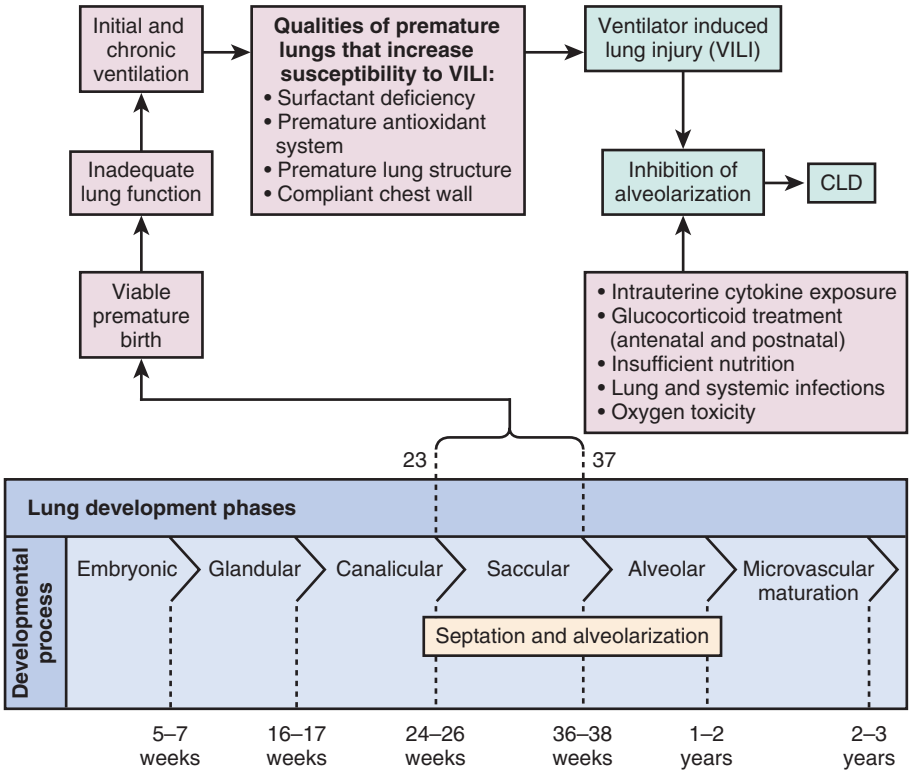
transmission of light on the involved side. Chest radiography is confirmatory. Tension pneumothorax is a medical emergency and requires prompt treatment. Needle aspiration (thoracentesis) can be used as a temporizing measure but generally needs to be followed by placement of a chest tube (thoracostomy) for resolution. Smaller gas collections may resolve spontaneously without further intervention but are likely to recur with ongoing mechanical ventilation.

The incidence of pneumothorax has diminished over the years. This may be related to a number of factors, including antenatal corticosteroid treatment, surfactant therapy, and the increased use of prenatal ultrasound, which has enabled the diagnosis of conditions such as congenital diaphragmatic hernia and pulmonary hypoplasia with predisposition to pneumothorax. Various ventilatory strategies have also been employed to reduce the risks of air leak. Rapid rate IMV (>60 breaths/min) has been utilized to decrease inspiratory time and the duration of positive pressure (and hence tidal volume) and to produce less asynchronous breathing. However, rapid-rate ventilation can also cause inadvertent PEEP and gas trapping. Synchronized ventilation, such as SIMV or A/C, may reduce the incidence of air leak by avoiding patient-ventilator asynchrony. The use of flow cycling enables complete synchronization, even during expiration. In rare instances, neuromuscular paralysis may be needed when a patient is actively "fighting" the ventilator despite adequate sedation.

Pulmonary interstitial emphysema often precedes the development of pneumothorax and can be localized or widespread throughout one or both lungs. It develops when the most compliant portion of the terminal airway ruptures, allowing gas to escape into the interstitial space. Gas may accumulate in the interstitium, compressing both the airway and adjacent alveoli. PIE alters pulmonary mechanics by decreasing compliance, increasing resistance, contributing to gas trapping, and increasing ventilation-perfusion (V/Q) mismatch; it also impedes pulmonary blood flow. Diagnosis is based on the chest radiograph, which shows fine linear or radial radiolucencies. Unilateral PIE that is less severe may respond to decubitus positioning. Left-sided PIE may be alleviated by selective intubation of the right main bronchus if the infant can tolerate single lung ventilation. Management of generalized PIE should aim to reduce inspiratory time and/or pressure. An often used strategy is to increase the PEEP in an attempt to stent the airways and allow more complete emptying of the alveoli during expiration. Alternatively, HFJV has been shown to decrease time to resolution and to improve survival in VLBW infants compared to rapid-rate IMV.[59]

Pneumomediastinum is usually of little clinical importance and usually does not need to be drained. However, its presence should alert the clinician of an increased risk for subsequent symptomatic air leaks. Symptomatic infants are often placed in 100% oxygen for up to 24 hours (nitrogen washout). Although this may make the infant more comfortable and potentially decrease the air leak, there is no evidence to support the practice.

Pneumopericardium occurs when air from the pleural space or mediastinum enters the pericardial sac through a defect that is often located at the reflection near the ostia of pulmonary veins. The diagnosis should be suspected from rapid clinical deterioration, which includes respiratory compromise and cardiovascular collapse, with a narrow pulse pressure and diminished perfusion. It can be diagnosed by transillumination and confirmed by radiography, which shows the air completely encircling the heart. Cardiac tamponade is a life-threatening event and requires immediate drainage. Needle aspiration (pericardiocentesis) via the subxiphoid route may be used to drain the air as a temporizing measure, but a pericardial drain is usually necessary. The majority of cases occur in infants ventilated with high PIP, high mean Paw, and long inspiratory times.



Pneumoperitoneum usually results from rupture or perforation of an abdominal viscus, but on rare occasions, gas from a thoracic leak can dissect trans-diaphragmatically to an abdominal location. Recognition of this phenomenon can avoid an unnecessary laparotomy. A sample of the abdominal gas may be aspirated by abdominal paracentesis and analyzed for its oxygen concentration (provided the baby is receiving more than room air). If the FiO_2 is greater than 0.21, the likely source is thoracic.

Ventilator-Induced Lung Injury

Despite the introduction of advanced ventilatory techniques based on sound physiologic principles, the incidence of chronic lung disease remains unacceptably high among babies who require mechanical ventilation, particularly for those born extremely prematurely. Bronchopulmonary dysplasia is multifactorial and involves a number of overlapping factors, such as prematurity, oxidant injury, inflammation, and injury related to mechanical ventilation, referred to as ventilator-induced lung injury (VILI).[5]

Various terms, such as *the pulmonary injury sequence*, have been used to describe the individual components of VILI (Fig. 65.13); these are interrelated and likely to act synergistically to damage the developing lung as part of the sequence.[5] Barotrauma, or excessive pressure, may disrupt airway epithelium and alveoli. Volutrauma refers to injury related to overdistension or stretching of the lung units by delivering too much gas. Atelectrauma refers to the damage caused by the repetitive opening and closing of the lung units (the cycle of recruitment and subsequent derecruitment). *Biotrauma* is a collective term to describe infection and inflammation, as well as the role of oxidative stress on the delicate tissue of the developing lung. *Rheotrauma* refers to damage evoked by inappropriate airway flow. If flow is excessive, inefficient gas exchange, inadvertent PEEP, turbulence, and lung overinflation may occur. On the other hand, if flow is inadequate, it may lead to air hunger (flow starvation) and increased work of breathing. The cumulative effect of both endogenous and exogenous insults to the developing lung is a reduction in alveolarization and diminished pulmonary surface area capable of effective gas exchange.

Mechanisms of ventilator-induced lung injury in premature infants. *Sem Neonatol*. 2002;7:353-360. Copyright, Elsevier Science Ltd, with permission).

With the introduction of newer techniques of mechanical ventilation, including pulmonary graphic monitoring, clinicians have now initiated strategies to avoid VILI. Monitoring of tidal volume delivery, irrespective of whether the target variable is volume or pressure, has become much more important in recent years. Indeed, delivering a physiologic tidal volume during conventional ventilation seems prudent. Of equal importance is the ability to customize ventilator settings to the specific needs of the patient.[33]

Bronchopulmonary Dysplasia (Chronic Lung Disease)

Despite high utilization of antenatal steroids, surfactant replacement therapy, and newer ventilation techniques, chronic lung disease remains the major problem of neonatal intensive care (see Chapter 69). Bronchopulmonary dysplasia is a severe form of chronic lung disease and is generally characterized by the presence of chronic respiratory insufficiency, a supplemental oxygen requirement, and an abnormal chest radiograph at 36 weeks' postmenstrual age. When Northway et al. originally described BPD in 1967, the affected infants ranged from 32-39 weeks' gestation and weighed 1474-3204 g at birth. Most had required high airway pressures and significant concentrations of supplemental oxygen. Their chest radiographs showed typical overinflation and cystic emphysema. More than a quarter of a century later, the demographics of BPD have changed. It occurs in more immature and very low birth weight babies who required only modest supplemental oxygen and ventilatory support. Their chest radiographs are also different and are characterized by diffuse haziness and a fine, lacy pattern. Infants with the "new" BPD do not seem to have had typical RDS, and many do not require ventilation during the first few days of life.[7]

Because BPD is associated with mechanical ventilation, some have advocated for the avoidance of assisted ventilation and the alternative use of noninvasive respiratory support such as NIPPV or NCPAP. However, randomized controlled trials that included more than 3000 preterm babies and compared noninvasive forms of respiratory support to mechanical ventilation through an endotracheal tube have not shown any reduction in either death or BPD, which were the primary outcome measures of these trials.[73,74,100,101] Attempts have also been made to use "gentler" ventilation by allowing "permissive hypercapnia" as a protective lung strategy.[71] The rationale for permissive hypercapnia is that by using less ventilation, there may be less volutrauma, a reduction of the duration of positive-pressure ventilation, and decreased alveolar ventilation. Although the secondary goals appear to be achievable, this approach has thus far failed to show a reduction in the incidence of BPD. In addition, it is very difficult to accomplish in the era of patient-triggered ventilation, because the baby with intact chemoreceptors will increase his minute ventilation to try to achieve normocapnia.

There is compelling evidence that excessive tidal volume causes lung injury, so targeting tidal volume in a normal range (4-6 mL/kg) is gaining support within the neonatal community. In one randomized clinical trial, babies receiving volume-controlled ventilation were shown to have a trend toward reduction in BPD compared with those managed with pressure-limited ventilation.[89] A 20-month follow-up study of these infants also showed a reduced frequency of respiratory symptoms and need for treatment in the babies who had received volume-controlled ventilation.[88] This has been confirmed in a subsequent meta-analysis.[80]

High-frequency ventilation is often used as an alternative to conventional ventilation, and there is a large pool of data, both from animal and human studies, suggesting that this form of ventilation may have an advantage over conventional tidal ventilation in reducing lung injury. However, the cumulative evidence from clinical trials does not show a reduction in BPD.[65,96]

Unfortunately, clinical investigation has not yet demonstrated a beneficial effect from any form of ventilation in preventing lung injury associated with mechanical ventilation. This may be the result of a number of other factors, including the underlying immaturity of the lung itself, which is more susceptible to the damaging effects of extrinsic factors.

Miscellaneous Complications

Imposed Work of Breathing

Infants placed on mechanical ventilation assume additional burdens of breathing. First, there is an increase in airway resistance because of the placement of the narrow lumen endotracheal tube. Resistance to airflow is proportional to the fourth power of the radius of the tube and is linearly related to tube length. Second, there is an increase in dead space created by tubing and connectors. Finally, if a demand system is used, there is effort required to open the demand valve. Collectively, these have been referred to as the imposed work of breathing, primarily affecting spontaneous breaths taken by the baby between mechanical breaths. These spontaneous breaths are supported only by PEEP, unless the baby is receiving assist/control or pressure support ventilation, which was developed to overcome the imposed work of breathing and enhance patient comfort and endurance.

Patent Ductus Arteriosus

Patency of the ductus arteriosus (PDA) is a common problem in preterm infants. Its incidence varies inversely with gestational age and may be as high as 60% in infants less than 28 weeks' gestation (see Chapter 74). Its relationship to lung disease and mechanical ventilation is well established. Preterm infants have an immature closure mechanism, decreased sensitivity to normal constrictors such as oxygen tension, and increased sensitivity to prostaglandin-E_2, all of which promote patency. Other factors that have been associated with a PDA include severe lung disease, exogenous surfactant therapy, phototherapy, high fluid administration, early use of furosemide, and lack of antenatal glucocorticoid exposure.

The pathophysiologic effects of a PDA are determined by the direction of shunting. When pulmonary vascular resistance is high, such as with early RDS or meconium aspiration syndrome, shunting will be in a right-to-left direction, resulting in mixing of deoxygenated and oxygenated blood and resultant hypoxemia. When pulmonary vascular resistance is less than systemic vascular resistance, shunting will be left-to-right. Overperfusion of the lungs can alter pulmonary mechanics, causing a need for higher levels of supplemental oxygen and ventilatory support and an increase in the cardiac workload. A diastolic steal may also occur, reducing blood flow to organs and increasing the risk of ischemic complications. Persistent PDA is also associated with increased risks for apnea, BPD, congestive heart failure, and impaired weight gain. Diagnosis and treatment of PDA is discussed in detail in Chapter 74.

Neurologic Complications

Intraventricular Hemorrhage and Periventricular Leukomalacia

Premature babies requiring mechanical ventilation are at increased risk of brain injuries (see Chapters 52 and 53). The spectrum of brain injuries observed in these infants includes periventricular-intraventricular hemorrhage (PV-IVH) and periventricular leukomalacia (PVL). The main reason for the increased susceptibility to hemorrhagic or ischemic brain injuries is the unique anatomical and physiologic immaturity of the brain. Absent or reduced autoregulation of cerebral blood flow creates pressure-passive cerebral circulation and thus renders the brain prone to damage during periods of systemic hypotension and hypertension. Cerebral circulation (and autoregulation) is also affected by changes in $Paco_2$ and to a lesser extent pH. A rise in $Paco_2$ (hypercapnia) during the first 3-4 days of life is a recognized risk factor for PV-IVH. Conversely, hypocapnia (Pco_2 <35 mm Hg) is also potentially dangerous, because it may cause cerebral ischemia and PVL, especially if $Paco_2$ decreases rapidly as can sometimes occur with the institution of HFV. Another recognized risk factor for PV-IVH is the fluctuation in cerebral blood flow observed in babies who fight the ventilator (asynchronous breathing). The use of high PIP or PEEP can result in lung overdistension leading to increased central venous pressure, which is transmitted to cerebral veins. Increased intrathoracic pressure can also decrease venous return to the heart and thus reduce cardiac output. Additional threats to central nervous system function may come from a patent ductus arteriosus, with right-to-left shunting; from focal or systemic infections, which initiate the inflammatory responses associated with white matter damage; and from pneumothorax or PIE, which may also aggravate respiratory failure and hemodynamic function. Concerns also exist that cerebral perfusion may be

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

jeopardized during routine procedures, such as endotracheal tube suctioning or re-intubation.

Retinopathy of Prematurity

Retinopathy of prematurity is a condition confined to the developing retinal vessels in very premature infants (see Chapter 96). The major risk factors for ROP are the degree of prematurity and a high arterial oxygen content. There is a higher incidence of ROP in low birth weight babies who require mechanical ventilation and supplemental oxygen. Hyperoxia, hypoxemia, and fluctuations of arterial oxygen content, even within the normal range, have all been implicated as etiologic factors. Many other risk factors have also been suggested, including vitamin E deficiency, exchange transfusions, necrotizing enterocolitis, treatment for patent ductus arteriosus, and other complications of prematurity. Despite meticulous neonatal care, ROP is not entirely preventable. Maintaining early arterial oxygen tension between 60 and 80 mm Hg and pulse oximetry between 88% and 92% has been shown to reduce the incidence of ROP in babies who receive oxygen treatment. With advancing postnatal age, it has been proposed that a higher target diminishes intermittent hypoxia and the neovascularization process in ROP. Nonetheless, the ideal level of oxygen saturation in ventilated preterm babies remains unknown.

The Neonatal Research Network SUPPORT trial utilized a factorial design to randomize infants between 24 and 28 weeks' gestation to either a higher or lower pulse oximetry range. Although the incidence of ROP was significantly reduced in the lower saturation group, there was a small but statistically significant increase in mortality. The reasons for this are unclear, and the optimal saturation range remains elusive.[100]

Key Points

- Newborn infants with respiratory failure will require ventilatory assistance, which ranges from supplemental oxygen to continuous distending pressure to assisted ventilation.
- No respiratory intervention is without risk to the baby, and it is the obligation of clinicians to minimize risk and maximizing benefit.
- Patients and diseases are all different, and a standard "one size fits all" strategy is no longer appropriate. Therapy must be customized to the individual patient.
- The principles of assisted ventilation are relatively simple. Mean airway pressure impacts oxygenation; amplitude impacts ventilation.
- The present popularity of noninvasive ventilation has not brought about the desired reduction in bronchopulmonary dysplasia. Additional investigation will be necessary to achieve this.

Neonatal Respiratory Disorders

MOIRA A. CROWLEY

Multiple pathophysiologic mechanisms can present with pulmonary manifestations in term and preterm infants. The clinical picture is most commonly dominated by respiratory distress, which presents as tachypnea, grunting, flaring, retractions, cyanosis, and hypoxemia. However, apnea and hypoventilation are also common. In preterm infants, these manifestations are commonly associated with respiratory distress syndrome (RDS) as discussed in Chapter 64. Nonpulmonary etiologies of respiratory distress include thermal instability, circulatory problems, cardiac disease, neuromuscular disorders, sepsis, anemia or polycythemia, and methemoglobinemia (Box 66.1). This section presents an overview of the many other respiratory disorders that can affect preterm and term infants.

Developmental Diseases

Pulmonary Underdevelopment: Pulmonary Agenesis, Aplasia, and Hypoplasia

Abnormal lung development varies from mild hypoplasia, which can either be a primary or secondary defect, to agenesis of a single lobe or whole lung.[21,136] Agenesis of the lung is a rare congenital anomaly defined as the total absence of pulmonary parenchyma, its supporting vasculature, and bronchi after the bifurcation.[20,109] Complete agenesis of the lung is usually unilateral (90%), although dysgenesis of the other lung has been reported.[40] Pulmonary aplasia can be classified as a subset of pulmonary agenesis, defined by the presence of a blind-ending, rudimentary bronchus without associated lung parenchyma or pulmonary vasculature.[18] It has been hypothesized that pulmonary agenesis is vascular in origin, most likely resulting from a disruption of the dorsal aortic arch blood flow during the fourth week of gestation. Although lung agenesis can be an isolated finding, in as many as 50%-76% cases it is associated with other congenital malformations, including urogenital, vertebral, cardiac, and gastrointestinal, as well as malformations of the first and second branchial arch derivatives and radial ray defects.[20,40,133] As a result, pulmonary agenesis has been considered a subset of the VACTERL (*v*ertebral, *a*nal atresia, *c*ardiac defect, *t*racheo-*e*sophageal fistula, *r*enal anomalies, *l*imb anomalies) sequence and Goldenhar syndrome. Malformations of the first and second branchial arches and/or radial ray malformations are the most common malformations associated with pulmonary agenesis, and all cases are ipsilateral to the pulmonary malformation. Those who do not have facial or radial ray anomalies appear to fit the VACTERL association.[40]

Diagnosis is confirmed on antenatal ultrasound by the presence of mediastinal shift in the absence of a diaphragmatic hernia. Antenatal echocardiogram reveals total absence of the pulmonary artery or one of its branches on the affected side. Magnetic resonance imaging (MRI) examination can confirm the diagnosis, evaluate the size of the remaining lung, and evaluate the presence of other congenital malformations. After delivery, diagnosis of infants with unilateral pulmonary agenesis can be suspected by decreased breath sounds and displacement of the mediastinum to the affected side. Some breath sounds, however, may be audible over the affected side if a portion of normal lung, which usually has undergone compensatory hypertrophy, has herniated across the midline into the affected hemithorax. The radiographic appearance of a radiopaque hemithorax helps confirm the diagnosis, and accompanying vertebral defects are not uncommon (Fig. 66.1). Treatment is largely supportive, and the prognosis depends on the presence or absence of other anomalies; those with isolated pulmonary agenesis have better survival.[133]

Pulmonary hypoplasia is the result of deficient or incomplete development of the lung parenchyma leading to decreased number of distal airways, alveoli, and associated pulmonary vessels. It can be classified as either *primary*, caused by intrinsic failure of normal lung development, or *secondary*, caused by a multitude of different pathologic processes that interfere with normal lung development. The pathophysiology of secondary pulmonary hypoplasia includes (1) oligohydramnios secondary to renal malformations, prolonged early amniotic fluid leak, placental abnormalities, or intrauterine growth restriction; (2) space-occupying lesions compressing the lungs and preventing normal growth as seen with congenital diaphragmatic hernia (which is thought to have some evidence of primary pulmonary hypoplasia as well), cystic lung disease, or cardiac malformations with extreme cardiomegaly (e.g., tricuspid

• BOX 66.1 Classification of Extrapulmonary Causes of Respiratory Distress

Neuromuscular Disorders (see Chapter 56)

- Central nervous system: asphyxia, hemorrhage, malformations, drugs, infection
- Spinal cord: cord injury, spinal muscular atrophy
- Nerves: phrenic nerve injury, cranial nerve palsy
- Neuromuscular plate: myasthenia gravis
- Muscular: dystrophies

Obstructive-Restrictive Disorders

- Airway obstruction (see Chapter 68)
  - Intrinsic: choanal atresia, floppy epiglottis, laryngeal web, cord paralysis, laryngospasm, malacia, tracheal stenosis
  - Extrinsic: tubes, secretions, Pierre Robin syndrome, macroglossia, goiter, vascular ring, cystic hygroma, mediastinal and cervical masses
- Rib cage abnormalities
  - Thoracic dystrophies
  - Rickets and bone disease
  - Fractures
  - Pectus excavatum

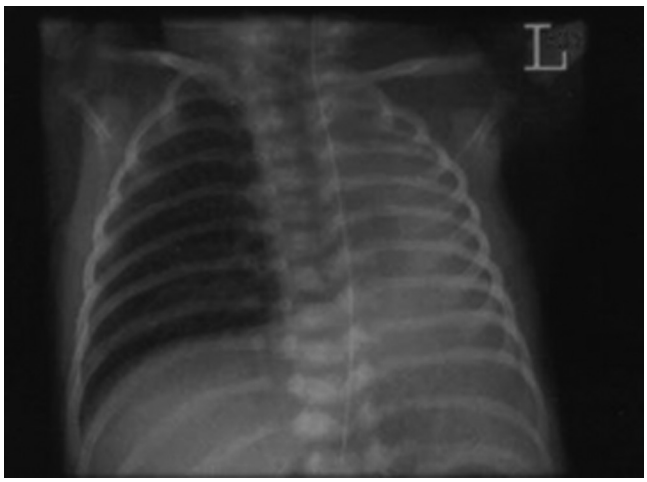
Diaphragmatic Disorders

- Congenital eventration
- Abdominal distention

Hematologic Disorders (see Chapter 79)

- Anemia
- Polycythemia
- Methemoglobinemia

Metabolic Disorders (see Part 15)



- Metabolic acidosis
- Hypoglycemia
- Hypocalcemia

Cardiovascular Disorders (see Part 12)

- Increased pulmonary flow
  - Patent ductus arteriosus
  - Ventricular septal defect
  - Transposition of the great arteries
  - Truncus arteriosus
- Decreased pulmonary flow
- Persistent pulmonary hypertension
  - Pulmonary atresia
  - Tetralogy of Fallot
  - Tricuspid atresia
- Cardiomegaly
  - Tricuspid atresia
  - Ebstein anomaly
- Left heart obstruction (e.g., coarctation, mitral atresia, total anomalous pulmonary venous return)
- Hypotension

Miscellaneous (see Parts 6 and 9)

- Sepsis
- Pain
- Hypothermia
- Hyperthermia

• **Fig. 66.1** Unilateral left lung agenesis. (From Greenough A, Ahmed J, Broughton S. Unilateral pulmonary agenesis. *J Perinat Med*. 2006;34:80, with permission.)

atresia or Ebstein anomaly); and (3) absence or abnormal diaphragmatic activity (which is essential for lung development) resulting from a central or peripheral nervous system disorder or musculoskeletal disease, which can prevent chest wall expansion and breathing movements.

Diagnosis of pulmonary hypoplasia is made pathologically by measuring the lung-to-body ratio; however, this truly only captures those with lethal pulmonary hypoplasia. Methods to diagnose pulmonary hypoplasia antenatally in those fetuses at risk for developing pulmonary hypoplasia because of associated findings have been reported and include the use of prenatal ultrasound techniques, both two- and three-dimensional, as well as fetal MRI. Ultrasound measurement techniques include thoracic circumference (TC) corrected for gestational age or femur length, TC:abdominal circumference ratio, and thoracic:heart area. These techniques, however, measure the thoracic wall rather than lung parenchyma itself and have inadequate positive and negative predictive values to be a reliable tool for predicting pulmonary hypoplasia in isolation. More recently, measurement of lung volume using three-dimensional ultrasound has been reported, but even in the most experienced hands, 8%-48% of cases did not have a calculable lung volume on at least one side.[159] MRI has shown promise in predicting pulmonary hypoplasia, especially in the setting of congenital diaphragmatic hernia (CDH), but seems to be no better for other causes of pulmonary hypoplasia.[159] Pathologic examination of the hypoplastic lung can show a low ratio of lung to body weight, low DNA content, or decreased radial alveolar count. Peripheral bronchioles are decreased in number, as are the pulmonary arterioles, which often exhibit hypertrophy of medial smooth muscle, a predisposition to persistent pulmonary hypertension.

Secondary pulmonary hypoplasia is most commonly encountered in oligohydramnios and congenital

diaphragmatic hernia (CDH). Survival of infants with pulmonary hypoplasia depends on the degree to which lung growth is restricted and the underlying cause of hypoplasia. It is not uncommon for these patients to present with severe respiratory distress associated with bilateral pneumothorax as well as hypoxia from both fixed and reactive pulmonary hypertension. Pulmonary hypoplasia is present in up to 33% of patients with oligohydramnios and can be associated with a high mortality rate (55%-100%) depending on the severity of hypoplasia[100] (see Chapter 24). Patients with pulmonary hypoplasia secondary to prolonged premature rupture of membranes (PPROM) starting in the second trimester have been shown to have a better prognosis than initially expected. In four retrospective series of mid-trimester PPROM (18 0/7 to 24 6/7 weeks' gestation), higher survival rates of 68%-73%[52,102,167] to as high as 90%[22] have been reported. This is thought to be secondary to improved obstetrical (prenatal steroids) and modern neonatal therapies. However, among survivors, 36%-46% had bronchopulmonary dysplasia. Both human and animal studies have shown that some of these infants who present with early severe respiratory failure consistent with pulmonary hypoplasia may benefit from inhaled nitric oxide (iNO).[138,167] Supportive therapy with gentle ventilation is the mainstay of therapy. Serial amnioinfusion has been proposed as a potential therapy to mitigate the effects of oligohydramnios/anhydramnios and pulmonary hypoplasia caused by both PROM and renal abnormalities. When used in the setting of PROM, there is no improved survival,[162] but success has been reported in a few case series when used for renal abnormalities.[16,66] At this time, no randomized control trials exist to prove its efficacy in either case.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) results from a developmental defect during the formation of the diaphragm that permits abdominal contents to herniate into the thoracic cavity. In some cases, the herniated viscera are covered with a membranous sac. Defects of the diaphragm are classified according to the anatomic region of the diaphragm that is defective. The most common defect involves the posterolateral diaphragm (Bochdalek) and accounts for 70% of diaphragmatic hernias. Anterior diaphragm defects (Morgagni) account for 25%-30% of diaphragmatic hernias, and central diaphragmatic defects are rare, occurring in 2%-5% of cases.[84] The incidence of CDH is 1 in 2000-3000 live births, and it occurs most commonly on the left side (85%), whereas bilateral hernias are rare (1%) and usually fatal. In CDH, there are fewer alveoli that have thickened septae, resulting in markedly diminished alveolar airspace and gas exchange surface area. Vascular development parallels that of the airways, thus there also are reduced number of vessels, adventitial thickening, medial muscle hyperplasia, and peripheral extension of the muscular layer into the smaller intra-acinary arterioles, resulting in a fixed increase in pulmonary vascular resistance. Both lungs are affected, the ipsilateral one more than the contralateral one. After delivery, these morphologic changes compromise effective gas exchange, resulting in respiratory failure and pulmonary hypertension.

To explain the severe respiratory failure at birth owing to pulmonary hypoplasia, a *dual hit hypothesis* has been proposed. Traditionally, it was thought that the pulmonary hypoplasia associated with CDH was caused by compression of the lungs by the herniated abdominal viscera during early development. However, as our understanding of the pathophysiology grew, it has been demonstrated that pulmonary development has already been disturbed prior to diaphragm development and before compression from abdominal organs can occur. Thus, the dual hit hypothesis has emerged to explain the severe pulmonary hypoplasia often seen in this condition.[86] The first insult affects both lungs before diaphragm development is complete. The second insult affects the growth of the ipsilateral lung because of compression of that lung by the herniated viscera. The origin of the diaphragmatic defect lies in the disruption of the mesenchymal substrata of the pleuroperitoneal folds, which form the scaffold for the eventual migration of muscular precursor cells into the nascent diaphragm. In human embryology, this would point to a defect as early as 4-5 weeks' gestation, long before the formation of the "muscular" diaphragm.[31,115]

The pathogenesis of CDH and associated pulmonary hypoplasia are slowly being unraveled in part owing to animal models, which have confirmed that developmental regulation of the lung and diaphragm are controlled by some of the same genes. The nitrofen mouse model has proposed that CDH is a result of a disturbance in the retinoic acid pathway. A defect in the retinoid signaling pathway, specifically, inhibition of retinal dehydrogenase-2 (Raldh2), has been proposed as the likely etiology of the embryonic disruption resulting in CDH.[60,63,69,115] However, despite convincing animal data, the use of nitrofen and retinol have not been linked to human CDH.[84]

Congenital diaphragmatic hernia is either an isolated defect or can be associated with other congenital anomalies, including cardiac, urogenital, chromosomal, and musculoskeletal. Most reports estimate that 40%-60% of patients with CDH have non-hernia-related anomalies, designated CDH+.[171] In a review of 3062 patients with CDH, the Congenital Diaphragmatic Hernia Study Group reported a 28% incidence of severe malformations (major cardiac, syndromal, and chromosomal disorders) in patients who did not undergo surgical repair secondary to unsalvageable hernia compared with 7% in repaired patients.[156] In some of these CDH+ infants, the constellation of anomalies suggests a well-described genetic syndrome, the most frequent of which is Fryns syndrome, which has an autosomal recessive inheritance pattern. Another proportion of these CDH+ infants have been found to have chromosomal rearrangements including aneuploidy (trisomies 13, 18, 21, and Turner syndrome), segmental deletions, or duplications and rearrangements. Genetic analysis has identified a

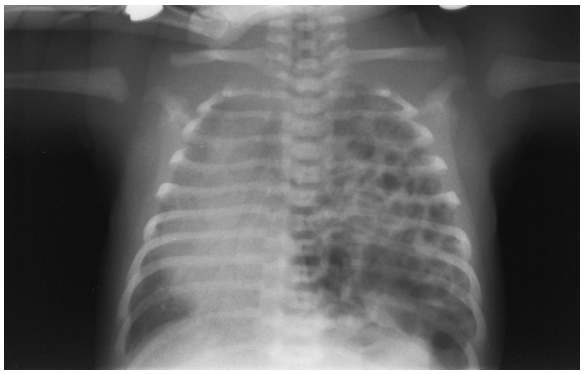
CDH critical region on chromosome 15q26, which codes for four genes involved in diaphragmatic morphogenesis. Microdeletions in this region have been described in several patients with nonisolated CDH and are associated with very high mortality. Other CDH "hot spots" include 1q41-q42, 3q22, 4p16, 8p23, 8q22, and 11p13. Haploinsufficiency or decreased expression of one or more genes encoded in these regions may cause or predispose to the development of CDH.

Recent advances in genetic diagnostic modalities along with the use of knockout mice have shed some light on specific genes that may be involved in the pathogenesis of CDH, including clues for both the diaphragmatic defect as well as the associated pulmonary hypoplasia. Several genes including Wilms tumor 1 (*Wt-1*) and members of the sonic hedgehog (*Shh*) pathway (*Shh*, *Gli2*, *Gli3*) have been implicated in CDH. *Wt-1*-, *Gli2*-, and *Gli3*-null mice have all been shown to have diaphragmatic defects. *Shh* has been demonstrated to be downregulated in human hypoplastic lungs of CDH patients. Another growth factor–related gene, platelet-derived growth factor (*PDGFRα*), was demonstrated to play a role in posterolateral diaphragm and lung development, but the mice knockouts demonstrate features of Fryns syndrome; thus *PDGFRα* may be involved in nonisolated CDH. As advances are made in molecular genetics, more candidate genes are being discovered.[82]

For all the reasons aforementioned, it is important to adequately evaluate for associated malformations in patients with CDH as well as genetic testing antenatally, if not then postnatally. About half of CDH cases are diagnosed antenatally. Antenatal diagnosis is associated with a poor prognosis, but the data suggest that infants with a prenatal diagnosis have a better chance of survival if they are born in a tertiary center with reported survival rates of isolated, operative CDH cases approaching 70%-90%.[105] Several antenatal parameters have been evaluated for their ability to predict survival and morbidity in cases of isolated CDH. Most of these predictors rely on the indirect assessment of the size of the contralateral lung as a proxy for pulmonary hypoplasia. Methods used include lung area to head circumference ratio (LHR) between 22 and 28 weeks' gestation, the presence of the liver in the chest (which has been thought to be most predictive), and estimated fetal lung volume by MRI.[24,68,75,77,110] Because it has been reported that the LHR increases exponentially with gestational age, some experts have advocated that the LHR should be corrected for gestational age and have used an observed:expected LHR (O/E LHR) based on the LHR in the CDH patient compared with what is considered normal for that gestational age.[74] When using the corrected LHR, the CDH registry has quoted the following numbers based on 184 fetuses with isolated left-sided CDH evaluated between 22 and 28 weeks' gestation[46]:



- Fetuses with O/E LHR less than 15% have extreme pulmonary hypoplasia, with virtually no survivors.
- Fetuses with O/E LHR between 15% and 25% have severe pulmonary hypoplasia, with a predicted survival of 20%. (Those with liver completely down in the abdomen fare better than those with liver herniated up into the chest.)
- Fetuses with O/E LHR between 26% and 35% and those with O/E LHR between 36% and 45%, but liver in the chest, have moderate pulmonary hypoplasia, with expected survival between 30% and 60%.
- Fetuses with O/E LHR between 36% and 45% with liver down and those with an O/E LHR greater than 45% have mild hypoplasia and are likely to survive (>75%).

More recently, authors have focused on the use of MRI to evaluate total lung volume (TLV), observed to expected TLV (O/E TLV), and the percentage of liver herniated into the chest (%LH) to predict survival and/or need for extracorporeal membrane oxygenation (ECMO) support. When using O/E TLV, thresholds of <25%, 25%-35%, and >35% were predictive of 0%-25%, 25%-69%, and 75%-89% survival respectively.[120] And when combining o/e TLV and %LH, severe CDH defined as an O/E TLV <32% and %LH >21% carried a 50% mortality; mild CDH were those with an o/e TLV >32% and %LH <21% had only an 8% risk of mortality.[131]

The ability of these parameters to predict survival has not been consistent. This is mostly secondary to the small number of patients in each series, challenges in measurement consistency among operators, lack of correlation with actual and functional lung volume and pulmonary vasculature size, inconsistent measures for survival or morbidity, and differences in postnatal management and survival. Nevertheless, these tools give clinicians some data to use when counseling families faced with the diagnosis of CDH.

The clinical presentation of patients with CDH can vary from asymptomatic in mild cases to severe respiratory failure at birth. Diagnosis should be suspected in previously undiagnosed patients by the presence of severe respiratory distress, cyanosis, scaphoid abdomen, and failure to improve with ventilation. Physical examination reveals absence of breath sounds on the affected side with displacement of heart sounds to the contralateral side, and occasionally bowel sounds can be heard over the thorax. Once the diagnosis is made or suspected, patients should be immediately intubated and an orogastric tube placed to evacuate the stomach. Aggressive ventilatory strategies should be avoided (see later). Chest radiograph shows the presence of bowel loops in the affected chest cavity with shifting of the heart to the contralateral side (Fig. 66.2). If the stomach is included in the hernia, the tip of the orogastric tube will be seen within the thorax. The presence of liver in the chest is suspected by deviation of the umbilical venous line. Late presentation of Bochdalek hernia occurs in less than 3% of cases.[91] These patients can be asymptomatic at birth and usually present later in life with respiratory or gastrointestinal symptoms. High index of suspicion is needed in these cases to prevent unwarranted and potentially dangerous interventions such as the insertion of a chest tube for suspected pleural effusion or pneumothorax. Diagnosis can be made after nasogastric tube insertion, contrast upper

• **Fig. 66.2** Left-sided diaphragmatic hernia in a 1-day-old term infant.

• BOX 66.2 Management of Congenital Diaphragmatic Hernia

- Accept preductal saturations greater than or equal to 85%, $PaCO_2$ less than or equal to 65 mm Hg, and pH greater than or equal to 7.25.
- Identify preset ventilatory limits that are not to be exceeded.
- Use high-frequency oscillatory ventilation if conventional mechanical ventilation fails.
- Use ECMO per preset criteria.
- Delay surgery until persistent pulmonary hypertension improves.

gastrointestinal study, or chest computed tomography (CT) scan. Prognosis for cases with late presentation is excellent once the correct diagnosis is made.

Improved survival has been reported using a consistent approach in the management of CDH that can be facilitated by the development of multidisciplinary standardized treatment guidelines, including input from neonatology, pediatric surgery, ECMO specialists, and respiratory therapy (Box 66.2). Predetermined criteria for the use of ECMO and an underlying protect-the-lung strategy are essential components in the care of these infants and can be as important as the specific medical interventions chosen. Whereas animal studies have suggested lung immaturity and surfactant deficiency in models of CDH, the use of antenatal steroids and surfactant replacement has not been shown to be beneficial.[161] A systematic review of strategies associated with improved survival among infants with CDH in 13 centers that cared for at least 20 patients and reported a survival rate of 75% or more has described multiple successful treatment strategies associated with this improved survival.[105] Although these centers used different mechanical ventilation strategies, most of these targeted the use of gentle ventilation or permissive hypercapnia. The basic elements of this treatment strategy are:

1. Ventilation of the patient with low peak inspiratory pressures (PIP) to minimize lung injury. The goal of PIP is usually less than 25 cm H_2O.
2. Accepting preductal saturations of greater than or equal to 85%, regardless of postductal saturation, and higher $PaCO_2$ levels of less than or equal to 65 with a pH of at least 7.25 as long as there is evidence of adequate tissue perfusion and oxygenation.
3. Instituting high-frequency oscillatory ventilation (HFOV) or high-frequency positive pressure ventilation once the preset limit failed to achieve adequate ventilation, although HFOV was used by some as the primary mode of ventilation.
4. Even though iNO might produce short-term benefits, the routine use of iNO is not supported by current data and might actually be associated with a worse outcome (see Chapter 70).
5. Using ECMO as rescue therapy with variable indications in different centers, including persistent oxygenation index (OI) greater than 40, persistent hypoxemia, or failure of ventilatory management to support oxygenation, ventilation, or tissue perfusion (see Chapter 70).
6. Delaying surgical repair until physiologic stabilization and improvement of PPHN.

Surgical repair is delayed until the pulmonary hypertension is resolved or significantly improved such that, if need be, support may be escalated postoperatively if necessary. The procedure often involves either a primary closure of the diaphragmatic defect, or if too large, the use of a prosthetic patch. Recently, centers are reporting on thoracoscopic closure, but no trials comparing the methods exist.

Postnatal survival rate at tertiary centers has improved with reported rates of 70%-92%.[47,57,58,83,107,118] However, the survival data might underestimate hidden mortality secondary to termination, stillborn, and referral pattern for outborn patients. With improvement in survival, there has been a focus on improving long-term morbidity of survivors. Infants born with CDH have multiple long-term morbidities affecting the pulmonary, gastrointestinal, neurologic, and skeletal systems. Respiratory complications include pulmonary vascular abnormalities presumably causing pulmonary hypertension, a higher incidence of obstructive airway disease, and a restrictive lung function pattern that continues into adulthood.[146] Gastroesophageal reflux disease (GERD), sometimes in combination with failure to thrive, is a well-recognized complication in patients with CDH, and several patients require antireflux surgery. It is unknown whether GERD has an effect on pulmonary function in this population. Pulmonary hypoplasia and PPHN predispose children born with CDH to a high risk for hypoxemia, which may result in neurodevelopmental delay. It has been reported that infants with CDH are at higher risk to have neuromotor delay, hypotonia, and delayed language skills.[29] There is also a high percentage of these infants with sensorineural hearing loss.[42] Chest wall deformities and scoliosis are more common among CDH patients, although deformities are mild and surgery is rarely required.[121] These data emphasize the need for a multidisciplinary team approach in the postoperative management and follow-up of all survivors of CDH. The American Academy of Pediatrics (AAP) section on surgery has provided a suggested schedule for follow-up for these children.[137]

More recently, fetal therapies, namely fetoscopic tracheal occlusion (FETO) in the most severe cases (where survival was nil given prenatal predictors), have shown some promise in improving survival in those cases, including improved lung growth in utero, less pulmonary hypertension, and overall improved survival when compared to expectant management. However, some of these successes have come at a cost of increased preterm delivery, although with improved techniques, the rate of preterm birth is declining.[76,132] There are several US centers trialing this approach now, and a large, international, multicenter, randomized control study is underway to evaluate not only FETO for severe CDH but also for moderately severe CDH and effectiveness performing fetoscopic tracheal occlusion at later gestational ages (30-32 weeks); this is the Tracheal Occlusion To Accelerate Lung Growth Trial.[27]

Alveolar Capillary Dysplasia

Alveolar capillary dysplasia with misalignment of pulmonary veins (ACD/MPV) is a rare, often fatal pulmonary disease that presents in the newborn period, usually within the first 48 hours of life with severe hypoxemia and PPHN unresponsive to treatment.[17] The true incidence of the disease is unknown, because the diagnosis is made by pathology, and if there is no autopsy or antemortem lung biopsy, the diagnosis cannot be made; thus, what is reported in the literature likely underestimates the true incidence of the disease. Histologically, ACD/MPV is characterized by paucity of capillaries proximal to the alveolar epithelium, anomalous distended pulmonary veins within the bronchovascular bundle (rather than within the interlobular septae), and immature alveolar development with medial thickening of small pulmonary arteries and muscularization of the arterioles, and in approximately one-third of cases, lymphangiectasis. These characteristic findings are diffuse in 85% of patients and patchy in the remainder. Although the mechanisms underlying the pathogenesis of ACD/MPV and its associated pulmonary hypertension are not fully understood, it has been suggested that it is related to a failure of fetal lung vascularization with capillary hypoplasia and discontinuity of these capillaries and pulmonary veins impairing pulmonary blood flow, as well as a component of reactive pulmonary vasoconstriction mediated by hypoxia.[39,145] More recently, the role of prominent right-to-left intrapulmonary vascular shunt pathways have been identified and implicated in the severe hypoxia seen in these patients.[59] Extrapulmonary findings are present in 50%-80% of cases, most commonly affecting the gastrointestinal, genitourinary, and cardiovascular systems.[11,140] Although the disease is mostly sporadic, reports of multiple affected siblings in subsets of families suggest an autosomal recessive inheritance pattern.[139,141] Mutations of the *FOXF1* gene located on chromosome 16q24.1 have been identified in 70%-90% of patients with ACD/MPV, and more recently, there is evidence that genomic imprinting plays a role in the development of ACD/MPV.[155] This may allow for prenatal genetic testing of high-risk families; however, it will not identify all cases of ACD.[147]

Most patients with ACD/MPV present within the first few hours of life. These infants are usually born at term and have appropriate size and normal Apgar scores. Although these babies might be asymptomatic at delivery, respiratory distress, cyanosis, and hypoxemia progress quickly to respiratory failure in more than half of these patients within hours after delivery. About 14% of these patients do not present with symptoms until 2-6 weeks of life. Treatment is always unsatisfactory. Although a transient response to iNO might be observed, PPHN is not responsive to medical treatment, and the disease progression is that of a fulminant course and rapid progression to death, although there are reports of survival beyond the neonatal period. High index of suspicion and diagnostic lung biopsy are required to avoid the use of more invasive and futile treatments, including ECMO.

Congenital Pulmonary Lymphangiectasia

Congenital pulmonary lymphangiectasia (CPL) is a pulmonary disorder first described by Virchow in 1856, characterized by dilation of lymphatic vessels in multiple areas of the lungs. Most cases of CPL are sporadic with a predilection for male involvement (2:1). However, familial presentations have been described, suggesting an autosomal recessive inheritance pattern. The incidence is difficult to estimate as few cases are reported in the literature. Congenital pulmonary lymphangiectasia is classified as primary or secondary. Primary CPL can present as either a primary pulmonary developmental defect that can be localized or diffuse or as a part of a more generalized lymphatic developmental defect. Patients with generalized lymphangiectasia tend to have less severe pulmonary involvement. Secondary cases of CPL are often associated with cardiac malformations with obstructed pulmonary venous return, including obstructed total anomalous pulmonary venous return, hypoplastic left heart syndrome, and cor triatriatum. Congenital pulmonary lymphangiectasia has also been described in multiple syndromes, including Noonan, Down, and Ullrich-Turner. The characteristic pathologic finding of CPL is pulmonary lymphatic dilation in the subpleural, interlobar, perivascular, and peribronchial lymphatics. It may be associated with nonimmune hydrops fetalis and congenital chylothorax.[15]

The etiology of CPL is not clear but is thought to be secondary to a failure of regression of lymphatics that normally occurs between 16 and 20 weeks' gestation. Multiple genes have been found to be involved in lymphatic development, including *FOXC2*,[158] vascular endothelial growth factor 3,[148] and integrin a9b1 genes. Mice homozygous for a null mutation in the integrin a9 subunit gene died of respiratory failure caused by bilateral chylothorax within 6-12 days after birth with pathologic features similar to those in CPL.[71]

Patients with CPL usually present with intractable respiratory failure, cyanosis, and hypoxia associated with bilateral

chylothoraces in the first few hours of life, although diagnosis can be delayed for several weeks in cases of unilobar involvement. Nonimmune hydrops is also a well-recognized presentation in patients with CPL. Examination of the pleural fluid shows characteristic findings of chylothorax, including a lymphocytosis and elevated triglycerides, although elevated triglycerides might be absent in nonfed infants (see later). Chest radiograph reveals hyperinflation of the lung with bilateral interstitial infiltrates and bilateral pleural effusions. High-resolution computed tomography demonstrates diffuse thickening of the peribronchovascular interstitium and the septa surrounding the lobules. Definitive diagnosis is made by lung biopsy showing the characteristic features: increased fibrous tissue with dilation of cystic lymphatic spaces and collapsed alveoli, although differentiation from lymphangiomatosis can be difficult.[15]

Treatment is mostly supportive. Intubation and mechanical ventilation; drainage of pleural and peritoneal effusions; and correction of hypoxia, acidosis, and shock might be needed in the delivery room for stabilization. Persistent chylothorax might require chest tube placement. Nutritional therapy with medium-chain triglycerides and total parenteral nutrition has been successful in the treatment of CPL. Case reports of using octreotide and antiplasmin to treat CPL as well as intestinal lymphangiectasia have been reported with success.[15] Pleurodesis with sclerosing agents has been used to treat persistent chylothoraces associated with the disease. More recently, reports of using lymphangiogram with ethiodized oil as a successful treatment modality have been reported.[61] The prognosis appears to depend on the severity of symptoms in the immediate newborn period. Although traditionally thought to be fatal, there are reports of survival in some patients presenting with respiratory failure, chylothorax, and hydrops fetalis in the immediate neonatal period. Later presentation carries a better prognosis with the possibility of spontaneous resolution, although respiratory morbidity might be common.

Chylothorax

Chylothorax is the accumulation of lymphatic fluid (chyle) in the pleural cavity. It is the most common cause of pleural effusion in neonates and can be primary (congenital) or secondary (acquired). It is a rare entity, with a reported incidence of 1:10,000 births, and affects males more than females (2:1).[49] Congenital chylothorax, which accounts for less than 10% of all chylothoraces, may be associated with abnormalities of the lymphatic system; congenital malformations such as congenital heart disease or mediastinal malignancies; or chromosomal abnormalities such as trisomy 21, Noonan syndrome, or Turner syndrome. Secondary chylothoraces are most commonly associated with trauma during thoracic surgery but can also be the result of increased superior vena caval pressure caused by venous thrombosis.

Clinical presentation is that of respiratory distress secondary to lung compression, pulmonary hypoplasia, or symptoms of the underlying pulmonary or cardiac disease. Many cases of congenital chylothorax are diagnosed by prenatal ultrasound, and antenatal management consists of thoracocentesis or thoracoamniotic shunt placement to try to prevent the development of pulmonary hypoplasia. However, even with prenatal treatment, these infants can still present with significant respiratory distress at birth as fluid reaccumulates, requiring postnatal treatment.

Physical examination is significant for decreased breath sounds on the affected side with shifting of the cardiac apex to the contralateral side. Chest radiograph shows a pleural effusion, compression of the lung on the affected side, and displacement of the heart to the opposite side. Diagnosis is established by analysis of the pleural fluid. In neonates with established feedings, chylothorax appears milky in color; however, in nonfed neonates, it is clear. Buttiker and colleagues have proposed the following criteria for establishing the diagnosis of chylothorax: absolute cell count of greater than 1000/μL with a lymphocyte fraction of greater than 80% and triglyceride levels greater than 1.1 mmol/L.[23]

Optimal treatment for chylothoraces has not been defined but is mostly supportive while awaiting resolution of the effusion. Mechanical ventilation and drainage of the chylothorax might be needed in patients with large effusions, and nutritional support using total parenteral nutrition is essential. When feedings are started, formulas containing a high percentage of medium-chain triglycerides (MCTs) are recommended, because lymphatics are not needed for MCT absorption. In most cases, spontaneous resolution occurs within 4-6 weeks. Several treatment strategies have been described for cases with persistent chylothorax, including pleurodesis, ligation of the thoracic duct, and pleuroperitoneal shunt.[10] Whereas povidone-iodine pleurodesis has been used successfully in persistent chylothorax, it has also been associated with renal failure. There is growing evidence from uncontrolled case studies suggesting a markedly positive effect of somatostatins, particularly octreotide, in the treatment of chylothorax with minimal side effects. In the absence of a controlled trial evaluating safety and efficacy, this therapy should be reserved for persistent and severe cases and not as first line of treatment.[130,143,170] Case reports of successful treatment with oral sildenafil, perhaps by generation of new lymphatic vessels, have been reported.[45,108] An emerging therapeutic modality is embolization of the thoracic duct with lipiodol; however, this procedure is in its infancy and will need further study before becoming a first-line therapy.[72]

Congenital Cystic Pulmonary Malformations

Congenital cystic lung disease encompasses a broad spectrum of rare, but clinically significant, developmental abnormalities that include congenital pulmonary airway malformation (CPAM; previously known as congenital cystic adenomatoid malformation CCAM), bronchopulmonary sequestration (BPS), bronchogenic cyst (BC),

TABLE 66.1 Characteristics of Congenital Pulmonary Airway Malformation versus Bronchopulmonary Sequestration

	Congenital Pulmonary Airway Malformation	Bronchopulmonary Sequestration
Classification	Types 0-4, microcystic and macrocystic	Intralobar and extralobar
Connection to tracheobronchial tree	Yes	No
Systemic blood supply	No	Yes
Associated malformation	Common	Less common
Location	Either lower lobe	Left lower lobe
Malignant transformation	Yes	Yes
Spontaneous regression of antenatally diagnosed cases	15%	75%

and congenital lobar emphysema (CLE). These lesions are rare with an estimated incidence of 1 per 11,000-35,000 births.[13,95] They were originally thought to be separate entities; however, the description of coexistence of multiple lesions (bronchogenic cyst, CPAM, and extralobar BPS) in the same patient as well as reports of bronchial atresia in some specimens of all four entities suggests a common embryologic origin. These lesions can be identified on prenatal ultrasound, but the classification of the lesion should wait until postnatal examination and histology are available. These lesions should be followed closely in utero as some of these lesions can predispose the fetus to develop hydrops, and when this occurs in the second trimester, fetal intervention is warranted. Intervention includes repeated cyst aspiration, thoracoamniotic shunting, sclerotherapy, fetal surgery, or more recently, maternal betamethasone treatment. However, fetal intervention is relatively rarely needed, as many of these cystic lung lesions appear to regress in utero.

Congenital Pulmonary Airway Malformation

Congenital pulmonary airway malformation (CPAM) constitutes multiple different hamartomatous lesions arising from the abnormal branching of the immature bronchial tree. This entity was first described by Ch'in and Tang in 1949,[28] and since then, the term has been evolving as our understanding of the entity improves. For the past 40 years, Stocker has classified the lesions into three types: I, II, and III.[152] Stocker has since described two new types, 0 and 4, and has revised his original term congenital cystic adenomatoid malformation, and now refers to this entity of cystic lung lesions as *congenital pulmonary airway malformations* (CPAM) to reflect the site of suspected development of the malformation in the tracheobronchial tree, and that only three types (1, 2, and 3) are adenomatoid and only types 1, 2, and 4 are cystic.[150] However, the term CCAM will still appear in the literature.

Congenital pulmonary airway malformation is the most common congenital cystic lung disease, occurring in 1 in 11,000-30,000 live births and affecting more males.[142] Both lungs are affected equally, and the disease is most commonly unilobar with predilection for the lower lung lobes. Unlike BPS, it is connected to the tracheobronchial tree and has a pulmonary blood supply (Table 66.1). Congenital pulmonary airway malformation develops during the pseudoglandular phase (7-17 weeks' gestation) of fetal lung development. In addition to the classification system described in the preceding, some have suggested classifying the lesions, at least during the prenatal period, as microcystic versus macrocystic based on the gross anatomy and antenatal ultrasound appearance. Whereas the latter classification has poor correlation with histologic features, it has a much better prognostic value, with microcystic lesions (cysts <5 mm) having a poorer prognosis than macrocystic lesions (>5 mm).[5]

Type 0 CPAM is the rarest form and arises from the trachea or bronchus and contains multiple small cysts. These infants also have other associated lesions, including cardiovascular anomalies, renal hypoplasia, and focal dermal hypoplasia. The lung itself is hypoplastic, weighing only 30%-50% of the expected weight. Microscopically, the tissue consists almost entirely of irregular bronchial-like structures lined by pseudostratified ciliated columnar epithelium surrounded by thick cartilage plates and bundles of smooth muscle fibers. Usually all lobes of the lung are involved; thus, this diagnosis is usually lethal.[150]

Type 1 CPAM is the most common form, representing 60%-70% of all CPAMs.[151] These lesions consist of large cysts (1-10 cm) surrounded by multiple small cysts that arise from the distal bronchus or proximal bronchiole and are rarely associated with other congenital malformations. These CPAMs can be large and can have significant mass effect in utero, which can lead to fetal hydrops and pulmonary hypoplasia. However, many of these cysts collapse as pregnancy progresses, allowing normal lung growth of the unaffected lobes. Radiographically, they appear as either a single or multiple air-filled or air/fluid-filled cysts in one or (much less frequently) multiple lobes. Depending on size,

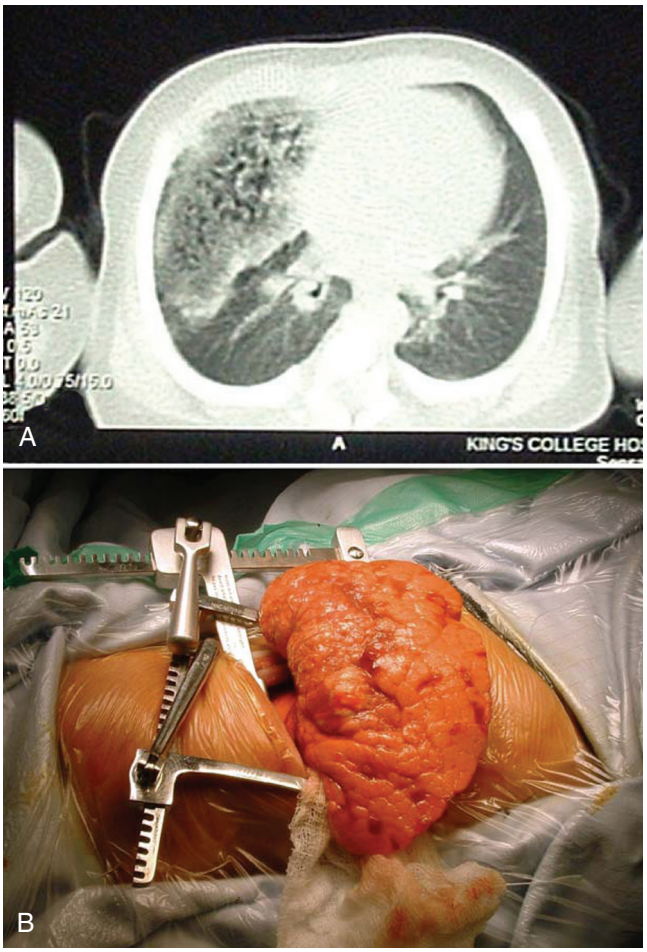
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

there can be flattening of the diaphragm, mediastinal shift, and compression of adjacent lung. Overall, these lesions have a good prognosis. However, a number of reports describe the occurrence of a bronchioloalveolar carcinoma, especially when the CPAM is not fully resected, with a malignant transformation risk of 1%.[166]



Type 2 CPAM accounts for 15% of all CPAMs and is the second most frequent type of CPAM. These malformations are of bronchiolar origin and consist of multiple small cysts (0.5-2 cm) and are often (≈50%) associated with other congenital anomalies, including renal agenesis/dysplasia, cardiovascular anomalies, congenital diaphragmatic hernia, and extralobar sequestrations.[32,150] Radiographically, they are characterized by multiple small cysts that may not even be visible on chest x-ray. Prognosis is usually related to the severity of the associated anomalies.

Type 3 CPAM accounts for 5%-10% of all CPAMs. These are of bronchiolar/alveolar duct origin and almost exclusively seen in males. These lesions were the original congenital adenomatoid malformation described by Ch'in and Tang in 1949.[28] They consist of multiple smaller cysts (rarely >0.2 cm) and appear as a solid mass that is associated with a significant risk of hydrops and polyhydramnios resulting from caval obstruction and cardiac compression secondary to mediastinal shift. This also leads to pulmonary hypoplasia, because unlike type 1 CPAMs, this lesion does not regress with progression of pregnancy. The extent of the pulmonary hypoplasia is the primary determinant of survival.

Finally, type 4 CPAM accounts for approximately 10% of CPAMs and is of distal acinar origin. The lesion primarily consists of large (up to 10 cm), air-filled, thin-walled cysts usually located at the lung periphery. This lesion can be asymptomatic at birth and presents from the neonatal period to 4 years of age. Often, this will be an incidental finding on an x-ray that was taken for other reasons, such as acute respiratory distress related to a tension pneumothorax, or pneumonia. This lesion can be confused with pleuropulmonary blastema; therefore, blastemas must be looked for histologically. Surgical resection of the lobe is accompanied by an excellent prognosis.[150]

With improvement in prenatal imaging, most of these lesions are diagnosed prenatally, but some may not present until the postnatal period either as acute respiratory distress or as an incidental finding on a chest x-ray that was obtained for other reasons. Although the diagnosis of a congenital lung lesion is able to be made on prenatal ultrasound, it is difficult to distinguish CPAM from other cystic lung lesions. Adzick et al. proposed the classification of antenatal cystic lung lesions based on their appearance on ultrasound as either macrocystic (cysts ≥5 mm) or microcystic (cysts <5 mm).[5]

Understanding of the natural history of CPAMs continues to evolve. Up to 15% of these lesions appear to "disappear" in the prenatal period, usually after 28 weeks' gestation when the growth of these lesions tends to plateau; however, in most all cases, postnatal CT scan or fetal MRI will show persistence of the anomaly (Fig. 66.3). The unpredictability of the in utero growth of these lesions requires careful follow-up. Midgestation, these lesions can grow quite rapidly, which can cause mediastinal shift, pulmonary hypoplasia, and impaired venous return leading to hydrops. It has been well established that the diagnosis of fetal hydrops associated with CPAM portends a poor prognosis, with mortality near 100%.[3,4,164] In 2002, it was hypothesized that the volume of the lesion would predict whether hydrops would develop in the fetus. The CPAM volume ratio (CVR) was developed as a prognostic tool and is calculated by measuring the three dimensions of the lung lesion and dividing by the head circumference. A CVR greater than or equal to 1.6 at initial diagnosis was found to reliably predict a subgroup of fetuses at increased risk for developing fetal hydrops and is now used to evaluate which infants might benefit from in utero interventions.[38] Fetal surgery using thoracoamniotic shunting or cyst aspiration has been successful for macrocystic lesions, with survival rates in hydropic fetuses of 50% and 69%, respectively.[26] Microcystic lesions require open fetal surgery in the presence

of hydrops with a survival rate of 52%[38,64,164] (see Chapter 13). Patients who are not suitable for surgery benefit from antenatal steroids, which have been shown to decrease the size of microcystic CPAMs as well as resolve the hydrops in several case series.[125] The ex utero intrapartum treatment (EXIT) procedure should be considered in patients with significant mediastinal shift and cardiac and lung compression at time of delivery.[12,89] Recently, Ehrenberg-Buchner and colleagues report that the maximum and final CVR are independent predictors of respiratory morbidity at the time of delivery and need for neonatal intervention. According to their work, a maximum CVR >1 portends a 75% likelihood of having respiratory distress at birth; thus, these babies should be delivered at a tertiary care center. If the maximum CVR is <1, nearly 100% of those infants are asymptomatic at birth.[50]

Postnatally, all CPAMs should have surgical evaluation. If the infant is symptomatic, surgical excision is indicated. However, there is still some debate over the appropriate management of those lesions that are asymptomatic at birth. All infants with CPAM should have a chest x-ray in the immediate neonatal period and chest CT scan at 4-6 weeks of age to evaluate the mass. There are justifications for prophylactic surgery: preventing chest infections and sepsis; preventing malignancy; early rather than delayed surgery may encourage compensatory lung growth; and reduction in postoperative complications (compared with emergency surgery).[81,92] The majority opinion seems to favor elective resection at 2-6 months of age; however, this continues to be debated in the surgical arena. Following successful resection, the long-term functional outcome of children with CPAM is excellent, with no physical limitations or increased risk for infection.[12]

Bronchopulmonary Sequestration

Bronchopulmonary sequestrations (BPSs) are microscopic cystic masses of nonfunctioning lung tissue thought to arise from the primitive foregut. Usually, these structures are not connected to the main airway, and their blood supply arises from the systemic circulation. Two forms are recognized: intralobar sequestration (ILS) and extralobar sequestration (ELS). Intralobar sequestration occurs when the accessory bud arises before the establishment of the pleura and is contained within the normal lung. If the accessory lung bud arises after the pleura are established, it has its own pleural covering and is completely separated from the normal lung and is classified as an ELS. Extralobar sequestrations are usually located supradiaphragmatic; however, a small portion (<10%) are located infradiaphragmatic.[55,97] This is dependent on the level of the foregut at which they arise.

On antenatal ultrasound, sequestrations appear as well-defined, solid, echogenic masses very similar to type 3 CPAM. A distinguishing feature of BPS is the documentation of systemic blood supply by color Doppler. If unclear, ultrafast MRI can establish the blood supply, define the lesion, and identify other associated malformations. It is difficult to distinguish ELS from ILS on prenatal ultrasound unless it is surrounded by a pleural effusion or is located below the diaphragm, which can only be features of an extralobar sequestration. Intra-abdominal ELS appears as a suprarenal solid mass and should be differentiated from other suprarenal masses, including neuroblastoma and mesoblastic nephroma.[142] Antenatal or postnatal echocardiography can show associated cardiac malformation. Bronchopulmonary sequestration appears on chest radiograph as a posterior thoracic mass mostly on the left. Chest CT scan or even MRI might be needed to further delineate systemic blood supply.

Like CPAMs, sequestrations, extralobar more so than intralobar, can be associated with multiple congenital malformations, including congenital diaphragmatic hernia, congenital heart disease, and vertebral anomalies. A feature unique to BPS is high-output cardiac failure owing to the sequestration's redundant circulation and occasionally massive left-to-left shunt. Like a CPAM, BPS can also cause fetal hydrops, either from the mass effect or from a tension hydrothorax that is the result of either fluid or lymph secretion from the BPS or from high-output cardiac failure. If there is significant in utero compromise of the fetus, fetal intervention may be necessary in the form of a thoracoamniotic shunt for decompression of pleural effusion, surgical excision, or EXIT procedure.[2,34,44]

The natural history of BPS is still being learned. Most BPSs (68%) dramatically decrease in size as pregnancy progresses.[2] Thus, most sequestrations are usually asymptomatic in the neonatal period. If the sequestration is large, it can act as a space-occupying lesion and present as respiratory insufficiency either from pulmonary hypoplasia or lung compression and may require emergent surgical repair. If asymptomatic in the neonatal period, sequestrations can present later with recurrent pneumonia, atelectasis, bleeding, or high-output congestive heart failure. It is felt that asymptomatic patients should undergo elective resection to prevent complications of malignancy or infection.[34]

While discussing CPAMs and BPSs, it should be noted that there are lesions, referred to as hybrid lesions, that exhibit clinical and histologic features of both entities, most commonly characteristics of ILS and type 2 CPAM.[55,97]

Bronchogenic Cyst

A bronchogenic cyst is a single cyst lined by respiratory epithelium and covered with elements of the tracheobronchial tree, including cartilage and smooth muscle. Bronchogenic cysts originate from an abnormal budding of the ventral surface of the primitive foregut between the 26th and 40th day of fetal life, a budding that does not undergo further branching, resulting in a blind cyst that may or may not communicate with the airways. These cysts are mostly found in the mediastinum near the carina but can occur within the lung parenchyma, pleura, or diaphragm.[111]

In the neonatal period, most patients with bronchogenic cysts are asymptomatic, and diagnosis is usually made on prenatal ultrasound and fetal MRI or incidentally on a chest radiograph after birth. On chest radiograph, bronchogenic

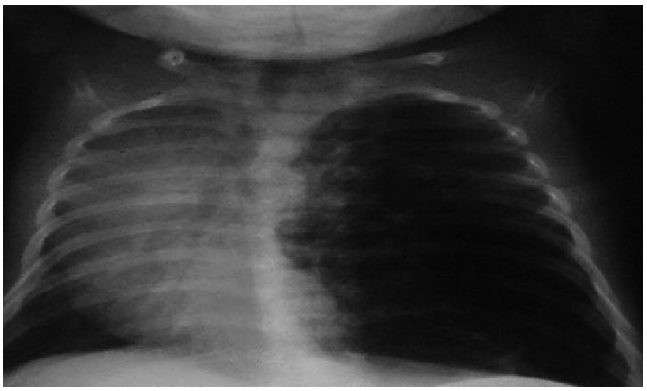
cysts can appear as radiopaque areas if they are fluid filled, but if connected to the airway, an air-fluid level may be seen. A CT scan is the study of choice before undergoing surgery and provides a thorough characterization of the lesion and its relation to mediastinal structures.

Symptoms, if present, are secondary to mass effect on the airways, gastrointestinal tract, or cardiovascular system. Even though major airway obstruction is uncommon, subcarinal lesions can present with severe obstruction. On the other hand, obstruction of smaller airways can cause air trapping, overdistension, and a clinical picture mimicking congenital lobar emphysema. Cases not diagnosed in the neonatal period usually present in older children or adults with pneumonia, hemoptysis, pneumothorax, dysphagia, or signs of caval obstruction.



Treatment of all cases of bronchogenic cysts is complete surgical excision. In symptomatic patients, this is performed after immediate clinical stabilization. Simple aspiration should be considered as a temporizing measure in patients with severe compromise, but complete resection is subsequently required. In asymptomatic newborns, surgery can be done electively at a few months of age. Patients who undergo resection of a bronchogenic cyst have an excellent outcome. Only a few patients develop life-threatening complications before surgery and have a poorer outcome. There are no long-term complications related to the resection of a bronchogenic cyst.[96]

Congenital Lobar Emphysema

Congenital lobar emphysema (CLE) is a rare anomaly of the lung that is characterized by postnatal overdistension of one or more segments or lobes of the lung. The mechanism underlying CLE is that of intrinsic or extrinsic obstruction of the airways resulting in air trapping, overdistension, and subsequent emphysema. Multiple mechanisms have been described to explain the development of CLE, including dysplastic bronchial cartilage, inspissated mucus, aberrant cardiopulmonary vasculature, and infection. In half of the cases, no underlying pathology is identified. The left upper lobe is most frequently affected (42%), followed by right middle lobe (35%) and the right upper lobe (21%). The lower lobes are involved in 1% of the cases. Congenital lobar emphysema is three times more common in males.[149]

Patients usually present in the neonatal period with respiratory distress (80% within the first month of life); however, later presentations have been described. The severity of the clinical picture depends on the size of the CLE and the degree of compression of the normal lung. Physical examination might be indistinguishable from that of a pneumothorax with decreased air entry, bulging of the affected hemithorax, and in severe cases, shifting of the apical heartbeat to the contralateral side. However, these children are often hemodynamically stable, thus differentiating it from a tension pneumothorax.

Congenital lobar emphysema can be detected at midgestation using a combination of ultrasonography and ultrafast fetal MRI, although differentiation from CPAM might be difficult. Diagnosis is usually made by chest radiograph that may show an early opaque mass due to delayed clearance of lung fluid followed by a hyperlucent, overexpanded area of lung with atelectasis of the adjacent lobes of the lung, depression of the diaphragm, and mediastinal shift to the opposite side (Fig. 66.4). The distinction of CLE from pneumothorax is essential to prevent attempted aspiration and potential development of tension pneumothorax. The presence of alveolar air markings throughout the emphysematous area is supportive of CLE. The emphysematous segment may also herniate anterior to the heart and great vessels. A CT scan of the chest is a useful adjunct.

• **Fig. 66.4** Congenital lobar emphysema with marked tracheal and mediastinal shift in a patient who required emergency lobectomy. (From Shanmugam G, et al. Congenital lung malformations—antenatal and postnatal evaluation and management. *Eur J Cardiothorac Surg*. 2005;27:45, with permission.)

Treatment of CLE depends on the severity of symptoms. Conservative and supportive management should be considered in milder cases. Surgical resection of the affected area should be considered in patients with life-threatening, progressive pulmonary insufficiency from compression of the adjacent normal lung. Once the emphysematous area is resected, the long-term prognosis is excellent.[94]

Pulmonary Arteriovenous Malformation

Intrapulmonary arteriovenous malformation is a rare vascular anomaly of the lung that is associated with cyanosis and may lead to significant morbidity. Such malformations are direct communications between the smaller pulmonary arteries and veins, allowing blood to bypass the capillary system.[6] Over 70% are associated with hereditary hemorrhagic telangiectasia[35] and present with cyanosis not responding to medical management. Antenatal diagnosis of an intrapulmonary arteriovenous malformation is possible and allows early treatment. Postnatal diagnosis is confirmed by angiography. Traditionally, treatment has been by surgical resection. More recently these lesions have been successfully managed by embolization with coils or endovascular plugs.[88] If left untreated, they can be complicated by strokes and cerebral abscesses.[36,119]

Acquired Neonatal Pulmonary Diseases

Meconium Aspiration Syndrome

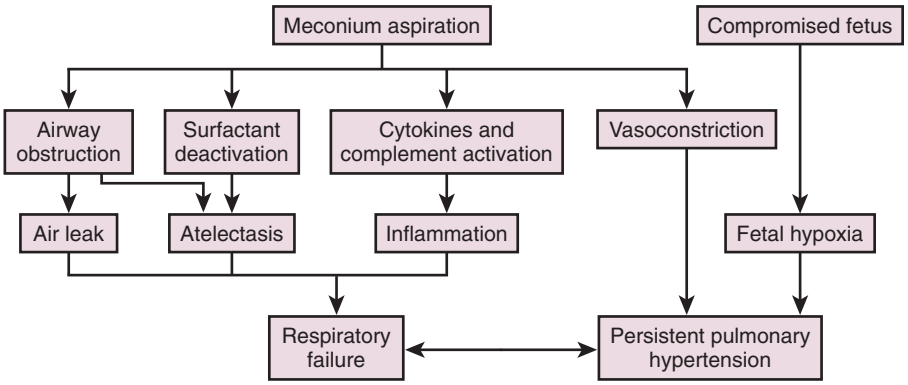
Meconium is comprised of desquamated fetal intestinal cells, bile acids, minerals, and enzymes, including alpha$_1$ antitrypsin and phospholipase A_2, as well as swallowed amniotic fluid, lanugo, skin cells, and vernix caseosa. Antenatal passage of fetal intestinal contents into the amniotic fluid is common in early gestation, stopping by 20 weeks, when there is innervation of the anal sphincter; thus meconium passage between 20 and 34 weeks is an infrequent occurrence.[127] Most babies who pass meconium during the labor process are term or post-term.

Meconium-stained amniotic fluid (MSAF) occurs in approximately 13% of normal pregnancies, and ~5% of these infants will develop respiratory distress.[168] Risk factors for MSAF include postmaturity (gestational age beyond 41 weeks), small for gestational age (SGA), fetal distress, and in utero conditions that can compromise fetal well-being, such as placental insufficiency and cord compression. The mechanisms underlying meconium passage in utero are not completely understood; however, there is evidence of increased parasympathetic activity causing increased peristalsis and relaxation of the anal sphincter secondary to enhanced vagal output during cord compression. Corticotropin-releasing factor, a known mediator of colonic motility, has been implicated in the pathogenesis of hypoxia-induced MSAF in a rat model.[98]

Meconium aspiration syndrome (MAS) is defined as respiratory distress and an oxygen requirement in an infant born through MSAF whose symptoms cannot be otherwise explained. This definition correctly implies that respiratory distress might occur in infants born through MSAF for a variety of reasons other than MAS. Infants born through MSAF were found to have a 100-fold increase in the likelihood of developing respiratory distress compared with those born through clear amniotic fluid, even in those with normal fetal heart tracing and Apgar scores. Meconium aspiration syndrome occurs in only 5% of infants born through MSAF, and it is unclear why only some infants born through MSAF develop MAS. The incidence of MAS has decreased secondary to improved obstetric standards, especially secondary to a decrease in the number of deliveries beyond 41 weeks' gestation in developed countries. Two large studies from the United States and Australia/New Zealand confirmed that the incidence of MAS increases with increasing gestational age for infants between 37 and 41 weeks in a study cohort involving more than 14 million babies. The incidence of MAS (United States) and MAS requiring intubation (Australia) in this cohort increased twofold to threefold at 41 weeks' gestation compared with neonates born at an earlier gestation.[43,173]

Pathophysiology

The pathophysiology of MAS, although extensively studied, remains incompletely understood. During normal fetal breathing, pulmonary fluid moves predominantly outward from the airways into the oropharynx. However, severe asphyxia in utero can induce gasping and aspiration of amniotic fluid and particulate matter into the large airways. The meconium inhaled by the fetus may be present in the trachea or larger bronchi at delivery. Meconium and squamous epithelium have been found as far as the alveoli in stillborn infants, and it is widely recognized that meconium aspiration can occur antenatally. After air breathing has commenced, especially if accompanied by gasping respirations, there is a rapid distal migration of meconium within the lung. Thick meconium-stained amniotic fluid, nonreassuring fetal heart tracing, low Apgar score at 5 minutes, instrumental delivery, especially emergency cesarean section, and planned home delivery are associated with increased risk for development of MAS.[43,90]



MAS can be regarded as a multifactorial disease resulting from the cumulative effect of aspiration of MSAF in an already compromised infant. Therefore, the underlying pathology is that of fetal compromise, discussed elsewhere, and pulmonary injury secondary to aspiration of meconium. Meconium aspiration causes injury to lung tissues through a variety of mechanisms, including complete or partial obstruction of airways, inflammation, complement activation and cytokine production, inhibition of surfactant synthesis and function, apoptosis of epithelial cells, and increased pulmonary vascular resistance (Fig. 66.5).

Aspiration of meconium particles can result in complete or partial obstruction of the airways. Complete obstruction causes collapse of the lung tissue distal to the obstruction and subsequent atelectasis and ventilation-perfusion mismatch. The effect of partial obstruction, however, has been traditionally thought of as a ball-valve effect, wherein air can enter during inspiration but is unable to escape during expiration. The resultant air trapping and overdistension increase the incidence of pneumothorax, which can occur in as many as 10%-30% of affected infants.[168,169]

The various components of meconium have been shown to induce inflammation and cytokine activation. Within hours, neutrophils and macrophages are found in the alveoli, larger airways, and the lung parenchyma. This is associated with activation of proinflammatory cytokines, tumor necrosis factor TNF-α, γ-interferon, and interleukins (IL)-1β, IL-6, and IL-8. Furthermore, meconium was found to activate the lectin and alternative complement pathways, and administration of complement 1 inhibitors efficiently reduced the level of these proinflammatory factors, thus adding a potential therapeutic target for the treatment of MAS.[134] Excessive activation of cells leads to oxidative damage of the lung tissue through release of cytotoxic and immune cell–activating agents such as reactive oxygen and nitrogen species.

The complex oxidative processes and inflammation via meconium and plasma proteins leaking through the alveolar-capillary membrane may destroy the alveolar type II cells, thus decreasing the production and function of surfactant,

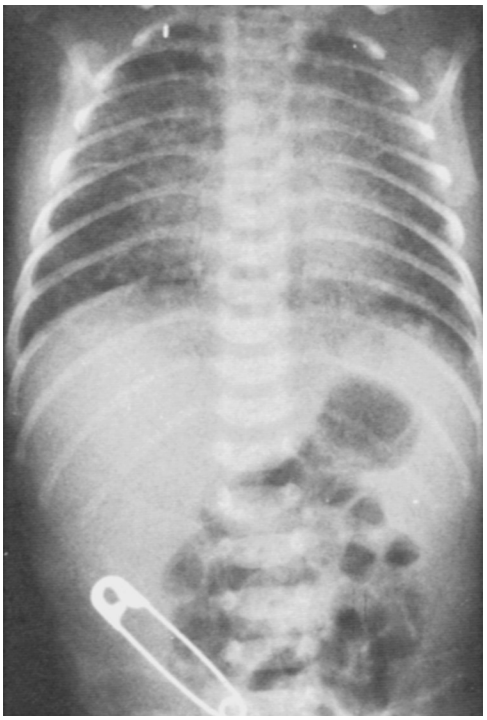
• **Fig. 66.5** Pathophysiology of meconium aspiration syndrome.

which may result in increased surface tension, atelectasis, decreased lung compliance, and subsequent hypoxia.[78,112]



Severe persistent pulmonary hypertension often complicates cases of MAS. The mechanism of pulmonary vasoconstriction in these patients is not clear but thought to be induced, in part, by fetal and neonatal hypoxia. The direct effect of meconium on the pulmonary vasculature is controversial. In vitro studies observed relaxation of tracheal and pulmonary vasculature smooth muscles in response to meconium exposure in rats. However, in vivo administration of meconium caused increased contractility of vascular and tracheal smooth muscles, suggesting that meconium induces pulmonary vasoconstriction through lung release of pulmonary vasoconstrictor humoral factors. The potent vasoconstrictors thromboxane A_2 and angiotensin II, as well as cytokines, have been implicated in this mechanism.

Clinical Features

The infant with MAS often exhibits the classic signs of postmaturity, with evidence of weight loss; cracked, peeling skin; and long nails, together with heavy staining of nails, skin, and umbilical cord with a yellowish pigment. These infants often are depressed at birth. In fact, the initial clinical picture can be dominated by neurologic and respiratory depression secondary to the hypoxic insult precipitating the passage of meconium. Respiratory distress with cyanosis, grunting, flaring, retractions, and marked tachypnea soon ensue.

Characteristically, the chest appears overinflated ("barrel-chested"), and rales can be audible on auscultation. The chest radiograph shows coarse, irregular pulmonary densities with areas of diminished aeration or consolidation (Fig. 66.6). Pneumothorax and pneumomediastinum are common in infants with severe MAS. Hyperinflation of the chest and flattening of the diaphragm secondary to air trapping are sometimes noted on chest radiograph. Cardiomegaly might be observed as a manifestation of the underlying perinatal hypoxia.

Arterial blood gases characteristically reveal hypoxemia with evidence of right-to-left shunting. Hyperventilation can result in respiratory alkalosis, although infants with severe disease usually have a combined respiratory and metabolic acidosis secondary to hypoxia and respiratory failure.

• **Fig. 66.6** Chest radiograph showing multiple linear streaks of meconium aspiration pneumonia.

One should be alert to the possible development of PPHN, which frequently accompanies MAS and can contribute substantially to morbidity.

Management

In the Delivery Room

Successful management of patients with MAS depends on close observation during and immediately following labor in at-risk mothers as well as appropriate intervention in newborns born through meconium-stained amniotic fluid (Box 66.3). This requires a collaborative effort by the obstetric and neonatology teams. Mothers at a gestational age of 41 weeks or greater with thick MSAF and nonreassuring fetal heart tracing require careful monitoring. Fetal scalp oximetry is a technique of fetal monitoring that might improve the accuracy of detecting newborns at risk. Fetuses with nonreassuring fetal heart rate patterns and fetal oxygen

• BOX 66.3 Management of Meconium Aspiration Syndrome

Delivery Room

- Women at risk should deliver in a center where immediate neonatal care is available.
- Meconium aspiration can develop in utero.
- Amnioinfusion for meconium-stained amniotic fluid (MSAF) in the setting of standard peripartum surveillance is not routinely indicated.
- Routine suctioning via endotracheal tube is no longer indicated.
- Routine suctioning of the oropharynx at the perineum is not recommended.

Neonatal Intensive Care Unit

- Surfactant administration may be beneficial.
- Inhaled nitric oxide is indicated for associated persistent pulmonary hypertension.

Unresolved Issues

- The use of amnioinfusion for MSAF when routine surveillance is not available, such as in developing countries
- The administration of surfactant as a bolus versus lavage
- The utility of anti-inflammatory agents

saturation below 30% had a high correlation with a scalp pH value of less than 7.2.[93]

Amnioinfusion refers to the instillation of normal saline or lactated Ringer's solution into the uterus through a catheter for the purpose of replacing amniotic fluid in cases of oligohydramnios and MSAF. Amnioinfusion might decrease the incidence of MAS by two mechanisms: diluting meconium consistency and decreasing cord compression, thereby resolving asphyxia and gasping. A meta-analysis of 13 studies demonstrated that the use of prophylactic intrapartum amnioinfusion for moderate or thick MSAF shows two distinct patterns. When standard peripartum and expert neonatal care are available, amnioinfusion does not improve outcome. In contrast, where antenatal and neonatal care is limited, such as underserved African communities, 75% of MAS is prevented. Furthermore, amnioinfusion decreased the frequency of cesarean section rate (OR, 0.74), meconium below the vocal cords (OR, 0.18), and neonatal acidemia (OR, 0.42) with no increase in the rate of chorioamnionitis (OR, 0.47).[124] A large, multicenter, randomized trial involving 1998 women concluded that in clinical settings with standard peripartum surveillance, amnioinfusion in the presence of thick MSAF did not reduce the risk of perinatal death, moderate or severe MAS, or other serious neonatal disorders.[56] This led the American College of Obstetricians and Gynecologists to issue an opinion statement: "Based on current literature, routine prophylactic amnioinfusion for the dilution of meconium-stained amniotic fluid should be done only in the setting of additional clinical trials. However, amnioinfusion remains a reasonable approach in the treatment of repetitive variable decelerations, regardless of amniotic fluid meconium status."[1]

Suctioning of the oropharynx upon delivery of the head and before delivery of the shoulders is used commonly in obstetric practices to decrease the possibility of meconium aspiration with the first breath. A multicenter, randomized, prospective study concluded that antepartum suctioning is not warranted and does not decrease the incidence of MAS even in high-risk infants. On the contrary, it may lead to added complications including bradycardia, desaturations, and increased incidence of pneumothorax.[160] Vain et al. also showed, in a prospective randomized trial, that routine intrapartum oropharyngeal and nasopharyngeal suctioning of term infants born through MSAF does not prevent MAS. With this evidence, the International Consensus on Cardiopulmonary Resuscitation currently does not endorse the routine intrapartum oropharyngeal and nasopharyngeal suctioning of infants born with clear or meconium-stained amniotic fluid.[122]

Routine endotracheal intubation is no longer recommended for infants born through MSAF even if the infant is not vigorous. Current NRP recommendations state that if a neonate born through MSAF presents with poor tone or respiratory effort, the initial steps of resuscitation should be performed and bag-mask ventilation initiated when/if appropriate. Routine intubation and suctioning is not recommended due to insufficient evidence to support this therapy.[123] Unfortunately, an appropriately powered randomized clinical trial to address optimal management of the nonvigorous meconium-stained infant has not been performed.[167a]

In the Neonatal Intensive Care Unit

Management of patients with MAS consists mainly of supportive respiratory and cardiovascular care. Maintaining normal blood pressure, adequate perfusion, and preventing hypoxia are essential to decrease complications. The use of antibiotics is indicated until infection is ruled out because MSAF could be the first sign of fetal sepsis or pneumonia, which may be indistinguishable from MAS on chest x-ray examination. Ventilatory support is indicated in the presence of respiratory failure or persistent hypoxemia not responsive to high fractional inspired oxygen. There is no clear evidence or consensus of an advantage of one ventilatory strategy. However, in the presence of air leak or failure of conventional ventilation, HFOV should be considered in units familiar with this ventilatory strategy. Pao_2 should be maintained such that there is minimal hypoxia-induced pulmonary vasoconstriction while not inducing hyperoxic injury.

Surfactant administration should be considered in severe cases of MAS. In a Cochrane review of available data, surfactant decreased the need for ECMO in patients with MAS (relative risk 0.64, 95% CI 0.46, 0.91), and the number needed to treat to prevent one ECMO case was 6.[51] Although surfactant administration in one study was associated with reduced hospital stay with a mean difference

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

of 8 days, it did not affect mortality, days on a ventilator or oxygen, BPD, pneumothorax, or pulmonary interstitial emphysema. Dargaville et al. conducted a randomized, controlled trial of ventilated infants with MAS to look at the effects of surfactant lavage therapy. Those treated with surfactant had a decreased risk of death or ECMO, but there was no difference in the duration of respiratory support. They concluded that the use of surfactant lavage may reduce mortality, especially in units not offering ECMO.[43] The most effective method of delivering surfactant, bronchoalveolar lavage versus bolus administration, as well as which surfactant to use, remains controversial.

In cases complicated by PPHN, iNO should be considered. Extracorporeal membrane oxygenation can be lifesaving in patients with continued hypoxia despite aggressive treatment. Survival rates among infants with MAS treated with ECMO are high and are discussed in Chapter 70.

Observational studies in infants with MAS showed some improvement of pulmonary function with the use of inhaled or systemic steroids. However, a Cochrane meta-analysis of data in 2003 concluded that there is insufficient evidence to assess the effects of steroid therapy in the management of MAS. Future directions for treatment of MAS aimed at reducing inflammation and cytokine production are promising. Recent animal studies instilling budesonide with surfactant have demonstrated improved respiratory status and decreased inflammation and may be a therapeutic option in the future if results are replicated in humans.[113]

The ultimate prognosis of infants affected with MAS depends not so much on the pulmonary disease but on the accompanying asphyxial insult and treatment required. No specific long-term deficits in pulmonary function have been attributed to this disorder, although BPD can result from prolonged assisted ventilation. Compromised infants born through MSAF have an increased incidence of acute otitis media, probably secondary to meconium contamination of the middle ear.

Other Aspiration Syndromes

Respiratory distress can develop in the newborn infant secondary to aspiration of other amniotic fluid material, including purulent amniotic fluid, vernix caseosa, and maternal blood. The clinical picture is that of respiratory distress as described in the preceding. X-ray findings can be indistinguishable from MAS, although lack of MSAF and other risk factors for MAS help in the diagnosis.

Aspiration of maternal blood can be difficult to differentiate from pulmonary hemorrhage, especially if there is no history of antepartum hemorrhage. However, infants with pulmonary hemorrhage are usually sicker, with cardiovascular compromise including hypotension, poor perfusion, coagulopathy, and low platelets. Furthermore, the presence of swallowed blood in the stomach of affected infants suggests aspiration. Treatment with antibiotics is indicated if pneumonia is suspected secondary to aspiration of infected amniotic fluid.

Postnatal aspiration is most likely to be seen in preterm infants, those with disorders of swallowing, and infants with esophageal atresia and tracheoesophageal fistula. Small preterm infants are at greatest risk when fed excessive volumes per gavage or through misplaced orogastric tubes. These infants might initially present with cyanosis, desaturation, or apnea and subsequent respiratory distress. Over subsequent hours, pulmonary infiltrates may become visible on radiographs. The severity of disease varies and can be indistinguishable from an inflammatory pneumonitis. Aspiration syndromes associated with disorders of swallowing may be suspected from the perinatal history (asphyxia, polyhydramnios), feeding history (cyanosis, excessive drooling, poor suck), and physical examination. The precise cause, however, might not be readily apparent, and these infants require extensive neurologic evaluation. Infants with recurrent aspiration, particularly those with disorders of the swallowing mechanism, present complex management problems and require good care coordination to optimize care and prevent recurrent events.

Neonatal Pneumonia

Neonatal pneumonia continues to account for significant morbidity and mortality, especially in developing countries. Although mortality rates from pneumonia have declined over the past decade, neonatal pneumonia continues to be a global health issue that disproportionately affects developing countries.[54] At autopsy, pneumonia, diagnosed by the presence of inflammation, has been diagnosed in 20%-60% of stillbirths and liveborn neonatal deaths.[129]

Etiology

Neonatal pneumonia is classified as *early*, presenting within the first 3-7 days of life, and *late*, presenting after 7 days of life. Congenital pneumonia is one subset of early pneumonia that is acquired in utero and usually presents immediately after delivery. Congenital pneumonia is acquired through aspiration of infected amniotic fluid, ascending infection through intact or ruptured membranes, or hematogenous spread through the placenta. Early pneumonia can also be acquired during labor secondary to aspiration of infected amniotic fluid or bacteria colonizing the birth canal. Late neonatal pneumonia, which includes ventilator-associated pneumonia (VAP), is usually a nosocomial infection and occurs most commonly in ventilated neonates, although infection through hematogenous spread can also occur.

Whereas bacterial, viral, and fungal agents can cause pneumonia, the etiologic agent is usually related to the timing of occurrence of pneumonia. Group B *Streptococcus* (GBS) is the most common cause of early pneumonia. However, the overall incidence of GBS sepsis has decreased dramatically since the introduction of universal screening and intrapartum antibiotic prophylaxis.[163] The impact of the decreased incidence of GBS sepsis on the incidence of GBS pneumonia is not clear; however, the incidence of gram-negative

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

sepsis, especially that caused by *Escherichia coli* (*E. coli*), has increased following the implementation of the revised AAP guidelines and is the most significant pathogen in preterm infants.[19,153] Other bacterial causes of pneumonia include: *Klebsiella*, *Enterobacter*, group A streptococci, *Staphylococcus*, and *Listeria monocytogenes*. Anaerobes such as *Bacteroides* are occasionally recovered, but the contribution of these organisms to early-onset pneumonia is minimal.

Herpes simplex is the major cause of early viral pneumonia and is usually acquired during labor. Pneumonia is associated with 33%-54% of disseminated herpes infection and is usually associated with a high mortality rate. Other causes of early viral pneumonia include adenovirus, enterovirus, mumps, and rubella, whereas early pneumonia is an unusual presentation of congenital cytomegalovirus (CMV) infection. Other TORCH infections, including syphilis and toxoplasmosis, can also present with early-onset pneumonia. Up to 70% of disseminated candidal infections are associated with pneumonia, especially in premature infants.

Late-onset pneumonia is usually caused by organisms that colonize the newborn during the hospital stay. These include *Staphylococcus* species, including coagulase-negative staphylococci and *Staphylococcus aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *E. coli*, *Klebsiella*, *Serratia*, *Enterobacter cloacae*, *Pseudomonas*, *Bacillus cereus*, and *Citrobacter*, all of which can cause severe pneumonia, especially in preterm infants. When *Chlamydia trachomatis* infection is acquired during labor, it usually manifests as pneumonia at 2-4 weeks of life because of its long incubation period. Respiratory syncytial virus is the most common viral agent causing late-onset pneumonia, although incidence and severity have decreased secondary to passive immunoprophylaxis. Other viral causes of late pneumonia include adenovirus, enteroviruses, parainfluenza, rhinoviruses, and influenza viruses and can result in severe disease. Cytomegalovirus pneumonia should always be considered in babies with congenital infection presenting with late respiratory decompensation. Prolonged courses of antibiotics and corticosteroids can increase the risk of candidal pneumonia, especially in colonized infants with extremely low birth weight.

Clinical Presentation

Risk factors for early pneumonia are similar to those for neonatal sepsis and include prematurity, prolonged rupture of membranes, GBS colonization, chorioamnionitis, and intrapartum maternal fever. However, in one study, 22% of neonatal cases did not have risk factors, and in almost half, the only risk factor was early onset of labor. Therefore, risk factors should not determine whether to start antibiotics in neonates with respiratory distress, especially infants with extremely low birth weight. The presence and duration of mechanical ventilation and central venous lines were the main risk factors for development of late-onset pneumonia.[37] Other risk factors include abnormal neurologic conditions predisposing to aspiration pneumonia, poor nutrition, severe underlying disease, and prolonged hospitalization.

Clinical manifestations of early-onset pneumonia can be nonspecific; therefore, a high index of suspicion should always be exercised. These symptoms include temperature instability, lethargy, apnea, tachycardia, metabolic acidosis, abdominal distention, poor feeding, and neurologic depression. Respiratory distress can present in the form of tachypnea and retractions in more than two-thirds of affected neonates. Cough is an unusual symptom in neonatal pneumonia and was present in less than one-third of neonates.[48] Delay in diagnosis and treatment can lead to PPHN and septic shock.

Differential diagnosis for early neonatal pneumonia includes transient tachypnea of the newborn (TTN), RDS, MAS, and pulmonary congestion secondary to obstructed anomalous pulmonary venous return or other left heart obstructive lesions. Radiographic findings characteristic of pneumonia are nonspecific and thus do not help differentiate pneumonia from the disorders mentioned in the preceding. Chest x-ray findings might include unilateral or bilateral streaky densities, confluent mottled opacified areas, or a diffusely granular appearance with air bronchograms. Differentiation from RDS is difficult in preterm infants, especially because preterm labor is a risk factor for pneumonia. Radiographic findings of TTN usually resolve by 48 hours and those of RDS are markedly improved after surfactant treatment, whereas radiologic changes of pneumonia may persist for weeks.

Late-onset pneumonia usually presents with nonspecific changes in the overall condition of the infant in the form of new-onset or increased apnea, abdominal distension or feeding intolerance, temperature instability, respiratory distress, hyperglycemia, or cardiovascular instability. Patients receiving ventilatory assistance usually present with an increased oxygen requirement or mechanical support.

The diagnosis of pneumonia requires a high index of suspicion in any infant with new onset of symptoms suggestive of sepsis. Sepsis work-up, including blood culture, blood count, and differential should be obtained before starting antibiotics. The presence of an elevated C-reactive protein, neutropenia, immature white blood cells, and thrombocytopenia is highly suggestive (although not diagnostic) of infection in newborn babies with risk factors. Tracheal Gram stain and culture should be considered in infants who require mechanical ventilation. A positive tracheal culture in the first 8 hours of life may correlate with a positive blood culture. After 8 hours, a positive tracheal culture might be secondary to colonization. Analysis and culture of pleural fluid, if present in adequate amount, can aid in the diagnosis in infants not responding to empiric therapy. Specific studies for viral or unusual bacterial infections should be obtained if suspected. Diagnosis of ventilator-associated pneumonia (VAP) can be troublesome, especially in preterm infants with underlying lung disease. Typically, these infants' tracheas are colonized, discounting the validity of tracheal cultures. The Centers for Disease Control and Prevention has proposed stringent diagnostic criteria to diagnose VAP in infants younger than 1 year of age that

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

rely on increased ventilator support, temperature instability, new onset of purulent tracheal secretions or a change in the character of sputum, leukopenia or leukocytosis, clinical signs of respiratory distress, bradycardia or tachycardia, and new changes in chest radiograph that persist in at least two consecutive films. However, the validity of these criteria in diagnosing VAP in preterm infants with underlying lung disease has not been substantiated. Further studies are clearly needed to better diagnose and treat pneumonia in ventilated infants with low birth weight.

Management

Successful treatment depends on identification of the causative organism, institution of early and adequate antibiotic therapy, and supportive care. Empirical antibiotic therapy is usually started before isolation of the organism. In early-onset pneumonia, ampicillin and gentamicin are adequate initial therapy. However, with the increasing incidence of antibiotic-resistant Gram-negative bacteria, this regimen may need to be altered based on specific institutional susceptibility data. Empiric therapy with vancomycin (for coagulase-negative staphylococci) and gentamicin is usually started for late-onset pneumonia. To decrease the possibility of developing vancomycin-resistant bacteria, an empirical regimen for late-onset sepsis/pneumonia may include nafcillin and gentamicin, and vancomycin is started if coagulase-negative *Staphylococcus* is identified or the clinical picture is deteriorating. In intubated infants, antibiotic coverage depends on the specific bacteria colonizing the trachea. When the causative organism is isolated, specific therapy is started according to susceptibility profile. The duration of therapy is dependent on the causative organism and response to treatment; however, in uncomplicated pneumonia, 10-14 days of therapy are usually adequate.

Whereas antibiotic therapy is the mainstay of treatment, supportive care is essential and has been shown to decrease the mortality and morbidity associated with pneumonia in developing countries. In the acute stage, circulatory support with fluids and inotropes might be needed, and mechanical ventilation and oxygen should be administered to correct hypoxemia. Special attention to correct acidosis, hypoglycemia, and other possible electrolyte imbalance is also warranted. Parenteral nutrition with amino acids, carbohydrates, and lipids can provide adequate nutrition and prevent protein catabolism as well as amino and fatty acid deficiency. Feeding should be started as soon as possible to supply adequate calories. In the absence of respiratory distress or abdominal pathology with concern for aspiration, gavage feedings can be started.

Transient Tachypnea of the Newborn

Transient tachypnea of the newborn is a common physiologic disorder of the newborn resulting from pulmonary edema secondary to inadequate or delayed clearance of fetal alveolar fluid. The initial clinical picture is usually completely resolved by 48-72 hours, hence the term *transient*. However, TTN continues to represent a diagnostic dilemma secondary to the inability to differentiate its initial presentation from that of other causes of respiratory distress, including pneumonia. The incidence has been estimated at 5.7 per 1000 births in term infants. Risk factors for development of TTN include premature or elective cesarean delivery without labor, large birth weight, maternal diabetes, maternal asthma, twin pregnancy, and male gender. The incidence of pulmonary pathology including TTN was found to be two- to threefold higher in infants born after planned cesarean delivery compared with a planned vaginal delivery.[67]

Fetal alveolar fluid is continuously secreted during pregnancy through an epithelial chloride secretion mechanism, and the rate of secretion decreases a few days before delivery. At birth, the balance of fluid movement in the alveolus switches from chloride secretion to sodium absorption, causing resorption of intra-alveolar fluid. Absorption occurs in two steps. First, sodium moves from the alveolar lumen into the cell by passive movement across a concentration gradient maintained by the Na-K-ATPase pump. Next, sodium is actively transported into the interstitium by amiloride-sensitive epithelial sodium channels (ENaC). Thereafter, the sodium and fluid are cleared through the lymphatic and vascular systems.

The mechanisms underlying failure or delay in clearance of intra-alveolar fluid in patients with TTN are not totally understood. The mechanical force of birth canal squeeze, originally thought to be the major factor in lung fluid resorption, is now believed to be only a minor contributor. Immaturity of ENaC has been shown, both in animals and neonates, to impair fluid resorption, and as ENaC expression is developmentally regulated, this is especially relevant in the late preterm infant. Hormonal changes associated with spontaneous labor, especially the surge of catecholamines and endogenous steroids, and activation of the β-adrenergic system seem to be important in increasing the expression and activity of ENaC, which partially accounts for the higher incidence of TTN in elective cesarean section cases not preceded by spontaneous labor.[73]

The clinical picture of patients with TTN is secondary to the decrease in lung compliance associated with pulmonary edema. Collapse of airways might also occur in response to fluid accumulation in the interstitium and peribronchial lymphatics. The net result is variable degrees of hypoxemia and respiratory acidosis.

Patients with TTN usually present very early after birth with symptoms of respiratory distress. Tachypnea is the most consistent finding, although increased work of breathing with expiratory grunting, nasal flaring, and retractions may also be present. Hypoxemia necessitating modest oxygen requirement (usually <40%), together with hypercapnia, can occur, whereas respiratory failure requiring CPAP is unusual. The most characteristic feature of TTN is the transient nature of this disease. In most patients, rapid continuous improvement in the clinical condition occurs within

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

24-48 hours of life, although in some patients, symptoms might persist beyond 72 hours of life. Characteristic radiographic findings consist of perihilar streaking that represents engorgement of the periarterial lymphatics and fluid-filled interlobar fissures. Both the horizontal and oblique fissures can be affected, although the horizontal is affected more commonly. Fluid-filled alveoli can present as fluffy bilateral infiltrates. Atelectasis and pleural effusion can also be seen. Although these radiographic changes can readily be distinguished from classic changes of RDS, TTN can conceivably accompany RDS in preterm infants. Radiographic changes are essentially resolved by 48 hours. Ultrasound has recently been described to be useful in the diagnosis of TTN as well as prediction of the need for respiratory support in infants affected by TTN.[33,103,126]

Treatment of TTN is supportive. However, because it is difficult to differentiate TTN from other disorders, most patients are usually started on antibiotics that can be discontinued after 48 hours if cultures are negative and the diagnosis is more clear. Lasix has no role in the treatment of TTN. Recently, the use of antenatal steroids prior to late preterm delivery has demonstrated decreased rates of TTN among other respiratory morbidities[65] perhaps through enhanced fluid resorption from alveolar spaces through increased transcription and activation of ENaC. However, this is not practice beyond 36 6/7 weeks' gestation. Exogenous steroids or catecholamines do not seem to provide benefit after birth once the patient is symptomatic, because recovery usually precedes the action of these agents. The use of inhaled β-agonist therapy has been suggested, but this is based on small observational studies, thus there is not enough evidence to support its routine use.[87,116] Delaying elective cesarean section until 39-40 weeks' gestation or until spontaneous labor starts will decrease the incidence of TTN. However, this should be weighed against possible complications of delaying a needed cesarean section.[62] Although TTN is considered a self-limited transient condition, there are increasing data to suggest that TTN increases a newborn's risk for developing a wheezing syndrome early in life.[101]

Pulmonary Hemorrhage

Pulmonary hemorrhage is a serious complication in neonates with RDS and has been associated with higher morbidity and mortality. Serious pulmonary hemorrhage has been defined as a gush of blood through an endotracheal tube in intubated neonates associated with a worsening clinical picture, requiring increased ventilatory support and blood product transfusion. The incidence of such severe hemorrhage is about 5% in very low birth weight infants and 10.2% in extremely low birth weight infants. Risk factors for development of pulmonary hemorrhage include extreme prematurity, surfactant administration, patent ductus arteriosus (PDA) with left-to-right shunting, multiple birth, and male gender. Other risk factors include severe systemic illness, coagulopathy, and asphyxia. More than 80% of cases of serious pulmonary hemorrhage occur before 72 hours of life with a median of 40 hours; however, some babies might present after 1 week of life.[157]

The pathophysiology of pulmonary hemorrhage is believed to be secondary to a sudden decrease in pulmonary vascular resistance, causing increased left-to-right shunting and pulmonary vascular engorgement, pulmonary edema, and ultimately, rupture of pulmonary capillaries. This is especially true in patients with a PDA after surfactant treatment. In a post hoc analysis of patients enrolled in the trial for indomethacin prophylaxis in premature infants, a reduced risk for PDA accounted for 80% of the beneficial effect of prophylactic indomethacin on serious pulmonary bleeds.[8] However, pulmonary hemorrhage can also occur in patients who never received surfactant or had a PDA, highlighting the importance of other etiologies in the pathogenesis of pulmonary hemorrhage, including aggressive suctioning, especially using a closed-circuit system.

Patients with pulmonary hemorrhage usually present with cyanosis, bradycardia, apnea, gasping, hypotension, increased work of breathing, hypoxia, and hypercapnia, requiring increased ventilatory support. In almost one-third of patients, serious pulmonary hemorrhage was preceded by prodromal episodes of suctioning frothy blood-tinged tracheal secretions. Chest radiographs demonstrate acute and varying degrees of worsening of the underlying pulmonary disease, ranging from bilateral fluffy infiltrates to complete whiteout in severe cases.

Treatment of pulmonary hemorrhage is mostly supportive. Increased ventilatory support, especially positive end-expiratory pressure (PEEP), serves two purposes: it is needed for adequate ventilation and oxygenation, and it acts to tamponade and stop the bleeding. Suctioning should be limited during the acute hemorrhage. The efficacy of instillation of epinephrine, although used clinically, has not been proved in clinical trials. Transfusion of blood products and correction of underlying or secondary coagulopathy is essential. Pulmonary hemorrhage can cause deactivation of surfactant, and exogenous surfactant administration has been used successfully.[9] Prophylactic indomethacin decreased the incidence of pulmonary hemorrhage by 26% in infants with extremely low birth weight.[135]

Pulmonary hemorrhage is associated with mortality approaching 50% in infants with extremely low birth weight. Whereas initial retrospective studies did not show worse neurodevelopmental outcomes in survivors of pulmonary hemorrhage, one study showed increased incidence of cerebral palsy and cognitive delay (OR 2.86 and 2.4, respectively).[8] Pulmonary hemorrhage was also associated with increased incidence of periventricular leukomalacia and seizures at 18 months of age.

Pulmonary Air Leak Syndromes

Air leak occurs more commonly in the newborn period than any other period of life. One to two percent of all live

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

births of term infants were found to have a pneumothorax on consecutive chest radiographs in 1930. The incidence increases with decreasing gestational age. Although the incidence was 6.3% in 1999 in very low birth weight infants in the Vermont-Oxford Network database, it approached 15% in those with a birth weight of 501-750 g.[70] Air leak syndromes include pneumothorax, pneumomediastinum, pulmonary interstitial emphysema, and pneumopericardium, and less commonly, pneumoperitoneum and subcutaneous emphysema. Even though air leaks can occur spontaneously, they mostly occur in patients with lung pathology, including MAS, pneumonia, RDS, diaphragmatic hernia, and pulmonary hypoplasia, especially when positive-pressure ventilation is required. The introduction of surfactant for treatment of RDS has caused a decrease in the incidence of air leaks. Conversely, the increasing practice of elective cesarean section before 39 completed weeks' gestation is associated with increased incidence of pneumothorax when compared with emergent cesarean section (OR 4.2) or vaginal delivery (OR 7.95).[172]

Pathophysiology

Air leaks occur when overdistended alveoli rupture into the perivascular bundle, from where air tracks toward the hilum or pleura, causing pneumomediastinum or pneumothorax, respectively. In the preterm infant in whom the interstitium is more abundant and less dissectible, air can stay in the perivascular sheets, causing pulmonary interstitial emphysema (PIE). Alveolar overdistension might occur in the presence of uneven alveolar ventilation or air trapping. Atelectasis in RDS and plugged small airways in MAS cause unequal distribution of the ventilated volume and transpulmonary pressure to the more distensible areas of the lung, increasing the risk of rupture and air leak. Partial obstruction during MAS causes air trapping when inspired air is not completely evacuated during exhalation. Further accumulation during subsequent breaths can rupture the alveolar space.

Different ventilatory strategies have been associated with the development of pneumothorax, including higher peak inspiratory pressure especially in the 24 hours preceding pneumothorax, long inspiratory time (>0.5 seconds), and frequent suctioning in the 8 hours before pneumothorax. Elective initial use of high nasal CPAP (8 cm H_2O) in infants at 25-28 weeks' gestation was associated with increased incidence of air leak from 3%-9% when compared with intubated infants who received surfactant therapy. However, there was no difference in the incidence of BPD or mortality rate between the two groups.[117] Use of CPAP (5 cm H_2O) in the delivery room in extremely low gestational age infants was associated with a decreased need for intubation and postnatal corticosteroids for BPD and fewer days of mechanical ventilation when compared with initial intubation and surfactant administration within 1 hour after birth, without an increase in the incidence of pneumothorax.[154] Factors possibly associated with decreased incidence of pneumothorax include positive-pressure ventilation (rate >60) and volume-targeted ventilation. The use of HFOV following pneumothorax was associated with a decreased incidence of secondary pneumothorax.[114]

Clinical Presentation

Although pneumothorax can be the presenting diagnosis, more commonly, it complicates underlying lung pathology. Sudden worsening in respiratory distress should always raise the suspicion of the development of a pneumothorax. Tachypnea, grunting, flaring, and retractions occur most commonly. Hypoxemia with cyanosis and increased oxygen requirement occur early in the course of pneumothorax while hypercapnia follows. Hypoxemia develops secondary to hypoventilation and ventilation-perfusion mismatch as the affected lung collapses. Physical examination reveals distant breath sounds, overdistension of the chest wall, and bulging abdomen on the affected side secondary to downward displacement of the diaphragm in patients with unilateral pneumothorax. The cardiac apex is displaced away from the affected side, as is the trachea.

Larger volumes of leaked air can cause significant increase in intrathoracic pressure, which impairs venous blood return and compromises cardiac output, causing poor tissue perfusion and metabolic acidosis. Although bradycardia and hypotension were not seen in a piglet model of moderate pneumothorax (30 mL of air), they can develop with a severe tension pneumothorax. The decreased cardiac output may cause a compensatory increase in carotid blood flow as the body tries to protect vital organs. The resultant increase in cerebral blood flow together with impairment of cerebral venous return secondary to increased central venous pressure might explain the increased incidence of intraventricular hemorrhage (IVH) in patients with pneumothorax.

Pneumomediastinum is often asymptomatic if not associated with pneumothorax and is mostly found on radiographic evaluation of patients with respiratory distress or distant heart sounds. Dissection of air through the anterior mediastinum into the neck can cause subcutaneous emphysema that is most commonly felt as subcutaneous crepitus in the face, neck, or supraclavicular notch area.

Pneumopericardium is a rare and serious complication probably caused by dissection of leaked air through the vascular bundle of great vessels. Trapped air in the limited pericardial space can quickly cause cardiac tamponade, decreasing venous return, and cardiac output. Pneumopericardium should be suspected in patients with an air leak and sudden cardiovascular compromise associated with a narrow pulse pressure. The clinical picture consists of worsening respiratory distress, hypotension, bradycardia, pallor, and/or cyanosis. Cardiac sounds are distant or muffled on auscultation and a pericardial rub might also be heard. Low voltage QRS complexes can also be seen.

Pneumoperitoneum occurs when an intrathoracic air leak decompresses into the abdomen. It is typically asymptomatic and usually diagnosed on radiographic evaluation. It should, however, be differentiated from free

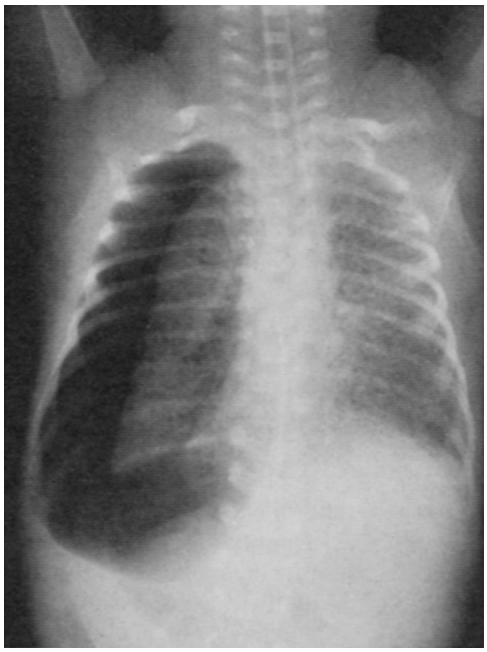
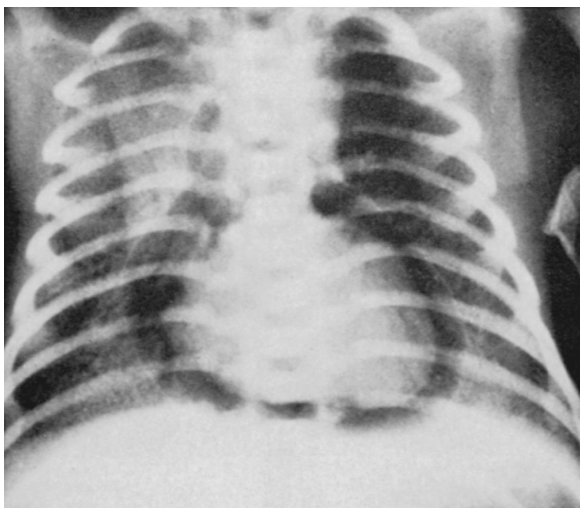
abdominal air secondary to a ruptured viscus in which patients are usually symptomatic with signs and symptoms of peritonitis.

Diagnosis



In unstable neonates with progressive deterioration of their clinical status, transillumination of the chest might provide a quick bedside diagnostic tool and allow for immediate intervention before x-ray confirmation. The technique involves the use of a fiberoptic light probe that is placed on the infant's chest wall while the room is darkened. In the presence of a large pneumothorax, the entire hemithorax on the affected side lights up and the opposite side shows diminished transillumination because of lung compression on that side. In such cases, decompression should be accomplished without awaiting radiographic confirmation. However, in stable neonates, radiographic confirmation should always be sought before intervention. Inconclusive results or inexperience with the use of transillumination should also be confirmed by x-ray before intervention. This allows for proper localization of the pneumothorax, as well as excluding other disorders that do not need evacuation, such as pneumomediastinum, congenital lobar emphysema, or diaphragmatic hernia.

The diagnosis is clear on radiographic evaluation of patients with a large or tension pneumothorax. Air accumulates between the parietal and visceral pleura, separating the lung from the chest wall and collapsing the ipsilateral lung. This can be seen as a curvilinear line silhouetting the collapsed lung (Fig. 66.7). External artifacts can also appear as a curvilinear line on chest radiograph; however, artifact can be differentiated from a pneumothorax by its tendency to extend beyond the chest cavity in either direction. With a tension pneumothorax, the mediastinal structures, including the heart, are shifted away from the affected side. Lung collapse might not be complete despite a severe pneumothorax in patients with RDS secondary to poor compliance of the affected lung. Smaller pneumothoraces might appear as a small sliver of free air lateral to the lung or above the diaphragm, causing the edge of the diaphragm or costophrenic angle to appear crisp. An anterior pneumothorax causes the affected lung to look translucent compared with the contralateral side. Confirmation of a small pneumothorax can be obtained with a lateral decubitus chest radiograph, where the unaffected side is dependent. As the free air rises, the reflection of the parietal pleura is seen clearly as a curvilinear line beyond which no lung markings are seen. This might also identify any contralateral pneumothorax or pneumomediastinum.



Pneumomediastinum can be diagnosed on chest radiograph by elevation of the edge of the thymus from the pericardium by mediastinal free air in a characteristic crescent or spinnaker sail configuration. A large pneumomediastinum can be differentiated from a pneumothorax by lateral decubitus radiographs as described earlier.

Pneumopericardium appears on plain chest radiograph as free air completely surrounding the heart but not extending beyond the aorta or pulmonary artery into the upper mediastinum. Although difficult to differentiate from a large pneumomediastinum, the presence of air between the heart and diaphragm is diagnostic of pneumopericardium (Fig. 66.8).

Pulmonary interstitial emphysema (PIE) is seen on chest radiograph as coarse, nonbranching radiolucencies that project toward the periphery of the lung in a disorganized fashion. This appearance must not be confused with an air bronchogram, a classic radiographic sign of respiratory distress syndrome. Air bronchograms show long, smooth, branching radiolucencies that follow normal anatomic distributions similar to the bronchial tree. Pathologically, PIE is seen in lung tissue as multiple irregular, air-filled cysts

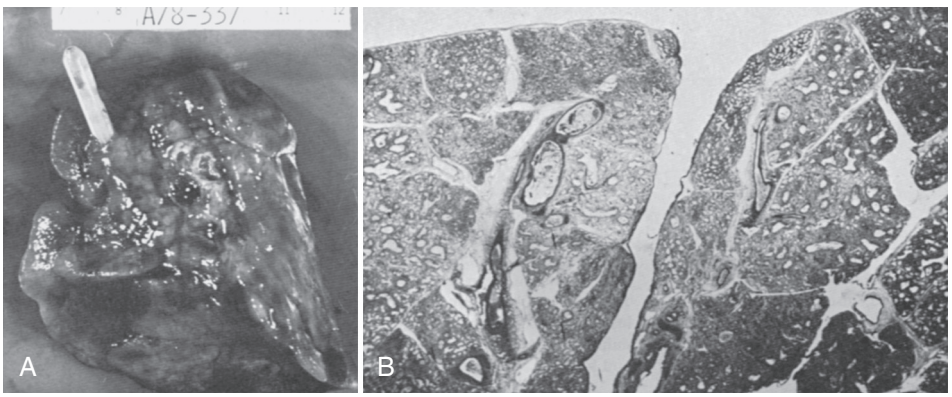
varying in diameter from 1 mm-1 cm, localized to interlobular septa, and extending radially from the hilum. Pulmonary interstitial emphysema can be localized to one lung or a lobe of a lung or can be diffuse bilateral disease. There is usually hyperinflation on the affected side that persists even after weaning ventilatory support.



Management

Treatment of a pneumothorax depends on the severity of clinical presentation and whether it occurs during mechanical ventilation. In asymptomatic patients without underlying pulmonary disease, no treatment is required; however, close observation for worsening pneumothorax and development of respiratory symptoms is clearly needed. The pneumothorax usually resolves spontaneously in 1-2 days. Follow-up radiographs can be obtained as mandated by the clinical picture. The association of symptomatic spontaneous pneumothorax with congenital renal malformations and the need for renal ultrasound evaluation in these patients is controversial. A review of 80 patients with spontaneous pneumothorax compared with normal controls showed no difference between the two groups in the rate of congenital renal malformations.[7]

Only supportive care is needed in the treatment of symptomatic patients with a mild pneumothorax without evidence of respiratory failure. Theoretically, 100% oxygen given by a hood might lead to nitrogen washout and resolution or decrease in the size of the pneumothorax. Recent retrospective reviews showed no difference in time to resolution of pneumothorax in infants treated with 21% oxygen vs. 100% oxygen vs. somewhere in between.[30,144] Oxygen is generally given only as needed to provide adequate oxygen saturations. Thoracocentesis is used for emergency evacuation of a large pneumothorax in unstable infants and might be the only treatment needed in nonventilated babies. However, recurrence of the pneumothorax should prompt the insertion of a chest tube. Thoracocentesis can also be used as a temporizing measure before chest tube insertion in ventilated infants.

In ventilated patients with a large or tension pneumothorax, the initial management is to wean PIP and PEEP to decrease further air leak while preparing for chest tube placement. Deciding on which brand of chest tube and which insertion technique to use depends most importantly on experience and comfort level. The tube should be inserted under complete aseptic technique and positioned anterior to the affected lung. The position of the tube should be confirmed by anteroposterior and lateral chest radiographs. When placed correctly, there is immediate improvement in oxygenation in affected patients, and the tube should be connected to an underwater seal with continuous suctioning at 10-20 cm H_2O. The chest tube should be secured when correct positioning is confirmed, with special attention given to prevent tension on the tube causing it to dislodge, particularly during radiologic examination. Chest tube insertion can be complicated by lung damage, which is usually diagnosed at autopsy, diaphragmatic paralysis secondary to phrenic nerve damage, or bleeding (Fig. 66.9). The use of a trocar or other sharp instrument during insertion should be avoided to decrease the chance of these complications. Once air bubbling stops, the chest tube should be clamped or put to water seal overnight, and if the pneumothorax does not reaccumulate, the tube can be successfully removed. Isolated pneumomediastinum is usually self-limiting and does not need intervention. However, these patients should be closely observed because a pneumothorax could develop.

Management of PIE can present a challenge. Increased support may lead to enlargement of the more compliant PIE cysts, which in turn compresses the relatively normal adjacent alveoli, causing worsening hypoxia and hypercapnia. The treatment strategy instead should target decreasing mean airway pressure while accepting higher CO_2 levels and oxygen requirement to allow for collapse of the dilated interstitial cystic lesions and expansion of the normal alveoli. High-frequency oscillatory ventilation is an acceptable ventilatory strategy for PIE because of the lack of inflating volumes that tend to worsen the PIE. In the case of failure of conservative management and persistent PIE, different treatment strategies have been tried, especially in unilateral cases, with varying degrees of success, including single-lung ventilation.[128]

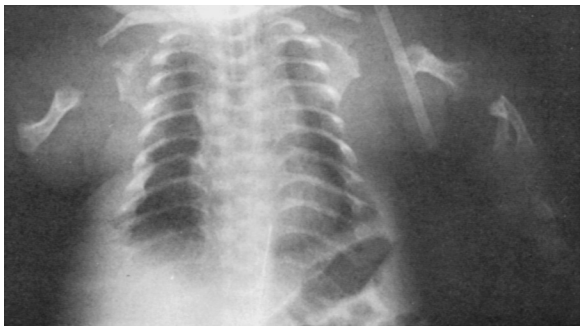
The occurrence of air leak is associated with increased incidence of mortality and morbidity. Together with the increased incidence of IVH mentioned earlier, very low birth weight infants who develop pneumothorax in the first 24 hours of life were 13 times more likely to die or develop bronchopulmonary dysplasia. Furthermore, extremely low birth weight infants with a pneumothorax who had a normal head ultrasound were more likely to develop cerebral palsy after controlling for other factors (OR 2.3).[99] Therefore, management strategies directed at avoiding the development of a pneumothorax should always be sought, including using minimal effective inspiratory pressures, low inspiratory time, high-frequency positive pressure ventilation, volume-targeted ventilation, early administration of surfactant in eligible patients, and rapid weaning of mechanical ventilation.



Rib Cage Abnormalities

Thoracic cage and skeletal abnormalities are a rare group of conditions that can cause respiratory distress by restriction of thoracic volume. They include a number of entities incompatible with life. In this group of diseases are those with hypoplasia of the ribs and thorax, including asphyxiating thoracic dystrophy (Jeune syndrome), thanatophoric dysplasia, achondrogenesis, homozygous achondroplasia, osteogenesis imperfecta (severe form), Ellis-van Creveld syndrome (chondroectodermal dysplasia), hypophosphatasia, spondylothoracic dysplasia, and rib-gap syndrome.

Respiratory distress caused by structural abnormalities of the chest wall should be readily apparent. However, marked narrowing of the thorax can result in what appears to be a distended abdomen, and the respiratory problem can be erroneously attributed to an intra-abdominal pathologic condition. The presence of other associated anomalies, for example, short-limbed dwarfism, together with close observation of respiratory excursions, examination of the bony thorax, and measurement of the circumference of the chest, establishes the diagnosis even before a review is made of the thoracic and skeletal radiographs.

With structural abnormalities of the chest wall, asphyxia and respiratory distress are present from birth. The infants are cyanotic and tachypneic and demonstrate severe retractions and characteristically, a virtually immobile chest. Diaphragmatic excursions are prominent; thus respiration appears entirely abdominal. Pulmonary hypoplasia accompanies the thoracic dystrophy, and radiographically, the lungs can appear airless.

Infants with asphyxiating thoracic dystrophy, thanatophoric dwarfism, achondrogenesis, homozygous achondroplasia, or Ellis-van Creveld syndrome have thoracic radiographs with a squared-off appearance, and the posterior rib arcs all appear to be the same length. The clavicles appear very high, and the diaphragms are low (Fig. 66.10). The transverse diameter of the thorax can appear diminished in comparison with the vertical diameter. On a lateral view, the ribs are very short and can appear clubbed anteriorly. The anteroposterior diameter of the thorax is decreased. The lungs may be poorly aerated, infiltrates are often present, and the heart might appear enlarged. Differentiating among the various syndromes of thoracic cage and skeletal abnormalities usually is accomplished by means of a skeletal survey. Multiple fractures and bone demineralization are characteristic of osteogenesis imperfecta and hypophosphatasia.

• **Fig. 66.10** Radiographic appearance in thanatophoric dwarfism showing the narrow thorax, low diaphragm, and foreshortened humeri.

Asphyxiating Thoracic Dystrophy (Jeune Syndrome)

Jeune syndrome is a rare autosomal recessive skeletal dysplasia with multiorgan involvement. Mutations in *WDR19*, *DYNC2H1*, *TTC21B*, and *IFT80* genes encoding intraflagellar protein have been identified in a small subset of Jeune syndrome patients.[14,165] The hallmarks of asphyxiating thoracic dystrophy are extreme constriction and narrowing of the thorax, short ribs, and variable shortening of the limbs with abnormalities of the bones of the pelvis and extremities. The thorax is relatively immobile, and the ribs are horizontally directed and short with bulbous ends. In addition to the thoracic abnormalities, the infants have trident iliac bones with a double-notch appearance of the acetabulum. Associated anomalies include polydactyly and deformed teeth. Renal abnormalities may be present, and renal failure can occur later in life.

These infants usually present with respiratory distress and recurrent respiratory infections during the neonatal period. It has been reported that 60%-80% of cases are fatal in early childhood, but if they survive the early years, the respiratory problems tend to decrease with age, and a subset of children affected by this disorder can have long-term survival.[41]

Thanatophoric Dysplasia

Thanatophoric dysplasia (see Chapter 30) was differentiated from achondroplasia in 1967. The disorder has been generally fatal in the perinatal period, with rare exceptions,

and probably is the most common form of lethal neonatal dwarfism. It is caused by de novo mutations in the *FGFR3* gene (fibroblast growth factor receptor 3) and is an autosomal dominant condition.[79] Appearance at birth is characteristic and includes striking micromelia in association with a normal trunk, a large head, and a narrow thorax. The radiographic findings include severely flattened vertebral bodies with markedly widened intervertebral disk spaces, small iliac rings, and flaring of the metaphyses of the long bones. There is a high incidence of polyhydramnios, and the infants often present in the breech position.

Infants present at birth with severe pulmonary insufficiency, requiring mechanical ventilation and intensive neonatal care. Immediate and accurate diagnosis is important in guiding medical decisions about continuation of support.

Phrenic Nerve Injury

Phrenic nerve injury with paralysis of the diaphragm is an unusual cause of respiratory distress. It is most commonly present on the right side following birth trauma; thus, an associated brachial plexus injury or Horner syndrome can coexist in approximately 75% of the patients. However, injury can also occur after cardiovascular or thoracic surgeries or following invasive procedures. The injuries are observed in infants who are large for gestational age, especially following shoulder dystocia or difficult breech extractions. Fractures of the humerus or clavicle are often observed. The nerve roots of C3 to C5 are stretched, with lateral hyperextension and traction on the neck. Recovery depends on the degree of injury; avulsion results in permanent injury, and diaphragmatic eventration secondary to muscle atrophy ensues. Lesser injury or edema of the nerve roots results in a spectrum of respiratory symptoms that can include cyanosis, weak cry, tachypnea, or apnea. On radiographic examination, the involved hemidiaphragm is elevated, and atelectasis usually is observed on that side. The heart and mediastinum are shifted away from the affected side (Fig. 66.11). Ultrasonographic or fluoroscopic evaluation should be diagnostic and reveal paradoxic movement of the diaphragm with elevation during inspiration and descent with expiration. Congenital eventration of the diaphragm also results in an elevated hemidiaphragm with paradoxical movement. Secondary pneumonia is the major source of morbidity and mortality. Treatment of phrenic nerve palsy initially is supportive and, in the absence of avulsion, spontaneous resolution is to be expected. Surgical plication of the diaphragm might be required for selected infants with avulsion.

• **Fig. 66.11** Phrenic nerve palsy. **A,** Note the elevated right dome of the diaphragm. **B,** Lateral view.

Key Points

- Not all respiratory distress after birth is due to respiratory distress syndrome.
- The degree of respiratory distress due to these other causes is dependent on the timing of the insult and the degree to which it causes pulmonary hypoplasia and decreased pulmonary vascular growth.
- Symptoms and outcomes can vary widely in this group of disorders and our therapies are ever evolving to improve the long-term morbidities and mortality associated with them.

Neonatal Apnea and the Foundation of Respiratory Control

MARY ELAINE PATRINOS

Breathing results in the exchange of oxygen and carbon dioxide between the lungs and the environment while maintaining homeostasis and control of blood pH. Energy-consuming breathing movements do occur in utero. Maturation of breathing is a continuous process that bridges fetal and neonatal life. Especially for premature infants, immature fetal breathing responses result in irregular respiratory effort, apnea, bradycardia, and hypoxemia.

Fetal Breathing

Fetal breathing activity has been described in many species and is present very early in gestation. Breathing activity in the human fetus can be detected by 11 weeks' gestation using ultrasound. Although the placenta is the site of gas exchange in utero, fetal breathing is important for lung growth and development. Moreover, decreased diaphragmatic activity has been associated with pulmonary hypoplasia. Fetal breathing movement (FBM) has also been shown to significantly increase fetal cardiac output and blood flow to a number of vital organs, including the heart, brain, and placenta. FBM changes from early continuous movement that seems to originate from the spinal cord to a phasic pattern that occurs only during rapid eye movement (REM) in the third trimester with total cessation of breathing during non-REM sleep, possibly secondary to descending inhibitory pontine input to the medullary rhythm-generating center. The mechanisms underlying loss of phasic FBM and the establishment of continuous breathing after birth are not clear. However, several factors have been implicated, including serotonin, γ-aminobutyric acid (GABA), corticotrophin-releasing factor, and prostaglandins.[2]

Fetal hypercapnia increases the incidence and depth of FBM only during REM sleep without affecting breathing frequency. This response is present from 24 weeks' gestation, and CO_2 sensitivity increases with advancing gestational age (GA). In contrast, fetal hypocapnia causes a decrease or disappearance of FBM, which implies that a baseline CO_2 level is essential for the presence of FBM. Although the fetus lives in a relatively hypoxemic state (PaO_2 23-27 mm Hg), oxygen delivery in utero is adequate, because it matches oxygen consumption and allows for fetal activity and growth. Unlike adults, the fetus responds to hypoxia with a decrease in breathing activity. The cause of this hypoxic ventilatory depression in utero appears to be central in origin. Brainstem transection or lesions in the lateral upper pons allow acute hypoxemia to stimulate FBM even in the absence of the carotid bodies. This is consistent with the concept that hypoxic depression is the result of descending pontine or suprapontine inhibition. Unlike the fetal breathing response to hypercapnia, the hypoxic response is logical in the sense that an increase in fetal respiratory activity in response to hypoxia would be counterproductive.

Postnatal Development of Respiratory Control

Although better developed than the fetal pattern, the degree of maturity of respiratory control in the newborn is directly related to gestational age at birth. Immaturity manifests in almost every aspect of respiratory control, from peripheral afferent input to central respiratory output and respiratory muscle responses. There seems to be an overriding inhibitory influence of central origin in the control of breathing in the neonate. This is manifested by a decreased response to CO_2, a paradoxical response to hypoxia, an exaggerated reflex apnea, and irregularities of breathing. The origin of this inhibitory effect on neonatal breathing could be secondary to increased inhibitory pathways, decreased excitatory pathways, or a combination of both.

Neonatal Breathing Pattern

Neonatal respiratory activity is irregular with spontaneous changes alternating between eupnea, apnea, periodic breathing, and tachypnea. Respiratory frequency, often inversely proportional to body weight, may be quite variable in the preterm infant. Periods of slow respiratory rates are secondary to prolongation of expiratory time (T_E),

Abstract

Maturation of breathing is a continuous process that bridges fetal and neonatal life. Especially for premature infants, immature fetal breathing responses result in irregular respiratory effort, apnea, bradycardia, and hypoxemia. Caffeine in conjunction with continuous positive airway pressure or other forms of noninvasive respiratory support are effective measures to reduce apnea severity and its consequences. The lack of consensus regarding the definition of a clinically significant cardiorespiratory event can impact length of stay and complicate hospital discharge.

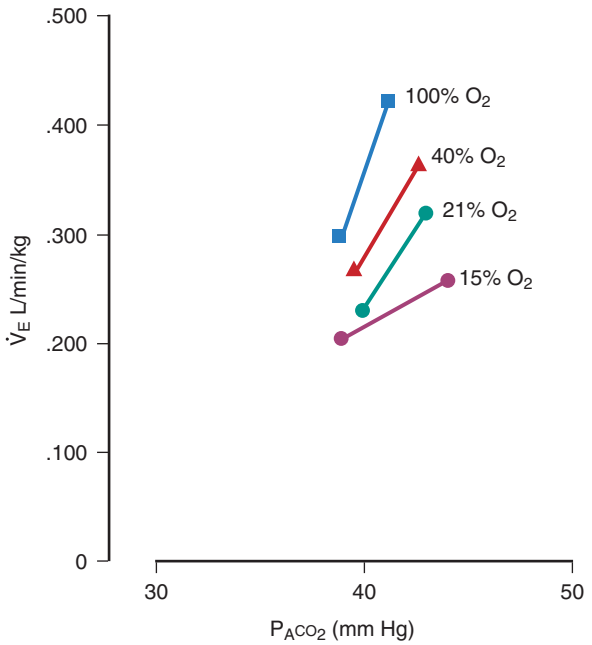
whereas inspiratory time (T_I) remains relatively unchanged during development. Extreme prolongation of T_E results in respiratory pauses and apnea, which occur frequently in preterm and, to a lesser extent, in healthy term neonates. Paradoxical inward movement of the rib cage during inspiration is especially common in preterm infants. The mechanism behind this paradoxical movement is related to a combination of a highly compliant rib cage and diminished intercostal muscle tone opposed by diaphragmatic contraction. The effort required to produce a tidal volume during these paradoxical movements is substantially greater than during "normal" breathing, which further hinders an already immature respiratory system. Because of chest wall instability and immature lung development, the preterm infant often compensates with a shortened expiratory time and expiratory breaking to maintain expiratory lung volume. Occasional sigh breaths re-open areas of atelectasis. Apnea often leads to a loss in lung volume, decrease in functional residual capacity (FRC), and reduction in oxygen stores.[12] The incidence of central apnea decreases with advancing gestational age and is present in almost all infants with a birth weight less than 1000 g or gestational age less than 28 weeks. At 43-44 weeks' corrected gestational age, the incidence of apnea is comparable to that of a term neonate. Apnea is not exclusively confined to preterm babies. Healthy term infants may also have apnea exceeding 20 seconds on home monitoring.[43]

Hypercapnia and Acidosis

Small increases in arterial P_{CO_2} resulting in central acidosis increase ventilation dramatically. The ventilatory response to CO_2 is the net result of activation of both peripheral and central chemoreceptors. The contribution of the peripheral chemoreceptors, mainly through the carotid body, is 10%-40% of the total hypercapneic response. Central chemoreceptors originally thought to be confined to the ventrolateral medulla have been found to be widespread in the brainstem, including the retrotrapezoid nucleus, the region of the nucleus tractus solitarius, the region of the locus coeruleus, the rostral aspect of the ventral respiratory group, and the medullary raphe.[34] Other sites of chemoreception include the fastigial nucleus of the cerebellum and the pre-Botzinger complex. The ventilatory response to CO_2 is impaired in preterm infants relative to term newborns and adults; however, it increases with advancing postnatal and gestational age. It has been demonstrated that, unlike adults, preterm infants and newborn animals are less able to increase their respiratory rate in response to CO_2, but tidal volume increases appropriately.[5] Possible mechanisms for this impaired response to CO_2 include changes in the mechanical properties of the lung, maturation in the peripheral or central chemoreceptors, or changes in the central integration of chemoreceptor or other neuronal signals. Multiple studies have indicated a central origin for the attenuated CO_2 response in preterm babies, in particular those with apnea. However, a cause-and-effect relationship between apnea of prematurity and the attenuated response to CO_2 has not been clearly established, and both might simply represent facets of a decreased respiratory drive.



Hypoxia

Unlike adults who express a sustained response to hypoxia, the neonatal hypoxic ventilatory response is biphasic, with an initial increase in ventilation that lasts 1-2 minutes, followed by a decline that falls below baseline ventilation in preterm infants (Fig. 67.1). This late decline has been traditionally termed *hypoxic ventilatory depression*. Although the increase in tidal volume is sustained, breathing frequency decreases during hypoxic exposure, hence the biphasic response. The increase in ventilation occurs through activation of peripheral chemoreceptors located primarily in the carotid body and is eliminated by carotid body denervation. During development, the initial rise increases, while the late depression decreases with advancing postnatal age; however, in one study, hypoxic ventilatory depression persisted in convalescing preterm neonates at 4-6 weeks of age.[32] Several mechanisms have been postulated to explain the pathogenesis of late respiratory depression, including a time-dependent decrease in carotid body stimulation, hypocapnea secondary to the initial hyperventilation, and a decrease in metabolism. Increasing evidence, however, suggests a central origin for hypoxic ventilatory depression,

• **Fig. 67.2** Steady-state carbon dioxide response curves at different inspired oxygen concentrations. The more hypoxic the infant is, the flatter the response to carbon dioxide.

probably through interaction of multiple neurotransmitters, including adenosine, GABA, and endorphins, or through descending inhibitory pontine tracts. Consistent with these findings is the observation that a progressive decrease in inspired oxygen concentration causes a significant flattening of carbon dioxide responsiveness in preterm infants (Fig. 67.2).

Laryngeal and Pulmonary Afferent Reflexes

Stimulation of the laryngeal mucosa, either chemically (water, ammonium chloride, or acidic solutions) or mechanically, causes inhibition of breathing and apnea in neonates and newborn animals. This reflex-induced apnea, known as the *laryngeal chemoreflex* (LCR), is usually associated with glottic closure, swallowing, bradycardia, and hypotension, and has been shown to undergo maturational changes with age. Although it may serve a protective function, preterm infants express an exaggerated LCR as evidenced by prolonged apnea response to instilling saline in the oropharynx. The mechanisms underlying such maturational change in reflex-induced apnea are not known but seem to be related to a decrease in central neural output or a dominance of inhibitory pathways. The inhibitory neurotransmitters adenosine and GABA have both been implicated where blockade of $GABA_A$ receptors prevented, and activation of adenosine A_{2A} exaggerated, the LCR.[3]

Lung afferents play an important role in regulating respiratory timing and may play a role in apnea of prematurity. Stimulation of pulmonary stretch receptors through increasing lung volume causes shortening of inspiratory time, prolongation of expiratory time, or both. This reflex is known as the *Hering-Breuer reflex*. The decrease in respiratory frequency and prolongation of expiratory time following institution of nasal continuous positive airway pressure (CPAP) is mediated through activation of this reflex. This probably serves to prevent lung overdistention on CPAP. The Hering-Breuer deflation reflex is activated on deflation of the lung and results in inspiratory augmentation. However, unlike term infants, preterm infants are less likely to initiate breathing and tend to have respiratory pauses on deflation of the lung, thus making them less likely to recover from an apnea event.

Neurotransmitters and Neuromodulators

There are limited data regarding the balance of excitatory and inhibitory neurotransmitters during development of respiratory control. Because invasive studies cannot be performed in newborn infants, most studies on the relationship of neurotransmitters to respiratory control are based on the effect of these substances or their inhibitors on the breathing responses to hypoxia, hypercapnia, and reflex apnea in animal models. The most widely studied neurotransmitters in relation to disturbances in control of breathing include adenosine, GABA, prostaglandins, endorphins, and serotonin.

GABA is the major inhibitory neurotransmitter in the central nervous system (CNS). It has been implicated in the attenuated ventilatory responses to hypoxia, hypercapnia, and LCR. Blocking $GABA_A$ receptors prevented hypoxic ventilatory depression and the decrease in breathing frequency in response to CO_2 and attenuated the LCR. Both structural and functional differences in $GABA_A$ receptors have been observed during development. $GABA_A$ receptors are hetero-oligomers assembled from five subunits. During embryonic and early postnatal development, the brainstem has a much higher $GABA_A$ receptor density than does the adult brainstem, and the "mix" of $GABA_A$ receptor subunits differs from that in adults. Therefore, GABA has the potential to play a key role in the vulnerability of preterm infants to disturbed breathing, including apnea of prematurity. Of interest is the observation that GABA may switch from an excitatory to inhibitory neurotransmitter during the transition from fetal to neonatal life.

Adenosine is a product of ATP that is ubiquitous to most brain tissue as well as the cerebrospinal fluid (CSF). Adenosine is known to depress neural function and respiration, and its level has been shown to increase during hypoxia in brain tissue, CSF, and plasma. Furthermore, adenosine antagonists reversed hypoxic depression in anesthetized newborn piglets. The role of adenosine in apnea of prematurity is suggested by the ability of the methylxanthines, theophylline, and caffeine, which are nonspecific adenosine receptor inhibitors, to decrease the incidence of apnea of prematurity. However, the exact mechanism and location of action of adenosine, as well as the interaction of adenosine with other neurotransmitters, remain to be identified. Adenosine receptors may be inhibitory (A_1) or excitatory

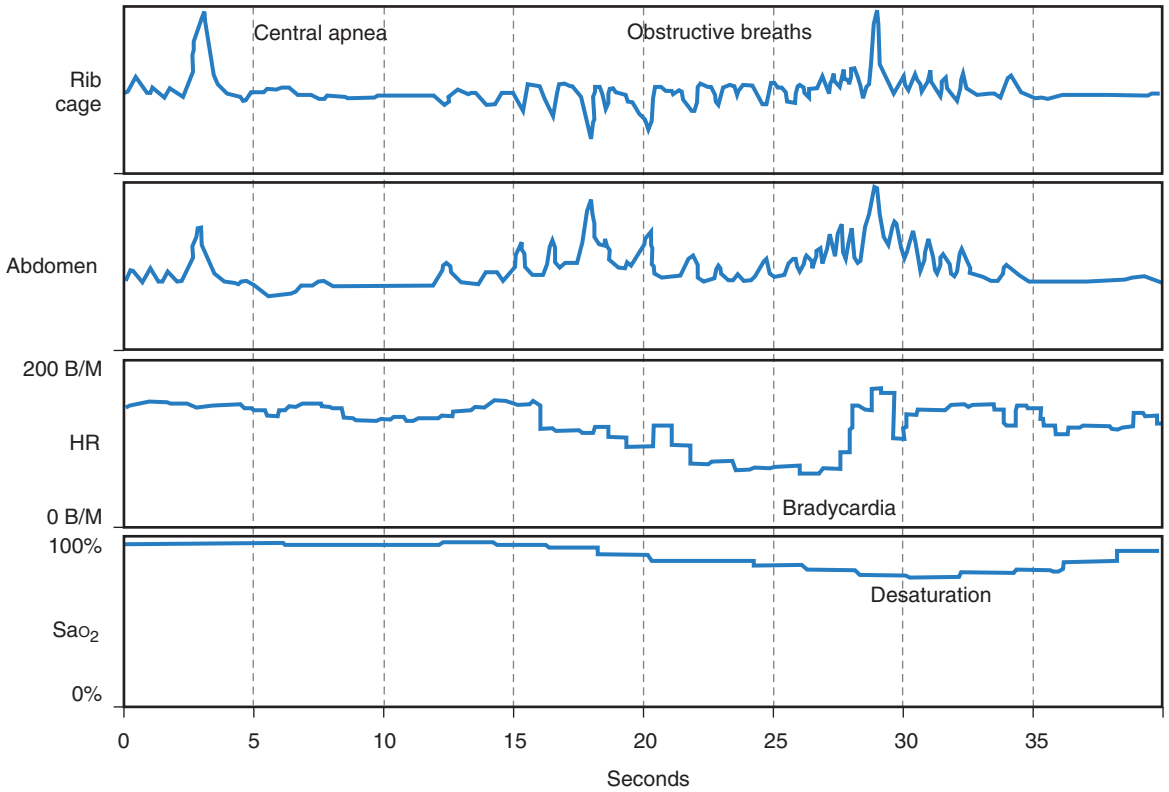
(A_{2B}). An interaction between adenosine and GABA in the regulation of breathing has been documented. Blockade of $GABA_A$ receptors abolished the inhibition of phrenic activity and the exaggerated LCR induced by adenosine A_{2A} agonist. Furthermore, A_{2A} receptors were found to co-localize on GABAergic neurons in the medulla oblongata of both piglets and rats. These data suggest that the mechanism of action of methylxanthines in the prevention of apnea of prematurity is through central blockade of either inhibitory A_1 receptors or excitatory A_2 adenosine receptors on GABAergic neurons.[3] In either case, respiratory inhibition is diminished.

Exogenous endorphin and enkephalin analogues have been shown to produce a consistent decrease in respiration in fetal and neonatal animals. Endorphin levels are elevated in the human neonate at birth, and endogenous opioids were found to modulate the hypoxic ventilatory response in newborn infants and animals. Furthermore, the opioid antagonist naloxone produced an improvement in apnea and periodic breathing in infants in whom β-endorphin–like immunoreactivity in the CSF was elevated. Although these data support a role for opioids in respiratory control in neonates, the effect of anesthesia in such studies and the interaction of opioids with other inhibitory neurotransmitters need to be clarified. Infusion of prostaglandin E_1 (PGE_1) may produce respiratory depression in infants during treatment for critical congenital heart disease. Prostaglandin E_1 has been shown to decrease, and indomethacin has been shown to enhance, phrenic activity in newborn piglets.

The involvement of serotonin in respiratory control is well established; however, the nature of this involvement is complex. Both activation and inhibition of breathing have been described with different doses and routes of administration. The different responses may owe, in part, to the effect on different subtypes of serotonin receptors preferentially expressed on respiratory neurons. Serotonin has been implicated as a regulatory factor in the production of apneusis. Blocking $5\text{-}HT_{1A}$ receptors has been shown to reverse apneustic breathing, which might result during hypoxia or ischemia. There is increasing evidence to suggest an important role for serotonergic neurons in the raphe nuclei in maturation of central chemoreception. This has been highlighted by findings in cohorts of sudden infant death syndrome (SIDS) victims (Japanese, African-American, and white) in whom there was a significant positive association with the presence of a homozygous gene that encodes for the long allele of the 5-HT transporter promoter (5-HTT), as well as the long allele itself. In both studies, SIDS victims were more likely than control subjects to express the long allele of 5-HTT, as well as to miss the short allele of 5-HTT.[53] Therefore, it is possible that a delay in maturation of serotonergic neurons or overexpression of the long allele for 5-HTT in the arcuate nucleus, as well as in other respiratory groups, might contribute to a failure of arousal and inadequate respiratory response to a life-threatening event. There is increasing evidence that this may be the underlying mechanism in the pathogenesis of SIDS.

Neonatal Apnea, Bradycardia, and Hypoxemia

Definition and Epidemiology



Apnea has traditionally been defined as the cessation of breathing for greater than 15-20 seconds. Shorter events (<15 seconds) may also be identified as apnea if accompanied by oxygen desaturation and bradycardia. Types of apnea include central, obstructive, and mixed (demonstrating both central and obstructive components). Central apnea is characterized by total cessation of respiratory effort with no evidence of obstruction. In obstructive apnea, the infant tries to breathe against an obstructed upper airway, resulting in chest wall motion without air flow. Mixed apnea consists of obstructed respiratory effort usually following a central pause (Fig. 67.3) and is the most common type of apnea in preterm infants. The site of upper airway obstruction is mostly in the pharynx; however, it may also occur at the larynx and possibly at both sites. It should be emphasized that these three patterns of apnea appear to form a continuum in which airway obstruction may also be involved in purely central events and vice versa.[41]

Standard bedside monitoring or impedance monitoring in the neonatal intensive care unit (NICU) detects central apnea and bradycardia but is unable to detect obstructive and mixed apnea. An automated computer algorithm to analyze ECG, chest wall impedance, and pulse oximetry from NICU bedside monitors was developed by investigators from the University of Virginia. The recognition of apnea, bradycardia, and desaturation (ABD) events require that all three components be present. Apnea was defined as >10 seconds if accompanied by bradycardia (HR <100 beats/minute) and desaturation (SpO_2 <80%).[51] The automated computer algorithm was found to be far more reliable at detecting ABD events than bedside nursing documentation. Although there is consensus that nursing observations do not correlate with electronically recorded events, it is still the practice in most centers to rely on nursing documentation as a measure of apnea, bradycardia, and oxygen desaturation frequency and severity.

Bradycardia may be defined as a HR <100 or <70-80 in the convalescing preterm infant approaching discharge. There is no consensus in the definition of a HR threshold or duration to identify a clinically significant bradycardia event.

More recently, hypoxia, especially intermittent hypoxia (IH), often associated with periodic breathing, has become a focus of research and ongoing debate about its significance and consequences. In animal models, chronic IH increases activation of the sympathetic nervous system with cardiovascular and metabolic consequences, including type 2 diabetes, hypertension, and heart failure.[11] Cardiovascular morbidity may be related to sensitization of the carotid body from free radical injury. Prolonged desaturation episodes in the absence of apnea or bradycardia, both in healthy preterm infants and more frequently in infants

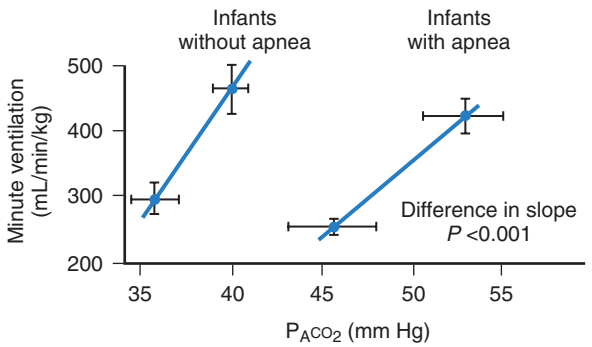
TABLE 67.1 Factors Implicated in the Pathogenesis of Apnea of Prematurity

Central Mechanisms	Peripheral Reflex Pathways	Others
Decreased central chemosensitivity	Decreased carotid body activity	Genetic predisposition
Hypoxic ventilatory depression	Increased carotid body activity	Sepsis and cytokines
Upregulated inhibitory neurotransmitters, e.g., GABA, adenosine	Laryngeal chemoreflex Excessive bradycardic response to hypoxia	Bilirubin

GABA, γ-aminobutyric acid.

with bronchopulmonary dysplasia, could represent obstructive apnea, hypoventilation, or intrapulmonary right-to-left shunting. Like bradycardia, the definition and duration of hypoxemia also lacks consensus and may be defined as SpO_2 <90%, <85%, or <80%. The long-term consequences of apnea, but perhaps especially bradycardia, and hypoxemia remain a concern. Recurrent or intermittent hypoxia has been associated with retinopathy of prematurity, necrotizing enterocolitis (NEC), and periventricular leukomalacia.

Pathogenesis



Apnea of prematurity is a developmental disorder that reflects physiologic rather than pathologic immaturity of respiratory control (Table 67.1). However, despite major advances in the understanding of the control of breathing, the exact mechanisms responsible for apnea in premature infants have not been clearly identified. This is understandable in view of the limitations of studying human infants and the lack of an animal model that exhibits spontaneous

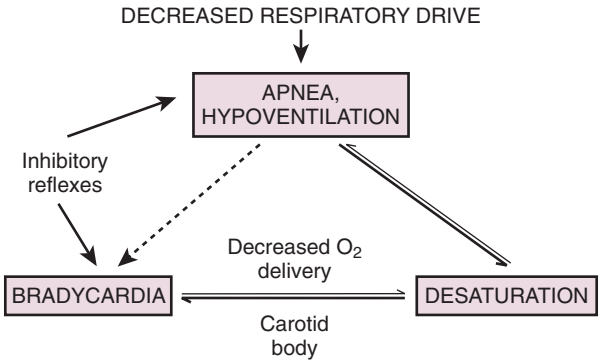
apnea. Therefore, most of our knowledge is derived from both physiologic studies in preterm infants and studies in immature animals. Immaturity of respiratory responses in preterm infants affects all levels of respiratory control, including central and peripheral chemosensitivity, as well as inhibitory pulmonary afferents. This immaturity is manifested by impaired ventilatory responses to hypoxia and hypercapnia and an exaggerated inhibitory response to stimulation of airway receptors. Although a direct relationship has not been demonstrated between a disturbed respiratory control mechanism and the occurrence of apnea in preterm infants, strong associations are very well established. Histologically, immaturity of the preterm brain is manifested by a decreased number of synaptic connections, dendritic arborizations, and paucity of myelin. Functionally, auditory-evoked responses are impaired in infants with apnea when compared with matched preterm control subjects, indicating a delay in brainstem conduction time. Interestingly, this delay improves after treatment with aminophylline, signifying a functional rather than an anatomic immaturity.

The impairment of central chemosensitivity in preterm neonates is evident by the flat ventilatory response to CO_2 when compared with that in term neonates or adults. This impairment of hypercapneic ventilatory response is more pronounced in preterm neonates with apnea when compared with their controls without apnea. In other words, at the same level of CO_2 and for the same degree of change in alveolar CO_2, minute ventilation in babies with apnea is decreased (Fig. 67.4). Whereas exposure to hyperoxia silences the carotid body and may induce apnea, hypoxic ventilatory depression does not seem to contribute to the initiation of apnea, because most infants are not hypoxic before apnea occurs. However, once apnea occurs it might prolong apnea and delay its recovery.

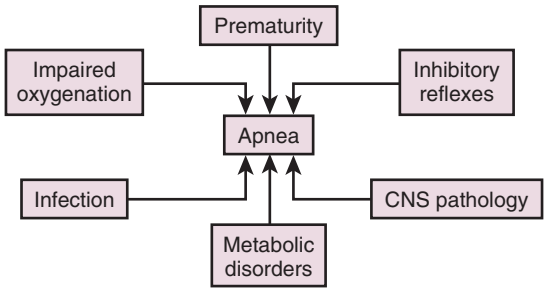
The peripheral chemoreceptors are located primarily in the carotid body and are responsible for stimulating breathing in response to hypoxia. Both enhanced and reduced peripheral chemoreceptor function may lead to apnea, bradycardia, or desaturation in the premature infant. In utero, the carotid chemoreceptor O_2 sensitivity is adapted to the normally low PaO_2 of the mammalian fetal environment

• **Fig. 67.4** The ventilatory response to carbon dioxide has a decreased slope in infants with apnea.



(23-27 mm Hg). In response to the fourfold increase in PaO_2 with the establishment of air breathing, the peripheral chemoreceptors are silenced. This is followed by gradual increase in hypoxic chemosensitivity, although the mechanisms underlying this maturation are not completely understood.[35] A similar developmental profile has been described for both preterm and term infants. However, the contribution of immaturity of the peripheral chemoreceptors to apnea of prematurity is not clear. Apnea can persist for many weeks to months in premature infants despite maturation of peripheral chemosensitivity. Excessive peripheral chemoreceptor sensitivity in response to repeated hypoxia as seen in babies with bronchopulmonary dysplasia may also destabilize breathing patterns in the face of significant fluctuations in oxygenation. Data in rat pups indicate that conditioning with intermittent hypoxic exposures results in facilitation of carotid body sensory discharge in response to subsequent hypoxic exposure. Furthermore, preterm infants with high frequency of apnea were found to have increased carotid body activity.[35] Hypoxia can also inhibit metabolism in the preterm infant and decrease CO_2 levels, thereby narrowing the difference between baseline CO_2 and the apneic threshold CO_2 (CO_2 level below which apnea occurs). The baseline $PaCO_2$ in both preterm and term infants was found to be only 1-1.3 mm Hg above the apneic threshold.[26] The closeness of the apneic threshold to baseline CO_2 together with excessive activation of the carotid body might allow small oscillations of CO_2 in response to mild hyperventilation, startles, or stimulation to cause apnea. Much remains to be learned about both the short- and long-term consequences of intermittent hypoxic episodes during early development.

Although LCR is thought to be an important contributor to apnea, bradycardia, and desaturation episodes associated with feeding and gastroesophageal reflux in preterm babies, the relationship of LCR to apnea of prematurity is less clear. The association of both apnea of prematurity and LCR with swallowing movements, as well as the observation of glottic closure and swallowing in fetal lambs during spontaneous apnea, points to the possibility of a common neural network controlling both functions. Furthermore, similar to apnea of prematurity, LCR matures with advancing gestational age and is thought to be exaggerated in immature newborns and animals secondary to decreased central neural output or a dominance of inhibitory pathways.[4]



Rapid eye movement (REM) or active sleep is the predominant sleep state in preterm infants. It has long been recognized that respiratory control is disturbed during REM sleep. The primary mechanism appears to be a loss of upper airway muscle tone, resulting in pharyngeal collapse and airway obstruction. Paradoxical breathing during active sleep may also lead to hypoxemia and apnea.

The mechanism underlying bradycardia associated with apnea is not clear; although, it has been postulated that bradycardia during apnea might be related to hypoxic stimulation of the carotid body chemoreceptors, especially in the absence of lung inflation (Fig. 67.5). On the other hand,

• **Fig. 67.5** Proposed physiologic mechanisms whereby apnea induces reflex bradycardia. This can occur secondary to hypoxemia in the absence of lung inflation or by stimulation of upper airway inhibitory afferents.

• **Fig. 67.6** Specific contributory causes of apnea. CNS, central nervous system.

bradycardia occurs simultaneously with apnea during stimulation of laryngeal receptors, suggesting a central mechanism for the production of both apnea and bradycardia. The interaction between central respiratory and cardiovascular centers in the production of bradycardia in association with apnea of prematurity needs further investigation.

The impact of genetic variability on regulation of breathing and apnea is suggested by the finding of a mutation in the *PHOX2B* gene in patients with congenital central hypoventilation. Similar to preterm infants with apnea, these children are characteristically symptomatic during the initial months of life and demonstrate absent or extremely reduced ventilatory responses to CO_2 and hypoxia even though no obvious brain, muscular, cardiac, or pulmonary lesions are apparent.[20] Tamim and colleagues found a higher incidence of apnea of prematurity in infants born to first-degree consanguineous parents than in other infants.[48] These findings raise the possibility of a role for developmentally regulated genes that might contribute to the vulnerability of preterm neonates to apnea. It has also been demonstrated that specific polymorphisms in the A2A adenosine receptor gene are associated with apnea of prematurity, BPD, and response to caffeine therapy.[27] Further studies are clearly needed to explore the role of genetics in the pathogenesis of apnea of prematurity.

Clinical Associations

Apnea can be physiologic, the presenting sign of a change in status, or may accompany other conditions that adversely affect the preterm infant. With the current and widespread early use of caffeine and broad application of noninvasive respiratory support strategies in the NICU, the severity of clinical apnea and accompanying bradycardia in the 21st century has substantially decreased. When apnea does become a concern, a thorough investigation of possible etiologies is always warranted, especially when an escalation in respiratory support is required (Fig. 67.6). Sepsis and other causes of inflammation and central nervous system disorders, particularly intracranial hemorrhage, hypoxic ischemic encephalopathy, and brain malformations, can precipitate apnea in both preterm and term infants. Term infants presenting with apnea require a thorough history and physical examination, monitoring, and evaluation for central nervous system abnormalities (especially seizures) and infectious, genetic, and metabolic disorders.[39]

Sepsis is a known trigger of apnea and is routinely investigated as a potential cause, especially when associated with other symptoms. In rat pups, systemic administration of cytokine IL-1β–inhibited respiratory activity, both at rest and in response to hypoxia, and this respiratory inhibition was diminished by prior blockade of prostaglandin synthesis with indomethacin. In subsequent work from the same group of investigators, evidence was presented for IL-1β binding to IL-1 receptors on vascular endothelial cells of the blood–brain barrier during a systemic immune response. Activation of the IL-1 receptor, in turn, induces synthesis of prostaglandin E2, which, when released into respiratory-related regions of the brainstem, results in respiratory depression.[22] Intrapulmonary inflammation has also been shown to increase cytokine expression in the brainstem and decrease hypoxic ventilatory response.[24] New-onset apnea or an increase in the baseline incidence of apnea should prompt an appropriate workup for sepsis or necrotizing enterocolitis. In the older infant, the presentation of respiratory syncytial virus (RSV) and other viral infections is sometimes heralded by apnea.

Episodes of hypoxemia often occur in infants with bronchopulmonary dysplasia. Immature respiratory control superimposed on abnormal lung function and pulmonary vasoconstriction may all play a role in the occurrence of these events.[31]

Anemia, whether iatrogenic, physiologic, or a result of acute blood loss, is also common in preterm infants and may contribute to an increase in apnea frequency or severity. The decision to transfuse an infant with apnea is often debated. The potential benefits from a packed red blood cell transfusion could be either from an improvement in oxygen-carrying capacity, elimination of hypoxic respiratory depression, or an increase in intravascular volume. Zagol and colleagues demonstrated the relationship between hematocrit and apnea in two ways. They found that not only were transfusions associated with fewer computer-detected apneic events, but that an inverse relationship

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

existed between admission hematocrit values and the probability of future apnea. These findings suggest that decreased oxygen-carrying capacity is a major trigger for apnea of prematurity.[56] Other conditions that may precipitate apnea include common metabolic disorders such as hypoglycemia, hypocalcemia and electrolyte imbalances, temperature instability, and metabolic acidosis perhaps associated with inborn error of metabolism. Medications including opiates, benzodiazepines, magnesium sulfate, and prostaglandin E1 can all cause apnea.

Periodic breathing is an immature respiratory pattern with short cycles of a few breaths alternating with respiratory pauses. Periodic breathing is absent in the first few days of life and becomes more frequent at 2-4 weeks of age (much like intermittent hypoxia). Even in term infants, periodic breathing may persist for up to 6 months of age and is related to progressive myelination and maturation of the central nervous system.[16] Patel and colleagues used an automated periodic breathing detection system to analyze bedside monitors on all infants <35 weeks' gestation. They concluded that on average, infants spend <6% of the time in periodic breathing and that an acute increase may reflect illness or physiologic stressors. Extreme periodic breathing was defined as periodic breathing for >10% of a 12-hour period and >6 standard deviations above the mean for GA and postmenstrual age. In 45% of infants with extreme periodic breathing, a temporal relationship was found between infection or NEC.[38]

Gastroesophageal Reflux and Neonatal Apnea

Gastroesophageal reflux (GER) is often implicated as a cause of neonatal apnea (also see Chapter 82). While it is true that both GER and apnea are common in preterm infants, investigations of the timing of reflux in relation to apneic events demonstrate that they are rarely temporally linked. Furthermore, when apnea and reflux coincide, there is no evidence that GER prolongs the apnea or worsens its severity.[10] Although physiologic experiments in animal models reveal that reflux of gastric contents to the larynx induces reflex apnea, there is no clear evidence that the treatment of reflux will treat apnea in most preterm infants. There are, however, two publications that challenge this premise and present conflicting evidence. Corvaglia and colleagues studied infants less than or equal to 33 weeks' gestation to characterize the features of reflux (acidity, duration, and height) that influence apnea. They found that the frequency of apnea detected after non–acid reflux episodes was significantly higher than before the reflux event.[8] In another study examining the temporal association between recorded cardiorespiratory events and GER identified by multichannel intraluminal impedance-pH probe, a subject-specific association was found in three of seven infants. These infants, born between 24 and 29 weeks' gestation, underwent polysomnography at 39-48 weeks postconceptional age because of persistent cardiorespiratory events and as part of a presurgical evaluation for fundoplication. Two of the infants improved following a fundoplication procedure.[36] Although a relationship between cardiorespiratory events and GER was identified in this select group of infants, the management of reflux with agents that decrease gastric acidity or enhance gastrointestinal motility should not be used routinely for the treatment of apnea and bradycardia of prematurity. Moreover, antacid therapy is not benign. Several studies have shown that the use of H_2 blockers and proton pump inhibitors pose an increased risk for infection and NEC. A safety study from Italy examined the association between ranitidine therapy and infections, NEC, and death in very-low-birth-weight infants. The ranitidine-exposed patients had a significant increase in all three adverse outcomes.[49]

Brief Resolved Unexplained Events (BRUE) (Formerly Known as Apparent Life-Threatening Events or ALTE)

Apparent life-threating events are often interpreted as apnea, which is rarely the case. In 2016, the American Academy of Pediatrics (AAP) issued a new clinical practice guideline that provides significant enhancements to the management of patients with an ALTE (apparent life-threatening event). One of the major contributions of the BRUE guidelines is the removal of the caregiver's perception that the event was life-threatening. Instead, it is the provider who is tasked with obtaining a thorough history and performing a detailed physical examination. In addition, the initiation of CPR is only relevant when performed by a health care provider. Choking or gagging is not included in the definition of a BRUE, thereby eliminating an event likely related to gastroesophageal reflux. Finally, criteria are listed that define an infant as low or high risk (Box 67.1). Low-risk infants should *not* be hospitalized, but instead, parents should be educated, shared decision making should occur between the parents and provider, and CPR training should be offered. Short-term observation with pulse oximetry, an ECG, and pertussis testing are options that may be considered.[50]

• BOX 67.1 BRUE Definition

An Event Occurring in an Infant <1 Year of Age That Is Not Resolved With ≥1 of the Following:

- Cyanosis or pallor
- Absent, decreased, or irregular breathing
- Marked change in tone (hyper- or hypotonia)
- Altered level of responsiveness

Low-Risk Criteria

- >60 days of age
- Gestational age ≥32 weeks; postconceptional age ≥45 weeks
- First BRUE
- Event duration <1 minute
- No CPR required by trained medical provider
- Benign history and physical exam findings

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Because of the high incidence of GER in infancy, symptoms of GER do not qualify as a BRUE, although GER may contribute to low-risk BRUE.

Treatment

Continuous Positive Airway Pressure

Various forms of noninvasive and invasive respiratory support are used to treat clinically significant apnea, usually in conjunction with caffeine. Because apnea, bradycardia, and intermittent hypoxia rarely occur in isolation, the noninvasive support that is selected should consider other common comorbidities such as RDS, pneumonia, and BPD. Continuous positive airway pressure (CPAP) at 4-6 cm H_2O has been used safely and effectively for more than 35 years. CPAP treats the obstructive component of apnea by splinting the upper airway with positive pressure, thereby reducing the risk of pharyngeal or laryngeal collapse. Continuous positive airway pressure also increases FRC and improves oxygenation. At a higher FRC, time from cessation of breathing to hypoxemia and resultant bradycardia is prolonged. Other noninvasive support strategies include BiPAP (bilevel CPAP), noninvasive positive pressure ventilation (NIPPV), and high-flow nasal cannula (HFNC) (or nasal high-flow therapy, nHFT). HFNC, defined as flows >1-2 LPM, is a popular alternative to CPAP largely because of its more comfortable and less traumatic patient interface, especially in more mature infants. A 2016 clinical report from the Committee on the Fetus and Newborn concludes that there is no evidence for the benefit of NIPPV or BiPAP in the treatment of apnea of prematurity and that safety concerns persist for the use of HFNC.[9] An experienced group of clinical researchers in the field of nHFT recently published a consensus approach with guidelines that include the need for adequate heating and humidification, prongs that are sized to prevent occlusion of the nares (to avoid extremely elevated airway pressures), and initial flow rates of 4-6 LPM with a maximum flow of 8 LPM. The assessment of FiO_2 or work of breathing should be used to determine flow escalation or weaning.[55]

Xanthine Therapy

Methylxanthines have been the mainstay of pharmacologic treatment for apnea of prematurity for more than 30 years. Both theophylline and caffeine are used, and both have multiple physiologic and pharmacologic mechanisms of action. Xanthine therapy increases minute ventilation, improves CO_2 sensitivity, decreases hypoxic depression of breathing, promotes bronchodilation, enhances diaphragmatic activity, and decreases periodic breathing. The precise way in which xanthines improve respiratory mechanics via an increase in respiratory neural output is still under investigation; however, competitive antagonism of adenosine receptors is well documented. Although adenosine acts as an inhibitory neuroregulator in the CNS via activation of adenosine A1 receptors, an effect on adenosine A2A receptors' activation of GABAergic neurons might also play a role. The methylxanthines, especially aminophylline, have some well-documented acute adverse effects. Toxic levels may produce tachycardia, cardiac dysrhythmias, feeding intolerance, and, infrequently, seizures. These effects are rarely seen with caffeine at the usual therapeutic doses. Mild diuresis is caused by all methylxanthines. The observation that xanthine therapy causes an increase in metabolic rate and oxygen consumption of approximately 20% suggests that caloric demands may be increased at a time when an infant's nutritional status is already compromised. Another positive attribute of caffeine is its direct anti-inflammatory effect on the lung.[54] The Caffeine Therapy for Apnea of Prematurity (CAP) trial randomized infants with birth weights between 500 and 1250 g to caffeine versus placebo therapy. This study was designed to test both the short- and long-term safety of caffeine, and although initial findings revealed a significant reduction in the rate of bronchopulmonary dysplasia (BPD),[46] the 5-year outcome data demonstrated no difference in the combined outcome of death or disability in the caffeine versus placebo groups.[45,47] Caffeine therapy for apnea of prematurity did not significantly reduce the combined rate of academic, motor, and behavioral impairments but was associated with a reduced risk of motor impairment in 11-year-old children with very low birth weight. At the doses used in this trial, neonatal caffeine therapy is effective and safe into middle school age. Most recent outcome data from this trial are very encouraging.[45,47] Importantly, Schmidt and colleagues confirmed that caffeine therapy was not only effective in treating apnea of prematurity but was also safe.

Perhaps because of the evidence of caffeine safety, investigators in Egypt compared high (40 mg/kg loading dose and maintenance of 20 mg/kg) with standard dosing (20 mg/kg loading dose and 5–10 mg/kg maintenance) in an effort to determine an optimal dose. Although there was a significant reduction in extubation failure and frequency and duration of apnea, there was a significant increase in tachycardia (not considered a significant side effect). No change was found in the incidence of BPD or length of stay.[33] At this time, many questions remain concerning optimization of the timing of caffeine therapy and its dose despite the success of this therapy (Box 67.2).[15a]

Other Therapeutic Approaches

Doxapram is an agent that stimulates peripheral and central chemoreceptors and for many years has been advocated by some as adjunctive therapy for persistent apnea of prematurity. A recent systematic review confirms previous reports that based on limited evidence, adverse effects of the drug, and no benefit over theophylline, routine use cannot be recommended.[52]

Any approach to nursing care that optimizes the infant's well-being is clearly desirable. Kangaroo care, or skin-to-skin nursing, has achieved widespread acceptance for high-risk infants and provides an opportunity for greater parental involvement. Although the advocates of this approach have suggested a decrease in apnea rates, the evidence does not

• BOX 67.2 Neonatal Caffeine Therapy: Unresolved Issues

	Pro	Con
Optimal dosage	Higher doses more strongly enhance respiratory neural output	• Adenosine receptor subtype inhibition of inflammation is variable and dose dependent, raising safety concerns • Preliminary report of cerebellar injury • Proposed need for postnatal dose adjustments
When to start	Early onset of therapy improves various morbidities	• Available data are largely based on associations rather than randomized trials
When to stop	Prolonged therapy decreases duration of intermittent hypoxic episodes	• May prolong hospitalization and potentially increase home monitor use

support this impression. Meanwhile, research on the biologic basis of sleep and awake states needs to be translated into preventive strategies for apnea.[28] Supplemental oxygen to avoid hypoxic respiratory depression is another treatment for apnea; however, the ideal SaO_2 target range remains elusive (currently in the 90%-95% range) and is likely on a continuum associated with gestational and postnatal age. The frequency and severity of oxygen desaturation accompanying apnea would be decreased at higher baseline SaO_2. A low O_2 saturation target is associated with an increased rate of intermittent hypoxemia.[14] A novel, alternative approach to apnea therapy is the supplementation of inspired air with a very low concentration of CO_2 to increase respiratory drive.[6,7] Although logical from a physiologic perspective, CO_2 was compared with theophylline in both trials, and the response to CO_2 was inconsistent, likely from fluctuations in gas delivery. Recently, investigators from UCLA published data using neuromodulation of limb proprioceptive afferents by means of a noninvasive vibratory device placed on one hand and one foot. Significantly fewer respiratory pauses, bradycardia, and intermittent hypoxia events occurred during vibration periods.[25]

Resolution and Consequences of Apnea, Bradycardia, and Intermittent Hypoxia

Apnea of prematurity generally resolves by 36-40 weeks' postconceptional age. Cardiorespiratory events in most preterm infants return to baseline "normal full-term" levels by 43-44 weeks' postconceptional age.[43] In infants ≤26 weeks' gestation, resolution may take longer. For a subset of infants, the persistence of cardiorespiratory events can delay hospital discharge despite having achieved other physiologic developmental milestones. In these infants, apnea longer than 20 seconds is rare; rather, these infants exhibit frequent bradycardia to less than 70 or 80 beats per minute with short respiratory pauses.[13] As mentioned earlier, bedside nursing observations are known to be an unreliable measure of apnea and bradycardia and do not correlate with electronic recordings of events; however, they may be beneficial when trying to determine which episodes are clinically significant. A 2016 Clinical Report from the Committee on Fetus and Newborn emphasizes the lack of consistent definitions for apnea, bradycardia, and desaturation and recognizes that monitoring practices vary among NICUs. These inconsistencies have major implications on length of stay (Box 67.3).[17] To assess the maturation of respiratory control in premature infants and better inform discharge planning, Lorch and colleagues examined the success rates (the percentage of infants who had no additional events) following various event-free intervals. They found that the risk of recurrence of apnea or bradycardia depends on both the gestational age and postmenstrual age at the time of the last event. For the entire cohort in this retrospective study, a 95% success rate was achieved with a 7-day apnea- or bradycardia-free interval.[29]

Because of the growing concern over the consequences of intermittent hypoxia and recognition that intermittent hypoxia persists after discontinuation of caffeine for the treatment of apnea of prematurity, extended caffeine dosing until term-adjusted age has recently been proposed and is under investigation.[15,44]

• BOX 67.3 Key Elements From the Committee of Fetus and Newborn: Clinical Report and Guidance for Hospital Discharge of Preterm Infants With Apnea

- Individual NICUs are encouraged to develop monitoring policies.
- Lower heart rate alarm settings in convalescing infants >33-34 weeks may be reasonable.
- A trial off caffeine may be considered when an infant has been free of clinically significant apnea or bradycardia events off positive pressure support for 5-7 days or at 33-34 weeks' postmenstrual age, whichever comes first.
- Brief, isolated bradycardias that spontaneously resolve and feeding events that resolve with interruption of feeding are common and generally need not delay discharge.
- Individual units are encouraged to develop policies and procedures for assessment, intervention, and documentation of bradycardia/desaturation events.
- Electronically archived monitoring data may reveal events of uncertain clinical significance that do not predict outcomes.

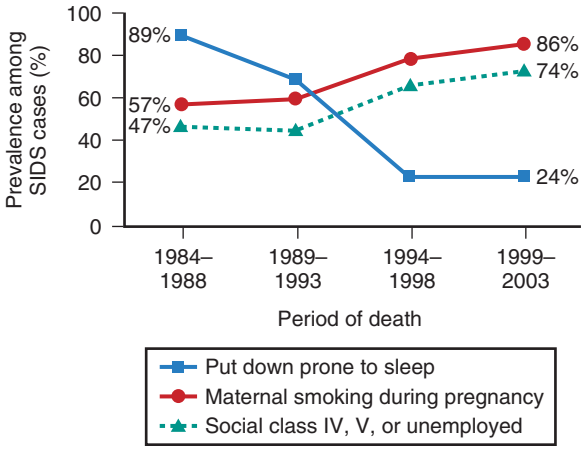
Correlating apnea and its consequences with an unfavorable neurologic outcome is problematic, because apnea and brain injury may coexist in premature infants, making it challenging to determine causality. However, evidence is mounting and there are data that suggest a link between delayed apnea resolution and the severity of the apnea course with impaired neurodevelopmental outcome.[40] A high number of cardiorespiratory events recorded after discharge via home cardiorespiratory monitoring also appear to correlate with a less favorable neurodevelopmental outcome.[23] A 2014 retrospective chart review in extremely low birth weight infants found an association between a greater frequency and severity of bradycardia and worse language development in the first 2 years of life after adjusting for neonatal and social variables.[21] And finally, in a post hoc analysis of the Canadian Oxygen Trial, prolonged hypoxemic episodes in the first 2-3 months of life were associated with adverse 18-month outcomes.[42] Former preterm infants appear to be at greater risk of later sleep-disordered breathing. Recurrent episodes of desaturation during early life and resultant effects on neuronal plasticity related to peripheral or central respiratory control mechanisms may serve as the underlying mechanisms for such a putative relationship.



Apnea and Sudden Infant Death Syndrome

Apnea of prematurity and sudden infant death syndrome (SIDS) are separate conditions. However, prematurity is known to be a significant risk factor for SIDS. Malloy and associates have shown that the mean postconceptional age at which SIDS occurs in preterm infants is younger than that of term infants and that clinically significant apnea of prematurity resolves by that postnatal age (Fig. 67.7).[30] The incidence of SIDS has decreased by more than half with the introduction of the international campaign to avoid all sleep positions except supine. However, the relative contribution of other risk factors, including maternal smoking and socioeconomic factors, to the incidence of SIDS increased during the same period (Fig. 67.8),[18] emphasizing the need for targeting these factors to further decrease the risk of SIDS.

In the 2016 AAP policy statement from the Task Force on Sudden Infant Death Syndrome, SIDS is considered a subcategory of sudden unexpected infant death (SUID). Ill-defined and unspecified causes of mortality and accidental suffocation and strangulation in bed are other recognized causes of SUID. As with SIDS, all other causes of SUID are inversely related to gestational age and the biologic, environmental, and sociodemographic vulnerabilities associated with prematurity.[1,37] Hospital discharge practices that include modeling a safe sleep environment and parent education that emphasizes safe sleep practices are paramount in the effort to prevent SUIDs post discharge.

• **Fig. 67.7** Schematic representation of the timing of sudden infant death syndrome (SIDS) in term (40 weeks' gestation) and very preterm (24 weeks' gestation) infants in relation to the decline in incidence of apnea of prematurity. It appears that apnea has largely resolved by 44 weeks' postconceptional age, which is before the peak incidence of SIDS at all gestational ages (GA).

• **Fig. 67.8** The prevalence of risk factors among victims of sudden infant death syndrome with the Back to Sleep campaign. Social class IV, Semi-skilled occupation; Social class V, unskilled occupation. (Adapted from Fleming P, Blair PS. Sudden infant death syndrome and parental smoking. *Early Hum Dev.* 2007;83:721, with permission.) Current practice remains to target these high-risk groups, including co-sleeping.[19]

Key Points

- Apnea of prematurity is a developmental disorder inversely associated with gestational age.
- Consensus is lacking regarding a clinically significant apnea, bradycardia, or desaturation event.
- The severity and duration of bradycardia and hypoxemia are likely of greater consequence than apnea to long-term neurodevelopmental outcome.

Upper Airway Lesions in the Neonate

TODD D. OTTESON AND TAMMY WANG

A spectrum of pathologic conditions can affect the neonatal upper airway, resulting in respiratory distress at birth or within the first few weeks of life. The clinical presentations of these disorders, however, are often quite similar. The most common symptom is stridor; other signs and symptoms include cyanosis, apnea, dyspnea, retractions, hypercapnia, difficulty feeding, abnormal cry, and cough. The physician's ability to arrive at a diagnosis and treatment plan in the neonate with respiratory distress requires an understanding of the unique anatomic and physiologic factors that affect neonatal upper airway physiology. Of primary importance in evaluating the neonatal airway is determining the degree of emergency and the need to establish an artificial airway (endotracheal intubation or tracheostomy).

The evaluation of an infant with a suspected airway problem should encompass the entire upper airway, from the anterior nasal vestibule to the tracheal bifurcation. Obstruction at any level can lead to respiratory distress. The duration and severity of the infant's symptoms and the progressive nature of the airway distress direct the examiner to either a congenital or acquired disorder. Division of the neonatal upper airway into four primary physiologic components—nasal, oral, laryngeal, and tracheal—allows orderly discussion of the pathologic conditions that could afflict the newborn infant's airway.

Nasal and Nasopharyngeal Lesions

Pyriform Aperture Stenosis

The pyriform aperture is defined as the bony inlet of the nose formed by the nasal bones superiorly, frontal process of the maxilla laterally, and the premaxilla and anterior nasal spine inferiorly.[15] Pyriform aperture stenosis is hypothesized to occur from bony overgrowth of the medial process of the maxilla, causing unilateral or bilateral nasal airflow restriction. Clinical presentation may include tachypnea, difficulty passing a nasogastric tube, apneic events, or cyclic cyanosis improved with crying. While the etiology remains uncertain, there is correlation with holoprosencephaly, absent maxillary frenulum, pituitary dysfunction, and central maxillary megaincisor. The diagnosis of pyriform aperture stenosis can be confirmed with computed tomography (CT) scanning; while various radiographic criteria have been proposed, a pyriform aperture width of less than 11 mm in a full-term infant is commonly considered diagnostic.[35] However, pyriform aperture dimensions do not correlate directly with symptoms, thus each infant should be evaluated based on specific symptoms and ability to compensate for the relative obstruction. In most patients, conservative therapy with judicious use of topical decongestants and topical steroids will reduce mucosal edema and provide symptomatic relief. A McGovern nipple or continuous positive airway pressure may also be helpful. The long-term prognosis of pyriform aperture stenosis is excellent, as the pyriform aperture will enlarge along with the craniofacial skeleton during normal development. However, in refractory cases, especially in infants with sleep apnea, growth restriction, and feeding difficulties, or failure to extubate, surgical intervention is indicated.[27] Surgical techniques typically include a sublabial approach and drillout of the stenosis with or without nasal stenting.

Nasolacrimal Duct Cysts

Nasolacrimal duct cysts (dacryocystoceles) are congenital mucoceles of the nasolacrimal duct system, which include a proximal and distal obstruction. Clinical exam is notable for a cystic swelling of the lower medial canthus, associated epiphora and mucopurulent discharge, and a submucosal nasal cyst that appears as a smooth, mucosa-covered mass under the inferior turbinate.[33] The diagnosis is confirmed with CT or MRI scanning. On CT, a cystic mass at the medial canthus and below the inferior turbinate is often noted (Fig. 68.1). Conservative therapy includes topical decongestants and/or antibiotics, warm compresses, and local massage. However, in the event of local infection, mass effect, or respiratory compromise, surgical intervention is recommended, usually with a combined endoscopic approach as well as via dacryocystorhinostomy to marsupialize the cyst[5] (Fig. 68.2). While the external approach is more commonly performed, the endoscopic approach has gained popularity and has demonstrated similar rates of success in the pediatric population.[28]

Abstract

Neonatal airway obstruction can result from a variety of processes and can vary in severity. A methodical but timely evaluation, including examination from the nasal vestibule to the tracheal bifurcation, will help direct any appropriate interventions.

Choanal Atresia

Neonates are preferential nasal breathers for the first 4-6 weeks of life. The entire length of the neonate's tongue is in close proximity to the hard and soft palate, which creates a vacuum and resultant respiratory distress when nasal obstruction is present. The posterior choanae are the bony outlet of the nose, formed by the undersurface of the sphenoid bones, the medial pterygoid plates, the vomer, and the horizontal portion of the palatal bone. Bony overgrowth of any of these structures may cause choanal atresia, defined as closure of the posterior choanae of the nasal cavity, eliminating communication between the posterior nasal cavity and the nasopharynx. The estimated incidence is 1 in 5000-7000 live births, with up to two-thirds of cases being unilateral, affecting the right side, and occurring in females.[23] Congenital anomalies are seen in about 50% of patients with choanal atresia, characteristically CHARGE syndrome. Other congenital anomalies include polydactyly, cleft palate, hypertelorism, laryngomalacia, and Treacher Collins and Crouzon syndromes. CHARGE syndrome is a clinical diagnosis that includes *c*oloboma or other ophthalmic anomalies, *h*eart defect, *a*tresia choanae, *r*estriction of growth and development, *g*enital hypoplasia, and *e*ar

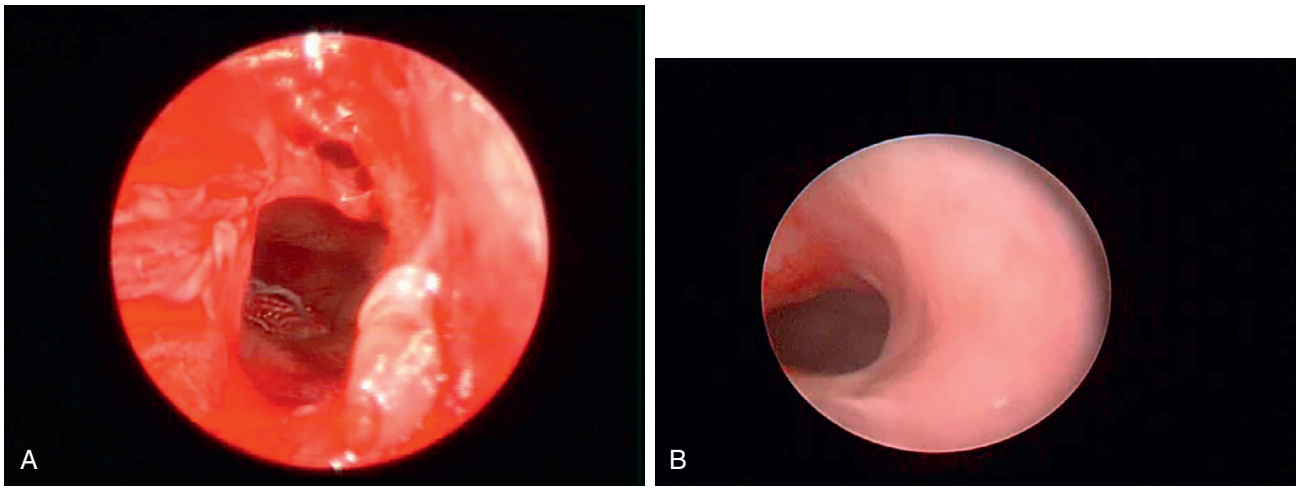
anomalies with hearing loss. Heterozygous mutations in the *CHD7* gene (chromodomain helicase DNA-binding protein) located on chromosome 8q12 have been identified in 90%-95% of neonates meeting diagnostic criteria for CHARGE syndrome.[18] Although there is phenotypic overlap between CHARGE and 22q11 deletion syndromes, including lymphopenia and hypocalcemia, no specific immune defects have been clearly linked with CHARGE syndrome.[19] Children with CHARGE syndrome require intensive medical management and multidisciplinary care. A complete evaluation to rule out associated anomalies is, therefore, mandatory in all infants with bilateral choanal atresia.

Although bilateral obstruction always produces symptoms in the neonatal period, the degree of distress and cyanosis varies from severe asphyxia with a history of multiple failed extubations to choking during feeding. Typically, the infant has a history of distress when resting that is relieved with agitation and crying. In contrast, unilateral choanal atresia is typically diagnosed later in life and may present with chronic nasal obstruction, rhinorrhea, or sinusitis.

In a suspected case of choanal atresia, an attempt should be made to pass a 6-French catheter into the nasopharynx. Failure of the catheter to pass suggests choanal atresia. Flexible nasal endoscopy has also become invaluable in assessing the presence and character of the atresia (Fig. 68.3). Definitive evaluation is obtained with a computed tomography scan to characterize the exact thickness and width of the atretic plate (Fig. 68.4).

Treatment of choanal atresia depends on the severity of the obstruction and the clinical presentation of the infant. Unilateral atresia rarely requires surgical intervention during infancy and is usually corrected before the child begins school (4-5 years of age). Bilateral atresia is usually repaired within the first few days of life. Historically, this was performed via a transpalatal approach using a posteriorly based mucosal flap and drilling of the atretic plate. Today, transnasal endoscopic repair is the predominant technique employed by pediatric otolaryngologists (Fig. 68.5). A 2.9 or 4.0 mm Hopkins rod is used while the



• **Fig. 68.4** Axial CT demonstrating unilateral right choanal atresia.

atretic plate is opened with a urethral sound or microdrill, then progressively dilated, and a backbiter may then be used to remove the posterior vomer.[29] Postoperative stenting remains a controversial topic and has not been shown to produce significant improvement in surgical outcomes while increasing rates of local infection, synechiae, and granulation tissue.[23] Topical application of mitomycin C, an antineoplastic agent inhibiting fibroblast proliferation, has been described in multiple studies but has not shown a difference in the restenosis rate for choanal atresia repair.[8] Regardless of the technique, recurrence rates following endoscopic techniques remain high, with risk factors including reflux, age less than 10 days, pure bony atresia, and associated malformations. Meanwhile CHARGE patients may require tracheostomy upfront due to multilevel airway obstruction or cardiopulmonary issues; surgical repair is also less likely to be successful in these patients because of more contracted anatomy and poor pharyngeal muscular control.[23]

Congenital Nasal Masses

Nasal obstruction with airway distress can result from congenital midline masses such as dermoids, epidermoids, cerebral heterotopia, and encephaloceles. Any infant with a midline nasal mass should be fully evaluated, generally with both CT and magnetic resonance imaging (MRI) to assess for skull base involvement and intracranial extension before intervention is undertaken. Biopsy of an unsuspected nasal

• **Fig. 68.5** **A,** Endoscopic view during repair of right choanal atresia. **B,** Postoperative view after right choanal atresia repair, 8 weeks.

encephalocele can lead to cerebrospinal fluid leak, meningitis, and death.

Congenital midline nasal masses are theorized to arise from failed retraction of a dural diverticulum, and tissue extension through the fonticulus frontalis or foramen cecum may produce an extranasal or intranasal mass, respectively. Dermoids contain ectodermal and mesodermal tissue, while epidermoids contain only ectodermal tissue. These lesions are often grouped together due to their similar embryologic origin and may present as cystic or solid masses located anywhere between the columella and the glabella. Dermoids may also present with sinus tracts and pits secreting sebaceous material, classically with a dimple at the rhinion and protruding hair. Intracranial communication should be suspected in the case of recurrent meningitis, and imaging revealing an enlarged foramen cecum, bifid nasal septum, or bifid crista galli.[36] Treatment consists of complete surgical excision, including associated tracts, and collaboration with neurosurgical teams as indicated.

Cerebral heterotopia (previously known as nasal glioma) represents sequestra of glial tissue following incomplete retraction of the dural diverticulum, and neonates may present with nasal obstruction and an intranasal mass. Up to 15% of lesions retain a dural connection, and 10%-30% retain a fibrous stalk.[36] Failure to recognize the fibrous stalk can lead to incomplete resection and tumor recurrence. Encephaloceles maintain their intracranial communication with the subarachnoid space, with herniated brain tissue, dura, and cerebrospinal fluid constituting the tumor. These masses are pulsatile, transilluminate with light, and demonstrate a positive Furstenberg test (expansion following jugular vein compression). Early surgical resection with multidisciplinary coordination is generally recommended to alleviate the risk of meningitis that accompanies these tumors. In addition, progressive growth of the lesion can result in marked nasal deformity. Recently, transnasal endoscopic approaches have been described for the surgical resection of these lesions while shortening operative time and decreasing complication rates.[1]

Nasopharyngeal Teratoma

Teratomas are benign tumors composed of all three germ layers with recognizable early organ differentiation. Females are disproportionately affected (6:1 ratio), and associated fetal conditions include hydrops and pulmonary hypoplasia. While these lesions are most commonly found in the sacrococygeal region, teratomas of the head and neck carry a notable risk of airway obstruction. In the nasopharynx, they may appear in the midline or lateral pharyngeal wall and appear heterogeneous on MRI with fat and bone. A persistently high alpha-fetoprotein (AFP) level may be suggestive of teratoma and may be used to monitor for disease progression or response to treatment.[30] Prenatal diagnosis with ultrasound and MRI, along with multidisciplinary prenatal care, is critical to evaluate the degree and extent of airway obstruction, and an EXIT procedure may be indicated in severe cases.[6]

Mucosal Obstruction

Neonatal rhinitis is a common cause of nasal obstruction that may present with stertor, difficulty feeding, and increased work of breathing.[39] Generalized mucosal hypertrophy or edema can result in significant anterior nasal congestion and symptomatic obstruction in the neonate until oral breathing becomes reflexive. Treatment of these patients is generally conservative and includes humidification, saline drops, and judicious suctioning. Excessive attempts at suctioning can result in increased edema and exacerbation of the infant's symptoms. Gastroesophageal reflux may reach the level of the nasopharynx and can exacerbate nasal obstruction as well. Appropriate treatment of reflux may improve the nasal airway. Intranasal steroid drops might be helpful during periods of increased congestion such as that associated with viral rhinitis. Prolonged use of intranasal decongestants can lead to rhinitis medicamentosa (paradoxical mucosal swelling) and should be avoided.

Continuous Positive Airway Pressure Trauma

Care must be taken with the use of continuous positive airway pressure (CPAP) nasal prongs and masks in the neonate, because nasal trauma can occur. Cosmetic and functional sequelae of nasal injury from nasal CPAP have been described not only in neonates but also in adolescents and adults with a history of nasal CPAP administration as a neonate.[26] Thus, if nasal injury is imminent and discontinuation of nasal CPAP is not possible, then changing to a different style of delivery (e.g., nasal mask) may be useful. Nasal cannulas cause significantly less nasal trauma than CPAP.

Oral and Oropharyngeal Lesions

Normal oral cavity and oropharyngeal development is critical in establishing a patent upper airway. A variety of congenital anomalies have a known association with micrognathia, glossoptosis, and posterior tongue displacement and subsequent airway obstruction. Pierre Robin sequence, Treacher Collins syndrome, Goldenhar syndrome (oculoauriculovertebral dysplasia), Crouzon disease, and Down syndrome are the most common congenital anomalies that have oropharyngeal airway obstruction as an important clinical feature.

In most of these patients, normal growth and development results in an increase in oropharyngeal space and a decrease in obstructive symptoms. Any treatment plan for these patients must take into consideration the knowledge that normal growth alleviates much of the obstructive pathology. Often, placing the infant in a prone position with slight head elevation during sleep dramatically decreases the degree of symptomatic obstruction. A McGovern nipple that maintains oral patency or a soft nasal trumpet may be sufficient to achieve adequate airway patency until growth of the mandible occurs. For patients with severe micrognathia and respiratory distress that does not respond to conservative therapy, multidisciplinary care should be coordinated with pulmonology and genetics, as well as a swallow evaluation, polysomnogram, airway evaluation, and computed tomography imaging. Those with craniofacial-microsomia-Goldenhar syndrome, persistent aspiration, poor neuromuscular tone, ventilator dependence, or other source of airway obstruction should receive tracheostomy as an initial procedure prior to mandibular distraction osteogenesis (MDO).[25] Otherwise, MDO represents an effective surgical technique to relieve the airway obstruction from severe micrognathia and may obviate the need for a tracheostomy or increase the likelihood of successful decannulation in those with pre-existing tracheostomies.

Lymphatic Malformations

Lesions of the floor of the mouth or base of the tongue that cause posterior tongue displacement also can be associated with secondary airway obstruction. Lymphatic malformations are benign congenital vascular anomalies with a predilection for the head and neck region and may infiltrate the soft tissue of the floor of the mouth and cause significant upper airway obstruction. Prenatal diagnosis of cervical lymphatic malformation with airway obstruction or floor of mouth involvement may necessitate an EXIT (ex utero intrapartum treatment) procedure to secure a safe airway.[24] Local infection of vascular anomalies is also an important entity to recognize, as localized swelling may compromise an existing airway, and long-term antibiotics have been proposed to prevent recurrent cycles of infection.[42] An increased incidence of sleep-disordered breathing has also been noted in this population[14] and may warrant formal evaluation with polysomnography.

In addition to airway compromise, lymphatic malformations may also cause dysphagia, dysarthria, and dental problems. Treatment should be tailored to the specific functional and cosmetic impact of each lesion, as well as the pathologic type (macrocystic versus microcystic). Surgery and sclerotherapy represent the mainstays of treatment, although radiofrequency ablation, lasers, propranolol, and sirolimus have also been described, albeit with limited data on objective efficacy. At present, multimodality and sequential treatment with surgery and sclerotherapy is most commonly used for extensive lesions. Isolated neck disease also holds an improved prognosis for resolution compared to lesions in the larynx, parotid, or oral cavity.[4]

Oral Cavity Cysts

Cysts of the base of the tongue are a rare but serious cause of airway obstruction in the newborn infant. An acute airway crisis could appear shortly after birth or several months later. These cysts may represent lingual thyroglossal duct remnants at the foramen cecum.[37]

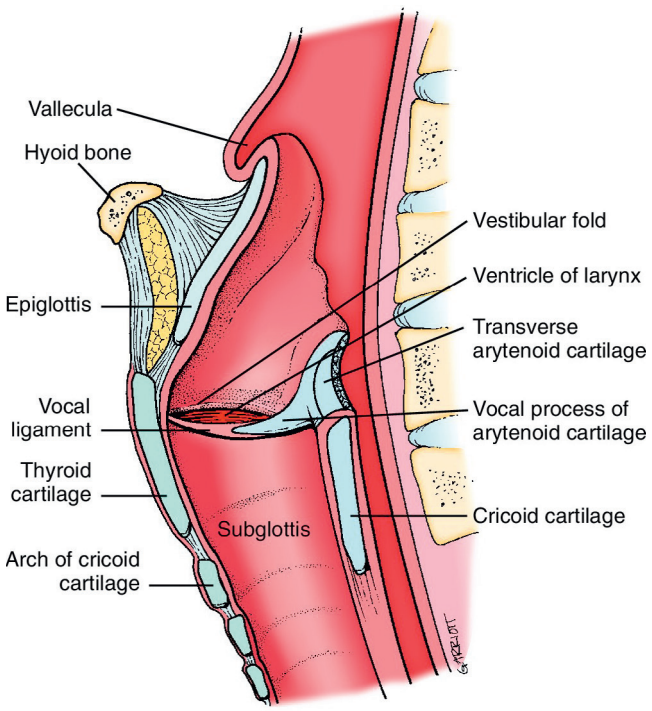
Dermoid cysts of the oral cavity are benign, slow-growing tumors that may cause progressive symptoms of dysphagia or airway obstruction in the pediatric population.[32] In contrast with the infant with a thyroglossal duct cyst at the base of the tongue, a more insidious onset of symptoms may be noted. Airway obstruction may be worsened by the mass effect in the hypopharynx and inferoposterior displacement of the epiglottis, which causes supraglottic obstruction.

Surgical excision is the treatment of choice in these patients. Marsupialization may be an option for the large cyst that is not amenable to complete resection. Significant tongue swelling can develop postoperatively, and temporary intubation may be necessary to ensure a protected upper airway.

Laryngeal Lesions

Embryologically, the larynx has three primary functions: airway protection, respiratory modulation, and voice production. The neonatal larynx has unique features, compared with that of an adult, that affect its ability to perform

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.



these three primary functions both in the normal and the diseased state.

Although the neonatal larynx is less than one-third the size of the adult larynx, the arytenoid cartilages are adult size at birth. This relationship between the supraglottic structures and the laryngeal inlet can contribute to the development of laryngomalacia in some infants. The subglottis is the smallest component of the pediatric larynx, whereas in the adult, the glottic aperture is the size-limiting factor. The development of subglottic stenosis in the infant following endotracheal intubation is directly related to the small size of the subglottic opening.

In addition to differences in size, the infant larynx differs in its position in the neck relative to the cervical and facial skeleton. At birth, the larynx may be found at approximately the level of the C4 vertebra. As the child grows, the larynx begins its inferior descent, ultimately resting at the level of C7. The high location of the larynx in the infant provides some protection against external trauma.

The cephalad location of the larynx also provides additional protection to the lower airway of the neonate, who has not yet fully developed the necessary protective reflexes to prevent aspiration during swallowing. In the young infant, the epiglottis rests on the nasopharyngeal surface of the soft palate. This position allows the infant to suckle without danger of aspiration and to breathe with the mouth closed.

Anatomically, the larynx may be subdivided into three components: supraglottis, glottis, and subglottis (Fig. 68.6). Disorders in one of these components produce a unique set of symptoms that allows narrowing of the field of possible causes of airway distress in the infant. An attempt should be made to characterize stridor, when present, as inspiratory, expiratory, or biphasic.

• **Fig. 68.6** Parasagittal view of infant larynx demonstrating cartilaginous relationships.

Although not uniformly true, the level of obstruction is often reflected in the character of the stridor. Supraglottic lesions tend to produce a coarse, inspiratory stridor, whereas glottic and subglottic disorders are more "musical" in quality and often biphasic in nature. Pure tracheal lesions often manifest with a prolonged expiratory phase and expiratory stridor. Changes in the quality of the stridor with the level of activity and position of the infant are also a crucial aspect of the history. The quality of the child's cry (normal, weak, or aphonic) can direct one to a glottic lesion, although severe subglottic narrowing could produce an abnormal cry because of limited air movement.

The presence or absence of cough should be documented. A feeding history is critical. Symptoms of aspiration or cyanosis with feeds can signal a specific disorder. Failure to thrive or other signs of systemic illness could indicate a more chronic disorder. The infant's prenatal and perinatal history could reveal an unsuspected history of traumatic delivery or neonatal intubation.

If the infant is in extremis, or there are signs to suggest significant airway compromise, extreme caution should be exercised. Manipulation of the infant should be minimized until the airway can be secured. The infant can be observed for tachypnea, tachycardia, retractions (supraclavicular, subcostal, intercostal), nasal flaring, cyanosis, drooling, cough, and level of consciousness (restless, agitated, stuporous) without increasing the level of the infant's anxiety.

Laryngeal examination should not be performed in the infant with an unstable airway unless the appropriate personnel and equipment are available for urgent airway access when necessary. Flexible fiberoptic nasolaryngoscopy is widely available and allows direct inspection of the larynx in the stable neonate.

Evaluation of the awake child has several distinct advantages. The larynx can be viewed in a dynamic fashion so that the degree of laryngeal collapse during active respiration is appreciated. In addition, vocal cord motion can be assessed. Flexible bronchoscopy allows further dynamic evaluation of the subglottic airway and lower tracheobronchial tree.

For more controlled laryngeal evaluation, direct laryngoscopy and rigid bronchoscopy under general anesthesia are necessary. If a deep inhalational anesthetic technique is used, dynamic laryngeal and tracheal function can be assessed using this method as well. Direct laryngoscopy with rigid bronchoscopy is the method of choice in evaluating an infant with air hunger, cyanosis, or any critical symptoms that may necessitate intubation.

Ancillary testing in the infant with a stable airway is useful in further identifying the site of the lesion before possible endoscopy and surgical intervention. Radiographic evaluation of the upper airway (usually with a CT scan with contrast) is useful in suspected subglottic stenosis (either congenital or iatrogenic), soft tissue laryngeal tumors (hemangiomas, papillomas), or congenital laryngeal or esophageal

cysts. Less commonly, anteroposterior and lateral soft tissue radiographs of the neck can be obtained. Ballooning of the hypopharynx is often seen on the lateral neck radiograph in an infant with significant airway obstruction. Reversal of the cervical lordotic curvature is suggestive of a retropharyngeal process. Airway fluoroscopy allows a dynamic assessment of the airway and can be done in conjunction with a modified barium swallow to evaluate for vascular anomalies or tracheoesophageal fistula or to better define the contribution of a swallowing disorder to the airway symptoms. Computed tomography scan is also useful for evaluating the infant with a laryngeal tumor for a severe laryngotracheal anomaly not fully delineated by endoscopy or for the evaluation of laryngeal trauma. Computed tomography scanning is also useful for virtual bronchoscopy to map extensive tracheal or bronchial stenosis. Magnetic resonance imaging is useful for defining mediastinal anatomy in the infant with a suspected vascular anomaly.

Disorders of the neonatal larynx are best subdivided into congenital and acquired lesions. Severe congenital laryngeal anomalies are quite rare and in general manifest themselves within the first few minutes of life. These include complete atresia, severe stenosis, or near-total laryngeal webs. If these disorders are recognized, tracheostomy may be a life-saving procedure. Often, these severe laryngeal anomalies are found in conjunction with other life-threatening neurologic, cardiac, gastrointestinal, and lower airway lesions. In the neonate, the acquired laryngeal injury is usually the result of endotracheal intubation (see Chapter 65). The overall prognosis for these neonates depends not only on the laryngeal problem but also on the infant's overall development and the impact of other concomitant lesions.

Laryngomalacia

Laryngomalacia (congenital flaccid larynx, congenital laryngeal stridor) is the most common cause of stridor in the infant. The etiology of laryngomalacia remains elusive, although generalized neurologic immaturity of the infant's airway and digestive tract is believed to play a role. Clinically, stridor develops between the second and fourth weeks of life, although it occasionally may be present at birth. The stridor is typically characterized as coarse inspiratory noise.

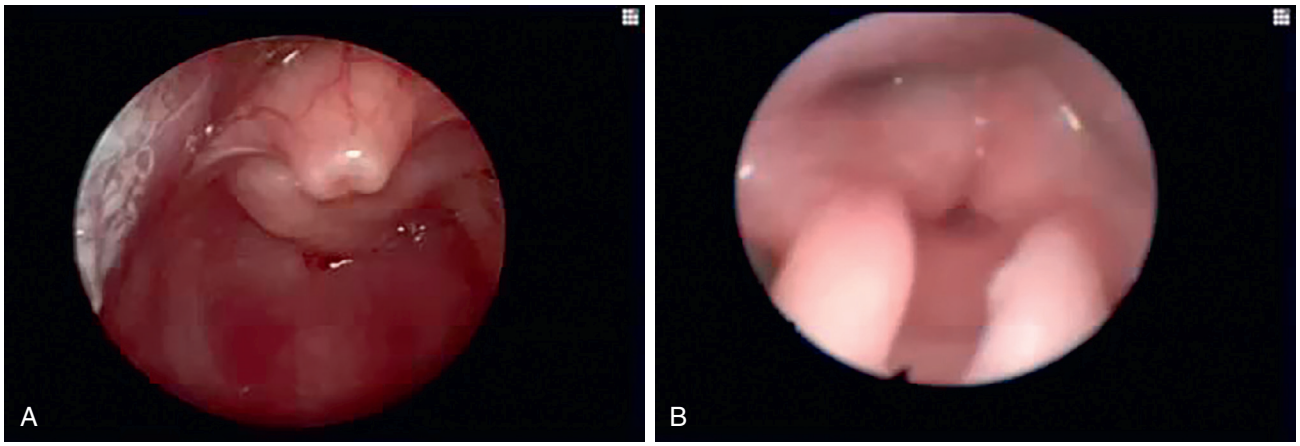
The infant is generally better in the prone position, because this serves to decrease the degree of supraglottic collapse on inspiration, although this must be weighed against the Safe to Sleep campaign advocating the supine sleeping position to reduce the risk of sudden infant death syndrome. Agitation tends to exacerbate the stridor, which tends to disappear completely during rest, and the cry is usually normal. The natural history of the disease is one of progression until 8-12 months of age, with complete resolution in most children by 2 years of age. However, in cases of severe laryngomalacia, infants may have constant stridor, increased work of breathing, periodic apneas, failure to thrive, cor pulmonale, or pectus excavatum.

Symptoms of swallowing or feeding difficulty have been reported in 50% of infants with laryngomalacia regardless of comorbidities,[38] and dysphagia evaluation should be included in standard workups in the form of clinical swallow evaluation (CSE), modified barium swallow (MBS), or functional endoscopic evaluation of swallowing (FEES). Gastroesophageal reflux often coexists with laryngomalacia and may exacerbate symptoms,[17] thus infants with signs and symptoms of reflux should be treated with acid suppression therapy. Concomitant neurologic disease is also described more frequently in infants with moderate or severe laryngomalacia. Concomitant obstructive or central sleep apneas also warrant formal evaluation with polysomnography.

Up to 50% of infants with laryngomalacia have a synchronous airway lesion such as congenital subglottic stenosis.[2] Direct laryngoscopy with rigid bronchoscopy is indicated in the atypical patient to confirm the suspected diagnosis of laryngomalacia and evaluate for the possible existence of a secondary lesion below the level of the glottis.

Diagnosis in the more typical patient begins with fiberoptic office nasolaryngoscopy. During inspiration, the supraglottic structures collapse into the laryngeal inlet, narrowing the air passage and creating the classic coarse stridor. Visualization of the vocal cords may be limited by shortened aryepiglottic folds, a curled omega-shaped or retroflexed epiglottis, and arytenoid collapse (Fig. 68.7). Each of these sites may contribute to airway collapse laterally, anteriorly, or posteriorly, respectively; description of the exact site and degree of collapse is critical in surgical planning.[41]

Surgical intervention is indicated for patients with respiratory or feeding difficulties not responsive to conservative therapy or for severe laryngomalacia characterized by cyanosis, apnea, failure to thrive, or aspiration. Supraglottoplasty may include division of aryepiglottic folds and trimming of redundant supra-arytenoid or epiglottic tissue, using CO_2 laser, cold instruments, or microdebrider. This procedure not only produces excellent success rates for symptoms of laryngomalacia but also improves concurrent obstructive sleep apnea.[16] Tracheostomy is reserved for severe laryngomalacia that results in significant airway obstruction despite supraglottoplasty.



Bifid or Absent Epiglottis

Both the bifid epiglottis and the absent epiglottis are extremely rare. Severe subglottic stenosis is usually seen with these unusual supraglottic anomalies. Tracheostomy is necessary because of the associated subglottic lesion. Aspiration is variable.

Laryngeal Cysts

Most cysts of the larynx develop in the supraglottic location (aryepiglottic fold, epiglottis, vallecula) and gradually increase in size during the first few months of life. Ductal obstruction may lead to accumulation of mucous within

• **Fig. 68.7** **A,** Infant supraglottis with laryngomalacia. Coiled epiglottis and tightened aryepiglottic folds. **B,** Infant supraglottis with laryngomalacia. Arytenoid edema and prolapse preventing visualization of vocal cords.

a saccular cyst. Owing to the location of these lesions as well as their slowly progressive course, they may be indistinguishable clinically from laryngomalacia. Patients may present with stridor and respiratory distress and require early intubation; others only exhibit inspiratory stridor that worsens with agitation and when in the supine position. In older children, the voice can become muffled as the cyst enlarges.

If undetected and untreated, these cysts can become quite large and cause complete laryngeal obstruction. Fiberoptic evaluation confirms the presence of a saccular cyst and is the minimum requirement for all infants with new-onset, progressive inspiratory stridor. Formal evaluation with rigid endoscopy under general anesthesia, as well as magnetic resonance imaging, may be needed in more extensive lesions. The treatment involves either endoscopic marsupialization or complete excision (either endoscopically or externally) of the cyst. Attempts to aspirate the cyst inevitably lead to cyst recurrence. Subglottic cysts can form just below the vocal cords and are caused by obstruction of mucosal glands related to intubation. Endoscopic marsupialization with a carbon dioxide laser or cold instrumentation is usually curative.

Vocal Cord Paralysis

Vocal cord paralysis is the second most common laryngeal anomaly of infancy. Bilateral vocal cord paralysis typically produces inspiratory stridor that worsens with agitation or infection, a weak voice, and airway obstruction. In contrast, unilateral vocal cord paralysis may be initially asymptomatic, with dysphonia or stridor that worsens with agitation. The child may have a history of choking, coughing, or brief cyanotic spells during feeds, which is indicative of aspiration. Concomitant airway disease such as laryngomalacia, tracheomalacia, and subglottic stenosis may also be present.[34]

Radiographic evaluation remains an important step in the management of these patients. Unilateral paralysis may be associated with cardiac atrial enlargement or anomalous great vessels, which can be detected on chest radiographs and barium swallow or echocardiogram. In the absence of a history of infection (syphilis, Guillain-Barre), traumatic delivery, prolonged intubation, or cardiothoracic surgery (e.g., ligation of patent ductus arteriosus [PDA], repair of tracheoesophageal fistula), the course of the vagus nerve should be investigated radiographically. An MRI of the brain, neck, and chest may reveal a Chiari malformation or mass effect from a mediastinal or cervical mass. Awake fiberoptic laryngoscopy is often necessary to confirm the diagnosis of vocal cord paralysis, and video recording may be helpful to examine findings in more detail.

The treatment of unilateral vocal cord paralysis depends on the severity of the child's symptoms. While many symptoms of difficulty feeding or dysphonia may resolve spontaneously, 20%-40% remain symptomatic after 8-12 months.[21] Thus, for the first few years after diagnosis of unilateral vocal cord paralysis, conservative measures and temporary injection laryngoplasty may be offered. Medialization thyroplasty is typically reserved for older patients who are able to tolerate an awake procedure under local anesthesia to fine tune exact placement of the implant. Reinnervation using ansa cervicalis to the recurrent laryngeal nerve has been shown to be effective in improving voice and vocal cord tone (but not mobility) without foreign material or alteration of the laryngeal framework.[7]

Bilateral vocal cord paralysis creates more severe respiratory symptoms because of significant encroachment on the glottic aperture. Often there are associated neurologic abnormalities, such as Chiari malformation and hydrocephalus. Unlike unilateral paralysis, bilateral vocal cord paralysis often necessitates tracheostomy.

Laryngeal Web

A laryngeal web is the result of a failure to recanalize the laryngeal inlet at approximately 10 weeks' gestation. A commonly referenced classification system was proposed by Cohen in 1985, with type 1 less than 35% glottic length

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

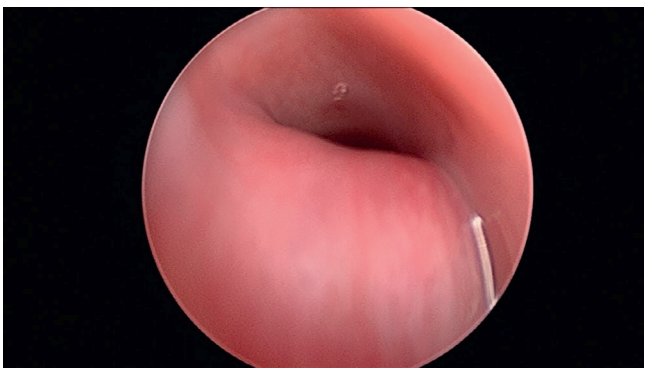
involvement; type 2 35%-50%; type 3 50%-75%; and type 4 thick web up to 99% and with associated subglottic stenosis.[10] Infants with type 1 webs may not be symptomatic at birth but then develop biphasic stridor between 4 and 6 weeks of age after activity levels begin to increase. For more severe glottic webs, respiratory distress and aphonia may be present. Frequent association with velocardiofacial syndrome (VCFS) and 22q11 deletion warrants fluorescence in-situ hybridization or genetic sequencing in patients with anterior glottic webs.[31] Treatment of a laryngeal web depends on the thickness of the web itself and the degree of subglottic extension. Type 1 and 2 glottic webs can often be treated endoscopically with web excision using cold instruments or lasers, sometimes with stent or keel placement to prevent scarring and web recurrence anteriorly. Type 3 and 4 glottic webs may require tracheostomy and an open approach with laryngotracheal reconstruction and cartilage grafts.[11]

Congenital Subglottic Stenosis

The normal subglottis measures between 5 and 7 mm in the neonate. Congenital subglottic stenosis occurs when the subglottic diameter of a full-term infant is less than 4 mm at birth and may be associated with 22q11 deletion, Down syndrome, and CHARGE syndrome. Congenital stenosis often results from an abnormally shaped cricoid ring, elliptical rather than circular, or from excessive thickening of the subglottic tissue. Rarely, the first tracheal ring may be displaced superiorly and come to lie within the cricoid itself.

In mild forms, the stenosis can go undetected until the child is 2-3 years of age, at which point recurrent croup-like episodes prompt endoscopic evaluation. In more severe cases, biphasic stridor is present with a classic croupy cough in the absence of any systemic signs of a viral illness. The cry is usually normal, and feeding is only an issue in cases of significant shortness of breath resulting from airway compromise. In general, congenital subglottic stenosis is concentric. Radiographic evaluation usually demonstrates symmetric subglottic narrowing.

Formal evaluation with direct laryngoscopy and rigid bronchoscopy is necessary to evaluate the full extent of the stenosis. A cuffless endotracheal tube is placed past the stenosis, and the largest size that allows a leak pressure of 10-25 cm H_2O is used to determine the Cotton-Meyer grade of stenosis: grade 1 (0%-50%), grade 2 (51%-70%), grade 3 (71%-99%), and grade 4 (no discernable airway).[31]



Management of these lesions depends on the severity of the infant's symptoms and the age at presentation. Congenital subglottic stenosis is usually less severe than the iatrogenic form following endotracheal intubation. In select cases, an anterior cricoid split can prevent the need for tracheostomy in infants up to 18 months of age. In more severe cases of stenosis or in the older child, laryngotracheal reconstruction using rib for augmentation is the treatment of choice.

Subglottic Hemangioma

Subglottic infantile hemangioma is the most common neoplasm of the infant airway and can lead to significant airway compromise if left untreated. These benign vascular growths are characterized by disorganized endothelial proliferation and stain positively for GLUT-1 and are more prevalent in infants from in vitro fertilization, premature births, and females.[20] In the larynx, the lesion generally appears as a smooth, eccentric, compressible mass in the subglottis, most commonly located in the left posterior subglottic space. Subglottic hemangioma is associated with a segmental beard distribution hemangioma, and any patient with a large cervicofacial hemangioma should be evaluated for PHACES (*p*osterior fossa anomalies, *h*emangioma, *a*rterial lesions, *c*ardiac/aortic anomalies, *e*ye abnormalities, *s*ternal defects) and undergo further imaging to evaluate for associated anomalies.

The clinical presentation of a subglottic hemangioma is similar to that of subglottic stenosis. The infant typically has progressive biphasic stridor beginning at 4-6 weeks of age. Unlike with the static subglottic lesion, the symptoms associated with a hemangioma can fluctuate in severity from day to day. The fluctuating character of symptoms is strongly diagnostic of subglottic hemangioma. The stridor is worse with crying or agitation owing to vascular engorgement of the hemangioma. Feeding difficulties are unusual unless severe airway obstruction exists. The cry is generally normal. Radiographic evaluation (CT scan with contrast or anteroposterior soft tissue neck film) may show an asymmetric narrowing of the subglottis. The diagnosis of a subglottic hemangioma is confirmed at the time of direct laryngoscopy with rigid bronchoscopy (Fig. 68.8).

The treatment of subglottic hemangiomas must take into account the natural history of the neoplasm. Initially, the lesion undergoes rapid postnatal growth for 8-18 months (proliferative phase) followed by slow but inevitable regression for the next 5-8 years (involutive phase). Since the serendipitous discovery of the efficacy of propranolol in the treatment of infantile hemangiomas in 2008, and its formal approval by the Food and Drug Administration in 2014, treatment with propranolol for hemangiomas causing airway symptoms has rapidly become a first-line therapy,

• **Fig. 68.8** Subglottic hemangioma before treatment.

although the exact mechanism of therapeutic reduction is not well understood. A consensus statement released in 2013 proposes a dosing protocol starting with 2 mg/kg/day in three divided doses, with titration customized to severity of side effects ranging from hypotension, bradycardia, and hypoglycemia.[13] Systemic steroids on a daily or every-other-day schedule may control the proliferative phase of the hemangioma in patients with minimal airway or feeding compromise. Surgical debulking or resection, lasers (CO_2, Nd:YAG, and pulsed dye lasers), and pharmacologic therapies (interferons, vincristine) are typically reserved for hemangiomas with airway symptoms refractory to beta blocker therapy.[9] In cases of extensive airway involvement, a tracheostomy provides a secure airway until the tumor involutes.

Laryngeal Cleft

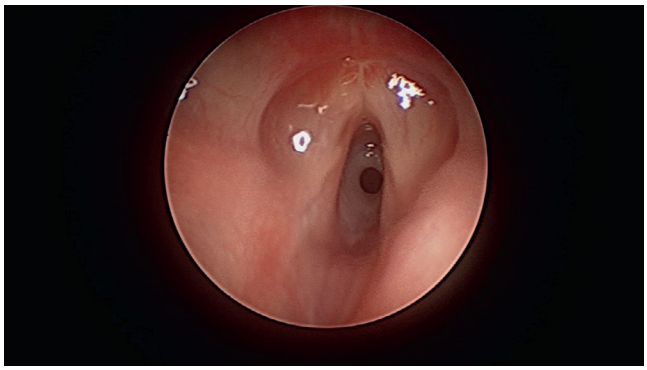
Failure of fusion of the tracheo-esophageal septum results in a posterior laryngeal cleft. The Benjamin-Inglis classification is commonly used to describe these clefts,[3] with type 1 extending to the level of the true vocal cords, type 2 involving part of the posterior cricoid plate, type 3 involving the cervical trachea, and type 4 extending to the thoracic trachea. Presentation may vary from dysphagia and recurrent aspiration pneumonia to cyanosis and respiratory distress. While most cases are sporadic, associated syndromes include CHARGE, VACTERL, Optiz-Frias, and Pallister Hall. Evaluation should include a swallow evaluation (modified barium swallow or functional evaluation of swallowing) and flexible laryngoscopy; however, definitive diagnosis requires formal evaluation in the operating room with palpation of the interarytenoid area. For type 1 clefts, dietary changes (thickened feeds), close coordination with speech-language pathology, and antireflux medications are sufficient in about one-third of cases, while the remaining two-thirds do need surgical repair.[40] Surgical repair may be performed via open or endoscopic approaches, with the latter being more common, especially for types 1-3 laryngeal clefts. Cold instrumentation or laser may be used to de-epithelialize the mucosa lining the cleft, and vicryl sutures are placed from an inferior to superior direct to close the defect. Open approaches may require a cartilage or muscle graft, laryngofissure, pharyngotomy, cardiopulmonary bypass, or extracorporeal membrane oxygenation.

Congenital High Airway Obstruction Syndrome

Congenital high airway obstruction syndrome (CHAOS) was defined by Hedrick and colleagues in 1994 as prenatally diagnosed upper airway obstruction with concomitant findings of large echogenic lungs, dilated airways, flattened or inverted diaphragms with associated fetal ascites, or nonimmune hydrops. These hallmark findings are found consistently only when there is complete high upper airway obstruction with no tracheoesophageal connection because of laryngeal atresia, severe subglottic stenosis, glottis web, obstructive laryngeal cysts, or a double aortic arch. This leads to trapping of the fluid secreted by the fetal lung tissue. If the lung fields expand to the point of producing esophageal compression, then polyhydramnios may occur as a result of impaired swallowing of amniotic fluid. These findings necessitate a more detailed scan for other abnormalities, because CHAOS may be one fetal presentation of Fraser syndrome, characterized by variable expression of laryngeal atresia, cryptophthalmos, syndactyly, renal agenesis, and abnormalities of the ears and external genitalia.[12]

This life-threatening condition was previously thought to be rare and uniformly fatal. Advances in prenatal imaging techniques have enabled this syndrome to be recognized more readily. Planning for the EXIT (ex utero intrapartum treatment) procedure can then be made to maximize survival.

If there is incomplete airway obstruction or a tracheoesophageal fistula, the degree of fluid trapping is lessened, and the diagnosis is less obvious on prenatal ultrasound imaging. In these cases, with the diagnosis less obvious, survival depends on the degree of upper airway obstruction, the ability to tracheally intubate the child past the tracheoesophageal fistula, or the ability to expeditiously perform a tracheostomy.



Intubation Trauma

The use of endotracheal intubation to secure the airway in the neonate for mechanical ventilation has become the standard of care for the critically ill newborn. Despite recent efforts to reduce the risk of iatrogenic injury, however, granuloma formation, arytenoid dislocation with true vocal cord fixation, and subglottic stenosis continue to occur.

Granuloma formation can follow endotracheal intubation. The infant is often hoarse following extubation, with progression rather than improvement of the symptoms with time. Evaluation of the larynx reveals a yellow-red pedunculated mass arising from the vocal process of the arytenoid. Subglottic cysts or mucoceles may develop when the opening of submucosal glands is interrupted by tissue reaction from an endotracheal tube. Microlaryngoscopy and removal of these lesions often result in resolution of the infant's symptoms. Repeat evaluation is recommended at 2-3 weeks to ensure that the granuloma has not reformed, which can be lessened by aggressive treatment of gastroesophageal reflux.

Several factors in the pediatric airway predispose the intubated neonate to subglottic stenosis (Fig. 68.9). The subglottic lumen is the narrowest aspect of the pediatric larynx. Premature infants and children with Down syndrome tend to have smaller cricoid rings than normal, thus increasing the overall risk of subglottic stenosis. Gastroesophageal reflux and infection at the time of intubation have been proposed as potential factors in the development of subglottic stenosis.[22] Difficulty in stabilizing the endotracheal tube in the neonate often results in repeated

• **Fig. 68.9** Iatrogenic subglottic stenosis following prolonged endotracheal intubation in a neonate.

intubations and increased injury to the subglottis. Extreme immaturity requiring intubation periods of several months predisposes to subglottic injury. Hypoxia and sepsis are important variables in the development of subglottic tissue damage and are commonly seen in the neonatal intensive care setting. Injury to the subglottis may be reduced if the following steps are taken:

- Use smaller endotracheal tubes.
- Avoid cuffed endotracheal tubes in the infant and young child.
- Aggressively treat systemic infection.
- Minimize patient movement to prevent abrasions of the subglottic mucosa and resultant exposed cartilage as well as to prevent accidental extubation requiring further manipulation (sedate as necessary).
- Consider tracheostomy if prolonged intubation is anticipated. Neonates tolerate intubation for much longer periods than the child or young adult.
- Extubate under ideal conditions. In the difficult airway, high-dose systemic steroids for 24-48 hours before and after extubation may aid extubation. Use of inhaled epinephrine immediately following extubation can help reduce airway edema.

Treatment of iatrogenic subglottic stenosis depends on the severity of the stenosis, the age of the child, and concomitant medical problems. Tracheostomy remains the cornerstone of treatment, especially in the infant with multilevel airway involvement, multisystem failure, or significant pulmonary disease. The anterior cricoid split may be used in the neonate up to 18 months of age if mild stenosis exists. As in congenital subglottic stenosis, laryngotracheal reconstruction using rib cartilage is the method most commonly employed for treatment of significant pediatric subglottic stenosis. In selected patients, laryngotracheal reconstruction may be performed as a single-stage procedure, allowing immediate decannulation in the patient with a pre-existing tracheostomy or avoidance of a tracheostomy altogether in the virgin trachea.

Conclusion

Management of the neonate with upper airway obstruction requires that a rapid evaluation and diagnosis be made based on a complete understanding of the unique anatomic and physiologic characteristics of the neonatal airway. The airway should be assessed from nasal vestibule to tracheal bifurcation in a search for the etiology of acute or progressive respiratory distress. Treatment of the neonate with upper airway pathology is tailored to the specific abnormality as well as coexisting medical problems.

Key Points

- Dividing the neonatal upper airway into four primary physiologic components (nasal, oral, laryngeal, tracheal) helps frame the discussion of airway abnormalities in the newborn.
- Evaluation of an infant with a suspected airway abnormality should encompass the entire upper airway, from the anterior nasal vestibule to the tracheal bifurcation.
- Neonates are preferential (almost obligate) nasal breathers; any process that causes bilateral nasal obstruction (such as bilateral pyriform aperture stenosis, bilateral choanal atresia, or bilateral nasolacrimal duct cysts) will precipitate significant airway obstruction requiring acute intervention.
- Infants with choanal atresia as a component of CHARGE syndrome are more likely to require a tracheostomy, more likely to have concurrent airway lesions, and less likely to experience a successful atresia repair.
- The pathophysiology and behavior of congenital midline nasal masses depends on a defect in the fonticulus frontalis or foramen cecum.
- Neonates with retrognathia with or without a cleft palate may have feeding abnormalities or airway obstruction requiring intervention (such as prone positioning, nasopharyngeal airway, mandibular distraction osteogenesis, or tracheostomy).
- Cervicofacial teratomas or lymphatic malformations diagnosed in utero may necessitate an EXIT (ex utero intrapartum treatment) procedure if impending airway obstruction is suspected.
- Disorders of the neonatal larynx may be congenital (laryngeal atresia, laryngeal web) or acquired (glottic intubation granulomas).
- Laryngomalacia is the most common cause of stridor in an infant and can also cause feeding issues in up to half of patients; typically symptoms resolve over time with no surgical intervention required.
- Subglottic hemangiomas can cause airway obstruction during their proliferative phase; propranolol has demonstrated efficacy in treating these lesions.

Bronchopulmonary Dysplasia in the Neonate

EDUARDO H. BANCALARI AND DEEPAK JAIN

The introduction of mechanical ventilation for the management of premature infants with severe respiratory distress syndrome (RDS) in the 1960s changed the natural course of the disease, resulting in increased survival of smaller and sicker infants, many of whom had severe chronic lung damage. Northway and associates were the first to describe this condition in 1967 and introduced the term *bronchopulmonary dysplasia* (BPD).[49] All these infants had severe respiratory failure and received prolonged mechanical ventilation with high airway pressures and fraction of inspired oxygen (FiO_2). Since then, the advancements in the field of neonatal and perinatal medicine have resulted in increasing survival of extremely preterm infants and evolution in the clinical presentation of BPD to a milder form of chronic lung disease.

Epidemiology of BPD

BPD continues to be the most important respiratory complication of preterm birth, and it is associated with long-term respiratory morbidities. Prematurity is the most important risk factor for BPD, with infants born at less than 28 weeks' gestation being at greatest risk (Fig. 69.1). According to the data from the Eunice Kennedy Shriver National Institute of Child Health and Human Development Neonatal Research Network (NRN), the incidence of BPD in this group decreased from 45% in 2000 to 40% in 2008, with some increase in incidence of BPD over the last few years.[64] The stable or increasing incidence of BPD is likely due to increasing survival of extremely preterm infants, with more infants surviving with milder forms of BPD as compared to before (Fig. 69.2).[61] The incidence of BPD varies widely among different centers[36] not only due to differences in clinical practices and population characteristics but also according to the definition used.[53]

Definition of BPD

Since Northway's first description of BPD for the clinical and radiographic course of a group of preterm infants with severe respiratory failure, the definition of BPD has been modified multiple times to reflect changes in patient population and to better predict pulmonary outcomes. Initial definitions of BPD consisted of oxygen use along with radiographic pictures consistent with BPD at 28 days.[4] With increasing survival of more immature infants over time, the implication of oxygen use at 28 days was questioned, and oxygen requirement at 36 weeks was shown to be more accurate predictor of long-term pulmonary outcomes.[59] In 2001, a workshop conducted by the National Institutes of Health (NIH) proposed a severity-based definition of BPD into three categories based on the duration and level of oxygen therapy required (Table 69.1). The assessment of severity of BPD adds richness to the outcome measure and identifies a spectrum of adverse pulmonary and neurodevelopmental outcomes. As the severity of BPD increases, the incidence of adverse events also increases. The use of supplemental oxygen as a criterion to define severity of BPD has some limitations. The use of supplemental oxygen in these infants is often inconsistent and is not based on a physiologic assessment, which can greatly affect the reported incidence of BPD. To overcome this inconsistency, a physiologic test to standardize the need for supplemental oxygen has been used.[71] Some of the other limitations of the current definition of BPD include failure to classify infants with nonpulmonary causes such as central apnea or airway complications for need for respiratory support, inability to classify infant dying secondary to severe respiratory failure prior to 36 weeks, or failure to appropriately categorize infants on more contemporary modes of respiratory support like high flow nasal cannula.[53] Definitions of BPD are currently evolving in an attempt to categorize infants by severity of disease based on level of support.[24a]

Pathogenesis

BPD, as described originally by Northway and colleagues, resulted from injury to developing lung secondary to prolonged mechanical ventilation with high airway pressures and inspired oxygen concentration. In contrast, BPD

Abstract

Bronchopulmonary dysplasia (BPD) is the most important respiratory complication of preterm birth, and it is associated with long-term respiratory morbidities. Since its first description by Northway half a century ago, the clinical presentation of BPD has evolved from a severe respiratory failure in relatively bigger preterm infants to a more common milder disease presenting in extremely premature infants today. The advancements in obstetric and neonatal care on one hand have resulted in survival of extremely preterm infants at earlier stages of lung development, while on the other have modified some of the risk factors associated with development of BPD. This has presented unique challenges in understanding the pathogenic factors and defining or devising strategies for prevention and management of BPD. It is quite clear that BPD is the end result of a complex interplay of altered alveolar and vascular development, injury, and reparative processes in a premature lung. With increasing knowledge of the mechanisms involved in the pathogenesis of BPD, various innovative strategies like stem cells and growth factors are being evaluated for prevention of BPD. In addition, the role of some established strategies such as patent ductus arteriosus management and postnatal steroids are being reevaluated. There is increasing evidence of the adverse impact of BPD on long-term pulmonary function and respiratory health. There is increasing realization that prevention and management of BPD will require a multipronged approach with novel therapeutic agents acting at different stages of the disease process.

currently is mostly seen in extremely preterm infants in late canalicular or early saccular stage of lung development at birth. Multiple pathogenic factors including pre- and postnatal infections, mechanical trauma from positive pressure ventilation, oxygen toxicity, and pulmonary edema secondary to increased pulmonary blood flow from patent ductus arteriosus (PDA) acts on the immature alveolar and vascular structure of the immature lung. The complex interplay of lung development, injury by pathogenic factors, and reparative processes results in the morphologic and functional lung alterations characteristic of BPD (Fig. 69.3).

Prenatal Factors

Prematurity is the most important risk factor for development of BPD. The prevalence of BPD is inversely related to gestational age and birth weight, strongly suggesting that incomplete development of the lungs plays a critical role in the pathogenesis of BPD.[30] Epidemiologic studies have identified male gender, white race, and maternal smoking and hypertension as risk factors associated with increased risk for BPD.[34,44] Intrauterine growth restriction is also associated with increased risk for BPD, likely secondary to impaired alveolar and vascular growth.[38,57] The role of maternal chorioamnionitis on the risk for BPD has been unclear, with multiple studies showing increased risk for BPD in infants born to mothers with evidence for chorioamnionitis; others, however, have failed to show such association.[24,67] The effect of chorioamnionitis on fetal lung varies from inflammation and lung injury to enhanced lung maturation depending on fetal inflammatory response, the organism causing the infection, and the severity or duration of infection.[29]

Postnatal Factors

Mechanical Trauma

Although high-peak inspiratory pressure is one of the factors implicated as a cause of BPD, it is difficult to separate the role of the high pressures from the underlying lung disease on the chronic lung damage. The damaging effect of high airway pressure and tidal volume on the surfactant-deficient lung was demonstrated in preterm lambs. Lung compliance was decreased after only a few breaths, with excessive tidal volumes given before surfactant replacement.[8] Experimental evidence strongly suggests that excessive tidal volumes can damage the lung, initiate an inflammatory cascade, and interfere with normal lung development.[25] The effect of prolonged ventilation was shown in newborn mice where ventilation for 24 hours resulted in increased apoptosis, inhibition of alveolarization, and angiogenesis in the lung.[43]

Although injury from the mechanical ventilation continues to be an important factor in the pathogenesis of BPD, today most premature infants who require prolonged ventilation due to milder respiratory failure or poor respiratory effort receive lower airway pressures. Therefore, mechanical trauma appears to play a lesser role among the multiple factors acting concurrently on a premature lung to result in milder BPD.

Oxygen Toxicity

Clinical and experimental evidence suggested that pulmonary oxygen toxicity was a major factor in the pathogenesis of the severe original BPD. Although many tissues can be injured by high oxygen concentrations, the lung is exposed directly to the highest partial pressure of oxygen. The precise concentration of oxygen that is toxic to the immature lung probably depends on a large number of variables, including gestational age, nutritional and endocrine status, and duration of exposure to oxygen and other oxidants. Although a safe level of inspired oxygen has not been established, any concentration in excess of room air might increase the risk of lung damage when administered over a long period of time.

The pulmonary changes of oxygen toxicity are nonspecific and consist of atelectasis, edema, alveolar hemorrhage, inflammation, fibrin deposition, and thickening of alveolar membranes. There is early damage to capillary endothelium in animals, and plasma leaks into interstitial and alveolar spaces. Pulmonary surfactant can be inactivated by protein in the airspaces, adding to the risk of atelectasis. Type 1 alveolar lining cells can be injured early, and bronchiolar and tracheal ciliated cells can also be damaged by oxygen. Total resolution after oxygen toxicity is possible if the initial exposure is not overwhelming.

Continued exposure to high inspired oxygen levels is accompanied by influx of polymorphonuclear leukocytes containing proteolytic enzymes. In addition, the antiprotease defense system is significantly impaired in infants exposed to prolonged high inspired oxygen levels, favoring proteolytic damage of structural elements in alveolar walls. This could be an important pathogenic factor in oxygen toxicity and BPD. High inspired oxygen concentration can also inhibit the normal process of alveolar and capillary formation in immature animals.

Although the cellular basis for oxygen toxicity has not been completely elucidated, the principal mechanisms involve the univalent reduction of molecular oxygen and formation of free radical intermediates. The latter can react with intracellular constituents and membrane lipids, thus initiating chain reactions that can cause tissue destruction.

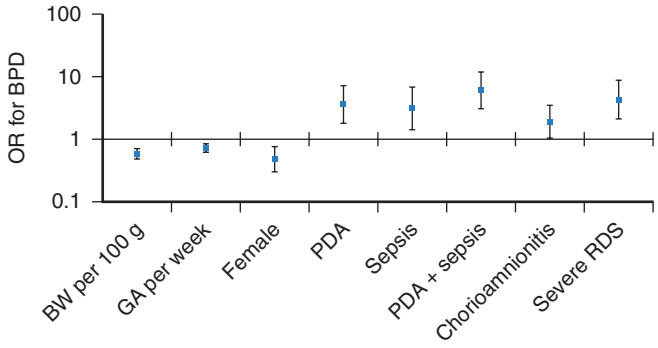
To resist the detrimental effects of oxygen, the organism has evolved a number of antioxidant systems. Antioxidant enzymes such as superoxide dismutase, catalase, and glutathione peroxidase seem to play an important role in preventing the toxic effects of oxygen. Other elements, such as vitamin E, glutathione, and selenium, are also part of the endogenous antioxidant mechanisms. The capacity for synthesizing these enzymes in some animal species follows a maturational trend similar to the production of surfactant; therefore, animals born prematurely have lower concentrations of antioxidant enzymes than those born at term.

Loss of mucociliary function may be an additional pathogenic factor in BPD, because exposure to high oxygen concentrations results in a reduction of ciliary movements.



Postnatal Infection

There is ample evidence supporting the role of infections in the development of BPD, especially in very small infants in whom nosocomial infections are associated with a marked increase in the risk of BPD.[56] Evidence suggests that postnatal adenovirus and cytomegalovirus infection might also increase the risk for BPD.[31] Pulmonary colonization with ureaplasma has been evaluated as one of the possible risk factors for BPD. Experimental studies in animal models have shown that colonization of fetal lung with ureaplasma resulted in increased inflammation, fibrosis, and impaired alveolar development.[12,69] Several studies have suggested an association between *Ureaplasma urealyticum* tracheal colonization and the development of BPD in infants with very low birth weight. Surprisingly, trials evaluating treatment with macrolide antibiotics have so far shown inconsistent effect on BPD.[11,47,68]

Patent Ductus Arteriosus and Pulmonary Edema

There is an association between the presence of a PDA and an increased risk for BPD (Fig. 69.4).[23,56] This may be secondary to increased pulmonary blood flow producing an increase in interstitial fluid and a decrease in pulmonary compliance and increased airway resistance. This can prolong the need for mechanical ventilation with higher ventilatory pressures and oxygen concentrations, increasing the risk for BPD. Moreover, the increased pulmonary blood flow can damage the pulmonary capillary endothelium and induce neutrophil margination and activation in the lung, contributing to the progression of the inflammatory cascade. Data from studies in preterm baboons also showed decreased alveolarization in animals that remained for a longer time with an open ductus arteriosus, supporting the role of a persistent ductus arteriosus in the pathogenesis of BPD.[41] Despite epidemiologic and experimental evidence of association between PDA and BPD, prospective clinical trials to evaluate early closure of the PDA have failed to show a decrease in the incidence of BPD.[62]

Infants with BPD have a predisposition to fluid accumulation in their lungs. Possible causes are an increase in pulmonary vascular resistance, low plasma oncotic pressure, and increased capillary permeability that favor the extravascular accumulation of fluid. Pulmonary vascular pressure can be increased because of remodeling of the pulmonary vessels aggravated by hypoxemia and hypercapnia. Fluid accumulation can also be secondary to left ventricular dysfunction that has been described in patients with chronic respiratory failure. Capillary permeability might be increased secondary to the effects of high inspired oxygen concentration, mechanical trauma, increased flow caused by a PDA, and infection on the capillary endothelium. The abnormal accumulation of lung fluid in infants with BPD further compromises lung function, perpetuating a cycle in which more aggressive respiratory assistance is required, which produces further lung damage.

Obtained by logistic regression analysis from all extremely premature infants born at University of Miami Jackson Memorial Medical Center during the period 1995-2000. (*N* = 505 alive at 28 days; birth weight [BW], 500-1000 g; gestational age [GA], 23-32 weeks). OR, Odds ratio; PDA, patent ductus arteriosus; RDS, respiratory distress syndrome. (From Bancalari E, et al. Bronchopulmonary dysplasia: changes in pathogenesis, epidemiology and definition. *Semin Neonatol.* 2003;8:63.)

Other Factors

The possibility of a genetic predisposition to BPD has been evaluated in recent years. Studies evaluating twin pairs have shown that genetic factors contributed to a significant proportion of the variance in risk for BPD. The efforts to identify specific candidate genes using genome-wide association studies have so far not been successful.[35]

There is also evidence that vitamin A deficiency could increase the risk for BPD in preterm infants. Vitamin A levels are lower in infants who develop BPD when compared to those who recovered without lung sequelae. This possible association is supported by the similarities between some of the airway epithelial changes observed in severe BPD and vitamin A deficiency and by the clinical evidence that vitamin A administration during the weeks after birth reduces the risk of BPD.[14]

Early adrenal insufficiency has also been suggested as a contributing factor in the development of BPD in the smallest infants. Infants with lower cortisol levels in the first week of life have an increased incidence of PDA, more lung inflammation, and increased incidence of BPD.[72]

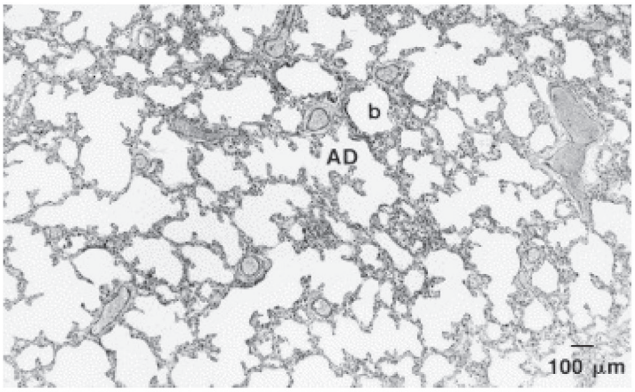
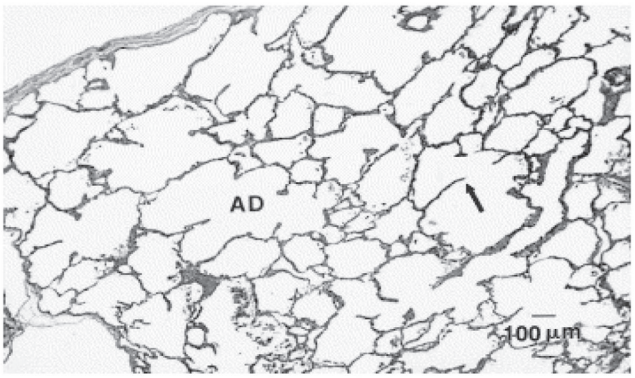
Final Common Pathway



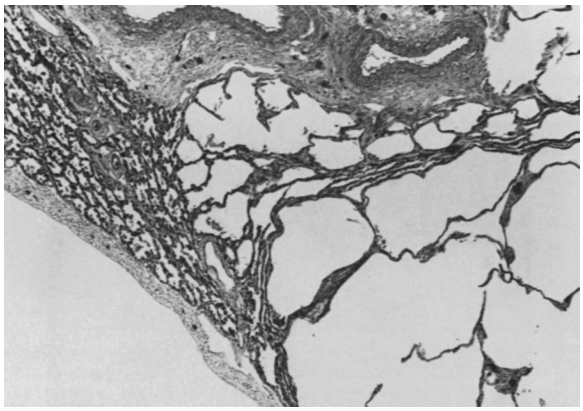
Inflammation plays a crucial role in the development of BPD and can be triggered by multiple factors such as oxygen, mechanical ventilation, PDA, and infections. Multiple studies have shown the presence of inflammatory cells, pro-inflammatory cytokines such as chemokines, interleukin, leukotrienes, and platelet-activating factor and other mediators in infants with BPD. Increased desmosine excretion in the urine during the first week of life has been described in infants who subsequently develop BPD, indicating increased elastin degradation resulting from lung inflammation and injury. Increased concentration of inflammatory mediators could contribute to the bronchoconstriction and vasoconstriction and the increased vascular permeability characteristic of these infants.

The inflammatory reaction might also be responsible for the decreased alveolar and capillary formation characteristic of infants with BPD.[30,74] This is a key component in the pathogenesis of BPD and results in a reduction in alveolar number and gas exchange surface area, as well as a decrease in lung capillaries. In experimental models of BPD, these findings have been accompanied by decrease in lung angiogenic growth factors, such as vascular endothelial growth factor and nitric oxide, and decreased expression of endothelial markers, such as platelet/endothelial cell adhesion molecule-1 suggesting impaired angiogenesis. In addition, reduced expression or impaired function of other growth factors associated with lung development, including connective tissue growth factor, fibroblast growth factor, and platelet-derived growth factor have been associated with BPD.[1,54]



Pathology

The pathologic picture of BPD has evolved significantly over the last few decades. Most of the infants with BPD nowadays are extremely premature and have milder forms of BPD. These infants have diffuse injury with little emphysema or fibrosis. The characteristic morphologic changes in lungs with mild BPD are reduced number and simplified alveoli, decreased and dysmorphic capillaries, and a reduction in the gas exchange surface area (Figs. 69.5 and 69.6).[10,26]



A small number of these infants still go on to require prolonged mechanical ventilation and high oxygen and end up with severe BPD. Macroscopically, the lungs of these infants are firm and heavy and have a darker color than normal. The surface is irregular, often showing emphysematous areas alternating with areas of collapse. On histologic examination, the lungs are characterized by areas of emphysema, sometimes coalescing into larger cystic areas, surrounded by areas of atelectasis, interstitial edema and increase in fibrous tissue, and widespread bronchial and bronchiolar mucosal hyperplasia and metaplasia (Fig. 69.7). Often, there are vascular changes of pulmonary hypertension, such as medial muscle hypertrophy and elastic degeneration. There also

may be evidence of right ventricular hypertrophy and, in some cases, left ventricular hypertrophy as well.

Clinical Presentation

In their original description of BPD, also often called *old BPD*, Northway and colleagues described the clinical, radiographic, and pathologic course of a group of infants with severe respiratory distress syndrome (RDS) requiring mechanical ventilation with high airway pressures and oxygen concentration. The respiratory course of these infants evolved from the initial severe RDS to final stage of chronic lung disease with high incidence of cor pulmonale and mortality. The radiographic picture of these infants with severe chronic lung disease was characterized by increased densities secondary to areas of collapse and fibrosis, with adjacent large emphysematous areas (Fig. 69.8).

The clinical picture of BPD has evolved significantly in the last few decades due to increasing survival of extremely premature infants and improvements in the care of these infants. The majority of these infants initially have mild respiratory disease requiring continuous positive airway pressure or ventilation with low pressures and oxygen concentration. During the subsequent days or weeks, a large proportion of these infants show progressive deterioration in lung function possibly triggered by pulmonary or systemic infections or increased pulmonary blood flow secondary to left to right shunting through a large PDA.[23] In these cases, the functional and radiographic changes are usually milder, revealing more diffuse haziness without the marked changes observed in the severe forms of BPD (Fig. 69.9). This entity has been termed *new BPD*.[30] Most of these infants show a slow but steady improvement in their lung function and radiographic changes and, after variable periods, can be weaned from respiratory support and supplemental oxygen prior to discharge.

A small group of preterm infants have atypical respiratory course with inadequate response to surfactant and continued severe respiratory failure requiring mechanical ventilation with high airway pressures and oxygen concentration. Their respiratory course is often complicated by pulmonary air leaks, secondary pulmonary infections, and recurrent pulmonary edema likely due to PDA or inflammation, progressing to severe BPD. The radiographic picture of these infants commonly resembles that of old BPD. These infants commonly develop pulmonary hypertension and signs of right heart failure. In these infants, severe airway damage with bronchomalacia can lead to severe airway obstruction, especially during episodes of agitation and increased intrathoracic pressure.[40] Furthermore, anastomoses between the systemic and pulmonary circulations can aggravate their pulmonary hypertension.

Because of the respiratory failure, infants with BPD take oral feedings with difficulty and often require nasogastric or orogastric feeding. Weight gain is usually less than the expected normal even when they receive an amount of calories appropriate for their age. This lower weight gain can be a result of chronic hypoxia and the higher energy expenditure required by the increased work of breathing.

The diagnosis of BPD is based on the clinical and radiographic course described earlier, but these signs are not specific for any given etiology. For this reason, specific etiologies that could lead or contribute to the lung damage must be considered before concluding that the infant has BPD. Among these, one must rule out congenital heart disease, congenital pulmonary anomalies, chemical pneumonitis resulting from recurrent aspiration, cystic fibrosis, or disorders of surfactant homeostasis.

Prediction of Bronchopulmonary Dysplasia

A number of studies have been performed to develop scores that can predict the risk for BPD in ventilated preterm infants. Most of these scores include the state of maturation of the infant and factors that reflect the severity of the initial respiratory failure. These scores are helpful in identifying patients for clinical trials and could become more useful in the future if effective preventive therapies become available.

Pulmonary Function

The disruption of pulmonary function in BPD reflects the structural alterations of the lungs with degree of pulmonary function abnormalities varying depending on age and the severity of lung injury. The early clinical course of infants who later develop severe BPD is marked by low compliance, low to normal functional residual capacity (FRC), and high airway resistance. These alterations in pulmonary function during the first weeks of life have been used with some success to improve accuracy of BPD prediction models.[39]

In infants with severe BPD, FRC increases to above normal range with age reflecting gas trapping secondary to small airway obstruction.[28] These infants have abnormal distribution of ventilation, reflecting involvement of the small airways, but in infants with milder forms of BPD, the distribution of the inspired gas is usually normal as measured by nitrogen clearance delay.

Infants with severe BPD characteristically have increased airway resistance and airway hyperreactivity. Multiple factors contribute to airway changes, including bronchiolar epithelial hyperplasia and metaplasia, mucosal edema secondary to trauma, oxygen toxicity, pulmonary edema secondary to PDA, and infection. These infants can also have bronchoconstriction resulting from smooth muscle hypertrophy. In some infants, tracheobronchomalacia develops, which is responsible for marked airway obstruction, especially during periods of agitation and increased intrathoracic pressure. Increased airway resistance can alter the time constant of different regions of the lung and impair the distribution of the inspired gas, favoring uneven lung expansion.

The lung compliance in BPD is decreased because of fibrosis, edema, overdistention, and collapse of lung parenchyma. It is also possible that some of these infants have a decreased concentration or inactivation of surfactant on the alveolar surface. In addition, the airway obstruction results in frequency dependence of dynamic compliance, thereby compliance decreases at higher respiratory rates.

The high resistance and decreased compliance result in a markedly increased work of breathing that contributes to the hypoventilation and hypercapnia frequently observed in these infants. Minute ventilation is usually increased, but because of the lower lung compliance, this is accomplished with a smaller tidal volume and a higher respiratory rate than normal. Thus, there is an increase in dead space ventilation that also contributes to alveolar hypoventilation and CO_2 retention. The increased $PaCO_2$ is also secondary to an increased alveolar-arterial CO_2 gradient produced by ventilation-perfusion mismatch and increased alveolar dead space. Chronic hypercapnia often results in an increased serum bicarbonate concentration that tends to compensate for the respiratory acidosis. This increase in base is often exaggerated by the use of loop diuretics.

Most infants with severe BPD have hypoxemia and require supplemental oxygen to maintain acceptable oxygenation levels. The hypoxemia results from a combination of ventilation-perfusion mismatch and alveolar hypoventilation. The oxygen requirement decreases gradually as the disease process improves, but it can increase during feedings, physical activity, or episodes of pulmonary infection or edema.

Prevention of BPD

There is a wide variation in the incidence of BPD among different centers, suggesting that certain steps in the management of preterm infants can influence the risk of BPD.[36] Since BPD is a multifactorial disease, effective prevention requires a combination of strategies to limit lung and vascular injury and promote normal development (Table 69.2).

Since BPD is exclusively seen in preterm infants, any strategy that can prolong pregnancy will reduce the incidence of BPD. Attempts to develop these strategies have not been very successful, but recent studies to evaluate use of progesterone prophylaxis in pregnant women at risk of preterm delivery have shown some effectiveness in reducing the incidence of preterm birth. Administration of antenatal steroids to promote maturation of surfactant system has been shown to reduce the incidence and severity of RDS, but the effect on the incidence of BPD has been less consistent partly due to improved survival of infants at increased risk for BPD.[9]

There is significant evidence from animal studies suggesting that injudicious use of respiratory support at birth, even for short duration, may result in lung injury[25]; therefore, the effort should be directed to reduce the infant's exposure to high airway pressures, tidal volumes, and oxygen, as much as possible. Surfactant replacement therapy after endotracheal intubation has been shown to decrease mortality, incidence of severe RDS, and the need for aggressive ventilation but has failed to show reduction in the incidence of BPD. To decrease the risk of lung injury associated with positive pressure ventilation during surfactant replacement, multiple less-invasive methods of surfactant instillation like nebulization or less-invasive surfactant administration (LISA) are currently being evaluated, showing some reduction in the incidence of BPD.[27]

Although the use of early CPAP to reduce the use of mechanical ventilation has been shown to have a small effect on reducing the incidence of death or BPD,[22] a large proportion of the more premature infants fail CPAP and require invasive ventilation. Nasal positive pressure ventilation (NIPPV) has been evaluated as an alternative mode of

€Lacking data from trials with BPD as primary outcome

noninvasive ventilation to avoid endotracheal intubation. The effect of NIPPV on the incidence of BPD has been inconsistent among trials with recent large RCTs failing to show a reduction in the incidence of BPD with its use.[32,51] High-flow nasal cannula (HFNC) is another mode of noninvasive respiratory support that has been evaluated because of its ease of use and less risk of injury to nares when compared to CPAP. There is increasing evidence that the HFNC is inferior to CPAP as primary mode of respiratory support after birth with increased risk of treatment failure and a trend toward increased incidence of BPD.[55,73] These data suggest the type of respiratory support for each infant should be individualized, with close monitoring of the respiratory status over time.

Since a large number of preterm infants require invasive mechanical ventilation, it is crucial to limit the exposure to excessive tidal volume. The use of volume-targeted ventilation has been shown to reduce the duration of mechanical ventilation and the combined outcome of death or BPD.[33] Although there is some data suggesting that high-frequency ventilation can reduce lung injury, it has not been shown to be consistently effective in reducing the incidence of BPD.[13]

Oxygen is one of the important factors in the pathogenesis of BPD, and continuous monitoring of arterial oxygen saturation by pulse oximetry (SpO_2) is a standard practice to titrate oxygen supplementation. To find the optimum target SpO_2 range, three large trials in extremely preterm neonates have compared the effect of lower (85%-89%) and higher (91%-95%) target SpO_2 range on mortality and neonatal morbidities. A recent meta-analysis of these trials showed a significant reduction in the incidence of BPD in the lower target group. However, the lower target was associated with a higher incidence of necrotizing enterocolitis (NEC) and mortality, suggesting a need to strike a critical balance when targeting SpO_2.[2]

Presently, there is no agreement among clinicians regarding the role of different PDA management strategies in the development of BPD. Although some epidemiologic data suggest that the persistence of a hemodynamically significant PDA is associated with an increased incidence of BPD,[37] the results of prospective clinical trials to evaluate whether early closure of the PDA would improve pulmonary outcome have not confirmed this hypothesis.[62] Postnatal growth failure is common in infants at high risk for BPD, and undernutrition has been associated with impaired lung growth in animal models. Despite paucity of clinical evidence, a nutritional strategy consisting of judicious fluid restriction while providing adequate macro and micronutrients and preventing growth failure is recommended. There is some evidence that exclusive breast-milk feeding is associated with lower incidence of BPD.[63]

Administration of postnatal systemic corticosteroids during the early stages of the respiratory failure to prevent its progression to BPD has been well studied, with several reports showing rapid improvement in lung function, facilitating weaning from the ventilator and decreasing the risk of BPD.[16,17] Many potential mechanisms for these beneficial effects include enhanced production of surfactant and antioxidant enzymes, decreased bronchospasm, decreased pulmonary and bronchial edema and fibrosis, improved vitamin A status, and decreased responses of inflammatory cells and mediators in the injured lung. Potential complications of prolonged steroid therapy include masking signs of infection, arterial hypertension, hyperglycemia, increased proteolysis, adrenocortical suppression, somatic and lung growth suppression, and hypertrophic cardiomyopathy. In addition, long-term follow-up studies suggest that infants who received early high-dose postnatal dexamethasone therapy have worse neurologic outcome than control infants.[75]

It appears that treatment with shorter courses and lower doses beyond the first week of life offers significant advantage and fewer side effects than the previous more aggressive treatment strategy, confirming the potential role of low-dose dexamethasone therapy specifically for infants at high risk for BPD.[19] Furthermore, a meta-regression analysis reported a significant effect modification by risk for BPD. With a risk

for BPD less than 35%, corticosteroid treatment increased the chance of death or cerebral palsy, whereas when the risk for BPD exceeded 65%, corticosteroid treatment reduced this risk.[18] Although the avoidance of steroids may in fact be detrimental to a class of infants at high risk for BPD, the optimal age of treatment, dose schedule, and duration of therapy still needs to be established.[52]

In an attempt to avoid the potential neurotoxic effect of dexamethasone, systemic hydrocortisone treatment has been evaluated as an alternative for prevention of BPD due to lower neurotoxic effects.[21] Earlier trials evaluating the use of hydrocortisone soon after birth in extremely preterm infants showed improvement in respiratory outcomes but with increased risk of gastrointestinal perforation. There is some recent evidence suggesting that a lower dose may improve respiratory outcomes without increasing the risk of gastrointestinal perforation or neurodevelopmental impairment in early childhood.[6,7] Most recent available data demonstrate that among mechanically ventilated very preterm infants, administration of a 22-day course of systemic hydrocortisone between 7 and 14 days after birth, compared with placebo, did not improve the composite outcome of death or BPD at 36 weeks' postmenstrual age. These findings do not support the use of hydrocortisone for this indication.[52a] To induce the beneficial effects on the lung but minimize the systemic side effects, steroids have been administered locally either alone by nebulization or by direct tracheal instillation with exogenous surfactant. Both of these therapies have been recently shown to significantly reduce the incidence of BPD, but concerns for long-term safety and neurodevelopmental effect need to be evaluated in large trials.[5,76]

The administration of caffeine to wean infants from mechanical ventilation and to treat apnea of prematurity has been associated with a significant reduction in the incidence of BPD.[58] Some of the possible mechanisms of this beneficial effect are shorter duration of mechanical ventilation and the anti-inflammatory or diuretic effects of caffeine. Vitamin A supplementation has been shown to result in small reduction in the incidence of BPD, likely because of its role in lung development and repair of respiratory epithelium after injury.[14]

Since endogenous nitric oxide is required for alveolar and vascular development, and the low-dose inhaled nitric oxide supplementation in animal models of BPD inhibits inflammation and reduces lung injury,[66] clinical trials have evaluated low-dose inhaled nitric oxide supplementation for the prevention of BPD. These studies have provided inconsistent results with a systematic review showing no significant effect of inhaled nitric oxide on BPD.[15]

Increasing knowledge of molecular pathways of alveolar and vascular development has resulted in the development of innovative strategies for prevention of BPD. Mesenchymal stem cells are among the most promising of these, with multiple reports of their effectiveness in prevention as well as treatment of hyperoxia-induced lung injury in animal models.[42,65] The results from a preliminary phase-1 clinical study have been promising, but additional work is needed to better understand its mechanism of action, safety and efficacy in preterm infants. Some of the other promising therapies currently being evaluated for the prevention of BPD include Clara cell protein (CC10), a protein secreted by nonciliated respiratory epithelial cells with anti-inflammatory and immunomodulatory properties, and growth factors involved in alveolar and vascular development such as insulin like growth factor (IGF-1).

Management of Established BPD

Prevention of further lung damage is the cornerstone of management by avoiding, as much as possible, all factors that predispose to more injury. There is a lack of good quality evidence base for managing infants with BPD, resulting in significant variation in treatment practices.

Respiratory Support

During the initial phase of respiratory failure, the goal is to avoid unnecessary intubation and mechanical ventilation-associated lung injury. When mechanical ventilation is used, the lowest peak airway pressure necessary to obtain adequate ventilation must be applied. The expiratory tidal volume (Vt) measured using a flow sensor at the endotracheal tube (proximal flow sensor) should be closely monitored with avoidance of excessively low (Vt <3 mL/kg) or excessively high tidal volumes (Vt >7 mL/kg) during acute phase of illness. Short inspiratory times between 0.3-0.5 seconds are used, as shorter inspiratory times exaggerate the maldistribution of the inspired gas while longer inspiratory times may increase the risk of airspace rupture and cardiovascular side effects. An end-expiratory pressure between 4 and 8 cm H_2O is usually applied to achieve lung recruitment without causing overdistension.

Adequacy of gas exchange should be monitored closely to avoid large fluctuation in ventilation and oxygenation status. The arterial oxygen tension (PaO_2) and arterial carbon dioxide tension ($PaCO_2$) measured in arterial blood are considered the reference standards, but the results from the samples obtained by arterial puncture should be interpreted carefully, because the infant responds to pain with crying or apnea. Pulse oximeters offer the most reliable estimate of arterial oxygenation and have the advantage of simplicity of use and the possibility of assessing oxygenation during feeding and crying. Although there are no conclusive data in the literature on the optimal level of oxygenation for these infants, in general, it is recommended to maintain the oxygen saturation in the range of 90%-95% to minimize the risk of oxygen exposure and toxicity and prevent hypoxemia with associated risk of morbidities.[2] The ideal range of $PaCO_2$ for infants with BPD is not established, but avoidance of values higher than 55 and less than 35 mm Hg during the initial period after birth is warranted to limit changes in cerebral perfusion.

Weaning these patients from the ventilator is often difficult and must be accomplished gradually. When the patient can maintain an acceptable SpO_2 and $PaCO_2$ with low peak pressures (15-18 cm H_2O) and FiO_2 lower than 0.3-0.4, the ventilator rate is gradually reduced to allow the infant to perform an increasing proportion of the respiratory work. During the process of weaning, it may be necessary to increase the FiO_2. Concurrently, the $PaCO_2$ can rise, but as long as the pH is within acceptable limits, some degree of hypercapnia must be tolerated to wean the patient from the ventilator. In small infants, caffeine is used as a respiratory stimulant during the weaning phase.[58] The use of nasal continuous positive airway pressure (CPAP) or nasal ventilation (NIPPV) after extubation can stabilize respiratory function and reduce the need to reinstitute mechanical ventilation.

Infants with chronic respiratory failure commonly have increased dead space, heterogeneous areas of different lung compliance, and airway resistance necessitating longer inspiratory times and higher tidal volumes than those used during early stages of illness. In some of the infants with severe airway obstruction, especially those with bronchomalacia, the use of high positive end-expiratory pressure levels of 5-8 cm H_2O may help reduce expiratory airway resistance and improve alveolar ventilation.

Although it is necessary to reduce the FiO_2 as quickly as possible to prevent oxygen toxicity, it is important to maintain the SpO_2 above 90% to ensure adequate tissue oxygenation and prevent the pulmonary hypertension and cor pulmonale that can result from chronic hypoxemia. Furthermore, infants with BPD might respond to episodes of acute hypoxemia with increased airway and vascular resistance. Because oxygen consumption increases and PaO_2 may decrease during feedings, it might be necessary to provide a higher FiO_2 to prevent hypoxemia. Oxygen therapy could be required for several weeks or months. Some of these patients are discharged with oxygen therapy at home. This practice offers significant advantages, such as a better environment for the patient and cost savings, but it requires a supportive family and home environment to be accomplished safely and successfully.

Bronchodilator Therapy

Infants with severe BPD can have airway smooth muscle hypertrophy and airway hyperreactivity. Because hypoxia can increase airway resistance in these patients, maintenance of adequate oxygenation is important to avoid bronchoconstriction. Bronchodilators, most of them β-agonists, administered by inhalation have been shown to reduce airway resistance in infants with BPD. However, their safety and efficacy have not been evaluated in randomized clinical trials. Their effect is usually short lived, and many of these drugs have cardiovascular side effects such as tachycardia, hypertension, and possible arrhythmias. Because of this, it is preferred to limit their use to the management of acute exacerbations of airway obstruction.

Corticosteroid Therapy

Systemic or inhaled steroids are commonly used in infants with BPD, both as short-term therapy for acute exacerbation as well as chronic therapy. The potential short-term benefits include decrease in inflammation, airway edema, capillary leakage, and lung fibrosis. The effects of steroids in infants with established BPD on long-term respiratory outcomes have not been evaluated. As described previously, chronic use of steroids is associated with significant side effects; therefore, their use should be limited with clearly defined goals after due consideration of risks and benefits of this therapy.

Management of Pulmonary Hypertension in BPD

The clinical course of infants with severe BPD is frequently complicated by pulmonary hypertension,[46] thereby necessitating the need for close monitoring and early diagnosis by echocardiogram. Oxygen therapy to prevent hypoxemia is probably the most important first step to reduce pulmonary hypertension in these infants. Because pulmonary vascular resistance is extremely sensitive to changes in alveolar Po_2 in infants with BPD, it is important to ensure normal oxygenation, not only when the infant is quiet or asleep but also when the infant is performing physical activity such as feeding and crying.

Despite increasing use of pulmonary vasodilators, the evidence for their efficacy in infants with pulmonary hypertension with BPD is very limited. These therapies include inhaled nitric oxide (iNO), phosphodiesterase inhibitors (sildenafil), endothelin receptor antagonists, and calcium channel blockers (nifedipine). Inhaled nitric oxide is commonly used as a pulmonary vasodilator in acute onset pulmonary hypertension and has been shown to decrease pulmonary vascular resistance, although its effect on long-term outcomes has not been evaluated. The potential role of iNO in the prevention of BPD has been evaluated in multiple trials with no clear long-term benefits so far. Sildenafil, a phosphodiesterase-5 inhibitor, is mostly used as long-term therapy for pulmonary hypertension in infants with BPD. There are limited data on safety or effectiveness of this drug in this population, but some clinical reports suggest that the therapy is safe and may be effective.[45] Nifedipine, a calcium channel blocker, decreases pulmonary vascular resistance but is also a systemic vasodilator and can produce depression of myocardial contractility. Other agents like endothelin receptor antagonists and prostacyclin analogs have been tried in infants who fail to respond to initial treatment, but their efficacy and safety have not been established.

Fluid Management

Infants with BPD do not tolerate excessive or even normal amounts of fluid intake and have a marked tendency to accumulate excessive interstitial fluid in the lung. This

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

excess can lead to a deterioration of pulmonary function, with exaggeration of hypoxemia and hypercapnia and longer ventilator dependency.

To reduce lung fluid in infants with BPD, water and salt intake should be limited to provide the calories necessary for metabolic needs and growth. When increased lung water persists despite fluid restriction, diuretic therapy can be used successfully. The use of diuretics in infants with BPD can be associated with an acute improvement in lung compliance and decrease in resistance, but blood gases do not always show improvement. Complications of chronic diuretic therapy include potential ototoxicity, hypokalemia, hyponatremia, metabolic alkalosis, hypercalciuria with nephrocalcinosis, and hypochloremia.

Because increased metabolic demands in infants with BPD are associated in severe cases with low arterial oxygen tension, it is important to maintain a relatively normal blood hemoglobin concentration. This may be accomplished with blood transfusions or by the administration of recombinant erythropoietin.

Nutrition

Infants with BPD frequently have impaired growth due to increased metabolic demand partially caused by increased work of breathing, growth suppression from frequent postnatal steroid and diuretic use, and frequent interruptions in oral feedings due to exacerbation of respiratory failure. Malnutrition can delay somatic growth and the development of new alveoli, making successful weaning from mechanical ventilation less likely. The malnourished patient may also be more prone to infection and oxygen toxicity. Decreased caloric intake potentiates oxygen-induced lung damage and can interfere with cell multiplication and lung growth. For these reasons, an aggressive approach should be taken toward supplying a parenteral or oral caloric intake that is adequate for growth. High-calorie formulas and supplements of protein, calcium, phosphorus, and zinc can be used to maximize the intake of calories while restricting fluid intake to prevent congestive heart failure and pulmonary edema.

Adequacy of nutrition should be closely monitored, and growth charts for weight, head circumference, and length must be kept. Rib fractures noted on routine chest radiographs, together with generalized bone demineralization, are often observed in infants with BPD and are usually a manifestation of rickets. The cause could relate to dietary or parenteral deficiency of calcium or vitamin D or to the calciuria resulting from long-term diuretic therapy. Administration of extra calcium and vitamin D is necessary to prevent rickets in these infants.

Infants who receive exclusively parenteral nutrition for prolonged periods are more susceptible to developing deficiency of specific nutrients, such as vitamins A and E, and trace elements such as iron, copper, zinc, and selenium, all of which play a role in antioxidant function, protection against infection, and lung repair.

Gastroesophageal reflux is often observed in infants with BPD, and when severe, may contribute to the chronic inflammatory process and lung damage. When severe reflux is documented, antireflux management might be indicated to alleviate respiratory symptoms.

Control of Infection

Any infection can have serious consequences for the child with BPD, and bacterial, viral, or fungal infection generally results in a profound setback. As a result, the child must be closely watched for early evidence of infection. Tracheal secretions are collected for culture and Gram stain, and a change in the quality and quantity of secretions indicates possible infection. A complete blood count, blood culture, and chest radiograph are obtained if pneumonia is suspected.

Although it is difficult to distinguish between colonization of the airway and true infection, this distinction is important because overtreatment with antibiotics can result in the emergence of resistant and more virulent organisms. Selection of antibiotics is based on the sensitivity of the implicated organism, and treatment is continued until the infection has been controlled. Measures to prevent pulmonary nosocomial infection are important. These include careful hand washing before handling the airway, maintenance of sterility of the respiratory equipment, and isolation from individuals with respiratory infections.

Infant Stimulation

The infant with severe BPD could be ventilator dependent for many months and thus deprived of normal parental stimulation. Developmental delays are common and are compounded if any gross neurologic disability exists. A well-organized program of infant stimulation can help the infant achieve maximum potential. Such a program instructs the caretakers in helping the infant with various social, language, cognitive, and motor skills. As a child grows, speech therapy is useful in teaching communication skills, which are especially important for children with a tracheostomy. Beanbag chairs, strollers, and other adaptive tools are employed to mobilize the child and teach gross motor skills. Progress is monitored by periodic developmental evaluations, and emphasis is placed on areas in which delay is evident.

Parental Support

The parents of an infant with severe BPD lose considerable control of their child to the hospital staff, particularly in areas related to medical care. Parental participation is critical for the child's development and for establishment of normal relationships. Therefore, parents are encouraged to visit as frequently as possible and to participate in the day-to-day care of their child. They are educated about relevant medical equipment and procedures. In time, many are able

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

to assume complete responsibility for procedures such as chest physiotherapy and tracheal suctioning, in addition to holding and playing with their child. During the prolonged hospitalization, every effort must be made to assign a permanent physician and nursing team to oversee the child's care and be available for continuing parental support. Parental support groups may also be a valuable resource for these families.

Outcome

The outcome of infants with BPD has improved in part because of better management but mainly because of the milder presentation of the disease. The mortality rate for infants with BPD is low. When death occurs, it is usually a result of respiratory failure, intercurrent infections, or intractable pulmonary hypertension and cor pulmonale. With adequate nutrition, somatic growth, and control of infection and heart failure, gradual improvement in pulmonary function may be accompanied by resolution of cor pulmonale and radiographic evidence of healing.

Lower respiratory tract infections are common during childhood in patients with BPD. Among survivors of BPD, hospitalizations for episodes of wheezing suggestive of bronchiolitis or asthma are common during the first 2 years of life, and infection with respiratory syncytial virus (RSV) can be life threatening. The American Academy of Pediatrics has recommended that all infants with BPD receive palivizumab during RSV season. Acute radiographic evidence of hyperinflation can be difficult to appreciate in infants with severe BPD who generally are already in a state of pulmonary hyperinflation. Such episodes of bronchiolitis are often accompanied by focal, transient areas of atelectasis.

Pulmonary function studies of children with a history of severe BPD indicate that pulmonary function may be impaired for many years even though the infants may be asymptomatic.[20,70] Northway and associates have reevaluated pulmonary function in their original cohort of infants with severe BPD reported in 1967.[50] At a mean age of 18 years, these adolescents and young adults still exhibited some evidence of pulmonary dysfunction, including airway obstruction and hyper-activity as well as hyperinflation. Infants and toddlers with severe BPD also have decreased pulmonary diffusing capacity consistent with decreased alveolar capillary surface area.[3] The ultimate clinical consequences of these findings remain to be determined, but most long-term studies suggest that with growth, pulmonary function tends to improve. In a study using 3He magnetic resonance, it was found that infants with BPD evaluated at 10-14 years of age had similar alveolar dimensions as term controls or preterm infants without BPD.[48] These interesting findings suggest that infants with BPD can have catch-up alveolarization.

Infants with severe BPD also have more neurodevelopmental sequelae when compared with similar control groups, and they exhibit transiently impaired growth curves. These neurodevelopmental and pulmonary impairments persist at 8 years of age, with 54% requiring special education classes compared with 37% of survivors born at very low birth weight without BPD.[60] Neurodevelopmental prognosis also depends on the severity of the BPD and on other associated risk factors that could be present in these infants.

Key Points

- Since its first description half a century ago, bronchopulmonary dysplasia continues to be the most important respiratory complication of preterm birth.
- Advancements in obstetric and neonatal care over time have altered the patient population at risk, thereby modifying the pathogenic factors and clinical course of BPD.
- The new BPD is the end result of a complex interplay of altered alveolar and vascular development, injury, and reparative processes in a premature lung.
- With increasing knowledge of the pathophysiology of BPD, the role of many of the proposed prevention strategies, such as different respiratory support modalities, PDA management, or postnatal steroids, is being reevaluated. New promising prevention strategies such as stem cells are being investigated.
- Management of infants with BPD requires a multidisciplinary approach to optimize lung and other organ development.
- Future prevention and management of BPD is likely to involve therapeutic agents tailored to different BPD genotypes and phenotypes and acting at different stages of disease process.

Therapy for Cardiorespiratory Failure in the Neonate

EILEEN K. STORK

Assisted ventilation and oxygen therapy remain the standard of care for neonatal respiratory failure. A few term and late preterm infants with a wide range of diagnoses develop intractable cardiorespiratory failure despite maximal ventilatory support. In these patients, severe pulmonary hypertension often contributes to persistent hypoxemia.

Two unique therapies for such patients are presented in this section: extracorporeal membrane oxygenation (ECMO), which is now well established as a rescue therapy for intractable respiratory failure in term and late-preterm neonates, and inhaled nitric oxide (iNO), a noninvasive inhalational therapy that can elicit selective pulmonary vasodilation.

Extracorporeal Membrane Oxygenation

In ECMO, techniques of cardiopulmonary bypass, modified from those originally developed for open heart surgery, are used over a prolonged period to support heart and lung function. In newborns with hypoxic respiratory failure, this allows the lungs to rest and recover and prevents the often damaging effects of aggressive mechanical ventilation and 100% Fio_2.

The use of ECMO offers support for mature neonates with life-threatening cardiopulmonary disease. Because of serious inherent risks, such as systemic and intracranial hemorrhage, the procedure is currently reserved for neonates with reversible pulmonary disease in whom trials of conventional or high-frequency ventilation as well as inhaled nitric oxide have failed (see next section on inhaled NO).

Several randomized trials have demonstrated improved survival in infants supported with ECMO. The most rigorous prospective, randomized trial was conducted in the United Kingdom, where 185 infants with severe respiratory failure were randomized to ECMO or conventional ventilatory management.[30] Survival in the ECMO-treated patients was 68% compared to 41% survival in the control arm ($p = .0005$), equivalent to one extra survivor for every three or four infants allocated to ECMO. Neurologic outcome was similar among survivors of either treatment arm, making it unlikely that ECMO contributed any added morbidity to this cohort of critically ill newborns.

Respiratory disease in the newborn is often complicated by persistent pulmonary hypertension of the neonate (PPHN), previously called persistent fetal circulation. In this circumstance, the pulmonary vascular resistance approaches or exceeds systemic vascular resistance, offering significant impedance to pulmonary blood flow. Desaturated blood returning to the right heart is shunted to the systemic circulation (following the path of least resistance) across one or both persistent fetal channels, the patent ductus arteriosus (PDA) and the foramen ovale, resulting in marked cyanosis.

The clinical course of such infants is variable, depending on the severity of the underlying disease process and the degree to which PPHN contributes to the cyanosis. Common diagnoses associated with severe hypoxic respiratory failure in neonates include congenital diaphragmatic hernia (CDH), meconium aspiration syndrome (MAS), respiratory distress syndrome (RDS), sepsis, and pneumonia. Idiopathic pulmonary hypertension is sometimes seen in patients who exhibit minimal or no lung disease and have clear chest radiographs. There is a large "other" category, which includes less common diagnoses but also includes infants with hypoxic respiratory failure (HRF) of unknown origin. Among these "unknown" diagnoses are some of the rarer causes of HRF associated with pulmonary hypertension, many of which carry serious or lethal outcomes. These include alveolar capillary dysplasia, surfactant protein abnormalities, pulmonary hypoplasia other than CDH, pulmonary interstitial glycogenosis, alveolar proteinosis, pulmonary lymphangiectasia, and pulmonary venous occlusive disease.[40] These diagnoses, if complicated by pulmonary hypertension, can seldom be determined in the first few days of life, and several require lung biopsies for confirmation. The International Extracorporeal Life Support Organization (ELSO) Registry reports a 5-year distribution of primary diagnoses and survival for patients undergoing ECMO support in the United States (Fig. 70.1).[28]

Abstract

Extracorporeal membrane oxygenation (ECMO) is a cardiopulmonary bypass support for term and late preterm infants with severe, life threatening, hypoxic respiratory failure. Affected infants present within the first 2 weeks of life, and the majority of these also have persistent pulmonary hypertension of the neonate (PPHN). For newborns who fail to improve with oxygen therapy, ventilator assistance, and judicious fluid/pressor support of systemic blood pressure, ECMO can improve oxygenation over a period of days to weeks, allowing the lung to rest and recover until pulmonary arterial pressures decline and blood flow to the lung is restored. Common diagnoses requiring ECMO support, details on the two types of bypass support commonly used, and patient eligibility criteria for ECMO are described in this chapter. Benefits and risks of the procedure are also addressed. The number of neonatal ECMO cases has declined significantly over the past 20 years since the introduction of inhaled nitric oxide (iNO), a potent vasodilator that can improve pulmonary blood flow and thus reverse PPHN. For the iNO-resistant newborn, however, there are a number of newer pulmonary vasodilators that are being studied, such as sildenafil, milrinone, inhaled prostacyclin derivatives, and bosentan. Unfortunately, nitric oxide has not been shown to improve survival or BPD in preterm infants, but subgroups within the preterm population, such as the ELBW infants with PPROM, oligohydramnios, and suspected pulmonary hypoplasia, may still benefit from iNO. Lastly, the emergence of pulmonary hypertension in infants with BPD as they approach term-corrected age and beyond remains a serious therapeutic challenge.

• **Fig. 70.1** International ECMO experience (through July 2018). CDH, Congenital diaphragmatic hernia; MAS, meconium aspiration syndrome; PPHN, persistent pulmonary hypertension of the neonate; RDS, respiratory distress syndrome. (Data are derived from the Extracorporeal Life Support Organization Registry.)

Traditional therapy for hypoxic respiratory failure complicated by PPHN consists of the use of oxygen, mechanical ventilation to minimize V-Q mismatch, and pharmacologic vasodilators to decrease pulmonary vascular resistance and increase blood flow to the lungs. Surfactant treatment should be considered if the infant has parenchymal lung disease such as MAS, RDS, or pneumonia, as this treatment has been shown to decrease the need for ECMO.[52,60] Surfactant is of no benefit in term or late preterm newborns with CDH and HRF, nor in infants with isolated PPHN.[60] Inhaled nitric oxide (iNO) is a well-studied, selective pulmonary vasodilator that enhances pulmonary blood flow and improves oxygenation in PPHN (see next section). It is for infants who do not respond to these measures that ECMO can be a life-saving therapy.

Basic Techniques

The standard ECMO procedure used most frequently in newborns with HRF today is venoarterial (VA) bypass, which provides both pulmonary and cardiac support. The right atrium is cannulated via the right internal jugular vein with a Silastic or polyvinyl chloride catheter (8- to 14-French diameter). Whether a roller head pump or centrifugal pump is utilized, blood is siphoned from the right atrium and circulated through the artificial lung. These pumps are servoregulated to slow or shut down if venous return is not adequate to meet circuit flow demands. As the blood circulates through the artificial lung, gas exchange occurs against a filtered mixture of oxygen, CO_2, and nitrogen in ambient air. The artificial lung commonly used in neonates in the United States is a hydrophobic, pediatric-specific, polymethylpentene hollow fiber membrane (Quadrox iD [diffusion membrane oxygenator]) that serves as a blood-gas interface, similar to the alveolar capillary membrane. Gas flows through the hollow fibers and venous blood flows around the outside of these fibers. Oxygen and carbon dioxide flow down their diffusion gradients, and gas exchange occurs across the hollow fiber membrane. Similar to the native lung, blood leaving the membrane lung has a normal to low CO_2 and a high Pao_2, with oxygen saturation of 100%. Depending on the size of the infant, CO_2 may need to be added to the gas mixture in order for the blood leaving the membrane lung to have a normal pH and pCO_2. Advantages of this newer artificial lung include a low priming volume and reduced blood/foreign surface area contact. This new generation of artificial lung also incorporates a heat exchanger to rewarm the oxygenated blood returning to the patient.

Oxygenation can be regulated by varying blood flow through the ECMO circuit. The higher the volume of cardiac output diverted through the membrane lung, the better the oxygen delivery from the ECMO circuit. Oxygenated blood exiting the artificial lung is returned to the infant via an 8- to 12-French catheter positioned in the ascending aortic arch through a right common carotid artery cannulation.

Blood flow through the ECMO circuit, at a rate of 80 to 100 mL/kg per minute, is usually adequate to provide excellent cardiac and respiratory support with maintenance of adequate blood pressure and oxygenation. Arterial wave dampening with narrowed pulse pressure is noticeable at flow rates approaching the infant's cardiac output, because the ECMO circuit provides relatively nonpulsatile blood flow. Pressor support and vasodilators can usually be stopped while the infant is on venoarterial ECMO support, because perfusion pressure from the pump largely replaces cardiac output. Only mild sedation—allowing the babies to breathe spontaneously, open their eyes, and move their extremities—is recommended on bypass support.

Systemic anticoagulation therapy with unfractionated heparin is administered for the duration of the bypass procedure to prevent clotting in the circuit and possible thromboembolization. Activated clotting times (ACTs) are measured at bedside every 1-2 hours and are maintained within a range of 180-240 seconds. Lower ACT targets are chosen in patients with elevated risk for bleeding (such as preterm infants or postoperative cases), although this increases the risk of thrombus formation in the ECMO circuit. Some centers monitor anticoagulation with anti-factor Xa assays, maintaining values between 0.3 and 0.7 unit/mL. Thromboelastography (TEG) can also be used to monitor coagulation status during an ECMO run.

Bivalrudin, a reversible direct thrombin inhibitor, is used instead of heparin for anticoagulation in some centers. Bivalrudin is particularly useful as an anticoagulant in cases where heparin-induced thrombocytopenia (HIT) is suspected. This complication, although not common, can occur in infants as well as adults, particularly in infants who have had cardiac surgery.[78]

Once the infant is placed on ECMO, ventilation and airway oxygen support are reduced to avoid further

ventilator-induced lung injury (VILI) while maintaining functional residual capacity (FRC). Wide practice variation exists with regard to ventilator settings used for "lung rest" during bypass support. A study was published detailing ventilator practices during ECMO, derived from more than 3000 neonatal cases submitted to the ELSO database between 2008 and 2013.[4] Conventional mechanical ventilation (CMV) was used in 88% of cases while 12% used high-frequency ventilation (HFV) during ECMO. Most practitioners who used CMV for lung rest used a rate of 10 cycles/minute and peak inspiratory pressures (PIP) of 15-20 cm H_2O. Fio_2 use ranged from 21%-40%. There was far more variation in the use of positive end expiratory pressure (PEEP) than in other parameters: 32% used low PEEP (4-6 cm H_2O), 43% used high PEEP (10-12 cm H_2O), and 22% used a mid-PEEP range (7-9 cm H_2O). The mean time on ECMO was reduced by 22 and 21 hours in the high and median PEEP groups, respectively. This confirms an older report where high PEEP shortened ECMO duration by 32 hours.[47] Lower PEEP may be used if the patient has a pneumothorax or pneumomediastinum. Use of HFV compared to CMV was associated with longer ECMO duration, although these were sicker patients with increased oxygenation indices (OIs), lower pH, and lower blood pressure prior to ECMO initiation. If volume ventilation is preferred, 4-6 mL/kg tidal volume can be used to achieve mild chest rise with each delivered breath. The goal is to maintain FRC and to allow for continued pulmonary toilet. The respiratory status of the infant can be monitored with intermittent arterial blood gases obtained from the umbilical or peripheral arterial line. An oxygen saturation electrode inserted on the venous side of the circuit allows continuous monitoring of the mixed venous saturation at the level of the right atrium. A mixed venous saturation of 70% or greater reflects adequate oxygen delivery. The efficiency of the membrane lungs in use today allows most neonates to have normal mixed venous saturations throughout the ECMO course.

As lung function improves and pulmonary hypertension abates, the mixed venous saturation and partial pressure of arterial oxygen (Pao_2) rise above the baseline oxygenation provided through the artificial lung. Blood flow through the artificial circuit can then be decreased in small increments (10-20 mL) while mixed venous and arterial oxygenation remain adequate. When ECMO flow has been reduced to 10-20 mL/kg per minute, the infant can usually be weaned from extracorporeal support.

Increased Fio_2 and ventilator settings are provided as the patient approaches decannulation, although the support required is usually far less than needed prior to ECMO. The duration of bypass support may be anywhere from 2-60 days with an average need for 9.2 days of support.[28] Two decades ago, the average time on ECMO support was only 5 days. The significant increase in ECMO-run duration and marginal increase in mortality rate among neonatal ECMO patients compared to years past likely reflects a sicker cohort of patients now requiring ECMO consideration. In 1992, 1345 neonates with HRF were placed on ECMO in the United States whereas, in 2017, only 533 infants required ECMO among cases reported to the ELSO Registry.[28] Over the same time period, the number of neonatal cardiac cases increased substantially to 275 in 2017. Continued ventilator support following ECMO can be quite variable (days to weeks) depending on the underlying cause of respiratory/cardiac failure, as well as the degree of barotrauma incurred before initiation of ECMO.

In most ECMO centers, the right carotid artery and internal jugular vein are permanently ligated at decannulation. This approach is technically easier and prevents any concern about acute embolic complications associated with vascular reconstruction. However, some surgeons reanastomose these vessels if the patient has been on bypass less than 7-10 days to prevent future ischemic risks to the developing newborn brain as well as during later adult life. Studies show no disadvantage to this approach. Magnetic resonance angiograms (MRAs) and Doppler flow studies confirm good antegrade flow through the reconstructed carotid artery in the majority of these infants with no embolic sequelae reported.[23] Neurodevelopmental outcome and neuroimaging were equally favorable. However, one study in 2006 reported a 72% occlusion or stenosis of the right common carotid artery (RCCA) at 2 years of age in a select cohort of 18 survivors with CDH. There was no difference in neurologic impairment compared to ligated controls in this study, however.[17] In 2015, a single center retrospective study of 51 ECMO survivors with varying diagnoses who underwent right common carotid reconstruction (RCCR) (at <7 days ECMO support) had Doppler ultrasound or MRA assessment of carotid patency at a median age of 63 days. Thirty-seven of 51 (73%) survivors who underwent carotid repair had follow-up imaging to determine carotid artery patency as well as auditory brainstem evoked response (ABR) testing prior to hospital discharge. Thirty-one of 37 (83%) patients showed good antegrade blood flow through the RCCA. Compared to ligated infants, there was no difference in right-sided brain lesions or failed ABR at discharge among infants with carotid reconstruction.[25]

Longer term follow-up of this cohort is of interest to pediatric surgeons and neonatologists alike. Unfortunately, carotid reconstruction is time sensitive and the longer ECMO runs reported over the past 5 years may preclude arterial reanastomosis in most. Beyond 7-10 days, scar tissue encasing the carotid artery at the cannulation site, a part of the natural healing process, often makes reanastomosis impossible.

Venovenous Extracorporeal Membrane Oxygenation

A growing experience supports the ability of venovenous ECMO to provide adequate oxygen delivery in patients with serious respiratory failure but adequate heart function. In adults, this technique usually involves draining desaturated blood from the right atrium and returning oxygenated

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

blood through the femoral vein. Similarly, the majority of pediatric ECMO patients with HRF are supported with venovenous (VV) ECMO, utilizing a double lumen catheter in the right atrium or a two-vein cannulation.

VV bypass in newborn infants has been greatly improved by the development of double-lumen catheters of varying sizes (13, 16, 19 French) that allow bypass support with cannulation of the right atrium alone. The 13 French catheter is appropriate for term newborns >2.5 kg birth weight. Desaturated blood is withdrawn from the right atrium through the outer fenestrated venous catheter wall. Oxygenated blood from the ECMO circuit is returned to the inner arterial, single lumen catheter, which is positioned to direct blood across the tricuspid valve. Higher flow rates are required to maintain adequate oxygen delivery with VV bypass, owing to the obligatory mixing of fully saturated blood returning from the ECMO circuit with desaturated systemic venous return within the right atrium.

Advantages of VV bypass include avoidance of carotid artery cannulation, which is highly desirable, and maintenance of normal pulmonary blood flow. The major disadvantage is that, unlike VA bypass, VV ECMO does not provide cardiac support. Oxygen delivery in VV bypass remains entirely dependent on adequate native cardiac output. The severity of cardiac dysfunction in ECMO-sick patients is highly variable, and often the heart function will improve once adequate oxygen content is restored on VV ECMO. Out of 3052 neonatal ECMO cases reported to the U.S. ELSO Registry between January 2013 and January 2018, 1010/3052 (33%) were supported on VV bypass with 75% survival; survival among infants supported on VA bypass, in comparison, was 61%.[28] VV ECMO complication rate and length of bypass support also compare favorably with VA bypass. Only 10%-12% of VV cases require conversion from VV to VA support should the patient's cardiac output prove to be subpar. Therefore, VV bypass should always be the first consideration in infants whose primary diagnosis is pulmonary disease.

Personnel Needs

ECMO is the most labor-intensive procedure in the neonatal intensive care unit (NICU). Specialists trained in managing patients on ECMO must remain at the patient's bedside for the duration of bypass. In addition to monitoring the infant's respiratory status, specialists must regulate the rates of blood and gas flow through the extracorporeal circuit to meet the infant's metabolic and respiratory demands. They must adjust anticoagulation by frequently measuring the activated clotting time or antifactor Xa assays in the blood and titrate the heparin infusion accordingly. Additionally, they must evaluate the patient for bleeding and replace losses appropriately. The specialists can be physicians, nurses, perfusionists, or respiratory therapists who have completed extensive training in ECMO support.

An ECMO physician trained in the clinical management of bypass patients must always be readily available for consultation, especially in case of mechanical failure or acute clinical decompensation. Additional support services required include 24-hour availability of personnel trained in radiology and ultrasonography, pediatric surgery, neurology, genetics, cardiology, and cardiothoracic surgery. The expertise and personnel needed to support these patients are extensive and costly.

• BOX 70.1 Patient Selection Criteria for Neonatal Extracorporeal Membrane Oxygenation

- Gestational age of 34 weeks or older
- Normal cranial ultrasound or stable grade I or II intraventricular hemorrhage
- Absence of complex congenital heart disease
- Less than 10-14 days of mechanical ventilation
- Reversible lung disease, including congenital diaphragmatic hernia
- Failure of maximum medical therapy
- No lethal congenital anomalies or evidence of irreversible brain damage

Criteria for Patient Selection

The cumulative experience of many ECMO centers has resulted in the establishment of guidelines that are currently used to decide whether ECMO support is appropriate.[89] These are described in Box 70.1.

Gestational Age of 34 Weeks or Older

Preterm newborns with respiratory failure carry a higher risk for intracranial hemorrhage (ICH) compared with term infants at baseline, and this risk is heightened with systemic anticoagulation required during ECMO support. Furthermore, changes in cerebral blood flow patterns associated with cardiopulmonary bypass can also place the immature brain at increased risk for bleeding.

In the early ECMO trials, premature infants less than 35 weeks' gestation had an 89% incidence of spontaneous ICH associated with heparinization.[15] Subsequent studies (all retrospective) revisiting this issue reported improvement in outcome but confirmed increasing rates of ICH as gestational age decreases.

ECMO management has changed over time, and technical refinements in bypass support have made this mechanical support possible for infants weighing as little as 1800 grams. However, even with improvements in management, gestational age remains a strong predictor of ICH risk. Late preterm infants who are recommended for ECMO (34 0/7 to 36 6/7 weeks' gestation at birth) experience higher mortality and morbidity on bypass compared to their term counterparts. In a review of 21,218 neonatal ECMO cases in the ELSO Registry (excluding CDH) from 1986-2006, late preterm infants (34 0/7 to 36 6/7 weeks' gestation) experienced the highest mortality on ECMO (26.2%) compared to early-term (37 0/7 to 38 6/7), 8% mortality,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

and full-term ($39^{0/7}$ to $42^{6/7}$), 11.2% mortality (p<.001), infants. Higher rates of intracranial hemorrhage (ICH) were also noted in late preterms (12.3%) compared to full terms (3.6%). Late preterm infants also experienced longer ECMO runs and higher rates of serious complication.[28,79]

Looking at a large cohort of preterm infants ≤34 weeks who were treated with ECMO prior to 1993, Hirschl reported a peak ICH incidence of nearly 50% at 33 weeks and a decrease to 30% by 34 weeks.[42] In 2004, Hardart reported that postconceptional age, rather than gestation at birth (corrected gestational age at initiation of ECMO), proved to be the highest predictor for ICH risk in preterm neonates. Out of 1524 neonates less than 37 weeks' gestation treated with ECMO between 1992 and 2000, ICH developed in 25% of infants at 32 weeks' estimated gestational age with linear decrease to 18% at 34 weeks.[35]

A study in 2018 comparing ECMO outcome at 34 weeks ($N = 509$) to that of preterms between 29 and 33 weeks' gestation ($N = 243$) reported survival was greater at 34 weeks' gestation (58%) compared to 48% survival in the <34-week cohort, $p = 0.05$. The rate of ICH peaked at 44% at 31 weeks and decreased incrementally to 17% by 34 weeks. A higher rate of cerebral infarction was also reported in the <34-week cohort. The authors suggest that while the risk of poor outcome in <34-week preterms is higher than seen at 34 weeks' gestation, the rate of ICH and cerebral infarction is not so high that ECMO should be completely contraindicated.[19]

No Major Intracranial Hemorrhage

The catastrophic extension of ICH, along with the attendant neurologic sequelae, is the primary risk reported in the early series of Bartlett and associates.[15] There is little argument that patients with grade III or IV ICH should not be offered ECMO, because these bleeds are likely to expand with exposure to anticoagulation, further augmenting poor long-term prognoses. Some centers have successfully managed infants with stable grade II intraventricular hemorrhage on bypass using minimal heparin dosage and high ECMO flow rates to prevent clotting in the extracorporeal circuit. This is not universal, however, as some centers exclude grade II hemorrhage cases due to concern for ICH extension.

Uncontrolled bleeding from surgical wounds, chest tubes, or other sites also worsens with heparin therapy and is a contraindication to ECMO. The septic infant is of concern in this regard because of the commonly associated coagulopathy. Although these infants have a higher risk of bleeding complications on ECMO, meticulous correction of their coagulopathy and careful heparin management have allowed them to be successfully treated without sequelae.

Absence of Complex Congenital Heart Disease

Infants in severe respiratory failure must have an echocardiogram to rule out congenital heart disease as the underlying cause for refractory hypoxemia. In some instances, the degree of hypoxemia is not easily explained based on the heart lesion alone (e.g., in a newborn with an atrioventricular canal complicated by meconium aspiration or sepsis). Use of ECMO can provide cardiovascular support to stabilize such a patient until the reversible component of the lung disease is no longer an issue, rendering the baby a more viable surgical candidate at some later date.

Similarly, an infant with suspected cyanotic congenital heart disease may present to an ECMO center with profound cyanosis and cardiogenic shock despite the use of prostaglandins and inotropes. Preoperative ECMO can stabilize such infants who are believed to have reparable cardiac defects but who are deemed to be poor surgical candidates by virtue of their clinical instability. Both venovenous and venoarterial ECMO have been used preoperatively in infants with cyanotic congenital heart disease and cardiovascular instability. Indications for ECMO include arterial saturations of 60% or less accompanied by hypotension and metabolic acidosis unresponsive to mechanical ventilation and pharmacologic support with inotropes and vasodilators. For most infants presenting with isolated cyanotic congenital heart disease, however, prompt surgical intervention, not ECMO, is the obvious treatment of choice.

Less Than 14 Days of Assisted Ventilation

Although ECMO can support cardiovascular function for days to weeks, it does not reverse serious pre-existing pulmonary damage. In early studies, infants subjected to prolonged mechanical ventilation with high pressures and Fio_2 before ECMO suffered extensive barotrauma and did not recover despite prolonged support (more than 2 weeks) on bypass. Severe bronchopulmonary dysplasia (BPD), or inability to wean from ECMO support, was the result.[15] Infants who have recovered from BPD, however, are eligible for ECMO later in life. Survivors of BPD have been placed on ECMO in later infancy or toddlerhood for life-threatening respiratory infections with good survival results: 59 of 76 (78%) patients from the ELSO registry.

Changes in ventilatory management with lower pressure and volume settings to avoid barotrauma (permissive hypercapnea or gentle ventilation) may protect the neonatal lung from irreversible damage for longer periods than earlier studies suggested. Use of surfactant and iNO may also blunt ventilator-induced lung injury. Nevertheless, the longer an infant is ventilated with high Fio_2 before initiating ECMO, the longer that infant will take to recover, owing to the barotrauma and oxygen toxicity superimposed upon the infant's underlying lung disease. Therefore, if a patient fails to respond favorably to available respiratory measures, ECMO support should be considered expeditiously. However, given the improvements in respiratory support used today, prolonged ventilation is considered only a relative contraindication to ECMO.

Reversible Lung Disease

Using reversible lung disease as a criterion to determine whether to offer ECMO is intended to exclude infants with severe lung hypoplasia incompatible with life. Patients with marked renal dysplasia and prolonged oligohydramnios,

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

large CDH presenting in extremis at birth with unfavorable lung to head (L:H) ratio in utero, and hydrops fetalis fall into this category. However, infants with respiratory failure in all these categories have survived with ECMO support, making the judgment of irreversible lung disease in the newborn extremely problematic.

Failure of Maximal Medical Therapy

Because ECMO is an invasive procedure, it is currently reserved for infants with HRF unresponsive to optimal conventional therapy. In the early days of ECMO (1975-1995), those with an 80% mortality risk based on retrospective data at the time were considered candidates for ECMO. In well-intentioned attempts to keep newborns with HRF/PPHN alive, neonatologists would increase ventilator settings to extreme levels in hopes to reverse life-threatening hypoxemia. Tolazoline, which often caused serious systemic vasodilation, was the only vasodilator available. Sometimes it worked, oftentimes it did not.

Over the past 25 years, however, much has changed in the ventilator and NICU management of HRF in the newborn, including our choice of blood gas parameters in ventilated patients. Hyperventilation, alkali therapy, and muscle paralysis are no longer recommended, as serious side effects are associated with each of these interventions. It is, therefore, difficult to know what might constitute an 80% mortality risk in the ECMO-sick newborn today. Box 70.2 offers guidelines utilized by ECMO intensivists for deciding when bypass is likely needed.

A screening echocardiogram should be obtained in all infants with severe HRF to rule out serious congenital heart disease and to assess cardiac function. Hyperoxia should be avoided because of adverse effects of the reactive oxygen species (ROS) generated in the lung with prolonged exposure to high oxygen levels. Lakshminrusimha reports that oxygen-induced pulmonary vasodilation is maximized at a Pao_2 of 60-70 torr, arguing against "maintaining a margin of safety" with pO_2s over 100 torr.[55] Although CDH infants may be an exception, utilizing conventional mechanical ventilation (CMV) or HFV to achieve a normal pH should be the goal in respiratory support. Maintenance of normal blood pressure with judicious use of fluid infusions and pressors may also be required.

Early surfactant therapy has been shown to decrease the need for ECMO when administered to infants with HRF associated with parenchymal disease such as MAS, RDS, or pneumonia.[52,60] Inhaled nitric oxide has proven to decrease the need for ECMO in term and late preterm infants by 40% in multiple prospective randomized trials[13,74] (see next section on inhaled nitric oxide).

The use of other potent vasodilators commonly used in adults with pulmonary hypertension, such as sildenafil, epoprostenol, and bosentan, is not recommended in newborns with HRF/PPHN until these agents are proven safe and efficacious alone or in combination with iNO. Systemic hypotension is the main concern. Milrinone, a PD3 inhibitor that enhances pulmonary vasodilation and improves cardiac output, is presently under study.[56]

• BOX 70.2 Formulas and Criteria for Neonatal Extracorporeal Membrane Oxygenation

Oxygenation Index (OI)

- $OI = (MAP \times Fio_2 \times 100)/Pao_2$
- Usual criterion is OI of 35-60 for 0.5-6 hours.

Alveolar-Arterial Oxygen ($Aado_2$) Gradient (at Sea Level)

- $AaDo_2 = Fio_2 (P - 47) - Pao_2 - Paco_2 (Fio_2 + (1 - Fio_2)/R)$
- Usual criterion is $AaDo_2 > 605$-620 mm Hg for 4-12 hours.

Partial Pressure of Arterial Oxygen

- Usual criterion is $Pao_2 < 60$ mm Hg for 2-12 hours.

Acidosis and Shock

- Usual criterion is pH < 7.25 for longer than 2 hours or with hypotension.

From Suttner DM, Short BL. Neonatal respiratory ECLS. In Annich GM, et al., eds. *ECMO: extracorporeal cardiopulmonary support in critical care*. 4th ed. Ann Arbor, MI: ELSO; 2012:226.

The Dilemma of Congenital Diaphragmatic Hernia (CDH)

Congenital diaphragmatic hernia (CDH) is an anatomic defect of the diaphragm resulting in herniation of abdominal contents into the thoracic cavity. The majority (85%) of CDHs are left-sided lesions. Pulmonary hypoplasia of variable severity results on the ipsilateral side of the defect (see Chapter 66 for more on CDH).

CDH is often associated with intractable PPHN/HRF. A combination of pulmonary arterial hypertension, right ventricular hypertrophy, and in some cases, left ventricular hypoplasia results in severe PPHN. Often these infants prove unresponsive to conventional management, including oxygen, ventilation (including HFV), and pulmonary vasodilators like inhaled nitric oxide. Pulmonary hypoplasia and decreased cross-sectional area of the pulmonary vascular bed contribute to the hypoxic respiratory failure in newborns with CDH. In large diaphragmatic defects, the stomach, intestines, and liver can herniate into the chest, causing displacement of the heart, which restricts the growth of the contralateral lung as well as the ipsilateral lung.

ECMO is reserved for CDH patients who are failing optimal medical treatment, including a strategy of pressure-limited (gentle) ventilation to minimize ventilator-associated lung injury. Criteria that predict high mortality prior to initiation of ECMO have not been universally established. Published indications for initiating ECMO in infants with CDH include the following: severe hypoxia and HRF with preductal oxygen saturations <80%-85%, metabolic acidosis (lactate >5) or respiratory acidosis with pH persistently <7.20, or hypotension with poor tissue perfusion and/or

oliguria unresponsive to intravenous fluid and inotropic support.[36]

The survival among CDH infants treated with ECMO over the last 5 years has declined to 47% within the United States, which reflects the highest mortality among neonatal etiologies of respiratory failure reported in the ELSO Registry.[28] In 1991, survival in this cohort was 64%. The reason for this decline is not entirely clear. A recent publication commenting on the decline in survival notes that over the past 10 years the prevalence of respiratory acidosis in this cohort has more than doubled ($p < .0001$), and the length of ECMO support has increased ($p < .001$), pointing either to a sicker population receiving bypass support or an unrecognized risk of permissive hypercapnea, a ventilator technique commonly used now in CDH infants to avoid serious lung barotrauma.[90] Stevens and colleagues suggest that improvements in ventilator management postdelivery have resulted in early survival of a sicker cohort of CDH patients who might otherwise have died but now are stabilized on ECMO.[88] In all, 25%-35% of infants with CDH require ECMO support, usually VA bypass, and the majority of these are cannulated prior to surgical repair of the hernia because of the infants' clinical instability.

Echocardiographic findings in a cohort of 44 CDH infants revealed no difference in the severity of pulmonary hypertension between ECMO ($N = 15$) and non-ECMO CDH patients ($N = 29$). However, compared to non-ECMO patients, those who required ECMO had significantly decreased left and right ventricular function with diminished cardiac output. The authors proposed that abnormal cardiac function may explain the lack of sustained response to pulmonary vasodilators in newborns with CDH. Focusing attention on support of cardiac function in these fragile infants may prove critical to outcome.[6]

Pre- and postnatal respiratory therapies that have improved survival in preterm infants have also been studied in term and late preterm CDH infants. An observational study of antenatal steroids administered at 34 weeks' gestation did not benefit survival in CDH patients.[58] Surfactant replacement therapy has also been investigated because of earlier evidence, mostly from animal data, suggesting surfactant deficiency in CDH. However, a large prospective observational study conducted by the CDH Study Group involving 424 preterm infants with CDH <37 weeks' gestation showed worse survival and increased complications associated with surfactant replacement.[59] Neither the length of bypass support, number of days of mechanical ventilation, nor the length of oxygen requirement were improved among those given surfactant therapy in this cohort.

Ventilatory management of infants with symptomatic CDH begins in the delivery room with early intubation and placement of a nasogastric (NG) tube to decompress the bowel in the chest.[7] Most ECMO centers focus on strategies to minimize ventilator-associated lung injury utilizing low distending pressure, minimal sedation, and avoidance of muscle paralysis. Hyperventilation and attempts to normalize pCO_2 for infants with CDH have largely been abandoned with this adoption of gentle ventilation. There is no particular mode of ventilation that has been shown to be superior in the management of CDH. A multicenter randomized trial of HFV versus conventional ventilation in CDH infants showed no advantage to HFOV with regard to survival or avoidance of ECMO.[84]

Currently, ECMO is used in CDH newborns largely for preoperative stabilization in sicker infants. The optimum timing for repair of the hernia in ECMO-sick patients remains unclear, however, because of variability among centers and lack of convincing data on how best to proceed. The CDH Study Group found that surgical repair of CDH on ECMO was associated with decreased survival, relative to repair after ECMO therapy (48.2% vs. 77.1%, hazard ratio, 1.41, 95% CI 1.03-1.92). Kays et al., who consistently publish one of the highest survival rates in CDH, reported a 92% survival in left-sided, liver-up CDH newborns (a higher risk cohort) who were repaired early, that is, before going on ECMO, compared to 65% survival among those placed on ECMO unrepaired.[45] Other reports reviewed by McHoney favor decannulation after CDH repair.[65]

A multidisciplinary CDH management team at the Children's Hospital, Colorado, choose to delay surgical repair of CDH infants until echocardiogram-estimated pulmonary artery pressure decreases to <80% systemic blood pressure. In a retrospective study of 77 infants with Bochdalek herniae managed between 2008 and 2015, they reported fewer postoperative decompensations and a trend toward improved survival to 30 days postoperatively among the infants repaired after improvement in pulmonary pressures (94% vs. 80%; $p = 0.06$).[22] This manuscript provides a detailed description of this group's management protocol for CDH patients, starting with initial stabilization in the delivery room, respiratory management in the ICU, timing of hernia repair on or off ECMO, and postoperative management.

The true impact of ECMO on survival and long-term outcome in newborns with CDH is difficult to ascertain. Infants with CDH who received ECMO support appear to have a higher risk and greater severity of neurologic morbidity compared to those who did not receive ECMO, or those who received ECMO for other causes of HRF.[36,64] Among neonatal ECMO patients who survived to hospital discharge, CDH patients had a 74% 5-year survival compared to 98% survival in MAS patients.[92] Most deaths in the CDH cohort were caused by chronic lung disease.[44] Neurodevelopmental morbidity and growth failure among children with CDH have been confirmed in several studies. Madderom assessed 35 CDH survivors at 8 years of age, ECMO-treated (N = 16) and non-ECMO-treated (N = 19). The mean intelligence quota for the ECMO group was 91.7 versus 111.6 for the non-ECMO group ($p = 0.015$). Both were within normal developmental quotient (DQ) range but significantly lower in the CDH-ECMO cohort. Motor problems were noted in 16% of all participants as were problems with concentration (68%) and behavioral attention (33%), compared to a normal Danish

reference group, but not different between ECMO-treated and non-ECMO-treated CDH groups.[61]

Because the sicker newborns with CDH were placed on ECMO for intractable HRF, it is hard to know what degree of their later morbidity is intrinsic to their underlying condition and greater severity of illness versus ECMO exposure. These issues should be discussed with parents before birth in the case of prenatal diagnosis of CDH and early in the NICU course of all CDH infants.

Extracorporeal Membrane Oxygenation Referral

One of the hardest decisions faced by neonatologists in tertiary care is when to refer a newborn in respiratory failure to an ECMO center. Because of the volatile nature of PPHN, the risk of sudden cardiorespiratory decompensation and death remains high in any infant not responding favorably to conventional supportive measures. Likewise, transporting these unstable babies is problematic, with one series reporting 25% mortality among ECMO transports before inhaled NO was available.[16] In 2016 in New South Wales, Australia, the use of inhaled nitric oxide improved oxygenation in a cohort of 57 out of 130 consecutive transports of high-risk newborns with HRF. The majority of these transports were over large distances, and all infants arrived at the referral hospitals safely.[8]

It is essential that ECMO referrals be made as expeditiously as possible, certainly before the infant is moribund and preferably before the baby reaches ECMO-eligible respiratory criteria. Early and frequent telephone contact with an ECMO physician to discuss the details of each case can help establish transport criteria agreeable to both parties.

The parameters most often used to predict poor outcome in infants failing conventional or high-frequency ventilator support and regarded as entry criteria for ECMO are listed in Box 70.2. These criteria are applied when the infant has reached optimal ventilatory support on 100% oxygen. Expert opinion has stated that when the oxygenation index (OI), described below, is greater than 25, a non-ECMO center should at least be in discussion with an ECMO center to determine the optimal time to transport the infant.

One criterion is the oxygenation index:

$$\text{OI} = \text{mean airway pressure} \times \text{Fio}_2 \times 100 / \text{postductal Pao}_2$$

This equation has a certain appeal in that it reflects the ventilator support being used to achieve any given Pao_2. The oxygenation index is the parameter used in most ECMO centers today to gauge the severity of respiratory insufficiency.

Another criterion is the alveolar-arterial oxygen gradient (AaDO_2):

$$\text{AaDO}_2 = \text{Fio}_2(\text{P} - 47) - \text{Pao}_2 - \text{Paco}_2(\text{Fio}_2 + (1 - \text{Fio}_2)/\text{R})$$

where P is the barometric pressure, 47 is the partial pressure of water vapor, R is the respiratory quotient (0.8), Fio_2 is the fractional inspired oxygen concentration, Pao_2 is the partial pressure of arterial oxygen, and Paco_2 is the partial pressure of arterial carbon dioxide. When Fio_2 is 100% and assuming PAo_2 (partial pressure of alveolar oxygen) is equivalent to Pao_2, the equation reduces to: $\text{AaDO}_2 = \text{P} - 47 - \text{Pao}_2 - \text{Paco}_2$, where P is 760 mm Hg at sea level.

An OI of 40 or greater or an AaDO_2 gradient of 605-620 or greater served as a baseline criterion for ECMO eligibility in the original UK randomized trial of ECMO versus conventional management alone. Assessment of respiratory failure parameters begins after infants have received surfactant or iNO, or both, when clinically relevant. Supporting cardiac output with judicious use of volume loading and pressor infusion is crucial to maintaining adequate oxygen delivery in newborns with borderline blood pressure and respiratory insufficiency. In the ventilatory management of these infants, equal attention must be paid to providing optimal ventilation without overdistending the lung, which compromises venous return and hence adversely affects cardiac output. Hyperventilation (to induce respiratory alkalosis) is no longer recommended in the ventilatory management of PPHN.

For the infant who remains severely hypoxic and/or hypotensive despite every supportive measure offered, the choice for ECMO is easily made. However, for the infant whose blood gases and systemic blood pressure are marginally stable on maximal support, including iNO, but who is unable to wean from these supports, the choice between invasive bypass support (ECMO) and the risk for extended volutrauma to the lungs remains difficult.

One large study in newborns with respiratory failure and PPHN confirmed that aggressive weaning of iNO over 96 hours can be accomplished without increasing the risk for ECMO.[20] Judicious but steady weaning of both Fio_2 and ventilator settings is recommended to avoid serious lung injury. If the infant's respiratory status fails to stabilize and improve over a number of days, then ECMO is an alternative.

Extracorporeal Membrane Oxygenation Follow-Up

More than 27,000 infants have been treated for respiratory failure in more than 200 ECMO centers worldwide for an overall survival to discharge of 74%.[28] The outcome of these children compares favorably with that of term and near-term infants surviving severe respiratory compromise and PPHN with conventional management.

A valid criticism of early ECMO follow-up studies was the lack of proper control data, that is, the outcome of infants with severe respiratory compromise who were managed during the ECMO era with conventional treatment alone. Such control data are essential for distinguishing morbid outcome caused by the underlying disease process and NICU management of respiratory failure, or both, from the morbidity that is secondary to the ECMO procedure itself.

To address this issue, Walsh-Sukys and associates were the first to report on the neurodevelopmental outcome of 74 consecutive neonates older than 34 weeks' gestation admitted to Rainbow Babies and Children's Hospital with severe respiratory failure.[96] Eighteen of 24 (75%) infants treated conventionally survived, whereas 43 of 48 (90%) treated with ECMO survived. Patients were evaluated at 8 and 20 months. Sixty-two of 72 (91%) survivors were seen in follow-up. Four of 17 (24%) conventionally treated survivors and 10 of 38 (26%) ECMO-treated survivors had neurodevelopmental impairment defined as either Mental Developmental Index Score lower than 80 or neurosensory impairment. The conventionally treated group had significantly more chronic lung disease, longer duration of oxygen therapy, more chronic reactive airway disease, and more rehospitalizations than those treated with ECMO. Macrocephaly was noted in 24% of ECMO survivors, all treated with VA bypass, but in none of the conventional group. This study concluded that ECMO survivors did not suffer increased neurologic morbidity compared with similarly ill neonates managed conventionally and that they may have fewer pulmonary sequelae.

Vaucher and colleagues prospectively assessed growth and neurodevelopmental outcome in a cohort of 190 infants surviving neonatal respiratory failure who met institutional criteria for the use of ECMO.[94] Fifty-two were managed with conventional or high-frequency ventilation, and 138 required ECMO. At 12-30 months of age, the mean developmental scores of ECMO survivors were similar to those for infants who survived without ECMO. Neuroimaging abnormalities or diagnosis of bronchopulmonary dysplasia each independently predicted adverse neurodevelopmental outcome regardless of treatment strategies used in the NICU. This observation mirrors the same predictors of poor outcome described in another high-risk cohort familiar to neonatologists, namely, infants with very low birth weight (less than 1000 g).

In 2006, the UK Collaborative ECMO Trial Group published the 7-year follow-up of their surviving patients from the largest prospective randomized ECMO trial carried out so far.[67] In this study, a single psychologist assessed 90 of the 100 children available for follow-up without prior knowledge of treatment allocation (ECMO versus conventional management). At age 7 years, there was no difference in cognitive function between the 56 patients randomized to ECMO versus the 34 controls; 68 (76%) children recorded a cognitive level within the normal range. Learning problems were similar in the two groups. There were notable difficulties with spatial and processing tasks; the children also had particular difficulty completing tasks of reading comprehension with 35 (39%) scoring below the 10th percentile. There was no difference in laterality of neuromotor disability between the two groups, which is important because VA ECMO is usually performed on the right-sided common carotid and internal jugular vessels; thus, no side preference would imply that there were no injuries related to complications from cannula placement. A higher respiratory morbidity and increased risk of behavioral problems among children treated conventionally (first reported in the 4-year follow-up) persisted. In the conventionally treated group, 11 of 30 (32%) children continued to have wheezing attacks and 14 of 32 (41%) regularly used an inhaler over the 12 months before study assessment. In comparison, 6 of 43 (11%) ECMO children wheezed and 14 of 48 (25%) used an inhaler. In behavioral assessment, the total deviant score was higher in the conventionally treated group—38% versus 18% in ECMO survivors. The most commonly described difficulty reported by parents and teachers in both groups was hyperactivity; overall, 22 of 85 (26%) children had difficulty with hyperactivity. In 1996, the primary outcome of death or severe disability in this UK trial occurred in 37% of the ECMO group compared with 59% in the conventional group (relative risk 0.64; $p = .004$), leading the authors to reaffirm that ECMO remains a beneficial treatment. These results, which have not changed between the 4- and 7-year follow-up, are equivalent to one additional child surviving without severe disability for every four to five children referred for ECMO. Overall, 31 of 56 (55%) ECMO survivors and 17 of 34 (50%) conventionally treated survivors were assessed with no disability at 7 years. The authors concluded that the data collected at 1, 4, and now 7 years' follow-up of the UK ECMO trial participants suggest that the underlying disease process (and associated physiologic instability) appears to be the major influence in long-term outcome. Their findings confirm significant long-term morbidity in many surviving children who had life-threatening respiratory failure soon after birth, regardless of their subsequent medical treatment. Furthermore, although both groups had problems, the beneficial influence of ECMO persists to 7 years.

Neurodevelopmental follow-up of ECMO survivors in the Netherlands was reported at 5, 8, and 12 years of age. There was no control group in this study of ECMO survivors, however. By 8 years (n = 135), intelligence was normal with 91% attending regular education, albeit with increased special education supports, compared to a normal Dutch reference cohort. Increased behavior and attention issues were also cited. CDH survivors scored at the lower end of normal in IQ testing compared to those with other newborn diagnoses. All children in this cohort received VA ECMO as infants.[61]

Two hundred and fifty-four children treated with ECMO in the neonatal period were also evaluated longitudinally for motor performance utilizing the Movement Assessment Battery for Children (MAB-C). At 5 (n = 78), 8 (n = 126), and 12 (n = 36) years, motor performance was normal in 73.7%, 74.8%, and 40.5%, respectively, compared to 85% expected based on Danish reference values, $p < 0.001$. In the 36 children evaluated at all three ages, Z scores were similar at 5 and 8 years but significantly lower at 12 years. The significant decline in motor scores at 12 years was most pronounced in children with chronic lung disease and CDH. Exercise capacity (based on the Bruce treadmill

protocol) also worsened significantly over time, that is, from assessment at 5, 8, and 12 years.[91]

The significance in such decline in motor performance and exercise capacity is troublesome and points to a serious need for long-term follow-up of these children into adulthood. In the United States, unfortunately, we do not have neurodevelopmental follow-up to compare to the UK and Netherlands programs. In 2016, a survey assessment of a cohort of 142 adult (>18 years, born before 1994) survivors of neonatal ECMO in the United States was published. While this self-reported outcome was largely favorable, this study represented only a small fraction (<2%) of neonatal ECMO survivors who have reached adulthood.[27] Finding these patients, particularly those not receiving routine medical care, will prove formidable.

ECMO and Hypothermia Therapy

Induced hypothermia for 72 hours to a depth of 33-34°C is now standard of care for newborns suffering moderate or severe encephalopathy, as this therapy has been shown in large, prospective, randomized trials to decrease death or disability in these infants.[82] In a study of 303 infants with HIE who were cooled, 67 (22%) had PPHN. The incidence of PPHN in the general newborn population is 1.9/1000 live births. Mortality was higher in the subset of cooled infants (27% vs. 16%), and the hospital length of stay was prolonged in PPHN/HIE survivors (26 vs. 10 days).[57] In the Optimizing Cooling Trial, among the infants with PPHN who were cooled to 32°C for 72 or 102 hours, 67% required iNO and 12% needed ECMO support, compared to 3% iNO and zero ECMO use in HIE infants without PPHN who were cooled in standard fashion (i.e., 33.5°C). Worsening PPHN at the lower temperature was an unexpected adverse outcome in this study. For this reason, deeper hypothermia (i.e., <33°C) is not recommended for infants with HIE.[83]

In a multicenter prospective study of 267 neonates (<30 days old) undergoing ECMO at eight clinical sites, 20 infants also received therapeutic hypothermia. Eighty percent of neonates who were cooled during ECMO had a primary respiratory diagnosis, and 65% had PPHN. Infants receiving therapeutic hypothermia were more likely to have ICH during the first 7 days on ECMO, compared to noncooled ECMO patients: 40% versus 15%. Not all infants had pre-ECMO head ultrasound screens, however, so it is not certain whether some of these bleeds might have occurred prior to the initiation of ECMO. The authors point out that hypothermia and rewarming have been associated with fluctuations of cerebral blood flow and that in combination with abnormal coagulation profiles and low platelets could offer an explanation for the association between therapeutic hypothermia and ICH on ECMO.[18]

Massaro and colleagues reported the use of ECMO in 5/117 patients who required hypothermia for moderate to severe encephalopathy. All five patients demonstrated prolonged coagulation studies and thrombocytopenia during hypothermia. Three of the five developed ICH while on ECMO. The authors posed a cautionary note that, while both ECMO for refractory HRF and cooling for HIE independently demonstrate improved outcome, the combination of the two therapies is less certain and needs further study. This uncertainty should be conveyed to parents before pursuing both therapies in tandem, especially in cases of severe encephalopathy.[63]

The Neonatal ECMO Study of Temperature (NEST) Trial randomized 111 neonates on ECMO to receive therapeutic hypothermia (34°C) for 48-72 hours after bypass initiation or ECMO alone. These children did not have HIE as a primary diagnosis. The hypothesis of this study was that therapeutic hypothermia during ECMO would reduce the proportion of infants with brain injury and, thus, later impairment. CDH and postoperative cardiac infants were excluded. The primary outcome was the cognitive composite score of the Bayley Scales of Infant and Toddler Development (3rd edition) at 2 years of age. The mean cognitive score of the hypothermic cohort was 88 (SD 16.2) compared to 90.6 (SD 13.1) for the noncooled infants, confirming no advantage in cognitive outcome at 2 years of age among survivors treated with moderate hypothermia while on ECMO. Indeed, a pattern of small differences favoring standard ECMO was observed across the health and neurologic outcomes investigated. No significant increase in ICH was found in the infants who were cooled, however, compared to noncooled ECMO patients. The proportion of infants who survived without impairment was, nonetheless, similar in both groups: 27/52 infants (52%) in the ECMO with cooling group versus 28/49 infants (57%) in the standard ECMO group.[29]

Cost Analysis

Although ECMO saves lives, it does cost more than conventional management of neonatal respiratory failure. A cost-effectiveness analysis of neonatal ECMO was published based on 7-year results from the UK Collaborative ECMO Trial.[77] Mean health service costs during the first 7 years of life were £30,270 in the ECMO group compared with £10,229 in the conventional management group. Data for this analysis included air and ground transport costs, initial and all subsequent hospitalizations, outpatient hospital care, and community health care, as well as other health care services. These combined costs over 7 years translated into a cost of £13,385 per life-year gained. The incremental cost per disability-free life-year gained was estimated at £23,566. These incremental costs should decrease as the surviving children grow older. The authors concluded that ECMO was not only clinically effective but also as cost-effective as other intensive care technologies in common use.

Alternative Uses for Extracorporeal Membrane Oxygenation

Support by ECMO has been extended to a broader array of high-risk candidates. A small number (5%) of infants

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

undergoing surgical repair of their heart defects cannot be successfully weaned from cardiopulmonary bypass or they develop low cardiac output syndrome several hours after repair. VA ECMO can provide circulatory support for these patients until their cardiac function improves. However, survival in postcardiac surgery infants requiring ECMO is low (41%) compared to respiratory case survival (74%).[28,41]

In a single-center retrospective study of 671 patients undergoing open-heart surgery between January 2001 and October 2003, 36 (5.4%) infants received extracorporeal life support within 1 day after surgery (age younger than 30 days, $N = 34$). Overall, 28 patients (78%) were weaned from extracorporeal support successfully, and 24 (67%) survived to hospital discharge. These infants had a variety of disorders, including single ventricle anatomy as well as failed hemodynamics postcardiotomy. The authors concluded that expanded use of extracorporeal support may improve outcome in some of the highest risk neonates, especially those with univentricular anatomy.[5] In another single-center review from Vanderbilt University Medical Center, 84 children with congenital heart disease required postcardiotomy ECMO between January 2001 and September 2004. The median age of the patients was 128 days (1 day-5 years), and median weight was 4.5 kg (2-18 kg). Fifty-two (61.9%) survived for more than 24 hours after decannulation, but only 31 (36.9%) survived to discharge. High arterial lactate levels at the time of ECMO initiation were strongly correlated with poor outcome. Inability to wean off ECMO by 6 days correlated with high mortality.[81]

ECMO has been used as a bridge to cardiac transplantation in infants with myocarditis or complex congenital heart disease, as well as support for early graft failure following heart transplantation in infancy. It has also been used to stabilize infants with refractory supraventricular tachycardia until antiarrhythmic drugs could be maximized or radioablation of the aberrant pathway accomplished.[95] Tracheal reconstruction in infants with serious congenital defects of the upper airway has also been successfully accomplished while on ECMO.[38]

Extracorporeal Membrane Oxygenation Present and Future

ECMO has become an established treatment for cases of hypoxic respiratory failure refractory to conventional management. Because of advances in neonatal respiratory care, the number of annual neonatal respiratory ECMO cases has declined from a peak of 1345 in 1992 to 533 infants in 2017.[28] Surfactant treatment, gentle ventilation, permissive hypercapnea, high-frequency ventilation, and inhaled nitric oxide have all contributed to the welcomed decline in the need for ECMO rescue in neonatal respiratory failure.

Research efforts continue to focus on PPHN treatment that could preclude the need for bypass altogether. Randomized controlled trials over the past decade have proven the efficacy of iNO as the selective pulmonary vasodilator that decreases the need for ECMO (see the next section). Other drugs used extensively in the treatment of adult and pediatric pulmonary hypertension have been reported, so far in small case series, and hold promise in the future treatment of PPHN. As the number of neonatal pulmonary cases declines, the use of ECMO support for cardiac low-output syndrome, as in myocarditis or postcardiotomy, has increased. Time is needed to determine whether this use of extracorporeal support will translate into increased survival or improve neurodevelopmental outcome in this high-risk cohort.

Nitric Oxide Therapy

Persistent pulmonary hypertension in the neonate (PPHN) is a serious and sometimes lethal cardiorespiratory complication of the transition to extrauterine life. The incidence ranges from 0.43-6.8 per 1000 live births.[97] It is well recognized that in the absence of congenital malformations of the lung, this condition improves if the patient can be supported through the period when pulmonary vascular resistance is most volatile, often exceeding systemic vascular resistance. Support is required for a matter of only days, usually less than 2 weeks.

Potent vasodilators such as tolazoline, nitroprusside, prostaglandin E_1 (PGE_1), and prostaglandin D (PGD) have been shown in small trials to reverse the severe pulmonary vasoconstriction that causes profound hypoxemia in PPHN. Although all these medications are efficacious in lowering pulmonary vascular resistance, their use is severely limited by a lack of pulmonary selectivity. Systemic vasodilation invariably occurs, leading to hypotension, compromised tissue perfusion, and inadequate oxygen delivery to vital organs.

In 1980, Furchgott and associates described an endogenous vasodilator called *endothelium-derived relaxing factor* (EDRF).[33] In 1987, NO was identified as the molecule responsible for the biologic activity of EDRF. Previously recognized as a toxic component in cigarette smoke and atmospheric pollution, NO has proved to be an important endogenous mediator of multiple physiologic processes in the human body, including regulation of vascular tone. When delivered by inhalation, NO can selectively decrease pulmonary vascular resistance and improve pulmonary blood flow without compromising systemic blood pressure or worsening $\dot{V}/\dot{Q}$ mismatch. At present, NO is the most selective pulmonary vasodilator available for clinical use in neonatal patients.

Physiology and Pharmacology

Nitric oxide (NO) is a short-lived (seconds) reactive molecule, with an unpaired electron cleaved from the terminal nitrogen of L-arginine by the enzyme nitric oxide synthase (NOS). Three distinct isoforms of NOS have been described. Neuronal NOS (NOS I, nNOS) is produced in central and peripheral nerves and is pivotal in neuronal transmission and cell-to-cell communication in the

central nervous system. Inducible NOS (NOS II, iNOS) is upregulated in the face of inflammatory stimuli such as infection. While NOS II is expressed by immune cells such as neutrophils and macrophages, it is also found in other cell lines, including hepatocytes. Endothelial NOS (NOS III or eNOS) is expressed by endothelial cells and is critical for the regulation of vascular tone, the subject of this section.[43]

In the classical mechanism of NO signaling, NOS converts arginine to citrulline and NO as follows. Pulmonary endothelial and epithelial cells are active sites of NOS activity in both fetal and newborn lungs. Nitric oxide generated in the endothelium enters the adjacent smooth muscle cell where it binds to the heme protein of soluble guanylate cyclase. This induces a conformational change and upregulation of this enzyme, promoting synthesis of cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP) (Fig. 70.2). Activation of a cascade of cGMP-dependent protein kinases results in calcium efflux from the adjacent muscle cells and sequestering of intracellular calcium within the sarcoplasmic reticulum. With less cytoplasmic calcium available for depolarization and contraction, smooth muscle relaxation follows, resulting in pulmonary vasodilation.[43] Intracellular cGMP is, therefore, a significant modulator of vascular smooth muscle tone. Its biologic half life is short, however. A family of phosphodiesterases hydrolyze and inactivate cGMP, regulating the concentration and duration of action of cGMP within the smooth muscle cell.

Lung endothelial NOS mRNA and protein are present in the early fetus and increase with advancing gestation in utero in the rat model. In the fetal lamb, intrapulmonary infusion of NOS inhibitors increases basal pulmonary vascular resistance by 35% as early as the second trimester.[1] Endogenous NO plays a pivotal role in the acute decrease in pulmonary vascular resistance at birth along with other vasodilators such as adenosine and prostacyclin. NOS expression is largely responsible for postnatal adaptation of the lung circulation following newborn delivery. Other nitrovasodilators, such as sodium nitroprusside, nitroglycerin, and the organic nitrates, donate NO through the NO-cGMP pathway to promote vasodilation. When administered by inhalation, NO rapidly diffuses across the alveolar membrane of ventilated portions of the lung to relax the pulmonary vascular bed through upregulation of cGMP production. In contrast to intravenous vasodilators, inhaled NO has minimal effect on systemic vascular tone because of rapid binding by reduced hemoglobin within the pulmonary circulation.

Nitric Oxide Toxicity

Clinicians should be aware of toxicity issues when using inhaled nitric oxide (iNO) in human subjects. Nitric oxide reacts with oxygen to form nitrogen dioxide (NO_2). Both NO and NO_2 are toxic in higher concentrations, causing death in dogs at concentrations between 0.1% and 2% because of methemoglobinemia and pulmonary edema. This concentration is much higher than the inhaled dose of NO used therapeutically in newborns (5-20 ppm) or the endogenous levels of NO produced in the endothelium (ppb). When NO reacts with superoxide in the lungs, peroxynitrite ($ONOO^-$) is formed, which can cause membrane lipid peroxidation. Furthermore, at levels used in clinical trials, NO can inhibit platelet aggregation and adhesion. In one study, prolonged bleeding time was noted in healthy adults breathing 30 ppm iNO. However, no studies to date have reported issues of systemic bleeding with iNO treatment. Occupational safety guidelines limit exposure to NO in the workplace to 8 hours a day at levels of 25 ppm, while 3 ppm is the upper limit for NO_2. Scavenging devices on most iNO delivery systems remove excess NO sufficiently enough to lower bedside workers' exposure to far below these limits.

• **Fig. 70.2** Nitric oxide (NO) is produced in the vascular endothelium during the conversion of L-arginine to L-citrulline by the enzyme NO synthase (NOS). Endogenous NO from the endothelium or exogenous NO inhaled into the alveolus diffuses to the vascular smooth muscle cell, stimulating soluble guanylate cyclase, which increases cyclic guanosine monophosphate (cGMP) production. Phosphodiesterase, specifically PDE_5, hydrolyzes cGMP, reversing smooth muscle relaxation. GTP, Guanosine triphosphate.

Patients treated with iNO must have methemoglobin levels monitored daily to ensure they do not exceed 5%-7%. Methemoglobin is a source of potential toxicity with exposure to high doses of NO (≥80 ppm), especially with prolonged use.

NO has multiple effects on cell signaling, inflammation, growth, differentiation, and metabolism throughout the human body. While NO-based signaling via soluble guanylate cyclase explains much of the activity, parallel studies suggest that NO elicits much of its physiologic effects through cGMP independent mechanisms. S-nitrosylation, a covalent post-translational modification of protein cysteins, has emerged as a paradigm of nonclassical NO signaling in which the reaction of NO with protein thiols forms S-nitrosothiols (SNOs). Hemoglobin (Hb) is the prototypical S-nitrosylated protein in that it can deploy NO bioactivity as the red blood cells (RBCs) transit the circulatory system.

NO binds to heme iron of deoxy tension (T) state Hb in the venous circulation to generate HbFeNO. In response to oxygenation within the lungs, the Hb molecule undergoes a conformational change from the T state to a relaxed (R) state, and the NO group is transferred to the cysteine residue on the β chain to form SNO-Hb. The transition from high to low oxygen tension in the distal circulation promotes the release of SNO-based vasodilatory activity from the RBCs, thereby improving oxygen delivery where it is needed most. The binding and release of NO bioactivity in the form of SNOs is thought to be a central component of the physiologic response to local hypoxia at the tissue level.[24,62]

Neonatal Studies of Inhaled Nitric Oxide

Term Infants

Inhaled nitric oxide has proven to be an effective pulmonary vasodilator in term and near-term neonates with hypoxic respiratory failure (HRF) and PPHN. Seventeen prospective, randomized trials have been published on the use of iNO in this cohort.[13] One of the largest of these was the NINOS Trial sponsored by the National Institute of Child Health and Human Development (NICHD), in which 235 infants older than 34 weeks' gestation who had a diagnosis of HRF were randomized to iNO at 20-80 ppm versus standard ventilation management with 100% Fio_2. Nearly all infants enrolled had echocardiogram confirmation of pulmonary hypertension, although this was not required for study eligibility. The primary outcome was death or need for ECMO. Although the mortality rate was no different in either treatment arm, there was a 40% reduction in need for ECMO among the babies treated with iNO: 54% of infants required ECMO in the control arm while 39% required ECMO in the iNO treatment arm.[75] Follow-up of survivors at 2 years showed no difference in neurodevelopmental outcome between treated and control patients, although abnormal outcome occurred in 25% of all newborns evaluated.[74]

In a later multicenter trial of iNO in term and late preterm newborns, Clark and coworkers reported a 38% reduction in ECMO use but no difference in mortality among 248 infants with PPHN randomized to low-dose, short-duration (96 hr or less) iNO treatment versus control.[20] This study, unlike previous trials, showed a significant decrease in chronic lung disease in infants treated with iNO. These two studies led to the eventual FDA approval for the use of iNO in term and preterm infants.

Following the success of the NINOS Trial in reducing the need for ECMO in infants with severe HRF, Konduri et al. in 2004 conducted a blinded, prospective, randomized study of 299 infants comparing the use of iNO in HRF of moderate severity defined as an OI between 15 and 25 and Fio_2 requirement ≥80%.[53] Infants randomized to the iNO arm started at 5 ppm, increasing to 20 ppm if only a partial response was noted. Control infants received simulated iNO with nitrogen gas alone, but if their OIs exceeded 25, they, too, were given iNO at 20 ppm. Unfortunately, the trial was terminated for slow enrollment (34 months) and an interim analysis, which confirmed that early iNO therapy, as defined in this study, did not reduce the combined incidence of ECMO/mortality from 35%-20% as the initial hypothesis proposed. In fact, only 12 infants in either arm of the study required ECMO, less than 10% of enrolled infants with HRF.

In 2013, Konduri published a post hoc analysis of this same cohort of 299 infants with moderate HRF and reported that early administration of surfactant and iNO therapy at a lower acuity of illness (OI < 20) was associated with decreased risk of ECMO/death, worsening progression of HRF, and decreased hospital stay.[52] Early use of surfactant for infants diagnosed with parenchymal lung disease (i.e., respiratory distress syndrome, meconium aspiration syndrome, and pneumonia/sepsis but not PPHN alone) was associated with lower risk of death/ECMO ($P = 0.002$). These data were consistent with the finding reported earlier by Lotze et al. in which the need for ECMO was significantly reduced among infants with severe HRF and parenchymal lung disease who were treated with surfactant alone. Again, infants with "black lung" (i.e., isolated PPHN) did not benefit from surfactant therapy.[60]

A meta-analysis of the results from 17 randomized trials (including the three studies detailed earlier) of iNO use in term and late preterm newborns with PPHN demonstrated that 50% of hypoxic late preterm and term infants responded to iNO within 30-60 minutes. The Pao_2 in the patients treated with iNO was 53 mm Hg higher (weighted mean difference) than in controls, and the OI was 15 units lower than in control patients. Mortality was not reduced in any study of iNO, perhaps because ECMO was used as a rescue therapy in nonresponders in whom severe hypoxic respiratory failure persisted.[13]

Unfortunately, iNO has not been shown to benefit newborns with congenital diaphragmatic hernia (CDH) in the first 2 weeks of life (see Chapter 66). In a prospective, masked trial of 52 infants with CDH who were randomized

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

separately in the NINOS Trial, iNO neither reduced mortality nor decreased the need for ECMO. In fact, the need for ECMO was higher in the CDH infants treated with iNO in this trial.[31] Clark et al. also reported lack of efficacy for iNO treatment in a similar cohort of 35 CDH infants randomized to iNO or standard therapy in the first 4 days of life.[20] In contrast, Kinsella's group reported iNO to be useful in treating a subset of older CDH patients after surgical repair, whose pulmonary hypertension by echocardiographic measurements remained severe at the time of elective extubation (26 ± 3 days). Although their respiratory status was much improved (OI average 4 ± 1) after surgical repair, 10 of 47 CDH infants were found to have late pulmonary hypertension and were successfully treated with iNO administered through nasal cannulae until subsystemic pulmonary artery pressures were achieved. The infants received iNO in this fashion for a median of 17 days (range 5-60 days).[50]

The toxicity of NO and its metabolites in the newborn lung warrant careful monitoring, particularly with regard to long-term exposure. Concern for methemoglobinemia (metHgb) is rare in newborns treated with 20 ppm iNO. In the NINOS Trial, infants who did not respond to 20 ppm of iNO did not derive additional benefit from 80 ppm, and a small number of infants exposed to the higher dose had elevated metHgb levels. For this reason, 20 ppm iNO is recommended as the starting dose for the treatment of PPHN in term/late preterm infants. Despite its known antiplatelet activity, there have been no increased bleeding complications reported among term or late preterm neonates treated with iNO in randomized clinical trials.

Given the available evidence, including the neurodevelopmental and general medical outcome information, term and late preterm infants with HRF unresponsive to oxygen, ventilator support, and inotrope/volume support of systemic blood pressure should be offered a trial of iNO. This therapy significantly reduces the need for ECMO in non-CDH infants with the number needed to treat (NNT) of 5.3.[13] Infants with CDH complicated by severe HRF and PPHN are unlikely to avoid ECMO with early iNO use.

Transient improvement in oxygenation can be seen with iNO, however, which may stabilize a CDH infant's clinical status prior to the initiation of ECMO or facilitate early surgical repair before ECMO.

Nitric Oxide in Premature Infants

In preterm infants, survival and outcome are limited by RDS and its sequelae, BPD. Findings from a substantial body of experimental work in developing animals suggested that nitric oxide may enhance lung growth and reduce lung inflammation independently of its effects on pulmonary vascular resistance. Improved outcome in term infants with HRF who were treated with iNO furthered the interest that iNO might substantially improve pulmonary outcomes in low birth weight infants, particularly those below 1500 g birth weight. However, the use of iNO was approached with trepidation because of the increased risk of intracranial hemorrhage in this high-risk cohort and nitric oxide's known antiplatelet effect. Early pilot trials confirmed acute improvement in oxygenation in preterm infants with severe HRF treated with iNO. However, survival was not improved, and the rate of intracranial bleeding was alarmingly high.

Several large randomized trials of iNO use in preterms have now been completed in which the primary outcome focused on survival without BPD[37] as well as incidence of intraventricular hemorrhage (IVH). In a single-center trial, Schreiber and colleagues randomized 207 infants with low birth weight (<1500 gm) to treatment with a 7-day course of iNO or placebo starting on the first day of life. The authors reported a 24% reduction in the incidence of BPD and death in the iNO group, largely accrued in the subset of infants with milder respiratory disease (OI < 6.94). A 47% reduction in severe ICH and periventricular leukomalacia (PVL) was also noted.[80] At 2-year follow-up, 24% of the iNO-treated patients had abnormal neurodevelopment compared with 46% of the control group (NNT = 5).[70]

Van Meurs and colleagues enrolled 420 newborns (401-1500 g birth weight) in a multicenter, randomized controlled trial through the NICHD.[93] Only responders (i.e., infants showing improved Pao_2) continued on iNO; the average treatment duration was 76 hours. They found no difference in the incidence of death or BPD at 36 weeks' postmenstrual age between the iNO and control groups. Post hoc analysis revealed that NO reduced these rates in neonates weighing more than 1000 g. However, a higher rate of ICH and PVL, noted in the infants weighing less than 1000 g (43% iNO vs. 33% control), was concerning. An editorial accompanying this manuscript, however, pointed out that Van Meurs and colleagues' patients were smaller, more immature, and had more severe respiratory failure at study entry compared with Schreiber's study, making comparisons between the trials problematic.

In 2006, two large, prospective, randomized trials of iNO in preterm babies were published in the United States. Kinsella and colleagues randomized 793 newborns less than 34 weeks' gestation within 48 hours of birth to 5 ppm iNO versus placebo gas for 21 days or until extubation. OI at study entry was 5.4-5.8. There was no difference in the incidence of death or BPD between groups. However, iNO reduced the incidence of BPD by 50% for infants with birth weights greater than 1000 g ($p = .001$, NNT 3). Low-dose iNO reduced the combined incidence of ICH, PVL, and ventriculomegaly for the entire study population receiving iNO ($p = .032$, NNT 16).[51]

Ballard and colleagues, also in 2006, reported on the outcome of their prospective, randomized, placebo controlled, and masked trial of iNO treatment in preterm infants at risk for BPD (NO CLD Study).[12] Five hundred eighty-two infants who required ventilatory support between 7 and 21 days of age were randomized (birth weight 500-1250 g). Infants were enrolled in the study with an estimated OI between 5 and 9; treatment with iNO versus placebo gas (nitrogen) lasted a minimum of 24 days. The incidence of

survival without BPD was increased in the iNO treatment group (43.9%) compared with controls (36.8%, $p = .04$, NNT 14). This effect was largely noted in those starting treatment between 7 and 14 days of life, suggesting that early treatment is important to prevent BPD. One-year follow-up of study survivors was notable for decreased pulmonary sequelae in the iNO cohort, reflected in decreased medication requirement at 1 year of age.[39]

In 2010, Mercier reported the results of a large, multicenter, masked, placebo-controlled trial of inhaled nitric oxide (iNO) for the prevention of BPD in preterm infants. Eight hundred infants between 24 0/7 and 28 6/7 weeks' gestation were randomized from 36 centers in 9 countries in the European Union. Infants were enrolled within 24 hours of birth and received either low-dose iNO (5 ppm) or placebo (nitrogen gas) for 7-21 days. In this industry-sponsored study, neither survival nor the incidence of BPD at 36 weeks' postmenstrual age was improved with iNO treatment.[69]

Differences in study design, entry criteria, dose, and duration of iNO therapy across 14 prospective randomized trials of iNO therapy in preterm infants make it difficult to understand why this treatment appears efficacious in some studies but not in the majority of infants studied. To address this issue, an individual patient data analysis was performed on the outcomes in 96% of the 3430 individual infants enrolled in these prospective randomized iNO studies. This analysis concluded no statistically significant effect of iNO on death or CLD (59% vs. 61%; relative risk 0.96, confidence interval 0.92-1.01), or severe neurologic events on head imaging (25% vs. 23%; relative risk 1.12, 95% confidence interval 0.98-1.28, $p = .09$). Inclusion or exclusion of the NO CLD study (enrollment after 1 week of life) did not affect the results of this meta-analysis. The authors concluded that use of iNO for treatment of mild to moderate respiratory failure in preterm infants cannot be recommended.[9] Neurodevelopmental outcome reported from six of the 14 trials has shown no adverse effects in iNO-treated preterm infants compared to controls up to 5 years of age. Interestingly, in 2018 Askie reported racial differences in outcome among randomized iNO trials where more than 15% of enrollees were African American. This select cohort appeared to derive considerable benefit from inhaled nitric oxide compared to other races, a factor that had not been previously evaluated. African Americans had a significant reduction in the composite outcome of death or BPD with iNO treatment: 49% treated versus 63% controls, $p = .003$. While mortality was not different between racial groups, African-American infants had a significant reduction in the incidence of BPD: NNT of 7.[10]

Two meta-analyses, including an individual patient analysis of more than 3000 preterm infants enrolled in iNO trials, together with the 2011 NIH Consensus Statement and 2014 AAP Report, all recommending against the use of iNO in premature infants, should have laid to rest the hypothesis that inhaled nitric oxide improves outcomes of preterm infants with mild to moderate respiratory failure.[9,13,21,54] While the common practice of iNO use to prevent BPD has declined substantially, its use in premature infants is far from eliminated.

In fact, the rate of off-label iNO treatment in preterm infants has increased in the years following the NIH Statement discouraging the use of iNO in this population. A query of the Pediatrix Medical Group Data Workhouse on the rate of iNO utilization among 23-29 week preterm infants between 2009 to 2013 revealed an increase in the use of iNO from 5.03%-6.19%, a relative increase of 23%, $p = .003$.[26] Of all neonates who received iNO therapy, nearly half were less than 34 weeks' gestation. With preterm infants accounting for more than half of all "first exposure iNO days" each year of the study period, the authors describe this increased use of iNO in a manner contrary to clinical evidence and expert opinion as "fascinating and provocative." The Canadian Neonatal Network also reported that 4.2% of preterms less than 34 weeks received iNO between 2010 and 2013, with the highest use in the most immature infants. Sixteen percent of infants between 22 and 25 6/7 weeks' gestation received iNO within the first 2 weeks of life.[85] Why is this happening?

The prevailing thought is that there exist subsets of premature infants who, in fact, benefit from the use of iNO but were not addressed in the multiple trials described previously. Small case series of preterm infants, usually <1250 g, who share a history of HRF following premature prolonged rupture of membranes (PPROM) and oligohydramnios, is one such cohort. In a 12-year prospective study from Finland, 2.2% of infants <32 weeks' gestation met criteria for acute HRF with echocardiographic evidence of pulmonary hypertension. All 17 infants had a prenatal diagnosis of PPROM for >7 days; all received iNO following confirmation of PPHN at a median age of 4 hours with good response to iNO reflected in decreased OI and decreased oxygen requirement and ventilator settings. The median duration of iNO treatment was 35 hours; survival was 15/17.[3] The incidence of BPD was high (65%) but was not different between extremely low birth weight (ELBW) infants receiving iNO and well-chosen comparison groups. It would appear, then, that the response to iNO in premature infants associated with PPROM, oligohydramnios, and presumed pulmonary hypoplasia is pathophysiologically similar to classic PPHN in term infants. However, unlike their term counterparts with PPHN, these immature infants are not eligible for ECMO and the majority carry the extra burden of BPD should they survive.

In a retrospective cohort study conducted over a 6 year period, Baczynski reported the short- and long-term outcomes of 89 preterm neonates with acute severe pulmonary hypertension receiving rescue treatment with iNO. The primary outcome was survival without moderate to severe disability at 18 months of age. Forty-six percent of this cohort, with a mean gestational age of 27.7 weeks and 1077 g birth weight, responded to iNO with a decrease in Fio_2 ≥20% within one hour of iNO treatment initiation.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Responders showed improved survival without disability: 51% versus 15%, $p < 0.01$ and lower mortality; 34% versus 71%, $p < 0.01$ compared to nonresponders.[11] The authors reported that preterm infants presenting with acute pulmonary hypertension after 3 days of age rarely responded to iNO therapy, however, particularly when associated with culture positive sepsis.

Nakanishi et al. investigated the characteristics of PPHN in ELBWs and its impact on neurodevelopmental outcome at 3 years of age. Among 12,954 preterm infants born in Japan between 2003 and 2012, the prevalence of PPHN was 8.1% (95%, CI 7.7%-8.6%) with a higher proportion as gestational age decreased: 18.5% for infants born at 22 weeks compared to 4.4% for those born at 27 weeks. The diagnosis of PPHN was determined during the peripartum period, utilizing echocardiographic assessment of pulmonary pressures, and/or greater than 10% difference in the pre- and postductal saturations. Among ELBW survivors seen at 3 years, those who had both BPD and PPHN had the lowest weights and head circumferences, as well as lower developmental quotient (DQ) scores, compared to those with BPD alone or those without BPD or PPHN. Of note, PPHN in this cohort was found to be an independent risk factor for visual impairment, even after adjustment for severe retinopathy of prematurity ≥ stage III. Greater than 60% of ELBWs with PPHN received nitric oxide treatment.[73]

Unfortunately, given the rarity of this finding of acute pulmonary hypertension in infants <32 weeks' gestation, the pursuit of a randomized trial of iNO therapy in this cohort seems unlikely.[32,49,52] Experts in the field of PPHN are particularly concerned about anecdotal reports of third-party payers refusing payment for any use of iNO in any preterm infants following the 2014 AAP statement reporting lack of efficacy of iNO in infants <34 weeks of gestation. The Pediatric Pulmonary Hypertension Network has proposed a prospective registry be established to identify preterms with HRF and PPHN, confirmed by echocardiographic assessment, who are treated with iNO or any other vasodilator as pulmonary hypertension therapy.[49] Although not a randomized control trial, this registry could provide outcome comparisons in premature infants who present with the diagnosis of HRF complicated by PPHN, a sicker cohort not addressed in the 14 randomized trials previously described.

In summary, the available evidence from randomized trials in low birth weight infants with mild to moderate lung disease demonstrates apparent lack of efficacy with iNO therapy. This is disappointing, especially in light of animal data that suggests that NO plays a vital role in lung morphogenesis. An NIH consensus statement on the use of iNO in preterm infants does not endorse the routine use of iNO, given the lack of consistent evidence. However, it does state that in rare clinical situations (i.e., pulmonary hypertension or pulmonary hypoplasia), iNO may be of benefit to preterm infants, but the risks and benefits as well as long-term uncertainties of use of this therapy in infants less than 34 weeks' gestation must be communicated with the parents.[21]

Alternative Treatments and Avenues for Future Research

Future clinical trials of nitric oxide will better define the neonatal subgroups for whom this inhalational treatment is efficacious. The optimum dose, when to start treatment, and how long to continue therapy require further refinement. For the 40%-50% of term and late preterm newborns with PPHN who fail to respond to iNO, or who do not sustain improvement in oxygenation, other drugs are now available for study. Particularly in countries with limited medical resources, alternative treatment to costly iNO or ECMO would be most welcome.

An alternate approach to the treatment of PPHN is to augment endogenous vasodilator therapy by inhibiting the rapid degradation of cyclic nucleotide second messengers, cGMP and cAMP, which play a central role in modulating smooth muscle relaxation in the pulmonary vascular bed. Phosphodiesterases (PDEs) have a wide distribution in normal mammalian tissues, with more than 11 distinct families based on substrate specificity and sensitivity. The neonatal lung is particularly rich in PDE5 and PDE3. PDE5 inhibitors block the degradation of cyclic GMP (NO pathway), and PDE3 blocks the degradation of cyclic AMP (prostacyclin pathway), both of which potentiate vasodilation.

Sildenafil is a specific PDE5 inhibitor marketed as Revatio for pulmonary hypertension and as Viagra for erectile dysfunction. In a double-blind, randomized, placebo-controlled study in 278 adults with primary pulmonary hypertension, sildenafil reduced mean pulmonary artery pressure and improved functional class of disease severity over 12 weeks of treatment. Sustained improvement over 1 year of treatment with sildenafil in adults with pulmonary arterial hypertension (PAH) was also confirmed, leading to U.S. Food and Drug Administration (FDA) approval for this drug in adults with PAH.[34] However, safety and efficacy of sildenafil to treat pulmonary hypertension in the pediatric and neonatal populations has not yet been established. Barst and colleagues studied the use of sildenafil in pediatric patients with pulmonary hypertension.[14] They randomized 235 children (ages 1-17 years old) who were treatment naïve to receive either a low, moderate, or high dose of sildenafil. All doses were well tolerated by their subjects. There was no difference in those treated with low-dose when compared to placebo, but improved outcomes were found in those treated with a moderate or high dose. However, in long-term follow-up at 3 years, those who were treated with high-dose sildenafil had a higher risk of death, although mortality rate was lower than that of the natural history of the disease. Based on the increased risk of death in the high-dose group and ineffectiveness of the low-dose group, the FDA published a warning on the use of oral sildenafil in pediatric patients, particularly for long-term use.

There have been several small studies on the use of sildenafil in neonates with PPHN.[76] Four of these trials, including 137 patients, evaluated the use of sildenafil versus placebo in term or near term infants with PPHN. The trials reported that sildenafil improved oxygenation and decreased mortality in the treatment group, 5.9% versus 44% in controls.[46] These studies were conducted in resource-limited countries where HFV, iNO, and ECMO were not available.

In 2009, Steinhorn et al. published a study on the kinetics of intravenous sildenafil in 36 newborn infants with PPHN.[87] Affected infants were treated within 72 hours of birth for a mean duration of 77 hours. Sildenafil clearance increased rapidly over the first 7 days of life, presumably because of increased hepatic clearance. Adverse side effects were mild to moderate in severity and included hypotension (three subjects), labile blood pressure (one subject), and PDA (one subject). These data will pave the way for future clinical trials of this drug in newborns who are particularly sensitive to systemic vasodilation and $\dot{V}/\dot{Q}$ mismatch.

Large, prospective, randomized studies investigating the safety and efficacy of sildenafil as a single treatment agent or in combination with iNO for refractory PPHN have yet to be reported. Fortunately, a multicenter randomized clinical trial to test the efficacy of sildenafil in iNO-resistant PPHN is nearing completion (NCT01720524). For the time being, however, the benefit and safety of sildenafil remain uncertain in term and premature infants in settings where HFV and iNO are available for treatment of PPHN.

Milrinone, a PDE3 inhibitor, is widely used in intensive care as an inotrope and afterload-reducing agent. It has been described in case series to be useful in the treatment of PPHN, particularly in the face of left ventricular dysfunction.[55] Infants with PPHN refractory to iNO therapy have responded favorably to IV milrinone.[68] Prostacyclin (PGI_2) (Flolan, epoprostenol sodium), which causes pulmonary vascular relaxation through upregulation of cyclic AMP levels, has emerged as one of the primary chronic treatments of idiopathic pulmonary hypertension in adults and children, wherein the drug is delivered by continuous intravenous infusion in nanogram doses.[66] Systemic hypotension has been a limiting factor in neonatal use. All PGI_2 analogs have the limitation of an extremely short half-life and variable effects on systemic blood pressure. Prostacyclin analogs currently approved for adult use include the following[56]:

- Epoprostenol (intravenous)
- Iloprost (intravenous and inhaled)
- Treprostinil (oral, intravenous, and subcutaneous)
- Beraprost (oral)

Randomized trials of IV prostacyclin in PPHN have not been done as hypotension is a major concern. Iloprost has proven efficacious in adults with pulmonary hypertension and has been successful in small case series of PPHN. Its drawback is the requirement for aerosol treatments 8-10 times per day. In the NICU, given the time frame of PPHN, this could be achievable for short-term use. Blood pressure instability remains an issue with iloprost, as with any prostanoid; therefore, its use should be confined to investigational pilot trials for the time being.[2] Randomized trials, especially with inhalational prostanoids, would be most welcome.

Endothelin is a potent vasoconstrictor and a smooth muscle mitogen that may contribute to the development of PPHN. Increased endothelin levels have been measured in newborns with PPHN. Medications are available that block the endothelin receptors on vascular smooth muscle cells in the lung and ameliorate pulmonary vasoconstriction in adults with pulmonary hypertension. Bosentan is the most widely studied of these and is approved by the FDA for the treatment of pulmonary hypertension in adults. Bosentan improved cardiac index and reduced mean pulmonary arterial pressure (PAP) and pulmonary vascular resistance (PVR); functional class also improved in adult patients treated with bosentan. Liver toxicity, which appears to be dose dependent, is seen in 25% of bosentan-treated adults.[2]

There have been two small, randomized, placebo-controlled trials of oral bosentan in PPHN. In a study of 47 infants with PPHN comparing bosentan to placebo in iNO naïve newborns, oxygenation improved in the treatment group and ventilator days were fewer in those receiving bosentan (4.3 days vs. 11.5 days). Survival was no different between the groups.[71] A multicenter trial (FUTURE 4 study) conducted over 2 years enrolled 21 infants with hypoxic respiratory failure and PPHN to receive bosentan ($n = 13$) versus placebo ($n = 8$). All infants were already receiving nitric oxide. The time to weaning from nitric oxide or the ventilator was not improved in the treatment group. Furthermore, it took 5 days for the blood concentration of bosentan to reach study state in the treated infants, which may have contributed to its lack of efficacy in acute PPHN.[86]

As with many new therapies, early reports of treatment response to iNO were almost euphoric. Randomized controlled trials have proven the efficacy of this inhaled vasodilator in mature infants with PPHN, but they have also tempered our enthusiasm with the reality that up to 40% of affected newborns with severe respiratory failure will not respond to iNO, many of whom still require ECMO support.

Last, the treatment of late-onset pulmonary hypertension in surviving infants with very low birth weight and BPD has emerged as a serious therapeutic challenge. Mortality in this cohort is high, and treatment with a variety of pulmonary vasodilators is being used with little evidence for which drug combinations are efficacious.[2,40] A study of patients with BPD and pulmonary hypertension reported survival rates of 64% at 6 months and 52% at 2 years after the diagnosis of pulmonary hypertension.[48] Mourani and coworkers reported the effects of long-term sildenafil use for the treatment of pulmonary hypertension in infants younger than 2 years with chronic lung disease stemming from the neonatal period.[72] Eighteen of 25 were infants with low birth weight and BPD. The drug was judged to be well tolerated and effective in treated patients; median treatment duration was 241 days (range 28-950 days). However, 28%

of treated patients also received other drugs for pulmonary vasodilation, including iNO, calcium channel blockers, milrinone, and bosentan. Five of the 25 (20%) died during the 8-month follow-up period, emphasizing the vulnerability of this uniquely fragile cohort of NICU graduates.

Adjunctive therapies, such as those discussed above, appear promising and may enhance the benefit of iNO or replace this inhalational agent altogether. Within the relatively short period of neonatal intensive care, the discovery and use of one selective pulmonary vasodilator, namely iNO, represents a significant advance in the management of PPHN. Hopefully, we can look forward to several treatment options for pulmonary hypertension in newborns once the therapeutic efficacy of these agents has been rigorously tested.

Key Points

- ECMO is a heart/lung mechanical support for mature neonates with severe hypoxic respiratory failure/PPHN who have not responded to ventilatory support or inhaled nitric oxide.
- Venovenous bypass is the preferred mode of ECMO support, but venoarterial bypass is required if the infant's cardiac output is not sufficient to meet oxygen delivery needs.
- Survival of ECMO patients in the NICU is tied to their underlying diagnosis, for example, 50% survival in CDH infants versus 90% survival in meconium aspiration syndrome infants.
- The number of infants requiring ECMO support for hypoxic respiratory failure in the United States has declined more than 50% over the past 25 years.
- In mature newborns with respiratory failure, the use of inhaled nitric oxide has been shown in multiple prospective randomized trials to significantly reduce the need for ECMO.
- Inhaled nitric oxide in premature infants with mild to moderate lung disease does not improve survival or prevent BPD.
- Pulmonary hypertension develops in up to 20% of infants with BPD, worsening survival in this high-risk cohort.

Cardiac Embryology

STEPHANIE M. FORD, MICHIKO WATANABE, AND ERIC J. DEVANEY

Introduction

Congenital heart defects (CHDs) affect about 1% of all live births around the world, with variations in reporting depending on birth rates and access to medical care.[73] The care of children with CHDs has increasingly become a neonatal specialty, aided by prenatal detection. The fetal diagnosis of critical CHDs decreases postsurgical morbidity and mortality,[27] and reparative or palliative cardiovascular surgery is commonplace in the first months of life. This success has led to a larger population of adults with CHDs and an expansion of a subspecialty for the care of these individuals. In parallel with these clinical advances, there has been exciting progress in understanding the cellular and molecular basis of normal and abnormal cardiogenesis and the relationship of heart defects to other congenital defects. The global incidence of CHDs has not decreased and has in fact increased as prenatal detection becomes more common worldwide.[73] Yet our knowledge of the pathogenesis of CHDs is far from complete. Understanding normal and abnormal cardiac embryology is critical to understanding the pathology underlying CHDs and ultimately their prevention.

The mature heart is the product of gene expression driven by endogenous and exogenous influences. The developing heart manifests its morphologic and physiologic plasticity under environmental stimuli. A detailed understanding of the factors that drive normal cardiogenesis is necessary for understanding the causes and consequences of abnormal development. Errors in cardiac morphogenesis involved with septation, valve formation, and proper patterning of the great vessels are responsible for most forms of CHDs. Normal heart development requires precise timing for coordination of the complex three-dimensional contortions of tissues; but paradoxically, these tissues also have a remarkable capacity for modification that compensate for mistakes. These adjustments allow abnormal heart structures and resultant function to be compatible with life up to and even after birth, but they complicate identification of the primary causes of cardiac anomalies. This chapter will focus on clinically relevant aspects of cardiac embryology and how disruptions of this process may lead to CHDs.

Overview of Normal Heart Development

The following description of human heart development, especially the earlier events, is synthesized from information provided by studies of animal models and human embryonic and fetal tissues. A timetable of selected events in human heart development is presented in Fig. 71.1,[63] which depicts the major transitions in early mammalian heart development.

The primordia of the heart are formed by bilaterally symmetric heart fields derived from the lateral plate mesoderm. These primordia migrate through the primitive streak, between the ectoderm and endoderm layers, to become symmetric mesoderm regions on either side of the primitive streak. During body folding, the primary heart fields fuse cranially and ventrally to form a tubular structure comprising an inner layer of endocardium, a thick layer of extracellular matrix, and an outer layer of myocardium. This apparently "simple" tube begins to contract rhythmically and grows differentially so that dilations (primordia of the heart chambers) and constrictions (primordia of the partitions between chambers) appear along its length. Later additions from the second heart field to the distal ends of the tubular heart form the outflow tract (OFT) and the sinus venosus. Dextral looping of the tube brings the venous caudal portion to a more dorsal position and to the left of the arterial cranial portion as septation of the tubular heart begins. The epicardium arises from tissue dorsal to the heart at the level of the atrioventricular (AV) junction and spreads over the outer surface of the myocardium as a layer of squamous epithelial cells and associated connective tissue during the early phase of septation.

The atrial chamber divides into two chambers by the growth of the septum primum, which forms perforations to create the foramen secundum. A second atrial septum subsequently grows to the right of the primary atrial septum and forms a one-way valve (right-to-left blood flow) between the two atria in the fetus. This avenue of blood flow, the foramen ovale, is permanently closed shortly after birth to functionally complete atrial septation. Ventricular septation is not complete at the time the primary atrial septum is formed. The ventricular septum results from the growth and remodeling of trabecular sheets, continues with

Abstract

Congenital heart defects (CHDs) affect about 1% of all live births worldwide, with variations in reporting depending on birth rates and access to medical care. The fetal diagnosis of critical CHDs decreases postsurgical morbidity and mortality, and reparative or palliative cardiovascular surgery is commonplace in the first months of life. This success has led to a larger population of adults with CHDs and an expansion of a subspecialty for the care of these individuals. Along with these clinical advances, there has been exciting progress in understanding the basis of normal and abnormal cardiogenesis. The global incidence of CHDs has not decreased and has, in fact, increased as prenatal detection becomes more common worldwide. Yet our knowledge of the pathogenesis of CHDs is far from complete. Understanding normal and abnormal cardiac embryology is critical to understanding the pathology underlying CHDs and ultimately their prevention. The mature heart is the product of gene expression driven by endogenous and exogenous influences. Understanding the effects of the factors that drive normal cardiogenesis is necessary for understanding the causes of abnormal development. Errors in cardiac morphogenesis involved with septation, valve formation, and proper patterning of the great vessels are responsible for most forms of CHDs. This chapter will focus on clinically relevant aspects of cardiac embryology that when disrupted lead to CHDs and touches on the efforts to predict, alleviate, and prevent CHDs.

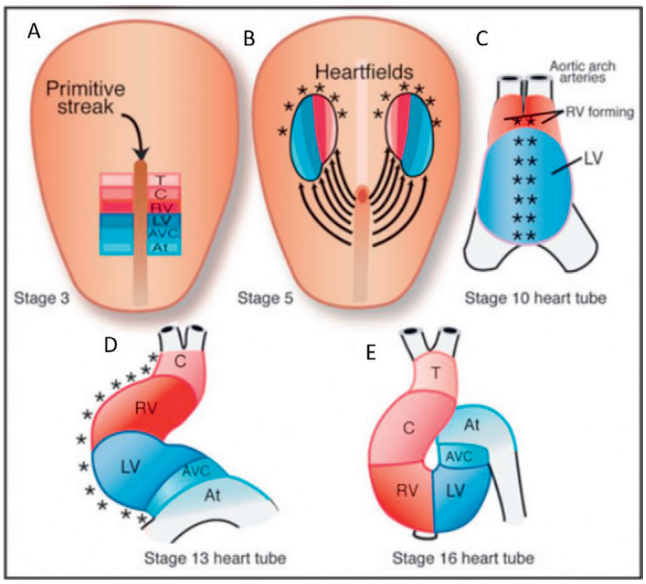
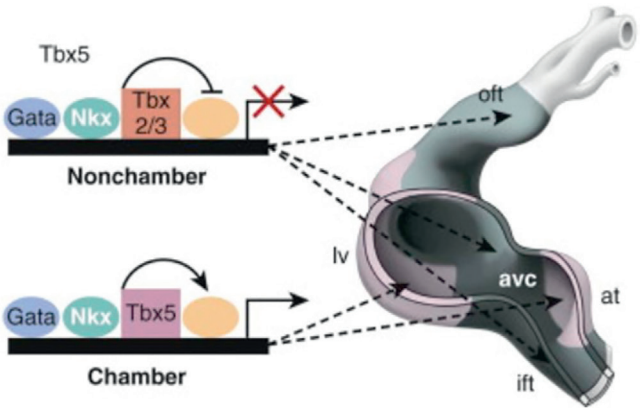
• **Fig. 71.1** Overview of cardiac embryology in human gestation. (From Schoenwolf G, Bleyl S, Brauer P, Francis-West P. *Larsen's human embryology.* 5th ed. Churchill Livingstone; 2014.[63])

expansion of the ventricular chambers, and ends with the fusion of several tissues, including endocardial cushions from several sources and the muscular septum, to form the membranous and muscular interventricular septum. The outflow tract septation is the result of growth and fusion of spiraling ridges that eventually divide the truncus into aortic and pulmonary tracts. The venous and arterial vessels (aortic arches) undergo partial incorporation into cardiac chambers, differential degeneration, fusion, and growth to attain the mature structures.



The human heart has completed the major morphogenetic processes 8 weeks after fertilization. What follows is the completion of maturation of structures, growth, accumulation of cellular junctions at the intercalated discs, biochemical and metabolic adjustments, and compensation for the abrupt changes in patterns of blood flow at birth, such as permanent closure of the foramen ovale of the atrial septum and closure and fibrosis of the ductus arteriosus and ductus venosus.

Scientific Basis of Cardiogenesis



Precardiac to Cardiac Tissues: Commitment and Formation of Primary Axes

The tissue regions giving rise to the heart have been mapped by the application of dyes, particles, and radiolabels at stages when the vertebrate embryo comprises two layers: the epiblast (or primitive ectoderm) and the hypoblast (or primitive endoderm). The process of gastrulation, the movement of precardiac epiblast cells through the primitive streak, appears to be important in specification (Fig. 71.2*A*).[37]

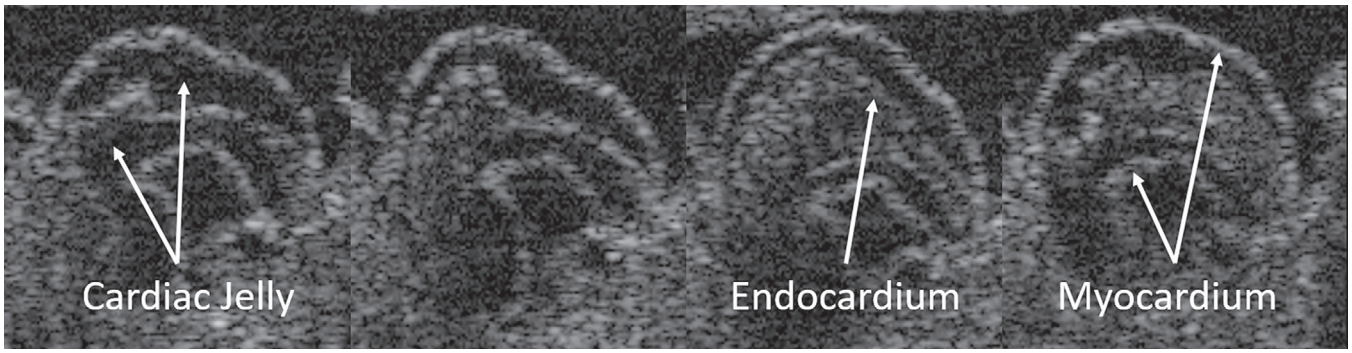
Cranial sections marked by asterisks **(B)** become the ventral portion of the heart tube **(C)** and later the right-most border of the looping heart **(D)**. At, Atrium; AVC, atrioventricular canal; C, conus; LV, left ventricle; RV, right ventricle; T, truncus. (Adapted from Kirby M. *Cardiac development.* Oxford University Press; 2007.[37])

• **Fig. 71.3** Model of transcription regulation of cardiac chamber and nonchamber genes. *NKX2.5, GATA4*, and *TBX5* are widely expressed in the developing heart and promote chamber-specific gene expression (chamber), whereas *TBX2* and *TBX3* are differentially expressed and inhibit chamber-specific gene expression by competing with *TBX5* binding (nonchamber). Chambers are the left ventricle (*lv*) and the atrium (*at*). Nonchamber regions include the outflow tract (*oft*), atrioventricular canal (*avc*), and inflow tract (*ift*). These proteins bind to DNA at specific sequences that are involved in controlling gene expression. The combinatorial effect of the binding of these proteins depresses or stimulates the transcription of cardiac-specific genes. (Modified from Christoffels VM, Burch JBE, Moorman AFM. Architectural plan for the heart: early patterning and delineation of the chambers and the nodes. *Trends Cardiovasc Med.* 2004;14(8):301-307.[12])

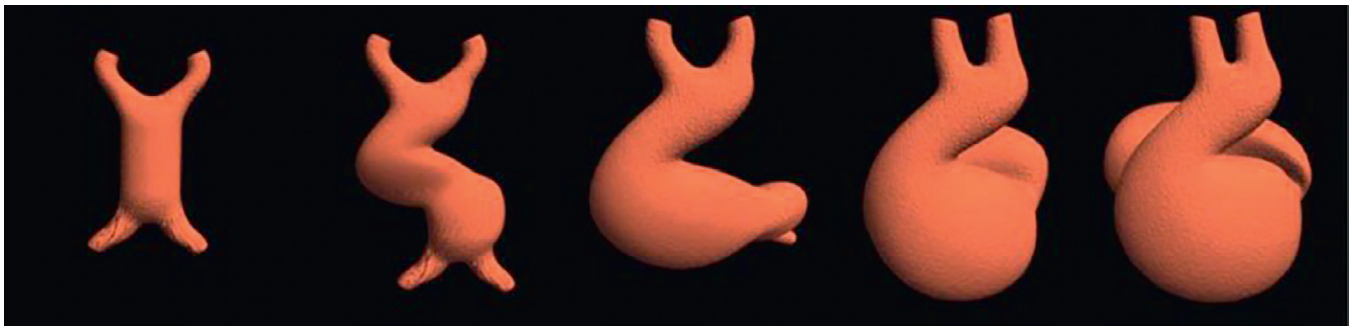
These cells migrate laterally to form the left and right heart fields (see Fig. 71.2*B*), which then create the horseshoe-shaped first and second heart fields around the end of the primitive streak, the primitive node. The second heart fields are adjacent to and influenced by cardiac neural crest cells, a process critical to understanding how the later steps in cardiogenesis are affected by neural crest–associated genetic syndromes.

Transcription factors are proteins that bind as part of complexes to specific DNA sequences and influence the expression of genes (Fig. 71.3).[12,18] Such factors influence many aspects of cardiogenesis[18] and include members of the following families: the helix-loop-helix proteins (dHand and eHand), zinc finger proteins (GATAs), homeobox gene proteins (NKX2.5), and MADS box proteins related to serum response factor. Of the zinc finger proteins, GATA4, 5, and 6 are much-studied members of the evolutionarily conserved transcription factor subfamily that recognizes a "GATA" DNA sequence motif. These have been implicated in the early specification of embryonic tissue destined to become heart.



An example from the homeobox gene family demonstrates how the study of fruit flies has advanced our understanding of human heart development. The dorsal vessel pumps hemolymph (insect blood) and is considered the insect heart. It is derived from mesoderm under the influence of homeobox genes. The mutation of one of these genes, *tinman*, results in absence of the dorsal vessel. Frog and mouse homologues of these homeobox genes were identified and localized in expression to the developing heart. Transgenic mice lacking a *tinman* homologue (*NKX2.5*) do not lack hearts but die at 9 days of development with severely abnormal hearts.[44] Humans in whom the *tinman* homologue *NKX2.5* is mutated suffer atrial septal defects with associated AV conduction delay and other complications.[56,67,68] The fruit fly findings led to the study of a set of genes critically important to many aspects of human heart development.

The Tubular and Looping Heart



Within each side of the first heart fields primitive endocardial tubes form, come together, and fuse as the lateral body portions fold to create the primitive heart tube. The most caudal cells of the right and left heart fields will form the most ventral portion of the primitive heart tube (asterisks in Fig. 71.2). The inflow portion of the heart quickly gains pacemaker activity and initiates slow, unidirectional contractions along the tube. Concurrent with this process, endocardial and myocardial cells—which form the layers of the developing heart—emerge from a common precursor.[41] The myocardium secretes a thick layer of acellular extracellular matrix, also known as cardiac jelly, which creates a distinct layer between the myocardium and the endocardium (Fig. 71.4). This tissue progression requires cell differentiation, sorting, and polarization. Evidence supports both negative and positive influences from the surrounding neural tissue and endoderm on these processes.

The primitive heart tube undergoes three connected steps, looping, convergence, and wedging, all of which are

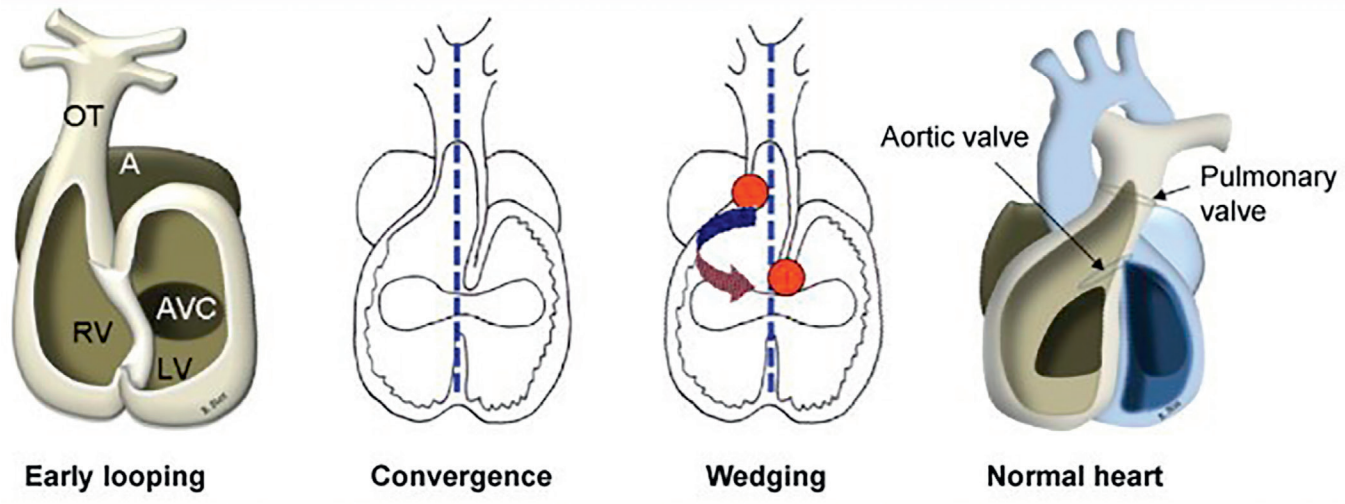
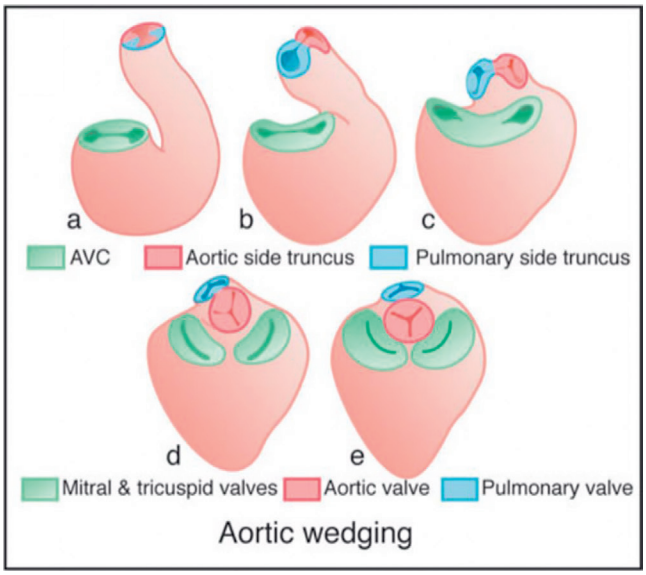
• **Fig. 71.4** In vivo images of a quail heart. The images demonstrate portions of the cardiac cycle in a stage 14 quail embryo. The cardiac jelly is an acellular (black) layer between the myocardium and the endocardium.



• **Fig. 71.5** The progression of looping in the tubular heart. (Modified from Schleich J-M, Abdulla T, Summers R, Houyel L. An overview of cardiac morphogenesis. *Arch Cardiovasc Dis*. 2013;106(11): 612-623.[62])

crucial to normal cardiac septation. Looping is the first obvious structural left–right lateralization in the developing embryo (Fig. 71.5). The heart tube elongates and folds into an "S" shape to the right. The direction of looping will determine the ultimate ventricular positions. Looping to the right will give the normal Dextro, or "D," looping. If the primitive tube loops to the left, this will result in Levo, or "L," looping and result in the left ventricle on the right side and the right ventricle on the left side. The left–right handedness of looping is directed by monocilia in the primitive node many stages before looping starts. These cilia are angled 40 degrees posterior and rotate in a clockwise direction, resulting in a leftward laminar flow of fluid containing key signaling molecules. Mutations in genes responsible for ciliary ultrastructure result in syndromes such as Kartagener syndrome.[28] Importantly, the primitive atrium is not involved in this portion of looping, so atrial position is not severely disturbed by abnormal looping. Atrial positions are affected by situs abnormalities as seen in heterotaxy syndromes. Left–right embryologic abnormalities have a wide range of known genetic causes in which mutations interfere with early breaking of left–right symmetry, abnormal signal transduction or gene expression in the lateral plate mesoderm, and abnormal morphogenesis of internal organs.[16]



Convergence is the process of proper orientation of the inflow and outflow tracts (Fig. 71.6). The inflow tract rises cranially behind the outflow tract such that the inflow and outflow tracts are aligned, with the outflow tract ventral to the inflow tract. Abnormalities can lead to irregularities in atrial and ventricular septa and outflow tracts. Convergence and looping are dependent on lengthening of the polar ends of the heart tube, which is achieved by the addition of cells from the second heart field. The original primitive heart tube will grow to become the left ventricle and portions of the atrioventricular canal, and additions from the second heat field will direct formation of the outflow tracts, right ventricle, and atria. As cardiac neural crest cells influence the second heart field, it becomes easier to understand how neural crest cell–associated disease such as DiGeorge syndrome, 22q11 deletion syndromes, and velocardiofacial syndromes result in abnormalities of these cardiovascular structures.

Occurring in parallel with convergence and septation (see Figs. 71.5 and 71.6) is wedging (Fig. 71.7). Here, the outflow tract rotates counterclockwise approximately 45 degrees, resulting in the future aorta residing behind the future pulmonary artery (see Fig. 71.7). The aortic portion shortens, and the future site of the aortic valve "wedges" between the future tricuspid and mitral valves. This separates the mitral valve from the septum, which is why the mitral valve has no connections to the septal wall. Irregularities in wedging result in conotruncal defects such as tetralogy of Fallot and double outlet right ventricle.

How is the program for cardiac muscle differentiation turned on and regulated? This question has been approached by studying the transcription factors that bind to promoter regions of the cardiac-specific cytoskeletal genes coding for molecules that appear in the early tubular heart. The discovery of MyoD, a helix-loop-helix DNA-binding protein that controls skeletal muscle expression, led investigators to search for similar factors in cardiac muscle. Current findings support the idea that both positive and negative regulators of cardiac genes exist and that they work in complexes that define the spatiotemporal pattern of expression of cardiac genes (see Fig. 71.3).

Closely related to the question of cardiac-specific gene regulation is the question of regional specification of the heart tube. Segmentation, although not as obvious in the vertebrate heart as it is in the insect body plan, is important in cardiogenesis. Chamber-specific expression of a number of endogenous genes and promoter-driven reporter genes suggests that the outflow tract, the left and right ventricles, the atria, and the sinus venosus can in some cases be considered separate cardiac segments. However, many of the endogenous cardiac genes do not strictly follow chamber-specific expression but rather appear to be modularly controlled based on their position along the anteroposterior axis[25] (see Fig. 71.2).

An understanding of segment specification has been greatly advanced by the study of the homeobox genes in the fruit fly.[1] The identity and differentiation of segments are determined by interactions among homeobox and other genes. These interactions occur in the mesoderm, which gives rise to the heart tissues and the tissues adjacent to the mesoderm.

The vertebrate heart tube normally loops to the right side of the embryo. Sidedness appears to be influenced by factors acting at a time when the heart is not recognizable as a distinct organ structure.[58] Transplantation studies using the early chicken embryo suggest that left and right sidedness are already determined in the precardiac mesoderm stages. Sidedness can also be regulated in part by retinoids. Retinoic acid–soaked bead implants in chicken embryos or application of all-*trans* retinoic acid in mouse embryos cause transposition of the great arteries.[32] Abnormalities in the direction of cardiac looping also occur in humans.[8] These abnormalities are linked to an autosomal recessive gene defect that has been detected in the Amish population and

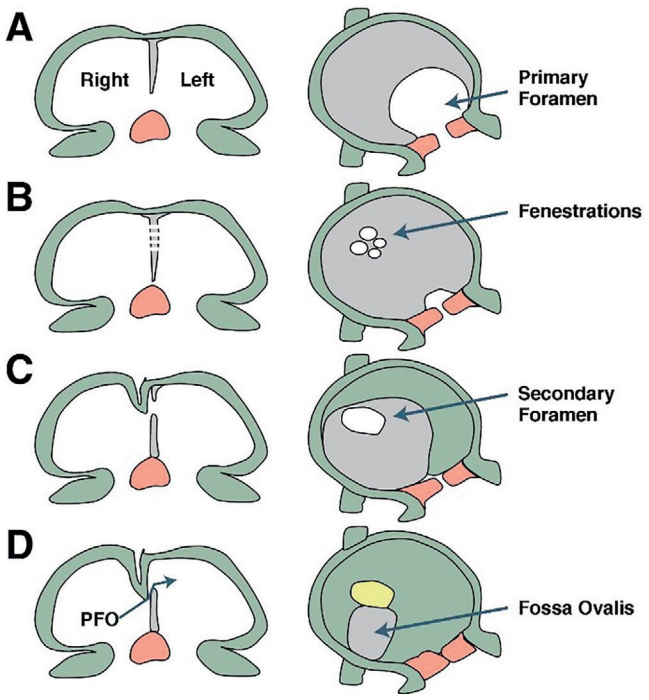
another gene defect in the X chromosome (Xq24-q27.1) in the general population.[9] Interestingly, abnormalities in genes associated with left–right asymmetry may also be responsible for apparently isolated cases of congenital heart defects. Mutations in the laterality *CFC1* gene have manifested as transposition of the great arteries in humans without other obvious laterality defects.

Two mouse mutants have abnormalities in sidedness. The iv/iv mutant mouse develops L-looping and dextrocardia 50% of the time.[29] A large percentage of these mice have a combination of cardiac defects, including persistent sinus venosus, atrial and ventricular septal defects, common AV canal, double-outlet right ventricle, tetralogy of Fallot, and transposition of the great arteries. This gene has been mapped to mouse chromosome 12, which is homologous to human chromosome 14. The *inv/inv* mutant mouse develops *situs inversus* close to 100% of the time.[75] Mutation screens using the zebrafish have uncovered a number of genes involved in laterality specification and indicate that there are organ-specific laterality regulators.[11] Identification of the genes involved in these human, mouse, and zebrafish mutations could provide valuable insight into the mechanisms of normal dextral looping of the heart.[4]

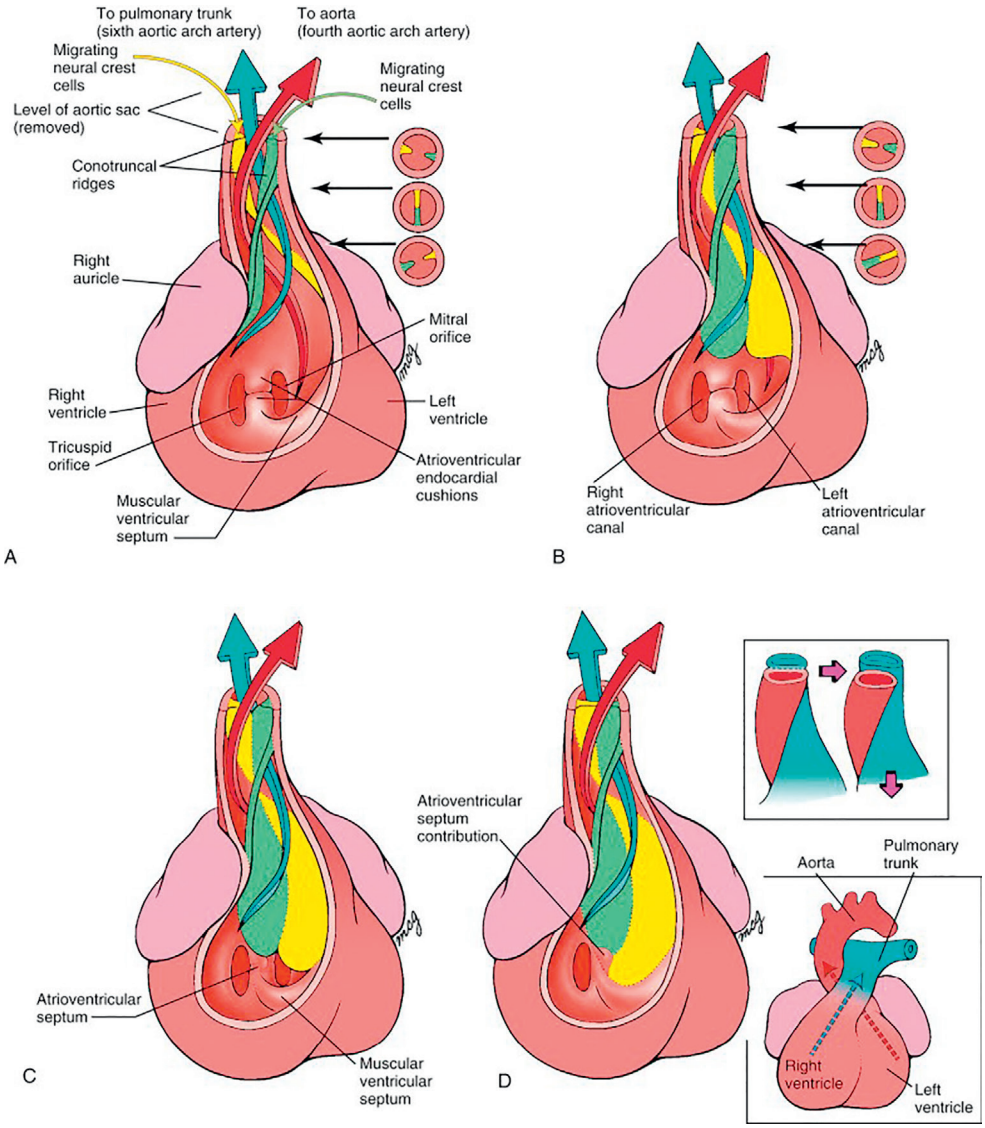
Septation



Endocardial Development: Formation of Cushion Tissue

Septation of the heart begins with the swelling of the extracellular matrix between the endocardium and the myocardium at specific regions of the heart tube. These regions include the AV junction, the outflow tract, the leading edge of the primary atrial septum, and the ridge of the interventricular septum. A complex set of inductive events has been elucidated by studying cushion formation of the AV junction and the outflow tract.[54] These events include signaling between the specialized myocardium and a subset of competent endocardial cells through growth factors (e.g., transforming growth factor-βs [TGFβs], vascular endothelial growth factor [VEGFs], bone morphogenetic proteins [BMPs]) and extracellular matrix molecules. Various proteases and homeobox genes are also involved.

The subsequent cascade of events includes release and migration of cells from the endocardial epithelium (termed *endothelial-mesenchymal transition*, EMT) into the previously acellular cardiac jelly and proliferation, death, and differentiation of these endocardial mesenchyme cells within a complex matrix. In the outflow tract, the cushions are also populated by cardiac neural crest cells. The endocardial cushions of the AV junction are also invaded by cells originating from the embryonic epicardium. The cushions eventually give rise to, or at least greatly influence, the subsequent development of septa and valves of the heart. Because a number of factors, cell types, and tissues are involved in this process at multiple levels and at different stages, there are many sites where mistakes can occur. It is, therefore, not surprising that septation defects are so common. The differentiation of resilient valves requires remodeling of the extracellular matrix, an aspect that is poorly understood. However, it has been revealed that steps in cardiac valve differentiation and maturation share mechanisms with those of cartilage, tendon, and bone development.[42]



In the primitive atrium, a ring of tissue, the septum primum, grows toward the endocardial cushions near the AV junction (Fig. 71.8). Through apoptosis, fenestrations form in this tissue, creating the osteum secundum. The osteum primum, between the tip of this outgrowth of the septum primum and the endocardial cushion, closes as the tissue advances. The atrial roof folds inward, and the septum secundum begins to grow down on the right of the septum primum and continues in a crescent shape to form to the right of the base of the septum primum. This makes the septum primum a flap over the foramen ovale, allowing only right-to-left flow across the atria.

Ventricular and outflow tract septation occur in tandem, and aberrations in one may have structural consequences for the other. The myocardium from the outer curvature of the ventricle invaginates, growing cranially. AV canal endocardial cushions grow toward the myocardium, completing the ventricular septum. Outflow tract endocardial cushions form ridges that spiral along the conotruncus (Fig. 71.9).

• **Fig. 71.8** Atrial septation. The septum primum extends from the roof of the common atrium toward the endocardial cushion **(A)**. Fenestrations appear, creating the osteum primum **(B)**, and then the septum secundum descends from the roof of the atrium to the right of the septum primum **(C)**, covering the osteum primum. This creates the patent foramen ovale (*PFO*) through which blood can flow in a right-to-left direction but not in the reverse **(D)**. (Modified from Rana BS, Thomas MR, Calvert PA, et al. Echocardiographic evaluation of patent foramen ovale prior to device closure. *JACC Cardiovasc Imaging.* 2010;3(7):749-760.[59])

• **Fig. 71.9** Septation of the ventricles and conotruncus. A portion of the right ventricle has been removed to show the positions of the outflow tracts. Conotruncal ridges (*yellow and green*) grow from the outflow tract, creating a spiral septum represented here at multiples levels in **(A-B)**. This septum separates the aortic and pulmonary outflow tracts. The conotruncal septum then extends to the muscular portion of the ventricular and atrial septa, completing the ventricular septum **(C-D)**. (Adapted from Schoenwolf G, Bleyl S, Brauer P, Francis-West P. *Larsen's human embryology.* 5th ed. Churchill Livingstone; 2014.[63])

These ridges grow together to divide the conotruncus into the trunks of the aorta and pulmonary arteries. The AV canal and outflow tract endocardial cushions join, completing ventricular septation.

Endocardial cushions act as primitive valves and include the precursor cells of mature valves. During EMT, TGF-B and Notch signaling induce endothelial cells to adopt an invasive phenotype, and cells invade the previously acellular cardiac jelly. These cells adopt a mesenchymal phenotype to create fibrous tissue and collagen (Fig. 71.10). As the cushions grow, they delaminate from the myocardium, forming thin strands (chordae tendineae) that attach to outgrowths of myocardium (papillary muscles). The tricuspid valve attaches to papillary muscles on the interventricular septum as well as the free wall of the right ventricle. The mitral valve, however, has attachments only to the apex and the free wall of the left ventricle. Septal attachments do not form because the aortic valve displaces the primitive mitral valve from the septum during wedging. These early valve differences help identify ventricles during fetal and neonatal echocardiography.

Semilunar valve formation is similar to that of the AV valves. However, the apical surfaces of the valve leaflets develop depressions, eventually molding the leaflets into cusps (see Fig. 71.10). The arterial surface of the cusps become a more condensed fibrous tissue. Rather than chordae tendineae and papillary muscles, the leaflets extend attachments into the vessel walls to anchor them.

• **Fig. 71.10** Atrioventricular (AV) and semilunar valve formation. During looping, the myocardium secretes cardiac jelly, which is a gelatinous matrix rich in hyaluronan. Some of the myocardial cells lining these regions release factors that activate a subset of the overlaying endocardium, resulting in select endocardial cells that invade the cardiac jelly and assume a mesenchymal phenotype. This process is known as endothelial-mesenchymal transition (EMT). These cells proliferate, migrate, and differentiate. In AV valves, the portion of the cushions adjacent to the underlying myocardium differentiates onto a fibroblastic phenotype. Fenestrations develop and coalesce beneath this layer, resulting in delamination of the tissue from the developing cushion. Fenestrations also develop in the residual mesenchymal tissue strands, and these will develop into the tendinous cords of the AV valves. Semilunar valves form similarly, but instead of delaminating, they form conical depressions facing the myocardium in a process called excavation. Fibrous tissue radiates from the primitive valve cusps into the myocardial wall, anchoring the valve leaflets. (From Butcher JT, Markwald RR. Valvulogenesis: the moving target. *Philos Trans R Soc Lond B Biol Sci.* 2007;362(1484):1489-1503.[6])

Neural Crest Contributions to Cardiogenesis

A subset of neural crest cells that originate and migrate from the dorsal region of the neural tube contributes significantly to the development of the heart and associated vessels (Fig. 71.11).[30,47] The role of the neural crest has been determined by the study of avian embryos using immunohistochemical neural crest markers, transplantation (quail-chicken chimeras), ablation, and genetic manipulation of mice. The neural crest cells from the cranial and trunk regions contribute to the walls of the aortic arch arteries, including the proximal aorta, the stems of the proximal coronary arteries, and the sympathetic and parasympathetic innervation of the heart (including the cardiac ganglia). A subset enters the heart within the endocardium and is involved in septation of the aortic and pulmonary trunk. A subset also appears to enter the heart and regulates the formation and maturation of the cardiac conduction system.[24]

Neural crest cells migrate from the cranial region of the neural folds through the pharyngeal arches and contribute to the aorticopulmonary septum and the tunica media of the great arteries that branch from the aorta. Removal of this subset of neural crest cells causes cardiac inflow anomalies, including double-inlet left ventricle, tricuspid atresia, and straddling tricuspid valve; cardiac outflow anomalies, including persistent truncus arteriosus; and abnormalities in the aortic arch arteries, including interruption of the aorta, double aortic arch, variable absence of the carotid arteries, and left aortic arch. In contrast, the systemic and pulmonary venous structures are not as affected by cardiac neural crest ablation.

• **Fig. 71.11** Origins of the endothelium: The ventral surface of the mouse heart with the sinus venosus-derived endothelial cells is labeled yellow (*left panel*) and the endocardial-derived cells are in green (*right panel*). (Adapted from Chen HI, Sharma B, Akerberg BN, et al. The sinus venosus contributes to coronary vasculature through VEGFC-stimulated angiogenesis. *Development.* 2014;141(23):4500-4512.[10])

A more global role for the cardiac neural crest is now recognized after the findings that removal or disturbance of cardiac neural crest cells can influence the function and proliferation of cardiomyocytes before neural crest cells migrate into the heart.[14] Findings point to a role for cardiac neural crest–derived cells in influencing the mesenchyme of the secondary or anterior heart-forming field that produces late-forming cardiac structures, including the outflow tract.[66,76] Because disturbances of neural crest development have the potential to cause cardiovascular anomalies, factors controlling normal neural crest cell development are receiving much attention. DiGeorge and related syndromes that include craniofacial and outflow tract abnormalities are believed to result from disruption of neural crest cell development.[19] These syndromes are often associated with deletions in 22q11, a region of human chromosome 22 that has been under close scrutiny.

The search for "the DiGeorge syndrome gene" was confounded by the number of candidate genes in the DiGeorge critical region and by the differences between the phenotypes of mice and humans mutated in homologous genes. It is also puzzling that individuals without the deletion can closely resemble those with the DiGeorge region missing. *TBX1* and *CRKL* are currently described as the best candidate genes within the most common 22q11 deletion. However, researchers continue to propose that there is no single affected gene responsible for the defects associated with DiGeorge or the 22q11 deletion syndrome. Rather, a combination of affected genes within that region, as well as those outside that region, appears to regulate the same critical cellular processes. Data suggest that many of the mutations identified in individuals with a range of craniofacial and cardiac syndromes that include DiGeorge syndrome are in genes associated with the extracellular-signal-regulated kinase (ERK) pathway.[2,52] These genes include upstream genes such as *TBX1* and *CRKL* and downstream genes such as *SRF*. A broader hypothesis is emerging that anything that dysregulates the activity of the ERK pathway up or down in developing neural crest cells results in craniofacial and cardiac syndromes.

Development of the Cardiac Conduction System

Primordia of the pulse-generating system function early in the caudal region of the tubular heart and allow unidirectional blood flow, but subsequent events in the development of the cardiac conduction system (CCS) are not well understood. Investigations of CCS embryogenesis in a variety of species, including the mouse, chicken, and zebrafish, have contributed to this understanding.[34] Classic histologic analyses are limited in the information they provide because the early CCS cannot be readily distinguished histologically or even ultrastructurally from the surrounding myocardium. Biochemical markers have been detected that transiently stain portions of the CCS and have been used to follow these tissues during the three-dimensionally complex morphogenesis of the heart. The rabbit model is unique in that there is a marker for it, NF-150, an antibody against neurofilament proteins, that delineates its cardiac conduction system throughout development and into the adult. These markers show that some of the tissues that give rise to the CCS can be distinguished from other cardiomyocytes as early as the tubular heart stages, because they have a different pattern of gene expression and cell proliferation.

The role of the differentially expressed CCS markers is still not completely understood; nevertheless, the markers have clarified issues about normal and abnormal morphogenesis. Marking the early CCS by using the markers' specific properties has allowed the CCS to be used as a point of reference to deduce which portion of the heart is growing and moving relative to others.[51]

Lineage tracing of myocardial cells provided clues to the origin of the CCS. The clonal relationship between CCS cells and working cardiomyocytes suggests that these specialized myocardia can be recruited from unspecialized myocardial cells. Evidence from avian systems supports the hypothesis that the vasculature can be the source of factors that initiate such recruitment, with endothelin-1 being a strong candidate for signaling.[22]

Less is known about the physiology of the developing CCS primarily because of technical barriers to resolution. This barrier is, however, being overcome by advances in biomedical engineering technologies such as optical mapping using voltage-sensitive fluorescent dyes and optical coherence tomography that allow the capture of images of the tiny beating heart at high spatiotemporal resolution. Different strategies are used by the embryo at different stages of cardiogenesis for coordinating the contraction of the heart. The tubular heart has a peristaltic-type contraction pattern resulting from a pulse-generating focus of cells and a slow distribution of action potentials radiating evenly from that region in all directions.[36] In the septating heart, alternating regions of relatively slow and fast conduction allow pumping of blood in one direction, with the endocardial cushions acting as primitive valves. Slow regions, the sinus venosus, atrioventricular junction, and outflow tract, cause a delay of the impulse conduction between chambers.[15] The ventricular conduction system achieves its mature morphology simultaneous with the appearance of the mature sequence of activation.[13] Subsequent differentiation allows for increasing speed of action potential conduction through the fascicular portion of this system and compensation for the growth of the heart. Maturation of the fibrous ring that separates the atrial from ventricular muscle and the connective tissue sheath around the conduction system also follows serving as insulative barriers to inappropriate conduction to neighboring working myocardium.

Epicardium

The epicardium is a relatively late-forming cardiac tissue that does not appear until septation is under way. It provides the bulk of the non-cardiomyocyte cellular components, including smooth muscle cells, fibroblasts, and endothelial cells. The progression of epicardial development has been studied in detail using avian and mouse models. The epicardium, the outer layer of the heart, forms by the growth of epithelial tissue from the dorsal mesothelium of the sinus venosus region. This single-cell layer spreads in a stereotyped pattern over the myocardium. The squamous epithelium of the primitive epicardium and the myocardium are initially juxtaposed, but a rapid accumulation and differentiation of connective tissue components between these layers ensues to thicken the epicardium. The cells within the epicardium invade the myocardium and the endocardium, giving rise to valve cells, fibroblasts, smooth muscle cells, and other components of the coronary vasculature.[45] The controversy regarding the origin of the coronary endothelial cells is understandable because of the apparently conflicting findings from lineage tracing studies. Using retroviral lineage tracing, precursor cells labeled in the pro-epicardial were found to give rise to endothelial cells as well as smooth muscle cells.[48] However, cre-lox lineage tracing using what appeared to be epicardial-specific promoters identified only a small subset of labeled coronary endothelial cells.[7,77] Other investigators using a novel lineage tracing approach showed evidence that endothelial cells come from the endocardial lining of the sinus venosus.[60] More recently, it was proposed that coronary endothelial cells within the myocardium originate from endocardial cells within the ventricles.[74] Another investigation using another lineage tracing method now proposes that the bulk of coronary endothelial cells come from the cells within the epicardium (subepicardial cells) that originate from the endocardium lining the atrium or sinus venosus.[70] These findings are not necessarily in conflict; the endothelium lining the myriad of vessels within the myocardium is likely to come from several sources, depending on location within the heart and the types of vessel (see Fig. 71.11).

The epicardium is also the tissue in which cardiac ganglia develop, nerves travel, and fat cells accumulate. Evidence suggests that the embryonic epicardium may also include cells that can contribute a subset of cardiomyocytes.[7,77] This interesting tissue and its interaction with the myocardium are the focus of much current research.

Lymphatics

Although it is known that the adult vertebrate heart has an extensive lymphatic network, the lymphatic vasculature of the embryonic heart has not been investigated in detail. The mature heart is thought to have two plexuses: (1) the deep plexus immediately under the endocardium and (2) the superficial plexus subjacent to the visceral pericardium.[23,49] The deep plexus opens into the superficial plexus, whose efferent vessels will form right and left collecting trunks. The study of lymphatic development during cardiogenesis is now revived with the identification of lymphatic markers. This area of study is in its early stages. One of the many questions not yet answered in this field is, where do the lymphatic precursors originate? Lymphatic cells, whether or not they arise in the epicardium, do end up in the epicardium surrounding coronary vessels. An understanding of the mechanisms driving development of the lymphatic vasculature of the developing heart and of lymphangiogenesis may help in treating edema or similar conditions.[38]

Cell Division and Cell Death

Differential control of cell division and cell death can in part account for the enormous differences in morphologic features of the various regions of the heart. For example, the cells of the thin-walled atria divide less than the cells of the thick-walled ventricle. The central structures of the fascicular CCS slow their proliferation rate early compared with surrounding myocardium.[64] Apoptosis—programmed cell death—is a developmentally controlled strategy in the morphogenesis of many structures. It occurs during the

pruning of the nervous system and the sculpting of digits of the hands and feet, and it occurs at many sites throughout cardiogenesis.[55] Endocardial cushion mesenchyme cells, which include cardiac neural crest cells, undergo a high level of apoptosis during septation. A high frequency of apoptosis of cardiomyocytes occurs coincident with outflow tract morphogenesis. Experimental manipulation to increase or decrease cell death at this stage results in conotruncal abnormalities.[61] Thus, regulated apoptosis of outflow tract cardiomyocytes is critical for the normal docking of the great arteries with the ventricles. Environmental and genetic factors that alter the level of apoptosis at these critical stages and sites in the developing heart may contribute to congenital heart defects.

Human Genetics

The entire human genome is sequenced, and efforts have been made to allow clinicians, basic scientists, industry scientists, and others to tap into the database and exchange information. Knowledge of the human genome helps in predicting potential problems, forming the basis for the growing field of genetic counseling. In addition, the study of human genetics allows identification of regions of the genome that might be adversely affected in patients with heart disease. Eventually, this information may be used in developing therapies for heart disease. Comparison of the human genome sequences with those of many other species has also provided important information. Sequences conserved across species often indicate regions of a gene that are critical for a particular function and that are worth focused scrutiny. The field of human genetics also provides information for the basic sciences, the "bedside-to-the-bench" links. Genetic analysis of individuals with certain syndromes can pinpoint genes and proteins that can be studied in detail in the laboratory to identify critical functions.

Epigenetics is the field investigating gene regulation that does not involve any changes in the sequence of DNA but rather the modifications to DNA and histones. These modifications, including methylation and acetylation, regulate transcription and translation. In addition to getting DNA sequence data, epigenetic data may become part of the diagnosis and assessment of therapeutic efficacy.

Cardiomyopathies are intrinsic disorders of heart muscle that are generally classified morphologically as hypertrophic, dilated, restrictive, and arrhythmogenic.[5,71] A genetic basis can be identified in a majority of these lesions, usually a mutation in a sarcomeric or structural gene that results in contractile abnormalities. Hundreds of mutations in dozens of genes have been identified as causative in familial and sporadic forms of cardiomyopathy.[71] The ultimate cardiac phenotype can develop at any age but occasionally presents in the neonatal period.[40] Left ventricular noncompaction is an increasingly recognized (particularly in neonates) form of cardiomyopathy characterized by dense trabeculation of the normally smooth-walled left ventricular cavity. This is a poorly understood defect that may be caused by abnormalities in the Notch signaling pathway or mutations in various sarcomeric genes.[40,43] Ongoing genetic studies will be focused not only on the identification of genetic abnormalities leading to cardiomyopathy but an investigation of the factors that lead to clinical disease progression.

Therapy

Strategies to repair heart tissue are relevant to both pediatric and adult cardiology and have been the focus of much effort. However, human myocardial cells lose their ability to divide soon after birth, and this terminal differentiation appears to be irreversible. It had been believed that, within adult heart tissue, no stem cells existed that could be activated to replace defective or damaged cardiomyocytes. To overcome this hurdle, investigators have been attempting to initiate cell division in cardiomyocytes[20,35] or stimulate myocardial differentiation in fibroblasts.[3,31] Fibroblasts are used because they continue to divide, are abundant in the postnatal and adult myocardium, and have been successfully transdifferentiated into myocardial muscle.[21,57]

Heart tissue appears amenable to such strategies. Myocardial cells (cell lines or embryonic myocytes) can integrate to some extent into the adult heart of animal models. Thus, they undergo some differentiation and integration in a foreign environment. Findings suggest that stem cells exist in the interstices of the adult heart and can be capable of differentiating into cardiomyocytes.[53] Endothelial cells, bone marrow cells, and umbilical cord cells are known to differentiate into cells with cardiac markers and are under study as potential candidates for use in cardiac tissue repair. Studies provide evidence, while controversial, that epicardial progenitor cells may have the capacity to contribute to the cardiomyocyte lineage in the developing heart.[7,77] Furthermore, investigators were able to induce the differentiation of adult epicardial cells into endothelial cells.[65] These findings suggest different strategies for therapy. The question remains whether any of these cells will be able to differentiate, integrate, and function appropriately in the adult heart as cardiomyocytes or endothelial cells without becoming malignant or causing malfunction. The potential for causing cancer or arrhythmias is possible with some of these therapies.

Commonly used graft materials offer no growth potential if used to correct tissue defects. However, the production of neo-vessels or neo-organ tissue from autologous cells using a biodegradable polymer scaffold is showing promise in the field of vascular tissue engineering. The autologous cells are seeded and produce an extracellular matrix with the inserted scaffolding eventually degenerating, leaving behind native-like tissue. Potential advantages of these tissue implants are that they will allow for growth, remodeling, and response to injury as the child ages, because these tissues resemble and act like original tissue.[39] Replacement heart valves are also being engineered using valvular interstitial cells seeded on a poly(glycerolsebacate) scaffold, and the mechanical properties of these valves have been retained or exceeded those of unseeded scaffolds.[46]

A fairly new area of research is the study of micro-RNAs and their potential therapeutic value.[69,72] Micro-RNAs are single-stranded RNAs, about 22 noncoding nucleotides in length that are present endogenously. They act as specific regulators of gene expression in development and disease by interfering with translation of messenger RNAs or by enhancing the degradation of messenger RNAs. The ability of a particular micro-RNA to regulate RNAs from related sets of genes has raised the possibility that manipulating the levels of micro-RNAs may be a comprehensive strategy to prevent or reverse complex disease. The finding that sequences for micro-RNAs are found within the very genes they control is intriguing.

Gene therapy, in combination with intravascular stents, is being considered for treatment of coronary and peripheral vascular disease in adults. Exogenous genes can be introduced by a variety of means to the heart or vasculature. In vitro studies or those in animal models have also shown that physiologically significant genes (e.g., plasminogen activator) can be introduced and cause significant levels of protein expression for enough time to have therapeutic effects.

The most controversial approach for therapy involves manipulating the genome of the germ cells so that the entire embryo can go through development with the corrected gene. This approach requires that the manipulation result in little or no effect besides the desired effect. Introducing the gene into a genome can by itself cause inadvertent wide-ranging defects. Such methods also require a thorough understanding of the gene being manipulated so that all controlling elements, as well as the structural portion of the gene, are intact.

A recently discovered genetic editing method uses the strategy of the "immune system" of microbes.[50] Humans deploy a complex immune system to combat bacterial and viral intruders. Microbes like bacteria likewise have to combat viruses that can usurp bacterial cellular biochemistry for their own means. The bacteria do this by identifying and cutting up the foreign virus DNA, strategies adapted to the CRISPR/cas9 technique.[17,26,33] CRISPR is an acronym for clustered regularly interspaced short palindromic repeats, which is what is used to make a guide RNA that identifies the DNA sequence targeted for modification. Cas9 is the enzyme that cleaves double-stranded DNA at the identified site.

The previous DNA editing methods relied on using restriction enzymes that cut DNA at specific sites that would be close to, but not precisely, the site of interest. CRISPR/cas9, in contrast, allows more precise editing down to the nucleotide and is simpler and faster to complete. This has allowed rapid generation of genetic engineered mice and other model organisms. It also makes it feasible to precisely edit the human genome for therapeutic purposes. This technique is being rapidly optimized and will result in further breakthroughs in our understanding of molecular mechanisms of heart development and disease.

Another strategy in preventing congenital heart defects is to correct at a level farther along the pathway from the genome. This can be done by turning on alternative biochemical pathways or by boosting compensatory mechanisms. This approach requires a thorough understanding of the network of pathways and all of its interactions and feedback loops.

Finding the appropriate strategy for therapy is complicated, because defects involve a combination of genes and environmental factors and include direct and indirect effects that are difficult to control with current knowledge and techniques. However, with the great and often serendipitous advances in our understanding of cardiovascular development, certain defects might be preventable or reversed in our lifetime.

Key Points

- The majority of cardiac development is complete by 8 weeks' human gestation.
- Much of what is known about cardiac development is revealed by the use of animal and *in vitro* models.
- The primary heart field is responsible for the left ventricle and portions of the AV canal, whereas the second heart field, adjacent to neural crest cells, is responsible for outflow tract, right ventricle, and atrial formation.
- Looping of the primitive heart tube to the right (D) or left (L) will determine ventricular position, but not atrial position.
- Neural crest cells play multiple roles in the development of the function and structure of the heart and great vessels.
- The epicardium, the last heart layer to appear, plays roles in coronary vessel and valve development.
- As the web of genetic, epigenetic, and other molecular interactions is revealed by scientific inquiry, the apparent complexity of heart embryogenesis continues to expand.

Pulmonary Vascular Development

ROBIN H. STEINHORN

Normal development of pulmonary vascular structure and function through prenatal and early postnatal life prepares the lung to perform its basic physiologic function of gas exchange across a thin blood–gas interface. Survival of the newborn is dependent upon rapid adaptation of the fetal cardiopulmonary system to the demands of extrauterine life. As development continues, normal lung function and growth depends on sustained low pulmonary vascular resistance. Abnormalities of vascular development can result in persistent pulmonary hypertension, which complicates the course and outcome of neonatal respiratory failure.

Fetal Pulmonary Vascular Development

Structural Development

Pulmonary vascular development begins during the embryonic phase of lung development and is highly coordinated with airway growth (Fig. 72.1). Endodermal lung buds arise from the ventral aspect of the foregut by the fifth week of gestation. The pulmonary trunk, derived from the truncus arteriosus, divides into the aorta and pulmonary trunks by 8 weeks of gestation by growth of the spiral aortopulmonary septum. The pulmonary trunk connects to the pulmonary arch arteries, which are derived from the sixth branchial arch arteries. The mesenchyme surrounding the lung bud then develops into the vascular network. In the human lung, the pre-acinar vascular branching pattern is present by the 20th week of fetal life. The intra-acinar arteries form later in fetal life and after birth during the alveolar phase of lung development. Development of the pulmonary veins parallels that of the arteries, but they arise separately from the loose mesenchyme of the lung septa and subsequently connect to the left atrium.

Angiogenesis and vasculogenesis are the two primary morphogenetic processes that form the pulmonary vasculature. Vasculogenesis is the de novo organization of blood vessels produced by the migration and differentiation of endothelial progenitor cells or angioblasts. These cells migrate, adhere, and form vascular tubes that become arteries, veins, or lymphatics depending on the local growth factors within the mesenchyme. Endothelial precursor cells, after differentiation into the endothelium, contribute either to the expression of smooth muscle phenotype in the surrounding mesenchyme or they recruit existing smooth muscle cells to the forming vessel. Angiogenesis refers to the budding, sprouting, and branching of existing vessels to form new ones. Vasculogenesis and angiogenesis are not necessarily sequential processes and both may occur early in lung development, perhaps giving rise to heterogeneous cell populations in the vasculature. In addition, a process of vascular fusion has been described that connects the angiogenic and vasculogenic vessels to allow for expansion of the vascular network.

Fetal lung septation and alveolarization begin at around 32-36 weeks' gestation in the human fetus and continue well into postnatal life. During this process, vascular growth and branching are tightly coupled with the growth and branching of the airway epithelium. The number of small pulmonary arteries increases, both in absolute terms and per unit volume of the lung. For example, in fetal lambs, lung weight increases by fourfold during the last trimester, while the number of small blood vessels in the lungs increases fortyfold. This dramatic increase in surface area of small blood vessels prepares the lungs to accept the tenfold increase in blood per unit of lung that occurs at birth. During the final stages of vascular development, the pulmonary capillaries surround the thinning alveolar walls, providing the increased alveolar and capillary surface areas necessary to support gas exchange at birth. Lung blood vessels actively promote alveolar growth during development and contribute to the maintenance of alveolar structures throughout postnatal life, and disrupted development of one system will have important consequences on the development of the other. Antenatal or postnatal events that affect the developmental program of the fetal or newborn lung may contribute to defective pulmonary vascular development.

The hypoxic conditions of fetal life support lung vascular growth. Hypoxia inducible factors (HIFs) are viewed as the "master regulators" of the transcriptional response to hypoxia and are involved in angiogenesis, survival, and metabolic pathways. HIFs are heterodimers consisting of oxygen-sensitive α-subunits (HIF-1α, HIF-2α) and constitutively expressed β-subunits. Hypoxia stabilizes the α-subunit, leading to nuclear accumulation and activation

Abstract

Normal lung vascular development is supported by a hypoxic intrauterine environment, which promotes expression of hypoxia inducible factor (HIF) and vascular endothelial growth factor (VEGF). Maternal factors such as diabetes, high body mass index, smoking, use of SSRIs or NSAIDs, and caesarean section increase the risk of PPHN; postnatal factors include perinatal asphyxia, hyperoxia, hypoxia, infection, and lung inflammation. Medical management of PPHN requires lung recruitment, optimization of right and left ventricular function, and maintenance of PaO_2 between 60 and 80. Inhaled nitric oxide at 20 ppm improves oxygenation and reduces the need for ECMO support in term and near-term infants with PPHN. New therapies focused on downstream cGMP signaling, prostanoid signaling, and endothelin signaling are undergoing testing. ECMO support is indicated for term and near-term neonates with severe PH and/or hypoxemia that is refractory to iNO and optimization of respiratory and cardiac function. Infants that survive moderate to severe PPHN are at high risk for neurodevelopmental impairment and should receive neuroimaging and neurodevelopmental follow-up.

• **Fig. 72.1** Changes in airway morphology and pulmonary vasculature during various stages of lung development and at birth. The cross-sectional area of pulmonary vasculature increases with gestation. However, pulmonary vasculature develops sensitivity to oxygen during later gestation, leading to hypoxic pulmonary vasoconstriction (thick red vessels). Pulmonary vasodilation secondary to ventilation and oxygenation at birth increases pulmonary blood flow. Changes in pulmonary blood flow (as a percentage of combined ventricular output) during the last half of human pregnancy and immediate postnatal life are shown in the bottom graph as a blue line. During early second trimester, pulmonary vasculature does not respond to changes in oxygen tension induced by maternal hyperoxia (*hyphenated red line*). During the third trimester, pulmonary blood flow increases with changes in oxygen tension (*hyphenated red line and red arrow*). After birth, following normal transition, the entire right ventricular output and left-to-right ductal shunt perfuses the lung, establishing this organ as the site of gas exchange during postnatal period. of multiple target genes. HIF-1 regulates genes involved in angiogenesis (e.g., vascular endothelial growth factor), oxygen transport (e.g., erythropoietin), and energy metabolism (e.g., glycolytic enzymes), among others.[60] Deletion of HIF-1 or HIF-2 produces embryonic lethality, and knockout of HIF-1α in the smooth muscle cells of mice results in pulmonary hypertension.[38]

Vascular endothelial growth factor (VEGF) is expressed in vascular endothelial and smooth muscle cells and in airway epithelium in the fetal lung and is a key mediator of pulmonary vascular development. VEGF transcription is regulated by HIF, and VEGF signaling is transduced via two transmembrane tyrosine kinase receptors, VEGFR-2 and VEGFR-1 expressed on vascular endothelium. Experimental inactivation of VEGF or its receptors before birth results in embryonic lethality characterized by deficient organization of endothelial cells and vascularization; VEGFR-1 and VEGFR-2 inhibitors (e.g., SU5416) impair alveolar development in fetal and newborn rodent models, producing pathologic findings similar to those seen in clinical bronchopulmonary dysplasia (BPD).[27] In the clinical setting, decreased VEGF and VEGFR-1 mRNA and protein is observed in the lungs of premature neonates who died with bronchopulmonary dysplasia (BPD).[8] In adult rats, chronic VEGF receptor inhibition causes pulmonary hypertension and enlarges the air spaces, suggesting that normal VEGF function is required for the maintenance of the pulmonary vasculature and alveolar structures even after lung development is completed.[35]

VEGF-induced lung angiogenesis is in part mediated by nitric oxide (NO). Nitric oxide is best known for its role as a pulmonary vasodilator, but it also plays a key role in lung vascular growth during fetal and neonatal life. Lung endothelial nitric oxide synthase (eNOS) mRNA and

protein are present in early fetal life in rats and sheep and increase with advancing gestation. The expression and activity of eNOS are regulated by multiple factors, including hemodynamic forces, hormonal stimuli (e.g., estradiol), paracrine factors (including VEGF), substrate and cofactor availability, oxygen tension, and others. The lungs of late fetal and neonatal eNOS-deficient mice have striking abnormalities of vascularization and are more susceptible to failed vascular growth following exposure to mild hypoxia.[5] Inhibition of VEGF receptors decreased lung eNOS protein expression and NO production, and lung vascular growth is restored by treatment with inhaled NO. However, in neonatal mice that are eNOS deficient, recombinant human VEGF protein treatment restores lung structure after exposure to mild hyperoxia, suggesting that VEGF operates in part through mechanisms independent of eNOS.

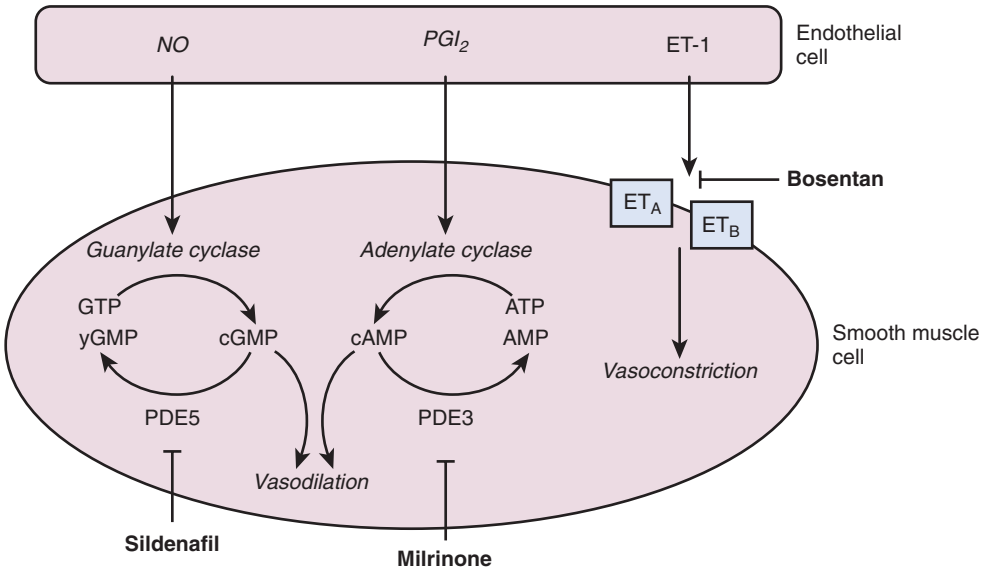
Numerous other transcription factors important to lung vascular development have been identified.[26] For example, the Forkhead Box (Fox) family of transcription factors regulate expression of genes involved in cellular proliferation and differentiation. Newborn mice with low *FOXF1* levels die with defects in lung vascularization and alveolarization, and endothelial-specific deletion of *FOXF1* produces embryonic lethality, growth restriction, and vascular abnormalities in the lung, placenta, and retina.[57] *FOXF1* haploinsufficiency is found in 40% of infants with alveolar capillary dysplasia, a lethal disorder of lung vascular development.[10]

Mediators of Fetal Pulmonary Vascular Tone

Pulmonary hypertension is a normal state during fetal life and a necessity for survival on placental support. In the fetal lamb, pulmonary arterial blood has a PO_2 of approximately 18 mm Hg and oxygen saturation of 50%.[59] Elevated pulmonary vascular resistance permits only ~16% of the combined ventricular output to be directed to the pulmonary vascular bed. Most of the fetal right ventricular output bypasses the lung via the foramen ovale and the ductus arteriosus and is directed to the descending aorta. The blood is then oxygenated in the placenta and returns to the body through the umbilical vein, with a PO_2 of ~32 to 35 mm Hg in lambs.

Multiple mechanisms maintain high PVR and low pulmonary blood flow in the fetus, including low oxygen tension, low basal production of vasodilator products (such as PgI_2 and NO), and increased production of vasoconstrictors. The fetal pulmonary circulation also exhibits a marked "myogenic response" as gestation progresses, meaning that the vasculature responds to vasodilatory stimuli with active vasoconstriction.

The low oxygen environment of the fetus plays a key role in maintaining high pulmonary vascular resistance. Maternal hyperoxygenation has no effect on human fetal pulmonary blood flow prior to 26 weeks' gestation but produces significant increases between 31 to 36 weeks of gestation, suggesting that the capacity of the pulmonary circulation to sense and respond to changes in oxygen tension is developmentally regulated. Because oxygen regulates activity of enzymes such as nitric oxide synthase, the low oxygen environment of the fetus may maintain low production of vasoactive mediators such as nitric oxide and prostacyclin. For example, maternal hyperoxygenation activates endothelial nitric oxide synthase and increases pulmonary blood flow to postnatal levels in fetal lambs.



Pulmonary artery endothelial cells produce multiple vasoactive mediators that maintain the normal patterns of fetal pulmonary circulation. Proposed fetal pulmonary vasoconstrictors include endothelin-1 and lipid mediators, such as thromboxane and leukotrienes C_4 and D_4, and platelet-activating factor, but none have been shown to play a central regulatory role. Endothelin-1 (ET-1) is produced by vascular endothelium and acts on the ET-A receptors in the smooth muscle cell to induce vasoconstriction by increasing ionic calcium concentrations. A second endothelial receptor, ET-B, on the endothelial cell stimulates NO release and vasodilation. PreproET-1 mRNA (the precursor to ET-1) has been identified in fetal rat lung early in gestation, and high circulating ET-1 levels are present in umbilical cord blood. Although capable of both vasodilator and constrictor responses, ET-1 appears to primarily act as a pulmonary vasoconstrictor in the fetal pulmonary circulation.

Endogenous serotonin (5-HT) production also appears to contribute to the high PVR of the fetus. In fetal lambs, infusions of 5-HT increase PVR,[18,19] and infusions of ketanserin, a 5-HT 2A receptor antagonist, decrease fetal PVR. Conversely, brief infusions of selective serotonin reuptake inhibitors (SSRI), such as sertraline and fluoxetine, produce potent and sustained elevations of PVR. These findings suggest that 5-HT causes pulmonary vasoconstriction and contributes to maintenance of high PVR in the normal fetus through stimulation of 5-HT 2A receptors and Rho kinase activation. These findings have clinical implications for SSRI treatment for maternal depression.

Additional evidence suggests a critical role for the RhoA/Rho kinase signal transduction pathway, a central downstream pathway that promotes vasoconstriction through inactivation of myosin light chain phosphatase, thus increasing calcium sensitivity of the smooth muscle cell. Hypoxia activates RhoA, which increases Ca^{38+} sensitivity of the contractile myofilaments in the vascular smooth muscle. Rho kinase activity maintains high PVR in the fetal lung, and its inhibition dilates the perinatal circulation by a mechanism independent of NO.[3]

As gestation progresses, NO and cGMP become central to the emergence of pulmonary vascular reactivity. Chronic inhibition of VEGF receptors downregulates eNOS and induces pulmonary hypertension in the late gestation fetus,[30] indicating the importance of both in the development and function of the developing pulmonary vasculature. Inhibition of eNOS increases basal PVR as early as 0.75 gestation (112 days) in the fetal lamb, indicating that endogenous NOS activity contributes to vasoregulation during late gestation. The response to NO is dependent on

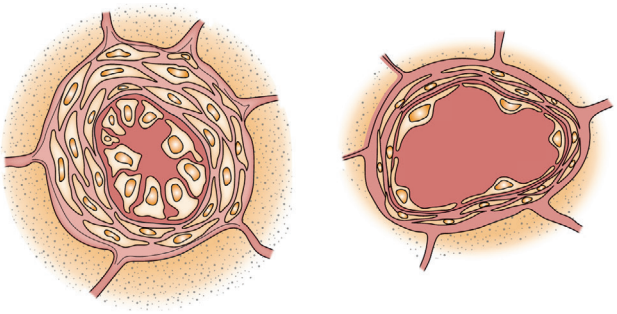
• **Fig. 72.2** Schematic of the nitric oxide (NO), prostacyclin (PGI_2), and endothelin (ET)-1 signaling pathways. NO stimulates soluble guanylate cyclase to increase intracellular cGMP, and PGI_2 stimulates adenylate cyclase to increase intracellular cyclic AMP (cAMP). Both cGMP and cAMP indirectly decrease free cytosolic calcium, resulting in smooth muscle relaxation. Sildenafil inhibits PDE5 in vascular smooth muscle, and milrinone inhibits PDE3 in cardiomyocytes and vascular smooth muscle. ET-1 produced by endothelial cells binds endothelin A (ETA) and endothelin B (ETB) receptors on smooth muscle cells. The ET-1 receptor antagonist bosentan alleviates smooth muscle vasoconstriction by blocking ET-1 effects.

activity of its receptor molecule, soluble guanylate cyclase, in the smooth muscle cell (Fig. 72.2). In the fetal lamb, sGC mRNA levels are low through the second trimester and markedly increase toward the end of the third trimester. Intracellular cGMP levels are also tightly regulated by cGMP-specific phosphodiesterase (PDE5) activity. PDE5 expression and activity increase during late gestation, and it plays a critical role in pulmonary vasoregulation during the perinatal period. Overall, prostaglandins appear to play a less important role than NO in regulating fetal and transitional pulmonary vascular tone.



Pulmonary veins are now recognized to function as more than passive conduits; instead they are reactive vessels that contribute to the regulation of total pulmonary vascular tone and resistance. In perinatal sheep, both endogenous and exogenous NO increase intracellular cGMP content and relaxation to a greater degree in pulmonary veins than in arteries, effects that are oxygen dependent. Pulmonary veins are also the primary sites of action of certain vasoconstrictors such as endothelin-1 and thromboxane, and pulmonary venous constriction in turn increases microvascular pressures and promotes pulmonary edema.

Pulmonary Vascular Transition

At birth, the fetal pulmonary circulation must rapidly adapt to direct blood flow to the lungs as the organ of gas exchange. A rapid and dramatic decrease in pulmonary vascular resistance redirects half of the combined ventricular output from the placenta to the lung, leading to an eight- to tenfold increase in pulmonary blood flow. This increase in pulmonary blood flow will increase pulmonary venous return and left atrial pressure, promoting functional closure of the one-way valve of the foramen ovale. Systemic vascular resistance also increases at birth, in large part due to removal of the low resistance vascular bed of the placenta. The largest drop in pulmonary vascular resistance occurs shortly after birth, although resistance continues to drop over the first several months of life until it reaches the low levels normally found in the adult circulation. In preterm lambs, delayed cord clamping for 3-4 minutes until after ventilation is established improves cardiovascular function by increasing pulmonary venous return and left ventricular filling prior cessation of umbilical venous return.[9] As pulmonary vascular resistance drops and oxygen tension rises, blood flow through the patent ductus arteriosus reverses and the ductus arteriosus functionally closes. This effectively separates the pulmonary and systemic circulations and establishes the normal postnatal circulatory pattern.

The stimuli most important in decreasing PVR are lung inflation with a gas and an increase in oxygen tension. Each will independently decrease PVR and increase pulmonary blood flow, with the largest effects seen when the two events occur simultaneously. Mechanical distension of the lungs initiates the process of rapid structural adaptation of the pulmonary vessels. The external diameter of the nonmuscular arteries increases, and the prominent endothelial cells assume a flattened appearance (Fig. 72.3). There is an increase in cell length and surface-to-volume ratio as the cells "spread" within the vessel wall to increase lumen diameter and lower resistance. This process is likely facilitated by the paucity of interstitial connective tissue, allowing for

• **Fig. 72.3** Changes in the small muscular pulmonary arteries during transition. Muscularized small pulmonary arteries from a near-term gestation fetus (*left*) demonstrate "swollen" endothelial cells and increased thickness of the muscular layer. Within 24 hours after birth (*right*), a considerable increase in luminal diameter is noted secondary to flattening of the endothelial cells, "spreading" of the smooth muscle cells, and an increase in external diameter caused by relaxation of the smooth muscle. These events contribute to the drop in pulmonary vascular resistance after birth. (From Lakshminrusimha S, et al. Pulmonary vascular biology during neonatal transition. *Clin Perinatol*. 1999;26:601-619).

greater plasticity of the vessel. In postmortem arterial-injected specimens, the number of nonmuscular arteries that fill with injection material increases rapidly during the first 24 hours, suggesting that there is a rapid increase in the number of precapillary arteries "recruited" into the pulmonary circulation after birth.

An increase in oxygen tension will reduce PVR independent of the effects of lung inflation. This oxygen response emerges at approximately 70% gestation in the fetal lamb and continues to develop as gestation progresses. The full vasodilatory effect of oxygen can be achieved with relatively modest increases in arterial concentrations: PaO_2 levels of ~50 mm Hg in the near-term fetal lamb will decrease pulmonary vascular resistance and increase pulmonary blood flow to levels comparable to postnatal lambs.[71] In addition to facilitating vasodilation, oxygen may also promote the rapid endothelial spreading and remodeling after birth.

Finally, the initial increase in pulmonary blood flow increases shear stress in the pulmonary vasculature, which further promotes rapid vasodilation in the pulmonary circulation of the newborn and late gestation fetus.[1] The mechanisms of shear stress-mediated responses are complex but involve stimulation of K^+ channels and activation of NO synthases.

Vasoactive Mediators of the Pulmonary Vascular Transition

Numerous vasoactive factors interact to facilitate the drop in pulmonary vascular resistance at birth, and increased vasodilator activity is probably more important than decreased vasoconstrictors. Of these, nitric oxide is a central mediator of pulmonary vascular tone at birth. NO stimulates soluble guanylate cyclase activity and increases cyclic guanosine monophosphate (cGMP) in vascular smooth muscle, producing smooth muscle relaxation via mechanisms involving decreased phosphorylation of myosin light chain (see Fig. 72.2). Pulmonary expression of all three isoforms of nitric oxide synthase (NOS) and its receptor molecule, soluble guanylate cyclase, increase late in gestation, preparing the lung for pulmonary vasodilation. Acute or chronic inhibition of NOS in fetal lambs produces pulmonary hypertension following delivery, illustrating the critical importance of the NO-cGMP pathway in facilitating normal transition. Expression of cGMP-specific phosphodiesterases also peaks at the time of birth, which maintains tight regulation of intracellular cGMP concentrations and signal transduction at birth.

Prostacyclin is a second central vasodilator that is upregulated in response to ventilation of the lung. Cyclooxygenase (COX) and prostacyclin synthase generate prostacyclin from arachidonic acid. COX-1 in particular is upregulated during late gestation, leading to an increase in prostacyclin production in late gestation and early postnatal life. Prostacyclin stimulates adenylate cyclase to increase intracellular cAMP levels, which, similar to cGMP, produces vasorelaxation through a decrease in intracellular calcium concentrations (see Fig. 72.2). Phosphodiesterase 3A (PDE3A) catalyzes the breakdown of cAMP. The decrease in PVR caused by PGI_2 at birth is modest in comparison to that induced by NO. Pharmacologic inhibition of cyclooxygenase does not prevent the drop in PVR after birth, indicating that while prostaglandin I_2 (PGI_2) is involved in the decrease in PVR at birth it is not absolutely required.

Abnormalities of Pulmonary Vascular Development

The most recent Nice classification of pulmonary hypertension was updated in 2013 and for the first time included a panel focused on pediatric disease.[64] Persistent pulmonary hypertension of the newborn (PPHN) is now included as a separate subcategory of pulmonary arterial hypertension (Group 1), recognizing its distinct anatomic and physiologic nature. The revised classification also recognizes the important role of abnormal lung vascular growth in the pathogenesis of pulmonary hypertension and impaired lung structure in developmental lung diseases. Conditions such as congenital diaphragmatic hernia, bronchopulmonary dysplasia, and other rare developmental disorders such as surfactant protein deficiencies and alveolar capillary dysplasia are listed in Group 3 (pulmonary hypertension caused by lung diseases and/or hypoxia).

Persistent Pulmonary Hypertension of the Newborn

Persistent pulmonary hypertension (PPHN) describes the failure of normal pulmonary vascular adaptation at birth and is characterized by elevated pulmonary vascular

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

resistance and right-to-left extrapulmonary shunting of deoxygenated blood that produces severe hypoxemia. The PPHN syndrome complicates the course of approximately 10% of term and preterm infants with respiratory failure and carries a significant risk of death, pulmonary morbidity, and neurodevelopmental impairment. PPHN is often thought of as falling into one of three categories: 1) pulmonary vasoconstriction caused by lung parenchymal diseases such as meconium aspiration syndrome, respiratory distress syndrome, or pneumonia; 2) normal parenchyma and remodeled pulmonary vasculature, also referred to as idiopathic PPHN; or 3) hypoplastic vasculature as seen in congenital diaphragmatic hernia. While idiopathic pulmonary hypertension is responsible for only 10%-20% of all infants with PPHN, severe cases of PPHN associated with parenchymal disease are almost always complicated by a significant degree of vascular remodeling.

Significant pulmonary vascular remodeling occurs antenatally in infants presenting with early, severe PPHN, characterized by vessel wall thickening and smooth muscle hyperplasia. An important feature includes extension of the smooth muscle to the level of the intra-acinar arteries (Fig. 72.4), which does not normally occur until much later in postnatal development. Because it is difficult to gain sufficient mechanistic insights in the clinical setting, animal models have provided many of the insights into the antenatal and postnatal vascular abnormalities associated with PPHN.

Potential causes of antenatal remodeling of the pulmonary vasculature include environmental exposures or genetic risk factors. Maternal use of salicylates was one of the earliest triggers identified for PPHN, and earlier reports suggested a strong association between clinically significant PPHN and the maternal use of NSAIDs (aspirin, ibuprofen, naproxen). However, a recent large multicenter epidemiologic study found no significant association between PPHN risk and maternal use of nonaspirin NSAIDs or ibuprofen use during the third trimester.[73]

Conflicting evidence exists whether maternal selective serotonin reuptake inhibitor (SSRI) use during pregnancy increases the risk of PPHN. Exposure of pregnant rats to fluoxetine produces pulmonary hypertension, hypoxia, and increased mortality in the pups.[7,24] In human epidemiology studies, the use of SSRIs during the last half of pregnancy was associated with an increase in the incidence of PPHN, although recent reports indicate the risk is modest when controlling for maternal depression.[14,29,34,37,56] The severity of PPHN has also not been well described, and one recent report found that neonatal mortality rates were not higher in SSRI-exposed versus nonexposed neonates with PPHN (3.4% vs. 8.3%, p = NS).[53] The mechanism by which SSRIs induce PPHN remains poorly understood, although there is some evidence that SSRIs induce concentration-dependent constriction of the ductus arteriosus.[33] These findings are in agreement with a recent report from a large Swedish registry, which suggested that SSRI-exposed infants are more likely to have idiopathic PPHN without lung disease.[53] The FDA continues to recommend that health care professionals treat depression during pregnancy as clinically appropriate, indicating that neonatologists should be alert to signs of hypoxemia in neonates born to mothers who used SSRIs.

Unlike pulmonary hypertension in children or adults, PPHN is rarely familial, and few genetic risk factors have been identified. Endothelial cells generate NO from the precursor L-arginine, an amino acid supplied by the urea cycle. In term neonates with respiratory failure, with and without

• **Fig. 72.4** Vascular maldevelopment is a hallmark of PPHN. The pulmonary vessels show thickened walls with smooth muscle hyperplasia. Further, the smooth muscle extends to the level of the intra-acinar arteries, which does not normally occur until much later in the postnatal period. (From JD Murphy, et al. *J Pediatr.* 1981;98:962).

PPHN, a polymorphism in the rate-limiting enzyme of the urea cycle, carbamoyl-phosphate synthetase-1, was associated with pulmonary hypertension, low plasma arginine concentrations, and low plasma nitric oxide metabolites.[54] Another single-center study reported the results of rigorous genotype analysis of 88 neonates with documented PPHN.[13] No differences were noted in most candidate genes, including BMPR2 and nitric oxide synthase. However, PPHN was significantly associated with genetic variants for corticotropin releasing hormone receptor-1 (*CRHR1*) and CRH-binding protein and with significantly increased levels of 17-hydroxyprogesterone. These data are supported by animal data indicating that antenatal and postnatal steroids reduce oxidant stress and normalize nitric oxide synthase and phosphodiesterase function in experimental PPHN.[15,55]

Children with Down syndrome (trisomy 21) commonly develop pulmonary hypertension in association with structural heart defects, and an elevated incidence of PPHN in the absence of cardiac disease has also been recognized.[16,61] In a Dutch cohort with excellent early ascertainment of Down syndrome, PPHN was documented in 5.2% of the infants.[77] Infants with Down syndrome are similarly overrepresented in the ECMO registry maintained by the Extracorporeal Life Support Organization, and their survival to discharge is significantly decreased compared to the general population.[65] Another recent study showed that 85% of autopsy specimens from Down syndrome children displayed pulmonary vascular remodeling.[12]

Delivery by elective cesarean section delays the decrease in pulmonary arterial pressure and increases the risk of PPHN,[48] and delivery before 39 weeks' gestation likely amplifies this effect. When compared to matched controls, infants with PPHN are more likely to have been delivered by cesarean section. Maternal diabetes, asthma, black or Asian race, and high body mass index are also important risk factors.[32,78]

Pulmonary hypertension complicates the course of 25% of infants with perinatal asphyxia. Fetal hypoxemia, ischemia, acidosis, meconium aspiration, and ventricular dysfunction delay the fall in PVR and increase the risk for PPHN. Acute asphyxia is associated with reversible pulmonary vasoconstriction, but chronic in utero asphyxia also induces vascular remodeling.[52] The adoption of therapeutic hypothermia for perinatal asphyxia raised concerns about its capacity to induce or aggravate PPHN in asphyxiated infants. Deep hypothermia (temperature decreased to 32°C) increased mean pulmonary arterial pressure by 30% in neonatal lambs and increased rates of PPHN and ECMO in human infants.[62] However, the effect of moderate hypothermia (33.5°C) on PVR appears to be modest, and analysis of randomized trials found that hypothermia does not significantly increase the incidence of PPHN.[70]

Disruptions in the production or function of vasoactive mediators in the perinatal period will also lead to pulmonary vasoconstriction and/or remodeling. Data from animal models and human infants indicate that disruptions of the NO-cGMP, prostacyclin-cAMP, and endothelin signaling pathways are among those that play an important role in the vascular dysfunction associated with PPHN. The NO-cGMP pathway has been a topic of particularly intense investigation, in part because of the ability to deliver inhaled nitric oxide gas as a therapeutic agent. Decreased expression and activity of eNOS have been documented in animal models, and decreased eNOS expression has been found in umbilical venous endothelial cell cultures from human infants with meconium staining who develop PPHN.[20] Furthermore, PPHN is associated with "uncoupling" of the eNOS enzyme, which reduces synthesis of nitric oxide and promotes production of reactive oxygen species, such as superoxide. Downstream vascular abnormalities include reduced levels of the critical second messenger, cGMP. For instance, in vascular smooth muscle from PPHN lambs, reduced cGMP concentrations are generated in response to NO, in part due to reduced activity of soluble guanylate cyclase and increased activity of cGMP-specific phosphodiesterase (PDE5). PDE5 activity is also elevated in fetal lambs with chronic intrauterine PH, and striking increases in PDE5 activity emerge in response to mechanical ventilation and oxygen therapy, further driving down cGMP levels.[21]

Less is known about the role of abnormal prostacyclin-cAMP signaling in PPHN. Some data suggest that abnormal prostacyclin synthesis and downstream adenylate cyclase signaling occur, analogous to the changes reported for NO-cGMP signaling. In addition, elevated production of the vasoconstrictor arachidonic acid metabolite, thromboxane, plays a role in pulmonary hypertension produced by chronic hypoxia.

Circulating levels of the potent vasoconstrictor endothelin (ET-1) are elevated in lambs and newborn infants with PPHN, and there is evidence that the balance of ET receptors is shifted to the vasoconstrictor (ET-A) pathways. In addition, endothelin may affect vascular tone by increasing production of reactive oxygen species such as superoxide and hydrogen peroxide, which also act as vasoconstrictors. Therefore, the elevated endothelin levels in PPHN may increase vasoconstriction through preferential stimulation of ET-A receptors and through increased production of superoxide.

Oxidant stress plays an important role in the pathogenesis of PPHN both antenatally and following birth. An increase in reactive oxygen species such as superoxide and hydrogen peroxide in the smooth muscle and adventitia of pulmonary arteries has been demonstrated in neonatal animal models of pulmonary hypertension.[11,23] Oxidant stress can be caused by immature or dysfunctional anti-oxidant defense mechanisms (e.g., superoxide dismutase, catalase) and/or increased activity of pro-oxidant enzymes such as NADPH oxidase, and reactive oxygen species can cause pulmonary vasoconstriction and trigger vascular remodeling as seen in PPHN.[11,40] Reactive oxygen species generated in response to hyperoxia can decrease eNOS expression and activity, decrease activity of soluble guanylate cyclase, and increase PDE5 activity, resulting in decreased cGMP levels.

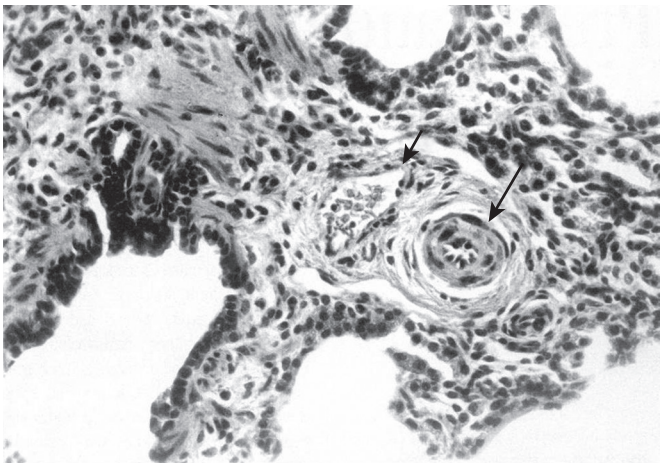
Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) represents ~8% of all major congenital anomalies and affects approximately 1 in 2500-3000 pregnancies when including patients identified by prenatal diagnosis. CDH includes abnormal diaphragm development, herniation of abdominal viscera into the chest, and a variable degree of lung hypoplasia. Herniation occurs most often in the posterolateral segments of the diaphragm, and 80% of the defects occur on the left side.

Severe CDH develops early in the course of lung development, and an arrest in the normal pattern of airway branching occurs in both lungs, resulting in reduced lung volume and impaired alveolarization. A similar developmental arrest occurs in pulmonary arterial branching, resulting in reduced cross-sectional area of the pulmonary vascular bed, thickened media and adventitia of small arterioles, and abnormal medial muscular hypertrophy extending distally to the level of the acinar arterioles. Although in utero lung compression by herniated viscera has been implicated as the primary mechanism responsible for producing the lung abnormalities of CDH, some evidence suggests that decreased pulmonary blood flow alone is sufficient to cause lung hypoplasia.[69]



After birth, PVR often remains at suprasystemic levels, causing extra-pulmonary right-to-left shunting across the foramen ovale and ductus arteriosus and profound hypoxemia. High PVR in the newborn with CDH is related to multiple factors, including the small cross-sectional area of pulmonary arteries, structural vascular remodeling, vasoconstriction with altered reactivity, and LV dysfunction causing pulmonary venous hypertension. The mediators of altered pulmonary vascular reactivity in CDH are not well understood, although substantial evidence points to disruptions in NO-cGMP and endothelin signaling.[36] Chronic pulmonary hypertension is commonly seen in infants with severe disease and is associated with persistently high endothelin levels.[36]

Abnormalities of cardiac development and function also play an important role in the pathophysiology of CDH. The left ventricle, left atrium, and intraventricular septum are hypoplastic in infants that die of CDH relative to age-matched controls,[63] perhaps due to low fetal and postnatal pulmonary blood flow as well as compression by the hypertensive right ventricle. Left ventricular hypoplasia and dysfunction increase left atrial and pulmonary venous pressures, and the resulting pulmonary venous hypertension will diminish the clinical response to inhaled NO during the first few days of life. Some infants may have exceptionally severe left ventricular dysfunction that leads to dependence on the right ventricle for systemic perfusion; this subset may benefit from clinical strategies that maintain patency of the ductus arteriosus.

Alveolar Capillary Dysplasia

Alveolar capillary dysplasia (ACD, with or without misalignment of the pulmonary veins) is a rare form of interstitial lung disease that presents as severe PH and hypoxemia early in life. The etiology of ACD is believed to be caused by a genetic defect or early antenatal insult that prevents normal development of the pulmonary capillary bed. Findings include remodeling of the pulmonary arterioles, simplification of the alveolar architecture, and development of congested "misaligned pulmonary veins" residing in the same adventitial sheath (Fig. 72.5). These so-called veins have recently been recognized to be bronchopulmonary anastomoses that link the systemic and pulmonary circulations and bypass the alveolar capillary bed.[25] ACD remains universally fatal despite treatment with all known modalities, including extracorporeal support, although limited survival after lung transplantation was recently reported.[72] More than 50% of infants present with other anomalies, most commonly affecting the genitourinary, cardiovascular, and gastrointestinal systems. The diagnosis can only be made with certainty based on microscopic examination of the lung. Therefore, a complete postmortem evaluation should be recommended for all newborns that die as a result of unexplained pulmonary hypertension, and a lung biopsy should be considered in infants with prolonged, refractory PPHN. While ACD classically presents in the neonatal period, late presentation at several months of life has been reported. Approximately 10% of reported ACD cases have a familial association, indicating a probable genetic component. In 40% of infants with ACD, mutations or deletions in the *FOXF1* transcription factor gene or deletions upstream to *FOXF1* are identified.[66] A murine model of *FOXF1* deficiency produces defects in lung vascularization and alveolarization, further demonstrating the importance of the *FOXF1* protein in embryonic development of the pulmonary vasculature.

In addition to ACD and other developmental lung disorders, severe refractory PPHN may accompany respiratory

• **Fig. 72.5** Vascular abnormalities associated with alveolar capillary dysplasia. The lung parenchyma shows airspace simplification and widened alveolar walls. A central membranous bronchiole is accompanied by adjacent thick-walled arteries (*long arrow*) with associated dilated veins (*short arrow*). The prominently muscularized arteries extend into adjacent alveolar walls where they are also accompanied by dilated veins.

failure caused by genetic abnormalities of surfactant deficiency. Surfactant protein B deficiency has been reported most commonly and is characterized by early presentation, radiographic findings of ground-glass opacities, progressive respiratory failure, and early death. The most common mutation is in codon 121 of the *SP-B* gene. Deficiencies in surfactant protein C also occur, but PPHN is not a known association. Mutations in the ATP-binding cassette (*ABC*) transporter 3 gene are now recognized to occur in neonates with severe neonatal lung disease and symptoms of surfactant deficiency and have been reported as a lethal cause of PPHN.

Pulmonary Hypertension in Premature Infants

Extremely preterm birth is associated with high rates of early pulmonary hypertension (PH), particularly when associated with oligohydramnios.[42] This disease should be considered when hypoxemia occurs out of proportion to the degree of parenchymal lung disease. Furthermore, echocardiographic findings consistent with early PH, such as ventricular septal wall flattening and right ventricle dilation, were found in ~40% of extremely low birth weight babies at 7 days of age and predicted BPD and late PH.[50]

Bronchopulmonary dysplasia is an important cause of chronic pulmonary hypertension, with an incidence of 16%-25% in infants with BPD and rates up to 40% in infants with severe BPD.[49] The pathogenesis of BPD-associated PH involves complex interactions between antenatal factors, such as growth restriction, preeclampsia, oligohydramnios, or fetal inflammation, and postnatal injury due to ventilator-induced lung injury, hyperoxia, hemodynamic stress, and infection. These injuries result in impaired angiogenesis, abnormal vascular signaling, and vascular pruning, culminating in a reduction in the alveolar-capillary surface area. The morphologic vascular alterations are accompanied by increased pulmonary vascular tone and heightened vasoconstrictor responses to acute hypoxia. Over time, reduced vascular growth limits vascular surface area and promotes high PVR, especially in response to high cardiac output at times of stress or exercise.

Pulmonary vein stenosis is a complication of severe bronchopulmonary dysplasia that can contribute to severe and progressive PH. The left-sided pulmonary veins (particularly the left upper vein) are most often affected, and severe PH can result after stenosis of only one vein. The true incidence and mechanisms producing pulmonary vein stenosis are not yet known. A number of findings, including a median age of diagnosis of 6 months, a lack of concordance in twins, and association with necrotizing enterocolitis indicate that the disease is postnatally acquired.[31,47] The disease tends to be progressive and is associated with high mortality (30%-50%) in the first 2 years after diagnosis.

Numerous preclinical and clinical studies are addressing the vascular signaling abnormalities in evolving and established BPD. In sheep and primate models of prematurity, lung endothelial nitric oxide synthase (eNOS) expression is decreased and nitric oxide inhalation normalizes patterns of lung growth and vascularization. However, clinical trials of inhaled nitric oxide have not demonstrated a convincing reduction in the severity of BPD.[4] Studies in preterm lambs indicate that deficient soluble guanylate cyclase activity could diminish vascular responses to nitric oxide and that elevated activity of the cGMP-specific phosphodiesterase (PDE5) may also disrupt the cGMP response to nitric oxide, but further study is needed to determine whether these findings will lead to new therapeutic insights.

Clinical Therapy of PPHN

PPHN presents with respiratory distress, labile oxygenation, differential saturation (higher Spo_2 in the right upper extremity compared to a lower extremity), or profound hypoxemia despite oxygen and mechanical ventilation. PPHN is most often recognized in the term or near-term neonate but should also be considered in premature neonates who have cyanosis out of proportion to their parenchymal lung disease.[39]

Echocardiography is mandatory to rule out congenital heart disease, establish an accurate diagnosis of PPHN, and identify extra pulmonary shunting. Findings that confirm PPHN include bidirectional or predominantly right-to-left shunting across the foramen ovale or ductus arteriosus, although other signs such as flattening or left deviation of the intraventricular velocity, tricuspid regurgitant velocity, and increased right ventricular dilation also suggest the diagnosis. Echocardiography also determines whether left ventricular insufficiency is present, which could trigger pulmonary venous hypertension that would only be aggravated by a pulmonary vasodilator. While levels of brain natriuretic peptide increase in the face of elevated right ventricular pressure, this biomarker does not have sufficient sensitivity and specificity to detect or monitor the severity of PPHN.

General Care

The American Heart Association (AHA) and American Thoracic Society (ATS) have published guidelines for management of pediatric pulmonary hypertension, including PPHN (Box 72.1).[2] General management principles for PPHN include maintenance of normal temperature (except for those undergoing therapeutic hypothermia), electrolytes (particularly calcium), glucose, and intravascular volume. Systemic blood pressure should be maintained at normal levels for age with volume and cardiotonic therapy, with the primary goal to optimize left and right ventricular function and enhance systemic O_2 transport. Maintaining normal left ventricular function is an important element of care. An "inodilator" such as milrinone may improve left ventricular function and reduce pulmonary venous hypertension, both of which may improve pulmonary blood flow and oxygenation in infants with refractory PPHN.[44] Increasing blood pressure to supraphysiologic levels for the sole purpose of

• BOX 72.1 AHA/ATS Management Guidelines for Persistent Pulmonary Hypertension of the Newborn[2]

1. Inhaled nitric oxide (iNO) is indicated to reduce the need for extracorporeal membrane oxygenation (ECMO) support in term and near-term infants with PPHN or hypoxemic respiratory failure who have an oxygenation index that exceeds 25 (Class I, Level A).
2. Lung recruitment strategies can improve the efficacy of iNO therapy and should be performed in patients with PPHN associated with parenchymal lung disease (Class 1, Level B).
3. ECMO support is indicated for term and near-term neonates with severe PH and/or hypoxemia that is refractory to iNO and optimization of respiratory and cardiac function (Class I, Level A).
4. Evaluation for disorders of lung development, such as alveolar capillary dysplasia and genetic surfactant protein diseases, is reasonable for infants with severe PPHN who fail to improve after vasodilator, lung recruitment, and/or ECMO therapy (Class IIa, Level B).
5. Sildenafil is a reasonable adjunctive therapy for infants with PPHN who are refractory to inhaled NO, especially with an oxygenation index that exceeds 25 (Class IIa, Level B).
6. Inhaled prostacyclin analogues may be considered as adjunctive therapy for infants with PPHN that are refractory to iNO and have an oxygenation index that exceeds 25 (Class IIb, Level B).
7. Intravenous milrinone is reasonable in infants with PPHN and signs of left ventricular dysfunction (Class IIa, Level B).
8. Inhaled NO can be beneficial for preterm infants with severe hypoxemia that is primarily due to PPHN physiology rather than parenchymal lung disease (Class IIa, Level B).
9. iNO and other PAH-targeted drug therapies should be used cautiously in subjects with CDH especially in those with confirmed or suspected left ventricular dysfunction (Class IIa, Level B).

CDH, Congenital diaphragmatic hernia; PAH, pulmonary arterial hypertension.

driving a left-to-right shunt across the PDA may transiently improve oxygenation but should be done with caution and combined with therapy to simultaneously reduce pulmonary vascular resistance.

Alveolar hypoxia and hypoxemia should be avoided, as they are pulmonary vasoconstrictors and contribute to the pathophysiology of PPHN. Oxygen is a mainstay of PPHN therapy to maintain oxygen delivery to the brain and other tissues and for its pulmonary vasodilator properties. High oxygen concentrations, frequently up to 100% oxygen, are commonly used to reverse hypoxemia and pulmonary vasoconstriction in infants with PPHN. However, hyperoxia may also exaggerate oxidative stress, increase pulmonary vascular contractility, and impair the pulmonary dilator response to nitric oxide. In normal lambs and lambs with PPHN, the vasodilatory effects of supplemental oxygen reach a plateau at about 60% oxygen or a PaO_2 of ~60 mm Hg.[45] The short-term pulmonary vascular benefits of hyperoxia should be carefully weighed against the risks of increased pulmonary vascular contractility, diminished vasodilator responses, as well as potential systemic risks. In patients undergoing therapeutic hypothermia, the oxygen dissociation curve is shifted to the left, which may influence PaO_2 levels at lower saturation levels. Factoring in this left shift when monitoring pulse oximetry and correcting blood gases to patient's actual body temperature help promote adequate oxygen delivery.

Lung recruitment should be optimized to 9-10 ribs expansion, and high-frequency ventilation and/or surfactant are often useful in infants with severe parenchymal lung disease. Surfactant deficiency (respiratory distress syndrome) or inactivation (e.g., from meconium aspiration syndrome or pneumonia) is commonly present. Surfactant improves oxygenation, reduces air leak, and reduces need for ECMO in infants with meconium aspiration, sepsis, and other parenchymal lung disease.[46] However, these strategies should be reserved for infants with parenchymal lung disease, as they are ineffective and run the risk of lung overdistension or acute airway obstruction in infants with idiopathic pulmonary hypertension. Registry studies indicate that surfactant does not benefit the infant with CDH.[74]

Acidosis is a pulmonary vasoconstrictor, particularly when combined with hypoxia, and pH should be maintained >7.3. Alkalosis induced by hyperventilation or infusion of sodium bicarbonate was frequently employed prior to the approval of inhaled nitric oxide.[76] While transient improvements in PaO_2 may be observed, there is no long-term benefit. Prolonged alkalosis may paradoxically worsen pulmonary vascular tone, reactivity, and permeability edema,[43] and may produce cerebral constriction, reduced cerebral blood flow, and worse neurodevelopmental outcomes.

Infants who fail to exhibit sustained improvement in oxygenation with good hemodynamic function should receive evaluation for treatment with extracorporeal membrane oxygenation (ECMO) in a center that is equipped with appropriate equipment and personnel. The oxygenation index (OI; calculated as [mean airway pressure x FiO_2 x 100]/PaO_2) is a useful gauge for the severity of disease, with OI >40 often used as an indication for referral to an ECMO center. Although ECMO is the only therapy that has been proven to reduce mortality for PPHN, it is also costly, labor intensive, and associated with potential adverse effects such as intracranial hemorrhage and ligation of the right common carotid artery. A registry maintained by the Extracorporeal Life Support Organization facilitates sharing of data and supports decision making for individual patients.

Pulmonary Vasodilator Therapy

The primary goal of PPHN therapy is selective pulmonary vasodilation. Pulmonary vasodilator therapies are based on abnormalities in the endogenous signaling pathways (see Fig. 72.2). Inhaled nitric oxide (iNO) is the only specific pulmonary vasodilator therapy approved by the FDA for PPHN. iNO acutely improves oxygenation and decreases the need for ECMO support in newborns with PPHN and an oxygenation index of >25. However, 30%-40% of infants fail to achieve a sustained improvement in oxygenation, and iNO has not reduced mortality or length of hospitalization in any study. Doses greater than 20 ppm

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

provide no benefit and increase the risk of methemoglobinemia and other complications. The optimal window for introduction of therapy with iNO remains under investigation. The use of iNO for milder or earlier respiratory failure (i.e., oxygenation index of 15 to 25) does not decrease the incidence of ECMO or death, reduce chronic lung disease, or decrease the incidence of neurodevelopmental impairment. However, at least one study suggests that delaying iNO initiation until respiratory failure is advanced (oxygenation index of >40) may increase the length of time on oxygen.[28] Similar to term infants, preterm infants with early PPHN, particularly after prolonged rupture of membranes or oligohydramnios, will show marked improvement in oxygenation after treatment with iNO.[39]

Once oxygenation improves, iNO can usually be weaned relatively rapidly to 5 ppm without difficulty and discontinued within 5 days. Infants who remain hypoxemic with evidence of PPHN beyond that time are more likely to have an underlying cause of dysregulated pulmonary vascular tone, such as developmental lung abnormalities like alveolar capillary dysplasia, pulmonary vein stenosis, severe pulmonary hypoplasia, or progressive lung injury. When iNO is stopped abruptly, "rebound" PH sometimes develops, even if no improvement in oxygenation was observed at the onset of therapy.[17] This interesting phenomenon can be life-threatening and raises questions about whether vascular cells respond to iNO by upregulating vasoconstrictor pathways. However, from a practical standpoint, the clinical problem can usually be overcome by weaning iNO to 1 ppm prior to discontinuation.

Up to 40% of infants will not respond or sustain a response to iNO. PDE5 activity is elevated in PPHN, leading to interest in a role for PDE5 inhibitors as primary or adjunctive therapeutic agents. The use of enteral sildenafil was reported in a small, randomized controlled trial that showed a dramatic improvement in oxygenation and survival.[6] A subsequent open-label pilot trial of intravenous sildenafil demonstrated improved oxygenation in infants with PPHN, with low mortality and utilization of ECMO.[68] This study also showed that sildenafil clearance in neonates is initially low and increases rapidly through the first week of life, reflecting the relative immaturity of the hepatic cytochrome (P) system in the early neonatal period.[51] Hypotension was the most commonly reported adverse effect, although it can be avoided by delivering the loading dose over a longer 3-hour period. A clinical trial is underway to determine the benefit of sildenafil as an adjunct to iNO therapy (NCT01720524). Sildenafil can be delivered intravenously or as an enteral preparation. Enteral use makes the drug feasible for long-term therapy for infants with chronic pulmonary hypertension associated with congenital diaphragmatic hernia and BPD, although no randomized trials have yet been completed to confirm its efficacy.

Prostanoids

Intravenous prostacyclin (PGI_2) is commonly used for pulmonary hypertension in children and adults but is rarely considered in neonates because of concerns about systemic hypotension and/or ventilation-perfusion mismatch in infants with parenchymal lung disease. Aerosolized PGI_2 is commonly used in adults with pulmonary hypertension.[75] In case series reports of infants poorly responsive to iNO, inhaled PGI_2 produced transient pulmonary vasodilation and enhanced oxygenation. However, the alkaline solution needed to maintain drug stability could irritate the airway, and delivery of precise doses can be difficult because of loss of medication into the nebulization circuit. New, more stable preparations are emerging that are specifically designed for intermittent nebulization, such as iloprost or treprostinil. Treprostinil is particularly promising, because it is also suitable for systemic administration, including by the subcutaneous route.[22] A clinical trial is currently underway to determine the efficacy of treprostinil for PPHN (NCT02261883).

Milrinone

cAMP concentrations are regulated in part by cAMP-hydrolyzing phosphodiesterases such as PDE3 and PDE4. PDE3A expression and activity increases after birth and in response to iNO, which could promote vasoconstriction. In animal studies, the PDE3 inhibitor milrinone decreases PAP and resistance, acts additively with iNO, and prevents rebound PH. Clinical reports indicate that milrinone may enhance pulmonary vasodilation of infants with PPHN refractory to iNO. Milrinone may also reduce left ventricular dysfunction and pulmonary venous hypertension by lowering systemic vascular resistance.

Endothelin Receptor Antagonists

Endothelin-1 plays a role in experimental PPHN, and plasma endothelin-1 levels are increased in infants with PPHN and severe CDH and appear to correlate with the severity of illness. Bosentan, a nonspecific ET-1 receptor blocker, is established treatment for PH in adults and is approved for children over 3 years of age. Endothelin blockade enhances pulmonary vasodilation in experimental PPHN, and one single-center trial found that bosentan improved oxygenation in an iNO-naïve population of PPHN infants. In contrast, the FUTURE-4 multicenter trial found that bosentan as adjunctive therapy for iNO did not improve PPHN outcomes, time on iNO, or time to extubation, possibly in part due to inconsistent intestinal absorption.[67]

Outcome and Follow-Up

Prior to the introduction of ECMO in the late 1980s, the mortality rate for severe hypoxic respiratory failure was nearly 40%, and the prevalence of major neurologic disability in survivors was estimated at 25%-60%. ECMO produced remarkable reductions in the mortality rate of PPHN, and based on the recent iNO clinical trials, contemporary mortality rates for PPHN are approximately 7%-9%. Post-discharge medical problems for the first year

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

of life include a >25% incidence of reactive airways disease and a 15%-20% incidence of significant feeding difficulty and/or poor weight gain (<5th percentile for age). The need for supplemental oxygen decreases substantially by 2 years of age, although the incidence of reactive airways disease and rehospitalization remains high through school age. Adult pulmonary outcomes are not yet known.

Approximately 25% of survivors of PPHN will display significant neurodevelopmental impairment when tested at 12-24 months of age. Neurodevelopmental disability rates are similar in infants with moderate versus severe disease, and no therapy to date has been demonstrated to improve developmental outcomes. Neuroimaging is suggested before discharge for all children with moderate to severe PPHN (OI >25), even when ECMO or therapeutic hypothermia are not required.

It is not clear that any therapy, including iNO, improves neurodevelopmental outcomes. In numerous clinical trials, a trend toward higher motor impairment was observed after iNO versus placebo. In the early iNO trial reported by Konduri et al., the decrease in the Bayley PDI was statistically significant.[41] The reasons for these findings remain unknown, but it is possible that other factors, such as antenatal injury and/or commonly used therapies such as hyperventilation, hyperoxia, or drugs such as pancuronium, play a significant role in adverse outcomes. Serial screening for late sensorineural hearing loss is mandatory, as its prevalence is 6%-10% and will continue to emerge through school age. Comprehensive follow-up of a large PPHN cohort through school age found a 9% incidence of severe intellectual disability (FSIQ <70) and a 7% incidence of moderate intellectual disability (IQ of 70 to 84).[58] Comprehensive screening is recommended for all HRF survivors before they enter school to determine if any subtle deficits may predispose them to learning disabilities.

Key Points

- Normal lung vascular development is supported by a hypoxic intrauterine environment, which promotes expression of hypoxia inducible factor (HIF) and vascular endothelial growth factor (VEGF).
- Maternal factors such as diabetes, high body mass index, smoking, use of SSRIs or NSAIDs, and caesarean section increase the risk of PPHN; postnatal factors include perinatal asphyxia, hyperoxia, hypoxia, infection, and lung inflammation.
- Medical management of PPHN requires lung recruitment, optimization of right and left ventricular function, and maintenance of Pao_2 between 60 and 80.
- Inhaled nitric oxide at 20 ppm improves oxygenation and reduces the need for ECMO support in term and near-term infants with PPHN.
- New therapies focused on downstream cGMP signaling, prostanoid signaling, and endothelin signaling are undergoing testing.
- ECMO support is indicated for term and near-term neonates with severe PH and/or hypoxemia that is refractory to iNO and optimization of respiratory and cardiac function.
- Infants that survive moderate to severe PPHN are at high risk for neurodevelopmental impairment and should receive neuroimaging and neurodevelopmental follow-up.

Prenatal Diagnosis of Congenital Heart Disease

JAMES STRAINIC, COREY STIVER, AND SARAH PLUMMER

Introduction

Congenital heart disease (CHD) affects 6-8 per 1000 live births. However, only 20% of babies with congenital heart disease would be identified if the examination of the fetal heart were confined to traditional high-risk groups such as increased nuchal translucency, family history of CHD, and teratogen exposure.[25]

The current American Society of Echocardiography guidelines suggest the optimal timing for performance of a comprehensive transabdominal fetal echocardiogram is between 18-22 weeks' gestation.[44] Repeat fetal echocardiograms are suggested for those fetuses identified with diseases that can be progressive, a suboptimal scan, or any patient with fetal arrhythmia. The interpreting physician must be able to recognize the full spectrum of simple and complex acquired and congenital heart disease and its manifestations and natural history throughout gestation. This includes knowledge of the principles of biologic ultrasound instrumentation; understanding of maternal–fetal physiology; familiarity with the latest developments in obstetric diagnostics; and knowledge of the growing field of invasive fetal intervention. It is important to recognize the limitations of fetal echocardiography in detecting important associated lesions and to have the skill to apply all modalities of echocardiography including two-dimensional, M-mode, pulsed-wave, continuous wave, and Doppler color flow mapping in recognizing and evaluating both the normal and abnormal fetal anatomy and physiology throughout the stages of human heart development. There should also be a thorough understanding of fetal arrhythmias and a team readily available to further aid in the diagnosis and treatment of dysrhythmias.[44]

Historical Perspective

The first real-time cardiac heart images and quantitative data were published by the Lange, Sahn, and Reed group in Tucson, Arizona, in 1980. Lindsey Allan published echocardiogram/anatomical correlates in the same year describing systematically real-time normal and abnormal ultrasonic anatomy of the fetal heart, laying the foundation for the field of fetal echocardiography. Using ultrasonic equipment available at the time, real-time, cross-sectional study and diagnosis of fetal cardiac anomalies in utero in the second trimester was possible.

Improvements in diagnostic capabilities over the past 40 years have had tremendous impact on fetal cardiac diagnosis. The use of direct Doppler interrogation of fetal intracardiac flow was first demonstrated in 1985. Use of Doppler color flow mapping in the assessment of fetal cardiac malformations and particularly in a screening situation was started shortly after. The use of color Doppler has become indispensable in the diagnosis of more complicated cardiac malformations. By the late 1990s, the diagnostic accuracy of the nature of complex cardiac malformations in utero was as high as 95%.[4,7,25,45]

Overview of Fetal Circulation and Cardiac Adaptation at Birth

One must not assume that the fully developed fetal heart is analogous to the infant or child heart. This section discusses the difference between the fetal myocardium and the postnatal myocardium and unique fetal blood flow through naturally occurring shunts, blood flow to the placenta, and pulmonary blood flow.

The fetal myocardium has significant differences from the pediatric and adult myocardium. It is composed of a greater proportion of noncontractile elements (60% versus 30%), and fetal cardiomyocytes can divide, whereas adult cardiomyocytes can only hypertrophy. In addition, the removal of calcium from troponin C is slower in the fetus, resulting in slower muscle relaxation. The right ventricle handles more volume, its radius is greater, the radius-to-wall thickness is greater, and it hypertrophies to maintain appropriate wall tension. As a result, the wall thickness of the right ventricle is approximately equal to that of the left in fetal life.

Abstract

Congenital heart disease (CHD) is one of the most common congenital defects in the fetus. Prenatal diagnosis has been shown to improve outcomes for infants born with CHD. The goals and objectives of this chapter are to discuss the historical perspective of fetal echocardiography and fetal cardiology, describe the fetal circulation and the effects of parturition on postnatal circulation, discuss indications for fetal echocardiogram, discuss assessment of fetal cardiovascular performance, discuss impact of prenatal diagnosis on outcome, discuss diagnosis and therapy of fetal arrhythmias, discuss the limitations of fetal echocardiograms, discuss fetal interventions, and discuss novel approaches to prenatal diagnosis and interventions of congenital heart disease. The field of fetal cardiology has experienced rapid growth in the last 40 years. Advances in image quality allow for the diagnosis of a wide array of cardiac pathology. This allows for well-coordinated, postdelivery care of complex congenital heart defects, preparation of the parents through prenatal counseling, and management of evolving fetal pathology. Potentially, we may be able to alter the natural history of certain congenital heart defects through invasive fetal cardiac interventions. However, even with advances in echocardiography, one must be aware of limitations of fetal ultrasound when evaluating acutely ill neonates in the delivery room.

These differences result in increased stiffness and impaired relaxation of the fetal heart as demonstrated in the Doppler pattern across the atrioventricular (AV) valves. In the fetus, passive ventricular filling is impaired, and active atrial filling is responsible for emptying the atria. As a result, the right ventricle is more sensitive to changes in preload and shows signs of dysfunction before the left ventricle. Increased preload, as seen in anemia, viral illness, and significant arterial to venous malformations (AVMs) results in fetal hydrops. There is a gradual change from the "fetal heart" to an "adult heart" that progresses throughout the neonatal period to adulthood. These changes can be easily demonstrated by echocardiography.

The fetus has a unique physiology consisting of various shunts to promote oxygenated blood to the brain and deoxygenated blood to the placenta. The foramen ovale is designed to allow higher oxygenated blood from the placental veins preferentially to the left atrium. The increased oxygenated blood from the placenta travels through the umbilical vein to the ductus venosus. The blood then travels to the inferior vena cava (IVC) and is directed across the foramen ovale by the Eustachian valve. Lower oxygenated blood flow from the fetal brain is preferentially directed from the superior vena cava (SVC) to the right ventricle and eventually across the ductus arteriosus to the placenta. The ductus arteriosus is responsible for carrying most of the cardiac output from the "pulmonary circulation" to the descending aorta and the placenta. The flow pattern is typically a predominant systolic peak with continuous low-velocity diastolic flow. Continuous diastolic flow toward the descending aorta is a result of low-resistance placental circulation. Elevated diastolic flow in the ductus arteriosus is a sign of ductal constriction or lower body arteriovenous malformations. The aortic isthmus has a distinctive wave form in the fetus. The aortic isthmus is located between the left subclavian artery and the insertion of the ductus arteriosus. It is unique in that it straddles two different output systems (the "systemic" output of the left ventricle and the "pulmonic" output of the right ventricle that is directed toward the placenta). Flow is normally toward the placenta in both systole and diastole at the level of the aortic isthmus. Decreased flow in the aortic isthmus from inappropriate shunting can result in isthmus hypoplasia and eventually coarctation of the aorta. Left ventricular outflow tract obstruction or significant left ventricular dysfunction results in reversal of flow toward the head in systole. Reversal of flow may also be seen in decreased upper body vascular resistance (AVMs or stressed fetus).

The circulation to the fetal lungs is uniquely different than the blood flow in the adult. The size and number of pulmonary arteries and veins increase as gestation advances. From 20-30 weeks' gestation, blood flow to the lung increases from 15%-25% of the combined cardiac output, accompanied with a significant decrease in weight-indexed pulmonary vascular resistance (PVR). In the animal lab, increasing oxygen tension from 24-46 mm Hg increases pulmonary blood flow by tenfold in term lambs.[43] This suggests that a substantial portion of the high PVR in the mature fetus is maintained by vasoconstriction in an oxygen tension-sensitive manner. Increased oxygen tension in lesions such as transposition of the great arteries may explain development of foramen ovale restriction or closure in the neonatal period. Increased pulmonary blood flow results in increased venous return to the left atrium, resulting in increased left atrial pressure and potential restriction at the foramen ovale.

There is a transition between fetal life and infancy during the first few hours in which the pulmonary vascular resistance decreases, resulting in increased pulmonary blood flow. It results from various birth-related events that occur concurrently and sequentially, which include ventilation, oxygenation, increasing shear stress of blood flow, and changes in the activities of a number of vasoactive agents and their signaling pathways, such as EDNO, PGI2, endothelin-1 (ET-1), and PAF.[12,17,18,39] However, in certain cases, the maturation of the pulmonary vascular bed is delayed, which results in persistent pulmonary hypertension of the newborn (PPHN). Understanding the transition period between fetal circulation and infant circulation is critically important in certain types of congenital heart disease, especially ductal dependent lesions.

A major difference in the fetal circulation compared with the postnatal circulation is the inclusion of the placental circulation. Typically, the placenta is a low-resistance circuit. The umbilical arterial flow is in part dependent on the placental resistance. The placenta has the lowest vascular resistance of any structure in the fetal circulation and, therefore, is the major contributor to umbilical arterial flow. The two vessels that arise from the iliac artery and travel to the placenta carry a large amount of blood. The pulsatility is low and progressively decreases during pregnancy. Reversal of diastolic flow indicates flow toward other vascular regions in fetus where resistance is low, such as an AVM or severe elevation in placental resistance. The ductus venosus connects the umbilical vein with the inferior vena cava (IVC) as it enters the right atrium (RA). Flow is generally phasic in the IVC toward the heart. Phasic periods with absent forward flow or reversal of flow are markers of impaired relaxation of the right ventricle or right atrium secondary to decreased compliance. This can be the result of a cardiomyopathy, ductal restriction, and/or severe volume overload.

Indications for Fetal Echocardiogram

Indications for a fetal echocardiogram fall within three categories that are listed in Table 73.1 with examples from each category.[4,7,25,44,45] However, if all high-risk fetuses meeting the recommended indications have a fetal echocardiogram performed, only 20% of CHD will be detected. Recent data demonstrates that only 48%-60% of congenital heart defects are detected prenatally. Detection rates are poorest in rural communities.[13] This suggests that better screening mechanisms and indications must be determined to bring

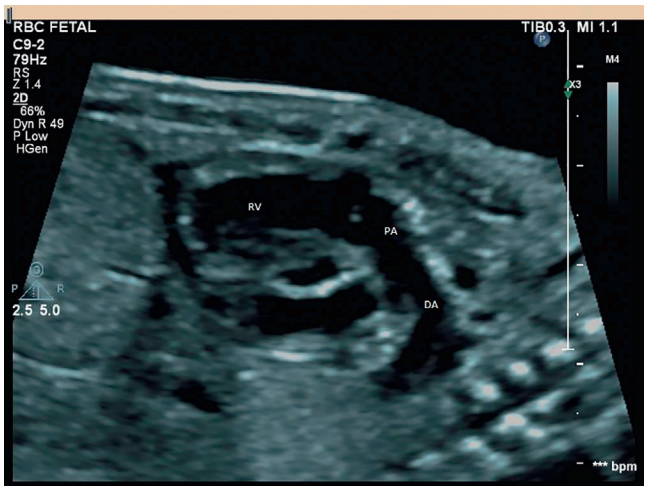
these mothers and fetuses to a center capable of advanced cardiac care.



Performance of a Fetal Echocardiogram

Each fetal echocardiogram must be individualized, depending on the nature of the suspected cardiac lesion, as well as the status of the mother and fetus. At a minimum, it must include a thorough two-dimensional imaging, color Doppler, and spectral Doppler examination of the four-chamber view, both arterial outflow tracts, three vessels and trachea view, and an assessment of pulmonary venous return (Figs. 73.1 to 73.8). There is broad variation in anatomy in the spectrum of congenital heart disease, including situs inversus, ventricular inversion, transposition of the great arteries, heterotaxy syndromes, and a host of other complex configurations of the heart. Therefore, the examiner should confirm anatomical relationships and functional

flow characteristics through a systematic analysis of the following areas:

- Ventricular morphology
- Cardiac axis and situs
- Pericardial effusions
- Venous-atrial, atrioventricular, and ventriculoarterial connections of the heart
- Interventricular septum, atrial septum, atrial chamber size, and foramen ovale
- Atrioventricular and semilunar valves
- Size and relationships of the left and right ventricular outflow tracts
- Ventricular morphology
- Ductal and aortic arches
- Pericardial effusions

The best approach to performing a fetal echocardiogram is to follow a segmental approach. The first step is to determine the fetal position in space and establish a right–left and cranial–caudal axis. The next step is to determine the fetal abdominal situs. This can be performed in the cross-sectional view of the abdomen. Next, using morphologic markers and a segmental approach, determine the following:

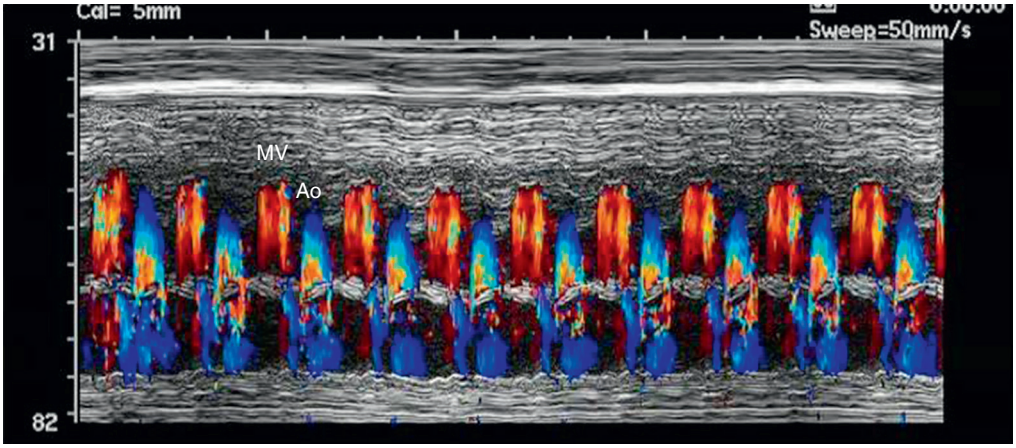
- Great artery looping
- Venous connections
- Atrioventricular connections
- Ventriculoarterial connections
- Cardiac rhythm (Figs. 73.9 and 73.10)

Fetal Pathology

Fetal heart pathology can be divided into three broad categories: structural anomalies, functional anomalies, and rhythm disorders. Diagnosis of functional and structural anomalies of the fetus can provide guidance for postdelivery management.

Fetal rhythm disorders can be diagnosed on fetal echocardiogram and treated prenatally in most circumstances. In addition, fetal echocardiogram provides information regarding the cardiac functional state in fetal-specific disease states including twin-to-twin transfusion syndrome.



• **Fig. 73.9** M-mode fetal scan through the atrial and ventricular walls, demonstrating normal atrial to ventricular intervals. The atrial wall motion (*A*) is in a one-to-one relationship with the ventricular wall motion (*V*).

Most congenital heart defects can be diagnosed prenatally. Detailed discussion regarding specific structural cardiac anomalies is provided in subsequent chapters. However, there are specific findings on fetal echocardiogram that are useful in guiding management at the time of delivery and in the immediate postnatal period. Need for urgent postnatal procedures in cases of hypoplastic left heart syndrome and transposition of the great arteries and the need for prostaglandin (PGE) can be predicted based on fetal echocardiogram findings.

Prostaglandin-dependent CHD lesions can be divided into two categories—those with too little pulmonary blood flow and those with too little systemic blood flow. In its most extreme form, tetralogy of Fallot can be ductal dependent when the pulmonary stenosis is severe. There are markers on fetal echocardiogram that can help predict whether a fetus with tetralogy of Fallot will require PGE or an intervention in the neonatal period. Morphologic markers including the pulmonary valve (PV) annulus size, the pulmonary valve to aortic valve ratio, and the main pulmonary artery to pulmonary valve ratio have been shown to predict both ductal dependence and need for neonatal procedures.[9] Functional variables including PV peak velocity and reversal of blood flow in the ductus arteriosus also predict need for PGE and early intervention.[9] Reversed flow in the ductus arteriosus and reverse orientation of the ductus arteriosus have been shown to be excellent predictors for the need for PGE in the postnatal period in any CHD with right-sided outflow obstruction.[14]

Transposition of the great arteries (TGA) results in systemic venous return with relatively low oxygen content directed to the ascending aorta. This results in central nervous system and cardiac hypoxia. Atrial-level mixing in this lesion is required to provide adequate oxygen to the brain and myocardium as well as to sustain cardiac output. In fetal life, the size of the foramen ovale versus the septal length, a hypermobile primum atrial septum, and reversal of flow in the ductus arteriosus have been shown to be predictive of the need for urgent postnatal

• **Fig. 73.10** Color M-mode fetal scan through the atrium and ventricle, demonstrating that mitral valve inflow (*MV*) and aortic outflow (*Ao*) are in a one-to-one relationship. Notice there are approximately 2.5 heartbeats per second, resulting in a heart rate of 150 bpm.

balloon atrial septostomy to insure adequate atrial level communication.[22,52]

Hypoplastic left heart syndrome with an intact or highly restrictive atrial septum has a mortality as high as 80 percent.[29,30] Urgent decompression of the left atrium after birth can improve survival. Fetal assessment of the pulmonary venous inflow and the vasoreactivity of the pulmonary vascular bed have been shown to be helpful in predicting the need for postnatal intervention. A normal pulmonary vein spectral Doppler typically shows a predominant antegrade wave form in systole and early diastole with flow reversal in late diastole. A flow reversal ratio of less than 5 [forward/reverse velocity time interval (VTI) <5] is highly predictive of need for emergent intervention in the immediate postnatal period.[31] Responsiveness of the fetal pulmonary vasculature to maternal hyperoxygenation (exposure of the mother to 60% inspired oxygen for 10 minutes) can also help identify fetuses that will require urgent postnatal intervention. Failure to augment fetal pulmonary arterial blood flow in response to maternal hyperoxygenation predicts need for emergent decompression of the left atrium[46] and may also identify candidates for fetal intervention with fetal atrial septoplasty and stent placement.

Fetal heart failure is associated with placental edema and resultant hypoxia. The mature heart's response to hypoxia is to increase the heart rate, but the fetus decreases its heart rate in response to hypoxia.[43] This results in hydrops fetalis. The differential diagnosis of the underlying cause of hydrops is broad (Box 73.1). Chemoreceptors in the fetal aorta respond to aortic pO_2 below 18-19 mm Hg, inducing bradycardia. The fetal cardiac output is maintained by redistributing blood flow. Blood flow to the myocardium, adrenal glands, and brain is increased (sampling of the middle cerebral artery may show increased diastolic velocities, the so-called brain sparing effect), while the flow to the renal system, skin, muscle, bones, and gastrointestinal system is decreased.[43]

One of the major causes of placental edema is increased right heart preload. This can be seen in any condition that volume-loads the right ventricle, including large AV malformations, sacrococcygeal teratomas, and twin–twin transfusion syndrome (TTTS).[43] There is a resultant increase in the combined cardiac output (CCO). The combined cardiac output increase reflects the amount of preload increase. Most infants do well without evidence of hydrops until the CCO reaches 700-800 mL/kg/min.[43]

A special situation of increased preload occurs in TTTS. The donor twin often exhibits volume depletion and nephrosclerosis. This results in elevated endothelin-1 and angiotensin II. Doppler of the umbilical artery shows decreased diastolic flow and increased resistance. The increased resistance rarely results in ventricular dysfunction. However, postnatal studies have shown abnormalities in vascular compliance and increased pulse wave velocities in the donor twin.[43] Donor hormones from the response to hypovolemia are transferred across the placenta to the recipient twin. The recipient is thus exposed to increased volume and vasoconstrictors. Angiotensin II is a potent stimulant for hypertrophy. Thus, the recipient twin often presents with cardiomyopathy; dilated, hypertrophic, or a combination of the two. Many fetuses demonstrate marked ventricular hypertrophy, which may result in right ventricular outflow tract obstruction, pulmonary stenosis, and tricuspid valve regurgitation.[43]

Studies have shown that fetal echocardiographic prognostic indicators can predict hydrops fetalis outcomes. These include the cardiac function; cardiac size; systemic venous Doppler profile of the ductus venosus or umbilical vein; presence of atrioventricular valve regurgitation; and presence of pericardial effusions, pleural effusions, ascites, or skin edema.[16] These indicators can be compiled to obtain a cardiovascular profile score (Table 73.2).[16] Treatment should be directed toward underlying pathology, including resolving abnormal peripheral impedance and treating high output failure, myocardial dysfunction, arrhythmia, anemia, or twin–twin transfusion.[16]

Doppler assessment of extracardiac structures can also provide information regarding fetal well-being and are thus included as part of a standard fetal echocardiogram. Assessment of the middle cerebral artery (MCA) helps assess effects of pathophysiologic states on the cerebrovascular flow.[33] Normally, resistance in the MCA is relatively high and diastolic velocity is low. In high output disease states such as anemia, the peak velocity of the MCA is frequently elevated.[33] In states of low cardiac output, the cerebral vascular resistance decreases in response to stress, resulting in increased diastolic velocity so as to preserve adequate blood supply to the brain (the brain sparing effect).[3]

Fetal rhythm abnormalities occur in up to 2% of all pregnancies and can be divided into three categories: ectopic beats, tachycardias, and bradycardias.[15] Accurate diagnosis of rhythm disturbances presents a unique challenge given the lack of access to conventional electrocardiogram. Diagnosis of fetal rhythm disturbances relies on ultrasound techniques including M-mode imaging, spectral Doppler, and tissue Doppler.[15,35,40] A more sophisticated modality to

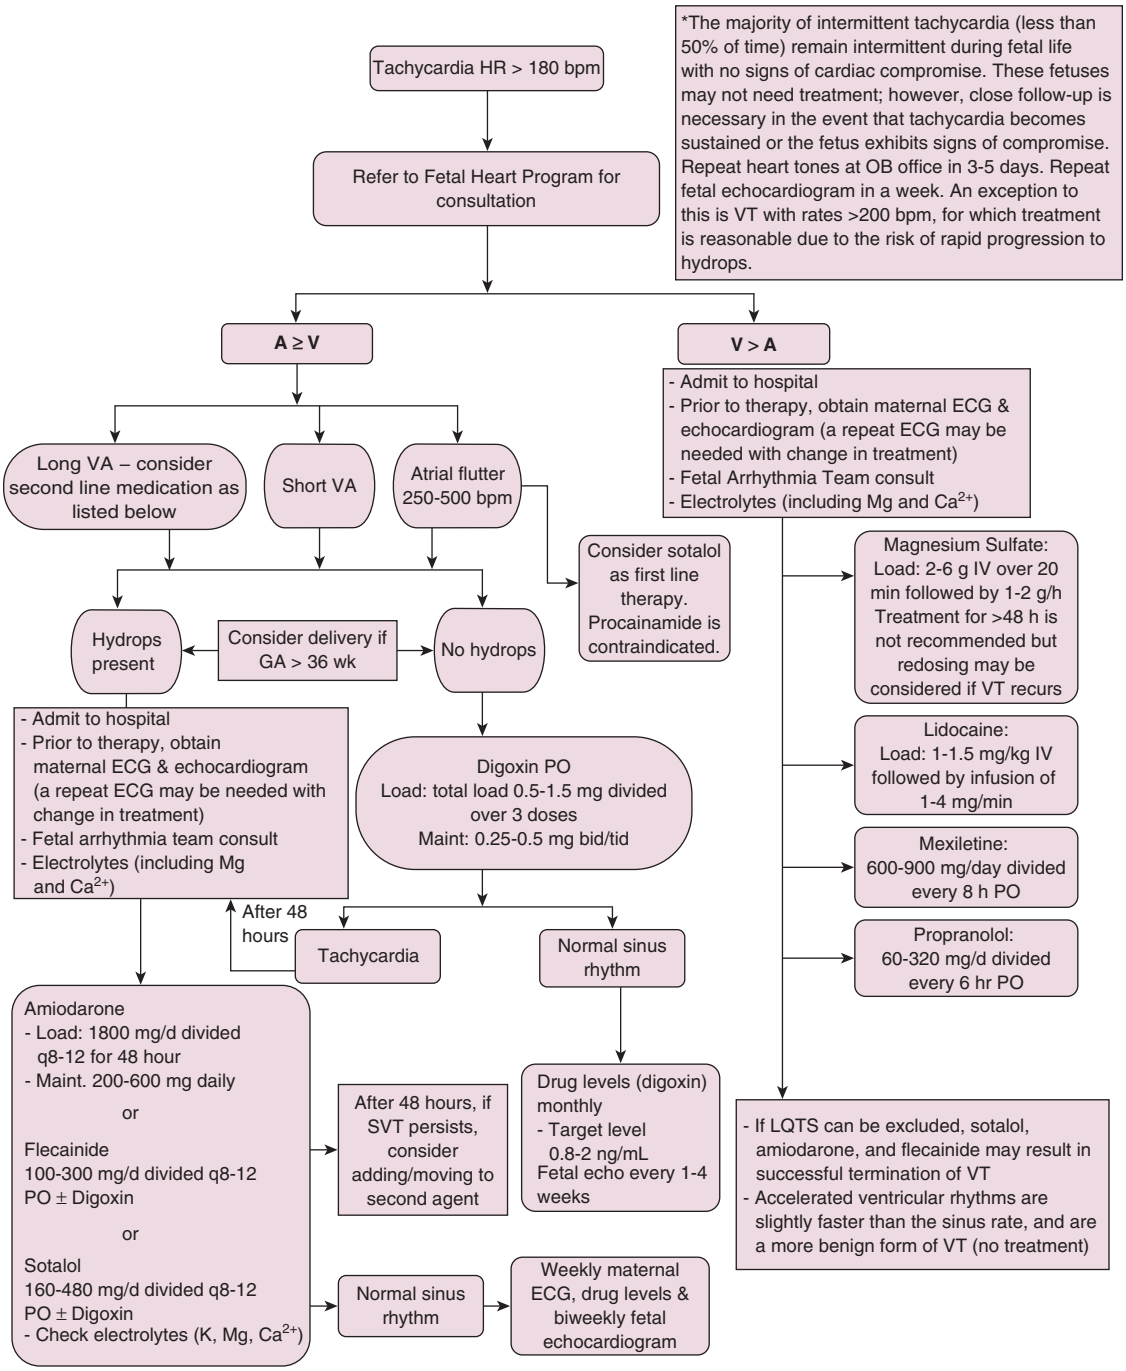
investigate fetal arrhythmia is magnetocardiography, which uses a magnetic field of the fetal heart to generate waveforms that are similar to an ECG. However, it requires magnetically shielded rooms and specialized equipment that are not universally available.[15]

Premature atrial beats are common, present in 1%-3% of pregnancies, and generally well tolerated unless a sustained tachycardia develops. The risk of fetal tachycardia once premature atrial contractions have been seen is approximately 0.5% to 1%, although couplets and blocked atrial bigeminy may increase this risk. Medical treatment is not recommended for either isolated premature atrial contractions or blocked atrial bigeminy; however, interval auscultation of the fetal heart rate by the obstetrician weekly is recommended for frequent premature atrial contractions or premature ventricular contractions until resolution of the arrhythmia is documented.[8]



Fetal tachycardia is generally defined as fetal heart rates greater than 180 bpm. The majority of fetal tachycardias are supraventricular in origin, and ventricular tachycardias are very rare. Management of fetal supraventricular tachycardia is targeted to those at risk for heart failure. Intermittent tachycardia is generally well tolerated by the fetus, with the risk for hydrops increasing proportionally with increased time spent in the abnormal rhythm. Therapy is generally felt to be indicated for sustained tachycardias—those which occur greater than 50% of the time while monitored. Most of these tachyarrhythmias can be treated through maternal administration of antiarrhythmic medications with transplacental delivery to the fetus.[15] However, the influence of certain medications, such as amiodarone, on the developing fetus and fetal myocardium must be taken into account. Ventricular tachycardia is very rare in the fetus. It may be associated with myocardial disease or observed in the presence of cardiac tumors. Rarely, incessant ventricular tachycardia warrants maternal antiarrhythmic medication.[8,15] Fig. 73.11 outlines a decision tree for maternal–fetal pairs presenting with fetal tachycardia.

Fetal bradycardia is defined as a fetal heart rate less than 110 beats per minute.[8,15] The most common cause of bradycardia in the fetus is sinus bradycardia, which often occurs during compression during ultrasound examinations. Fetal atrioventricular (AV) block can present with varying degrees of bradycardia depending on whether it is first-, second-, or third-degree (complete) AV block. Fetal AV block is associated with maternal Sjögren antibodies (SSA/SSB) and complex structural heart disease.[8,15] Rarely, it is an isolated phenomenon. In the setting of immune-mediated heart block, fluorinated glucocorticoids and intravenous immunoglobulin have been used in therapy. Studies have supported the use of hydroxychloroquine in known SSA/SSB-positive mothers to prevent the development of heart block.[19] In the era of steroid use and postnatal cardiac intensive care with early pacemaker therapy, mortality for congenital AV block has decreased from 45% in the 1990s to less than 15% in the early 2000s.[15] Rarely, bradycardia may be a sign of long QT syndrome, and an ECG on the mother and family members is recommended. Fig. 73.12 outlines a decision tree for maternal–fetal pairs presenting with fetal bradycardia.

Parental Counseling after Fetal Diagnosis of Congenital Heart Disease

Effective counseling after the prenatal diagnosis of congenital heart disease can be summarized by four aims: to provide an accurate diagnosis of the malformation, to provide an honest prognosis, to review various treatment and management strategies, and finally, to support the family and help them reach a decision that is best for them.[2] Despite the benefits of accurate prenatal diagnosis of congenital heart disease, receiving a prenatal diagnosis can be a traumatic experience for parents. Posttraumatic stress, depression, and anxiety are common in mothers after a prenatal diagnosis of congenital heart disease. Psychological distress may

persist for months after birth. There is a need for research to determine the most effective techniques for counseling and family support, as well as investigating potential modifiable variables of maternal stress that may alter the impact.[42]

Prenatal diagnosis does allow for sustained education and guidance between diagnosis and delivery. Little research has been done looking into the most effective methods for prenatal counseling and family support. Some important elements to address during prenatal counseling include findings and limitations, results given in close proximity to the time of testing (preferably the same day), natural history in utero, prognosis for the remainder of pregnancy and beyond as able, possible associations with genetic anomalies, alleviating parental guilt, and potential range of management options.[8] The practitioner must utilize good communication skills and empathy. The level of parental understanding must be assessed continuously during

counseling, with the knowledge that understanding may be limited by grief and multiple counseling sessions may be required.[8]

Impact of Prenatal Diagnosis

The goal of early detection of a pathologic state is to alter long-term outcome in a favorable way. Early studies of the impact of fetal diagnosis on postnatal outcome were not satisfying. However, subsequent publications suggest an improvement in postnatal mortality and morbidity. One study looking at the impact of prenatal diagnosis in hypoplastic left heart syndrome (HLHS) showed that preoperative status and first-stage mortality were affected by prenatal diagnosis with a total survival of 75% in those who elected to undergo surgery. All of the patients who were diagnosed prenatally survived, whereas only 65% of the patients who were diagnosed postnatally survived. In addition, patients diagnosed prenatally had a lower incidence of preoperative acidosis, tricuspid regurgitation, and ventricular dysfunction

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

and were also less likely to need preoperative inotropic medications or bicarbonate. Preoperative risk factors that correlated with early mortality included postnatal diagnosis, more severe acidosis, need for bicarbonate or inotropes, and ventricular dysfunction.[51] Another study on prenatal diagnosis of congenital heart disease evaluated the neurologic outcomes in fetuses with HLHS. Although the overall mortality did not differ in the prenatal versus postnatal groups, prenatal diagnosis was associated with fewer adverse neurologic events when compared with those with postnatal diagnosis.[28] Similarly, diagnosis, metabolic acidosis level, preoperative mortality, length of stay, and postoperative mortality were all significantly better in patients with a prenatal diagnosis of transposition of the great arteries compared with the group diagnosed postnatally.[5]

Although these data are encouraging, further studies are needed to evaluate the CHD outcomes in the setting of prenatal diagnosis. Certain populations continue to have poor outcome despite prenatal diagnosis, including those with HLHS with intact or restrictive atrial septum, right atrial and left atrial isomerisms (heterotaxy), and pulmonary atresia with intact septum with right-ventricular-dependent coronary circulation. Further studies into markers of outcome in these patients and improved survival may depend on fetal intervention.[27,47,48]

Specific findings on fetal echocardiogram allow for comprehensive delivery planning to prevent hemodynamic compromise in high-risk CHD. Disease-specific delivery room recommendations are currently well accepted in clinical practice.[8,21,37] Level-of-care recommendations should include follow-up, possible need for transport to a tertiary care center, likelihood of neonatal intervention (catheter-based or surgical), or in rare cases, the need for emergent intervention at the delivery. Table 73.3 summarizes risk-stratified level-of-care assignment and coordinating action plans based on reported algorithms.

Limitations of Fetal Echocardiogram

Advances in ultrasound technology have greatly improved the sensitivity of fetal echocardiogram over the past 15-20 years, and it is currently expected that fetal echocardiogram can diagnose even complex congenital heart disease in specific detail. However, it is important to realize that ultrasound and fetal echocardiography are more sensitive for some types of congenital heart disease than others. Even in the most optimal of situations, fetal echocardiography is less sensitive to detect abnormalities of smaller structures. Thus, diagnoses such as partial anomalous pulmonary venous return (PAPVR), small ventricular septal defects, and minor valve abnormalities including bicuspid aortic valve cannot be ruled out on fetal echocardiogram. In addition, fetal echocardiogram is limited by the necessary presence of fetal circulation, making it impossible to rule out atrial septal defects or patent ductus arteriosus prenatally. In addition, while certain findings can raise concern for coarctation of the aorta, including small isthmus diameter, great vessel discrepancy (smaller aorta than main pulmonary artery), abnormal aortic arch flow, left superior vena cava, and ventricular disproportion (smaller left ventricle than right ventricle), this diagnosis cannot be ruled out prenatally.[6] The rates of prenatal detection for specific types of CHD lesions offer some insight into which defects are more likely to be identified on obstetric ultrasound and subsequently on fetal echocardiogram (Table 73.4).[24]

Fetal Therapies

The first attempt at performing a fetal cardiac intervention was in 1987, when attempts were made to pace the fetal heart to prevent progression of hydrops fetalis. The first attempt at fetal aortic valve intervention was made more than 25 years ago by attempting to dilate the aortic valve in a fetus with severe aortic stenosis. This attempt was successful and the infant eventually underwent a biventricular repair.[10,26,29,30,36,47] To date, there is a growing body of evidence in support of fetal cardiac intervention. Several techniques have been attempted for fetal balloon interventions. Ideally, fetal cardiac interventional procedures are performed percutaneously to limit maternal risks. The least invasive technique involves maternal sedation with percutaneous access to the fetus. More invasive methods, which increase maternal risk, have the benefit of better fetal position.[10,26,29,30,36,47] The goal after fetal intervention is to allow the fetus to spend as much time in utero as possible to promote remodeling and allow the fetal lung to complete maturity. The underlying hypothesis in support of many fetal interventions is that the left ventricle undergoes severe myocardial injury or fibroblast damage, compromising the pressure-generating capability of the ventricle prenatally.[10,26,29,30,36,47] If the underlying cause of the injury, such as is the case in severe aortic stenosis, can be resolved, the left ventricle has the potential to remodel, allowing for improvement in contractile function, and hopefully, a biventricular repair.

As in all procedures, appropriate selection of patients is of utmost importance. The goal is to offer the appropriate procedure to the right patient. Criteria for selection for fetal aortic valve balloon dilation currently include: a large left ventricle with persistent patency of the aortic valve, a normal-appearing mitral valve, reversed flow in the aortic arch, and a left-to-right shunt at the atrial level.[10,26,29,30,36,47]

The most promising group to offer fetal intervention may be in the patients with HLHS with intact or restrictive atrial septum. Postnatal mortality is extremely high in this group of patients, with reported rates of 48%-80%. Intact atrial septum can be found in up to 6% of patients with HLHS, with the majority of their mortality reported during the first few weeks of life. This suggests that mortality risk may be associated with intrapulmonary arterial or venous changes.[29,30]

TABLE 73.3 Risk-Stratified Level-of-Care Assignment and Coordinating Action Plans

Level of Care Code	Level of Care	Action	Examples
Code 0	No identified cardiac anomaly or resolution of cardiac anomaly	Delivery per obstetrician at patient's preferred hospital. Standard newborn care per neonatal team.	• Normal fetal echocardiogram • Premature atrial contractions that resolve
Code 0P	CHD in which only palliative care is planned	Arrange for family support/palliative care services. Delivery per obstetrician at patient's preferred hospital. Cardiology consult for supportive care and confirmation of diagnosis is available.	• CHD with severe/fatal chromosome anomaly or multisystem involvement
Code 1	Cardiac anomaly that is not expected to cause hemodynamic instability in the neonatal period	Delivery per obstetrician at patient's preferred hospital. Standard newborn care per neonatal team. Cardiology evaluation prior to hospital discharge or as an outpatient within 1-2 weeks if the patient is delivering at an outside hospital.	• Muscular ventricular septal defect • Atrial septal defect • Isolated ventricular septal defect
Code 2	Cardiovascular anomaly or disease expected to not cause hemodynamic instability at birth	Neonatology management in delivery room. Nonemergent cardiology consultation. For fetal echocardiogram findings of an unclear etiology, as long as the baby's clinical presentation allows, recommend a cardiology evaluation in conjunction with the neonatology team to confirm fetal findings prior to ultimate disposition (CTICU or NICU).	• Balanced atrioventricular canal • Tetralogy of Fallot (TOF) (pink) • Benign/controlled arrhythmia (nonsustained SVT without hydrops) • LV/RV size discrepancy without concern for coarctation • CDH without significant cardiac pathology
Code 3	Cardiovascular anomaly of moderate severity (including ductal dependent lesions) where hemodynamic instability is possible but not anticipated	Neonatology management in delivery room. May allow for maternal–infant bonding time. Transfer to NICU for transitional care and line placement. Transfer to the CTICU/NICU for further evaluation and management. Urgent cardiology consultation within 1 hour of delivery.	• HLHS with no risk factors • Single ventricle with critical RVOT or LVOT obstruction • Coarctation of the aorta • ToF with moderate to severe obstruction • Sustained tachyarrhythmia
Code 4	Cardiovascular anomaly with high likelihood of hemodynamic instability	Cardiology and neonatology notification of labor. Neonatology and cardiology to co-manage delivery. Disposition of the patient will be determined by clinical presentation. Emergent transfer to the operating or cardiac catheter lab may be necessary (see details medical record note). Lines may need to be placed in NICU, CTICU, catheter lab, or operating room pending disposition decision. Final disposition to CTICU- vs. NICU-based on established center guideline.	• Transposition of great arteries • ToF with absent pulmonary valve • HLHS with suspected atrial septal restriction • CHD with ventricular dysfunction • Complete heart block • Hydropic fetus with cardiac anomaly

TABLE 73.4 Prenatal Diagnoses by Specific Congenital Heart Disease (CHD) Type

CHD Type	Percent Prenatal Diagnosis
Single ventricle (all)	85%
Hypoplastic left heart syndrome	83%
Complex single ventricle	87%
D-transposition of the great arteries (TGA) (all)	54%
D-TGA with intact ventricular septum	47%
D-TGA with ventricular septal defect	64%
Tetralogy of Fallot	75%
Isolated arch anomaly	58%
Arch anomaly with additional anomaly	75%
Total anomalous pulmonary venous return	2%
Pulmonary valve stenosis	44%
Double-outlet right ventricle	97%
Double-outlet right ventricle with malpositioned great vessels	83%
Balanced atrioventricular canal	79%
Interrupted aortic arch	61%

Novel Approaches to Prenatal Diagnosis of Congenital Heart Disease

Just as in fetal intervention, there continue to be advances in the diagnostic realm. Promising results have been seen with the performance of fetal echocardiograms during the first trimester. A study evaluating the feasibility and accuracy of first trimester echocardiography identified fetuses with ventricular septal defects, transposition of the great arteries, and HLHS. The sensitivity of these early echocardiograms compared with the standard study performed at 18-22 weeks' gestation was calculated as 60.0% and the specificity was 98.7%, with a positive predictive value of 75.0% and a negative predictive value that reached 97.4%.[32] Earlier detection of significant heart defects allows for more timely counseling and decision making.

Newer indices of ventricular performance including the Tei index (also known as the myocardial performance index) are currently being evaluated in the fetus. The Tei index has been used widely as a measure of global (combined systolic and diastolic) myocardial function in adults and children. It has also been shown to be useful in the assessment of fetal cardiac function.[1]

Three-dimensional fetal echocardiography also shows promise in both increasing efficiency of fetal echocardiography and accuracy of diagnosis. However, poor frame rates and false positive results continue to be an issue.

Summary

In summary, the field of fetal cardiology has experienced rapid growth in the last 40 years. Advances in image quality allow for the diagnosis of a wide array of cardiac pathology. This allows for well-coordinated, postdelivery care of complex congenital heart defects, preparation of the parents through prenatal counseling, and management of evolving fetal pathology, including arrhythmias and TTTS. Potentially, we may be able to alter the natural history of certain congenital heart defects through invasive fetal cardiac interventions. However, even with advances in echocardiography, one must be aware of limitations of fetal ultrasound when evaluating acutely ill neonates in the delivery room.

Key Points

- Congenital heart disease is common, and the vast majority of lesions can be detected prenatally on fetal echocardiogram.
- Indications for fetal echocardiogram are broad and include maternal factors, family history, and fetal factors.
- Details of fetal cardiac anatomy can be useful in delivery planning and prognosis of postnatal course, including need for prostaglandin therapy and/or neonatal intervention.
- Fetal arrhythmias are relatively common, rarely cause fetal compromise, and can be treated medically when necessary.
- Fetal cardiac intervention is a promising novel therapy that has the potential to alter the natural history of some severe types of congenital heart disease.

Patent Ductus Arteriosus

WILLIAM E. BENITZ AND SHAZIA BHOMBAL

In utero, the ductus arteriosus provides a connection between the pulmonary artery and descending aorta through which deoxygenated blood returning to the right heart is diverted to the placenta for reoxygenation. Although essential to normal fetal physiology, it normally constricts, closes, and becomes a fibrous remnant after birth. Failure of those processes, resulting in persistent ductal patency into childhood or adulthood, has been recognized as a significant pathology for many years. Increasing survival of more immature infants, who are at greatest risk for persistent ductal patency, was quickly followed by recognition of a potential role of patent ductus arteriosus (PDA) in pathogenesis of disease in preterm infants. More than 50 years ago, Burnard reported that the murmur of a PDA was heard more frequently and for longer after birth in preterm infants and typically was associated with respiratory distress.[3] Subsequently, prolonged ductal patency in preterm infants was linked to more severe respiratory distress syndrome (RDS), prolonged assisted ventilation, pulmonary hemorrhage, bronchopulmonary dysplasia (BPD), necrotizing enterocolitis (NEC), renal impairment, intraventricular hemorrhage (IVH), periventricular leukomalacia (PVL), cerebral palsy, and death.[1] Recognition of these associations, appreciation of the hemodynamic effects of a large left-to-right shunt through the ductus, and the plausible hypothesis that these morbidities might be caused by excessive pulmonary blood flow or systemic ischemia led many practitioners to adopt strategies for closing the ductus, either in anticipation of or after confirmation of prolonged patency. Evidence of benefit from those interventions was slow to develop, however, and concerns arose about adverse effects of medical or surgical closure of the ductus. Although consensus regarding many aspects of management is lacking, the current approach consists of recognition of pathologic persistence of ductal patency, evaluation of hemodynamic consequences, and selection of strategies to minimize deleterious effects.

Pathogenesis

The ductus arteriosus is derived from the distal portion of the embryonic sixth brachial arch and is approximately the diameter of the descending aorta in utero. In the normal term infant, the ductus arteriosus constricts soon after birth, stimulated by the rapid postnatal increase in arterial oxygen tension. The muscularis of the ductus is uniquely responsive to oxygen, reacting to an increase in ambient oxygen with sustained contraction. The mechanisms of this response are not fully understood, but the cytochrome P450 system (CYP450), endothelin-1 (ET-1), and intracellular oxidation-reduction (redox) balance appear to be important.[8] Glucocorticoids may have an essential role in maturation of the ductal oxygen-sensing apparatus, as antenatal exposure to glucocorticoids is associated with both increased expression of genes for calcium and potassium channels implicated in the oxygen response and decreased risk of persistent ductal patency. This direct response is augmented by a rapid decline in circulating levels of PGE_2, a potent ductal smooth muscle relaxant that has a major role in keeping the ductus arteriosus open in the fetus. The placenta is the primary source of fetal PGE_2, leading to a precipitous fall in circulating levels upon umbilical cord clamping. Maximal effects of PGE_2 withdrawal seem to require antenatal priming of the ductal muscle by the rising levels of PGE_2 normally seen late in gestation. Dynamic functional closure initiates at the pulmonary end of the ductus and usually is complete within the first 4 days after birth, but anatomic obliteration is not achieved until after 1 week of age.

In otherwise normal infants born at or near term, it is unusual for the ductus arteriosus to fail to close within the first 4 days. With decreasing gestational age at birth, both the age at spontaneous closure and the proportion of infants with PDA at any postnatal age progressively increase.[29] Before interventions to close the PDA in preterm infants were widely adopted, ductal closure nearly always occurred spontaneously if given sufficient time, sometimes as late as 4-6 months of age. However, those observations date from an era before adoption of antenatal steroid treatment and availability of exogenous surfactant, when VLBW infants rarely and ELBW infants essentially never survived. Data from placebo arms of clinical trials since adoption of those measures indicate that many such infants never develop signs of a hemodynamically significant ductal shunt. In many trials, numerous control subjects were eventually

Abstract

Approaches to management of patent ductus arteriosus in the preterm neonate continue to be a topic of discussion and controversy. Prolonged ductal patency in preterm neonates has been associated with morbidities such as bronchopulmonary dysplasia, necrotizing enterocolitis, and pulmonary hemorrhage, and with increased mortality. However, a multitude of studies have failed to demonstrate improvement in long-term outcomes with medical or surgical closure of the ductus. This chapter aims to present current evidence regarding diagnosis, evaluation, and management of the patent ductus arteriosus in the preterm neonate. In the normal term infant, the ductus arteriosus constricts soon after birth. With decreasing gestational age, the proportion of patients with a patent ductus and time to closure progressively increases. From the first report on prolonged ductal patency in the preterm infant over 50 years ago, approaches to the patent ductus arteriosus have ranged from prophylactic closure to conservative symptomatic management. Modalities for evaluation to identify patients at risk for adverse effects of ductal shunting, including echocardiography to assess hemodynamic significance, near infrared spectroscopy, and biomarkers, continue to evolve. Current approach to the patent ductus arteriosus in the preterm neonate consists of recognizing the pathologic persistence, evaluating consequences, and determining strategies to minimize deleterious effects. While a majority of premature patients will close their ductus without intervention and without increased long-term morbidities, further research is needed to identify those patients who may benefit from intervention to close the ductus arteriosus.

treated to achieve ductal closure, typically late in or after the first week after birth, obscuring the natural course of spontaneous ductal closure as well as risk factors that might predict failure of that process. Nonetheless, ductal closure without intervention is very likely in babies who are born at greater than 28 weeks' gestation, weigh greater than 1000 g at birth, or do not have RDS. In recently reported cohorts of VLBW infants from centers that avoid interventions to close the ductus, including more than 800 subjects, more than 90% achieved ductal closure without treatment (87% before discharge).[5,22,29-31]

The mechanisms underlying delay or failure of ductal closure in preterm infants have not been fully elucidated.[8] Birth before term may simply come before the ductus is prepared, functionally or structurally, to respond to signals that normally induce closure. For example, lamb studies have demonstrated gestational age-dependent response of the ductus to oxygen. In addition, genes essential to ductal responses, including K^+ and Ca^{2+} channels involved in muscle contraction and phosphodiesterases that degrade cyclic guanosine monophosphate (cGMP) and cyclic adenosine monophosphate (cAMP) mediators of the vasodilator responses to nitric oxide (NO) and PGE_2, are developmentally upregulated in the ductus arteriosus of the fetus approaching term. Lack of preconditioning by PGE_2 in late gestation may make the ductus arteriosus less sensitive to withdrawal of that vasorelaxant. Inadequate glucocorticoid production, common in extremely preterm infants, may compromise oxygen-sensing pathways, particularly in infants not exposed to maternal antenatal steroids. Cytokines produced by a fetal inflammatory response, a frequent correlate of preterm birth, may directly impede ductal responses.[18] These potential mechanisms correspond to the clinical observations that PDA is strongly associated with extreme immaturity, lack of exposure to antenatal steroids, and signs of fetal inflammation or infection.

Pathophysiology

Before birth, the pulmonary vascular resistance is high and approximately 75% of the right ventricular output flows right-to-left through the ductus arteriosus. With the first breath, lung inflation and oxygenation produce a rapid decline in pulmonary vascular resistance, a decrease in pulmonary arterial pressures, and a large increase in pulmonary blood flow. Removal of the low-resistance placenta from the systemic circulation increases systemic arterial pressures, and ductal flow quickly reverses direction to left-to-right. Pulmonary blood flow substantially exceeds systemic cardiac output until the ductus arteriosus closes. If ductal closure occurs in the first few days, this imbalance in distribution of the total cardiac output is well tolerated. If the ductus arteriosus remains open, however, the continued decline in pulmonary vascular resistance over the first several days and weeks results in progressively increasing left-to-right shunting through the PDA, with excessive pulmonary blood flow, increased volume work for the left heart, and the potential for systemic ischemia.

Term infants can often tolerate large left-to-right shunts with high pulmonary-to-systemic blood flow ratios (Q_P:Q_S) without developing pulmonary edema. In preterm infants, surfactant deficiency, low serum oncotic pressures, and compromised capillary integrity (e.g., that which accompanies bacteremia) lower the threshold for development of pulmonary edema. Accumulation of alveolar and interstitial fluid increases the alveolar-arterial oxygen gradient and reduces lung compliance. A large left-to-right shunt increases volume work for the left heart, leading to atrial and ventricular enlargement and myocardial dysfunction. This may produce electrocardiographic and serum biomarker signs of myocardial ischemia, including ST segment depression and elevated serum troponin levels. In addition to documentation of left atrial and ventricular distention, echocardiography may demonstrate abnormal left heart function. The combination of left heart dysfunction and diversion of aortic flow into the lungs (a "ductal steal") compromises systemic cardiac output, with consequent risk of end-organ ischemia. Increasing ductal left-to-right shunting may be associated with Doppler ultrasound evidence of decreased, absent, or reversal of diastolic flow in the middle cerebral, superior mesenteric, and renal arteries, as well as the descending aorta. Impaired cerebral blood flow has been associated with PDA in several studies, implicating but not proving a causal role for PDA in development of IVH and, possibly, PVL. Similarly, bowel or kidney ischemia resulting from compromised mesenteric or renal arterial flow may be associated with NEC or impaired renal function. Reversal of aortic diastolic flow in term infants with surgical congenital heart disease has been associated with NEC, but empiric data have not demonstrated a direct correlation between estimates of severity of the ductal steal and the risk of ischemic complications in preterm infants with PDA.

Clinical Presentation

The clinical presentation of a preterm infant with a persistent PDA typically begins with recognition of the characteristic coarse systolic murmur, heard best along the left sternal border. The continuous "machinery murmur" typical of PDA in an older child is rarely present. Infants with a very large PDA and substantial pulmonary overcirculation may have no audible murmur. An increase in murmur intensity may reflect increasing flow velocity through a narrowing ductus arteriosus rather than increasing shunt volume. Hemodynamic effects of the large left-to-right shunt may be evident in an increased precordial impulse (owing to the increased left ventricular stroke volume) and in arterial pulses that are prominent, bounding, or palpable where they are not normally, such as in the palms (resulting from diastolic runoff into the low pressure pulmonary circulation). In preterm infants greater than 1000 g, systemic arterial diastolic blood pressures are reduced and pulse pressures may be increased. Among babies less than

1000 g, reduction in both systolic and diastolic pressures without a widened pulse pressure is more typical. These findings are nonspecific, insensitive, and correlate poorly with echocardiographic findings. Similar physical findings may be present in infants with an aortopulmonary window, large arteriovenous malformation, hemitruncus, or certain other cardiac defects, or they may simply reflect a relatively hyperdynamic state of another cause. Often, a hemodynamically significant PDA is suspected only because of signs of excessive pulmonary perfusion, such as an increasing $Paco_2$ and/or alveolar-arterial oxygen gradient, decreasing lung compliance, or inability to wean the infant from supplemental oxygen, distending airway pressure, or positive pressure ventilation. Pulmonary hemorrhage is an infrequent complication that is usually attributed to pulmonary overcirculation from a PDA.

Diagnostic Evaluation

Patent ductus arteriosus is most readily confirmed by color Doppler echocardiography, which documents anatomic patency and the direction and velocity of ductal blood flow throughout the cardiac cycle (Fig. 74.1). Echocardiography also allows characterization of the hemodynamic consequences of the ductal shunt, including assessment of left heart volume load, cardiac function, and systemic hypoperfusion. Findings that correlate with a large shunt include large ductal diameter; increased left atrial to aortic root diameter (LA:Ao) ratio; left ventricular distention; and absent or reversed diastolic flow in cerebral, renal, or mesenteric arteries or descending aorta (Fig. 74.2). Measures of myocardial dysfunction, such as the velocity of a mitral regurgitant jet, ratio of early passive to late atrial contractile transmitral filling (E wave to A wave ratio), left ventricular isovolumic relaxation time (IVRT), and strain, have been proposed as potential indicators of hemodynamic significance (Table 74.1).[10] The utility of individual markers is low, but combination in composite scores appears to increase diagnostic utility, and preliminary results suggest that high composite scores may be predictive for development of chronic lung disease.[10,12,28] These results need to be confirmed and extended to other adverse outcomes potentially attributable to PDA but represent essential first steps toward establishing the role of such measures in identifying candidates for enrollment in management trials and ultimately for targeted interventions.

Near-infrared spectroscopy (NIRS) has also been proposed as a tool for assessing hemodynamic significance of the ductus arteriosus.[6] Echocardiographic findings consistent with hemodynamically significant PDA (using differing criteria) have been correlated with lower renal (r_rSO_2)[6] and mesenteric[19] (r_mSO_2) regional oxygen saturation levels. Lower regional cerebral oxygen saturations (r_cSO_2) correlated with larger ductal diameters but not with other echocardiographic measures of hemodynamic significance.[9] Other studies have failed to identify significant effects of ductal patency on r_rSO_2[32] or r_cSO_2,[24,32] however. In an observational study of the relationship of PDA and brain volumes measured by MRI at term-equivalent age, r_cSO_2 measurements were lower in infants treated with indomethacin for PDA and lowest in those who underwent surgical ligation.[21] Lower pretreatment r_cSO_2 values were associated with smaller cerebellar volumes in infants treated surgically but not in other infants. No studies have evaluated the utility of NIRS for identification of infants with PDA for selective treatment.

Serum biomarkers are potential tools for evaluation of hemodynamic significance of PDA, guiding treatment of PDA and predicting adverse outcomes.[35] Plasma levels of B-type natriuretic peptide (BNP) or NT-pro-BNP, an inactive byproduct of BNP production, are elevated in infants with significant PDA, correlate with echocardiographic

TABLE 74.1 Echocardiographic Correlates of Hemodynamic Significance of Patent Ductus Arteriosus*

Echo Assessment	Small PDA	Moderate PDA	Large PDA
Ductus arteriosus			
Narrowest diameter (mm)	<1.5	1.5-3	>3
Maximum flow velocity (m/s)	>2	1.5-2	<1.5
Ductal shunt magnitude			
Left ventricular output (mL/kg/min)	≤314	≤314	>314
Left atrial:aortic ratio	<1.4:1	1.4-1.6:1	>1.6:1
E wave to A wave ratio	<1	1-1.5	>1.5
Isovolumic relaxation time (ms)	>45	36-45	<35
Systemic hypoperfusion			
Descending aorta end diastolic flow	Normal	Decreased or absent	Reversed
Celiac artery end diastolic flow	Normal	Decreased or absent	Reversed
Middle cerebral artery end diastolic flow	Normal	Decreased or absent	Reversed

markers of ductal shunting, and decrease after the ductus arteriosus closes. Among infants less than 32 weeks' gestation with PDA, NT-pro-BNP levels at 48 hours were higher in those who died or had grades III/IV IVH than in those who survived without IVH, and survivors with higher NT-pro-BNP levels had worse neurodevelopmental outcomes.[11] Elevated levels of troponin T at 48 hours of age are associated with presence of PDA, correlate with echocardiographic indicators of ductal shunting, predict death or grades III/IV IVH, and may help identify infants at greatest risk for poor neurodevelopmental outcome at age 2 years.[11] A recent review of the role of natriuretic peptides in PDA assessment noted substantial heterogeneity in laboratory methodologies and concluded that their utility should be limited to screening to identify candidates for echocardiography. There have been no studies evaluating these markers as criteria for intervention to close the ductus arteriosus.

Chest radiographs may demonstrate an enlarged cardiac silhouette, prominent pulmonary vascular markings, or evidence of pulmonary edema. Although these signs may suggest the diagnosis, they are nonspecific and insensitive.

Management

Because PDA in preterm infants is so strongly associated with several adverse outcomes, surgical and medical strategies for closing the ductus arteriosus were widely adopted soon after they became available. Surgical ligation in preterm infants with respiratory distress syndrome was first reported in an abstract in 1968, and the first case series appeared in 1972. Medical induction of ductal closure with indomethacin was described in 1976. The conviction that ductal closure was beneficial became so pervasive that the landmark National Collaborative Study of indomethacin in preterm infants with PDA had no nontreatment arm: all three regimens mandated ductal closure by either indomethacin or ligation. These reports were followed by numerous descriptions of successful surgical or medical closure of the ductus, which heavily influenced practice for many years, but the utility of routine intervention to achieve ductal closure late in the first or during the second week of life has come into question.

The seminal reports that nonsteroidal anti-inflammatory drugs (NSAIDs, now called cyclooxygenase inhibitors or COIs) induce constriction and closure of the ductus arteriosus have been followed by more than 50 randomized, placebo-controlled trials of COIs in preterm infants.[3] Indomethacin and ibuprofen are equally effective in reducing rates of persistent PDA, resulting in lower rates of ductal

ligation. Indomethacin appears to be less likely to induce ductal closure in infants more than 10-14 days of age. Repeated courses of indomethacin or ibuprofen may be effective in infants who do not respond to the first or second course of treatment.[33] Neither individual trials nor meta-analyses have identified improvements in long-term outcome with these treatments.[1] Rates of any IVH and of grades III/IV IVH are reduced by indomethacin prophylaxis started within 12 hours of birth[1] but not by treatment later in the course. These effects do not correlate with improved long-term neurodevelopmental outcomes. Compared with placebo-treated controls, infants given low-dose indomethacin prophylaxis had better vocabulary skills and a lower probability of an IQ less than 70 at age 4.5 years, but their mothers were more likely to describe them as having significant problems on the daily living domain of the Vineland scale at age 8. No effects on many other neurodevelopmental outcome measures were evident. Indomethacin prophylaxis reduces severe pulmonary hemorrhage during the first week but not over the entire hospital course. Indomethacin reduces cerebral, mesenteric, and renal arterial blood flow. These effects are associated with diminished cerebral oxygen levels, reduced creatinine clearance, and oliguria. Meta-analyses of randomized trials indicate that these hemodynamic changes do not increase rates of mortality or potential complications, including BPD, NEC, bowel perforation, retinopathy of prematurity (ROP), or neurodevelopmental impairment.[1] Co-administration of indomethacin with a glucocorticosteroid increases the risk of bowel perforation, however. Ibuprofen has less impact on cerebral and renal blood flow and minimal if any effect on mesenteric perfusion. Consequently, ibuprofen is less likely than indomethacin to cause significant oliguria and may be less likely to be associated with NEC.[25] In vitro studies suggest that ibuprofen may displace bilirubin from its binding site on albumin. Ibuprofen does not have the short-term neuroprotective effects associated with indomethacin. Recent small case series have suggested that acetaminophen may be an alternative COI for PDA management,[14] but the role of this agent in management of preterm infants with PDA remains to be determined.

Although many case series of surgical ligation have appeared, only three randomized trials have assessed the impact of this intervention.[1] The two trials in which ligation was used to treat PDA after it was deemed pathologic demonstrated no improvement in mortality, BPD, death or BPD as a combined outcome, or NEC. The single trial of prophylactic ligation found no reduction in rates of mortality, IVH, grades III/IV IVH, or ROP; the rate of NEC was reduced and the proportion of infants who required supplemental oxygen at 36 weeks' postmenstrual age was significantly increased after ligation. Ligation is a reliable and fast method for closing the ductus arteriosus but is not without hazard. In up to one-third of infants, ligation precipitates severe left ventricular dysfunction and cardiorespiratory decompensation requiring major increases in intensive care support in the immediate postoperative period. The risk of this complication decreases with postnatal age, so later ligations (>4 weeks of age) are better tolerated than earlier surgeries. Infants who develop postoperative hypotension refractory to catecholamine infusion have lower postoperative serum cortisol levels than those who do not become hypotensive or respond to catecholamine treatment.[7] While some have reported that milrinone infusion reduces postoperative hemodynamic instability,[16] others have not found this treatment to be beneficial.[13] Other surgical complications include chylothorax, pneumothorax, phrenic or recurrent laryngeal nerve injury, and scoliosis.[2] Paralysis of the left vocal cord, which occurs in up to 67% of ELBW infants following ductal ligation,[4] is associated with prolongation of assisted ventilation and oxygen supplementation, a higher probability of BPD, feeding difficulties, tube feeding, longer neonatal hospitalization, and vocal and respiratory impairments in adulthood.[26] Infants who undergo early ductal ligation are at increased risk for BPD and have higher rates of neurodevelopmental impairment; these adverse outcomes may result from the indication for surgery rather than the surgery itself.

Closure of PDA in preterm infants by surgical ligation or medically with a COI may be justified on the basis of an expected reduction in severe IVH or severe early pulmonary hemorrhage with indomethacin prophylaxis or by reduction in NEC with prophylactic ligation. In most settings, these putative benefits are not sufficient to justify prophylactic intervention for all extremely low or very low birth weight neonates.[15] Current evidence indicates that routine, early treatment to achieve ductal closure does not improve long-term outcomes.[1] Because essentially all of the trials that provide that evidence addressed treatment early in the postnatal course, with frequent resort to treatment of infants in the "control" arm if PDA persisted beyond the second week or so,[3] the effects of prolonged exposure to a moderate or large left-to-right shunt in ELBW infants remain unknown. Consequently, the indications (if any) for, potential benefits from, and optimal timing of later ductal closure remain indeterminate. Similarly, these global observations do not imply that there cannot be some infants for whom ductal closure would be beneficial, particularly within groups that are not well represented in those older studies (e.g., those less than 26 weeks' gestation). Better strategies for assessment of the magnitude of ductal shunting, based on echocardiographic findings such as those listed in Table 74.1, or scores based on those measurements with or without additional clinical or biomarker variables,[10,12] promise to help identify infants who may be candidates for ductal closure,[10,28] but benefits of treatment for infants selected using such criteria remain to be demonstrated. Until such information is available, practice will be guided by consensus, belief, and individualized clinical judgment. The perceived balance between benefits (reduced IVH and early pulmonary hemorrhage) and disadvantages (more severe respiratory disease, intestinal perforation with concomitant glucocorticoid use) will guide the choice between use and avoidance of indomethacin prophylaxis. High rates

of spontaneous closure in infants greater than 1000 g, and their demonstrated ability to tolerate longer periods of ductal shunting, support a permissive approach to PDA management in those infants. Infants less than or equal to 1000 g who develop hypotension or signs of overt congestive heart failure may be deemed to require ductal closure, but criteria for that decision remain uncertain. The decreasing efficacy of COIs and increasing safety of surgical ligation with postnatal age suggest that treatment, if indicated, might better consist of medical interventions in the third or fourth postnatal weeks and direct surgical management thereafter.

Experience with less aggressive strategies for management of PDA continues to accumulate.[1] While earlier studies mostly described effects of moderate reductions in the proportion of infants with PDA who received treatment, there are now several reports of cohorts in which treatment was rare (<10% of VLBW infants). In addition to informing the natural history of ductal closure (see above), these observations provide reassurance that strategies that permit prolonged ductal patency do not greatly increase adverse outcomes. Among 139 infants less than 30 weeks' gestation who required ventilation and surfactant replacement, elimination of COI treatment was associated with rates of chronic lung disease (8% vs. 18%-28%) and necrotizing enterocolitis (0% vs. 4%-6%) lower than contemporaneous network benchmarks, comparable rates of intraventricular hemorrhage (7% vs. 6%-7%) and mortality (13% vs. 12%), and use of ligation in fewer than 5%.[34] Adoption of a conservative treatment approach in 72 very low birth weight infants (<1500 g) was followed by significant reduction in the rate of oxygen use or ventilation at 36 weeks' postmenstrual age (from 49% in prior treatment eras to 18%) among those diagnosed with PDA, despite treatment of PDA with ibuprofen in only 7% and no use of ligation, without any increase in rates of necrotizing enterocolitis, intraventricular hemorrhage/periventricular leukomalacia, or death.[22] Among 132 infants 23-26 weeks' gestation who required ventilation and had a hemodynamically significant PDA at least 2 mm in diameter, transition from mandatory PDA closure to nonintervention eliminated indomethacin use and ligation (compared to baseline rates of 58% and 82%, respectively). Bronchopulmonary dysplasia declined from 58% to 38% ($P = 0.006$), without changes in other morbidities or mortality.[31] Semberova et al. reviewed experience in 321 infants <1500 g monitored by serial echocardiography at two centers. Fewer than 5% were treated for PDA, and rates of chronic lung disease; severe IVH, PVL, NEC; and severe ROP compared favorably to contemporaneous Vermont Oxford Network benchmarks.[29] These analyses do not prove that permissive management strategies for preterm infants with PDA result in improved outcomes, as outcome changes may result from contemporaneous changes in other practices, but they do suggest that permissive approaches to PDA management do not substantially worsen outcomes. Recent data indicate that in preterm infants age <28 weeks with moderate-to-large PDAs who were receiving respiratory support after the first week, early routine treatment did not reduce PDA ligations or the presence of a PDA at discharge and did not improve any of the prespecified secondary outcomes, but delayed full feeding and was associated with higher rates of late-onset sepsis and death in infants born at ≥26 weeks of gestation.[7a] The effect of prophylactic indomethacin on BPD remains unclear, with recent data from contemporary cohorts indicating either no reduced or increased risk or a decrease in BPD incidence.[17,23] Available data do not exclude possible effects of nontreatment that have not been studied, such as late development of pulmonary hypertension or pulmonary veno-occlusive disease, so vigilance for unexpected sequelae of practice changes is essential.

Growing awareness that aggressive intervention to achieve ductal closure may not be beneficial should not lead to an assumption that a persistently patent ductus arteriosus can simply be ignored. As with other large shunts, the hemodynamic and secondary pulmonary, cerebral, or visceral effects may require active management.[2] Factors that may delay ductal closure, such as late-onset bacterial infection and excessive fluid administration (>150 mL/kg per day), should be avoided. Furosemide apparently does not compromise ductal closure in response to indomethacin[20] but may prolong ductal patency in untreated infants. Circulatory imbalance while the ductus arteriosus remains patent may be managed by measures that increase pulmonary vascular resistance (permissive hypercapnia, increased distending airway pressure, or maintenance of a higher hematocrit) or that avoid or correct circumstances that may lower pulmonary vascular resistance (metabolic alkalosis, excessive supplemental oxygen, nitric oxide). Reduced systemic blood flow may be improved by agents that decrease systemic afterload (captopril, milrinone) or exacerbated by those that increase systemic vascular resistance (systemic vasopressor agents), which may increase diversion of cardiac output to the pulmonary circulation. Compromised systemic cardiac output may also be helped by measures that increase pulmonary vascular resistance, reducing ductal steal (Q_P/Q_S), and by increasing total cardiac output if Q_P/Q_S remains constant. Ensuring adequacy of preload may require invasive monitoring of central venous pressures or frequent assessment with functional echocardiography. Hydrocortisone and/or cardiotonic agents may be useful, particularly in hypotensive infants. Congestive heart failure can be managed with the usual strategies of preload reduction (fluid restriction, diuretics), inotropic support, and afterload reduction. It may be useful to prevent or correct ancillary factors that may predispose to pulmonary edema (hypoproteinemia, bacteremia) or augment the risk of injury to the brain (infection, anemia, hypoglycemia), kidneys (hypovolemia, nephrotoxic drugs), or bowel. These measures must be chosen and balanced carefully to ensure optimal effect; excessive fluid restriction to avoid pulmonary edema may exacerbate renal ischemia, for example. None of these strategies have been evaluated in clinical trials.

Key Points

- Delayed closure of the ductus arteriosus is common in extremely premature neonates and is associated with a variety of untoward outcomes, but there is a lack of evidence for improvement in outcomes with treatment for closure.
- Observational studies of nonintervention strategies provide evidence that permissive approaches to PDA management do not appear to worsen outcomes; however, some data suggest an association between patency of a large ductus arteriosus and BPD.
- Presence of a ductus arteriosus in premature neonates may lead to hemodynamic and secondary pulmonary, cerebral, or visceral effects that may require active management, such as fluid restriction, ventilator adjustments, or circulatory support.
- Evaluation with clinical tools such as biomarkers or echocardiography may delineate a population of preterm infants who will benefit from medical or surgical closure of the ductus arteriosus.

Congenital Defects of the Cardiovascular System

SANMIT K. BASU AND NANCY C. DOBROLET

Summary

Congenital heart defects are the most common type of birth defect in infants worldwide. The following chapter provides an overview of the anatomy, physiology, clinical presentation, diagnostic evaluation, and management strategies for a wide range of congenital heart disease encountered in neonates and infants. While the information herein is detailed, it is important to keep in mind that many different anatomic and physiologic variants are encountered in practice, often altering clinical management. The chapter is generally organized based on the predominant pathophysiology—cyanotic, obstructive, or shunting—for a given congenital heart defect. There can be considerable overlap between these physiologies, particularly in complex forms of congenital heart disease involving multiple defects. Defect physiology can also change considerably over time, particularly in the immediate postnatal transitional period around ductal closure. Prompt recognition and diagnosis of significant congenital heart defects contribute greatly to effective management and improved outcomes in affected infants.

Cyanotic Heart Defects: Mixing-Dependent

D-Transposition of the Great Arteries

Anatomy and Pathophysiology

In D-transposition of the great arteries (D-TGA), the aorta arises from the right ventricle, which receives systemic venous deoxygenated blood, and the pulmonary artery arises from the left ventricle, which receives pulmonary venous oxygenated blood. The blood flow in these patients is in parallel with the deoxygenated blood entering the aorta and recirculating to the body, while the richly oxygenated pulmonary venous return is recirculated to the lungs. In the absence of any shunting across connections between the systemic and pulmonary circulations to allow mixing of the deoxygenated and oxygenated blood, this results in systemic hypoxia and is often lethal. In D-TGA, three levels where mixing can occur are an atrial level defect (patent foramen ovale or atrial septal defect), patent ductus arteriosus (PDA), or ventricular septal defect (VSD). The best site of blood mixing has been shown to be at the atrial level through a patent foramen ovale (PFO) or atrial septal defect (ASD), with the other forms (PFO and VSD) being less reliable. It is, therefore, extremely important at birth to make sure not only that there is an atrial level communication, but also that it is adequate in size.

Associated Defects

Associated defects have a dramatic effect on the presentation and pathophysiology of newborn infants with D-TGA. At a minimum, an atrial level defect with balanced bidirectional shunting is essential for survival. The presence of a PDA also allows for additional shunting from the aorta (deoxygenated blood) to the pulmonary artery (oxygenated blood), resulting in increased pulmonary venous return and left-to-right shunt at the atrial level. A VSD occurs in about 25% of infants with D-TGA. Its presence contributes to mixing of the oxygen-rich and desaturated blood, but as previously stated, atrial level mixing is the most reliable. Coarctation of the aorta or aortic arch interruption can also occur in association with D-TGA with VSD.[72]

Clinical Presentation

D-TGA is the most common cyanotic heart defect identified in the first week of life, and the diagnosis should be considered in any cyanotic neonate. Fetal diagnosis is common but not uniform. Even with prenatal diagnosis, however, profound hypoxia caused by a highly restrictive atrial level defect can lead to rapid deterioration and death within the first hours of life.[48,82] Respiratory symptoms in this disorder are absent or limited to hyperpnea or tachypnea without dyspnea. The patient's second heart sound is loud and persistently single because of the anterior position of the aorta and the posterior position of the pulmonary artery. A holosystolic murmur, when present, suggests an associated VSD; a systolic ejection murmur is auscultated

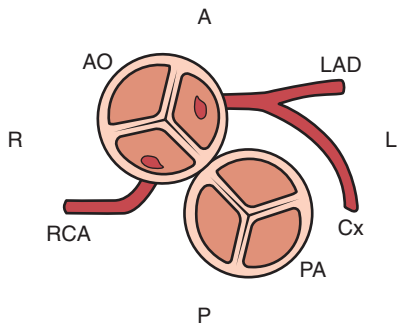
when the patient has pulmonary stenosis. In the absence of these associated defects, murmurs are generally not heard. The peripheral pulses are normal unless coarctation of the aorta is present. Persistent ductal patency or high pulmonary vascular resistance will affect the clinical findings of an associated ventricular septal defect or coarctation of the aorta.

Diagnostic Evaluation



The electrocardiogram is normal or may demonstrate right ventricular hypertrophy after a few weeks of life. Similarly, the classic egg-shaped heart with increased pulmonary vascularity on the chest radiograph might not be seen in the newborn period. Echocardiography defines the associated defects and coronary artery anatomy, which is central to surgical planning.[57] Cardiac catheterization is usually reserved for neonates requiring balloon atrial septostomy, but it is occasionally useful for clarifying the coronary anatomy or other anatomic details (Fig. 75.1).

Management and Prognosis

Establishing patency of the ductus arteriosus with intravenous prostaglandin E_1 infusion in newborn infants with D-TGA often improves arterial oxygenation by increasing shunting from the oxygen-rich pulmonary artery to the deoxygenated aorta. Aortic to pulmonary artery shunting at the ductal level may increase pulmonary venous return, distending the left atrium and facilitating left-to-right atrial shunting of fully oxygenated blood across the atrial level defect. If the prostaglandin E_1 infusion does not result in adequate systemic oxygenation, a balloon atrial septostomy is performed either at the bedside or in the cardiac catheterization lab with echocardiographic guidance. This enlarges the atrial level defect, allowing improved atrial mixing of the systemic and pulmonary venous return.

History

Historically, the surgical interventions for D-TGA were the atrial switch operations of Senning (1959) and Mustard (1964). In these procedures, the deoxygenated blood from the vena cavae is baffled to the morphologic left ventricle and thence the pulmonary artery, while the oxygenated pulmonary venous blood is directed to the morphologic right ventricle and the aorta. This results in physiologic correction. However, the Senning and Mustard procedures are associated with a number of long-term consequences, including right ventricular dysfunction, systemic venous baffle obstruction and leaks, and atrial arrhythmias.[2,42]

• **Fig. 75.1** Most common coronary artery arrangement in D-transposition of the great arteries. The aortic root is anterior and rightward of the pulmonic root in D-TGA. The right coronary artery arises from the rightward posterior-facing sinus, whereas the left coronary artery arises from the leftward anterior-facing sinus. A, Anterior; Ao, aorta; Cx, left circumflex coronary artery; L, left; LAD, left anterior descending coronary artery; P, posterior; PA, pulmonary artery; R, right; RCA, right coronary artery.

Arterial Switch Operation

Drs. Jatene and Yacoub pioneered the anatomic repair of D-TGA via the arterial switch operation, which requires transection of the aorta and main pulmonary artery, reconnection to establish ventriculoarterial concordance (systemic left ventricle to the aorta and pulmonic right ventricle to the main pulmonary artery), and reimplantation of the coronary arteries to the neoaortic root. Other associated intracardiac defects are generally repaired at the time of surgery. The arterial switch operation is optimally performed in the first week of life for infants with D-TGA. If there is a prolonged delay, the risk increases for left ventricular deconditioning and resultant inability to function adequately as the systemic ventricle. The follow-up data on patients who have undergone the arterial switch operation are quite favorable.[59,82,89] Risk factors for early mortality include prematurity and right ventricular hypoplasia. Abnormal coronary anatomy (particularly intramural coronary arteries), a risk factor in earlier experiences, can now be managed effectively, although with potentially higher hospital morbidity.[57] Long-term follow-up studies demonstrate excellent ventricular function, normal rhythm, and low incidence of obstruction at the aortic and coronary suture lines.[19,75] Narrowing in the supravalvar pulmonary area and branch pulmonary arteries may require subsequent surgeries or catheter interventions.[30,82] Neoaortic root dilation and aortic regurgitation are found in some children, but these rarely require further intervention.[60,82] Follow-up data in children 16 years of age with D-TGA from the Boston Circulatory Arrest Study suggest that adolescents with D-TGA who have undergone the arterial switch operation are at increased neurodevelopmental risk and may benefit (along with other children born with congenital heart disease) from ongoing surveillance to identify emerging difficulties.[10]

Cyanotic Heart Defects: Restricted Pulmonary Blood Flow

Tetralogy of Fallot

Anatomy and Pathophysiology

In 1888, Fallot described the association of a large ventricular septal defect, infundibular (subvalvar) and valvar pulmonary stenosis, right ventricular hypertrophy, and a large aorta overriding the ventricular septum—the tetralogy which now bears his name. The spectrum of pulmonary

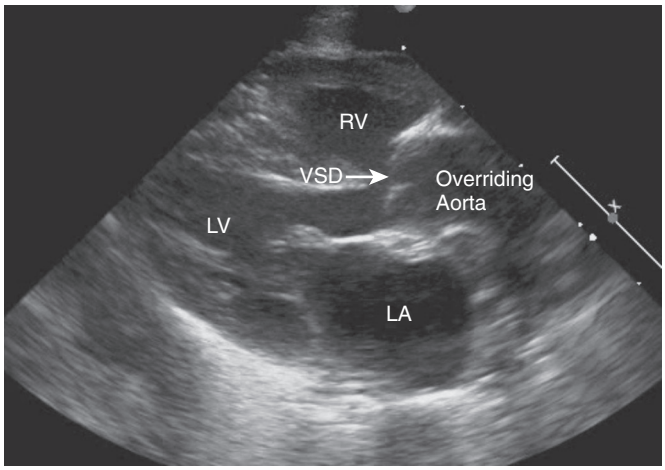
lesions in tetralogy of Fallot (TOF) can range from mild pulmonary stenosis with excellent saturations to pulmonary atresia with very low saturations. Infants with severe pulmonary stenosis or atresia may have severely hypoplastic or absent pulmonary arteries with major aortopulmonary collateral arteries serving as the primary source of pulmonary blood flow. In TOF, cyanosis is proportional to the degree of right ventricular outflow tract (RVOT) obstruction, with severe obstruction limiting pulmonary blood flow and leading to very low saturations. Shunting across the VSD is determined by an intricate balance between the systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR). Acute narrowing or stenosis from the release of endogenous catecholamines, for example, increases PVR more than SVR, resulting in right-to-left shunting and worsening systemic desaturations.

Associated Defects



A right aortic arch is found in approximately 25% of patients with TOF. Coronary artery anomalies (e.g., left anterior descending coronary artery arising from the right coronary artery) are not uncommon and must be identified prior to surgical intervention. The branch pulmonary arteries may be stenotic or discontinuous with collateral supply from the aorta. Some patients also have multiple ventricular or atrial septal defects, anomalous systemic venous drainage, or atrioventricular valve abnormalities. A rare, complex form is tetralogy of Fallot with absent pulmonary valve, which results in pulmonary valve annulus hypoplasia and severe branch pulmonary artery dilation with significant bronchial compression and airway abnormalities, including bronchomalacia.

Clinical Presentation

The clinical presentation of TOF is directly related to the severity of RVOT obstruction. The intensely cyanotic newborn infant generally has severe pulmonary stenosis or atresia with markedly diminished pulmonary blood flow and right-to-left shunting across the VSD. The minimally cyanotic or acyanotic infant has a lesser degree of pulmonary stenosis with mainly left-to-right shunting across the VSD. On exam, in neonates with TOF, the primary murmur is a systolic ejection murmur along the left sternal border secondary to pulmonary stenosis/RVOT obstruction. There may also be a single second heart sound due to marked diminishment of its pulmonary component and a palpable right ventricular impulse. The VSD in TOF is generally large and unrestrictive and does not produce a significant murmur. A continuous murmur may suggest systemic-to-pulmonary collaterals as the source of pulmonary blood flow.

Diagnostic Evaluation

In the newborn with TOF, the classic finding on chest X-ray is a boot-shaped heart caused by right ventricular hypertrophy and consequent upturned cardiac apex. The pulmonary vascular markings should also be carefully examined and may indicate the severity of RVOT obstruction. Echocardiography is the primary diagnostic tool and illustrates the anterior malalignment VSD with RVOT obstruction, right ventricular hypertrophy, and overriding aorta (Fig. 75.2). The levels and degrees of pulmonary obstruction and the size of the main and branch pulmonary arteries should be elucidated, as well as other associated abnormalities, including coronary artery anomalies, additional VSDs, or collateral vessels. Presurgical diagnostic cardiac catheterization is only indicated if the pulmonary artery anatomy and pulmonary blood flow sources cannot be defined by noninvasive imaging modalities.

• **Fig. 75.2** Parasternal long-axis view on echocardiogram of a newborn infant with tetralogy of Fallot. The right ventricle (*RV*) is anterior, and left ventricle (*LV*) is posterior, with a large ventricular septal defect (*VSD*) and overriding aorta. LA, Left atrium.

Management and Prognosis

Neonates with severe cyanosis in the immediate postnatal period are stabilized via intravenous prostaglandin E_1 infusion to maintain patency of the ductus arteriosus and increase pulmonary blood flow. In general, these neonates require a palliative systemic-to-pulmonary shunt (e.g., Blalock-Thomas-Taussig or central shunt) or complete repair in the newborn period to provide a reliable source of pulmonary blood flow. Balloon dilation or stenting of the stenotic pulmonary valve or RVOT has been favored in a few centers as an alternative to shunts.[26] Rehabilitation of branch pulmonary artery stenosis by surgery or interventional catheterization is another important step at the time of primary repair or as part of a staged approach. This is of particular importance in patients with pulmonary atresia and major aortopulmonary collaterals.

Complete TOF repair consists of relief of pulmonary stenosis and RVOT obstruction (often with a transannular patch) and patch closure of the VSD. Associated intracardiac defects such as atrial level defects are also addressed. In the absence of marked pulmonary artery hypoplasia or unfavorable coronary artery anatomy, surgery can be undertaken at virtually any age, with most centers doing elective repairs when infants are between 4-6 months of age.

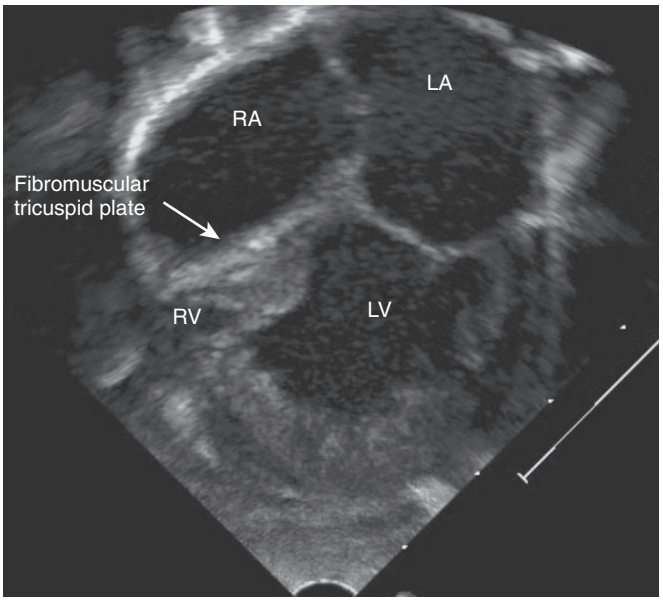
Neonatal TOF repair is feasible for babies with normal or appropriate pulmonary artery size at birth.

Tricuspid Atresia

Anatomy and Pathophysiology

Tricuspid atresia (TA) is defined by platelike tissue in place of the tricuspid valve with no direct communication between the right atrium and right ventricle. Systemic venous return from the vena cavae enters the right atrium and crosses the atrial septum with resultant complete mixing of the systemic and pulmonary venous return in the left atrium. Pulmonary blood flow is supplied by left-to-right shunting through either a PDA or VSD. Associated right ventricular hypoplasia and pulmonary artery hypoplasia are proportional to the size of the VSD and the degree of subpulmonary and pulmonary stenosis. Systemic hypoxia is proportional to the relative systemic and pulmonary blood flows. Neonates with tricuspid atresia, a small VSD, and severe pulmonary stenosis have severely limited pulmonary blood flow and are ductal dependent. Those with a large VSD and no pulmonary stenosis have high pulmonary blood flow, and when PVR falls in the postnatal period, pulmonary flow dramatically increases with resultant pulmonary overcirculation and risk for respiratory issues and feeding/growth failure.

Associated Defects



Tricuspid atresia is not a diagnosis that occurs in isolation. All neonates with TA must have an atrial level defect for postnatal survival. Other associated lesions include VSD, transposition of the great arteries (TGA), atrioventricular septal defect, and aortic coarctation. The size of the VSD is extremely important in neonates with TA with TGA since oxygenated blood flows through the VSD into the right ventricle and then the aorta. Any restriction through the VSD in this case severely compromises systemic circulation.

Clinical Presentation

The typical neonatal presentation of TA is cyanosis at or before ductal closure in an infant with a murmur. Precordial activity is normal, and the second heart sound is often single. There may be a systolic ejection murmur if there is RVOT obstruction. If the VSD is large, tachypnea, a left ventricular impulse, and a third heart sound may develop during the first few days of life as the PVR falls. Hepatic enlargement is an indicator of a restrictive atrial septal defect and elevated right atrial pressures.

Diagnostic Evaluation

The electrocardiogram is usually diagnostic in neonates with TA, demonstrating right atrial enlargement and left axis deviation. The chest radiograph tends to be nonspecific, although severely cyanotic neonates show decreased pulmonary vascularity. The echocardiogram (Fig. 75.3) clearly defines the anatomy in this disorder, particularly the RVOT, pulmonary arteries, atrial level defect, and PDA, in addition to the presence or absence of associated anomalies such as TGA or aortic coarctation. Catheterization is indicated only for balloon atrial septostomy in those with a restrictive atrial septum.

• **Fig. 75.3** Apical four-chamber view on echocardiogram of a neonate with tricuspid atresia. There is no tricuspid valve with a fibromuscular plate in its usual place. A large atrial septal defect permits flow from the right atrium (*RA*) to the left atrium (*LA*) and into the left ventricle (*LV*). The right ventricle (*RV*) is severely hypoplastic.

Management and Prognosis

Flow across the VSD to supply the pulmonary circulation may be adequate in the first months of life as long as the atrial level defect remains nonrestrictive. It is generally possible to predict by echocardiogram when infants require a PDA to maintain adequate arterial saturations. A balloon atrial septostomy is rarely necessary unless there is significant restriction at the atrial level. If an infant is ductal-dependent or if hypoxia increases in the first month of life, a systemic-to-pulmonary shunt is necessary to provide adequate pulmonary blood flow and oxygenation. Conversion to a bidirectional cavopulmonary (Glenn) anastomosis is usually considered when an infant is between 3 and 6 months of age.[50] Some infants with well-balanced systemic and pulmonary flows can proceed directly to an early bidirectional Glenn operation[74] or a total cavopulmonary (Fontan) operation at about 2-3 years of age. Among children who undergo the Fontan type of operation, those with TA have excellent long-term prognosis, with a low prevalence of ventricular dysfunction, mitral regurgitation, arrhythmias, and systemic venous congestion.[81]

Pulmonary Atresia With Intact Ventricular Septum

Anatomy and Pathophysiology

The pulmonary valve in pulmonary atresia with intact ventricular septum (PA/IVS) can range from a well-formed

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

pulmonary annulus with a plate that obstructs outflow to complete absence of the valve. All forms may lead to severe right ventricular hypertrophy with right ventricular dysfunction and varying right ventricular hypoplasia. Since the ventricular septum is intact, pulmonary blood flow in PA/IVS is ductal-dependent and can only occur via shunting at the atrial level and flow through a PDA. The tricuspid valve is rarely normal in patients with PA/IVS, ranging from severely hypoplastic and stenotic to regurgitant.

Associated Defects

A very important prognostic feature in PA/IVS concerns the presence or absence of ventriculocoronary connections (sinusoids and fistulae) and coronary artery abnormalities. These must be well defined prior to surgical or transcatheter intervention. In the case of right ventricular (RV)–dependent coronary circulation, where coronary artery flow depends on high RV pressures for adequate myocardial perfusion, any decompression of the RV can lead to untoward consequences such as myocardial ischemia, infarction, and death.

Clinical Presentation

Fetal diagnosis of PA/IVS frequently identifies risk factors for subsequent transcatheter and surgical management, including tricuspid valve and RV hypoplasia and coronary sinusoids and fistuale.[32] Neonates with PA/IVS have severe hypoxia with PDA closure and can rapidly become unstable with tachypnea, tachycardia, hepatomegaly, and cardiorespiratory collapse. Cyanosis becomes apparent within hours of birth and is progressive. Tachypnea may be prominent. The first and second heart sounds are single, and there may be a holosystolic murmur heard best at the left lower sternal border consistent with tricuspid regurgitation. A PDA murmur may be audible, particularly following initiation of prostaglandin infusion. Unless there is severe tricuspid regurgitation or a restrictive atrial communication, the liver generally is not enlarged while ductal patency is maintained.

Diagnostic Evaluation

Chest radiography in PA/IVS often shows cardiomegaly, owing to right atrial enlargement. Echocardiography is diagnostic, demonstrating the pulmonary atresia, tricuspid valve abnormalities, RV hypoplasia severity, and coronary anomalies, including sinusoids and fistulae. Cardiac catheterization is indicated to assess coronary flow, the presence (including size and location) or absence of coronary sinusoids and fistulae, and pulmonary blood flow sources and for consideration of pulmonary valve intervention.

Management and Prognosis

Intravenous prostaglandin E_1 infusion is essential for maintaining ductal patency in PA/IVS. Careful assessment of the anatomy and physiology provides a framework for transcatheter and surgical management.[5] Balloon pulmonary valvuloplasty is feasible in infants with even a tiny orifice in the pulmonary valve, and other transcatheter techniques, including radiofrequency perforation of the valve, may be considered.[3] If interventional catheterization is unsuccessful, surgical valvotomy is indicated unless there is clear RV-dependent coronary flow. In that circumstance, RV decompression can result in coronary hypoperfusion, so a systemic-to-pulmonary shunt is recommended as initial palliation to provide pulmonary blood flow. In infants with successful surgical or transcatheter valvotomies, RV growth is possible and biventricular circulation can be restored.[41,44] Severe tricuspid and RV hypoplasia or RV-dependent coronary circulation is an indication for single ventricle palliation.[37] Infants with RV hypoplasia should also be considered candidates for superior cavopulmonary (Glenn) anastomosis combined with closure of the atrial level defect (the so-called 1.5 ventricle repair). This results in direction of inferior vena cava flow across the tricuspid valve into the RV, promoting potential RV growth.

Ebstein Anomaly

Anatomy and Pathophysiology

In Ebstein anomaly of the tricuspid valve, there is arrested delamination of the leaflets during valve development. In particular, the septal leaflet can become tethered to the interventricular septum to varying degrees with apical displacement of its annular attachment, potentially leading to significant tricuspid regurgitation. The anterior tricuspid leaflet can also become markedly enlarged and redundant ("sail-like"), causing RVOT obstruction with decreased blood flow and functional or anatomic pulmonary atresia. Secondary to apical tricuspid annular displacement into the right ventricle, a portion of the RV becomes atrialized, detrimentally affecting its contractile efficiency. Forward pulmonary blood flow is, therefore, dependent on the severity of tricuspid valve displacement and regurgitation and RV atrialization and dysfunction. If functional or anatomic pulmonary atresia occurs, an obligatory right-to-left shunt must exist at the atrial level. The degree of this atrial shunt is proportional to the severity of the tricuspid valve abnormality.

Associated Defects

Patients with Ebstein anomaly often have other associated intracardiac lesions, including the aforementioned pulmonary atresia and atrial level defects. Conduction system abnormalities such as accessory pathways (e.g., Wolff-Parkinson-White syndrome) are found in up to 20% of patients.

Clinical Presentation

Infants with severe manifestations of Ebstein anomaly may present with profound cyanosis, tachypnea, and cardiovascular collapse. Cyanosis is dependent on the extent of atrial right-to-left shunting. A low-frequency holosystolic murmur of tricuspid regurgitation is often heard on exam, and the first heart sound may be widely split.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

Diagnostic Evaluation

The electrocardiogram of infants with severe Ebstein anomaly shows an RSR′ pattern across the right side of the chest, suggesting RV dilation. Chest radiography can demonstrate severe cardiomegaly caused by right atrial dilation. Echocardiography helps delineate the extent of tricuspid valve displacement, atrial level shunting, and functional or anatomic pulmonary atresia. The ratio of the right atrial plus atrialized RV size to the functional RV plus left heart (left atrium and ventricle) size has been a useful measure of severity and outcome.[90]

Management and Prognosis

Mild forms of Ebstein anomaly require no specific treatment, and these infants in general do well. The severely affected neonate with severe tricuspid valve displacement and regurgitation is often ductal dependent with minimal or no anterograde flow across the pulmonary valve.[90] Maintaining ductal patency with prostaglandin E_1 infusion can be useful in the short term. However, ductal flow into the pulmonary artery can make anterograde flow more difficult. In severe Ebstein anomaly, measures to lower the pulmonary vascular resistance, including nitric oxide, and several attempts to wean prostaglandin E_1 might be necessary before anterograde flow across the pulmonary valve can be established. Brief support with extracorporeal membrane oxygenation to facilitate this fetal to neonatal transition has been successful in limited cases. Surgical repair or replacement of the valve is feasible in older children, but this is not useful in neonates. Either surgical exclusion of the right ventricle, with plans for a long-term, single-ventricle palliation, or transplantation might be the only alternatives for the neonate with severe Ebstein anomaly and persistent cyanosis.[54]

Cyanotic Heart Defects: Complete Mixing

Total Anomalous Pulmonary Venous Connection/Return

Anatomy and Pathophysiology

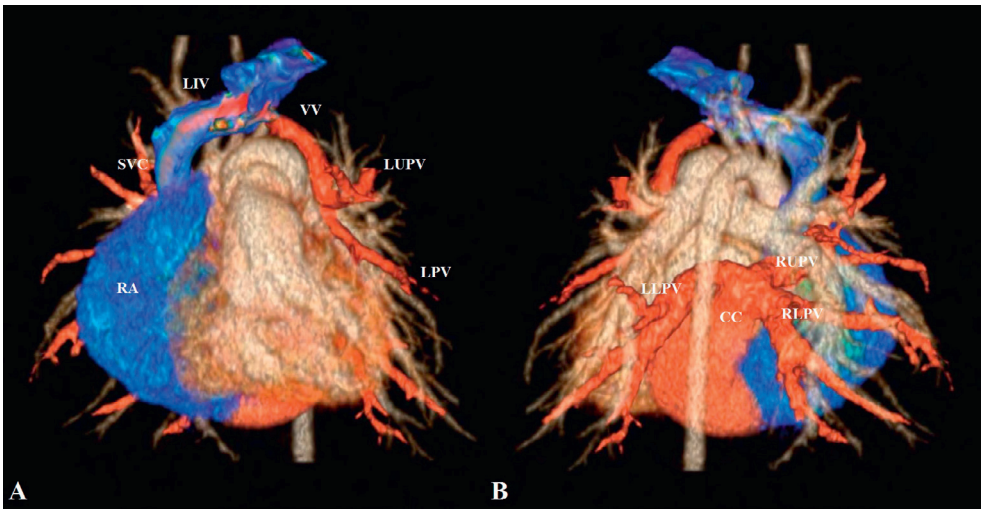
Total anomalous pulmonary venous connection or return (TAPVC/TAPVR) comprises a group of defects in which all the pulmonary veins carrying oxygenated blood drain into the systemic venous circulation rather than normally to the left atrium. A number of distinct variants have been identified:

1. Supracardiac type: A vertical vein emanates from the pulmonary venous confluence posterior to the left atrium and courses superiorly to the left innominate vein, which then drains to the superior vena cava and right atrium.
2. Infracardiac type: A descending vertical vein emanates from the pulmonary venous confluence posterior to the left atrium and courses inferiorly, crossing through the diaphragm and the liver with variable drainage to the ductus venosus, hepatic veins, portal vein, or inferior vena cava and eventual pulmonary venous return to the right atrium.
3. Cardiac type: Pulmonary veins drain to the right atrium via an intracardiac connection—generally the coronary sinus or directly to the right atrium.
4. Mixed type: Anomalous pulmonary venous connections occur at two or more levels. Typically, the left pulmonary veins may drain into the systemic veins through the ascending vertical vein (supracardiac), and the right pulmonary veins drain into the coronary sinus or directly into the right atrium (cardiac). Other complex variants exist as well (Fig. 75.4).

The supracardiac form is most commonly encountered, occurring in roughly half of cases, while the mixed form is least common. Infracardiac TAPVC in particular may present in extremis in the neonatal period, owing to obstruction of the descending vertical vein at either the diaphragm or the ductus venosus. The supracardiac form can also less commonly present with obstruction when the vertical vein passes between the left bronchus and the left pulmonary artery or at the junction of the superior vena cava and the innominate vein. In TAPVC, the oxygenated pulmonary venous return mixes completely with deoxygenated systemic venous return in the right atrium. Systemic blood flow is dependent on shunting from the right atrium to the left atrium through an atrial level defect. In the absence of any form of pulmonary venous obstruction, pulmonary blood flow is increased and hypoxia is mild. In contrast, if the anomalous pulmonary venous connection is obstructed at any point in its course, this results in pulmonary venous hypertension with pulmonary edema and decreased pulmonary blood flow. The combination of decreased pulmonary blood flow and impaired pulmonary function caused by edema produces profound systemic hypoxemia.

Associated Defects

An atrial level defect is essential for postnatal survival with TAPVC. Left-sided heart defects, transposition of the great arteries, and tetralogy of Fallot have also been reported in association with TAPVC. Neonates with heterotaxy syndrome commonly have associated TAPVC.



Clinical Presentation

The neonatal clinical presentation of unobstructed TAPVC is generally asymptomatic. These patients are either diagnosed at an older age secondary to recurrent pneumonias or are identified by echocardiogram in evaluation for a murmur. Cyanosis and respiratory distress are generally limited to infants with the severe form of obstructed pulmonary venous connections. In infants without obstruction, volume overload and increased pulmonary blood flow can gradually develop.

Diagnostic Evaluation

Chest radiography is very helpful in TAPVC since it may demonstrate pulmonary edema, which is highly suggestive of pulmonary venous obstruction. Dilated mediastinal

• **Fig. 75.4** Three-dimensional reconstruction from computed tomography angiography demonstrating complex mixed (supracardiac + cardiac) total anomalous pulmonary venous connection (TAPVC) with the left upper and lingular pulmonary veins draining to the left innominate vein via a vertical vein (supracardiac) and the right upper, right lower, and left lower pulmonary veins draining to a common channel and then the coronary sinus (cardiac). **A,** Anterior view showing the left upper and lingular pulmonary veins draining to a vertical vein and then the left innominate vein, which drains into the SVC and right atrium. LIV, Left innominate vein; LPV, lingular pulmonary vein; LUPV, left upper pulmonary vein; RA, right atrium; SVC, superior vena cava; VV, vertical vein. **B,** Posterior view showing the right upper and lower and left lower pulmonary veins draining to a common channel and then the right atrium via the coronary sinus. CC, Common channel; LLPV, left lower pulmonary vein; RLPV, right lower pulmonary vein; RUPV, right upper pulmonary vein.

veins give an appearance of fullness to the superior mediastinum (the snowman sign), although in neonates, this is usually masked by the thymus. An ECG is usually not helpful. Echocardiography is the gold standard, and careful examination of each pulmonary vein for its entry into the pulmonary venous confluence and drainage of the confluence is paramount. Sites of venous obstruction can also be illustrated via spectral and color flow Doppler imaging. The size of the individual pulmonary veins and the confluence should be measured since pulmonary vein diameters less than 2 mm have been associated with a poor prognosis. The atrial level defect must be imaged to document that it is not restrictive. If there is any question of a restrictive atrial level defect, balloon atrial septostomy is recommended. If echocardiography cannot provide all the necessary information, CT angiography (see Fig. 75.4), cardiac catheterization, or magnetic resonance imaging may be necessary.

Management and Prognosis

Unobstructed TAPVC generally requires minimal medical management until the infant is ready for surgical intervention. Neonates with restrictive atrial level defects should undergo balloon atrial septostomy. Neonates with pulmonary venous obstruction tend to be profoundly hypoxic and require significant respiratory and metabolic support. Extracorporeal membrane oxygenation has been used as a bridge to complete repair. Urgent neonatal surgery is essential for those with pulmonary venous obstruction. Elective repair via anastomosis of the common pulmonary venous confluence to the left atrium is done in neonates with unobstructed TAPVC in the first months of life. Postoperative pulmonary artery hypertension and pulmonary vascular reactivity is most troublesome in neonates with preoperative pulmonary venous obstruction. The long-term prognosis is excellent except in neonates with hypoplastic pulmonary veins or single ventricle anatomy.[40] Recurrent or persistent pulmonary venous obstruction at the anastomotic site or within the veins is difficult to treat by either surgery or interventional catheterization. Arrhythmias and poor chronotropic response to exercise have been reported in some patients after surgery.[85]

Truncus Arteriosus

Anatomy and Pathophysiology

In truncus arteriosus, there is common origin of aorta and pulmonary artery from a single arterial trunk. This single trunk overrides a large VSD that allows mixing of systemic and pulmonary venous return. In type I truncus, there is a short main pulmonary artery segment arising from the truncus, which then gives rise to branch pulmonary arteries. In type II truncus, both the branch pulmonary arteries have a direct origin from the truncus. In type III truncus, the pulmonary arteries arise from opposite sides of the truncus and are remote from each other. Both pulmonary and systemic blood flows are determined by the relative systemic and pulmonary vascular resistances. As the pulmonary vascular resistance falls, there tends to be increased

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

pulmonary blood flow, resulting in pulmonary overcirculation and increased left atrial and ventricular size.

Associated Defects

A number of other cardiac defects are associated with truncus arteriosus. Most importantly, the single semilunar truncal valve demonstrates variable morphology with anywhere from one to six leaflets and differing degrees of valvar stenosis and regurgitation. The truncal valve leaflets also tend to be thickened and dysplastic. Unilateral or bilateral branch pulmonary artery stenosis occurs in about 10% of cases. If the origin of the pulmonary artery is atretic, there can also be aortopulmonary collaterals supplying the lungs. Coronary artery stenoses and malposition are rare but are surgically important variations.[1] A right aortic arch is found in 15%-25% of patients with truncus, and an aortic coarctation or interrupted aortic arch may also be present. In addition, 22q11 chromosomal microdeletion (DiGeorge) syndrome is a very common associated genetic abnormality, so all patients with truncus arteriosus should be screened.

Clinical Presentation

The neonatal presentation of uncomplicated truncus arteriosus can be subtle, with mild tachypnea or cyanosis being the only symptom. Systemic oxygen saturations are generally in the mid-80s, with higher saturations indicating falling pulmonary vascular resistance and increasing pulmonary blood flow. Lower saturations indicate increased pulmonary vascular resistance, branch pulmonary artery stenosis, or pulmonary dysfunction from edema. Acidosis can be present in infants with associated truncal stenosis and regurgitation or aortic arch interruption. As the pulmonary vascular resistance drops, pulmonary blood flow increases, resulting in signs and symptoms of pulmonary overcirculation. Truncal valve stenosis and regurgitation murmurs can be identified on exam. Infants may have bounding pulses and increased pulse pressures secondary to decreased diastolic pressure caused by runoff into the branch pulmonary arteries. Poor perfusion and decreased leg pulses may indicate aortic coarctation or arch interruption. Given the association with 22q11 chromosomal microdeletion syndrome, all patients with truncus arteriosus should also be screened for the presence of a thymus and serum calcium derangements.

Diagnostic Evaluation

Chest radiography in truncus arteriosus typically demonstrates cardiomegaly and pulmonary overcirculation. An electrocardiogram may show biventricular hypertrophy or be normal. Echocardiography is the gold standard for diagnosis—attention must be paid to define the truncal valve, branch pulmonary arteries, aortic arch anatomy, and coronary arteries. Cardiac catheterization, CT angiography, and MRI are reserved for neonates with pending questions after echocardiography. Chromosomal microarray testing should be done on all infants with truncus arteriosus.

Management and Prognosis

In infants with truncus arteriosus, increased pulmonary blood flow and resultant symptomatology generally respond well to agents such as diuretics and digoxin. Supplemental oxygen should be avoided since this decreases pulmonary vascular resistance, increasing pulmonary blood flow. Infants with moderate to severe truncal valve stenosis or regurgitation generally do not respond to medical management and require balloon dilation or early surgical repair. In 22q11 infants, careful management of calcium levels is required. Truncus arteriosus is typically repaired in the first months of life. This repair includes VSD closure and placement of a right ventricle to pulmonary artery (RV-PA) conduit. Associated defects, including truncal valve stenosis, aortic arch interruption, coronary abnormalities, and branch pulmonary artery atresia, increase procedural risk but do not preclude it.[86] If truncal valve stenosis or regurgitation is severe, then the truncal valve may be replaced to provide a competent neoaortic valve. The long-term prognosis for infants with uncomplicated truncus arteriosus status postrepair is excellent. RV-PA conduit replacement is generally required by age 5 years in about 20% of patients, and the conduit must always be replaced at some point in the child's life, sometimes multiple times. The truncal/neoaortic valve may develop worsening stenosis and can require valve repair or replacement in 25% of patients.[43] Ventricular dysfunction and arrhythmias are generally poor prognostic indicators.

Cyanotic Heart Defects: Variable Physiology

Single Ventricle Anatomy/Physiology

Congenital heart disease resulting in single ventricle anatomy or physiology encompasses a wide range of defects and structural variants. A methodical segmental approach to determine a patient's venous, atrial, ventricular, and arterial connections generally allows accurate diagnosis. Furthermore, basic physiologic principles help guide management in this population. For example, there must be adequate mixing of systemic and pulmonary venous return to support single ventricular output. This mixing occurs most effectively through an atrial level defect (PFO or ASD). Additional shunting and mixing can also occur via a VSD or PDA. The single ventricle predominantly pumps blood to either the systemic or pulmonary circulation, and the predominant circulation must then support the other via shunting through a PDA. Systemic oxygen saturations are determined by the relative resistances across the pulmonary and systemic vascular beds. It is important to recognize that many infants have low pulmonary vascular resistance, resulting in unrestricted pulmonary blood flow. Oxygen acts as a pulmonary vasodilator, further increasing pulmonary blood flow, often at the cost of systemic blood flow. This may produce acidosis and diminished end organ perfusion. Consequently, the use of supplemental oxygen

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

or other pulmonary vasodilators must be very carefully weighed in the single ventricle population.

Once single ventricle anatomy/physiology has been diagnosed, the next step is to determine whether the pulmonary or systemic circulation requires support. This primarily guides the interventions needed for effective management, including long-term surgical planning. Increasing prenatal diagnosis via fetal echocardiography has allowed better expectant management and teamwork between obstetrics, pediatric cardiology, intensive care, and cardiothoracic surgery teams to optimize care for these patients, as well as better preparation for affected families for the complicated road ahead.

Hypoplastic Left Heart Syndrome

Before 1980, no effective palliation was available for infants with hypoplastic left heart syndrome. Staged surgical palliation, including the Norwood operation,[67] and neonatal cardiac transplantation have afforded new hope to the families of newborn infants with this otherwise uniformly lethal cardiac defect. Advances in both approaches have greatly improved duration and quality of life for these patients.

Anatomy and Pathophysiology

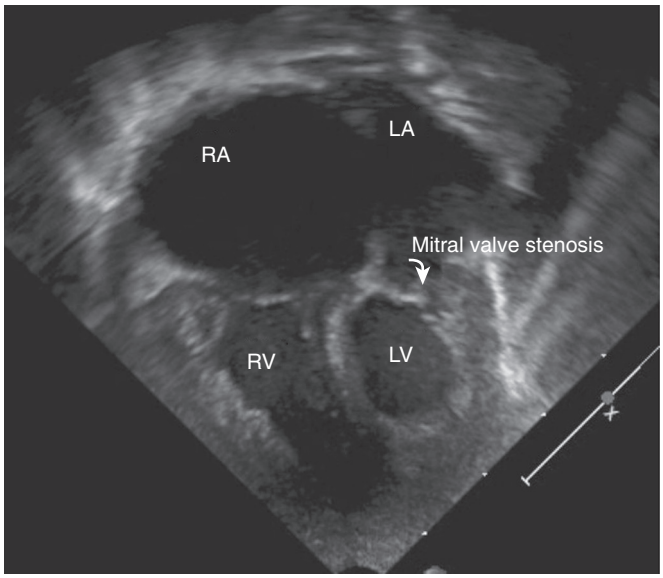
Hypoplastic left heart syndrome (HLHS) can result from a variety of congenital heart defects, but it is classically associated with abnormalities of the mitral and aortic valves, ranging from mitral stenosis and aortic stenosis to mitral atresia and aortic atresia in the most severe variants. There is resultant left ventricular (LV) hypoplasia and varying degrees of ascending aorta and transverse arch hypoplasia. Aortic coarctation may be present in rare cases. LV endocardial fibroelastosis or infarction can result from in utero subendocardial ischemia. Coronary artery abnormalities have also been identified but have uncertain impact on long-term myocardial function. In HLHS, the systemic circulation is ductal dependent—ductal flow courses retrograde to the transverse arch and ascending aorta to supply the head/neck vessels and coronary arteries, as well as anterograde to the descending aorta. In utero, when pulmonary vascular resistance is high, this circulation provides excellent organ perfusion, and fetal growth is usually normal. Postnatally, even as pulmonary vascular resistance falls and pulmonary blood flow increases, right ventricular output remains adequate to supply both the systemic and pulmonary circulations. However, ductal closure dramatically alters this balance, leading to profound systemic hypoperfusion with acidosis and multisystem organ failure.

Associated Defects

The most important associated intracardiac defect in HLHS is an unrestrictive atrial level shunt. An absent or restricted atrial defect in utero creates severe pulmonary venous hypertension, leading to detrimental pulmonary vasculature changes. Significant atrial restriction can result in greatly increased morbidity and mortality in the neonatal period and is a major negative prognostic factor in postnatal outcomes.[34] Other important associated defects for HLHS include pulmonary venous return anomalies. Occasional neonates with aortic atresia have a normal mitral valve and normal left ventricular size because of an associated ventricular septal defect. Central nervous system anomalies, including absent corpus callosum, are also quite common in infants with HLHS. Furthermore, there is increasing recognition of the in utero effects of congenital heart disease, including HLHS, on prenatal brain development and postnatal neurodevelopmental outcomes.[27,36,58]

Clinical Presentation

Increasing prenatal diagnosis of HLHS has greatly helped prepare affected families and contributed to improved coordination between the various medical teams involved in the delivery and initial management of these infants. Infants with HLHS often have tachypnea and mild cyanosis in the postnatal period. There can be a moderately increased right ventricular impulse on exam with a single second heart sound and variable murmurs. With ductal patency, pulses can be nearly normal. Pulse oximetry varies widely, ranging from 70% to greater than 90% depending on the amount of pulmonary blood flow and degree of pulmonary edema. A restrictive atrial level defect can produce significant pulmonary edema because of increased left atrial pressure and resultant increased pulmonary venous pressure. The combination of pulmonary edema and restricted pulmonary blood flow produces profound hypoxia.[34]



Diagnostic Evaluation

The electrocardiogram in HLHS generally demonstrates dominant RV forces, often with a QR pattern in the right chest leads. Chest radiography shows cardiomegaly and increased pulmonary blood flow with more prominent pulmonary vascular markings and pulmonary venous congestion. Echocardiography (Fig. 75.5) defines the underlying anatomy, including the atrial level defect and its degree of restriction, atrioventricular valve regurgitation, ventricular function, outflow tract obstruction, coronary anatomy, and aortic arch morphology, as well as associated abnormalities such as systemic or pulmonary venous return anomalies. All these are crucial to delineate prior to any type of intervention.

Management and Prognosis

In HLHS, there is ductal-dependent systemic circulation, so maintaining ductal patency in the immediate postnatal period with intravenous prostaglandin E1 infusion is critical for survival. Beyond this period, most centers use a staged surgical strategy to more definitely manage these infants. Neonatal cardiac transplantation[9] remains an option but is greatly limited by donor heart availability. No matter the chosen strategy, careful postnatal assessment and management to prevent complications from excessive pulmonary blood flow are essential for good long-term results. The overall goal of staged surgical palliation for HLHS is to

LA, Left atrium; RA, right atrium.

separate the systemic and pulmonary circulations in stepwise fashion while ensuring adequate systemic blood flow at each stage and protecting the pulmonary vasculature from excessive flow and pulmonary hypertension. Surgical techniques and postsurgical management have evolved greatly over a number of decades to address the various issues and problems that have been recognized during the evolution of the current staged approach.

In most centers, initial (stage I) surgical palliation is done in the immediate postnatal period with a Norwood procedure, including aortic reconstruction, systemic-to-pulmonary arterial shunt placement (modified Blalock-Thomas-Taussig [mBTT] shunt or RV-PA conduit [Sano modification]),[14] and atrial septectomy. A Damus-Kaye-Stansel anastomosis may be utilized if the ascending aorta is of sufficient size.[66] Stage I palliation may also be accomplished via a hybrid procedure done by surgical and interventional catheterization teams working in tandem. Hybrid stage I palliation consists of surgical bilateral branch pulmonary artery banding and transcatheter PDA stent placement. The theoretical advantages of this approach are avoidance of cardiopulmonary bypass and circulatory arrest (and their potential associated adverse effects) in the neonatal period and delay of major aortic intervention/reconstruction to an older age when infants are larger.[31] The primary goals of both Norwood and hybrid stage I palliation are to provide adequate systemic blood flow and to effectively control pulmonary blood flow. Postoperative management requires very close monitoring of systemic perfusion and appropriate titration of medications and respiratory support as needed to avoid tissue/organ hypoxia. Typical systemic arterial saturations following stage I palliation are in the mid-60% to mid-70% range. Even with greatly improved surgical and intensive care techniques, a proportion of infants after stage I palliation require extracorporeal membrane oxygenation support to achieve stability with eventual poor results.[73]

Following either stage I technique, stage II palliation entails completing a superior cavopulmonary (Glenn) anastomosis or hemi-Fontan procedure to allow the superior vena cava to directly drain to the pulmonary arteries.[28] In the hybrid approach, the previously deferred aortic reconstruction must also be completed, and the total operation is denoted a comprehensive stage II procedure. Stage II palliation is typically completed between 2 and 6 months of age and results in systemic venous return from the upper body (via the SVC) being the sole source of pulmonary blood flow. Since SVC flow is no longer draining to the systemic single ventricle, ventricular volume load is reduced, lessening its overall work load and reducing the potential for ventricular dysfunction. Typical systemic arterial saturations following stage II palliation climb into the mid-70% to mid-80% range.

Staged surgical palliation for HLHS is completed at approximately 2-3 years of age via a total cavopulmonary connection (Fontan procedure) to direct inferior vena cava drainage to the pulmonary arteries. A number of different surgical techniques have been utilized through the years and are now grouped together as Fontan variants, including direct atriopulmonary anastomosis (the classic Fontan first done in 1973), intracardiac connection (lateral tunnel Fontan), and extracardiac conduit connection (extracardiac Fontan).[71] Following any Fontan variant, the pulmonary and systemic circulations have been separated, with the single systemic ventricle accepting oxygenated pulmonary venous return and supplying the systemic circulation in pulsatile fashion and systemic venous return passively draining to the lungs via the cavopulmonary anastomoses. This generally results in normal systemic arterial saturations greater than 90%.

The evolution of the current staged surgical palliation strategy for HLHS has been an iterative process with great advances achieved due to the coordinated and dedicated efforts of entire medical teams and heart centers, including nursing, social work, and multiple medical and surgical specialties. Mortality and morbidity were high during the development of the Norwood procedure, and early experiences with stage I palliation resulted in 1-year survival rates less than 50%. These results have greatly improved into the current era, and staged single ventricle palliation has resulted in significantly increased survival and quality of life.[4,17,25,47] A multicenter prospective clinical trial comparing the mBTT shunt and Sano modification in Norwood stage I palliation failed to show any major differences between the two procedures.[68] Most series comparing the different stage I strategies, including the hybrid approach, have failed to demonstrate a significant difference in outcomes, but there is some data demonstrating a survival benefit with the Norwood-Sano technique in certain HLHS

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

variants.[29,33,45,88] Risk factors for poor stage I survival include low birth weight, a restrictive atrial level defect, ventricular dysfunction, and significant AV valve regurgitation.[25,78,87] Interstage mortality (between stage I and stage II palliation) remains a complicated, vexing issue. Long-term morbidity and mortality may occur secondary to recurrent coarctation or arch obstruction,[56] AV valve regurgitation, sinus node dysfunction, various arrhythmias, and ventricular dysfunction. Increasing data are demonstrating the association of HLHS and higher risk for neurodevelopmental issues.[6,27,35,36,58,62]

Double Outlet Right Ventricle

Anatomy and Pathophysiology

In double outlet right ventricle (DORV), the aorta and the pulmonary artery both arise from the right ventricle. There are four distinct subtypes based on the location of the VSD and its relationship to the great arteries: (1) subaortic, (2) subpulmonary, (3) doubly committed, or (4) remote from the great arteries. The Taussig-Bing malformation is a DORV variant with a subpulmonary VSD and transposition of the great arteries.[76] DORV physiology is determined by VSD location and associated defects, ranging from large VSD shunt physiology to transposition physiology.

Associated Defects

The most important associated defect in DORV is subpulmonary or pulmonary stenosis. The DORV variant with a subaortic VSD and pulmonary stenosis results in physiology similar to tetralogy of Fallot. The Taussig-Bing variant is particularly associated with aortic arch anomalies, including coarctation or interruption.

Clinical Presentation

Clinical presentation of DORV in the neonatal period can vary widely, including significant cyanosis in transposition variants or shock and cardiovascular with ductal closure in Taussig-Bing variants with coarctation or interrupted aortic arch. A murmur generally suggests the presence of pulmonary stenosis.

Diagnostic Evaluation

The electrocardiogram and chest radiograph in DORV are nonspecific. Echocardiography helps identify its important features, including VSD size and location, VSD relation to the great arteries, and great artery configuration. The relationship of the great arteries to each other and presence of pulmonary stenosis or aortic arch abnormalities should be easily identified.

Management and Prognosis

Surgical intervention for DORV is dependent on the predominant physiology, as well as VSD location and its relationship to the great arteries. Hence, definitive repair could simply entail VSD closure or become increasingly complex to involve components such as an arterial switch operation or coarctation/interrupted arch repair.[15,76] DORV repair is generally done in the first 6 months of life.

Obstructive Heart Defects

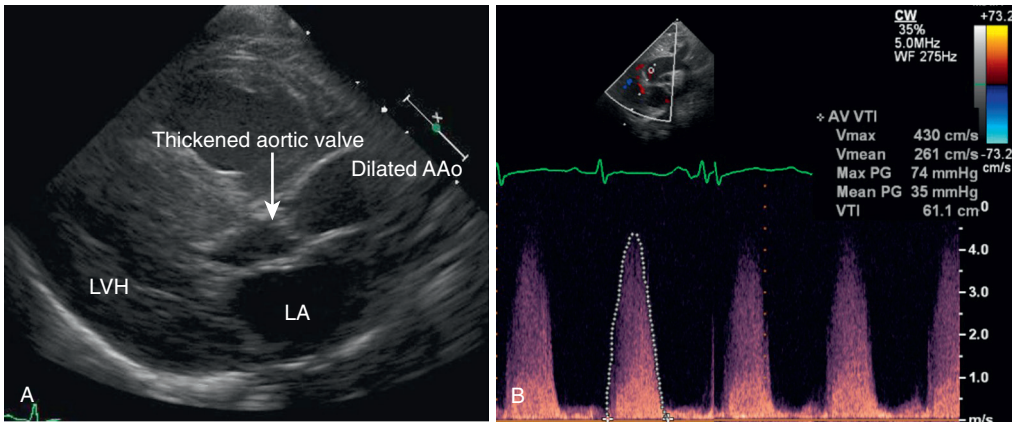
Valvar Aortic Stenosis

Anatomy and Pathophysiology

Isolated aortic valve disease ranges from asymptomatic bicuspid aortic valves to critical valvar aortic stenosis. Mild to moderate aortic valve stenosis is well tolerated in utero, generally resulting in left ventricular hypertrophy. Severe aortic stenosis in utero leads to significant left ventricular hypertrophy and compromised coronary circulation, sometimes resulting in endocardial fibroelastosis and eventual left ventricular (LV) dilation with poor systolic function. These patients often require ductal patency to maintain adequate systemic output to meet the body's metabolic demands.

Associated Defects

Mild aortic stenosis can be accompanied by a large patent ductus arteriosus, which may exaggerate the pressure gradient across the aortic valve because of pulmonary overcirculation and increased pulmonary venous return and left heart blood flow. Significant aortic insufficiency is rare in neonatal aortic stenosis. If present, it should raise suspicion for a tunnel from the LV to the aorta.[63] Aortic root dilation of varying severity is present in patients with aortic stenosis. Supravalvar aortic stenosis should prompt evaluation for Williams syndrome.[53] Diffuse aortic root or ascending aorta hypoplasia is generally a sign of associated aortic coarctation or left heart hypoplasia with severe aortic valve stenosis.



Clinical Presentation

The cardinal physical finding in neonatal aortic stenosis is a systolic ejection murmur radiating upward to the neck. Its intensity and length are dependent on the severity of stenosis and cardiac function/output. A systolic ejection click may also be appreciated at the apex of the heart. For critical aortic stenosis, ductal patency is required for adequate systemic perfusion, so ductal closure can lead to rapid cardiovascular collapse with shock, acidosis, and multiorgan failure.

Diagnostic Evaluation

Since the severity of neonatal aortic stenosis may be difficult to fully assess clinically, thorough diagnostic assessment is essential. The electrocardiogram is usually normal or may show left ventricular hypertrophy. Chest radiography is most useful in detecting pulmonary edema. Echocardiography (Fig. 75.6) is the standard for elucidating aortic valve anatomy, stenosis severity, including pressure gradient by spectral Doppler (see Fig. 75.6*B*), ventricular dysfunction, and other associated defects, including PDA and coarctation. A pulse oximetry differential between the upper and lower extremities suggests right-to-left shunting at the

• **Fig. 75.6 A,** Parasternal long-axis view on echocardiogram of an infant with significant valvar aortic stenosis (AS). The valve leaflets are thickened with systolic doming (*arrow*). There is associated left ventricular hypertrophy (*LVH*) and ascending aorta (*AAo*) dilation. LA, Left atrium. **B,** Continuous-wave spectral Doppler interrogation of the left ventricular outflow tract from the suprasternal notch demonstrating peak velocities up of 4.3 m/sec (74 mm Hg peak gradient, 35 mm Hg mean gradient), consistent with severe AS.

ductal level. Arterial blood gas and serum biomarkers can be followed to assess tissue perfusion.

Management and Prognosis

Mild valvar aortic stenosis is well tolerated, with no immediate intervention required aside from outpatient follow-up. Moderate to severe aortic stenosis can progress in the first few months of life, necessitating closer follow-up. Any evidence of inadequate systemic perfusion or ventricular dysfunction in an infant with severe aortic stenosis is an indication for balloon or surgical valvotomy. Critical aortic stenosis is a neonatal emergency and continues to result in relatively high morbidity and mortality when not expediently diagnosed. Success rates with neonatal balloon aortic valvuloplasty have been good and considered acceptable when faced with the alternative of surgery, but the procedure can result in residual stenosis or iatrogenic insufficiency, eventually necessitating reintervention.[39,65] Surgical valvotomy remains an alternative as a primary intervention or secondary measure if balloon aortic valvuloplasty is unsuccessful. If the aortic valve or LV is unsuitable for these procedures, single ventricle palliation might be a more suitable long-term solution.[69] The selection of infants with borderline criteria for a two-ventricle approach remains controversial and challenging.[20,22]

Aortic Coarctation and Interrupted Aortic Arch

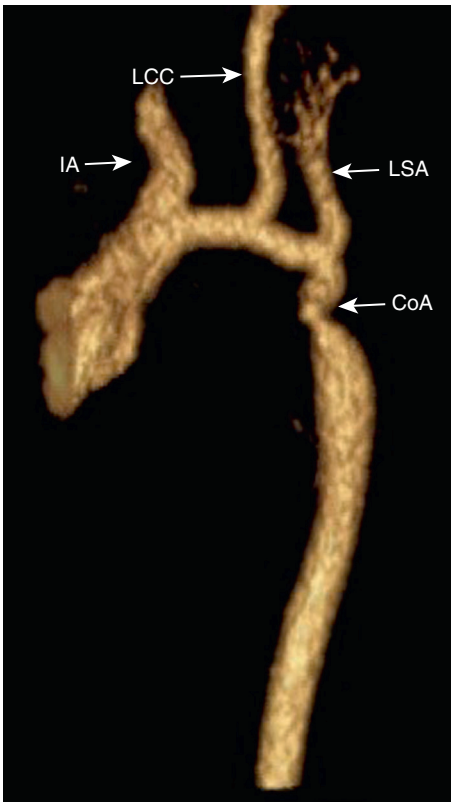
Anatomy and Pathophysiology

Aortic development is a complex embryologic process that can lead to a number of aortic arch variants and pathologic anomalies.[52] These anomalies can result in aortic obstruction distal to the valvar and supravalvar levels. The most common obstructive arch lesion is aortic coarctation. In its most simple form, coarctation consists of discrete narrowing in the juxtaductal region of the distal arch/aortic isthmus where the PDA joins the aorta. In more severe manifestations, it may be associated with more extensive transverse arch and isthmic hypoplasia. The most severe form of arch obstruction is an interrupted aortic arch (IAA) with complete aortic discontinuity. IAA is classified according to the location of the discontinuity in relation to the head and neck vessel origins. In type A IAA, the interruption occurs distal to the last head and neck vessel (typically the left subclavian artery) in the distal arch/isthmic region. In type B IAA, the interruption occurs more proximally between the second and third head and neck vessels (typically the left common carotid and left subclavian arteries). In type C IAA, the interruption occurs further proximally between the first and second head and neck vessels (typically the right brachiocephalic and left common carotid arteries). Type B is the most common IAA variant, occurring in just over half of cases. In both aortic coarctation and IAA, abnormalities of the head and neck vessel origins—e.g., an aberrant subclavian artery—may be present. Aortic coarctation and IAA produce increased LV afterload, resulting in systemic hypertension and LV hypertrophy. Severe aortic obstruction from a severe coarctation or IAA can lead to LV failure and inadequate perfusion distal to the obstruction, particularly with ductal closure. Thus, maintenance of ductal patency is critical to survival in these infants. Conversely, a significant coarctation may be unmasked during ductal closure. Aside from effects on the LV myocardium, neonatal coarctation may also affect the RV myocardium due to interventricular interactions, leading to RV hypertrophy and dysfunction.

Associated Defects

The most common defects associated with aortic coarctation are bicuspid aortic valve (50% to almost 85% of cases in some series) and VSD. Mitral valve anomalies may also be present. IAA is invariably associated with VSD. The VSD in coarctation or IAA is sometimes posteriorly

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.



malaligned, causing subaortic obstruction. Other associated lesions include aortopulmonary window, truncus arteriosus, and transposition of the great arteries. Both aortic coarctation and IAA may complicate other forms of complex congenital heart disease. With regards to genetic disorders, aortic coarctation has a recognized association with Turner syndrome, and IAA can be seen with partial or complete 22q11 chromosomal microdeletion syndrome, particularly with right arch–sidedness and branching.

Clinical Presentation

Mild aortic coarctation with no valvar aortic stenosis or VSD is generally asymptomatic. These infants will often have diminished femoral pulses on exam but no other outward signs or symptoms. More severe manifestations can lead to tachypnea, tachycardia, poor feeding, and lethargy, particularly around the time of ductal closure. In cases of critical coarctation or IAA, rapid cardiovascular collapse with shock, hypoperfusion, and multiorgan dysfunction can occur with ductal closure. Early signs and symptoms of congestive heart failure in any infant with coarctation should raise concern about the presence of associated defects. The hallmarks of significant arch obstruction are diminished femoral pulses and blood pressure and oxygen saturation differentials between the upper and lower extremities, although all these may be less pronounced with cardiac dysfunction. Careful palpation of all pulses, including the carotid arteries, can provide valuable anatomic data. Blood pressure discrepancies should be evaluated with four-extremity measurements. Precordial hyperactivity, a single second heart sound, a gallop rhythm, and hepatomegaly are markers of significant obstruction or associated defects. The typical systolic murmur of aortic coarctation—most prominent over the left infraclavicular region and under the left scapula—is well appreciated in older children with coarctation but may not be heard in neonates.

Diagnostic Evaluation

The electrocardiogram of a neonate with aortic coarctation or IAA may demonstrate LV hypertrophy. Chest radiographs are usually normal. Significant cardiomegaly suggests associated lesions or ventricular dilation or dysfunction after ductal closure. Echocardiography generally defines the arch obstruction and morphology with considerable accuracy. However, ascertaining coarctation severity in the presence of a sizable PDA can be difficult. Fig. 75.7 shows a three-dimensional volume-rendered reconstruction of a CT angiogram in a neonate with coarctation. Clinically significant neonatal coarctation can also produce moderate to severe right heart dysfunction. Right-to-left shunting at the ductal level is an important sign of significant obstruction. Transverse arch hypoplasia, especially with an elongated segment between the left carotid and left subclavian arteries, also suggests significant aortic coarctation. Pre- and postductal pulse oximetry and arterial blood gas measurements in the upper and lower extremities are instrumental in assessing ductal shunting and perfusion.

• **Fig. 75.7** Three-dimensional reconstruction from computed tomography angiography demonstrating a severe aortic coarctation (*CoA*) just distal to the left subclavian artery take-off with associated transverse arch hypoplasia and post-stenotic descending aorta dilation. IA, Innominate artery; LCC, left common carotid artery; LSA, left subclavian artery.

Management and Prognosis

Neonates with aortic coarctation or IAA manifesting with signs or symptoms of congestive heart failure or poor perfusion must be started on intravenous prostaglandin E_1 infusion to maintain or restore ductal patency. All neonates with IAA undergo early surgical repair of the aortic arch abnormality and associated defects. Long-term results with IAA and aortopulmonary window or VSD are good, but recurrent arch obstruction and subaortic stenosis are frequent problems.[64] Mortality and morbidity in newborns with IAA and truncus arteriosus remain significant. Those with significant arch hypoplasia might require mobilization of the descending aorta to provide enough tissue to relieve the obstruction.[21] Neonates with aortic coarctation and a large VSD undergo early complete repair.[49] Simple (noncritical) aortic coarctation, on the other hand, is repaired electively in early childhood. Indications for early repair in infancy include significant hypertension, ventricular dysfunction, or cardiovascular collapse with ductal closure. Surgical repair remains the gold standard for primary intervention. In the absence of hemodynamically significant intracardiac defects, a lateral thoracotomy approach is utilized. A number of surgical repair techniques are used, including coarctation resection and end-to-end anastomosis. Balloon angioplasty of native aortic coarctation is usually reserved

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

for older children but might be useful in the treatment of selected neonates, particularly as a palliative procedure.[77] This remains a topic of considerable debate. Postoperative systemic hypertension, a very common occurrence following coarctation repair in older children, occurs less frequently in neonates. However, long-term growth of the repaired aortic segment might be an issue in up to 30% of infants, resulting in significant aortic narrowing or recurrent coarctation, particularly in premature infants.[51] Balloon aortic angioplasty has become the preferred treatment for recurrent coarctation in infants and young children with demonstrated safety and efficacy.[79]

Serial Obstructive Left Heart Defects

When any form of left heart obstructive disease is suspected, the entire left heart must be thoroughly investigated with echocardiography. Mitral valve abnormalities are commonly encountered, including leaflet, chordae, or papillary muscles anomalies, including single mitral valve papillary muscle (parachute deformity).[80] Supravalvar mitral rings and subaortic membranes can also be identified and may become progressively obstructive, necessitating close longitudinal follow-up. Shone complex is a recognized association of multiple left heart lesions, including supravalvar mitral ring, parachute mitral valve, subaortic membrane/stenosis, and aortic coarctation, resulting in multilevel obstruction.[83]

Valvar Pulmonary Stenosis

Anatomy and Pathophysiology

Isolated neonatal valvar pulmonary stenosis (PS) most commonly results from dysplasia of the valve leaflets with resultant thickening and decreased mobility, leading to varying degrees of right ventricular outflow tract obstruction at the valvar level. Associated right ventricular hypertension and hypertrophy occur in proportion to obstruction severity. Post-stenotic main pulmonary artery dilation is also commonly found. Any atrial or ventricular level shunts are generally left-to-right unless there is severe obstruction with significantly elevated RV pressures.

Associated Defects

The most commonly associated abnormality with PS is subvalvar (infundibular) narrowing or stenosis. This can be fixed or dynamic. The combined subvalvar/valvar RVOT obstruction can be overestimated when atrial or ventricular shunts are present or underestimated in the context of increased pulmonary vascular resistance (especially in the immediate postnatal period) or decreased RV function. Valvar PS may also be associated with Noonan syndrome, so this should be investigated if there are additional findings such as characteristic facial features.

Clinical Presentation

Neonates with PS generally remain asymptomatic in the postnatal period and are initially identified via auscultation of a harsh systolic ejection murmur at the left upper sternal border radiating to the infraclavicular regions and over the back. Murmur intensity correlates with obstruction severity. In moderate to severe PS, an RV impulse may be noted.

Diagnostic Evaluation

Echocardiography delineates pulmonary valve morphology and extent of outflow obstruction in PS. The RVOT gradients by spectral Doppler are an accurate measure of severity. Neonates with mild valvar PS may not be initially diagnosed until they are noted to have a murmur beyond the immediate postnatal period as pulmonary vascular resistance falls and the pressure gradient across the RVOT and murmur intensity increase.

Management and Prognosis

The natural history of isolated valvar PS is excellent. Most studies demonstrate minimal progression of mild PS with spontaneous resolution in the majority of cases. However, up to a third of patients in some series may progress to moderate or severe obstruction, typically in the first 6 months of life. Moderate to severe PS may also worsen during the first year of life, although there are cases of severe PS that spontaneously resolve as well. In rare cases of critical PS with ductal-dependent pulmonary blood flow, neonatal intervention via transcatheter balloon valvuloplasty or surgical valvotomy may be necessary. Generally, neonatal valvar PS should be longitudinally monitored over the first 6-12 months of life for any worsening. Transcatheter balloon pulmonary valvuloplasty is indicated for persistent severe PS, with intervention timing determined by the severity of RVOT obstruction and RV hypertrophy on echocardiogram or evidence of RV dysfunction. Even with significant RVOT obstruction, however, infants with isolated valvar PS are rarely symptomatic. In the current era, surgical pulmonary valvotomy is reserved for patients with significantly dysplastic valves not responsive to balloon valvuloplasty or valvar PS with concomitant intracardiac defects requiring repair.[70]

Shunting Lesions

Ventricular Septal Defect

Anatomy and Pathophysiology

Ventricular septation is a complex embryologic process involving the development and fusion of the muscular ventricular septum, membranous ventricular septum, conal (outlet) septum, and atrioventricular endocardial cushions to form the interventricular septum. Abnormalities in this process result in abnormal interventricular communications, or ventricular septal defects (VSDs). VSDs are the most common congenital heart defect, making up 20% of identified lesions in some population studies. They are classified according to their location: perimembranous, muscular, inlet, or conal (supracristal or subpulmonary). Perimembranous VSDs are the most common, representing approximately 80% of VSD lesions. The amount of

shunting through these defects is dependent on their size, as well as the relative pulmonary and systemic vascular resistances. Isolated VSDs have left-to-right shunting given higher LV (systemic) pressures compared to RV (pulmonic) pressures under normal circumstances. In the immediate neonatal period, when PVR and RV pressures remain high, left-to-right flow may be more limited. However, with normal postnatal physiologic transition, PVR falls significantly over the first hours to days of life, with more gradual decrease to adult levels within the first couple of months. This results in lower RV pressures and increasing left-to-right shunting. With sizable defects, pulmonary overcirculation can become considerable with resulting clinical sequelae, as well as intracardiac effects, namely left atrial and ventricular dilation.

Associated Defects

VSDs often exist as a component of more complex congenital heart disease, including many defects discussed elsewhere in this chapter. Their presence can result in different pathologic variants and dramatically alter the natural history and outcomes of lesions such as D-TGA, DORV, and aortic coarctation.

Clinical Presentation

VSDs can be identified by their characteristic holosystolic murmur and location on exam, generally best heard along the left sternal border with localization to the left lower sternal border. This murmur is produced by disturbed shunt flow through the defect. For muscular VSDs, the murmur may be more of a crescendo–decrescendo systolic ejection murmur caused by changes in the defect size as the muscular septum contracts during systole. Larger VSDs can be more difficult to identify in the immediate postnatal period given elevated PVR and less disturbed shunt flow. Similarly, clinical evidence of significant left-to-right shunting and resultant pulmonary overcirculation may not become apparent until PVR drops after the immediate neonatal period. Most infants with isolated VSDs are discharged home with no symptoms, and many VSDs are not diagnosed until initial follow-up visits with primary care providers.

Diagnostic Evaluation

Smaller VSDs are routinely diagnosed with careful clinical examination, given their characteristic murmur location and quality. Echocardiography identifies and defines all types of VSDs in detail, including location and size, as well as other associated defects.

Management and Prognosis

Most VSDs require no intervention and undergo spontaneous closure within the first few months to years of life, particularly small to medium perimembranous and muscular VSDs. These lesions are hemodynamically insignificant and generally remain asymptomatic. Larger VSDs of any type can result in considerable left-to-right shunting with pulmonary overcirculation and associated symptomatology, including tachypnea, increased work of breathing, poor feeding, and suboptimal weight gain. These are all indications for initiation of medical therapy, which usually starts with oral diuretics to help reduce pulmonary symptoms and improve feeding and growth. Exposure to significant left-to-right shunting and pulmonary overcirculation over the long-term can precipitate maladaptive pulmonary vascular changes with increased risk for pulmonary vaso-occlusive disease. Indications for surgical VSD closure include persistent respiratory symptoms or suboptimal feeding and growth despite maximal medical therapy, evidence of right ventricular hypertension, deleterious intracardiac changes such as left heart dilation or aortic valve leaflet prolapse/insufficiency, or defect types with minimal likelihood of spontaneous closure (e.g., supracristal or subpulmonary VSD).

Atrial Septal Defect

Similar to ventricular septation, embryologic atrial septation is a complex process, and derangements in this process can result in abnormal interatrial communications in various parts of the atrial septum. Atrial septal defects (ASDs) are classified according to their location and embryologic origin. There are four major types: ostium secundum ASD, ostium primum ASD, sinus venosus (superior and inferior) ASD, and coronary sinus ASD. Secundum ASDs are the most common type, representing over two-thirds of cases. Primum ASDs are a cardinal component of atrioventricular septal defects. Sinus venosus ASDs are associated with partial anomalous pulmonary venous return given their location. Isolated secundum ASDs diagnosed in a neonate are generally an incidental finding and may represent persistence, stretching, or incomplete closure of the foramen ovale rather than a true septal defect. True secundum ASDs rarely cause clinical sequelae in the immediate postnatal or neonatal period in the absence of other associated defects or conditions. Isolated small to moderate secundum ASDs often close spontaneously over time. However, persistent or more sizable secundum ASDs with left-to-right shunting must be longitudinally monitored for intracardiac effects such as right heart dilation or evidence of increasing right ventricular pressures, indicative of developing pulmonary vascular disease. The most severe manifestation of pulmonary vascular disease due to persistent shunting is Eisenmenger syndrome, with shunt reversal (right-to-left), cyanosis, and irreversible pulmonary hypertension. Therefore, continued shunting with intracardiac sequelae is an indication for secundum ASD closure. Transcatheter ASD device closure has become the preferred method with excellent overall results in children.[24]

Atrioventricular Septal Defect

Anatomy and Pathophysiology

Atrioventricular septal defects (AVSDs) lie on a spectrum of malformations resulting from failure of the endocardial

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

cushions to fuse during embryologic cardiac development. The most severe form is a complete AVSD, consisting of an ostium primum ASD, inlet VSD, and common atrioventricular (AV) valve. Other commonly seen variants include partial AVSD (ostium primum ASD with a cleft mitral valve) and transitional AVSD (ostium primum ASD, cleft mitral valve, and small inlet VSD). The pathophysiology of any AVSD variant is dependent on the extant lesions and resultant shunting. For example, the physiology of a partial or transitional AVSD mirrors that of a simple ASD since the majority of shunting occurs at the atrial level. The physiology of a complete AVSD, on the other hand, combines ASD and VSD physiology since considerable shunting occurs at both the atrial and ventricular levels. These lesions are rarely symptomatic in the postnatal or neonatal period in the absence of other defects or conditions.

Associated Defects

The common AV valve in AVSD is often structurally abnormal and can demonstrate varying degrees of regurgitation. Common AV valve abnormalities may also cause unbalanced ventricular development, leading to right- or left-ventricular dominance or outflow tract obstruction. In more extreme cases, this produces single ventricle anatomy and physiology. A common atrium with near complete absence of the atrial septum can be found in some AVSD variants. Systemic and pulmonary venous anomalies may also be present. AVSD may exist in conjunction with other complex congenital heart disease, including tetralogy of Fallot and double outlet right ventricle. There is a very well-recognized, strong association between complete AVSD and trisomy 21, with almost 20%-30% of trisomy 21 patients also having a complete AVSD.[23]

Clinical Presentation

Significant common AV valve regurgitation, if present, can be appreciated as a holosystolic murmur at the apex on exam. If regurgitation is significant, pulmonary venous congestion may result with increasing pulmonary edema and associated symptomatology, including tachypnea and increased work of breathing. The ostium ASD and inlet VSD components do not tend to produce significant or characteristic murmurs, particularly in the immediate postnatal phase with elevated PVR and more limited shunting across the defects. Systemic oxygen saturations tend to be normal in complete AVSD. Cyanosis is generally encountered with more complex AVSD variants, such as severely unbalanced AVSD with single ventricle physiology or tetralogy of Fallot with AVSD.

Diagnostic Evaluation

The electrocardiogram in neonates with AVSD can be characteristic with significant left axis deviation and right atrial enlargement. The axis deviation results from displacement of the conduction pathways away from their usual locations because of the intracardiac defects. Echocardiography is the primary diagnostic tool and should delineate the different AVSD components, including the septal defects and shunts, AV valve morphology and function, ventricular morphology and balance and function, outflow tracts, and other associated anomalies.

Management and Prognosis

A balanced, complete AVSD with no significant common AV valve abnormalities, ventricular dysfunction, or outflow tract anomalies is repaired on an elective basis in the first 4-6 months of life with a high degree of success.[84] Infants with trisomy 21 sometimes undergo earlier repair because of the potential for early development of significant pulmonary hypertension. Following complete repair, long-term issues primarily involve AV valve function (stenosis or regurgitation). Infants with a partial AVSD can often wait until almost 1 year of age for complete repair in the absence of any respiratory or feeding or growth issues.

Patent Ductus Arteriosus

Please see Chapter 74 for additional coverage.

Anatomy and Pathophysiology

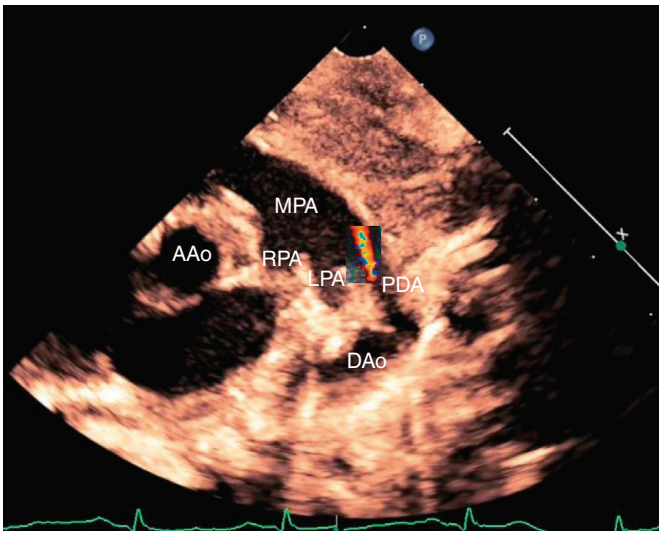
The ductus arteriosus connects the pulmonary artery to the aorta in utero and is an essential structure during fetal life. Since fetal pulmonary vascular resistance is very high, only 10%-15% of blood ejected by the right ventricle goes to the lungs, with the rest flowing through the ductus into the descending aorta. The ductus arteriosus generally undergoes spontaneous closure in the immediate postnatal period, and the entire RV output is then ejected to the pulmonary circulation. If the ductus arteriosus remains patent postnatally, the shunt becomes primarily left-to-right (aorta to pulmonary artery) as PVR falls in normal fashion, resulting in left heart (left atrial and ventricular) volume loading. An important exception to this pattern of left heart volume loading occurs in neonates with persistent transitional circulation. In these infants, PVR is comparable to or higher than the systemic vascular resistance, resulting in bidirectional shunting through the PDA. If PVR is significantly higher than SVR, the shunting can become exclusively right-to-left (pulmonary artery to aorta), causing systemic desaturations.

The mechanisms responsible for postnatal ductal closure are not fully understood. The ductus arteriosus is highly sensitive to changes in oxygen tension, so the normal postnatal increase in arterial oxygen tension may serve as the stimulus for ductal closure. The mediation of this response is less certain and is likely attributable to a complex interaction between autonomic chemical mediators, nerves, prostaglandins, and the ductal musculature. The ductus arteriosus functionally closes in most full-term infants during the first day of life, but anatomic obliteration of the ductus arteriosus generally does not occur until after the first week of life. A persistent PDA is uncommon in otherwise normal children. In contrast, 30% of infants with birth weights less than 1.5 kg have a PDA, possibly as a result of hypoxia and

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

immaturity of the ductal closure mechanisms, and spontaneous PDA closure by the fourth postnatal day only occurs in approximately one-third of infants less than 1000 g birth weight.[55] Therefore, a majority of significantly premature infants are potential candidates for pharmacologic or surgical intervention, though the merits of active therapy for PDA closure remain controversial.

Associated Defects



A PDA is present at birth in infants with all but a few congenital heart defects. Although the presenting features of the associated defects are usually clear, occasionally the PDA is the most easily recognized component clinically and by echocardiogram. Aortic coarctation in particular is more difficult to definitively diagnose in the presence of a large PDA. Absence of the ductus arteriosus is notable in some neonates with tetralogy of Fallot and pulmonary atresia. In these infants, the central pulmonary arteries are markedly hypoplastic where the ductus arteriosus would insert, and multiple aortopulmonary collateral vessels may be present. The ductus arteriosus is also often absent in neonates with the absent pulmonary valve TOF variant in which the failure of ductal formation or closure at a critical time in cardiogenesis may play a role in the pathogenesis of the pulmonary valve and arterial abnormalities.

Clinical Presentation

The murmur heard in a neonate with a PDA may be unlike that heard in an older infant or child with a persistent PDA, where the classic continuous (machinery) murmur is present. In newborn infants, especially premature ones, diastolic flow through the PDA may be limited because of persistently elevated PVR and consequently is difficult to hear. A systolic murmur of uneven intensity throughout systole may be appreciated at the left upper sternal border. Even in the absence of a murmur, however, the hemodynamic consequences of a sizable PDA can become clinically evident. Significant left-to-right shunting with resultant increased blood flow and pulmonary overcirculation may result in a supplemental oxygen requirement to maintain appropriate saturations or cause weaning difficulties in infants with existing ventilatory support. A sizable PDA can also result in wide pulse pressures with bounding pulses caused by run-off into the pulmonary arteries during diastole. Clinical evidence of a hemodynamically significant PDA may lag behind echocardiographic signs.

Diagnostic Evaluation

In symptomatic infants, clinical suspicion of a PDA should be confirmed by echocardiography. Echocardiography (Fig. 75.8) permits accurate diagnosis—with assessment of both the hemodynamic impact of the shunt, reflected by the extent of left heart enlargement, and estimated pulmonary artery pressures—and excludes other defects presenting with similar symptomatology, including an aortopulmonary window or significant aortopulmonary collateral vessels. Chest radiography may demonstrate pulmonary vascular congestion but is generally not diagnostic. Serum B-type natriuretic peptide (BNP), produced in response to myocardial stretch with chamber dilation, may be a useful bedside screening tool for response to therapy in premature infants with PDA.[38,46]

• **Fig. 75.8** Parasternal short axis view on echocardiogram with color flow Doppler imaging demonstrating a patent ductus arteriosus (*PDA*) with flow from the descending aorta (*DAo*) to the main pulmonary artery (*MPA*). AAo, Ascending aorta; LPA, left pulmonary artery; RPA, right pulmonary artery.

Management and Prognosis

Full-term infants with a small PDA are followed clinically, and spontaneous ductal closure generally occurs in the first months of life. Isolated moderate or large PDAs may also close spontaneously but require longitudinal follow-up, often with repeat imaging to assess the shunt and potential intracardiac effects. Closure is indicated for any PDA with symptoms associated with significant left-to-right shunting or pulmonary overcirculation, left heart dilation, or evidence of increasing right-sided pressures on echocardiogram. Conventional surgical closure or video-assisted thoracoscopic surgery[16] is appropriate for infants with a moderate to large PDA, while transcatheter closure with coils is often pursued for smaller defects. Newer devices such as specifically designed ductal occluders have allowed increasing transcatheter closure of larger ducts with excellent results and minimal complications.[13]

In premature infants, spontaneous ductal closure is common, but persistent or recurrent symptoms and respiratory distress caused by shunting and pulmonary overcirculation may require therapy for ductal closure. The optimal approach to the PDA in preterm infants is still unknown. A proportion of infants will have spontaneous closure over the first week of life. Thus, some have advocated for delaying assessment of patency until the end of the first week of life. However, there is concern that prolonged exposure to a large hemodynamically significant PDA may compromise

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

the pulmonary vascular bed and may be associated with an increased risk of bronchopulmonary dysplasia.[12,18] Progressive increases in ventilator or supplemental oxygen support requirements in these infants may also be manifestations of an increasingly hemodynamically significant PDA. Medical management with fluid restriction and diuretics is occasionally effective at improving symptomatology. Indomethacin, a prostaglandin synthetase inhibitor, and ibuprofen, a nonselective cyclooxygenase inhibitor, have both been shown to close persistent PDAs in a large fraction of premature infants up to 14 days of age and occasionally as late as 1 month of age. Ibuprofen has been further shown to be equally effective for ductal closure with fewer renal side effects. Surgical PDA ligation is also an option but has been associated with increased morbidity and adverse neurodevelopmental outcomes,[61] as well as a relatively high incidence of postoperative left vocal cord paralysis in extremely low birth weight infants.[11] Surgical intervention remains a consideration if a PDA remains hemodynamically significant by clinical or echocardiographic criteria following indomethacin or ibuprofen therapy or if pharmacotherapy is contraindicated. There is also increasing evidence for effective transcatheter PDA device closure in infants at weights less than 6 kg, including extremely (<2 kg) and very low (2 to <4 kg) birth weight infants, but the risks of associated adverse events must be carefully weighed.[7]

Aortopulmonary Window

Anatomy and Pathophysiology

An aortopulmonary (AP) window, as its name implies, is an abnormal connection between the ascending aorta and the main pulmonary artery. It forms from failure of the conotruncal ridges to fuse during cardiac development. The defects tend to be large, allowing high-pressure shunting from the systemic to the pulmonary circulation and resulting in considerable pulmonary overcirculation. AP window pathophysiology mimics that of a large VSD or PDA with significant left-to-right shunting that increases as the pulmonary vascular resistance falls.

Associated Defects

AP windows exist in conjunction with other cardiac anomalies in approximately half of cases, including other conotruncal defects such as tetralogy of Fallot, transposition of the great arteries, and interrupted aortic arch (type A). Additional associated abnormalities include right pulmonary artery origin from the aorta and anomalous coronary artery origin from the pulmonary artery.

Clinical Presentation

Patients with an AP window are at increased risk of early pulmonary overcirculation and associated symptomatology, often in the first weeks of life. On examination, the precordium is active, and there is single second heart sound with bounding pulses.

Diagnostic Evaluation

Chest radiography often demonstrates cardiomegaly and increased pulmonary vascular markings consistent with significant pulmonary overcirculation. Echocardiography can visualize the defect nicely, but special care must also be taken to identify an associated patent ductus arteriosus or interrupted arch, as well as coronary artery or branch pulmonary artery abnormalities.

Management and Prognosis

Surgical closure of an AP window is usually done shortly after diagnosis with excellent short- and long-term results.[8] Delaying repair risks development of significant pulmonary vascular hypertension and potential irreversible vascular disease with Eisenmenger syndrome.

See Table 75.1 for findings to aid in the diagnosis of common congenital heart diseases.

Acknowledgments

The authors would like to recognize and thank the authors of previous editions of this chapter, particularly Drs. Ravi Ashwath and Christopher Snyder.

TABLE 75.1 Important Findings That Aid in the Diagnosis of Common Congenital Heart Diseases

Cardiac Diagnosis	Physical Examination	Chest X-Ray	ECG
Atrial septal defect	Wide and fixed splitting of S2 Pulmonary flow murmur	Pulmonary overcirculation proportional to the left to right shunt	Right atrial dilation RVH
Common atrioventricular canal defect	Occasional loud P2	Pulmonary overcirculation when pulmonary vascular resistance falls	Left axis deviation/abnormal superior vector Biventricular hypertrophy
Coarctation of aorta	Radiofemoral pulse delay Weak femoral pulses Upper and lower extremity BP discrepancy (UE > LE by at least 15-20 mm Hg)	Rib notching in long-standing cases only with severe coarctation and collateral formation	Biventricular hypertrophy based on severity

TABLE 75.1 Important Findings That Aid in the Diagnosis of Common Congenital Heart Diseases—cont'd

Cardiac Diagnosis	Physical Examination	Chest X-Ray	ECG
Ebstein anomaly	Cyanosis Multiple systolic clicks	Massive cardiomegaly or wall-to-wall heart	Right atrial dilation Bundle branch block
Hypoplastic left heart syndrome	Cyanosis Single S2 Shock	Nondiagnostic	RVH
Partial anomalous pulmonary venous return	Pulmonary flow murmur	Scimitar sign if RLPV to the IVC Increased pulmonary vascularity	RVH
Patent ductus arteriosus	Wide pulse pressure Bounding pulses	Increased pulmonary vascularity	Left atrial dilation LVH
Pericardial effusion/ tamponade	Pulsus paradoxus Hypotension	Water bottle appearance	Decreased voltages
Pulmonary hypertension	Loud P2 With PDA and right-to-left shunt, the LE oxygen saturations can be lower than UE saturations	Peripheral pruning in severe cases	RVH
Pulmonary atresia with intact ventricular septum	Severe cyanosis Single S2	Pulmonary oligemia	
Pulmonary stenosis	Soft P2 Systolic ejection click	Pulmonary oligemia	RVH
Total anomalous pulmonary venous return	Cyanosis	Snowman sign in supracardiac type Increased pulmonary vascularity	RVH
Tetralogy of Fallot	Cyanosis ± pulmonary ejection murmur Soft P2	Boot-shaped heart Absent thymus (in the presence of 22q11 deletion) Look for right aortic arch	RVH
Transposition of great arteries	UE saturations are lower than the LE (at least by 5%) Cyanosis No murmur	Increased pulmonary vascularity Egg on string appearance	
Tricuspid atresia	Cyanosis Single S1	Left axis deviation	LVH
Truncus arteriosus	Cyanosis Single S2	Increased pulmonary vascularity	

BP, Blood pressure; IVC, inferior vena cava; LE, lower extremity; LVH, left ventricular hypertrophy; P2, pulmonary component of second heart sound; PDA, patent ductus arteriosus; RLPV, right lower pulmonary vein; RVH, right ventricular hypertrophy; S1, first heart sound; S2, second heart sound; UE, upper extremity.

Key Points

- Congenital heart defects are the most common type of birth defect worldwide and are often encountered in neonates and infants.
- Specific heart defects generally have a predominant pathophysiology—cyanotic, obstructive, or shunting—that can be considerably altered in the presence of associated defects.
- Complex forms of congenital heart disease often involve multiple defects, complicating pathophysiology and management.
- Defective physiology can change considerably over time, particularly in the immediate postnatal transitional period around ductal closure.
- Clinical presentation of significant congenital heart disease can vary widely, so recognition of typical patterns (e.g., tachypnea and increased work of breathing with significant pulmonary overcirculation) is invaluable for early diagnosis.
- Echocardiography is the major diagnostic tool for congenital heart disease, but very useful information can

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

be gleaned from careful physical examination and other work-up prior to echocardiography, including ECG, chest radiography, pre- and postductal saturations, and four-extremity blood pressures.

- Early recognition of ductal-dependent congenital heart defects is critical for effective management and improved outcomes in affected infants.
- Infants with congenital heart defects often have other associated conditions, including genetic abnormalities and disorders, which must be investigated and identified.

Cardiovascular Problems of the Neonate

CHRISTINA M. PHELPS AND JILL SHIVAPOUR

Cardiac Malposition and Abnormalities of Abdominal Situs

Bodily Arrangement and Situs

The development of morphologically right-sided structures on one side of the body, and morphologically left-sided structures on the other side, is termed *lateralization* or *situs*. The normal arrangement, in which right-sided structures are on the right side of the body and vice versa, is known as *situs solitus*. The term *visceroatrial situs* is often used to refer to the situs of the viscera, or noncardiac organs, and *atria* when their situs is in agreement. In normal atrial arrangement or *atrial situs solitus*, the left atrium is on the left side and right atrium is on the right side. In *atrial situs inversus*, the left atrium is on the right side and right atrium is on the left side. The morphology of the lungs and the relation between the tracheobronchial tree visible on chest radiograph[37,45] and the pulmonary arteries are useful in determining situs. A morphologically right lung typically has three lobes, and a morphologically left lung typically has two lobes. Furthermore, the right lung tends to have an eparterial bronchus, or one that branches superior to the first lobar division of the pulmonary artery, in contrast to the left-sided lung, which has a hyparterial bronchus, or one that branches inferior to the first lobar division of the respective pulmonary artery (Fig. 76.1).

Visceral situs solitus occurs when the abdominal organs are lateralized normally with the spleen and stomach on the left side and liver on the right side. The assessment of abdominal situs can be made by physical examination and other routine tests, such as radiography and ultrasound. The liver is palpable on the left in situs inversus with the stomach bubble on the right side. Ultrasound of the abdomen will confirm these findings along with demonstration of other structures such as the kidneys and spleen. If the spleen is not visible on routine abdominal ultrasound, an abdominal CT or MRI may be indicated to demonstrate the presence or absence of a spleen. A nuclear scan is rarely indicated. Another finding that is generally present if the spleen is absent or nonfunctional is Howell-Jolly bodies on the peripheral smear, because these are usually removed by a normal spleen.

Dextrocardia is present when the base to apex axis of the heart is directed to the right side of the chest (Fig. 76.2). Another possible location for the heart is mesocardia, where the apex is in the midline. Situs solitus is the normal location of the atria and abdominal organs as described previously. Situs inversus is present when the right atrium is on the left, the left atrium is on the right, and the liver and stomach are similarly reversed. Situs ambiguous, with the liver and stomach in the midline, is seen in neonates with either bilateral right-sidedness or left-sidedness, also commonly referred to as *heterotaxy syndrome*. Babies with bilateral right-sidedness tend to have asplenia, and their atrial and pulmonary morphologic features are characteristic of bilateral right atria and lungs. Babies with bilateral left-sidedness tend to have polysplenia and bilateral morphologic left atria and lungs. These conditions are invariably associated with a multitude of other intracardiac abnormalities.

Associated Lesions

Dextrocardia with situs inversus is referred to as the mirror image; dextrocardia may be a part of Kartagener syndrome or immotile cilia syndrome but is generally associated with normal cardiac anatomy. It is frequently detected by clinical exam with the heart sounds auscultated in the right chest and incidental chest radiograph demonstrating dextrocardia (see Fig. 76.2). In contrast, babies born with dextrocardia and situs solitus frequently have associated congenital heart defects, ranging from simple septal defects to complex lesions such as L-transposition of the great arteries.[13] The same is true for those neonates with situs inversus of their abdominal organs with levocardia (normal cardiac position with base to apex axis to the left) who almost always have associated cardiac defects.

Asplenia syndrome or bilateral right-sidedness should be suspected whenever complex cardiac defects are identified

Abstract

Cardiovascular issues in the neonate may present within the first few days of life and are easily delineated and classified with noninvasive testing. Outcomes for each of these disorders are worse in those with significant early symptomatology requiring intervention whether with heterotaxy and right atrial isomerism, neonatal cardiomyopathy, symptomatic PDA in a preterm infant, neonatal Marfan syndrome, or Vein of Galen malformation presenting with heart failure before 5 months of age. The high morbidity and mortality associated with these lesions necessitates accurate diagnosis and expert medical, interventional, and surgical management. Early involvement of palliative care after diagnosis may mitigate parental distress and enable consistent messaging regarding the infant's expected course.

• **Fig. 76.1** Figure showing the normal relationship of pulmonary arteries and bronchi. Note that the first branch of the right main stem bronchus is superior to the right pulmonary artery (eparterial bronchus), whereas the first branch of the left main stem bronchus is inferior to the left pulmonary artery (hyparterial bronchus).

• **Fig. 76.2** Chest radiograph showing dextrocardia with apex pointing to the right. Also note the right bronchus being more horizontal than the left mainstem bronchus, suggesting situs inversus. The stomach bubble is on the right side of the abdomen, and the liver shadow is on the left side.

in association with total anomalous pulmonary venous connection.[61] Because there is no morphologic left atrium, pulmonary venous drainage is rarely directly to the patient's left-sided atrium. Similarly, in this condition, the coronary sinus, which lies posterior to the normal left atrium, is usually absent. Systemic venous return is also abnormal, with the presence of bilateral superior vena cava. The left superior vena cava may enter directly into the roof of the left-sided morphologic right atrium or the coronary sinus, whereas the right superior vena cava generally enters the right atrium in a normal fashion. The right inferior vena cava is present, and there might be an additional left inferior vena cava. Another relatively common variety encountered in cardiac position is dextrocardia with an associated common atrium and a single atrioventricular valve, resulting in either a common ventricle or a large ventricular septal defect. Severe pulmonary stenosis or atresia is common in this particular defect.[17] Surgical palliation beginning as a neonate and terminating in a palliated univentricular circulation is the norm for over 80% of asplenia patients. Survival at 5 years in a live-born cohort of asplenia infants is 53% and is worse in those with stenotic pulmonary veins.[24] In addition to their complex congenital heart disease, these babies are often immunologically compromised because of the lack of a spleen.[62] Severe, life-threatening septic events are a considerable concern and daily, lifelong administration of a prophylactic antibiotic to reduce the risk for bacterial sepsis is critically important.

Absence of the hepatic segment of the inferior vena cava, so-called interrupted inferior vena cava, is an excellent clue to the presence of polysplenia or bilateral left-sidedness in a neonate with ambiguous abdominal situs.[70] Because the baby has no true right atrium, the course of the inferior vena cava is abnormal. Drainage of the inferior vena cava is through the azygos or hemiazygos veins and into the superior vena cava. With bilateral left atria, the pulmonary veins usually return to the heart in a bilateral fashion to their closest atrium (right-sided pulmonary veins return to the right-sided atrium). The presence of polysplenia is often associated with levocardia, normally related great arteries, a common atrium, and two ventricles with a ventricular septal defect. The pulmonary valve in these cases is usually normal. A quarter of fetuses with polysplenia may have bradyarrhythmias in utero, including sinus bradycardia and complete heart block.[24] Survival to birth in fetal bradyarrhythmia associated with polysplenia is nearly 80% in fetuses where termination is not chosen upon diagnosis.[24,25] Survival at 5 years in a live-born cohort is 86% in polysplenia.[24] Although the patient has multiple small spleens, splenic function can be either normal or abnormal regardless of the presence of Howell-Jolly bodies on blood smear, which as previously stated may indicate hyposplenism.[56] Assessment of splenic function and identification of the subset requiring daily prophylactic antibiotics are important prior to discharge home from the hospital following birth.

Arteriovenous Malformations

Arteriovenous malformations (AVMs) are an abnormal, direct connection between arteries and veins via a network of vessels called the nidus that lack an intervening capillary bed. Depending upon the type of cerebral AVMs,

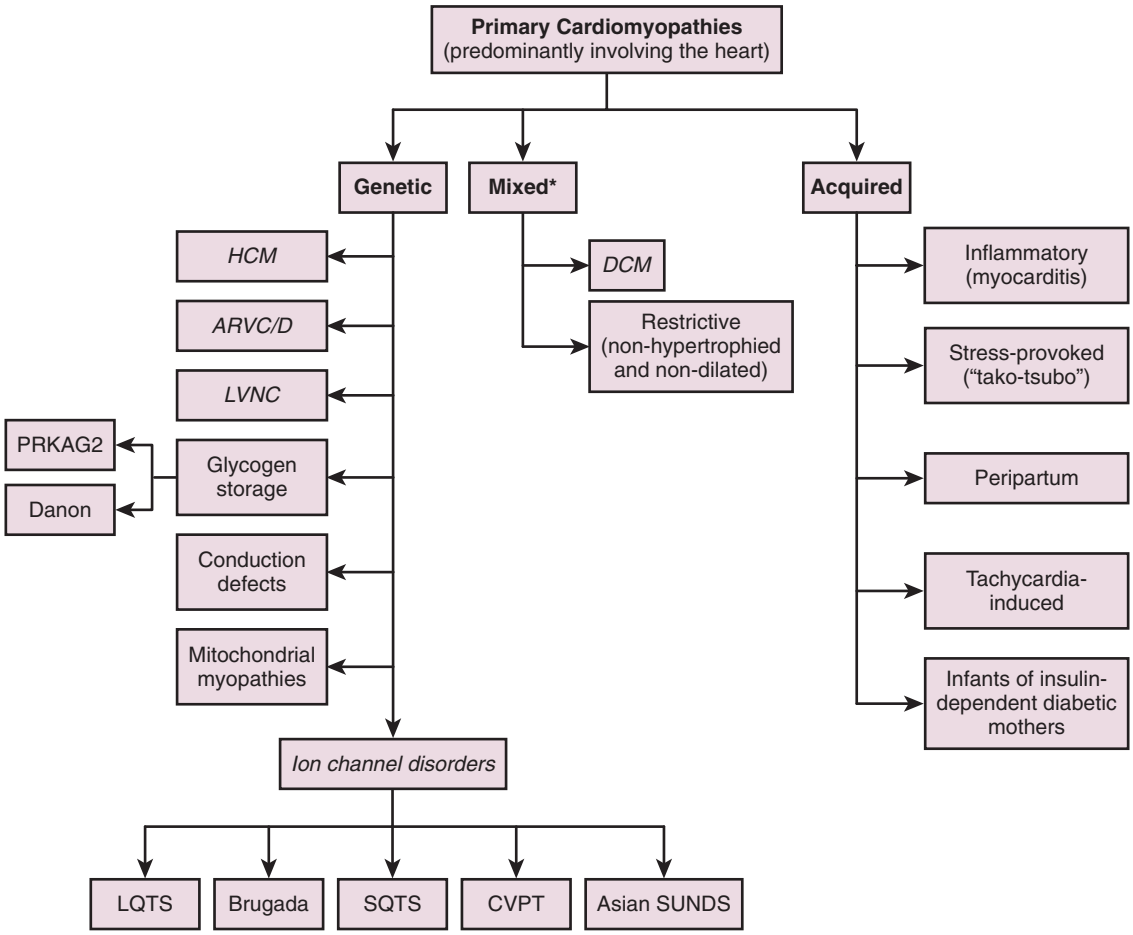
manifestation in the neonatal period with signs of congestive heart failure, including a hyperdynamic precordium and hepatomegaly, may result. Most of these are vein of Galen malformations, although neonates with large pial malformations and congestive heart failure have been described. Vein of Galen malformations can be classified as choroid and mural type, of which the choroidal type usually presents in the neonatal period.[36]

Diagnosis

Even large vein of Galen malformations may not result in fetal heart failure, because the low resistance of the malformation is offset by the utero-placental circulation. Thus, fetal cardiac failure is an ominous sign.[55] As systemic vascular resistance increases at birth, progressive blood flow is diverted into the malformation from the systemic circulation. Congestive heart failure, right heart dilation, lactic acidosis, persistent pulmonary hypertension of the newborn, and diastolic runoff in the ascending aorta or arch on echocardiogram are clues to the diagnosis. Presence of cranial bruit, a louder pulmonary component to the second heart sound, and a systolic ejection murmur of increased aortic and pulmonary artery flow are also typically present. The chest radiograph shows cardiomegaly. Early heart failure presentation of vein of Galen malformations is associated with worse outcomes.[55] An ECG may demonstrate right ventricular hypertrophy and ST-T wave abnormalities due to coronary artery steal. In addition to flow reversal in the aorta, an echocardiogram will frequently demonstrate a dilated, noncompliant right ventricle with systemic or suprasystemic pulmonary artery pressures and a hyperdynamic left ventricle. Ductal flow may be right to left resulting in significant cyanosis. Diagnosis is confirmed with CT or MRI.

Treatment

Arteriovenous malformations in the neonatal period usually present as congestive heart failure, and initial medical management goals consist of stabilizing systemic cardiac output. Recently, milrinone and inhaled nitric oxide have been utilized along with loop diuretics.[27,55,59] Half of patients are unable to be medically managed and are referred for a procedural palliation.[12]



Endovascular embolization has replaced surgery as the mainstay of treatment of vein of Galen malformation.[51] The goal is reduction in the size of the shunt and resultant heart failure symptoms. Complete occlusion is not required during the initial procedure. Outcomes have improved and a neurologically normal to mild developmental delay is expected.[31,33,40,60,81] Neonates showed the worst mortality rate of 52%, following endovascular treatment with only 36% of survivors being neurologically normal.[40,55] If symptoms can be managed medically, survival after treatment from 5 months to 2 years increases to more than 90%, with 78% of survivors classified as neurologically normal.[55]

Myocardial Diseases: Cardiomyopathy and Myocarditis

Cardiomyopathy refers to a diverse group of myocardial diseases with multiple causes. These are rare disorders that account for only approximately 1% of childhood cardiac disease. In 1995, the World Health Organization classified cardiomyopathies into hypertrophic, dilated, restrictive, and mixed type.[63] This classification is based on the pathophysiology of the disease. However, with rapid evolution of molecular genetics in cardiology, the American Heart Association in 2006 has classified cardiomyopathies into two major groups based on predominant organ involvement and etiology.[48] Primary cardiomyopathies are those solely or predominantly confined to heart muscle and are relatively few in number (Fig. 76.3). Secondary cardiomyopathies show pathologic myocardial involvement as part of a large number and variety of generalized systemic (multiorgan) disorders (Box 76.1).[48] Myocarditis, an inflammatory, usually infectious process affecting the myocardium, may also result in either a dilated (common) or restrictive (rare) cardiomyopathy.

Dilated cardiomyopathy is characterized by left ventricular enlargement, with systolic dysfunction of either the left ventricle or both ventricles causing variable degrees of congestive heart failure. The patient's cardiac output (heart rate × stroke volume) is often decreased, and ventricular filling pressures are increased. Total ventricular mass is increased, but chamber volume is disproportionately enlarged. These neonates present with symptoms of poor cardiac output, including pallor, irritability, poor feeding, respiratory distress, and diaphoresis. Physical signs include tachypnea, tachycardia, narrow pulse pressure, and hepatomegaly. Decompensated infants will present with shock and cardiovascular collapse. Cardiac auscultation often reveals muffled heart sounds with a gallop rhythm (S3, S4). Occasionally, a murmur of mitral regurgitation can be auscultated. Arrhythmias, although rare, are an ominous, often undetected presentation.[64] The electrocardiogram in a patient with dilated cardiomyopathy shows flattening of the T waves with possible depression of the ST segments. The chest x-ray often shows cardiomegaly with pulmonary edema. Echocardiogram is diagnostic, illustrating dilation of the ventricle(s) and poor cardiac contractility. Cardiac MRI is increasingly part of the diagnostic work-up, often demonstrating myocardial fibrosis and scarring. MRI has become useful in differentiating dilated cardiomyopathy from acute myocarditis, both of which can appear clinically and echocardiographically nearly identical. An extensive family history is essential when evaluating neonates, specifically asking for the first-degree relatives with dilated cardiomyopathy, metabolic disorders, degenerative neurologic diseases, or diseases of mitochondria. The management of these patients involves targeting the body's neurohormonal activation during heart failure, including spironolactone and loop diuretics, angiotensin-converting enzyme inhibitors or receptor blockers, and inotropes for acute decompensation.

• **Fig. 76.3** Primary cardiomyopathy classifications. ARVC/D, Arrhythmogenic right ventricular cardiomyopathy/dysplasia; CVPT, catecholaminergic ventricular polymorphic tachycardia; DCM, dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy; LQTS, long QT syndrome; LVNC, left ventricular noncompaction; SQTS, short QT syndrome; SUNDS, sudden unexplained nocturnal death syndrome. (Adapted from Maron BJ, Towbin JA, Thiene G, et al. Contemporary definitions and classification of the cardiomyopathies: an American Heart Association scientific statement from the Council on Clinical Cardiology, Heart Failure and Transplantation Committee; Quality of Care and Outcomes Research and Functional Genomics and Translational Biology Interdisciplinary Working Groups; and Council on Epidemiology and Prevention. *Circulation*. 2006;113:1807-1816.)

There is conflicting data in neonates and infants for use of beta-blockers in management of dilated cardiomyopathy, with many experienced institutions continuing to add carvedilol to augment medical management.[58] The primary goal of therapy is to relieve symptoms and prolong survival. Often, these patients may require the use of extracorporeal membrane oxygenation (ECMO) and/or ventricular assist device (VAD) as a bridge to recovery or transplant. As mechanical support technology has improved, ventricular assist devices have demonstrated improvement in survival over ECMO.[26] All forms of mechanical support have a high incidence of adverse event rates, particularly hemorrhage and thrombosis events in children under 10 kg.[46]

Hypertrophic cardiomyopathy is characterized by increased cardiac mass and wall thickness that generally affects the left ventricle. The left ventricular mass/volume ratio is increased, resulting in a left ventricular cavity that is decreased in size because of thickening of the muscle, particularly in the interventricular septum, resulting in dynamic outflow obstruction. The systolic function of the heart is preserved or increased in this disorder when assessed by echocardiogram. The patient's clinical picture is generally dominated by diastolic dysfunction, with elevated ventricular filling pressures. Infants who have hypertrophic cardiomyopathy present with symptoms of congestive heart failure, including tachypnea, poor feeding, and growth failure. The diagnosis is frequently made during screening because of a known immediate family member with hypertrophic cardiomyopathy or an unexplained early death in the family.[18] Occasionally, a near-miss sudden death episode with arrhythmia is the sentinel event. In babies with a primary disorder of the myocardium, either hypertrophy and/or myofibrillar disarray is often the result of mutations of the proteins of the cardiac sarcomere.[47,53] The ECG often shows left ventricular hypertrophy with

Adapted from Maron BJ, Towbin JA, Thiene G, et al. Contemporary definitions and classification of the cardiomyopathies: an American Heart Association scientific statement from the Council on Clinical Cardiology, Heart Failure and Transplantation Committee; Quality of Care and Outcomes Research and Functional Genomics and Translational Biology Interdisciplinary Working Groups; and Council on Epidemiology and Prevention. *Circulation.* 2006;113:1807-1816.

ST and T changes that may be consistent with s rain. The echocardiogram is generally diagnostic for this disorder and is helpful in assessing overall myocardial thickness, chamber dimensions, and systolic and diastolic performance of the ventricle. Cardiac MRI can demonstrate myocardial fibrosis and scarring even early in the time course.[35] The primary goal of management of these patients is similar to that of dilated cardiomyopathy—symptomatic relief and prolonging survival. Medical management includes the use of beta-blockers to augment diastolic filling time, thereby increasing the left ventricular cavity and thus relieving dynamic outflow obstruction. Diuretics are counterproductive, because they decrease the patient's overall volume, thereby decreasing the ventricular cavity and increasing the outflow tract obstruction. Systemic vasodilators, such as ACE inhibitors, and inodilators, such as milrinone, again increase the ventricular outflow gradient and, therefore, should be avoided. Negative inotropes such as calcium channel blockers may be used judiciously, as the neonatal myocardium is particularly reliant on calcium. The prognosis of hypertrophic cardiomyopathy in this age group is rather poor compared with older children.[42] Neonates with underlying inborn errors of metabolism and malformation syndromes have a poorer prognosis when compared to neonates with idiopathic infantile hypertrophic cardiomyopathy.[42]

Another form of hypertrophic cardiomyopathy seen in the neonatal period is the myopathy of infants of diabetic mothers, which carries an excellent prognosis with complete resolution within the first 6 months of life, and steroid-induced hypertrophic cardiomyopathy, which typically resolves after discontinuation of the steroids.[69,76] Dexamethasone and methylprednisone both have an increased risk of developing hypertrophic cardiomyopathy in the early newborn period in premature infants.[21] Therefore, the American Academy of Pediatrics cautioned against the treatment with dexamethasone of infants with birth weights less than 1500 g (very low birth weight) and recommended to limit its use to exceptional clinical circumstances.[77] Left ventricular noncompaction is an imaging-based diagnosis referring to prominent left ventricular trabeculae, a thin compacted layer, and deep recesses continuous with the LV cavity.[3] Noncompaction may be associated with muscular dystrophies, Barth syndrome, or with hypertrophic or dilated cardiomyopathy. Genetic testing for common mutations is available. Several genes overlap with known mutations affecting the conduction system and contributing to prolongation of the QT interval and polymorphic ventricular tachycardia.[3] Individual treatment plans should be tailored toward associated arrhythmia or cardiomyopathy risks. Restrictive cardiomyopathy is an extremely rare condition in which ventricular cavities are small, and there is impaired diastolic function of both the ventricles, with preserved systolic function, at least initially. Neonates with this disorder present with signs and symptoms of congestive heart failure and pulmonary hypertension. The ECG often shows conduction abnormalities and evidence of ischemia

at faster heart rates. The echocardiogram shows normal or small ventricles with dilation of both atria and signs of right ventricular pressure load. Although uncommon in neonates, it should be differentiated from constrictive pericarditis, as the conditions could have similar presentation. Median transplant-free survival for newly diagnosed restrictive cardiomyopathy is very poor. In the Pediatric Cardiomyopathy Registry analysis, freedom from death or transplant was 48% at 1 year in patients with pure restrictive cardiomyopathy.[78] Recommendations for early evaluation and listing for transplantation at the time of diagnosis persist.[78]

Diagnosis and Treatment

The approach to neonates with suspected cardiomyopathy or myocarditis must include a methodical approach to the diagnosis (Box 76.2) and a level of support appropriate for their clinical symptoms. The evaluation and management are multidisciplinary, involving neonatology, metabolism, genetics, cardiology, and psychological and family support. Specialized early referral to heart failure and cardiac transplant teams is critical in long-term management of these infants. Endomyocardial biopsy can guide therapy and help in defining the prognosis by identifying pathologic features, but is not routinely recommended due to its not insignificant risks including tamponade and lethal arrhythmia. The improvement in MRI technology has permitted noninvasive diagnosis.[19,29,66] Evidence of active inflammation or immune suppression can be treated with intravenously administered immune globulin, although its role in the treatment of myocarditis, especially in neonates and infants, remains to be fully validated.[23,29,34,49] The prognosis is often good if the baby can be managed through an episode of myocarditis. In contrast, if a biopsy shows endocardial fibroelastosis or the echocardiogram shows endocardial thickening, the likelihood of recovery of myocardial function is very poor.

Pericardial Diseases

A pericardial effusion is present when there is increased fluid within the existing pericardial space. This fluid can be serous, serosanguinous, pus, lymph, or blood. Pericardial effusion is usually seen in neonates who have fetal hydrops resulting from a variety of etiologies. Small effusions may also be found in neonates with neonatal pneumonia. Pericardial effusions can also be the result of open heart surgery, specifically repair of atrial septal defects and/or complications of hyperalimentation through central venous catheters, resulting from local irritation of the atrial or superior vena caval wall by fluids with high osmolality. Pneumopericardium is a complication of mechanical ventilation and can have hemodynamic effects similar to those of fluid. If the pericardial fluid accumulates gradually, the intrapericardial pressure remains low and symptoms are generally absent until the effusion becomes large. Rapid accumulation of a pericardial effusion, regardless of etiology, can result in pericardial tamponade, even with small volumes.

The diagnosis of pericardial tamponade is clinical and should be suspected in any baby with early signs of poor cardiac output, including tachycardia and poor perfusion. Pulsus paradoxus, an exaggerated fall in blood pressure with inspiration, is easiest to observe in neonates with arterial lines for continuous blood pressure monitoring. A dramatic increase in heart size on a chest radiograph supports the clinical diagnosis. Intrapericardial air is usually obvious on the radiograph and can be differentiated from mediastinal air because it encircles the heart. Echocardiography is the best way to confirm the diagnosis of pericardial effusion and to assess the physiologic impact of the effusion. Diastolic collapse of the right atrium and right ventricle is highly specific for diagnosing tamponade physiology. Respiratory variation of tricuspid and mitral inflow can exceed 30% and confirm the clinical picture.[2] Pericardiocentesis by the subxiphoid approach can be used to drain fluid or air to help alleviate symptoms. If fluid or air returns, a small catheter can be placed percutaneously or surgically and left to continuously drain the fluid.

Pericarditis is an uncommon diagnosis in the neonatal period and usually is associated with myocarditis and/or systemic inflammation. Treatment is symptomatic and consists of nonsteroidal anti-inflammatory agents. Prognosis is generally good, but this condition can lead to constrictive pericarditis.

Cardiac Tumors

Primary cardiac and mediastinal tumors are rare at all ages and even less common in infants and children. Most of

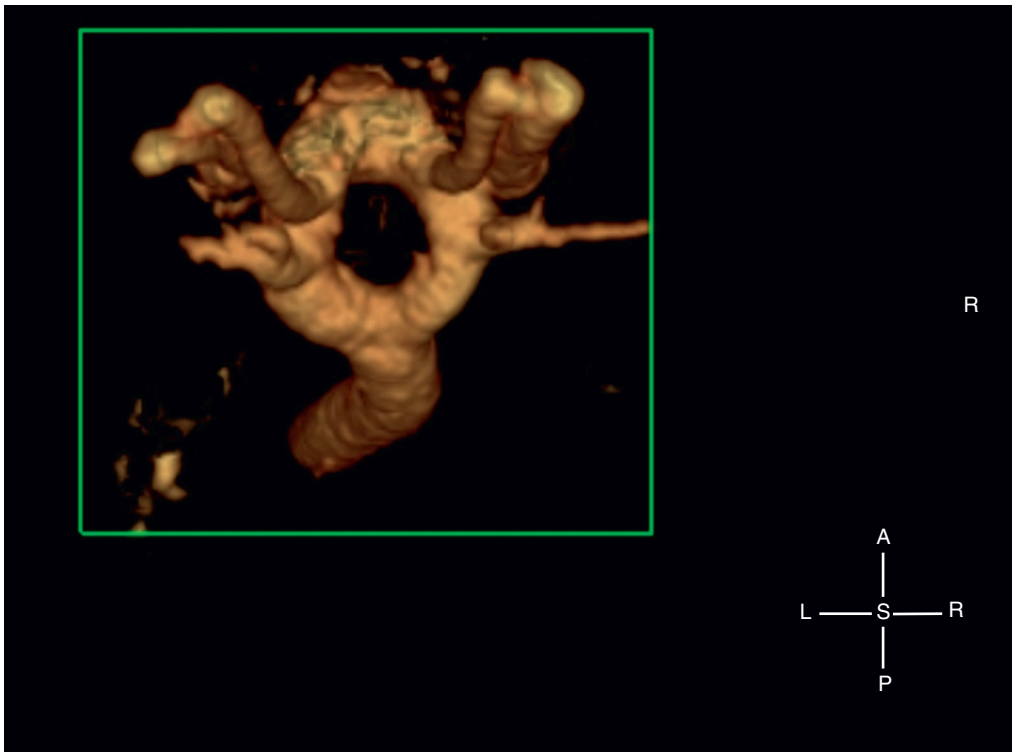
the cardiac tumors reported are benign. Rhabdomyoma is the most common tumor type in this age group, whereas malignant cardiac or mediastinal tumors are extremely rare.[9,15,41,73,75] Clinical manifestation of these tumors varies from incidental findings on fetal or neonatal echocardiogram to life-threatening cardiac events.[1,30]



In 30%-91% of cases, cardiac rhabdomyomas are associated with tuberous sclerosis.[30] Depending upon the size and placement, rhabdomyomas can interfere with ventricular filling or emptying. When they are located near the atrioventricular valves, the tissue can serve as a bypass tract and mimic the features of Wolff-Parkinson-White syndrome.[52] Confirmation by myocardial biopsy in a symptom-free neonate is not necessary, especially if the skin and central nervous system features of tuberous sclerosis are present. Rhabdomyomas typically regress,[50] and surgical excision is not necessary unless the tumor is obstructing flow and is discrete or pedunculated enough to allow excision.

Other rare tumors that can occur in the neonate include myocardial hemangioma,[14] hamartomas,[41] fibromas, and pericardial teratomas. Myocardial hemangiomas are tumors with dense capillary beds that can have connections to the coronary arteries. They are on the epicardial surface with intrusion into the myocardium. Hemangiomas can cause subpulmonary stenosis if they are located in the right ventricular outflow tract. Small hamartomas cause histiocytoid or oncocytic cardiomyopathy, which is associated with severe and persistent ventricular arrhythmias. Myocardial fibroma can be located in the myocardium or on the atrial wall or can involve the mitral valve and cause obstruction. Fibromas can also disrupt the conduction system and contribute to ventricular arrhythmias. Intrapericardial teratoma is a benign tumor attached to the base of the aorta. It is associated with mediastinal compression and pericardial effusion in the fetus, neonate, or young infant. Successful excision of intrapericardial teratoma has been reported, although large tumors can cause fetal death. Atrial myxomas have not been reported in the neonatal period. Surgical excision is required if there is obstruction to the inflow or outflow of the heart. Associated arrhythmias should be treated with antiarrhythmics as described in the other sections of this book. There is an increasing role of cardiac MRI in distinguishing cardiac tumors and avoiding cardiac surgery for biopsy.[28]

Vascular Rings and Slings

Vascular rings are anomalies that result from abnormal development of the aortic arch complex and cause compression on the trachea, esophagus, or both.[65] Vascular rings can be complete (double aortic arch or right aortic arch with left ligament) or incomplete (innominate artery compression and pulmonary slings).[65]

If both the right and left fourth branchial arches persist, this results in a double aortic arch with each of the arches passing above the main stem bronchus on the right and left side and joining together behind the trachea to form the descending aorta (Fig. 76.4). These result in compression of

• **Fig. 76.4** Computed tomographic (CT) angiogram of the arch, showing double aortic arch with each arch giving rise to a carotid and subclavian artery. A, Anterior; L, left; P, posterior; R, right; S, superior.

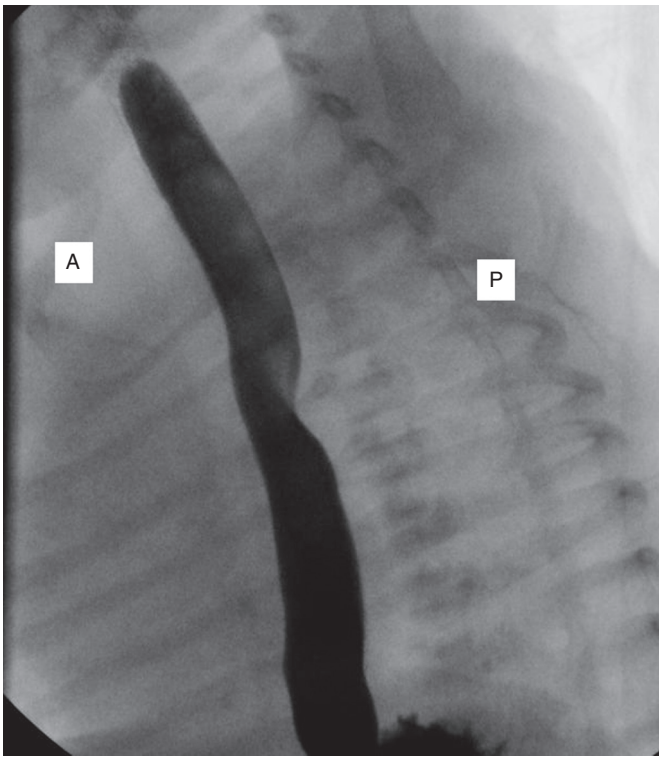
the trachea, causing symptoms such as respiratory distress and stridor. In most cases of double aortic arch, the right arch is the dominant one, with the left arch being smaller.

If the left fourth arch involutes, it results in a right aortic arch. Not all patients with a right aortic arch have vascular rings. Only if the ligamentum arises from the descending aorta and attaches to the pulmonary artery does it form a complete vascular ring with compression of the trachea between the arch on right side and ligamentum between the descending aorta and pulmonary artery on the left side. Patients with a right aortic arch and a left ligamentum may also have a Kommerell diverticulum at the origin of the left subclavian artery from the descending aorta.[38]



A pulmonary artery sling is caused when the origin of all or part of the left pulmonary artery comes from the right pulmonary artery.[10] The embryonic origin of a pulmonary artery sling occurs when the developing left lung captures its arterial supply from derivatives of the right sixth arch through capillaries caudal, rather than cephalad, to the developing tracheobronchial tree.[67] The left pulmonary artery passes around the right main stem bronchus and courses between the trachea and esophagus, forming a "sling." This might be associated with circumferential cartilage rings in the trachea with absence of the membranous portion posteriorly, the so-called ring-sling complex.[11]

Innominate artery compression syndrome is caused by the anterior compression of the trachea anteriorly by the innominate artery. The exact etiology of this syndrome is not well understood. The innominate artery in some children originates more posteriorly in the left aortic arch, and as it courses posteriorly and superiorly, anterior to the trachea, it causes compression.[4,68]

An aberrant subclavian artery (left aortic arch with retro-esophageal right subclavian artery) results from disappearance of the right fourth aortic arch. The right subclavian artery arises from the descending aorta, coursing superiorly behind the esophagus. This is the most common arch anomaly seen in 0.5% of the general population.[79] Most infants are asymptomatic, and the diagnosis is suspected on an incidental echocardiogram. Barium swallow is usually diagnostic, showing posterior indentation on the esophagus (Fig. 76.5). Right aortic arch with retro-esophageal left subclavian artery is usually associated with other conotruncal abnormalities.

Clinical Presentation and Diagnosis

Many children with vascular rings presenting within their first year of life require surgery.[5] These infants commonly present with respiratory difficulties (e.g., stridor or wheezing), recurrent pulmonary infections, and/or difficulty feeding.[22,32] Infants may hold their heads hyperextended, thereby decreasing the obstruction. In older infants and children, the presenting features might be dysphagia with solid foods. Children with innominate artery compression may present with apnea. The diagnostic evaluation includes chest radiography, echocardiogram, barium swallow studies, CT angiogram, and cardiac MRI. A CT-angiogram often provides the final diagnosis and is considered the gold standard diagnostic test.[6]

• **Fig. 76.5** Barium swallow study showing posterior indentation by the aberrant left subclavian artery passing posterior to the esophagus. A, Anterior; P, posterior.

Treatment

Surgery is indicated in all symptomatic vascular rings. Delayed treatment may result in sudden death or further tracheobronchial damage. All patients referred for surgery should have a bronchoscopy performed to evaluate for the site of tracheal stenosis and evaluation of cartilage rings.[65] The nondominant arch is divided in the case of a double aortic arch. Coarctation and other associated anomalies should be ruled out before referral for surgery. The ligamentum is divided and ligated in the case of a right arch and left ligamentum. If a Kommerell diverticulum is 1.5-2 times the size of the left subclavian artery, it should be resected.[65] Management of compression of the trachea by the innominate artery may be treated by reimplanting the innominate artery. A pulmonary artery sling is corrected by reimplantation of the left pulmonary artery into the main pulmonary artery anterior to the trachea. An aberrant subclavian artery needs treatment only if associated with aneurysm at the origin of the subclavian artery.[39]

Neonatal Marfan Syndrome

Marfan syndrome is an infrequent diagnosis in infancy. The cardiovascular complications associated with this disorder

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

are the major cause of morbidity and mortality in Marfan syndrome. Prognosis and morphologic characteristics in infantile Marfan syndrome may be quite different from those reported in older patients. The diagnosis of neonatal Marfan syndrome, because of its clinical and phenotypic variability, is made following criteria of skeletal, ocular, cardiovascular, cutaneous, neurologic, and pulmonary manifestations, as well as family history.[44]

Morbidity and mortality tend to be high when Marfan syndrome is diagnosed during infancy, and prompt recognition of this phenotype can facilitate management and counseling. Most such severe cases appear to be caused by a sporadic mutation in a single germ cell of one parent. Many familial cases may have milder manifestations, be more difficult to detect during infancy, and have a better prognosis.[54] Skeletal features are recognizable, and clinical signs of congestive heart failure caused by mitral or tricuspid regurgitation could be evident in the first days of life. Aortic root dimensions are often increased, and aortic regurgitation can be seen by color flow mapping. Genetic testing to exclude Loeys-Dietz syndrome may also be indicated in the neonate presenting with physical findings of connective tissue abnormalities.[43] This exclusion may be recognized clinically, as infants with Loeys-Dietz syndrome will have a bifid uvula and, more critically, severe dilation of the aorta and cerebral arteries leading to earlier pathology and rupture. Surgery is often required early in these infants because of persistent heart failure and the risk of death from aortic rupture. In a rare case, quadruple valve replacement has been reported.[71]

The Premature Baby With Congenital Heart Disease

The prevalence of congenital heart disease in low birth weight infants born between 25 and 32 weeks is as high as 116 per 1000 in contrast to 10 per 1000 term births with a five-fold increase in severe congenital heart disease.[16] Although outcomes of neonates with congenital heart disease have improved significantly over the past few decades, low birth weight and prematurity remain challenging problems. Infants with birth weights less than 2.5 kg have 1.5 to 3 times higher mortality.[20] When compared with term infants, low birth weight/premature infants were more likely to have pulmonary atresia with ventricular septal defect, complete atrioventricular septal defect, coarctation of the aorta, tetralogy of Fallot, and pulmonary valve stenosis. Fewer low birth weight/preterm infants had pulmonary atresia and intact ventricular septum, transposition of the great arteries, and single ventricle.[72] Perioperative management of these high-risk infants must take into account the patient's small size; the clinical implications of prematurity; IUGR and associated extracardiac anomalies; the cardiac pathophysiology; and issues related to anesthesia, surgery, and cardiopulmonary bypass.[80]

Systemic to pulmonary artery collaterals are seen in 66% of very low birth weight infants between 1-90 days of life. Often, these are infants who require surfactant therapy or need closure of a patent ductus arteriosus either by surgery, catheter, or medical treatment. Comorbidities with surgical and medical management of persistent ductus arteriosus in the preterm infant have sparked interest in catheter-based closure.[7,57,74] The combination of low birth weight, prematurity, and congenital heart disease makes the management of these patients challenging. It is unclear whether a strategy of medical management and deferment of surgical intervention is beneficial over more expeditious intervention.

Palliative Care

Many congenital cardiac centers are engaging palliative care services at the time of diagnosis for complex congenital disease. The cardiovascular disorders noted in this chapter have high morbidity and mortality rates when symptomatic in the neonatal period. Early input and consistent messaging from the medical teams can be augmented by the addition of palliative care from the onset.[8]

Acknowledgments

The author would like to acknowledge the contributions of Dr. Kenneth Zahka, Christopher Snyder, and Manish Bansal, who were the authors of this section in previous editions.

Key Points

- Earlier symptomatic presentation of Marfan syndrome and vein of Galen malformation are associated with worse outcomes.
- Cardiomyopathies diagnosed in the neonate should prompt expert heart failure team involvement to determine genetic or underlying causes and to assist in management.
- Right and left atrial isomerism associated with heterotaxy syndrome have distinct cardiac presentations and different mortality risks.
- Preterm infants with cardiac disease are at increased risk for complications and mortality compared with term peers.
- Early involvement of palliative care after cardiac diagnosis may mitigate parental distress and enable consistent messaging.

Disorders of Cardiac Rhythm and Conduction in Newborns

BRYAN CANNON AND CHRISTOPHER S. SNYDER

Neonates experience a variety of cardiac arrhythmias, varying from benign and asymptomatic to life threatening. In this chapter we will discusses the normal and abnormal variations in cardiac rate and rhythms that are frequently encountered in the newborn period.

Normal Sinus Rhythm and Sinus Node Dysfunction

Normal Sinus Rhythm and Its Variations

The initiation of cardiac electrical activity typically begins in the sinus node, a small, epicardial structure that is located at the posterior junction of the superior vena cava and right atrium.

The sinus node receives input from both the sympathetic and parasympathetic nervous systems. The balance of the two inputs determines the underlying heart rate at any given moment. At rest and during sleep, vagal nerve stimulation (parasympathetic) is increased, resulting in slowing of the heart rate and potentially sinus bradycardia. During periods of stress, stimulation, or activity, the sympathetic nervous activity tone predominates, leading to an increase in heart rate and potentially sinus tachycardia.

It is important to remember that in children with normal cardiac anatomy, sinus bradycardia or sinus tachycardia are usually physiologic findings. It can be determined that the electrical impulse is generated from the sinus node, characterized on the electrocardiogram (ECG) by a positive P wave deflection in leads I and aVF; it is quite rare to have an underlying cardiac conduction issue.

Sinus Bradycardia

Sinus bradycardia is defined as heart rate less than 60 beats per minute (bpm) in older children and adults. However, in newborns, the resting heart rate is typically faster with a normal resting heart rate between 90 and 160 bpm, with intermittent decreases to as low as 70 bpm during rest or sleep.

Sinus bradycardia generally is physiologic in infants with a structurally normal heart and is secondary to transient increases in vagal tone. This increase in vagal tone is almost always related to an underlying process, such as increased intracranial pressure, an acute abdominal process (e.g., necrotizing enterocolitis), suctioning of an endotracheal tube, gastric reflux, apnea of prematurity, or medications (e.g., sedatives, beta blockers).

Most episodes of sinus bradycardia in neonates are episodic and related to an abrupt increase in vagal tone that may result in sinus pauses or dropped heart beats, resulting in heart rate decreasing to 40-50 beats per minute. Episodic abrupt decreases in the heart rate with an otherwise normal heart are caused by a secondary process and almost never have a primary cardiac etiology, but the pauses can be relatively long lasting, up to several seconds.

The initial evaluation of bradycardia involves obtaining an electrocardiogram (ECG) to ensure that there is no evidence of atrioventricular (AV) block or other primary cause such as a cardiac channelopathy as the cause of the bradycardia. The primary method used to assess the overall function of the sinus node in a neonate is a 24-hour cardioscan monitor (Holter) that records every electrical cardiac impulse during the monitoring period. This monitor is used to evaluate the infant's heart rate variability as well as maximum and minimum heart rates. Even though rarely there are ways to demonstrate that sinus bradycardia is caused by increased vagal tone and is not secondary to sinus node disease, administration of a vagal nerve antagonist such atropine (muscarinic-cholinergic blocking agent) increases heart rate almost immediately if the bradycardia is secondary to vagotonia, although this is only rarely clinically indicated. There is minimal or no heart rate increase to atropine in those infants and children with primary sinus node dysfunction. Patients with sinus node dysfunction also typically have bradycardia that persists throughout the day and may only reach a maximum heart rate of 100-130 beats per minute.

Treatment of sinus bradycardia is rarely required. Evaluation for an underlying cause (e.g., seizures, reflux, or apnea) should be undertaken, particularly in cases of episodic bradycardia. If a neonate has a slow underlying rate but has no evidence of hemodynamic compromise, in general, no

Abstract

In this chapter, we describe the findings of the normal cardiac conduction as well as the abnormal conduction. We give examples of both and discuss the diagnosis as well as the treatment for each of the conduction abnormalities found in neonates. With regard to treatment, we discuss options from observation to medications to cardioversion and pacing.

Keywords

sinus tachycardia
sinus bradycardia
premature beats
supraventricular tachycardia
complete atrio-ventricular block

intervention is required. A pacemaker may be placed if there is persistent hemodynamically significant sinus node dysfunction, but this is exceptionally rare in the neonatal population.

Sinus Tachycardia

Sinus tachycardia is defined as increase in the sinus rate above 160-180 bpm in infants. It is usually a normal physiologic response to anemia, hyperthyroidism, fever, agitation, infection, or medications to name just a few causes. It is rarely caused by a primary cardiac etiology, unless there is underlying cardiac dysfunction such as seen with myocarditis.

It is important to ensure that an elevated heart rate is truly sinus tachycardia and is not caused by an abnormal cardiac rhythm such as supraventricular tachycardia (SVT). The typical maximum heart rate in a "normal" infant is 220 bpm minus the age of the patient. Critically ill neonates may sometimes exceed this rate; sinus tachycardia at rates greater than 220 bpm should warrant evaluation for the presence of pathology.

Some other findings that suggest a pathologic mechanism of tachycardia are:

1. The lack of heart rate variability
2. Abnormal P-wave morphology or axis (normally upright in leads I and aVF) on ECG
3. Prolongation of PR interval
4. Very rapid increases or decreases in heart rate
5. Abnormal cardiac function on echocardiogram

The best method for initial evaluation of sinus tachycardia typically involves obtaining an ECG to ensure that there is no evidence of a pathologic arrhythmia. Similar to sinus bradycardia, a 24-hour Holter can be helpful in ruling out SVT in questionable cases when one evaluates it for heart rate variability, episodes of pauses, and/or changes in the P-wave axis.

Treatment of sinus tachycardia is directed at treating the underlying cause. Neonates with high resting heart rates generally do not require any treatment but should be closely evaluated to make sure they do not have a secondary cause such as infection or anemia.

Sinus Arrhythmia

In children with sinus arrhythmia, sometimes called respiratory sinus arrhythmia, phasic variations in heart rate are seen with an increase in heart rate during inspiration and a decrease in heart rate with expiration (Fig. 77.1).

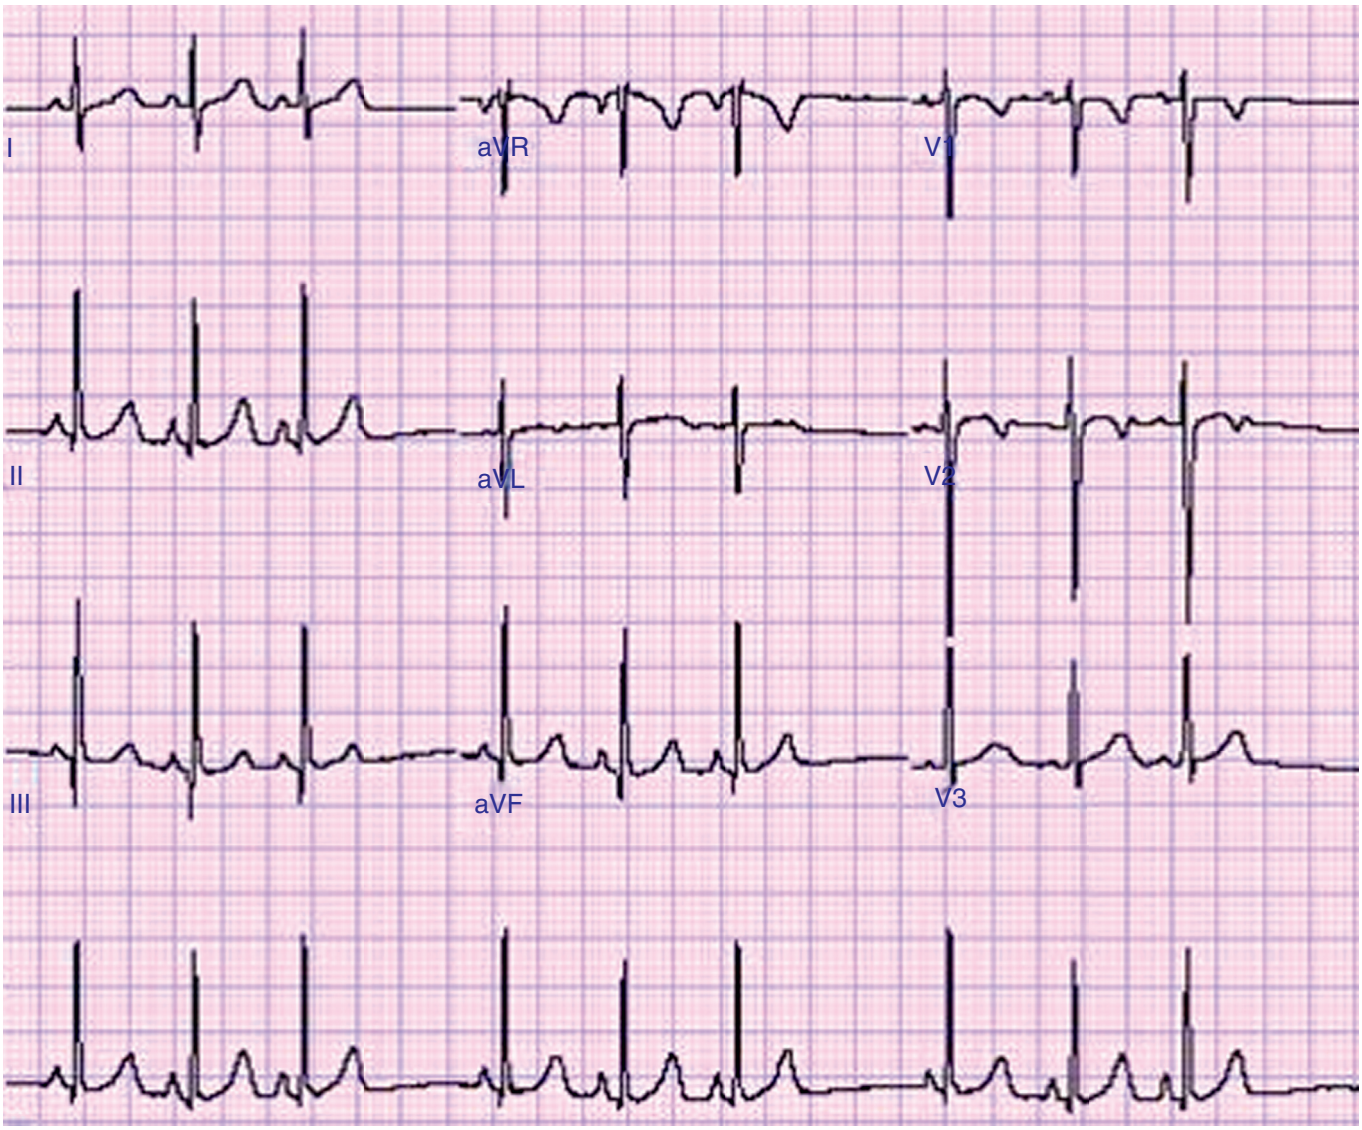
Sinus arrhythmia is caused by the so-called Bainbridge reflex (baroreceptor reflex). During inspiration, the intrathoracic pressure decreases and triggers increased venous blood return to the right atrium. The increased volume in the right atrium is registered by stretch receptors, which causes increase in heart rate. The opposite situation occurs during expiration, and heart rate decreases.

This variation is sometimes thought to be a pathologic arrhythmia, because the heart rate variability is often quite pronounced during auscultation in young children and infants. However, in most situations, the diagnosis can be made by noting heart rate variation that correlates with the respiratory cycle. Appropriate ECG interpretation is helpful if the diagnosis is in question. On an ECG, there is variation in the rate but no change in the appearance of the P-wave morphology or axis, thus confirming the diagnosis.

This condition is physiologic and does not require any treatment or follow-up.

Tachyarrhythmias

Atrial Tachycardia



Premature Atrial Contractions

Premature atrial contractions (PACs) are early depolarizations of atrial tissue distinct from the sinus node. As the impulse originates from the area different than the sinus node, the P wave will often have a different morphology than the "normal" P wave from the sinus node.

Premature atrial contractions usually conduct through the AV node, bundle of His, and right and left bundle branches to the ventricles. If atrial activation occurs early enough that the AV node or bundle of His is refractory, the PACs will not be conducted to the ventricle; this is commonly referred to as a "blocked" PAC. In this case, the premature P wave is seen without a following QRS complex. When this occurs clinically, these block PACs are often read as bradycardia, which is not an accurate description of what is occurring electrically in the heart. If a PAC activation wavefront passes through the AV node, but either the right or left bundle branch is still refractory, then it will be followed by a wide QRS (aberrant ventricular conduction). This can be mistaken for a premature ventricular contraction, but close observation will show atrial activation before the QRS, thus making the diagnosis of a premature atrial contraction. All three of these examples, conducted, nonconducted, and aberrantly conducted PACs, may be present in the same patient.

Premature atrial contractions are commonly seen in healthy newborns and may occur frequently (>200 per hour) in an individual patient. In patients with isolated PACs, they may occur in a pattern of two PACs in a row, which is referred to as an atrial couplet. If every other beat is a PAC, then this pattern is referred to as *atrial bigeminy*. Atrial couplets and bigeminy are benign and make no impact on the individual's prognosis when compared with those with isolated PACs as long as no evidence of atrial tachycardia is present. Rarely, PACs in a bigeminal pattern will block (i.e., every other beat is a nonconducted PAC), thus resulting in bradycardia. It is important to evaluate the ECG in fetuses and neonates with bradycardia to ensure that this pattern is not the cause of their "bradycardia." This pattern is especially common in fetuses that are referred for episodes of extreme bradycardia with intermittent episodes of normal conduction. These fetuses are usually not in distress, and it is worthwhile to explain these circumstances

• **Fig. 77.1** Sinus arrhythmia in a healthy child. Note that all P waves look exactly the same, although there is marked variation in their rate.

to other care providers before any rush decisions are made concerning early or emergent delivery.

Isolated PACs usually are benign and do not require any therapy. In most newborns, PACs will resolve in the first few months of life and cause no hemodynamic compromise or clinical symptoms. A follow-up visit with a pediatric cardiologist may be recommended at 4-6 months postdelivery to ensure resolution.

Atrial Ectopic Tachycardia

When three or more consecutive PACs occur in an infant or neonate at a rate faster than 120 beats per minute, the term *atrial ectopic tachycardia* (AET) is used. Atrial ectopic tachycardia is typically the result of an increased automaticity of atrial myocardium. With this mechanism, there is abnormal firing of atrial tissue originating outside the sinus node. With an automatic focus, there are typically "warming up" and "cooling down" periods for the tachycardia. This frequently involves rapid increases or decreases in heart rate over several beats rather than initiation or termination in a single beat. Most AETs are paroxysmal in nature, resulting in little if any harm to the patient, but they may be incessant. The majority of neonates with AET also have frequent isolated PACs. The abnormal focus can be located almost anywhere in the atrium, with common foci being along the crista terminalis in the right atrium or the pulmonary veins. In AET, the activation of atria is different from that of normal sinus rhythm, resulting in a different P-wave morphology on the ECG. Occasionally, the focus may occur near the sinus node (i.e., right upper pulmonary vein or right atrial appendage), producing P-wave morphology similar to the one in sinus rhythm, so careful inspection of the P-wave morphology using a 12- or 15-lead ECG is warranted to look for subtle changes in P-wave morphology.

Although an abnormal focus of atrial tissue is the usual cause of atrial tachycardia, mechanical stimulation of the

• **Fig. 77.2** Atrial flutter with 4:1 AV conduction in a 1-day-old newborn.

atria can also cause an atrial tachycardia. This is frequently seen in neonates who have an intravenous catheter with the tip located in the atrium. This catheter then creates an atrial tachycardia by directly stimulating the atria. One differential clue to the mechanism of this unique form of SVT is a very fast and irregular atrial tachycardia. A chest radiograph to visualize line position should be performed to ensure that the cause of the tachycardia is not line related before initiation of treatment.

Evaluation of an atrial tachycardia involves an ECG and Holter monitoring. Rapid, incessant AET can negatively affect ventricular function because of the heart's inability to "rest" or slow down. Therefore, an echocardiogram is usually part of the initial evaluation in the newborn period to evaluate function and rule out congenital heart disease with a dilated atrium as the cause of the atrial tachycardia. Electrolyte disturbances are a very rare cause of AET in neonates but should be corrected if present.

Treatment of atrial ectopic tachycardia may be attempted with medications such as beta blockers (propranolol), sodium channel blockers (flecainide), or class III antiarrhythmic medications (sotalol, amiodarone). The majority of neonatal AETs resolve spontaneously in the first 6 months of life, and long-term therapy is rarely necessary. Cardiac catheterization and radiofrequency ablation (RFA) are very high-risk procedures in neonates and are typically not performed except in extreme cases of medically refractory atrial tachycardia with depressed function. In very rare cases, mechanical support using extracorporeal membrane oxygenation (ECMO) is required to support the circulation until the tachycardia can be controlled.

Atrial Flutter

Atrial flutter is a classic example of atrial reentry tachycardia. In this type of tachycardia, the circuit or substrate for reentry is the atrial myocardium located around the tricuspid valve. The area of relatively slow conduction in this type of arrhythmia is generally located between the inferior vena cava (IVC) and the tricuspid valve annulus in an area referred to as the *isthmus*. The velocity of the impulse propagation is slow through the isthmus, allowing recovery of the atrial myocardium ahead of it and, therefore, allowing the atrial wave front to propagate.

The typical atrial rate of neonatal atrial flutter is between 300 and 600 beats per minute and is much faster than the flutter seen in older children and adults. However, the ventricular rate is much less because of the decremental properties of the AV node not allowing for such rapid conduction. The conduction to the ventricles is generally 2:1, 3:1, or 4:1 (Fig. 77.2) and may vary among these conduction rates, resulting in an irregular rhythm. Occasionally, the AV conduction can be rapid, resulting in ventricular rates greater than 200 bpm, which can be poorly tolerated by the fetus and neonate alike.

In most cases, the diagnosis can be made with a simple surface ECG, noting the continuous sawtooth pattern of atrial activity. However, it may be necessary to administer adenosine to the patient while recording an ECG, which blocks atrial conduction down the AV node and allows for rapid, easy identification of the sawtooth pattern classically described for this arrhythmia in patients when the P waves are masked by QRS complexes or T waves.

The initial treatment for atrial flutter is synchronized electrical cardioversion with 0.5-2 Joules per kilogram, but higher doses may be required because of the relatively small surface area of the cardioversion paddles/patches in neonates.[3,9] The best position for the paddles or patches is front to back, slightly to the left side of the chest, and it is often necessary to turn the infant on its side to get the paddles into position. Rapid atrial pacing (overdrive pacing) may also terminate the tachycardia but is difficult to achieve with the rapid atrial rate seen in neonatal flutter and has a lower overall success rate.[11,20] In addition to these two methods, some physicians use antiarrhythmic medications and observe for up to 48 hours to see if the tachycardia terminates spontaneously, but this method has lower success rates when compared to synchronized cardioversion.

Atrial flutter in an otherwise healthy newborn generally does not return once the patient is successfully treated unless there is another arrhythmia such as atrial tachycardia. Therefore no routine antiarrhythmic treatment is necessary for either short- or long-term treatment of standard atrial flutter once the patient is cardioverted.[3,9,11,20] If there is underlying atrial dilation, recurrent atrial flutter, or structural heart disease, treatment with antiarrhythmic medications such as propranolol or digoxin may be warranted.

Atrial Fibrillation

Neonatal atrial fibrillation (AFib) is an exceptionally rare dysrhythmia in this patient population and is typically seen only in patients with severe structural congenital heart disease (such as Ebstein anomaly of the tricuspid valve) or in conjunction with an accessory pathway (Wolff-Parkinson-White) or those with cardiac channelopathies.[25]

It is important to distinguish atrial fibrillation from a rare form of AET called chaotic atrial tachycardia (or multifocal atrial tachycardia) because both result in an irregular tachycardia with disorganized atrial activity on the ECG.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

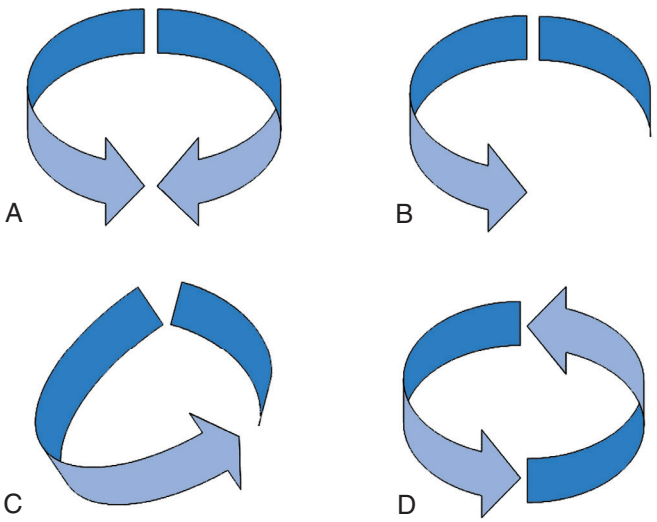
Chaotic atrial tachycardia (also referred to as multifocal atrial tachycardia) is a form of atrial tachycardia in which there are rapid bursts of tachycardia from multiple areas of the atria. Atrial fibrillation is an incessant arrhythmia that typically will respond to cardioversion. However, chaotic atrial tachycardia tends to occur in short bursts with sinus beats interspersed with runs of tachycardia and a varying P-wave axis. This type of tachycardia either does not respond to cardioversion or quickly returns after cardioversion.

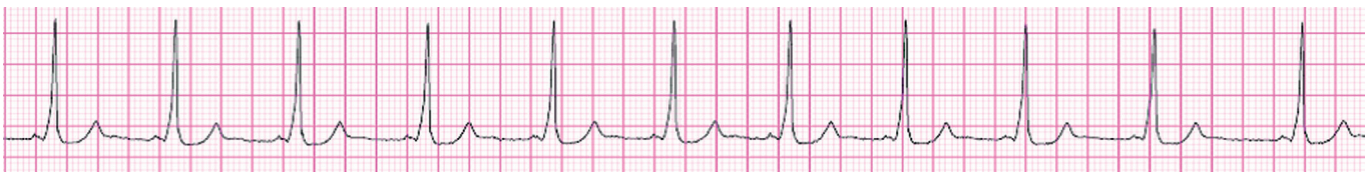
Treatment of AFib in neonates involves synchronized cardioversion. Pediatric cardiology consultation should be obtained because AFib is extremely rare in neonates and generally occurs in only the sickest neonates with other cardiac disorders. Chaotic atrial tachycardia requires medical treatment with antiarrhythmic medications such as beta blockers, flecainide, sotalol, or amiodarone, alone or in combinations, with a goal simply to control the ventricular rate, not to cure the atrial tachycardia.

Reentrant Supraventricular Tachycardia



Supraventricular tachycardia (SVT) caused by a reentrant mechanism is the most common form of SVT in this population. In a reentrant tachycardia, there are two distinct conducting pathways linked around an area of nonconducting tissue. Failure to conduct in one of these pathways (block) causes the impulse to turn around in the other pathway, creating an electrical loop that causes tachycardia (Fig. 77.3).

There are two common reentrant mechanisms of supraventricular tachycardia seen in the neonatal population. The first, and by far the most common in newborns and infants, is caused by an accessory pathway.[1] The second form is due to reentry around the atrioventricular node, also known as atrioventricular nodal reentry tachycardia or AVNRT.



Supraventricular Tachycardia Caused by a Manifest Accessory Pathway

In the normal cardiac conduction system, only a single connection exists linking atrial impulses to the ventricles, which is the bundle of His. The bundle of His penetrates the fibrous atrioventricular ring and normally is the only structure capable of conducting electrical impulses from the atria to the ventricles. During normal sinus rhythm, the activation wavefront travels from the sinus node across the atrial myocardium, then to the atrioventricular node, bundle of His to the right and left bundle branches, and ultimately exiting to the ventricular myocardium to cause a depolarization.

If an accessory pathway is present, it serves as an additional conduction pathway for electrical impulses to travel between the atria to the ventricles. Accessory pathways can conduct an impulse in both directions (antegrade, from atria to ventricles, and retrograde, from ventricles to atria) or only in one direction (either exclusively from the atria to the ventricles or from the ventricles to the atria). If an accessory pathway is capable of conducting the impulse only from the ventricles to the atria (retrograde), it is referred to as a *concealed accessory pathway*, and the baseline ECG will appear normal. If an accessory pathway is capable of conducting an impulse from the atria to the ventricles, it is referred to as a *manifest accessory pathway*,[12] resulting in what is known as preexcitation on the baseline ECG. Patients with preexcitation (also known as Wolff-Parkinson-White [WPW]) have an area of early ventricular activation on their ECG. This early ventricular activation on the ECG is called a delta wave and results in a short PR interval and widened QRS complex (Fig. 77.4). Preexcitation is present because the electrical impulse travels from the atria to the ventricles over two pathways—through the AV node/bundle of His, which has decremental properties, and down the accessory pathway. When activation travels down the conduction system (AV node), a normal physiologic delay of conduction occurs. This delay is necessary

• **Fig. 77.3** Re-entrant supraventricular tachycardia (SVT): **A,** Normal conduction down both sides of a re-entrant circuit. The electrical impulses collide and there is no reentry. **B,** Block in one pathway and conduction in the other. **C,** The impulse from the conducting pathway reaches the other pathway. **D,** This pathway now conducts setting up an electrical circuit of reentrant tachycardia.

• **Fig. 77.4** Electrocardiogram of a patient with Wolff-Parkinson-White syndrome shows a short PR interval, widened QRS, and slurring of the upstroke of the QRS.

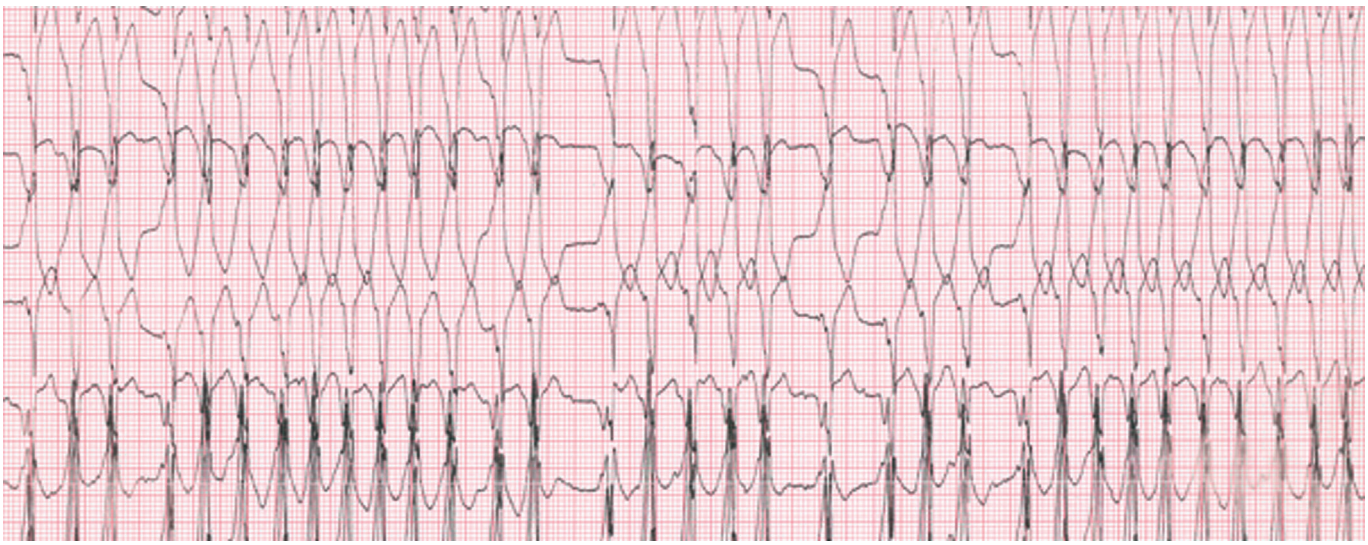
to make sure that atrial systole will occur before ventricular systole. Although there is a delay in conduction through the AV node, no such delay exists when electrical activity conducts down the manifest accessory pathway. Therefore, the atrial impulse travels quickly from the atria to the ventricles across the accessory pathway and activates the ventricular myocardium before it would normally be activated through the normal conduction system, resulting in a delta wave on the ECG.

About 20% of patients with Wolff-Parkinson-White have underlying structural heart disease (most commonly Ebstein anomaly); therefore, an echocardiogram should be performed when the diagnosis is made. Wolff-Parkinson-White syndrome can be hereditary but most times is sporadic, occurring in about 1-3 per 1000 individuals.[22]



Patients with WPW, a manifest accessory pathway, have an increased risk of atrial fibrillation for reasons that are not well understood. If atrial fibrillation occurs in a patient with WPW, an irregularly irregular wide complex tachycardia ensues (Fig. 77.5). In infants and neonates, there are almost no other causes of an irregularly wide complex tachycardia other than atrial fibrillation in the presence of an accessory pathway, although this occurrence is extremely rare in infants and neonates. Patients with WPW and atrial fibrillation also have the risk of sudden cardiac death.[16] In atrial fibrillation, these accessory pathways may conduct atrial impulses rapidly to the ventricles, resulting in rapid ventricular activation that may result in ventricular fibrillation and cardiac arrest. For this reason, adenosine, which blocks AV nodal conduction, should be used in a very controlled environment by an individual with knowledge of how to resuscitate an infant in cardiac arrest. In addition, other medications such as digoxin that block AV nodal conduction are relatively contraindicated with WPW.

Supraventricular Tachycardia Caused by a Concealed Accessory Pathway

Patients with a concealed accessory pathway are at risk of developing supraventricular tachycardia secondary to a reentrant mechanism.[8,37] Supraventricular tachycardia is usually initiated by a premature atrial or ventricular contraction. The premature beat will block in one of these two conduction pathways—the accessory pathway or the AV node. If the premature beat blocks in the accessory pathway, the activation wavefront travels down the normal conduction system (AV node and bundle of His) to the ventricles. The conduction wavefront then passes through the ventricular myocardium. The wavefront then reaches the accessory pathway, which has had time to recover and is able to conduct electrical impulses. The electrical impulse travels retrograde, from the ventricle to the atria then back down the AV node to perpetuate the tachycardia. This type of tachycardia, known as *orthodromic* tachycardia, is generally a narrow complex in nature as it travels down the normal conduction system to get to the ventricles. Each of the components of this circuit is integral to allow for propagation of the tachycardia, and disruption of the circuit in any of the limbs will terminate the tachycardia (Fig. 77.6).

Supraventricular Tachycardia Caused by Atrioventricular Nodal Reentry Tachycardia

A third form of reentrant tachycardia seen in neonates is atrioventricular nodal reentry tachycardia (AVNRT). In this form of SVT, the entire circuit is contained within the proximal portion of the AV node and no true accessory pathway is present. Its reentry circuit is located between the slow and fast pathway limbs of the atrioventricular node.[2,10] In most individuals, the AV node has both of these inputs, which coalesce to form the compact AV node,

• **Fig. 77.5** Preexcited atrial fibrillation in a patient with Wolff-Parkinson-White syndrome. Note the irregularly irregular wide complex rhythm.

• **Fig. 77.6** Baseline electrocardiogram (first 10 beats) shows preexcitation. The QRS complex #11 *(arrow)* represents premature atrial contraction followed by a reentrant narrow complex tachycardia (orthodromic supraventricular tachycardia).

which then continues to the bundle of His. Because slow and fast pathways have different conduction properties, a reentry tachycardia between these inputs can and often does occur. The resulting tachycardia is referred to as *atrioventricular nodal reentry*. Because AVNRT has a reentry mechanism, it is usually started by a premature atrial or ventricular beat. On ECG, it usually presents as a narrow complex tachycardia that is indistinguishable from an accessory pathway-mediated tachycardia. Atrioventricular nodal reentry tachycardia has a developmental component and is rare in neonates and infants but is relatively common as a mechanism of tachycardia in older teenagers and adults.[1]

Supraventricular Tachycardia

The clinical presentation of SVT in neonates or infants with AVRT and/or AVNRT are the same, with a rapid increase in heart rate and narrow complex tachycardia on ECG. Ventricular rates are typically greater than 200 beats per minute, but rates as fast as 300 beats per minute can be seen. It is rare to have a sinus rate greater than 220 beats per minute, and any rate exceeding this number should raise the possibility for the presence of an abnormal mechanism of tachycardia, including reentrant SVT.

In the neonatal period, it is not uncommon for SVT to present as a wide complex tachycardia, generally with a left bundle branch block. In this situation, there is aberrant conduction to the ventricles because of a long recovery or refractory period of one of the bundles, generally the left. The differential diagnosis for a wide complex tachycardia in a newborn is ventricular tachycardia or SVT with aberrancy, with the latter being much more common in this age group.

In patients with a concealed accessory pathway or AV node reentry tachycardia, the major clinical manifestation is a rapid heart rate discovered either by auscultation or monitoring. Occasionally, infants can present with depressed myocardial function if the tachycardia is persistent. Infants generally tolerate these rapid heart rates for hours to days, manifesting generalized symptoms such as poor feeding and irritability. Patients with WPW (manifest accessory pathway) may be diagnosed when tachycardia occurs or if preexcitation is noted on a monitor or routine ECG.

Asymptomatic patients with WPW syndrome and no evidence of tachycardia do not require medical treatment.[4] They should be followed by a pediatric cardiologist or electrophysiologist to ensure that SVT does not develop, but up to 80% have spontaneous resolution of their preexcitation within the first year of life.[23]

If a patient presents with an acute episode of SVT, the goal is to terminate the tachycardia in the most humane, stable way in an environment in which intubation, cardioversion, and resuscitation can be carried out capably. If the patient is hemodynamically unstable, the doctor must decide which method of cardioversion is immediately available, whether adenosine or direct current cardioversion. The doctor must also be prepared to intubate the patient and have intravenous pressors and even ECMO available to support the infant afterward. The typical dose required to cardiovert a neonate is between 0.5 and 1 joule per kilogram, but larger doses may be required, particularly in smaller neonates. If there is a QRS complex that is generating a pulse, the cardioversion should be synchronized to the QRS complex.

If the patient is hemodynamically stable, other methods should be attempted before heading directly to electrical cardioversion. Automated blood pressure machines may not register an accurate blood pressure in the face of a rapid tachycardia, and other methods of assessing cardiac output such as skin perfusion, level of consciousness, and peripheral pulses may be needed to determine if adequate perfusion is occurring. The first line of therapy in the hospital used for cardioversion in a neonate is either adenosine administration or vagal stimulation. Vagal stimulation slows conduction through the AV node and interrupts a reentrant supraventricular tachycardia. An effective maneuver frequently utilized to convert infants is placing a small bag or glove filled with ice over the entire face for 10-15 seconds. To elicit the appropriate dive reflex, the majority of the face/mouth and nose must be covered. Care must be exercised not to cause frostbite to the delicate neonatal skin from prolonged or repeated ice exposure. Holding a child upside down (with proper support) can also induce a vagal response. Gagging, ocular pressure, and anal stimulation in general should be avoided in the neonatal population.

If the child is in the hospital, IV adenosine (0.1-0.4 mg/kg per dose) would generally be the recommended step to convert the infant/neonate back into normal rhythm. Adenosine must be administered in a rapid IV push followed by a 5-10 cc bolus of normal saline or Ringer's lactate. This form of cardioversion is extremely effective, resulting in normalization of the neonate's rhythm in the vast majority of cases.

The use of IV digoxin has fallen by the wayside since the advent of adenosine. The use of IV (or oral) calcium channel

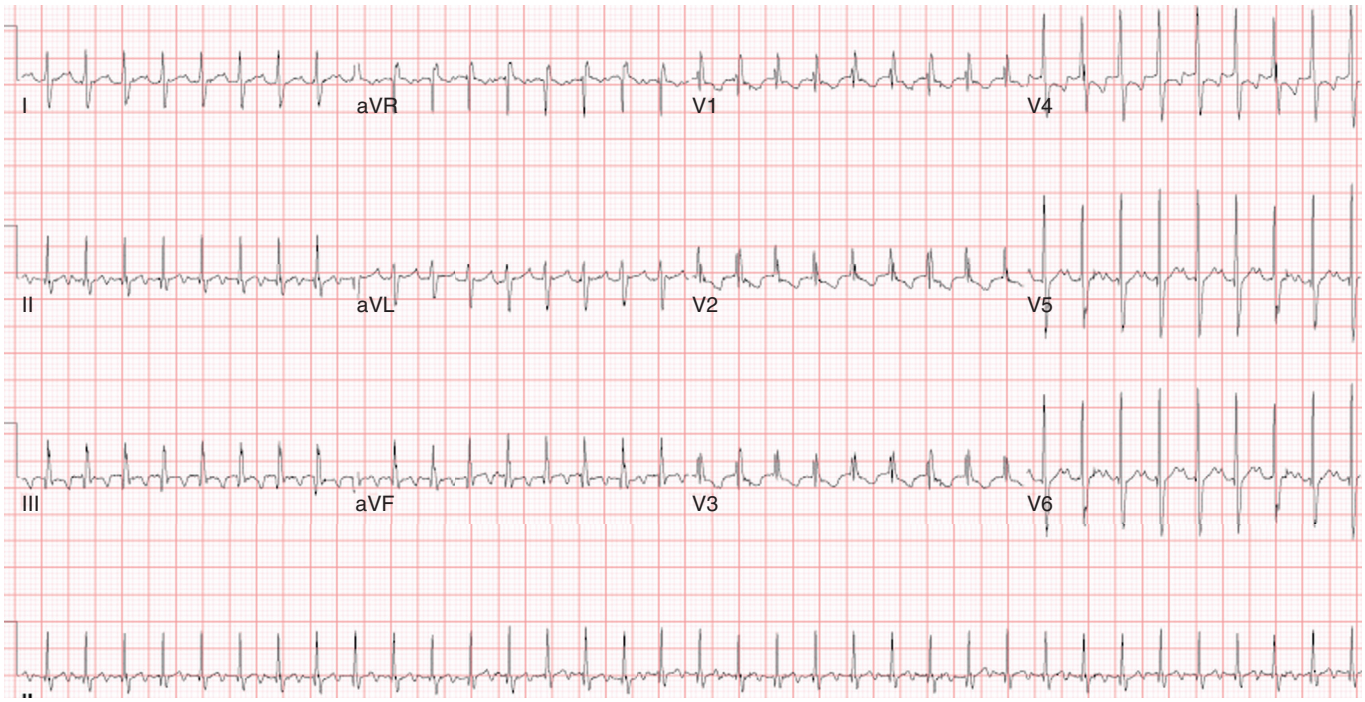
blockers is relatively contraindicated in patients less than 1 year of age, because there have been reports of sudden death, likely caused by the extreme sensitivity of the infantile conduction system to calcium. The use of IV amiodarone is included in Pediatric Advanced Life Support (PALS) and Neonatal Advanced Life Support (NALS) algorithms, but the use of this medication should be reserved for the conversion of refractory cases of SVT and is best administered in conjunction with consultation by a pediatric cardiologist who can assist with the long-term management of the patient, especially considering that the half-life of amiodarone can be up to 90 days in a neonate.

The long-term goal is to prevent SVT recurrence. Around 60%-80% of supraventricular tachycardias that present in the neonatal period resolve spontaneously within the first year of life.[7,39] In older patients, generally around 15 kilograms, there is the possibility of performing a cardiac catheterization and electrophysiology study with the potential for an ablation to eliminate the mechanism of tachycardia. The risks of this procedure are significantly higher when performed in children less than 4 years of age.[34] For this reason, ablations in neonates and infants are reserved for those patients with drug-refractory tachycardias and decreased function in whom no other options exist. In general, medical treatment is recommended after a single episode of tachycardia for the vast majority of cases.



Beta blockers such as propranolol are a generally safe and quite effective first-line medical therapy for the treatment of SVT. Propranolol is dosed at 4 mg/kg per day or 1 mg/kg per dose, dispensed every 6 hours or every other feed in a neonate. Once the infant begins sleeping through the night, the dosing can be spaced out to every 8 hours. Some centers also use digoxin, another relatively effective first-line agent in the treatment of SVT. Digoxin is frequently used to successfully treat fetal tachycardias. Digoxin is generally dosed at 4-5 μg/kg per dose given twice a day.

Second-line agents for the treatment of neonatal tachycardias, when propranolol and/or digoxin have failed to completely control the arrhythmia, include sotalol, flecainide, or amiodarone.[13,18] Each of these potent medications works extremely well for the treatment of neonatal tachycardias, but all have potential side effects. Before the use of any of these medications alone or in combination, consultation with a pediatric cardiologist is recommended.

Permanent Form of Junctional Reciprocating Tachycardia

A unique type of accessory pathway–mediated tachycardia is the permanent form of junctional reciprocating tachycardia (PJRT). Initially, this tachycardia was thought to arise from the AV junction, but it is actually caused by a concealed, slowly conducting retrograde-only accessory pathway. Because these accessory pathways conduct very slowly, the tachycardia presents with P waves clearly visible on the surface ECG.[15] The ECG in tachycardia has a characteristic morphology with deeply negative P waves in the inferior leads II, III, and aVF (Fig. 77.7).

This type of tachycardia frequently is present immediately after birth, but because of its slow rate (potentially as slow as 150 beats per minute), it may not be noted during examinations in newborns and infants. In addition, the tachycardia has P waves before each QRS complex, which

• **Fig. 77.7** Electrocardiogram in a patient with permanent form of junctional reciprocating tachycardia shows a narrow complex tachycardia with negative P waves in the inferior leads II, III, and aVF.

may be mistaken for sinus rhythm if it is not recognized that the atrial impulse is not coming from the sinus node (sinus P waves should be positive in leads I, II, and aVF). Permanent form of junctional reciprocating tachycardia also tends to be an incessant tachycardia with minimal variation in the heart rate and may lead to a tachycardia-induced cardiomyopathy if left untreated. There may be spontaneous termination of the tachycardia followed by several sinus beats with spontaneous reinitiation of the tachycardia (Fig. 77.8).

Treatment of PJRT in the neonatal and infantile period is typically done with antiarrhythmics. Beta blockers may be initiated but are frequently ineffective. Flecainide is currently the treatment of choice for this incessant tachycardia, and it is often effective, even after a single dose. Ultimately, the vast majority of these patients will require an ablation when they are older because this form of tachycardia does not resolve spontaneously.

Junctional Ectopic Tachycardia

In patients with junctional ectopic tachycardia (JET), the focus of tachycardia is located within the bundle of His (most commonly) or proximal bundle branches (very rarely). The mechanism of JET is caused by increased automaticity in this region.[10] Junctional ectopic tachycardia can be either congenital, of which many are of genetic

• **Fig. 77.8** Permanent form of junctional reciprocating tachycardia with deeply negative P waves in leads II, III and aVF. Note the spontaneous termination followed by a sinus beat (denoted by *) and reinitiation of the tachycardia, with the first beat of tachycardia being aberrantly conducted (*arrow*), seen on the rhythm strip at the bottom of the electrocardiogram.

• **Fig. 77.9** Narrow-complex tachycardia with VA dissociation (no relationship between the P waves and QRS complexes) diagnostic of junctional ectopic tachycardia.

etiology, or acquired, which occurs after congenital cardiac surgery. Congenital JET is rare but very frequently leads to arrhythmia or tachycardia-induced cardiomyopathy, resulting from its incessant and rapid rates upwards of 260 beats per minute. Congenital JET generally presents in fetuses, neonates, and infants less than 6 months of age and is likely to be incessant, have faster rates, and have an associated mortality rate of greater than 50% (Fig. 77.9).[14,36]

Postoperative JET is seen in patients who have undergone surgical repair of congenital heart defects. The cause of JET in these patients is multifactorial and is thought to be caused by swelling/edema, electrolyte imbalances, catecholamine surges, and use of certain pressor medications such as epinephrine and dopamine, as well as longer aortic cross clamp and bypass times. As the localized edema or the electrolyte or catecholamine imbalance resolves, the JET will frequently subside. If not, short-term medical management with amiodarone or procainamide is warranted.

Because the focus of tachycardia is located within the His complex, the QRS complexes are expected to be narrow and identical to the sinus QRS.[5] Because the focus of the tachycardia is located within the bundle of His, the relationship between the atria and ventricles is variable. The typical presentation of this tachycardia is no association between the P waves and the QRS complexes on the ECG (VA dissociation), with the narrow ventricular rate being faster than the atrial rate. However, in the majority of pediatric cases, there is retrograde conduction through the AV node, resulting in 1:1 VA conduction, or VA Wenckebach is present with the P wave occurring simultaneously with the QRS complex. The tachycardia typically has minimal response to adenosine other than it can be used to disassociate the atrium from the ventricle, with continuity of the tachycardia at the same rate.

Congenital JET is a rare, life-threatening tachycardia that may not respond to any form of intervention. The current medical management for JET is to remove additional catecholamines and initiate amiodarone, which is currently considered the most effective antiarrhythmic agent available.

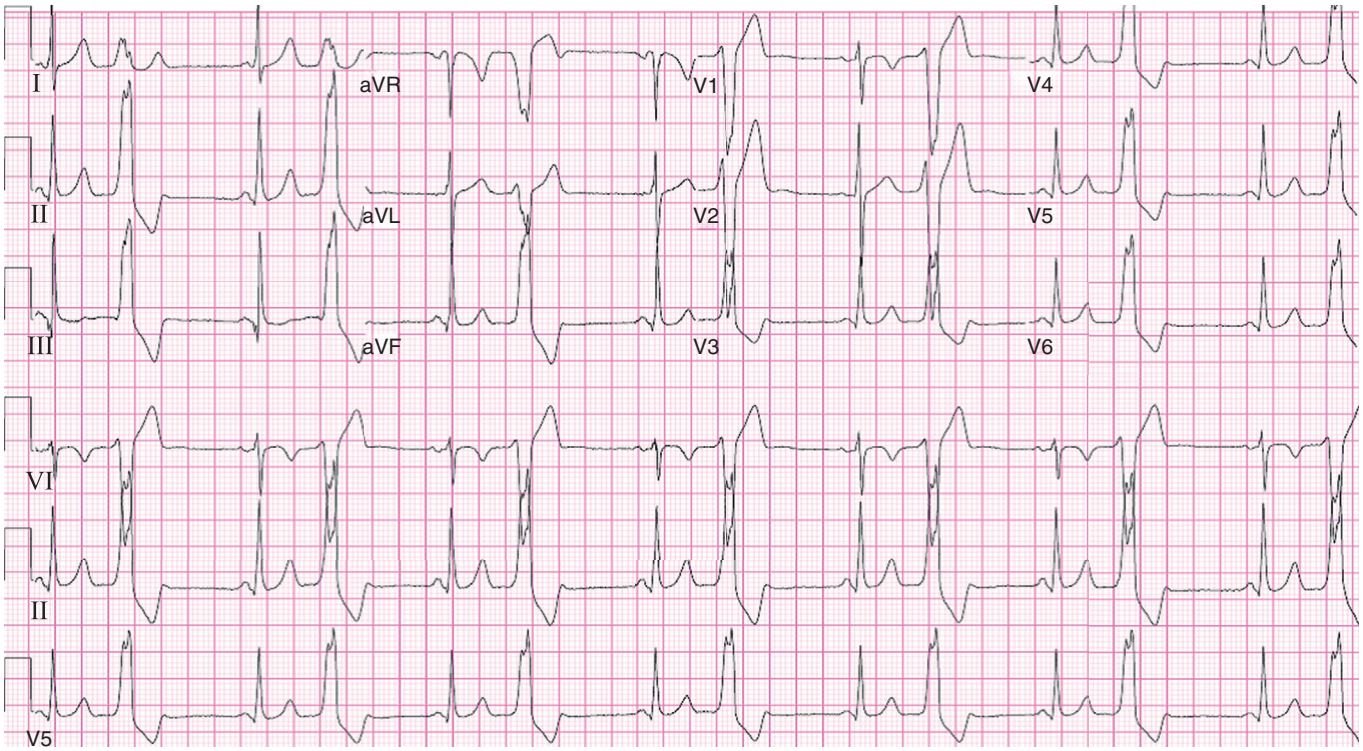
Postoperative JET generally resolves within 3-5 days after surgical repair. The decision to treat or not to treat these fragile neonates depends on the overall patient status. The heart rate during JET generally is in the range of 150-170 beats per minute, but the main question is whether the patient is hemodynamically stable. If so, then no specific treatment is required. In postoperative neonates when JET does affect hemodynamic status, the following steps should be taken:

1. Treat fever and/or cool the patient.
2. Decrease/wean all catecholamines.
3. Initiate atrial pacing at rates faster than the JET rate to restore AV synchrony.
4. Administer amiodarone or procainamide intravenously for at least 48 hours.

Ventricular Arrhythmias

Premature Ventricular Contractions

A premature ventricular contraction (PVC) is a spontaneous depolarization of the ventricle myocardium resulting in an early or premature ventricular contraction (Fig. 77.10). PVCs in infants or neonates may not have as wide of a QRS duration as seen in older patients, but they frequently have a morphology that is different and wider than that of the normal sinus QRS. Intermittent preexcitation or an aberrantly conducted premature atrial contraction are in their differential diagnosis, but these can be ruled out with a simple ECG. Premature ventricular contractions in neonates with a structurally normal heart typically have a benign prognosis and do not require any form of treatment. Exceptionally rarely, PVCs may cause symptoms or a decrease in systolic function if they occur with an extremely high frequency.



Characteristics of Benign Premature Ventricular Contractions

1. Lack of symptoms
2. Structurally normal heart and normal cardiac function by echocardiogram
3. Disappearance of PVCs at faster heart rates
4. Negative family history for sudden death or inherited arrhythmia disorder

Evaluation

Premature ventricular contractions in this population are generally heard on physical exam as either an extra or skipped beat, or they may be found during routine monitoring on babies in the newborn nursery or intensive care unit for other reasons. The standard for evaluation of PVCs is first an ECG to make the appropriate diagnosis, then a 24-hour Holter monitor to quantify the burden of

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

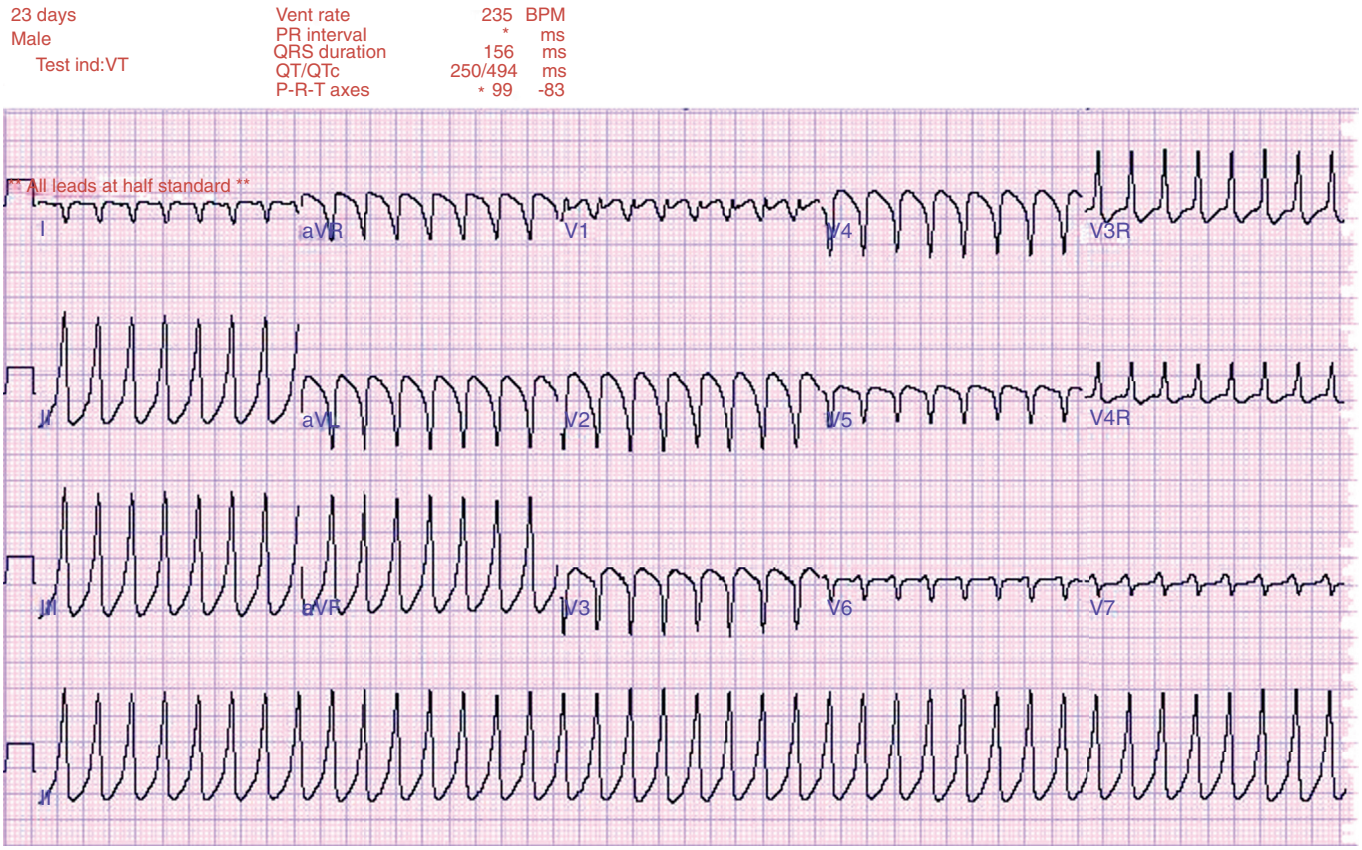
• **Fig. 77.10** A patient with a structurally normal heart and frequent monomorphic premature ventricular contractions in bigeminy pattern.

ventricular ectopy and to evaluate for ventricular tachycardia (three or more PVCs in a row.) It is reasonable to perform an echocardiogram on selected patients with PVCs to evaluate for the presence of congenital heart disease and to assess ventricular function. It is very rare for electrolyte abnormalities or hyperthyroidism to result in PVCs, but these, plus the placement of all intravenous lines, should be evaluated if clinically indicated.

Treatment

The vast majority of infants and neonates with isolated PVCs and a negative family history for sudden cardiac death or channelopathies require no treatment. The only recommendation is that these patients follow up with a pediatric cardiologist within their first 3-6 months of life to assess if the PVCs are still present. If they persist, the pediatric cardiologist may wish to place another 24-hour Holter monitor and potentially re-evaluate their cardiac function if PVCs remain frequent.



Ventricular Tachycardia

Ventricular tachycardia (VT) is a rhythm disturbance that originates below the bifurcation of bundle of His. This typically presents with a wide complex rhythm, which in neonates constitutes a QRS duration of greater than 80 ms (Fig. 77.11). Any time one is faced with a patient with "ventricular tachycardia," one must differentiate it from the benign rhythm called accelerated ventricular rhythm or *idioventricular rhythm*. Idioventricular rhythm is characterized by its rate, which by definition is no more than 20% faster than the underlying sinus rate and the patient is asymptomatic and hemodynamically stable. This rhythm is almost always considered benign and requires no intervention.[24] In infants with structurally normal hearts, true VT is quite rare and generally has a benign prognosis. However, there are ventricular tachycardias that are either so fast or so frequent that they may affect the patient's hemodynamics and cardiac function and require aggressive treatment.

In neonates with structurally normal hearts, VT generally is caused by an automatic focus. The focus of the tachycardia is frequently from the outflow tract (most commonly the right ventricular outflow tract) or one of the fascicles in the left ventricle (most commonly the left posterior fascicle). Additional, yet rare, causes of neonatal ventricular tachycardia are myocardial hamartomas or tumors. These extremely rare causes of neonatal ventricular tachycardia tend to be incessant and extremely difficult to control with medications. However, if the tachycardia can be controlled, hamartomas frequently regress in the first several years of life, but some cardiac tumors require surgical resection.

Infants with poor ventricular function (e.g., patients with neonatal myocarditis) or structural cardiac disease can also present with ventricular tachycardia; therefore, it is very important to assess these patients with a complete echocardiogram prior to the initiation of any form of treatment to help assess the overall patient's status and potentially get clues as to the longevity of treatment and the patient's prognosis.

• **Fig. 77.11** A 15-lead electrocardiogram in a 23-day-old patient with a structurally normal heart with ventricular tachycardia. Note the relatively narrow QRS complex.

Treatment

1. In children with a structurally normal heart, the type of therapy usually depends on the stability of the patient and the rate and frequency of the tachycardia. In asymptomatic individuals with idioventricular rhythm, no therapy is required, but close follow-up is recommended. Frequently, this type of ventricular dysrhythmia resolves in the first several months of life.
2. In patients with rapid (above 200-220 bpm) or frequent ventricular tachycardia and normal ventricular function, therapy with beta blockers, generally propranolol at 1 mg/kg per dose every 6 hours, is the initial choice. If propranolol is ineffective, or beta blockers are contraindicated, then treatment with flecainide, sotalol, or amiodarone may be used with close follow-up for potential side effects.
3. In children with very fast or incessant tachycardia, or in those with decreased ventricular function, rapid control of tachycardia is important. This is best achieved with the use of intravenous medications such as amiodarone or sotalol.

Long-term therapy of neonatal ventricular tachycardia depends on its underlying cause. Many neonatal ventricular tachycardias resolve spontaneously within the first several months to years of life. Radiofrequency ablation is an option to treat those patients with refractory tachycardia but is generally not performed in these patients except under the direst of circumstances because of the risk in patients this age. If a hamartoma or tumor is identified, surgical excision should be considered, because these tumors' borders or edges are frequently visible to the naked eye on the ventricular myocardium and removing them often eliminates the tachycardia. In neonates with poor ventricular function and ventricular tachycardia, these patients may require ventricular assistance until cardiac function recovers. In severe cases, ECMO may be required to sustain perfusion until the arrhythmias can be controlled.

Implantable cardioverter-defibrillator (ICD) therapy is quite difficult in this size of patient, at least in part because of the size and bulk of the device. Their placement is typically not possible in neonates and small infants because of the large size of the ICD, ICD lead, and coil necessary for the system to function properly, but has been done.[31] The implant of these life-saving devices can be considered in children less than 1 year who are at high risk for recurrent, life-threatening ventricular arrhythmias such as long QT syndrome with multiple ventricular tachycardia/fibrillation episodes, but this is quite difficult and requires a very knowledgeable team consisting of a pediatric electrophysiologist and cardiovascular surgeon. Placing an ICD in young children is typically done by an epicardial approach requiring a median sternotomy to position. The shocking coil can either be placed over the heart or outside the pericardium, or arrays can be placed in the subcutaneous

tissue that will allow for the appropriate delivery of energy to the patient.

Toxicities and Depletions

Hyperkalemia, medication overdosing, and other metabolic disturbances such as acidosis or hypoxemia can affect the ventricular depolarization and myocardial function and result in arrhythmias. Neonates, particularly the most premature ones, may be more susceptible to these conditions, and recognizing this and the ECG characteristics of each of these conditions is important. The hallmark feature of severe electrolyte or acid-base disturbances is a loss of delineation between the QRS complex and the T wave. This ultimately results in a "sine wave" pattern on the ECG.[19] Additional abnormalities caused by electrolyte excess include a peaked appearance of T waves, ST segment elevation, and prolongation of the QT interval (Fig. 77.12). Recognition of these patterns, especially in premature neonates, allows for rapid treatment to correct the underlying disturbance, because antiarrhythmic medications are generally not helpful in these situations. For hyperkalemia, treatment depends on the severity of the hyperkalemia and ranges from removal of supplemental potassium to calcium gluconate, administering glucose, and insulin to dialysis.

Tachycardia-Induced Cardiomyopathy

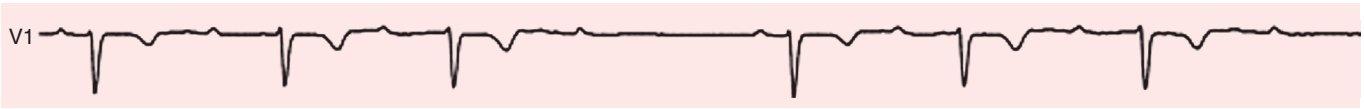
In some cases, incessant tachycardia can result in a decrease in the patient's ventricular function. When dysfunction occurs, it is often described as severe. It is important to perform an echocardiogram on all neonates with tachycardia episodes if the duration of the episode is unknown to evaluate their ventricular function or contractility and to evaluate for underlying structural abnormalities. Any form of tachycardia, be it SVT or VT, can result in depressed cardiac function if the rate is fast enough and the duration is long enough. Knowing the patient's function, by a quick function check prior to cardioversion, is a critical part of the planning for this procedure and can assist with the patient's outcome post-cardioversion. Rarely, these patients' function is so bad prior to cardioversion that they may require intubation and even circulatory assistance with either pressors or ECMO.[6]

Atrioventricular Conduction Disturbances

During normal sinus rhythm, the electrical activation wavefront initiates from the sinus node to activate the right and left atria. The activation wavefront reaches the AV node, bundle of His (the only structure penetrating fibrous AV annulus connecting atria and ventricles), and finally travels to the right and left bundle branches to activate the right and left ventricle correspondingly. There is typically a delay as the impulse goes through the AV node and bundle of His, and this delay creates the PR interval noted on the ECG in neonates.

First-Degree Atrioventricular Block

First-degree AV block (FAV) is manifested by prolongation of the PR interval on the ECG while each sinus or atrial



• **Fig. 77.12** Electrocardiogram in a patient with hyperkalemia (potassium level of 11 mEq/L). Note the sine wave pattern (particularly in lead V1) with no distinction between the QRS and T waves.

• **Fig. 77.13** Example of first-degree atrioventricular block.

• **Fig. 77.14** Patient with type 1, second-degree heart block during sleep. Progressive PR prolongation seen until QRS complex drop.

beat reaches the ventricles (Fig. 77.13). To make the diagnosis of FAV in the newborn or neonate, the PR interval needs to measure longer than 160 msec. The PR interval reflects the time from initiation of atrial activation, travel time through the atrial tissue and the AV node. Any delay of impulse propagation at any level during this activation will result in prolongation of the PR interval and the diagnosis of FAV. Although this is referred to as *first-degree heart block*, it is not true block within the conduction system, and a better terminology is "prolonged AV conduction."

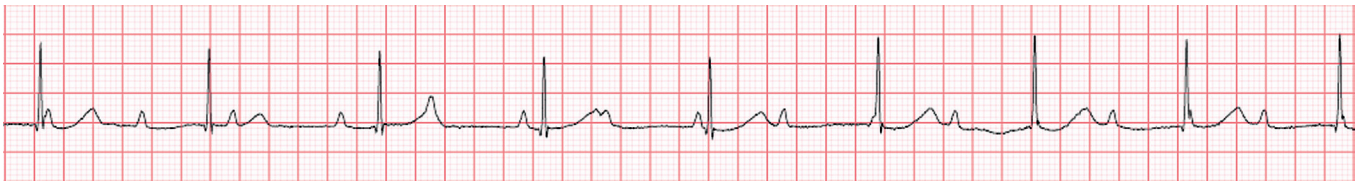
The AV node, similar to the sinus node, receives innervation from both parasympathetic and sympathetic nervous systems. Increased parasympathetic or vagal tone often leads to delay in impulse conduction through the AV node. This increase in vagal tone is the most common cause of first-degree heart block. A first-degree block frequently resolves when a catecholamine or sympathetic surge is present. The abnormal or nonphysiologic reasons for PR prolongation in a neonate are cardiomyopathies, congenital heart disease (Ebstein anomaly, primum atrial septal defect, and AV canal), and medications like digoxin.

No treatment is indicated for first-degree AV block. In cases in which a significant PR prolongation is seen, periodic follow-up may be indicated to ensure that a more advanced block does not develop. An increase in vagal tone that can be seen with reflux or apnea can result in transient prolongation of the PR interval with rapid normalization after the episode. Secondary causes such as this should be evaluated for in patients that experience episodic PR prolongation. In the neonatal period, persistent PR prolongation is uncommon and should warrant evaluation, including an echocardiogram to evaluate for structural abnormalities or myocarditis.

Second-Degree Atrioventricular Block

In patients with second-degree AV block, some, but not all, sinus beats do not conduct to the ventricles. On ECG, this results in some of the P waves not being followed by a QRS complex.

Second-degree AV block is usually divided into two forms, type 1 and type 2 block. Type 1 second-degree AV block is also referred to as Wenckebach. The ECG in patients with Wenckebach shows progressive lengthening of the PR interval until one QRS is not conducted or is "dropped." The next conducted beat typically will have a normal PR interval (Fig. 77.14). Wenckebach frequently is a physiologic phenomenon and is caused by increase in vagal tone, which can be seen in normal sleeping infants. As common as this disorder is, it is relatively rare in neonates and requires further evaluation with a Holter monitor and a cardiology consult to determine if there are any other causes. The same potential causes for sinus bradycardia also apply to Wenckebach, and careful observation for reflux, apnea, or seizures is indicated.



Second-degree type 2 AV block is another conduction abnormality that is almost never seen in the neonatal population. This type of block involves a failure of propagation of a P wave without prolongation of the PR interval before the block. Careful measurement of the PR interval is essential to determine the difference between type 1 and type 2 AV block in neonates, because the prolongation of the PR interval may be only a few milliseconds in type 1 AV block. Type 2 second-degree AV block is abnormal and requires pacemaker implantation.[12]

Third-Degree Atrioventricular Block

In the patients with third-degree or complete AV block (Fig. 77.15), there is no conduction of sinus beats from the atria to the ventricles due to abnormality of the AV node or bundle of His or both bundle branches. In this situation, ventricular activation will depend on the underlying junctional or ventricular escape rhythm from below the level of the block. The underlying junctional rhythm is typically a narrow complex, because it comes from a junctional focus. If the escape rhythm originates below the His bifurcation, the QRS will be wide.

To make the diagnosis of complete AV block, there should be no relationship between the atria and ventricles (atrioventricular dissociation) at any time. The atrial rate should be faster than the ventricular rate, and there should be P waves present that should conduct but do not. It is frequently necessary to obtain a long ECG strip or Holter

• **Fig. 77.15** Complete AV block with AV dissociation and a narrow complex junctional escape rhythm.

monitor to confirm the diagnosis, because the atrial rate and ventricular rate may be similar, giving the appearance of AV conduction when actually none is present.

Complete AV block can be either acquired or congenital. The acquired form of complete AV block in neonates is usually a complication of cardiac surgery but rarely can be caused by myocarditis or endocarditis.

The congenital form of complete AV block may be seen as an isolated anomaly or in association with a congenital heart defect. As an isolated anomaly, complete AV block is seen in children born to mothers with systemic lupus erythematosus or mixed connective tissue disease, particularly Sjögren syndrome. Antibodies that are present in the mother (most commonly anti-Ro and anti-La antibodies) cross the placenta and directly affect the function of the AV node.[29] The majority of mothers are asymptomatic during their pregnancy but have detectable antibodies when tested. Occasionally, there will be progression of the AV block from second degree to complete AV block during the pregnancy.

Congenital complete AV block occasionally goes unnoticed for many years in the patient if the underlying junctional rate is relatively fast, especially considering that most young patients tolerate complete AV block without symptoms.

Fetuses with complete heart block diagnosed in utero should *not* be delivered early solely on the basis of their heart rate. If poor ventricular function or hydrops fetalis is present, a decision should be made about delivery timing with the obstetrician, neonatologist, and pediatric cardiologist. In the immediate newborn period, assessment of hemodynamic stability should be performed immediately. Neonates frequently tolerate heart rates as slow as 50 to 60 bpm with little or no hemodynamic compromise.[26]

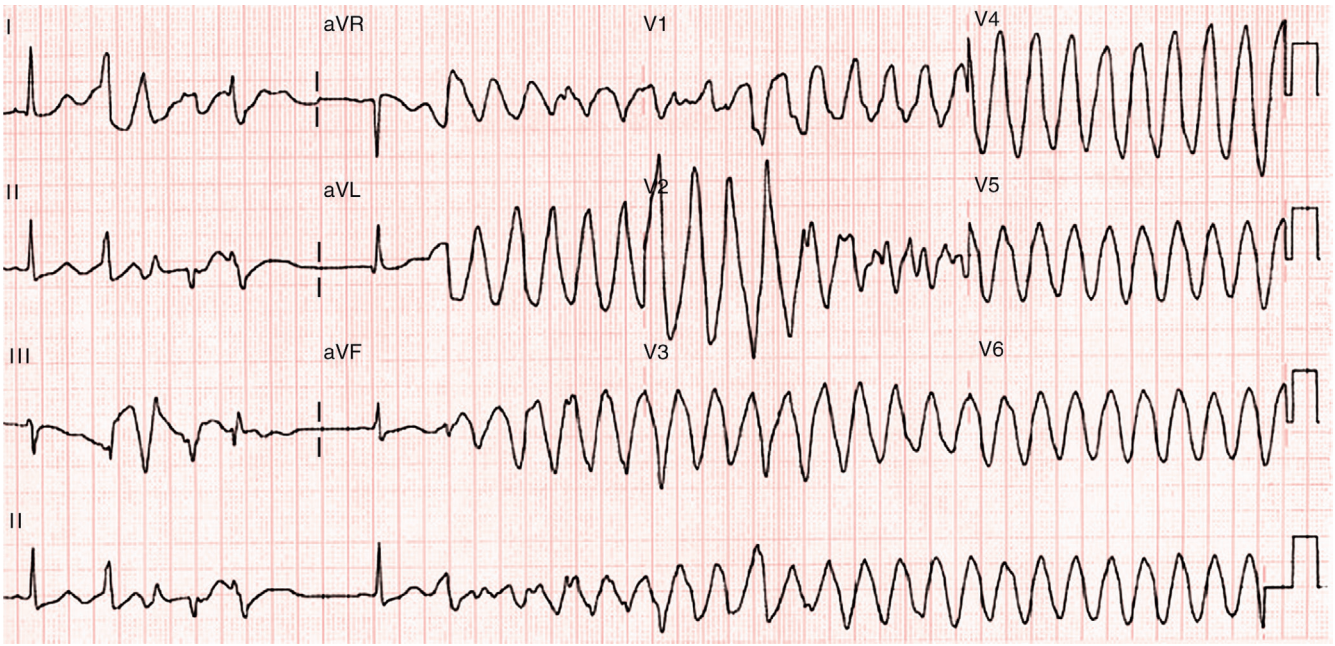
If temporary pacing is required to assist with hemodynamic compromise, this requires insertion of a temporary transvenous pacing lead since long-term transcutaneous pacing is technically challenging because of the size of the pads and the patient's need for sedation and muscle relaxation.

Long-term treatment of third-degree AV block requires the placement of a pacemaker. In many children with congenital heart block, the pacemaker implantation can be delayed until they are older, unless there are specific indications for permanent pacemaker placement, including[21,35]:

1. Presence of symptoms
2. Wide-complex escape rhythm
3. Significant pauses (more than 3 seconds or more than 2-3x the underlying basic cycle length) on Holter monitor or ECG monitoring
4. The mean heart rate below 50 bpm in patients with a structurally normal heart or 70 bpm in patients with coexisting significant congenital heart disease
5. Left ventricular dysfunction
6. Complex ventricular ectopy

If indicated, pacemakers can be placed using a transvenous (insertion through the subclavian vein, across the tricuspid valve into the right ventricle) or epicardial approach in which leads are directly sewn onto the epicardial surface of the heart after a sternotomy. In general, an epicardial approach is almost always used in neonates because of the small size of the veins and heart and the patient's future growth.

Genetic Arrhythmia Syndromes



Genetic arrhythmia syndromes are inherited disorders that lead to cardiac dysrhythmias and even death. Most of these genetic disorders are categorized as channelopathies that affect myocardial ion channels (e.g., sodium, potassium, calcium) that are responsible for the electrical impulses within the myocardium. Disruptions in these channels result in altered electrical depolarization and repolarization that can lead to atrial and/or ventricular arrhythmias. Examples of channelopathies include long QT syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT), Brugada syndrome, and short QT syndrome. Although CPVT may be a potential cause of sudden infant death syndrome (SIDS), generally long QT syndrome is likely a major culprit of neonatal arrhythmia and sudden death.

Long QT Syndrome

Congenital long QT syndrome (LQTS) is a multifaceted genetic disorder that manifests by prolongation of the corrected QT interval (QTc) on the ECG. The clinical importance of this syndrome is that it is associated with potentially lethal cardiac arrhythmias such as torsades de pointes (TdP) (Fig. 77.16). Torsades de pointes is a form of polymorphic ventricular tachyarrhythmia that frequently degenerates into ventricular fibrillation and may lead to sudden death. Because TdP frequently is not sustained, the patient with LQTS may present with recurrent syncopal episodes or seizure episodes. The syncope is the result of significantly reduced cardiac output during the arrhythmia and brain hypoperfusion that can result in true seizures.

Based on the type of channels or currents that are malfunctioning, LQTS is subdivided into multiple different subtypes. The majority of known LQT cases are caused by

• **Fig. 77.16** Episode of torsades de pointes initiation in a patient with long QT syndrome.

LQT1, LQT2, and LQT3 syndromes, and the type of mutation frequently can be determined by genetic testing.

Although patients may have a prolonged QT interval on their ECG, they may not have long QT syndrome. There are other causes of a prolonged QT interval on the ECG, including medications (methadone, erythromycin, albuterol, etc.) and electrolyte disturbances (hypocalcemia, hypokalemia). These must be evaluated as a cause or exacerbating factor for the prolongation of the QT interval on the neonate's ECG. Drug-induced QT prolongation (particularly when the QTc is >500 msec) can result in life-threatening ventricular arrhythmias similar to congenital long QT syndrome.

Clinical Presentation

In older patients, there are typical triggers for each of the long QT syndromes. The typical event triggers in patients with LQT type 1 are exercise or emotional stress. In patients with LQT type 2, symptoms are usually triggered by sudden noise (e.g., alarm clock, doorbell), but can be caused by exercise as well. Patients with type 3 LQT syndrome typically become symptomatic at rest or during sleep.

In neonates, LQTS can present in a multitude of ways. It may be picked up incidentally on an ECG done for another reason or done for a family history of LQTS. It may present as a pseudo or pure AV block, either complete or 2:1. In any patient with AV block, the QT interval must be carefully evaluated to ensure that an underlying diagnosis of long QT syndrome is not present. Long QT syndrome may also present with ventricular arrhythmias. In fact, some SIDS cases may result from arrhythmias due to LQTS.[27,38] Any patient presenting with torsades de pointes should have a high index of suspicion for having long QT. Other ventricular arrhythmias should warrant evaluation of the QT interval on a routine ECG.

Electrocardiogram Findings and Diagnosis

The hallmark of LQTS is prolongation of the corrected QT interval. Measuring the QT interval in newborns can be difficult, because they frequently have flattened T waves, making determination of the exact end point of the T wave difficult. There may be transient prolongation of the QT interval seen immediately after birth that may resolve in the first week of life. QTc intervals greater than 500 msec should always be considered to be abnormal and require further evaluation. Intervals greater than 500 msec are likely caused by LQTS in the absence of a medication prolonging the QTc, electrolyte disturbances, or other medical conditions known to prolong the QTc interval (e.g., brain injury). In the immediate newborn period, QTc intervals are typically less than 450 msec, but those identified between 450 and 500 msec require further evaluation, because many patients with corrected QT intervals in this range will not have an underlying channelopathy. However, the longer the QTc interval, the more likely it is that the patient has an abnormality causing the QT prolongation, and a QTc of >500 is never normal.

By general consensus, the QTc interval is best measured in leads II and V5 on the ECG. To prevent common errors in measuring and overestimating the QT interval, the complex with a sharp T-wave ending should be selected if possible. U waves that are not greater than 50% of the height of the T wave should not be included when measuring the QT interval. Because the QT interval varies with heart rate, it must be corrected using one of several formulas. The most commonly used is Bazett's formula, in which

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

the measured QT interval is divided by the square root of the previous R to R interval (interval from one QRS complex to the next QRS complex) with all values measured in seconds (not milliseconds):

$$\text{Corrected QT } (QT_C) = \text{QT Interval (sec)} \Big/ \sqrt{(\text{RR interval})}$$

Because a long QT syndrome is a genetic disorder, screening with an ECG of all first-degree relatives of affected individuals is recommended. If a positive genetic test is noted in the index case for a long QT mutation, genetic testing is recommended on all first-degree relatives. Genetic testing is available and positive in at least 75%-80% of patients with long QT syndrome. If no genetic testing is available, ECG screening of all first-degree relatives should be performed. Genetic testing should be considered in all patients with LQTS, because it may predict the course of disease and suggest medication therapy.

Treatment

All patients with LQTS should avoid medications known to have QTc prolonging effect (www.crediblemeds.org, accessed February 18, 2018). Patients with LQTS should be started on a nonselective beta blocker (typically nadolol or propranolol) as soon as a diagnosis is made or suspected and consultation with a pediatric cardiologist with expertise in long QT syndrome is indicated.[28,33] Neonates with AV block caused by LQTS are at a particularly high risk of life-threatening ventricular arrhythmias and sudden death. Pacing may be an effective treatment in preventing episodes of pause-dependent torsades de pointes in this population, and placement of a permanent pacemaker is generally indicated in these patients prior to discharge. Some have attempted sympathectomy.[30]

Treatment of Torsades de Pointes

In patients who present with recurrent TdP, in addition to standard therapy, the following therapy should be considered:

1. Discontinue any potential offending drug. Avoid amiodarone if possible because this may further prolong the QT interval.
2. Magnesium bolus and continuous infusion even if the serum magnesium level is normal. Magnesium decreases calcium influx, thus lowering the amplitude of early after-depolarizations (EAD), which frequently cause TdP.[17,32]
3. Isoproterenol can be used if magnesium is unsuccessful. Isoproterenol may increase the baseline heart rate and may prevent bradycardia or pause-dependent episodes.

Key Points

- Neonates can experience all forms of arrhythmias from the benign to life threatening.
- Atrial flutter is seen in newborn babies, and the initial treatment is synchronized cardioversion.
- Intravenous adenosine is the treatment of choice for the hospitalized neonate in supraventricular tachycardia to convert the baby back into normal rhythm.
- Sixty to eighty percent of newborn supraventricular tachycardias resolve by 1 year of age.
- Not all patients born with congenital complete atrioventricular block require the immediate implantation of a pacemaker.

Neonatal Management of Congenital Heart Disease

MARTIN L. BOCKS, BRIAN A. BOE, AND MARK E. GALANTOWICZ

Introduction

Neonates with congenital heart disease require a well-integrated and multidisciplinary team approach to achieve optimal outcomes. The complexity of managing a critically ill newborn is compounded greatly when the cardiovascular physiology and/or anatomy are significantly altered. Many of the important management principles routinely followed by neonatologists can be applied to critically ill newborn cardiac patients, including thermal regulation, prematurity issues, nutritional strategies, and ventilator support. However, cardiac-specific management strategies, procedures, and surgeries are often required during the neonatal period for patients with congenital heart disease (CHD). These unique strategies must be understood and carefully integrated into the management plan. The objective of this chapter is to describe these management strategies and procedures typically performed based on the prevailing anatomic or physiologic deficit faced by the infant during the neonatal period, as opposed to each specific anatomic variant of CHD. Since many of these conditions have similar underlying physiologies as well as early goals for palliation or treatment, the strategies employed can be applied to many different disease conditions.

As described in earlier chapters, the vast majority of congenital heart conditions (e.g., small ventricular septal defects [VSD] or bicuspid aortic valves) either do not require any interventions whatsoever or require interventional or surgical procedures later in infancy or early childhood. Although patients in the latter category may be managed in the neonatal ICU or co-managed with the pediatric cardiology service, their clinical courses are often straightforward and team discussions are typically focused on the anticipated follow-up and postdischarge planning. Examples of such conditions include the "pink" tetralogy of Fallot patient that will undergo surgical repair at 4-6 months of age or the mild valvar pulmonary stenosis patient that develops worsening obstruction in the coming months requiring balloon pulmonary valvuloplasty. This chapter focuses on congenital heart disease typically requiring medical management, catheter-based interventions, or surgeries in the neonatal period. It describes current approaches to moderate and severe forms of congenital heart disease in which neonatal palliation or treatment is required to avoid early mortality or long-term disability. The chapter also discusses those situations in which early intervention would not alter clinical course and for which the best course of management may be cardiac transplantation or palliative comfort measures.

Moderate and severe forms of congenital heart disease can be largely grouped as cyanotic and acyanotic conditions (Table 78.1). Within these major silos, conditions can also be classified based on the degree of pulmonary blood flow and whether or not they are dependent on the patent ductus arteriosus (PDA) for either pulmonary or systemic blood flow. By classifying these conditions in this manner, neonatologists will be able to more readily identify the major physiologic deficit and anticipate necessary treatment options. For patients requiring surgery in the neonatal period, the focus within this chapter is on the indications and types of surgery that can be offered. The postoperative management of these patients is not discussed, as a detailed description of the theories and summary of available evidenced-based practice is outside the scope of this chapter.

Cyanotic Congenital Heart Conditions

Cyanotic congenital heart disease (CCHDs) includes a broad class of anatomic and physiologic derangements that result in patients with decreased systemic oxygenation following birth, including 1) obstruction to pulmonary blood flow with an intracardiac shunt such as an atrial septal defect (ASD) or VSD or 2) admixture lesions in which there is a common site for mixing of systemic and pulmonary venous blood (atria or ventricles) which is pumped to both circulations, 3) transposition physiology in which systemic venous blood is pumped to the systemic circulation, 4) pure right to

Abstract

Neonates with congenital heart disease require a well-integrated and multidisciplinary team approach to achieve optimal outcomes. The complexity of managing a critically ill newborn is compounded greatly when the cardiovascular physiology and/or anatomy are significantly altered. Many of the important management principles routinely followed by neonatologists can be applied to critically ill congenital heart patients; however, cardiac-specific management strategies, procedures, and surgeries are often required during this period to allow for long-term survival and to avoid significant morbidity. These unique strategies must be understood and carefully integrated into the management plan. The objective of this chapter is to describe these management strategies and procedures that are used to achieve early repair or temporary palliation for these many different disease conditions.

TABLE 78.1 Physiologic Classification of Congenital Heart Disease

Cyanotic			Acyanotic	
Right-side Obstruction	Admixture Lesions	Transposition Physiology	Left-side Obstruction	Left-to-right Shunts
Pulmonary atresia with intact ventricular septum	Common atrium	Transition of the great arteries	Aortic stenosis	Atrial septal defect
Pulmonary atresia, VSD, and MAPCAs	Double inlet left ventricle		Coarctation of the aorta	Atrioventricular septal defect
Pulmonary stenosis	Double outlet right ventricle		Interrupted aortic arch	Patent ductus arteriosus
Tetralogy of Fallot	Hypoplastic right/left heart syndrome			Ventricular septal defect
	Total anomalous pulmonary venous connection			
	Tricuspid atresia			
	Truncus arteriosus			

MAPCA, Major aortopulmonary collateral arteries; VSD, ventricular septal defect.

left shunting (e.g., pulmonary arteriovenous (AV) malformations). The first three broad categories are more frequently encountered in the neonatal period and will be discussed more in the coming sections. The therapies required for palliation or repair of CCHDs differ tremendously within these three classes depending on other anatomic variations that are present. For example, in the admixture lesion tricuspid atresia, pulmonary blood flow is determined by the size of the VSD and relationship of the great arteries. If the VSD is large and the great arteries are normally related (i.e., the pulmonary artery arises off the rudimentary right ventricle), there is normal to increased pulmonary blood flow. This infant's oxygen level will be fairly normal in the neonatal period. However, if the VSD is restrictive and/or the great arteries are transposed (i.e., the pulmonary artery is remote from the VSD and right ventricle), pulmonary blood flow can be considerably limited, resulting in significantly low oxygen levels in the absence of a PDA. Therefore, as we discuss cyanotic congenital heart disease palliation and treatment, the following sections focus more on the immediate goals required to stabilize, palliate, or definitively treat patients in the neonatal period, including approaches for maintaining patency of the ductus arteriosus and less on the specific type of CCHD. Historically, most of these conditions requiring neonatal treatment were managed in the operating room, including a number of surgeries still currently performed (Table 78.2). However, advancements in device technology and increasingly available devices small enough for neonatal use, has led to an increasing number of CCHD that are treated via transcatheter interventions (Table 78.3).

Procedures to Increase Pulmonary Blood Flow

There are many CCHDs in which obstruction of pulmonary blood flow (PBF) is the underlying etiology for systemic desaturation. The specific anatomic or physiologic issue causing the limited PBF varies considerably and, therefore, the approach to augment pulmonary blood flow is situation dependent. The different methods and approaches used to increase pulmonary blood flow are described in this section.

Balloon Pulmonary Valvuloplasty

Balloon pulmonary valvuloplasty (BPV) was first described by Kan in 1982[27] and is an effective strategy to increase pulmonary blood flow in patients with either isolated pulmonary valve stenosis or when found in combination in more complex congenital heart disease (Fig. 78.1*A, B*). Current indications for balloon pulmonary valvuloplasty include patients with either critical pulmonary stenosis (ductal-dependent pulmonary blood flow and/or severe right ventricular dysfunction) or in a patient with a peak instantaneous gradient of ≥40 mm Hg on echocardiography.[16] The procedure typically results in a significant reduction in the pressure gradient across the valve and carries very good mid- and late-term results.[11,59,63] A small number of patients will develop significant subvalvar gradient immediately following balloon pulmonary valvuloplasty secondary to significant right ventricular hypertrophy and infundibular narrowing. This temporary obstruction can be managed medically with increased right ventricular volume and beta blockers.[60] Balloon pulmonary valvuloplasty can also be performed in patients with tetralogy of Fallot when the predominant level of obstruction is at the valvar level. This is typically a palliative intervention to allow patients to mature and grow until a complete repair can be done at 4-6 months of age.

Pulmonary Valve Perforation With Balloon Pulmonary Valvuloplasty

Pulmonary atresia with intact ventricular septum is a right-sided obstructive lesion in which there is no antegrade

TABLE 78.2 Common Named Cardiac Operations Performed in Infants

Named Surgery	Surgical Description	Purpose
Norwood	Anastomosis of PA to hypoplastic ascending aorta, arch augmentation	Create new "aorta" from pulmonary trunk and patch
Damus-Kaye-Stansel	Anastomosis of PA to ascending aorta	Combine great arteries for systemic flow to bypass subaortic obstruction
Blalock-Taussig shunt	Gore-Tex tube from subclavian artery to PA	Supply pulmonary blood flow
Sano shunt	Gore-Tex tube from the RV to PA	Supply pulmonary blood flow
Bidirectional Glenn	Anastomosis between SVC and PAs	Supply low-pressure pulmonary blood flow
Fontan	Anastomosis between IVC and PAs	Supply low-pressure pulmonary blood flow
Jatene	Arterial switch for d-transposition of the great arteries	Anatomical correction
Rastelli	VSD closure and RV-PA conduit placement	Create new "main pulmonary artery"

IVC, Inferior vena cava; PA, pulmonary artery; RV, right ventricle; SVC, superior vena cava; VSD, ventricular septal defect.

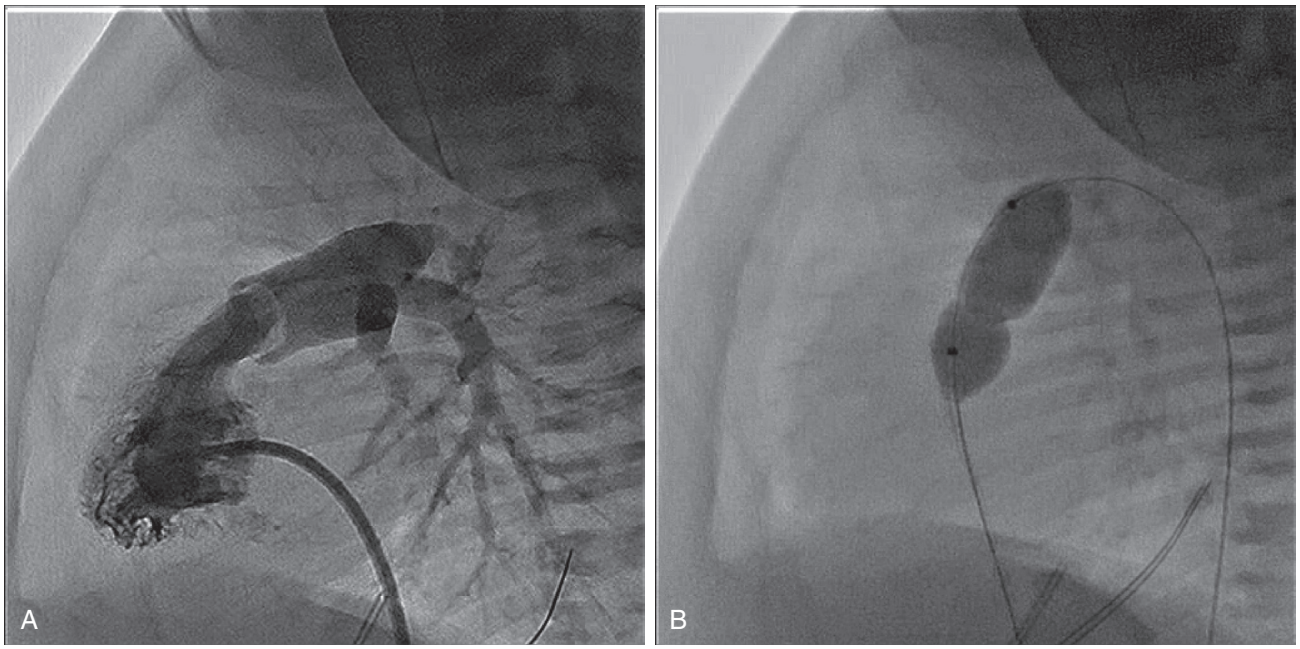

TABLE 78.3 Neonatal Cardiac Lesions and Typical Catheter-Based Therapy

Primary Problem	Hemodynamic Etiology	Defects	Intervention(s)	Result
Cyanosis	Atrial septal restriction	d-TGA with restrictive atrial septum	Balloon atrial septostomy	Improvement in atrial mixing and oxygen saturation
	Decreased pulmonary blood flow	Critical pulmonary stenosis Pulmonary atresia	Balloon pulmonary valvuloplasty Valve perforation and valvuloplasty	Improvement in pulmonary blood flow and oxygen saturation
		TOF	RVOT stenting PDA stenting	
		BT shunt occlusion (HLHS, TOF, TA, PA)	BT shunt balloon dilation and/or stenting	
Left-sided obstruction	Left ventricular outflow tract obstruction	Critical aortic stenosis	Balloon aortic valvuloplasty	Decrease left-sided obstruction
		Critical coarctation	Angioplasty/stenting of coarctation	
Decreased cardiac output	Pulmonary overcirculation causing congestive heart failure	Patent ductus arteriosus Atrial septal defect* Ventricular septal defect	Device closure*	Eliminate or decrease left-to-right shunt
Vascular obstruction	SVC syndrome	Typically iatrogenic	Angioplasty and/or stent*	Unobstructed flow

BT, Blalock-Taussig; HLHS, hypoplastic left heart syndrome; PA, pulmonary artery; PV, pulmonary vein; RVOT, right ventricular outflow tract; SV, single ventricle; SVC, superior vena cava; TA, tricuspid atresia; TAPVR, total anomalous pulmonary venous return; TGA, transposition of the great arteries; TOF, tetralogy of Fallot.
*Only rarely performed in the neonatal period.

flow from the right ventricle, and pulmonary blood flow is entirely dependent on the PDA. Complete mixing occurs at the atrial level, and all blood is pumped from the left ventricle to the aorta. In this condition, neonates must be started on prostaglandins to maintain ductal patency immediately after birth. If the tricuspid valve and right ventricle are of adequate size, a biventricular repair may be considered. In these situations, patients will be referred to the catheterization laboratory to ensure the coronary arteries fill normally from the aorta and not the hypertensive right ventricle (i.e., not right ventricular–dependent coronary circulation). Pulmonary valve perforation with

• **Fig. 78.1** Balloon pulmonary valvuloplasty in a neonate with critical pulmonary valve stenosis. A baseline lateral angiogram shows the stenotic and doming pulmonary valve **(A)**, which then undergoes balloon pulmonary valvuloplasty using a standard balloon **(B)**. During balloon inflation, a waist is seen at the level of the valve annulus.

balloon pulmonary valvuloplasty is indicated in patients with favorable anatomy (membranous atresia) without right ventricular–dependent coronary circulation. This intervention was first reported by Latson in 1991.[31] The technique involves advancing a guidance catheter antegrade from the femoral vein, across the tricuspid valve, and into position directly beneath the atretic pulmonary valve. The optimal target site for perforation is then defined by both right ventricle angiography and aortic angiography, which fills the main pulmonary artery via the PDA. Currently, the most commonly performed method to perforate the membrane is to advance a small radiofrequency (RF) wire within the guide catheter into contact with the membrane. The RF wire delivers a focused energy pulse at the tip to precisely "burn" a small hole in the pulmonary valve membrane. The RF wire is passed through the pulmonary valve membrane into the main pulmonary artery. Perforation can also be accomplished by using a small coronary wire, but the RF wire approach is considered safer and more controlled. Once the valve is perforated and crossed, balloon pulmonary valvuloplasty is performed (Fig. 78.2*A-D*). This procedure can result in improved antegrade flow from the right ventricle to the pulmonary artery, often allowing for the eventual discontinuation of prostaglandins. This process can sometimes take many weeks before prostaglandins can be discontinued and months before growth of the annulus and entire right ventricular outflow tract is observed. It is not uncommon for patients to require repeat balloon pulmonary valvuloplasty in the first 6 months. If repeat balloon pulmonary valvuloplasty does not result in adequate antegrade pulmonary blood flow, surgical intervention is typically required.[35]

Right Ventricular Outflow Tract Stenting

Severe obstruction of the right ventricular outflow tract (RVOT) can be seen in patients with tetralogy of Fallot and double outlet right ventricle leading to severe cyanosis. Some patients will undergo a complete surgical repair in the neonatal period depending on the patient's weight, size of branch pulmonary arteries, and extracardiac medical issues. Certain centers will perform aortopulmonary shunts (see below) for cyanotic patients with small branch pulmonary arteries and bring them back for complete surgical repair at 4-6 months of age. Balloon pulmonary valvuloplasty is typically not effective in this anatomy given the severe subvalvular obstruction across the right ventricular outflow tract. Over the past 10 years, centers have started palliating these patients by implanting stents across the right ventricular outflow tract.[12,20] During the procedure, the RVOT and main pulmonary artery are imaged using angiography. The RVOT is then crossed with a catheter, and wire position is established to guide the procedure. A stent is selected based on the size of the right ventricular outflow tract. The stent is advanced over the wire and typically through a long introducer sheath until it is positioned across the RVOT. The stent is deployed within the RVOT and follow-up angiography is then performed to assess the adequacy of antegrade flow through the implanted stent. Multiple stents may need to be placed depending on the anatomy of the right ventricular outflow tract. Most patients maintained on prostaglandins can be weaned off the medication following stent implantation within the right ventricular outflow tract. In premature or small neonates or those with vascular access issues, hybrid per-ventricular stenting of the RVOT, whereby

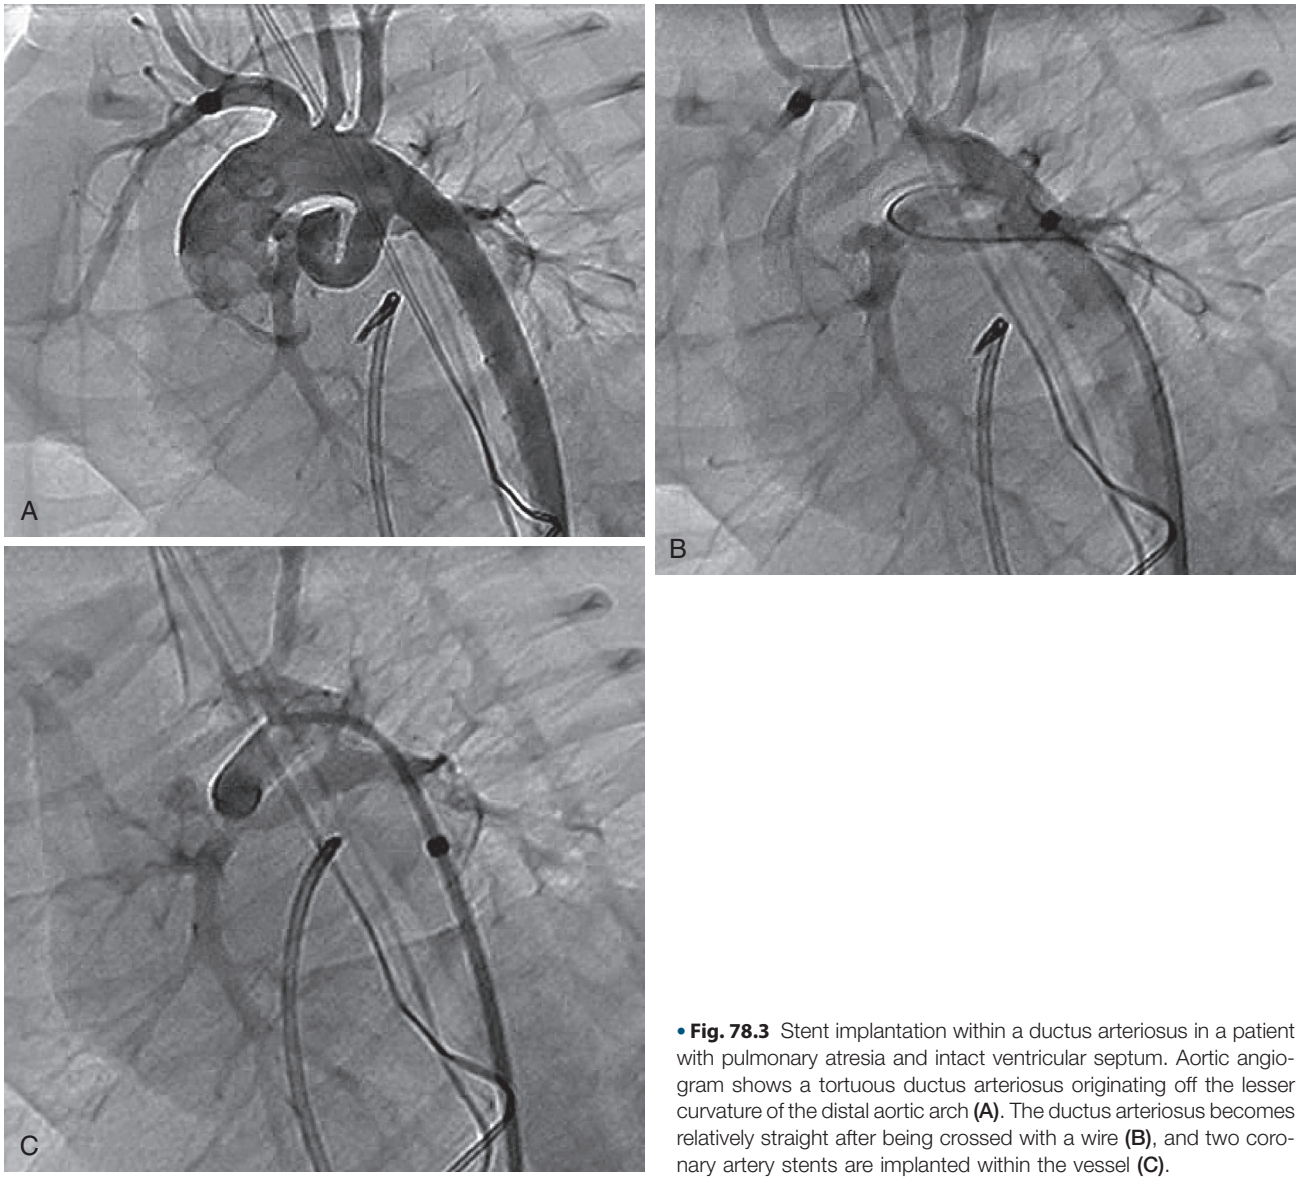
• **Fig. 78.2** Pulmonary valve perforation in a neonate with pulmonary atresia and intact ventricular septum. The lateral view of the right ventricular outflow tract angiogram confirms the diagnosis **(A)**. Simultaneous right ventricular and aortic angiogram show both sides of the pulmonary valve plate **(B)**. The valve is perforated with a radiofrequency wire **(C)**, and subsequent balloon valvuloplasty results in good antegrade flow through the right ventricular outflow tract **(D)**.

the pediatric heart surgeon places the sheath directly into the right ventricle via a small sub-xiphoid incision, allows effective palliation in this challenging population.[10] In either approach, these stents are removed at the time of surgical repair, which is ultimately delayed to allow for growth in both the patient and branch pulmonary arteries.[55]

Surgical Opening of the Right Ventricular Outflow Tract

In neonates that are not candidates for a complete surgical repair or palliation with balloon angioplasty/stenting of the RVOT, either percutaneously or using hybrid techniques, an open surgical procedure can be used. The operation is performed via a median sternotomy on cardiopulmonary bypass. The goal of the procedure is complete relief of right ventricular outflow tract obstruction whereby the actual technique used depends on the level of obstruction—valvar, supravalvar, or subvalvar—and can range from a simple pulmonary valvotomy or valvectomy to a complete transannular patch opening of the subvalvar, pulmonary valve, and supravalvar regions. The resultant pulmonary insufficiency is usually very well tolerated.

Implantation of a Stent in the Ductus Arteriosus



There are many congenital heart defects in which pulmonary blood flow is dependent on flow via the ductus arteriosus. The most common of these lesions are the more severe cases of tetralogy of Fallot. Additional congenital heart lesions where pulmonary blood flow is dependent on ductal arterial flow includes pulmonary atresia with and without a

VSD, double outlet right ventricle with pulmonary atresia, and some forms of tricuspid atresia. The vast majority of these patients are typically treated with surgical palliation, including an aortopulmonary shunt (e.g., modified Blalock-Taussig shunt). Similar to RVOT stenting, advancements in catheter-based technology and techniques have allowed for some of these patients to be palliated by implantation of a stent in the ductus arteriosus. The procedure is typically performed retrograde from the femoral artery or via a vessel off the aortic arch (carotid or axillary artery). The procedure may also be accomplished antegrade from the femoral vein, particularly when there is antegrade flow through the right ventricular outflow tract.[58] The prostaglandin infusion is usually stopped a few hours before the anticipated start of the procedure to allow for some constriction of the ductus arteriosus to occur. Prostaglandins are kept in line in case of severe ductal spasm causing profound cyanosis. Angiography is performed to delineate the length and size of the ductus arteriosus. A guide wire is used to carefully cross the often tortuous ductus arteriosus and used for procedural guidance. An appropriately sized stent is then advanced over the wire and deployed across the ductus arteriosus (Fig. 78.3*A-C*). This interventional palliation procedure can last many months until the patient can undergo complete surgical repair.[53]

Systemic to Pulmonary Artery Shunts

The ability to augment pulmonary blood flow by a surgically created shunt between the aorta, or one of its branches, and the central pulmonary arteries has a long history dating back to 1945 with the introduction of the Blalock-Taussig (BT) shunt. The classic BT shunt was performed using the divided subclavian artery as an end-to-side anastomosis to the pulmonary artery. Soon other shunt techniques were introduced, such as the Potts shunt, a direct anastomosis between the descending aorta and the left pulmonary artery,

• **Fig. 78.3** Stent implantation within a ductus arteriosus in a patient with pulmonary atresia and intact ventricular septum. Aortic angiogram shows a tortuous ductus arteriosus originating off the lesser curvature of the distal aortic arch **(A)**. The ductus arteriosus becomes relatively straight after being crossed with a wire **(B)**, and two coronary artery stents are implanted within the vessel **(C)**.

and the Waterston shunt, a direct anastomosis between the ascending aorta and the right pulmonary artery. These techniques had in common a shunt that not only augmented pulmonary blood flow but could palliate over a long period of time because of the growth potential of the native tissue construction of the shunt. These shunt techniques are essentially obsolete today for two reasons: 1) with growth of the shunt there is a lack of control over the amount of pulmonary blood flow creating the risk of pulmonary overcirculation, pulmonary vascular disease, and pulmonary hypertension; and 2) the advent of rapid second-stage procedures for successful infant complete repair for two ventricle anatomies or the use of subsequent cavopulmonary shunts for single ventricle anatomies. Therefore, today the most common palliative, neonatal surgical shunt is the modified BT shunt whereby a prosthetic graft is anastomosed proximally end-to-side to the innominate artery or ascending aorta and distally end-to-side to the central pulmonary artery, with flow being controlled by the diameter of the graft chosen, typically 3-4 mm in a neonate.

Procedures to Decrease Pulmonary Blood Flow

In the previous section, the focus was on cyanotic CHD in which pulmonary blood flow is restricted. The conditions described in that section usually tend to make intuitive sense since less pulmonary blood flow is easily reconciled with cyanosis and hypoxia. However, there are forms of cyanotic heart disease, particularly admixture lesions, in which there is often excessive pulmonary blood flow and arterial saturations are often only mildly decreased.

Admixture lesions are forms of congenital heart disease in which blood from the systemic and pulmonary veins mix within the heart via a single or multiple defects (predominantly at the atrial level). When blood is completely mixed within the heart, then arterial saturation is dependent on the size of the left-to-right shunt or amount of pulmonary blood flow and whether or not there is preferential streaming of saturated or desaturated blood to the aorta. Variations in the size and location of the outflow tracts determine where the "mixed" blood is ejected. Patients with admixture lesions and unrestricted pulmonary blood flow develop pulmonary overcirculation which can result in respiratory distress/failure, difficulty feeding, failure to thrive, and potentially necrotizing enterocolitis. If left unabated, excessive pulmonary blood flow (PBF) can lead to changes in the pulmonary arterioles causing irreversible elevation of the pulmonary vascular resistance. This is of particular importance for single ventricle patients as elevated pulmonary vascular resistance can make the patient ineligible for eventual Fontan surgical palliation. To prevent these problems from developing, patients with admixture lesions and excessive PBF require interventions to limit or control the amount of flow to the lungs, often as part of a series of staged palliation surgeries for functional single ventricle anatomy and physiology.

Pulmonary Artery Banding

The current mantra in congenital heart surgery is early complete repair due to improved operative techniques as well as improved peri-operative management, resulting in excellent outcomes even with complex neonatal CHD. Therefore, the tendency is away from palliating babies to allow for growth or an older age before two ventricle repair is considered. Nevertheless, there are certain forms of CHD in which a palliative step, such as pulmonary artery banding to restrict pulmonary blood flow is necessary before complete repair is attempted. Examples include anatomic defects that continue to carry a higher risk of suboptimal early repair, such as multiple apical ventricular septal defects or patients with otherwise repairable anomalies, but have significant associated co-morbidities, such as prematurity or intracerebral hemorrhage. In these situations, a pulmonary artery band can be an effective palliative technique to control pulmonary blood flow. Also, pulmonary banding is frequently used as a first-stage procedure in the management of certain single ventricle physiologies, such as tricuspid atresia or double inlet left ventricle. The procedure can be performed via a thoracotomy or sternotomy depending on the anatomy, planned concomitant procedures, and surgeon preference. Technical aspects include creating a space between the aorta and main pulmonary artery through which a nondistensible band of prosthetic material is passed as a ring around the main pulmonary artery. The band is located between the valve and the origin of the branch pulmonary arteries. The band is then tightened to the desired effect again based on the underlying anatomy, physiology, and planned next stage. In general, the goals of a pulmonary artery band are to improve the balance of systemic to pulmonary artery circulation and to protect the distal pulmonary vasculature from unrestricted pressure and flow. Achievement of balanced flow guided by the changes in systemic oxygen saturation with tightening, and the pressure restriction is demonstrated by reduction in the pulmonary artery pressure distal to the band. In patients without a main pulmonary artery, such as truncus arteriosus, and those in which complete neonatal repair is not possible, separate banding of the left and right branch pulmonary arteries is possible. Recovery from pulmonary artery banding is usually fairly quick and patients are often easier to manage once the degree of PBF is appropriately restricted.

Procedures to Increase Mixing of Systemic and Pulmonary Venous Blood

Certain forms of cyanotic congenital heart disease are dependent on adequate intracardiac mixing of blood to maintain adequate oxygen saturations in the neonatal period. This includes conditions with transposition physiology and most admixture lesions. When inadequate mixing occurs in patients with admixture lesions, disproportionate streaming of the deoxygenated blood to the systemic circulation results

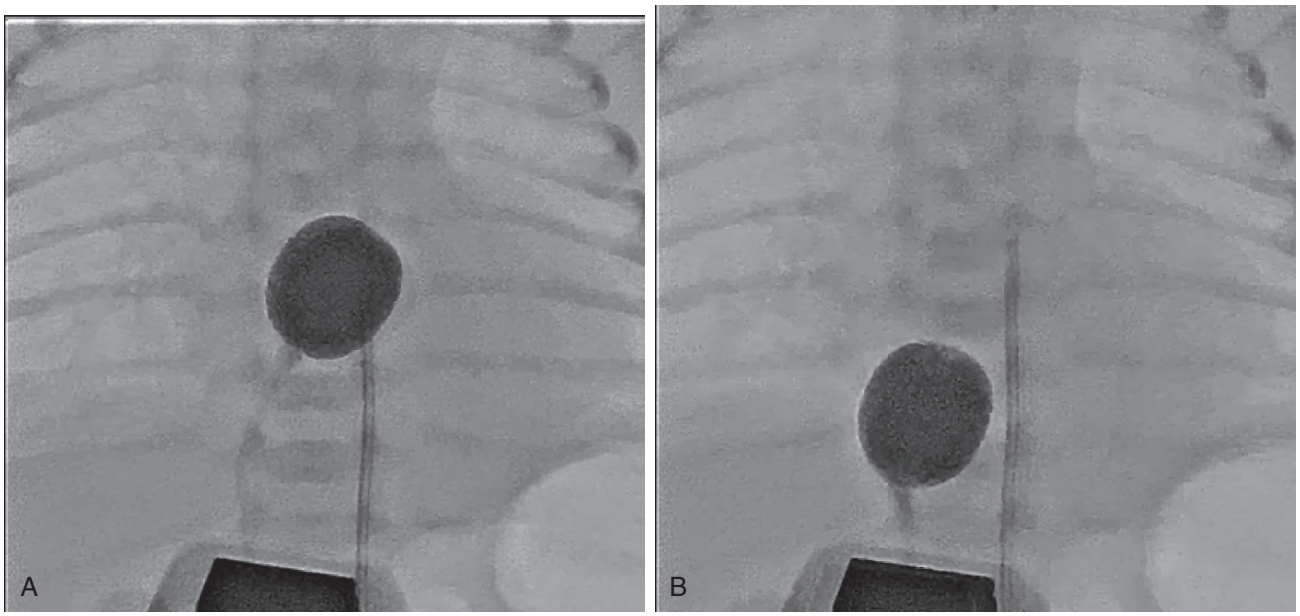
TABLE 78.4 Congenital Heart Lesions That May Require Neonatal Atrial Septostomy

Diagnosis	Reason for Intervention	Flow after Intervention	Special Considerations
d-Transposition of great arteries	Cyanosis	Bidirectional	
Tricuspid atresia	Decreased cardiac output	Right-to-left	If late—may need blade septostomy or stent placement
Ebstein anomaly	Decreased cardiac output	Right-to-left	
Total anomalous pulmonary venous return	Decreased cardiac output	Right-to-left	
Hypoplastic left heart syndrome	Pulmonary edema	Left-to-right	If septum is thick—may need septostomy or stent placement

in severe cyanosis. To demonstrate this, consider hypoplastic left heart syndrome (HLHS), in which the left-sided structures are not adequate to support a full cardiac output. To provide the systemic circulation with adequate quantities of oxygenated blood, there must be unrestricted flow from the left atrium to the aorta (left atrium→right atrium→right ventricle→pulmonary artery→ductus arteriosus→aorta). Thus, unrestricted atrial communication is necessary for both adequate oxygenation and maintenance of cardiac output. Furthermore, without unrestrictive atrial communication, left atrial hypertension develops because of the inability of pulmonary venous return to unload. This leads to pulmonary venous hypertension and subsequent pulmonary edema with pulmonary artery hypertension. This can be devastating for patients with single ventricle admixture lesions.

In the cyanotic condition d-transposition of the great arteries (D-TGA), the pulmonary and systemic circulations are maintained in parallel as opposed to in series. Oxygenated blood is pumped from the right ventricle to the lungs and deoxygenated blood is pumped from the left ventricle to the aorta. Unlike admixture lesions, cardiac output to the systemic circulation is normal and is not dependent on atrial level shunting. Similarly, though, if there is inadequate mixing of blood predominantly at the atrial level, the resulting physiology is not compatible with survival because of the development of severe hypoxemia. In the early newborn period, for a D-TGA patient with restrictive or intact atrial septum, the patent ductus arteriosus provides the minimal mixing necessary to maintain arterial saturations still compatible with life. However, as the ductus arteriosus constricts, the two circulations have almost no communication and severe prohibitive cyanosis results. For these patients, it is crucial to begin a prostaglandin infusion immediately after birth when the diagnosis is known or suspected. In these situations, despite maintenance of a PDA, severe cyanosis results as the ductus arteriosus alone is not an adequate source of mixing, and atrial opening is required.



In summary, all admixture lesions and conditions with transposition physiology require adequate mixing at the atrial level for survival in the neonatal period. In some cases, this involves the creation of an atrial level communication, and in other cases, enlargement of a restrictive existing communication (patent foramen ovale [PFO] or ASD) is required. In this section, we describe current approaches available to provide unrestrictive atrial level communication for both admixture lesions and conditions with transposition physiology (Table 78.4).

Balloon Atrial Septostomy

Balloon atrial septostomy (BAS) is the standard method for enlarging an existing atrial communication when there is inadequate mixing. The most common indication is d-transposition of the great arteries with restrictive atrial septum, which occurs in one-third of neonates with this condition.[5] Following TGA, the second-most common indication for balloon atrial septostomy occurs in the single ventricle admixture lesion HLHS. The balloon atrial septostomy procedure has been performed for more than 50 years and remains the optimal approach in most cases because of the relative safety and efficacy when performed by experienced operators.

The standard BAS procedure can be done either in the catheterization laboratory or bedside in the neonatal intensive care unit. Procedural guidance is typically provided by fluoroscopy, echocardiography, or combination of both. Performing the procedure in the catheterization laboratory allows for additional procedures to be performed (i.e., coronary angiography) and allows easy access to additional catheterization equipment should the procedure be technically difficult. Bedside BAS under echocardiographic guidance has been shown to be a safe and more cost-effective approach in patients with d-transposition of the great arteries.[67] The procedure can be performed via femoral venous access or by taking over the umbilical vein catheter. The BAS catheter is advanced under fluoroscopic or echocardiographic guidance until it is seen to be in the left atrium across an existing PFO/ASD (Fig. 78.4*A, B*). The balloon is inflated in the left atrium and a quick, forceful, yet controlled, "jerk" is performed to pull the inflated balloon through the existing communication. The septum tears during this process,

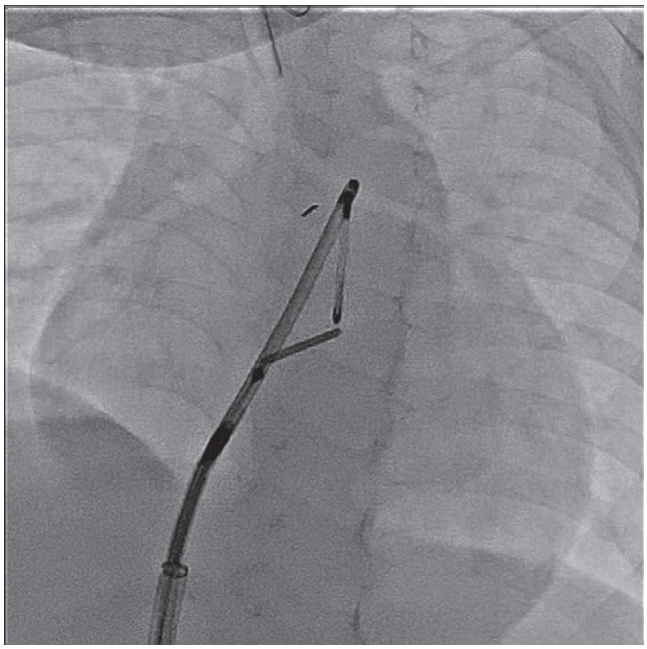
resulting in a larger atrial communication and hopefully unrestricted atrial shunting.

In the event of a thick septum that does not tear, repeat BAS is not advised and a different approach must be sought for the patient. If the patient is profoundly hypoxemic before and during the procedure, it is not uncommon to develop pulmonary hypertension or maintain high pulmonary vascular resistance (PVR). In this setting, pulmonary blood flow is restricted and does not allow for enough of the mixed blood to be pumped to the lung to receive oxygen. Profound cyanosis may persist despite echocardiographic evidence of an unrestrictive atrial communication. In these situations, patients should be started on inhaled nitric oxide and allowed time for their pulmonary vascular resistance to drop, which results in improved arterial saturations.

Other Atrial Septostomy Techniques

Balloon atrial septostomy may not be effective if the atrial septum is thick or completely intact. If there is an existing communication between the atria, this can be crossed and made larger with other transcatheter interventions. If no atrial communication exists, the atrial septum may be crossed using the radiofrequency wire (described in the RVOT perforation section), a radioperforation transseptal needle, or with a standard transseptal needle.[9,23,32] Once the thick or intact septum is perforated, a guidewire can then be passed through the perforation and positioned into a left-sided pulmonary vein. At this point, there are multiple options that the operator can choose for opening the atrial septum, including static balloon septoplasty, blade atrial septostomy, and atrial septal stenting.



Static Balloon Septoplasty

Static balloon atrial septoplasty involves inflating a balloon that is stretched across the newly created perforation. As opposed to a standard BAS, a static BAS is repeated several times with progressively larger balloons. Static BAS is rarely effective for a sustained period of time if only standard angioplasty balloons are utilized. Cutting balloon septoplasty is much more effective at widening a newly created perforation and producing a more sustained outcome. Cutting balloons have four small atherotomes (microsurgical blades) attached to the longitudinal surfaces positioned 90 degrees to each other. These are designed to score the tissue against which it is in contact during inflation. The balloon is deflated and rotated/repositioned, and additional inflations are performed to create more score lines. The opening can then be further dilated with larger diameter static balloons, which tears the tissue along the multiple scored cut lines.

Blade Atrial Septostomy

The Park blade septostomy catheter is a catheter with a retractable blade at its distal end (Fig. 78.5). Once the atrial septum has been crossed, typically a long sheath is advanced over the wire into the left atrium. The blade septostomy catheter is advanced out the tip of the sheath, which is withdrawn into the right atrium. The blade is then pulled back through the septum, slicing the atrial septal tissue along the way. The blade produces a deeper slice in the atrial tissue compared to the cutting balloons, so it is important that the septum is crossed at a fairly central point. After blade septostomy, the cut hole can then be dilated with progressively larger static balloons.

• **Fig. 78.5** A blade septostomy performed in a patient with tricuspid atresia who underwent banding of the main pulmonary artery. The procedure involves opening a retractable blade on the end of a catheter and making a small slice in the atrial septum. This is followed by a balloon septostomy or septoplasty.

Atrial Septal Stenting

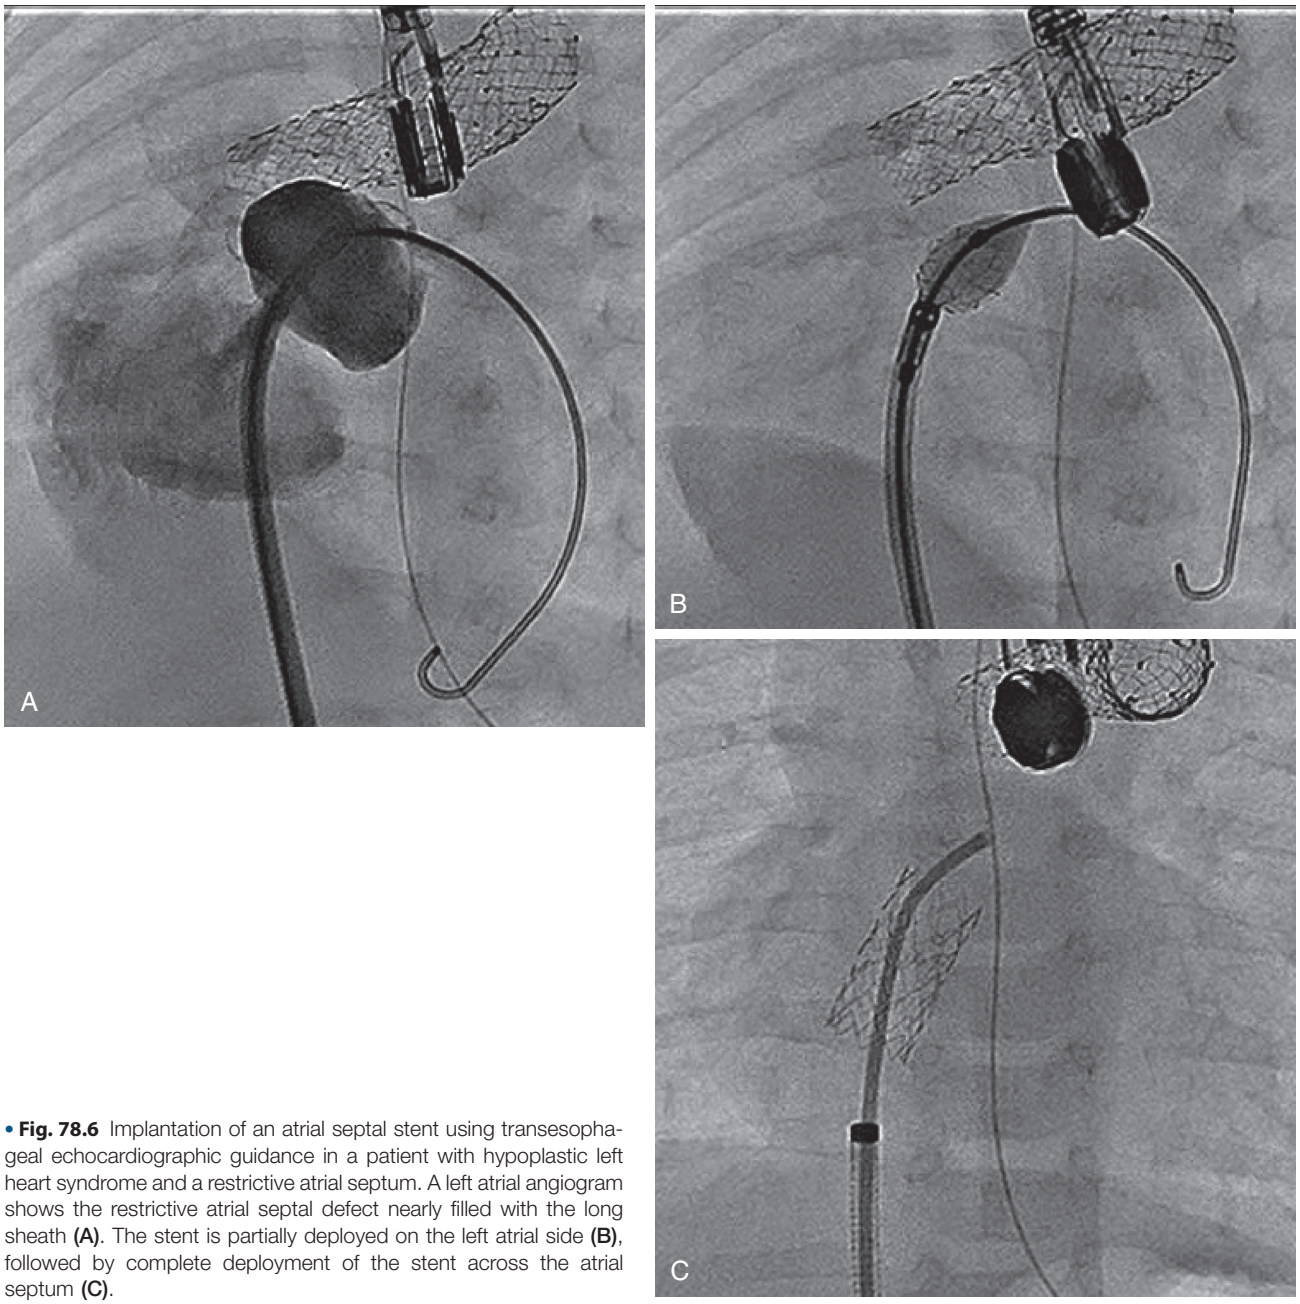
In very small patients with thick and/or intact atrial septa, cutting and static BAS are often ineffective and the blade septostomy unsafe, as the blade is too large for the small left atrium. In these situations, an atrial communication is best created by implanting a premounted stent across the atrial septum. After perforating, crossing the atrial septum, and gaining stable wire position, a long sheath is passed into the left atrium. A premounted stent (typically 6-8 mm in diameter) is advanced through the delivery sheath and over the guidewire until half of it is seen in the left atrium using fluoroscopy and transesophageal echocardiography guidance. The delivery sheath is slowly retracted and efforts are made to ensure positioning is balanced on both sides. Once this is confirmed, the balloon is inflated and the stent is deployed (Fig. 78.6*A-C*). The stent is resected with the atrial septectomy procedure during a subsequent planned surgical operation.

Atrial Septectomy

A hybrid approach to opening the atrial septum is sometimes an option whereby the surgeon places a sheath directly into the atrium, without the use of cardiopulmonary bypass, through which the interventional cardiologist can perform the atrial septal balloon or stenting techniques previously described. In newborns that are not candidates for hybrid or percutaneous transcatheter strategies to open the atrial septum, a surgical atrial septectomy can be performed. The operation is performed through a median sternotomy on cardiopulmonary bypass. The goal of the operation is complete excision of the atrial septum creating a reliable and durable opening. Surgical atrial septectomy in the neonate is almost exclusively performed on patients with single ventricle anatomy and physiology.[23]

Acyanotic Congenital Heart Conditions

Acyanotic forms of congenital heart disease represent a much more straightforward class compared to the cyanotic conditions discussed in the prior sections. Acyanotic conditions that require interventions or medical management in the neonatal period are typically those that involve outflow obstruction. As such, the management approaches tend to be more standardized and consistent, but patient comorbidity and clinical status can necessitate the use of novel methods of treatment.



Left-Sided Obstruction

Patients born with obstruction on the left side of the heart (e.g., valvar aortic stenosis, interrupted aortic arch, coarctation of the aorta) are often asymptomatic in the immediate newborn period. The oxygen saturation might be normal during the screening pulse oximetry if only checked in the upper extremity. These patients may appear well clinically and have been discharged to home. However, as the ductus arteriosus closes, systemic cardiac output is dramatically reduced and the neonate will present in shock and with end organ dysfunction. Although the incidence of undiagnosed postnatal presentation has dramatically dropped with contemporary prenatal and postnatal congenital heart disease screening, studies have shown that the prenatal detection rate for isolated aortic arch obstruction still hovers around 20%-30%.[51] Therefore, there continues to be a significant number of patients who will present postnatally every year, and the neonatologist will need continued vigilance for these patients. The approaches to dealing with these left-sided obstruction lesions are discussed in the following sections.

Balloon Aortic Valvuloplasty

Balloon aortic valvuloplasty is performed in the newborn period in patients who present with critical or severe valvar aortic stenosis. The first reported balloon aortic valvuloplasty was reported in 1983 by Lababidi, and the procedure has been markedly improved upon over the last few decades, predominantly related to the availability of a compliant balloon with very small crossing profiles (down to 3 French).[64] Recommendations for limiting the balloon diameter:annulus ratio to 80%-100% has greatly improved the procedural results, in which relief of obstruction is obtained without causing severe degrees of valvar regurgitation.[7,38] However, the procedure itself can be technically difficult and has a much higher risk profile in the neonatal population, and balloon aortic valvuloplasty should only be performed by experienced operators and with surgical backup nearby. The condition is most commonly approached retrograde

from the femoral artery but can also be performed via the femoral vein if an atrial communication is present. In smaller patients, the procedure can be performed via a surgical cut-down or direct percutaneous access of the common carotid artery.[46] A smaller balloon:annulus ratio can be performed first, with progressively larger balloons if a significant residual pressure gradient remains. Multiple studies have defined a successful neonatal balloon aortic valvuloplasty as a reduced aortic valve gradient ≤35 mm Hg with no worsening aortic valve insufficiency.[7,50,61]

Surgical Aortic Valve Repair or Replacement

In newborns with aortic valve stenosis not amenable to transcatheter techniques, surgical repair or replacement is indicated. These operations are performed via a median sternotomy on cardiopulmonary bypass with aortic cross-clamping, allowing direct visualization of the aortic valve. In the newborn with isolated aortic valve stenosis, the most common anatomic construct is a bicuspid or unicuspid valve with fused commissures. In this setting, a controlled commissurotomy can effectively increase the valve orifice without significant insufficiency. Other surgical repair techniques can be utilized depending on the anatomy encountered.

For neonates with aortic valves that cannot be repaired, replacement options are limited and suboptimal, because there are no bioprosthetic valves manufactured small enough to fit a neonate, and even if there were, they cannot grow to match

the rapid somatic growth of an infant. In these situations, or in infants with combined aortic valvar and left ventricular outflow tract (LVOT) obstruction, the only option is aortic root replacement with either a cryopreserved human cadaveric homograft or the patient's own pulmonary valve as an autograft (Ross procedure). The disadvantage of a homograft includes the known risk of early calcification especially in the neonate, leading to valve dysfunction, the lack of growth potential, and the increased risk of repeat coronary artery reimplantation. Therefore, the Ross procedure has become the replacement option of choice in neonates.[14,39] The principles of the operation include reconstructing the LVOT and replacing the aortic valve with the child's own living tissue—a pulmonary root autograft (rim of right ventricular muscle, valve, and the main pulmonary artery), reimplantation of the coronary arteries, and replacement of the pulmonary valve with a pulmonary valve homograft. In theory, this operation exchanges aortic valve disease for pulmonary valve disease with the reasoning that repeat interventions on the aortic valve carry increasing risk, while repeat interventions on the pulmonary valve are not only less frequent but less risky.

Coarctation of the Aorta

Coarctation of the aorta is often discovered on prenatal ultrasound and with early postnatal screening. However, as stated above, many cases are still missed even when standard prenatal care is provided. The cases of coarctation detected prenatally are typically the more severe forms, and it is usually recommended that these mothers deliver these infants at centers where neonatal and surgical treatment can be provided. For cases in which prenatal detection has not occurred, postnatal symptoms develop with the advent of ductus arteriosus closure. These symptoms include poor feeding, respiratory distress, and eventually shock-like appearance because of low cardiac output. The postnatal diagnosis is typically confirmed using surface echocardiogram, which typically shows isthmus hypoplasia (periductal area), a posterior shelf causing flow acceleration on Doppler interrogation, and often varying degrees of transverse arch hypoplasia. The severity and even presence of coarctation of the aorta can often not be fully appreciated in the setting of a moderate- or large-sized patent ductus arteriosus, so it is helpful to get echocardiographic confirmation as soon as possible when a prostaglandin infusion is started. However, in cases of severe low cardiac output, the initiation of prostaglandins should not be withheld to allow time to obtain the echocardiogram. Coarctation of the aorta that presents in the neonatal period is often long segment and less likely to be discrete. Surgical repair of native coarctation presenting in the neonatal period remains the standard treatment of choice. Interventional therapies can be considered in certain situations, in which surgery is thought to be too high risk and an interim palliative procedure is required.

Surgical Repair of Coarctation

The most common form of neonatal coarctation is often referred to as "juxtaductal" coarctation, which manifests as a discrete area of aortic narrowing at the junction of the ductus arteriosus to the aortic isthmus. It occurs within the first few days or weeks of life as the constrictive process that normally closes the ductus arteriosus extends into the adjacent aortic tissue leading to the clinical manifestations previously described. In this setting, the typical operation is a coarctation segment resection with a primary end-to-end anastomosis of native aortic tissue. This operation is performed via a thoracotomy without cardiopulmonary bypass. The principles of the operation include division of the ductus arteriosus, complete resection of the coarctation segment of the aorta and any adjacent ductal tissue, and mobilization of the proximal and distal segments of aorta, establishing a tension free end-to-end anastomosis. Sometimes the proximal opening needs to be extended into the undersurface of the distal aortic arch to enlarge that segment, hence the term extended end-to-end anastomosis. The benefits of this operation include complete relief of obstruction, and growable and durable repair, at very low risk. The potential downsides of the operation include inability to address any transverse aortic arch hypoplasia as well as a circumferential aortic suture line that may develop resistant scar tissue leading to recurrent stenosis at this site.

The other form of neonatal coarctation is hypoplasia of the entire aortic arch. This is repaired via a median sternotomy on cardiopulmonary bypass, allowing access to the entire aortic arch. The typical reconstruction includes division of the ductus arteriosus, resection of ductal tissue, and long segment patch augmentation of the entire aortic arch from distal ascending aorta to mid-descending thoracic aorta. The patch augmentation leaves a posterior wall of native aortic tissue that allows growth of the reconstructed aorta.

Transcatheter Treatment of Coarctation

Transcatheter therapies for neonatal coarctation are typically performed when definitive surgical repair is deferred because of patient comorbidities. The most common reason for intervention is a patient presenting in shock because of ductal closure in whom the ductus arteriosus cannot be opened or cannot be opened enough to allow for effective resuscitation and resolution of end organ dysfunction.[52] In these situations, the coarctation is treated with balloon angioplasty, during which a balloon is inflated across the lesion to provide temporary relief of the obstruction and resuscitation of end organs until eventual surgical correction can be performed. The most common acute complication associated with balloon angioplasty is femoral arterial injury. Long-term complications of balloon coarctation angioplasty that does not end up needing surgical repair include pseudoaneurysm formation and recurrent coarctation. Recurrent coarctation of the aorta following surgery is often treated in the catheterization laboratory with balloon angioplasty and/or implantation of a stent.[6,17] Implantation of a stent across a neonatal coarctation lesion is rarely performed, and usually only when palliative angioplasty alone does not open the obstructed area adequately. The use of primary stenting in the neonatal period is limited by the size of introducer sheath required to implant the stent

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

via the femoral artery. This limitation can be overcome by using a hybrid surgical approach via a cut-down on the carotid artery or percutaneously via direct carotid access. Work is currently underway to develop bioresorbable stents that could be implanted in the neonatal period, dissolve over a period of 6-18 months, and then be stented again with larger stents, potentially obviating the need for surgical repair.[22]

Pulmonary Artery Stenosis

Isolated branch pulmonary artery stenosis outside of the commonly encountered peripheral pulmonic stenosis (PPS) is rarely encountered in the neonatal period. The most common cause is due to constriction of the proximal left pulmonary artery following ductus arteriosus closure. In severe cases, the left pulmonary artery can become completely obstructed or isolated if not treated early. Moderate lesions can typically be treated via balloon angioplasty, but severe lesions often require stent implantation for a sustained result. Although there are stents that can be placed in the neonate, many of them cannot be dilated to the size of an adult pulmonary artery. As a result, these stents are placed as a palliative step when future surgical intervention is anticipated. At the time of surgical intervention, these small stents can either be surgically removed or transected, allowing for enlargement of the vessel. Studies have demonstrated that some of these stents may be fractured with high pressure balloons or "unzipped," but this is highly dependent on the type of stent used.[40,57] Similar to neonatal stenting of aortic coarctation, bioresorbable stents may prove to be a useful therapeutic option in this patient population.[37]

Treatment of Patent Ductus Arteriosus

A patent ductus arteriosus is commonly encountered in the premature neonate. Large PDAs can result in significant left-to-right shunting with medical consequences, including respiratory failure, renal insufficiency, and feeding intolerance. The management of hemodynamically significant PDAs in the neonatal period, particularly the premature and extreme premature population, is controversial and very institutional and provider dependent. Longstanding methods for PDA closure include medical therapy with prostaglandin inhibitors and surgical ligation. Medical closure of PDA is covered extensively in other chapters (Chapter 74), so will not be addressed in this section. Surgical closure has been the gold standard for over 60 years and remains the standard approach when medical therapy fails. This is performed via posterolateral thoracotomy, and typically a clip is placed on the PDA vs. suture ligation and division. Surgical PDA ligation is essentially 100% effective and is typically performed safely when done by experienced operators. However, the procedure is not without risk, and complications include vocal cord paralysis, pneumothorax, diaphragm paralysis, and postligation cardiac syndrome. Much of the morbidity and mortality of PDA surgical ligation is related to the preoperative clinical status of the neonate and, therefore, the timing of when patients are referred for surgical ligation is crucial.

Over the past 5 years, many institutions have started pursuing transcatheter approaches for neonatal PDA closure using off-label devices approved for other vascular occlusion indications. Transcatheter PDA closure in older infants and children with stainless steel coils and nitinol-based devices has been performed since the 1970s with great success. As a result, PDA surgical ligation outside of the neonatal population is almost never performed. The unique neonatal ductal anatomy and small patient size have limited the occlusion of neonatal PDAs with traditional FDA-approved devices. However, the development of smaller interventional devices and delivery catheters has now allowed for safe transcatheter occlusion of the ductus arteriosus in premature neonates.[33,56,66] Although a learning curve for this procedure exists and widespread experience is limited, by instituting a thoughtful and intentional approach, PDA device closure can be performed safely and effectively in premature infants.[3,33,56,66] To this point, the FDA recently approved the first device designed for occlusion of a PDA in a neonate (Piccolo, Abbott). The most common complication is arterial vascular injury when arterial access is used as part of the procedure.[3] When only venous access route is used, obstruction of the left branch pulmonary artery or descending thoracic aorta is the next most commonly observed issue. This is usually discovered before the device is released by angiography or transthoracic echocardiogram, at which time the device can be safely removed and another size or device can be tried, or the patient is referred for surgical ligation. Further research and cumulative experience with both approved (on-label) and off-label devices will hopefully demonstrate transcatheter PDA closure to be safe and effective for many premature infants.

Miscellaneous Procedures

Some heart conditions or combination of conditions cannot be easily placed into one of the major physiologic groups detailed above or deserve special attention on their own. The following section contains surgical, transcatheter, or hybrid interventions that do not fall fully into one of the rubrics above.

Pulmonary Vein Stenosis

Isolated pulmonary vein stenosis is a rare anomaly in the neonate, is associated with poor outcomes, and is commonly seen in conjunction with other defects. Stenosis of multiple pulmonary veins is associated with pulmonary venous hypoplasia, poorer prognosis and is more common in infants born extremely premature, especially those with coexisting intracardiac shunt lesion.[13] This condition can be congenital or acquired after a pulmonary vein repair operation. Interventional experience with this condition is growing, with multiple case series describing balloon angioplasty (both conventional and cutting balloons) and stent implantation for this lesion.[4,47] The process of progressive pulmonary vein

stenosis is poorly understood but appears inflammatory or sclerosing in nature. There have been some reports of successful outcomes using drug-eluting stents and balloons to attempt to reduce or halt the inflammatory process.[42]

There are few neonatal cardiac surgeries that need to be performed emergently, as medical or catheter-based therapies can usually allow more time for adequate diagnostic imaging and screening. An exception to this is obstructed total anomalous pulmonary venous return, wherein pulmonary venous blood does not have an adequate egress. This leads to pulmonary edema and severe pulmonary hypertension. Respiratory failure quickly develops, followed by a drop in cardiac output caused by profound cyanosis and sequestered pulmonary venous blood from the heart. Stenosis of a vein that drains pulmonary venous flow in total anomalous pulmonary venous return (i.e., vertical vein) can be stented to stabilize or palliate the patient until a surgical repair can be performed.[29] Surgical treatment of obstructed total anomalous pulmonary venous return is described in the next section.

Surgical Repair of Total Anomalous Pulmonary Venous Return

Total anomalous pulmonary venous return (TAPVR) is an embryologic failure of fusion of the confluence of the pulmonary veins to the adjacent left atrium. The pulmonary venous return finds its way back to the heart via a communicating vein in one of four ways: 1) supracardiac—is the most common, whereby the confluence of the pulmonary veins drain into an ascending vertical vein that connects to the innominate vein then the superior vena cava; 2) infracardiac—has a descending vertical vein draining into the portal vein or inferior vena cava; 3) cardiac—has a direct communication from the confluence to the coronary sinus; and 4) mixed— is the least common and has some combination of the previous three. If there is any obstruction or stenosis of this communicating pathway, profound cyanosis and hemodynamic compromise rapidly ensues, creating a surgical emergency. Often these newborns are in crisis before a diagnosis is made, winding up on ECMO support without a clear etiology. Once on ECMO, the diagnosis may be more difficult to make by echocardiography; therefore, the treating clinicians need to maintain a high index of suspicion for TAPVR, sometimes requiring advanced imaging or catheterization to confirm the diagnosis. The surgical repair of TAPVR is done via a median sternotomy on cardiopulmonary bypass. The principles of the operation include direct anastomosis of the anterior wall of the confluence of the pulmonary veins to the posterior wall of the adjacent left atrium as well as ligation of the communicating vein. Typically, a PFO or small atrial septal defect is left to help the management of potential postoperative pulmonary hypertensive events.

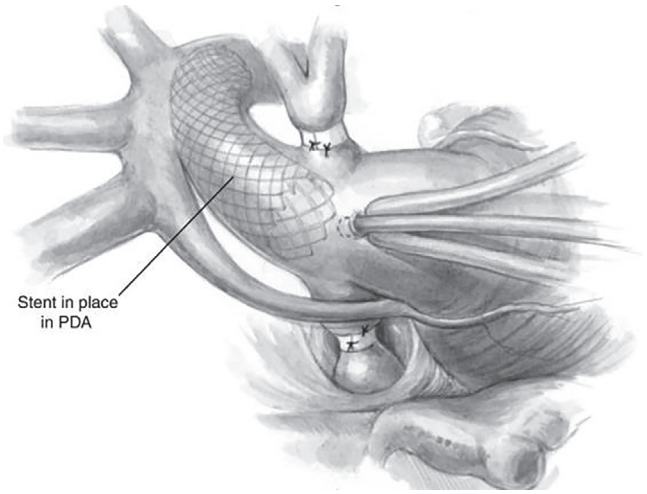
Central Line Placement

Neonates with congenital heart disease often require indwelling central venous catheters and arterial monitoring lines for prolonged periods of time. This is the reason there is a high prevalence of venous and arterial occlusion in the congenital heart disease population, especially in those with functional single ventricle heart conditions. The importance of obtaining umbilical venous and arterial access immediately after birth cannot be emphasized enough. Studies have shown that single ventricle patients who have umbilical venous lines placed instead of femoral lines have had significantly lower complication rates of vascular thrombosis and occlusion.[1] Furthermore, these patients require multiple catheterization procedures in their lifetime, and occluded femoral veins or arteries complicate these procedures considerably and can make some future interventions impossible to perform. If nonumbilical access is required, practice is to use the smallest catheter necessary for medical management. Use of single lumen instead of double lumen results in less vascular occlusion. Tunneling central lines is associated with less thrombosis and a decreased rate of central line–associated blood stream infections. Placement of catheters in the upper extremities or neck vessels is not recommended in single ventricle patients prior to the Fontan operation. If catheters are necessary in these positions, anticoagulation should be administered immediately after placement, and the line should be removed as soon as it is safely possible to reduce the risk of vascular stenosis or occlusion. Finally, when other alternative sites of access have been exhausted, transhepatic lines can be placed in the catheterization laboratory and have been shown to be a feasible and safe alternative in infants with otherwise limited access.[41]

Pericardiocentesis

Pericardiocentesis or pericardial drain placement can be safely performed in the neonate. The procedure is typically guided by transthoracic echocardiogram but can be performed by landmark alone in emergency cases when the patient is suffering from cardiac tamponade. There are multiple causes for tamponade, but in the neonate one of the most common causes is associated with indwelling central venous catheters. It is not known whether the mechanism of tamponade is perforation or simple diffusion across a very thin atrial wall, but analysis of the effusion often shows similar fluid composition to the infusate.[62]

Fetal Cardiac Intervention



Fetal cardiac intervention (see Chapter 13) has been the subject of much interest over the past 10 years. Its use is attractive in some of the congenital cardiac defects with poor outcomes secondary to valvar obstructions, which can lead to ventricular hypoplasia. There are currently three catheter-based interventions that have been performed in fetuses with congenital heart disease: balloon valvuloplasty in aortic valve stenosis (with impending hypoplastic left heart syndrome), balloon valvuloplasty in pulmonary atresia with intact ventricular septum (with impending hypoplastic

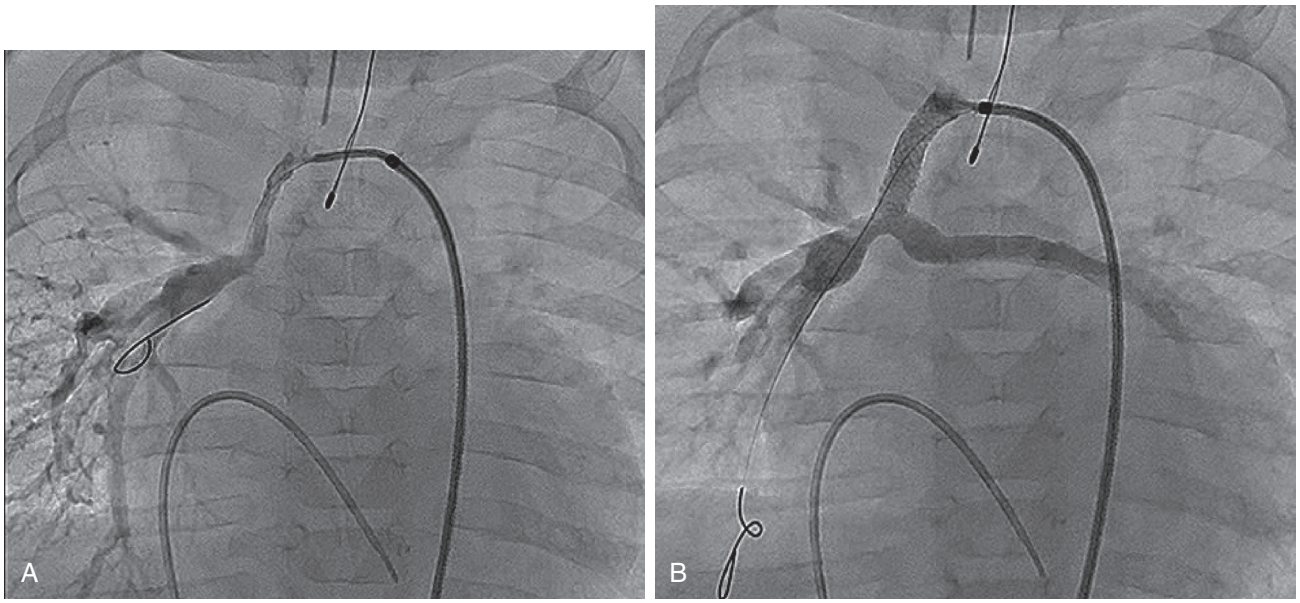
right ventricle), and atrial septal defect creation or enlargement in hypoplastic left heart syndrome with restrictive or intact atrial septum. Fetal cardiac interventions are not performed as standard of care at all heart centers and are typically only performed at centers with experienced teams made up of high-risk OB (maternal-fetal medicine), fetal cardiology, and interventional cardiology. As such, it is common for centers who do not offer the procedure to refer patients to one of the experienced centers. There is a non-insignificant risk to the fetus and potentially the mother, so candidates for fetal cardiac intervention must be carefully screened and vetted before the decision to proceed is made. Accurate diagnosis and referral for intervention must be made early enough in gestation to allow for potential reversal of disease progression following. Lastly, information regarding the natural history of these defects is not completely understood, making it difficult to predict which fetus will develop ventricular hypoplasia and should undergo these high-risk fetal interventions.[34] The mortality associated with these procedures is improving as experience is gained. Nevertheless, it is still not clear-cut that early fetal intervention will consistently alter disease progression beyond the watchful waiting and treating the high risk neonate with established strategies.[36]

Hybrid Stage I Palliation

The hybrid approach has emerged as an alternative treatment strategy for the management of hypoplastic left heart syndrome (HLHS) and other complex neonatal heart anomalies beginning in the early 1990s.[19,54] The term *hybrid* refers to procedures performed, during which a combination of surgical and interventional methods are utilized. Because published medium-term results of the hybrid procedure demonstrated outcomes comparable to surgical palliation, this alternative approach was adopted by many more institutions.[18] The initial palliation with a Hybrid Stage 1 procedure is performed without the use of cardiopulmonary bypass and typically includes three steps: 1) bilateral branch pulmonary artery bands that protect the lungs from persistent high pressure and flow, while balancing the pulmonary versus systemic circulations 2) a stent in the patent ductus arteriosus (PDA) to assure unobstructed systemic blood flow; and 3) atrial balloon septostomy, or rarely stenting, to assure unrestricted flow from the left atrium to the right atrium (Fig. 78.7). This Hybrid Stage 1 palliation has been used successfully in patients with standard risk factors, those with a high-risk profile, as a tool for salvage, as a bridge to heart transplantation, and as a bridge to a two-ventricle repair. All forms of HLHS have been successfully palliated with a Hybrid Stage 1 procedure including aortic atresia/mitral atresia with a diminutive ascending aorta. Moreover, neither patient size nor prematurity have proven to be a contraindication to using this strategy nor has significant associated co-morbidities. That is why the Hybrid Stage 1 is used in many centers for their high-risk patients with known poor outcomes with more traditional surgical approaches. The Hybrid Stage 1 procedure is performed via a median sternotomy, without cardiopulmonary bypass, whereby bilateral branch pulmonary artery bands are placed and a PDA stent is inserted. A balloon atrial septostomy (BAS) can be performed at the same time using a hybrid transatrial approach or standard percutaneous femoral approach, or the BAS can be performed several days later in the cardiac catheterization lab. Serial echocardiography is used to assess for obstruction at the atrial septum, through the PDA stent, or restriction to antegrade or retrograde flow in the transverse aortic arch. Any sign of obstruction and/or worsening right ventricular function or worsening tricuspid valve regurgitation warrants a cardiac catheterization. Any obstruction can almost always be successfully treated in the cardiac catheterization lab with return to baseline function.



• **Fig. 78.7** Artistic depiction of a Hybrid Stage I palliation from the surgical view. Surgical bands have been placed on the bilateral branch pulmonary arteries. The main pulmonary artery is directly accessed above the pulmonary valve and a stent has been implanted along the entire length of the ductus arteriosus (from branch pulmonary arteries to the descending aorta).

Shunt Obstruction

One of the most feared complications of systemic to pulmonary artery shunts is complete or near complete shunt occlusion in patients dependent solely on the shunt for pulmonary blood flow. When severe cyanosis develops secondary to shunt obstruction, the two treatment strategies include surgical revision or transcatheter intervention. If possible, this is best dealt with in the cardiac catheterization lab to avoid another midline sternotomy. In the event of complete occlusion, patients sometimes need to be stabilized on extracorporeal membrane oxygenation (ECMO) to provide adequate oxygenation and then can be transported to the cardiac catheterization lab. Transcatheter interventions include simple balloon dilation, thrombus evacuation, or stent implantation within the shunt (Fig. 78.8*A, B*).[28] Interventions for modified Blalock-Taussig shunt obstructions are usually approached from the femoral artery. RV-PA (Sano) shunts are typically approached from the femoral

• **Fig. 78.8** Stent implantation within a modified Blalock-Taussig shunt. A selective angiogram shows a stenotic shunt with poor filling of the left pulmonary artery (**A**). Following stent implantation, there is improved diameter of the shunt and improved filling of the left pulmonary artery (**B**).

vein.[48] For partial or near occlusion, these procedures carry a high risk, as crossing the already obstructed shunt further decreases the diminutive pulmonary blood flow and can lead to severe cyanosis and cardiac arrest. Nevertheless, when performed by experienced operators the success rate is encouraging and surgical revision is rarely required.

Neonatal Heart Transplantation

Heart transplantation in the neonate continues to be reserved for those babies with congenital cardiac anomalies or cardiomyopathies that are not amenable to repair. Even high-risk single ventricle conditions such as hypoplastic left heart syndrome are rarely treated primarily with heart transplantation. The reasons for this are many, as highlighted in the 2017 report of the International Society for Heart and Lung Transplantation.[8] The number of infant (<1 year old) heart transplantations performed in North America and Europe combined has been stable for years at only about 120 per year. Not only is this a reflection of the limited indications for transplantation, but more importantly it reflects the severely limited donor pool of this rare resource. Patient survival is about 75% at 8 years and 50% at 22 years, which is somewhat better than reported results for older children.[26] Reasons for the improved survival rate include the immaturity of the immune system leading to decreased antibody-mediated rejection. In addition, neonatal transplant patients have been shown to have less graft vasculopathy[68] and require less immune suppression.[25] However, there are lifelong challenges with immunosuppression and the balance of rejection and infection that lead to a continuous risk hazard of significant morbidities. The continuous risk of developing a malignancy is 10% at 10 years, primarily lymphomas as well as the continuous risk of life-threatening infections. The cumulative risk of graft failure secondary to cardiac allograft vasculopathy is 50% at 15 years. Unfortunately, despite the ability to perform re-transplantations for graft failure, both patient and graft survival are less compared to primary transplantation. Therefore, considering a lifelong management strategy for newborn congenital heart disease transplantation needs to be reserved for those without other options. Nonetheless, in neonates that require transplantation there are ongoing efforts to expand the donor supply, for example, by considering donation from anencephalic donors. Also, the ability to successfully perform ABO-incompatible heart transplantation is unique in the neonate by taking advantage of their somewhat naïve immunologic response to antigens.[65]

Medical Management

Prostaglandin E_1

In infants with a known prenatal diagnosis of ductal-dependent CHD, prostaglandin E1 (PGE1) infusion should be initiated shortly after birth and after intravenous access is obtained. For infants in whom ductal-dependent CHD is suspected based on cyanosis or shocklike clinical picture, PGE1 infusion should also be initiated immediately and continued until further testing, usually an echocardiogram, can be performed to either confirm or negate the diagnosis. In these undiagnosed clinical situations, prompt initiation of PGE1 is critical and can be lifesaving. PGE1 can be infused through virtually any vascular access that can be obtained, including the intraosseous route. The standard dose for maintenance of ductal patency is 0.03 mcg/kg/min. For infants with suspected ductal-dependent CHD who present with severe cyanosis or shock, an initial dose

of 0.1 mcg/kg/min is often a recommended starting dose to open the ductus arteriosus. This dose can be increased in certain situations to 0.2 mcg/kg/min if the ductus arteriosus remains closed at the 0.1 mcg/kg/min dose. Conversely, the dose can often be decreased back to a maintenance dose of 0.03 mcg/kg/min once the ductus arteriosus is reopened and the infant has begun to stabilize clinically. The short-term side effects of PGE1 include apnea/hypopnea, skin flushing, and fever, and these tend to be dose-dependent effects.[24] If side effects are occurring and causing management issues, the dose can be titrated down to as low as 0.01 mcg/kg/min as long as the ductus arteriosus remains patent and an adequate size at that level. There is no limit for how long PGE1 can be infused, and sometimes it is necessary to maintain an infant on PGE1 for prolonged periods of time, especially for those infants with significant medical co-morbidities or extreme prematurity. As stated in the previous sections, the alternative for prolonged PGE1 infusion is implanting a ductal stent to maintain patency and, therefore, avoid the long-term effects of PGE1, including periosteal hyperostosis[15] or gastric outlet obstruction.[30,49]

Oxygen and Ventilation

Most patients with mild and moderate forms of congenital heart disease do not require special consideration regarding oxygen therapy and ventilation strategies. They can typically be managed following standard neonatal strategies appropriate for age and size. Patients with single ventricle physiology and some with two ventricles who will require a PDA for ductal-dependent CHD require more specific management strategies to maintain pH levels within tighter ranges and judicious use of delivered oxygen. Neonates with single ventricle heart conditions in which the systemic and pulmonary circulations are connected by the PDA have oxygenation, cardiac output, and tissue perfusion that is extremely dependent on relative changes in the vascular resistances. As the pulmonary vascular resistance drops over the first week, keeping an appropriate balance of circulations becomes more difficult and close attention to arterial blood gas parameters becomes increasingly important. The most exemplary situation when ventilation and supplemental oxygen therapy can affect the balance between the systemic and the pulmonary vascular beds is in the care of infants with hypoplastic left heart syndrome.[2] Preoperatively, systemic output is dependent on right-to-left flow across the PDA, which is typically maintained by PGE1. When pulmonary vascular resistance (PVR) is high, blood flow through the PDA is right-to-left in systole as well as during a portion of diastole. As such, oxygen saturations will be relatively low because of relatively reduced amounts of pulmonary blood flow, and systemic perfusion will be adequately maintained. As the PVR falls during the first day to week of life, blood flow remains right-to-left in systole across the PDA but becomes left-to-right in all of diastole, resulting in rising oxygen saturations with increasing pulmonary blood flow. If the PVR falls significantly and measures are not taken to counterbalance this change in physiology, systemic perfusion can become inadequate and end organ injury (acute renal insufficiency, necrotizing enterocolitis) can result. This condition termed "pulmonary overcirculation/systemic hypoperfusion" can happen after even a very short period of time in the preoperative period. As such, regular checks of arterial blood gases (preferably) or capillary gases can provide significant insight into the balance of circulations. Elevation in arterial lactate levels can precede clinical instability and end organ injury, so it is recommended to follow and trend these levels serially. In general, pH should be maintained at 7.34-7.40 and alkalosis should be avoided. The P_{CO_2} and serum bicarbonate levels are less reliable to follow, especially when the neonate is receiving diuretics, because of the contraction alkalosis these medications can cause. If pH is maintained in this range, most patients will not overcirculate to a significant degree. In nonintubated neonates, relative overcirculation can lead to hyperventilation, and respiratory rates in the 80s to 90s are not uncommon. In these situations, the neonate may develop hypocapnia, leading to alkalosis and worsening pulmonary overcirculation. When these situations arise, it is sometimes necessary to intubate and assume control of the ventilation by dropping rate and minute ventilation until the pH is back into the desired range.

Oxygen, particularly alveolar or delivered oxygen, is a potent pulmonary vasodilator. The administration of supplemental oxygen can lead to dramatic drops in PVR and increasing pulmonary blood flow. In general, supplemental oxygen should be avoided in single ventricle patients, especially HLHS, unless there is significant lung disease leading to suspected pulmonary venous desaturation in which saturations are consistently less than 70%. On the contrary, in patients with high saturations from pulmonary overcirculation, it is sometimes necessary to provide subambient levels of oxygen, which raises the PVR and "discourages" pulmonary blood flow. Subambient oxygen can be administered by bleeding in nitrogen gas into a ventilation tent or through the endotracheal tube in an intubated infant. An FiO_2 of 18%-20% can be effective at raising PVR, but close monitoring of oxygen saturations and PaO_2 is necessary if this therapy is pursued.

Blood Products

Infants with cyanotic congenital heart disease often have deficient oxygen delivery to vital tissue and organs because of the high levels of fetal hemoglobin and its high oxygen affinity. Therefore it is important to maximize the oxygen-carrying capacity in these patients, and studies have shown that increasing the hemoglobin to >13 gm/dL or hematocrit to >40% is ideal. This can be accomplished in the short term by transfusing packed red blood cells (15-20 cc/kg) or over a longer period of time by administering weekly erythropoietin injections.[45] The exposure to many different blood donors can lead to antigen sensitization and make future

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

matches for cardiac transplantation difficult. Furthermore, excessive use of packed red blood cell transfusions has been linked to transfusion-related acute lung injury (TRALI), prolonged length of ICU stay, increased risk of infection, and higher mortality. Therefore, neonatal transfusions should be used only when absolutely necessary for optimizing clinical status. Platelet transfusions are uncommon in the preoperative state in neonatal patients with CHD. The presence of thrombocytopenia in neonatal CHD is likely related to other perinatal pathophysiology and unlikely related to the cardiac diagnosis. Usual replacement practices should be followed by the neonatology team in these cases. Similarly, the need for fresh frozen plasma, cryoprecipitate, or other factor replacement is rare in the preoperative state for neonates with CHD. Postoperatively, however, the need for platelets and plasma is common and usually directed by the cardiothoracic intensive care unit (CTICU) team or cardiac intensivists to address postoperative bleeding and to optimize oxygen delivery.

Preload

Preload or the overall volume status of neonates is often very difficult to assess because of the tendency for capillary leak and the third-spacing of fluid. For neonates with congenital heart disease, especially those with fetal hydrops or those who develop edema shortly after birth, trying to assess and optimize preload can be extremely difficult. However, preventing fluid overload when hypotension is present and withholding fluid when the neonate appears edematous from third-spacing in the presence of end organ hypoperfusion are management decisions that have potential for tremendous impact on the overall course for neonates requiring complex operations. Profound fluid overload has been correlated with increased duration of mechanical ventilation, prolonged ICU times, and delayed recovery of kidney function. These situations can develop even in the absence of concomitant conditions such as atrioventricular or semilunar valve dysfunction, hypoalbuminemia, anemia, and sepsis, which can all make assessments and treatment decisions that much more complex and difficult. Therefore, it is crucial that the management teams pay close attention to daily weights, input/output totals, clinical exam findings such as liver span and fullness of fontanelle, and electrolytes and renal function (BUN and creatinine) on a daily if not shift basis. Teams must take the entirety of information into account to decide if fluid restriction or resuscitation is required.

There are specific times when fluid management techniques may differ from simply attempting to achieve euvolemia. In the postoperative period, edema is extremely common because of fluid received in the operating room, capillary leak syndrome associated with cardiopulmonary bypass, and the need for perioperative blood products. In an attempt to combat this fluid overload, crystalloid or colloid administration should be used judiciously while maximizing the cardiac output with the use of inotropic and vasoactive agents. Often, medication drips or hyperalimentation can be concentrated or even discontinued if not immediately critical. Urine output can be maximized by maintaining good cardiac output and the aggressive use of diuretics. First-line diuretic therapy is generally a loop diuretic such as furosemide or bumetanide, often used in combination with a thiazide diuretic such as chlorothiazide for potentiation of effect. Hypokalemia is common with higher doses of loop diuretics, and patients may require either potassium supplementation or a potassium-sparing diuretic such as spironolactone (which also has beneficial ventricular remodeling properties) to avoid the hypokalemic hypochloremic metabolic alkalosis associated with long-term diuretic therapy.

Besides the postoperative period, it is common for patients with lesions resulting in pulmonary overcirculation (left-to-right shunts) to become fluid overloaded and need diuretic therapy. Although the pulmonary vascular resistance is still somewhat elevated and may temporarily protect the patient from overcirculation, certain lesions, such as a large patent ductus arteriosus, unrestrictive ventricular septal defects, certain forms of truncus arteriosus, and large aortopulmonary collaterals will result in excessive pulmonary blood flow, and diuretics will almost certainly be required prior to neonatal surgical repair.

In other situations, it may be beneficial to keep the patient relatively fluid loaded but not overloaded. For example, in patients with RVOT obstruction, such as tetralogy of Fallot, subpulmonary obstruction is somewhat dynamic, and a preloaded right ventricle can help to keep these patients from having hypercyanotic spells. A volume-loaded right ventricle will physically stretch or distend the subpulmonary area thereby decreasing the amount of dynamic collapse that leads to limited pulmonary blood flow and cyanosis. Similarly, patients with certain forms of cardiomyopathy will have stiff, noncompliant ventricles with significant diastolic dysfunction. These patients also need to have adequate preload to maintain ventricular filling and stroke volume.

Afterload

Afterload refers to the cumulative pressure against which the systemic ventricle must work to eject blood during systole. Although systemic blood pressure makes up the most significant portion of the afterload, the condition of the ventricle (wall stress and preload) must also be considered. For example, in a healthy heart with normal systolic and diastolic ventricular function, increasing afterload can be overcome by the ventricle by increasing ventricular wall stress and contractility. If the high afterload is chronic, myocardial hypertrophy will develop to assist the ventricle in overcoming this stress. However, in a dysfunctional ventricle the capacity to overcome acute and chronically elevated afterload is not as robust. In this situation, high afterload leads to higher systolic pressures and wall stress, which then leads to rising filling pressures and atrial hypertension. Although

For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

fluid resuscitation may allow for maintained cardiac output over a short period of time, fluid overload may ensue and other measures are required to assist the diseased ventricle. Oral afterload-reducing agents are typically antihypertensive medications that lower systemic vascular resistance and systemic blood pressure. Although medications like angiotensin-converting enzyme inhibitors (ACE-I) and angiotensin receptor blockers (ARB) do provide long-term ventricular remodeling effects, in the short term they only affect afterload by the blood-pressure-lowering effects. For critically ill neonates, these medications are rarely used. The medication most commonly utilized for this situation is milrinone, which has afterload-reducing, inotropic, and lusitropic (ventricular relaxing) properties. The net effect of milrinone is to have improved ventricular filling, improved stroke volume, and lower afterload for overall increase in cardiac output. Dobutamine has similar effects but usually results in significantly elevated heart rate. For neonates that have much higher resting heart rate, the tachycardia of dobutamine makes it less desirable compared to milrinone. Nitroprusside infusion is rarely used in neonates as it is a potent vasodilator and afterload-reducing agent but lacks the inotropic and lusitropic properties of milrinone. The relatively low blood pressure of most neonates does not lend itself to treatment by this drug on a regular basis.

To reduce afterload in the subpulmonary ventricle, any agent that selectively decreases pulmonary vascular resistance can be considered in neonates. Oxygen and inhaled nitric oxide are potent pulmonary vasodilators and reduce pulmonary afterload very well. Other agents (sildenafil or bosentan) used to treat pulmonary hypertension can be considered for use under the guidance of pediatric pulmonary hypertension experts.[43]

Contractility

Agents that increase inotropy and cardiac contractility can improve cardiac output. A commonly used oral agent to increase contractility is digoxin, which has been shown to be safe in the neonate with left ventricular volume overload and systolic dysfunction.[21] However, this oral medication is rarely used in the neonatal period solely for the purpose of treating ventricular systolic dysfunction or heart failure unless added to a regimen that includes afterload-reducing agents and diuretics, as it is typically a secondary or tertiary agent.

Intravenous inotropic support is more commonly encountered in the neonatal period to treat perinatal, preoperative, and postoperative systolic dysfunction.[44] Dopamine and dobutamine have similar inotropic effects, although dopamine is usually preferred because of its greater effect in premature infants and because it causes less tachycardia and systemic vasodilation than dobutamine. Epinephrine is used in low doses for its inotropic effect, although counterintuitive effects of increasing myocardial oxygen demand through increased heart rate and systemic vascular resistance can limit its use. As discussed in the afterload section, milrinone is commonly used in the postoperative period because of its improved inotropy, lusitropy, and afterload-reducing effects.

Treatment of Hypercyanotic Spells

Hypercyanotic spells or "tet spells" are acute episodes that can develop in patients with tetralogy of Fallot when there is dynamic subpulmonary obstruction of the right ventricular outflow tract. When acute worsening of RVOT obstruction develops, there is a significant decrease in pulmonary blood flow and subsequent shunting of blood right to left at the ventricular level leading to severe hypoxia and cyanosis. The infundibulum of the right ventricle is thought to be reactive to circulating catecholamines, which increase with increasing patient agitation, resulting in increased gradient across the RV outflow tract forcing deoxygenated blood across the ventricular septal defect into the aorta, resulting in cyanosis. Other factors such as decreased right ventricular filling owing to relative hypovolemia and lack of preload or tachycardia may further predispose these patients to hypercyanotic episodes. The treatment for hypercyanotic episodes is to find ways to decrease the subpulmonary obstruction, encourage more pulmonary blood flow, and increase the relative degree of left to right shunting at the ventricular level. If these maneuvers are followed, hypercyanotic spells can often be treated quickly before the infant is hypoxic for an unsafe amount of time. Some of these maneuvers and the physiologic rationale for their use are illustrated in Table 78.5.

What the Future Holds

The field of congenital heart disease is constantly changing and innovation is typically the rule and not the exception. The past 20 years have seen a tremendous improvement in the medical, surgical, and interventional therapies for neonates and children with congenital heart disease. Fortunately, through the fervent work of many individuals and organizations (www.pediatricdeviceconsortium.org; www.pediaworks.org), the FDA became more aware of these limitations in the treatment of children and in 2007 passed the Pediatric Medical Device Safety and Improvement Act. The PMDSIA was the first major legislation ever exclusively directed toward pediatric devices and has already stimulated innovation, provided new incentives for pediatric device development, and allowed for better safety monitoring of devices. In 2012, the PMDSIA was renewed by congress and additional funding for the Pediatric Device Consortium Grant Program was secured.

Pediatric Interventional Cardiology has benefitted recently from the approval of two transcatheter pulmonary valves: Medtronic's Melody Transcatheter Pulmonary Valve in 2010 and the Edwards Sapien XT Transcatheter Heart Valve for Pulmonic Indications in 2016. The first FDA-approved stent for coarctation of the aorta was approved in 2016 after an extensive investigation of the NuMED

TABLE 78.5 Treatment Strategies and Physiologic Rationale for Hypercyanotic Episodes Associated With Tetralogy of Fallot

Treatment of Cyanotic Episodes	Rationale/Physiologic Effect(s)
100% oxygen	Decreases PVR and improves oxygen delivery
Knees to chest	Increases SVR and preload
Manual compression of abdominal aorta	Increases SVR
Nonprovocation	Decreases catecholamines and infundibular spasm
Fluid bolus (0.9% saline, 5% albumin, blood), 10-20 mL/kg	Increases RV preload
Morphine, 0.1-0.2 mg/kg IV/IM/SC	Decreases catecholamines and infundibular spasm
Ketamine, 0.4-1 mg/kg IV/IM	Decreases catecholamines and infundibular spasm
Fentanyl, 1-4 mcg/kg IV/IM/SC	Decreases catecholamines and infundibular spasm
Phenylephrine, 5-20 mcg/kg IV bolus or IV infusion 0.1-0.5 mcg/kg/min, 0.1 mcg/kg SC/IM	Increases SVR
Propranolol, 0.05-0.15 mg/kg slow IV	Increases RV filling and decreases catecholamines

IM, Intramuscular; IV, intravenous; PVR, pulmonary vascular resistance; RV, right ventricular; SC, subcutaneous; SVR, systemic vascular resistance.

Cheatham Platinum (CP) Stent System. Although these valves and stents are not currently for use via typical transcatheter route in neonates and infants, the miniaturization of this technology is underway so that more infants will be candidates for hybrid implants in the near future. Furthermore, devices used for transcatheter occlusion of PDAs are currently being studied for their use in the premature infant population, and the first occluder, Piccolo (Abbott Medical) has just been approved by the FDA.

Biodegradable materials and devices remain one of the most important focuses of research and are at the forefront of innovation in pediatrics because of the ideal potential to allow placement or implantation of a device that would eventually resorb or degrade and not inhibit growth of the vessel or heart structure in which it has been placed or inhibit access to a particular area of the heart. Catheters are also being made smaller and more versatile to avoid some vascular complications that occurred using adult-sized equipment in children.

We are also becoming more organized in the way we share information. Patient populations are too heterogeneous to be able to provide good, large-scale evidence for the therapies provided. Multi-institutional and even multinational registries (IMPACT, CCISC, C3PO, NPC/QIC, etc.) are now allowing compilation of more useful data than ever before and will certainly be sources of solid evidence-based studies in the future. This will allow the field to advance, given that only 2% of the 2011 AHA recommendations on cardiac catheterization in children are level of evidence A.[16]

Key Points

- Neonates with congenital heart disease require a well-integrated and multidisciplinary team approach to achieve optimal outcomes.
- The vast majority of congenital heart disease does not require specific neonatal management.
- Moderate to severely complex congenital heart conditions can be classified into cyanotic and acyanotic forms.
- Cyanotic congenital heart disease includes conditions with too little pulmonary blood flow and excessive pulmonary blood flow.
- Surgical methods to increase pulmonary blood flow in cyanotic CHD include surgical systemic-pulmonary artery shunts and surgically opening the right ventricular outflow tract.
- Interventional methods to increase pulmonary blood flow include PDA stenting and RVOT stenting.
- The most reliable approach to limit pulmonary blood flow is placement of a main pulmonary artery band.
- Numerous methods exist to improve mixing at the atrial level in conditions such as transposition of the great arteries.
- In premature infants, PDA closure can be done medically, surgically, and now via interventional approach with small vascular plugs.
- Prompt initiation of PGE1 infusion in patients with suspected ductal-dependent CHD who present with cyanosis or shocklike picture can be a life-saving treatment.

Hematologic and Oncologic Problems in the Fetus and Neonate

JOHN LETTERIO, IRINA PATEVA, AGNE PETROSIUTE, AND SANJAY AHUJA

Human Hematopoietic Development

Hematopoietic Stem Cells

Blood cells arise from the differentiating embryonic mesoderm. Human erythroid and macrophage progenitor cells have been observed in the yolk sac by days 16-19 and at day 19 in the aortic-gonad-mesonephros (AGM). After the development of the circulatory system on day 21, pluripotent hematopoietic cells localize in the AGM, placenta, and liver by days 24-28. Myeloid, lymphoid, and megakaryocytic precursors have been noted in fetal liver at this stage. Definitive erythropoiesis occurs in the fetal liver, thymus, spleen, and bone marrow. A knowledge gap exists regarding the details of in situ hematopoiesis between weeks 3 and 12, but fetal liver is recognized as the major site of hematopoiesis between weeks 6 and 16. The bone marrow assumes this role by week 24 (Fig. 79.1).[58]

Proper blood cell formation is necessary for survival. Much has been learned about the origin and regulation of blood cells through studies of congenital and acquired defects in hematopoiesis. Studies of mouse hematogenesis identified pluripotent cells in the murine inner cell mass. These embryonic stem (ES) cells are capable of self-renewal as well as differentiation into hematopoietic cells. Human ES cells were isolated in 1998, fueling research efforts to generate pluripotent stem cells from early embryos and to perform genetic manipulation of differentiated somatic cells. Somatic cells can be reprogrammed into an ES-like state, and these induced pluripotent stem (iPS) cells are another tool researchers are using both to understand and manipulate progenitor cells.[58]

The earliest blood cells produced by colony-forming cells (CFCs) in the yolk sac are very large, primitive erythroid cells expressing embryonic globins. Subsequently, CFCs produce definitive erythrocytes expressing fetal globins and macrophages. Later still, multipotent CFCs and lymphoid progenitor cells arise. The adult-type globins are not expressed until just before birth and rapidly assume primacy afterward (Table 79.1; Fig. 79.2). With each transition from primitive to definitive to adult erythroid cells, the mean corpuscular volume (MCV) decreases.

Regulation of Hematopoiesis

Few hematopoietic stem cells enter the cell cycle at any given time. Most are in a resting state. Proliferation and differentiation occur within a suitable microenvironment of stroma and humoral factors. The WNT/β-catenin and Notch-δ signaling pathways drive stem cell development. Transcription factors involved in stem cell development include GATA2, RUNX1, TEL/ETV6, SCL/TAL1, and LM02. Other transcription factors such as PU.1, GFIX, C/EBPα, and GATA1 are considered to be more lineage-specific, but most also participate in lineage priming, where stem cells differentiate along a pathway depending upon cellular and environmental stimuli. Multiprotein complexes assemble and bind DNA regulatory elements to modulate transcription. Epigenetic regulatory mechanisms of transcription include DNA methylation on CpG residues and histone modification.[58]

Factors promoting hematopoiesis include BMP4, VEGF, WNT, and FGF. Hematopoietic cytokines such as stem cell factor, fms-like tyrosine kinase receptor-3 ligand, interleukin-6, thrombopoietin, erythropoietin, and granulocyte colony-stimulating factor (G-CSF) play critical roles in the maintenance and differentiation of human hematopoietic cells. Some hematopoietic growth factors are produced in the vicinity of hematopoietic progenitors, and others are synthesized remotely (Table 79.2). Few of the glycoprotein growth factors are available for clinical use, but that number is expected to increase.

Some of the earliest hematopoietic growth factors discovered were referred to as *colony-stimulating factors* (CSFs), because in culture they stimulate progenitor cells to form colonies of recognizable maturing blood cells. The prefixes refer to the maturing cell produced. GM-CSF is granulocyte-macrophage CSF. The interleukins (ILs) were named for the fact that they are derived from, or act upon, leukocytes. Other factors are named for the cell surface receptor to

Abstract

The newborn faces a unique and diverse spectrum of hematologic problems that are a consequence of events such as maternal–fetal blood group incompatibilities, maternal drug usage and medications, prematurity, birth asphyxia, and other systemic disorders. The growth of knowledge regarding the etiology and treatment of these conditions has led to the emergence of neonatal hematology as a complex subspecialty of pediatric hematology. The co-management of these conditions by hematologists and neonatologists is necessary to insure careful assessment of the unique aspects of the maternal–fetal relationship, the delicate balance of coagulation factors, and the distinctive physiologic conditions of the newborn period that influence the production of blood elements necessary for tissue oxygenation, clotting, and immunity. This chapter reviews specific hematologic disorders that commonly present in the newborn period, as well as oncologic conditions that may present in the neonatal period. A review of disease pathophysiology is accompanied by a discussion of signs and symptoms associated with various hematologic conditions that present in the newborn period and current treatment strategies.

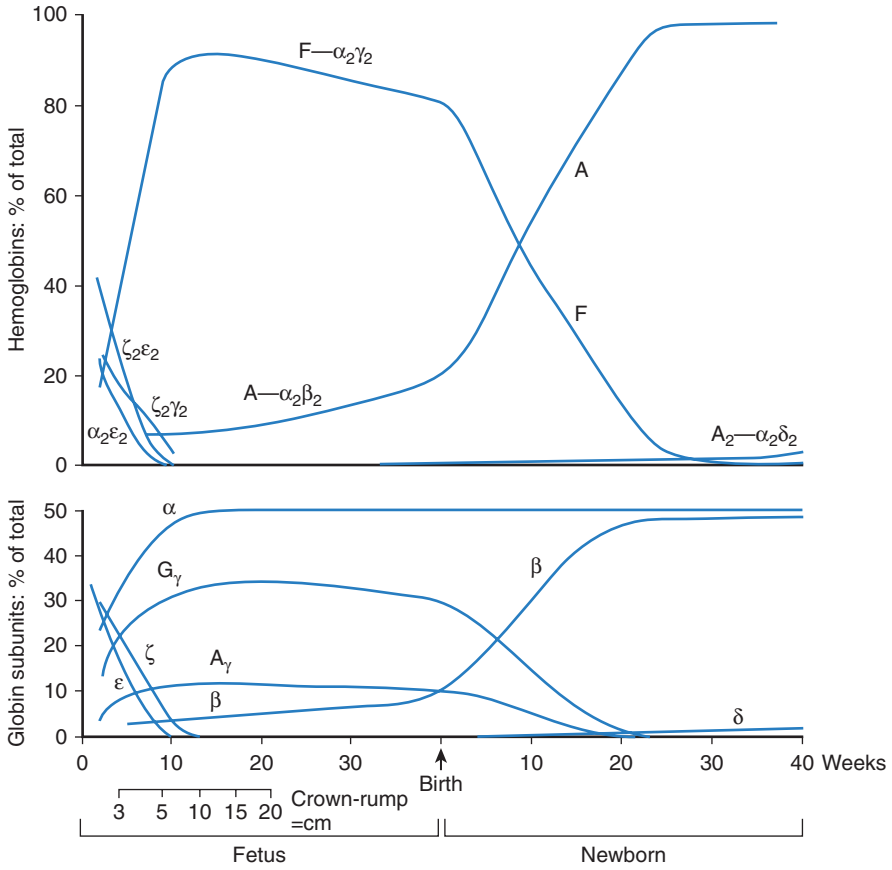
TABLE 79.1 Human Hemoglobins Expressed during Development

Hemoglobin	Predominates	Globin Composition
Hb Gower 1	Embryonic (yolk sac)	$\zeta_2\varepsilon_2$
Hb Gower 2	Embryonic (yolk sac)	$\alpha_2\varepsilon_2$
Hb Portland	Embryonic (yolk sac)	$\zeta_2\gamma_2$
Hb F	Fetal (liver)	$\alpha_2\gamma_2$
Hb A	Adult (bone marrow)	$\alpha_2\beta_2$
Hb A2	Minor adult (bone marrow)	$\alpha_2\delta_2$
Hb Barts	Fetal-alpha thalassemia	γ_4
Hb H	Adult-alpha thalassemia	β_4

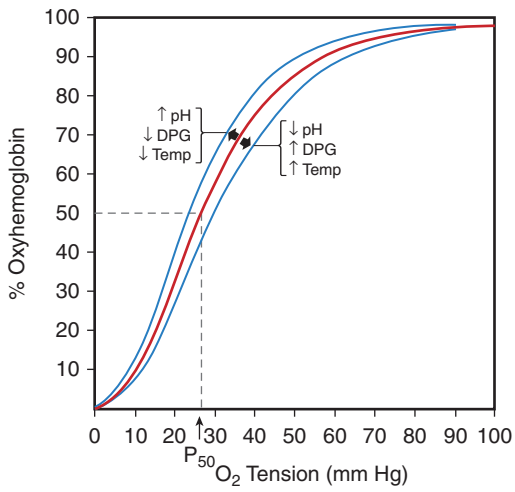
which they bind, such as thrombopoietin receptor agonists that stimulate megakaryocyte differentiation and platelet production. Growth factors such as IL-3 and GM-CSF stimulate proliferation, differentiation, and survival of a broad range of precursors, including stem cells. Others such as erythropoietin and granulocyte CSF (G-CSF) are lineage restricted.

Red Blood Cells



Hemoglobin and Oxygen-Carrying Capacity

The function of red blood cells (RBCs) is to transport oxygen (O_2) to tissues to meet metabolic demands. Hemoglobin (Hb), the most abundant protein in erythrocytes, facilitates oxygen delivery by reversibly binding O_2 molecules. The binding of oxygen to hemoglobin tetramers is cooperative, resulting in the familiar sigmoidal oxygen dissociation curve (Fig. 79.3). The affinity of Hb molecules for oxygen is influenced by a variety of factors, including temperature, pH, carbon dioxide pressure (P_{CO_2}), and the concentration of red blood cell organic phosphates (2,3-biphosphoglycerate or 2,3-BPG, also known as 2,3-diphosphoglycerate or 2,3-DPG). In the case of adult hemoglobin (Hb A), oxygen affinity for the molecule varies directly with pH and inversely with temperature and the concentration of 2,3-BPG. Fetal hemoglobin (Hb F) has a high oxygen affinity. Some mutations of hemoglobin affect oxygen affinity, as explained later.



Hemoglobin Switching

The hemoglobin tetramer is composed of two heterodimers consisting of an α- and β-type globin. Different globin genes are sequentially expressed in RBC precursors, a process known as *hemoglobin switching* (see Fig. 79.2 and Table

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

• **Fig. 79.2** Changes in expression of hemoglobin tetramers (*upper panel*) and individual globin chains (*lower panel*) during development. (Adapted from Bunn HF, et al. *Hemoglobin: molecular, genetic, and clinical aspects*. Philadelphia: Saunders; 1969.)

• **Fig. 79.3** Oxyhemoglobin dissociation curve. Factors that influence the position of the curve are indicated. DPG, Diphosphoglycerate. (Adapted from Bunn HF, et al. *Hemoglobin: molecular, genetic, and clinical aspects*. Philadelphia: Saunders; 1969.)

79.1). During development, α- and β-type globin gene clusters are activated sequentially from the 5′ (embryonic) end to the 3′ (adult) end. The α-type globin genes, ζ-globin, α_1-globin, and α_2-globin, are located on chromosome 16 with the ζ gene 5′ to a pair of duplicated α-globin genes. The β-type genes on chromosome 11 are oriented 5′ to 3′ as ε-, $^{G}\gamma$, $^{A}\gamma$, δ, and β (see Fig. 79.2). The protein products of the $^{A}\gamma$- and $^{G}\gamma$-globin genes are functionally similar and differ by a single amino acid residue. Globin gene expression is controlled by cis-elements of individual globin gene promoters, proximal and distal enhancer regions, and positively acting transcription factors, such as GATA1, GATA2, NFE2, MYB, EKLF, RBTN2, and SCL. Other mechanisms that also regulate globin switching are silencers, DNA conformational changes, and DNA methylation.[58,135] In fact, discovery of the ability to chemically demethylate CpG residues in the silenced γ-globin gene promoter launched translational research efforts to enhance fetal hemoglobin production in patients with β-globin defects such as β thalassemia and sickle cell anemia.

During yolk sac hematopoiesis, RBCs produce the embryonic hemoglobins (see Table 79.1). Hb F is the predominant hemoglobin in the fetus and neonate. Production of the major adult hemoglobin (Hb A) increases significantly between birth and 6 months of age, as Hb F production declines. Synthesis of HbA_2, a minor adult globin, also increases gradually over the first months of life (see Fig. 79.2). After 6 months of age, Hb F usually constitutes less than 1% of the total hemoglobin and is unevenly distributed among red blood cells. Each of the different types

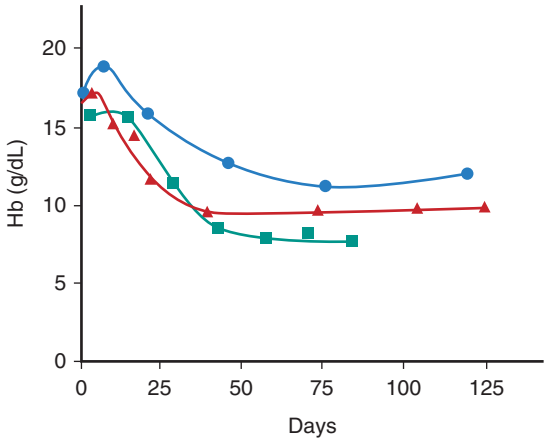
TABLE 79.2 Hematopoietic Growth Factors

Factor	Source	Receptor	Target Cells	Effects
Erythropoietin (EPO)	Kidney, hepatocytes	EPO-R	E, Meg	Stimulates growth and differentiation of erythroid precursors
Stem cell factor (SCF) (also known as steel factor [SF], KIT ligand [KL], and mast cell growth factor [MCGF])	Ubiquitous	KIT	E, mast cells, melanocytes, germ cells	Stimulates growth and differentiation of erythroid and myeloid precursors; enhances growth of mast cells
Granulocyte colony-stimulating factor (G-CSF)	Stromal cells, macrophages	G-CSF-R	N	Stimulates growth and differentiation of neutrophil precursors; activates phagocytic function of mature neutrophils
Granulocyte-macrophage colony-stimulating factor (GM-CSF)	Stromal cells	GM-CSF-R (α and β chains)	M, N, Eo, Endo	Stimulates growth and differentiation of neutrophils, eosinophils, and monocytes; activates endothelial cells; induces cytokine expression by monocytes
Macrophage colony-stimulating factor (M-CSF)	Mesenchymal cells	FMS	M	Stimulates growth and differentiation of monocytes; induces phagocytic function in monocytes and macrophages; is involved in bone remodeling
Interleukin 1 (IL-1)	Ubiquitous	IL-1RI, IL-1RII	T, E, B, M, S	Induces production of cytokines and prostaglandins by stromal cells, T cells, and many other cell types; induces fever
Interleukin 2 (IL-2)	T cells	P55, P75	B, T, NK	Induces proliferation and activation of T, B, and NK cells; induces IL-1 expression by monocytes
Interleukin 3 (IL-3)	T cells	IL-3Rα, GM-CSF-Rβ	M, N, Eo, Meg	Stimulates growth and differentiation of myeloid and erythroid precursors, induces cytokines
Interleukin 4 (IL-4)	T cells, mast cells, basophils	IL-4R	M, Ba, B, T	Induces proliferation and activation of B and T cells
Interleukin 6 (IL-6)	Ubiquitous	IL-6R/GP130	B, N	Induces activation of neutrophils; induces B-cell maturation, synergistic with IL-3
Interleukin 7 (IL-7)	Stromal cells	IL-2R	B, T, meg	Stimulates T cells; induces monocytes
Interleukin 8 (IL-8)	Stromal cells, macrophages, T cells	IL-8R	T, N	Induces neutrophils and chemotaxis
Interleukin 10 (IL-10)	T cells, macrophages	IL-10R	Meg, E	Induces B and mast cells; inhibits T cells
Interleukin 11 (IL-11)	Stromal cells	IL-11R, GP130	Meg	Stimulates megakaryocytes
Interleukin 12 (IL-12)	Neutrophils, monocytes	IL-12R	T, NK	Induces differentiation of cytotoxic T cells
Thrombopoietin (TPO)	Unknown	MPL	Meg	Stimulates megakaryocytes



B, B cells; Ba, basophil; E, erythroid precursors; Endo, endothelial cell; Eo, eosinophil; M, monocyte; Meg, megakaryocyte; N, neutrophil; NK, natural killer cell; S, stroma cell; T, T cell.

of globin exhibits distinctive functional properties. Fetal erythrocytes, which contain mostly Hb F, have a higher oxygen affinity than adult red blood cells. This allows the transport of oxygen from maternal Hb A–containing erythrocytes across the placenta to fetal red blood cells. The increased O_2 affinity of fetal hemoglobin has been ascribed to the diminished interactions of Hb F with red blood cell 2,3-BPG. Embryonic erythrocytes also display a greater affinity for oxygen than adult cells.

Erythropoietin, Erythropoiesis, and the Physiologic Anemia of Infancy

Erythropoietin (EPO), the essential glycoprotein growth factor for erythropoiesis, binds to erythropoietin receptors on early erythroid progenitor cells and via the JAK2 signaling pathway regulates RBC production by protecting them from apoptosis. Erythropoietin is produced primarily in the fetal liver and later in the cortical peritubular cells of the kidney, so that in adults renal production of EPO is the most important. Erythropoiesis is highly responsive to blood oxygenation. Hypoxia inducible factors (HIFs), constitutively expressed EPO transcription factors, are destroyed in the presence of oxygen. Under hypoxic conditions, EPO production increases. Levels of EPO in cord blood are higher than in adult blood samples (Table 79.3), but there is a dramatic decrease after birth in response to higher levels of tissue oxygenation. By 1 month of age, serum levels in healthy term infants reach their nadir. This is followed by a rise to maximal levels at 2 months of age and then a slow drift down to adult values.

The postnatal changes in tissue oxygenation and erythropoietin production result in a physiologic anemia of infancy with a mean minimal hemoglobin concentration in healthy term infants of about 11 g/dL at 8-12 weeks of life (Fig. 79.4; Table 79.4). Because of the shorter life span of RBCs in preterm infants with low EPO levels, the nadir is noted by 6 weeks of age and ranges from 7-10 g/dL. In very low birth weight (VLBW) and extremely low birth weight (ELBW) infants, the nadir is more than 20% below the value of the Hb at birth. In ELBW infants whose nadir falls below 7 g/dL, this so-called physiologic anemia of prematurity can be associated with pallor, tachypnea, tachycardia, poor feeding, and poor weight gain.[2,97] Other causes of blood loss and suppression of erythropoiesis in the ill neonate can contribute to more severe and earlier anemia. Although preterm infants will respond to hypoxia with a rise in EPO levels, the increase is lower than that expected for term infants. The suboptimal EPO response may be because of developmental changes in transcription factors or to the site of fetal EPO production. The use of recombinant EPO in premature and sick newborn infants is discussed later.

Red Blood Cell Indices during Prenatal and Postnatal Development

The RBC count, Hb concentration, and hematocrit (Hct) increase throughout gestation, as shown in Table 79.5. In term infants, the mean capillary hemoglobin at birth is 19.3 g/dL (see Table 79.4). The capillary Hct has a mean of 61 g/dL. Premature infants have lower Hb levels than do full-term infants. In addition to gestational age, Hb levels are influenced by a variety of factors that must be kept in mind when analyzing the neonate with anemia or polycythemia. One important determinant is the site of sampling: Capillary Hb values are higher than peripheral venous samples, and umbilical venous Hb results are the lowest. The interval between delivery and clamping of the umbilical cord and the height of the baby relative to the placenta can significantly affect a newborn's blood volume and total RBC mass. The placenta contains about 100 mL of blood. The mean blood volume of a full-term infant is about 85 mL/kg. Early or delayed clamping of the umbilical cord alters this mean blood volume by about 10% lower or higher,

Hb, Hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cells.
Data from Matoth Y, Zaizov R, Varsano I. Postnatal changes in some red cell parameters. *Acta Paediatr Scand.* 1971;60:317-323.

respectively. The average Hb at birth is relatively unchanged; however, 48 hours later, after redistribution of plasma volume, Hb values will reflect the lower or higher red cell mass. Racial differences also occur. One study reported significantly higher Hb, Hct, and MCV in white infants compared with black infants of similar gestational ages.[4] Reticulocyte counts in the cord blood of infants average 4%-5%, and nucleated RBCs are evident in most cord blood samples (40,000/μL). These findings are presumed to reflect high EPO production secondary to low oxygen retention in utero. Infants who experience placental insufficiency and intrauterine growth restriction have higher than normal EPO production and an even greater degree of erythrocytosis. The mean MCV of RBCs in the newborn is increased. The RBCs of the neonate have an increased Hb content, but the mean corpuscular hemoglobin concentration (MCHC) is comparable to that of adults.

Delayed (30-90 seconds) cord clamping (DCC) has been shown to prevent hypotension, raise hematocrit, and decrease the need for transfusions in preterm infants.[102] In addition, term infants who have had delayed cord clamping have reduced iron deficiency anemia in the first year of life but have an increased risk of early jaundice.[79] Thus, it has been recommended that both preterm and full-term infants undergo routine delayed cord clamping.

A new population that has also shown benefit is the neonate who has needed in utero transfusion because of red cell alloimmunization. Garabedian et al. studied a series of 72 neonates who needed in utero transfusion because of alloimmunization. Thirty-six of the neonates had DCC, and 36 neonates did not have DCC. More infants without DCC Hb had anemia at birth. The rate of transfusion, maximum level of bilirubin, the rate of intensive phototherapy, and the total duration of phototherapy were similar in the two groups. Postnatal exchange transfusions (ET) were more likely performed in the group without DCC than in the group with DCC. The interval between birth and the first transfusion was higher in the group with DCC. The authors recommended DCC with duration of 30 seconds in infants at risk for neonatal anemia because of red blood cell alloimmunization, provided that the management of jaundice is optimized.[44]

Red Blood Cell Survival

The normal life span of adult RBCs is about 120 days. The life span of RBCs in newborns at term is 60-80 days and 30-50 days in ELBW infants. In general, red blood cell survival is affected by changes related to aging (senescence) and by random hemolysis of red blood cells, or portions of red blood cells, in the spleen and the rest of the reticuloendothelial system. Some of the changes in neonatal RBCs compared with adult RBCs listed in Table 79.6 affect survival. Aging erythrocytes with declining RBC enzyme activity become progressively less tolerant of oxidative challenges during the transportation of oxygen molecules and exposure to circulating oxidants. Any additional deficiencies in the enzymatic pathways of the RBC may affect the ability of the erythrocyte to tolerate oxidative challenges and further reduce red blood cell survival. With transit through the kidneys and lungs, the RBCs experience cycles of osmotic swelling and shrinkage. Shear forces in high-pressure areas of the circulation buffet the erythrocytes. Each passage through the cords of Billroth within the spleen requires the RBCs to deform and squeeze through tiny slits in the walls of the cords or face destruction if they cannot. Congenital or acquired defects in membrane stability or decreases in the ratio of surface area to red blood cell volume will also decrease erythrocyte survival. Alterations in the deformability of neonatal erythrocytes and relative intolerance to oxidative challenges result in shorter survival for neonatal red blood cells. Random hemolysis can be increased with splenic enlargement or activation of the phagocytic system. Infants with hemolysis may have exaggerated anemia because of decreased erythropoiesis, enhanced splenic filtration, and activation of phagocytes.

Red Blood Cell Disorders

Anemia

Anemia is defined by a hemoglobin or hematocrit value that is more than two standard deviations below the mean for age. In the neonate, the causes of anemia can be divided into two broad categories: anemia resulting from accelerated loss or destruction of red blood cells and anemia caused by a defect at some stage of red blood cell production (Box 79.1). The defects may be congenital or acquired, and the abnormality may be intrinsic to the RBCs or extrinsic. Anemias also may be categorized on a morphologic basis. Using the normal range of the MCV for age and gestation, the anemia may be characterized as microcytic, normocytic, or macrocytic (Box 79.2). Hypochromicity, abnormal RBC shapes (poikilocytes), polychromasia, and cell inclusions (e.g., basophilic stippling or Howell-Jolly bodies) also provide clues to the etiology of the anemia (Table 79.7).

Evaluation of Anemia

The clinician begins the evaluation of anemia by taking a thorough history. Appropriate data vary with the patient's age but often include the medical and dietary history of the pregnancy, the estimated gestational age at birth, the chronologic age, the infant's diet, and details of any previous anemia, blood loss, transfusions, medications, and illnesses, as well as the family history of anemia. The physical

Accelerated Loss

- Hemorrhage
  - Fetal
  - Fetal–maternal
  - Placental
  - Traumatic delivery
  - Coagulation defects
- Early umbilical cord clamping
- Twin–twin transfusion
- Excess phlebotomy losses

Accelerated Destruction

- Hemolytic anemia
  - Immune
    - Alloimmune: Rh, ABO, minor blood group
    - Autoimmune
  - Nonimmune
- Hemoglobinopathy
- Thalassemia
- Unstable hemoglobin
- Red blood cell enzyme defect
- Structural defect of red blood cell membrane
- Mechanical destruction
- Microangiopathic hemolytic anemia
- Infection
- Vitamin E deficiency

Diminished Red Blood Cell Production

- Congenital
  - Diamond-Blackfan anemia
  - Pearson syndrome
  - Fanconi anemia
  - Congenital dyserythropoietic anemias
  - Anemia of prematurity
- Acquired
  - Parvovirus B19
  - Transient erythroblastopenia of childhood
  - Human immunodeficiency virus
  - Syphilis
  - Iron deficiency
  - Lead toxicity
  - Infection

examination should evaluate the infant's general health, growth, and development. Identification of any dysmorphic features, abnormal masses, or skin lesions can aid the diagnosis (Table 79.8). The patient also should be assessed for jaundice, hepatosplenomegaly, vascular malformations, cardiovascular function, and lymphadenopathy.

The initial laboratory evaluation includes a complete blood count (CBC) with RBC indices, a reticulocyte count, and evaluation of the peripheral blood smear (Fig. 79.5). The results of the preliminary laboratory testing, combined with information from the history and physical examination, should dictate the need for further tests, such as hemoglobin analysis of the infant or parents, CBCs and blood smears of the parents, analysis of hepatic or renal function, direct or indirect antiglobulin (Coombs) testing, cultures or titers to identify infectious agents, a bone marrow aspirate or biopsy, osmotic fragility tests, and quantitative or qualitative testing for glucose-6-phosphate dehydrogenase (G6PD) deficiency.

The neonatal patient presents the diagnostician with a number of unique challenges. Because of the small total blood volume of the infant, who already is anemic, testing must be limited. Major pediatric medical centers can perform many of the necessary tests on very small quantities of blood, especially if the tests are appropriately batched when they are submitted. Because of the many morphologic and biochemical differences in neonatal and adult RBCs (see Table 79.6), some diagnoses are best made by testing the parents for evidence of disease or carrier states. At times, a definitive diagnosis can be made only with repeat testing later in infancy, when the infant would be expected to have a much higher percentage of adult-type RBCs or when the infant has recovered from an acute hemolytic crisis that may have destroyed the older, more biochemically or morphologically abnormal cells.

TABLE 79.7 Morphologic Findings on Peripheral Blood Smears

Morphologic Abnormality	Etiology
Acanthocytes	Alteration of lipid bilayers Liver disease Abetalipoproteinemia
Blister cells	G6PD deficiency
Basophilic stippling	Ineffective erythropoiesis: iron deficiency, lead poisoning, thalassemia, nonimmune hemolytic anemias
Elliptocytes	Structural defects of red cell membrane: hereditary elliptocytosis
Heinz bodies	Precipitated hemoglobin: normal in newborn; nonimmune hemolytic anemias
Howell-Jolly bodies	Splenic hypofunction or post splenectomy
Hypochromia	Iron deficiency, thalassemias, lead poisoning
Nucleated red blood cells	Normal in newborn; hemolytic anemias, semi-acute blood loss
Polychromasia	Normal in newborn; reticulocytosis
Pyropoikilocytosis	Neonates with hereditary elliptocytosis, hereditary pyropoikilocytosis, thermal injury of red cells (burn)
Rouleaux	Increased fibrinogen, inflammation
Schistocytes	Microangiopathic hemolytic anemias
Sickle cells	Hemoglobin SS and sickle variants
Spherocytes	Decreased cell membrane: volume—IgG+ hemolytic anemia, hereditary spherocytosis, artifact of area of blood smear
Target cells	Increased red blood cell surface: volume ratio Alteration in lipid structure of red blood cell membrane Hemoglobin C, hemoglobin S, thalassemias, liver disease, abetalipoproteinemia

Rationale for Transfusion Therapy

See Chapter 80 for discussion of liberal versus restrictive transfusion practices in preterm infants. Because the primary function of the RBC is to transport oxygen from the pulmonary bed to other tissues for release, anemia diminishes oxygen-carrying capacity and can compromise tissue oxygenation. Tissue oxygenation is a complex concept involving not only the Hb concentration but also the oxygen affinity of the Hb in the patient's red blood cells, blood viscosity, and the patient's cardiorespiratory status. The only absolute indications for rapidly correcting anemia by RBC transfusion are to restore tissue oxygenation and to expand blood volume after severe, acute loss. In most pediatric centers, the sicker patients, especially those with cardiopulmonary dysfunction, receive transfusions to maintain the Hb closer to normal for age. Neonatal exchange transfusions are also performed with the goal of replacing "doomed" infant RBCs with healthy adult RBCs, which have superior oxygen-transporting ability. This has the triple benefit of limiting hyperbilirubinemia and other byproducts of RBC breakdown, reducing the body load of maternal antibodies, and supplementing with cells that contain Hb A.

Anemia Caused by Blood Loss

Blood loss can occur in the fetus, at birth, or in the postnatal period. The bleeding can be acute or chronic. Anemia caused by chronic blood loss generally is better tolerated because the neonate will at least partly compensate for a gradual reduction in RBC mass. Chronic blood loss can be diagnosed by identifying signs of compensation. Doppler assessment of the fetal middle cerebral artery peak systolic velocity is a noninvasive method for determination of fetal anemia, independent of the etiology. The infant may be pale and may exhibit signs and symptoms of congestive heart failure. Anemia will be present, often with reticulocytosis, hypochromia, and microcytosis.

An infant with acute blood loss may not be anemic if blood sampling is done soon enough after the acute event so that hemodilution has not yet occurred. Anemia usually develops within 3-4 hours after blood loss; repeat testing 6-12 hours after the event should reveal the true extent of the loss. In acute blood loss, the infant may exhibit signs and symptoms of hypovolemia and hypoxemia (e.g., tachycardia, tachypnea, hypotension). The RBCs should be morphologically normal. With either kind of hemorrhage, infants tend to have fewer problems with hyperbilirubinemia, because they have a reduced RBC mass. Jaundice can result if entrapped RBCs in a hematoma break down.

Internal bleeding can occur if the fetus has anatomic abnormalities or defects in the hemostatic system or with interventional obstetric procedures. A surprisingly large amount of blood can be lost within a cephalohematoma, and even greater bleeding can occur in the subaponeurotic area of the scalp (subgaleal hemorrhage), where bleeding is not limited by periosteal attachments. Traumatic or assisted deliveries and vitamin K deficiency are commonly associated with such bleeding. Full-term infants may have intracranial bleeding, which usually occurs in the subarachnoid or subdural regions. Full-term infants with intracranial hemorrhage should be evaluated for hemostasis abnormalities, because this type of bleeding is associated with qualitative and quantitative platelet defects and with abnormalities of several of the coagulation proteins. Hemorrhage into the adrenals, kidneys, liver, spleen, or retroperitoneum also can occur after difficult or breech deliveries. Splenic or hepatic rupture can occur after trauma, especially if the organs are enlarged as a result of extramedullary hematopoiesis. Occult or superficial vascular tumors can bleed and sequester large volumes of red blood cells and platelets.

Maternal factors can cause prenatal blood loss. Maternal history of vaginal bleeding, placenta previa, abruptio placentae, nonelective cesarean delivery, and cord compression are associated with anemia. Hemorrhage from the umbilical cord may be the result of intrinsic vascular abnormalities, inflammation of the cord, velamentous insertion of the cord, coagulation defects, or an unusually short cord. A normal cord can rupture during a precipitous or assisted delivery or if it becomes tangled around the infant. Accidental incision of the placenta during delivery also can result in bleeding.

Fetal–Maternal Hemorrhage

Fetal cells may be found in the maternal circulation in about half of all pregnancies. At 20 weeks' gestation, the fetoplacental volume is 30 mL, and it is rare for transplacental hemorrhage to exceed 1 mL of fetal red blood cells. By term, fetal–maternal hemorrhage (FMH) during delivery can exceed 30 mL of fetal blood, although in only 0.3% of pregnancies.[61] Fetal–maternal hemorrhage is associated with procedures such as external cephalic version or traumatic amniocentesis. The diagnosis is made by demonstrating fetal RBCs, which contain mostly Hb F, in a maternal blood sample; therefore, the analysis must be done before the fetal cells are cleared from the maternal circulation. The test usually is performed within the first few hours after delivery. In cases of ABO blood group incompatibility, the red blood cells may be cleared more rapidly, and the test may be falsely negative.

The prevention of maternal Rh D alloimmunization requires accurate detection and quantification of fetal blood cells in the maternal circulation. If a D-negative mother has evidence of FMH, Rh immune globulin (Rh IgG) can reduce D-sensitization and the resultant hemolytic disease of the newborn. Vaginal or peripheral blood samples from women with vaginal bleeding late in pregnancy may also be evaluated for the presence of fetal blood cells. The rosette screen is a sensitive, FDA-approved screening test for FMH when the mother is D-negative. Maternal red blood cells are incubated with anti-D and then washed. Indicator D-cells are added, and in the presence of fetal D-positive cells, aggregates or rosettes will be seen by light microscopy. Confirmation of a positive screening test is performed with a quantitative method. The acid elution

technique, or Kleihauer-Betke test, is the most widely available quantitative test for FMH. This method exploits the stability of Hb F–containing RBCs in acid solution relative to cells containing Hb A. False-positive test results are seen in women with any condition (including many of the hemoglobinopathies) that elevates their own Hb F level. The Kleihauer-Betke test suffers from problems with standardization and is labor intensive. Some centers now offer flow cytometry–based quantification of FMH by detecting either Hb F or Rh D or a combination. Flow cytometry can distinguish adult F cells from fetal RBCs.[61]

Twin–Twin Transfusion Syndrome

In monochorionic diamniotic multiple gestations, twin–twin transfusion syndrome (TTTS) (see Chapter 21) can be diagnosed by ultrasound-demonstrating oligohydramnios in the donor sac and polyhydramnios in the recipient sac. Twin–twin transfusion syndrome occurs in 8%-10% of twin pregnancies with monochorionic diamniotic placentation and accounts for about half of the perinatal deaths.[87,118] Twin anemia polycythemia sequence (TAPS) is defined as the presence of anemia in the donor and polycythemia in the recipient twin. Prenatal middle cerebral artery peak systolic velocity criteria have been established for diagnosis in the absence of oligohydramnios–polyhydramnios. Blood can be exchanged unequally between the fetuses through placental vascular interfetal connections. Transfusion can be problematic for the hypovolemic donor who develops oligohydramnios, but the recipient often experiences greater difficulties with hyperbilirubinemia, hypervolemia, and hyperviscosity that arise from the increased RBC mass. Cardiac, neurologic, and developmental disorders have been associated with TTTS.[87,118]

Hemolytic Anemia: Accelerated Red Blood Cell Destruction

Accelerated destruction of RBCs is the end point of a number of intrinsic, extrinsic, congenital, and acquired RBC abnormalities. Because the RBCs of premature infants and newborns have a shorter life span, *hemolysis* is defined as a process that shortens the survival of the RBCs relative to the expected life span for the infant's gestational and postnatal age. In contrast to anemia caused by blood loss, most infants with hemolysis have some evidence of indirect hyperbilirubinemia and elevated lactate dehydrogenase for age. Reticulocytosis should accompany the hemolysis, although in conditions complicated by bone marrow suppression (congenital infections, chronic illness, or nutritional deficiency) or decreased erythropoietin production, the reticulocyte count may be inappropriately low for the degree of anemia present. With maximal response, the bone marrow can compensate for RBC survival of 20-30 days without anemia. The bone marrow may show hyperplasia and a reversal of the usual myeloid-to-erythroid ratio of 3 : 1. Because optimal conditions for bone marrow response are not present in the newborn, hemolysis with anemia and hyperbilirubinemia may be evident in the neonate. In chronic hemolytic states, compensatory hypertrophy of the bone marrow may result in bony changes and other evidence of extramedullary hematopoiesis. Intrinsic hemolytic anemias are caused by inherited abnormalities of the RBC membrane, hemoglobin, or RBC intracellular enzymes. Some intrinsic hemolytic anemias also result in extrinsic damage to the RBC membrane. Extrinsic factors cause hemolytic anemia by damaging the RBC chemically, physically, or immunologically. Extrinsic hemolysis can be divided into immune and nonimmune etiologies (see Box 79.1); the most common causes of immune hemolytic anemia are discussed first.

Immune Hemolytic Anemia

Alloimmune Hemolytic Anemia

Alloimmune hemolytic disease of the newborn (HDN) (see Chapter 23) is caused by the destruction of fetal or neonatal RBCs by maternal immunoglobulin G (IgG) antibodies. Alloimmune HDN involves the major blood group antigens of the Rhesus (Rh) and the A, B, AB, and O systems, but minor blood group incompatibilities (Kell, Duffy, MNS, and P systems) can also be associated with clinically significant disease. Particularly for Rh (D), anti-c, anti-E, and anti-K (Kell) antibodies, intrauterine or direct fetal transfusion may be indicated prenatally, and exchange transfusion may be necessary postnatally. Maternal IgG antibodies can cross the placenta, enter the fetal circulation and cause hemolysis, anemia, hyperbilirubinemia, and hydrops fetalis. In utero, the process is called *erythroblastosis fetalis*, whereas postnatally it is called *hemolytic disease of the newborn* (HDN). Maternal sensitization occurs through a prior transfusion of incompatible RBCs after fetal–maternal hemorrhage of incompatible fetal RBCs or from production of a pre-existing antibody developed against antigens from bacteria, viruses, or food. Transfer of antibodies across the placenta depends on the F_c component of the IgG molecule. Because both IgM and IgA antibodies lack this component, only IgG antibodies cause hemolytic disease of the newborn. Immunoglobulin G_1 antibodies cross the placenta earlier and are responsible for more prenatal hemolysis. Immunoglobulin G_3 antibodies cross the placenta later in gestation and are responsible for more severe hemolysis postnatally.

Rh Hemolytic Disease. The original description of HDN was caused by Rh D incompatibility, and it remains the most severe cause. The spectrum of clinical problems caused by Rh HDN ranges from mild, self-limited hemolytic anemia to hydrops fetalis. With the widespread use of antenatal and postpartum Rh immunoglobulin administration, Rh D sensitization is less common in pregnancies when prenatal care is received. Most cases today are caused by failure to administer Rh immunoglobulin when indicated, lack of identification of a large FMH, and chronic transplacental hemorrhage.

The Rh antigens are inherited as a linked group of two genes, *RHD* and *RHCE*, located on chromosome 1. Persons are typed as Rh negative or positive based on the expression

TABLE 79.9 Prevalence of Rh-Negative Genotype (CDE/cde) by Population

Population Group	Percent Affected
European whites	11-21
US whites	14.4
Indians (India)	8
US African Americans	5.5
Native Americans	0
Chinese	0
Japanese	0

Adapted from Prokop O, et al. *Human blood and serum groups.* Barking, UK: Elsevier; 1969.

of the major D antigen on the RBC, and their RBCs will also express C or c and E or e antigens. Rarely, Rh deletions of D, C/c, and E/e loci can occur. Anti-c and anti-E are emerging as the most frequent causes of HDN as the incidence of Rh(D) disease decreases. The incidence of Rh disease depends on the prevalence of Rh-negative antigens in the population studied (Table 79.9). Even in white populations, only a small percentage of pregnancies are affected because not all women who are Rh negative develop antibodies, Rh immunization of the mother does not usually occur during the first pregnancy, and some of the second infants will be Rh negative.

Because the interaction of the anti-D IgG with a D-positive RBC does not usually involve complement, hemolysis is extravascular. Hyperbilirubinemia and jaundice can occur in the first day of life when the placenta is no longer available to clear bilirubin from hemolyzed RBCs. The peripheral blood smear may show anemia, reticulocytosis, and macrocytosis. Microspherocytes are usually not seen in Rh disease. A direct antiglobulin (Coombs) test should demonstrate anti-D IgG. Partial or total exchange transfusions may be necessary to reduce the load of antibody and remove the antibody-coated cells. Management of hyperbilirubinemia is discussed in Chapter 91.

ABO Hemolytic Disease. Although the incidence of blood group O mothers delivering babies of blood group A or B is about 15%, ABO hemolytic disease is estimated to occur in only 3% of pregnancies and requires treatment with exchange transfusion in less than 0.1% of pregnancies. In contrast to Rh hemolytic disease, ABO hemolytic disease tends to be less severe, and the severity does not depend on birth order. Most anti-A and anti-B antibodies are IgM molecules, which do not cross the placenta. However, maternal anti-A or anti-B IgG antibodies, which may have been raised against A or B substances occurring in food or on bacteria or in response to fetal–maternal hemorrhage, can cross the placenta and react with the sparsely distributed A or B antigens on the neonatal RBCs. Hemolysis is primarily extravascular. Infants may develop anemia, reticulocytosis, and hyperbilirubinemia within the first 24 hours of life. The hallmark of ABO hemolytic disease (in contrast to Rh disease) is the presence of microspherocytes on the peripheral blood smear. The direct antiglobulin test (DAT), or Coombs test, should be at least weakly positive for anti-A or anti-B; however, because of the sparse distribution of antigenic sites on a newborn's RBCs, ABO hemolytic disease may be present even without a positive result on the DAT. The maternal serum should have high titers of IgG directed against A or B (positive indirect antiglobulin test or IAT, which is the indirect Coombs test). In the absence of clinical hemolytic disease, laboratory evidence of erythrocyte sensitization should not be considered HDN.

Minor Blood Group Hemolytic Diseases. The incidence of HDN for minor blood group antigens is related to the antigenicity of the particular blood group antigen and the expression of that antigen on fetal RBCs. Maternal antibodies against minor blood group antigens develop after exposure from a transfusion or prior pregnancy or from contact with bacteria or viruses that express the antigen. Hemolytic disease of the newborn has been associated with the minor group antigens Kell, Duffy, MNS system, and P system. Most clinically significant HDN not attributed to ABO or Rh incompatibility is caused by anti-Kell, anti-E, and anti-c. Kell HDN may require intrauterine intervention. The severity of anti-Kell HDN is owing both to hemolysis and suppression of erythropoiesis in progenitor cells. Screening for minor group antibodies is recommended for all women in the 34th week of pregnancy: Routine screening with cells containing only high-frequency antigens would not detect antibodies to low-frequency antigens. The diagnosis and treatment of hemolytic disease are identical to those for Rh hemolytic disease. Identification of low-frequency antibodies associated with HDN is especially important for mothers who plan additional pregnancies. The role of IVIG in treatment of neonatal hemolytic disease, especially ABO incompatibility, is discussed in Chapter 91.

Natural History of Hemolytic Diseases of the Newborn. Hydrops fetalis is the most severe consequence of hemolysis, but anemia generally is less problematic than hyperbilirubinemia in the acute phase of illness. Hyperbilirubinemia may be evident within the first 24 hours of life. Anemia can occur in the first few weeks in both those who received exchange transfusions and those who required only phototherapy for management of hyperbilirubinemia. The anemia can be caused by ongoing hemolysis, hypersplenism, inadequate replacement by transfused red blood cells, and shortened survival of transfused red blood cells. Because the half-life of IgG molecules is about 28 days, hemolysis should resolve within the first 3 or 4 months. Resolution often occurs sooner if the antibodies are cleared by adhering to RBCs or by exchange transfusion. Thrombocytopenia and bleeding can complicate hemolytic disease. Usually, thrombocytopenia without other laboratory evidence of disseminated intravascular coagulation (DIC) is noted, but DIC can be triggered by massive hemolysis or shock and acidosis.

Other Immune Hemolytic Anemias

The other immune hemolytic diseases of early childhood are relatively rare. Autoimmune hemolytic anemia occurs, as do anemias associated with infections, drugs, and immunodeficiency syndromes. IgG antibodies, with or without complement, are often directed against one of the Rh erythrocyte antigens. These antibodies are most active at 37°C and often are called *warm autoantibodies*. The IgG-coated cells, with or without the assistance of complement, are cleared by the spleen and, to a lesser extent, by the liver. Congenital infections (syphilis, cytomegalovirus, rubella, toxoplasmosis, herpes, HIV, hepatitis) and acquired infections can cause hemolytic anemia and bone marrow suppression with reticulocytopenia (see Chapters 48, 49, and 50). Immunoglobulin M autoantibodies can cause disease and are usually referred to as *cold agglutinins*, because they are most active at between 0°C and 30°C. These antibodies, with complement, coat RBCs and are usually cleared in the liver. Intravascular hemolysis is less common. The best-known causes of cold hemagglutinin disease are *Mycoplasma pneumoniae*, adenovirus, and Epstein-Barr virus. Immunoglobulin A–mediated hemolysis is quite rare but is remarkable for its severity (Table 79.10).

The natural history of autoimmune hemolytic disease in infancy is that of a rapid onset of anemia with hyperbilirubinemia, splenomegaly or hepatomegaly, and hemoglobinuria (with intravascular hemolysis). Initially, reticulocytopenia may be noted, especially if antibodies are directed against RBC progenitors in the bone marrow, but a brisk reticulocytosis usually follows. Resolution within 3-6 months is common. Anemia with reticulocytosis and spherocytosis may be seen on the peripheral blood smear, but the diagnosis depends on demonstration of antibody-coated cells, with or without complement, in the DAT and antibodies in the serum by the IAT. Therapy includes treatment of underlying infection, removal of the offending drug, and supportive measures to limit hyperbilirubinemia. Response to corticosteroids is common, as is complete recovery. Steroids are less effective in IgM-mediated disease. A subset of patients younger than 2 years, and with a slower onset of disease at presentation, develops chronic hemolytic anemia. Difficulties with identifying compatible blood during a hemolytic crisis, as well as the usually self-limited nature of the disease, restrict blood transfusions to cases in which severe anemia impairs tissue oxygenation.

TABLE 79.10 Acute Hemolytic Anemia: Causative Mechanisms and Representative Infectious Agents

Mechanism	Infectious Agent
Hemolysin production	*Clostridium perfringens*
Direct invasion of RBCs	Malaria
Alteration of RBC surface:

Nonimmune Hemolytic Anemia

Erythrocyte Structural Defects

During its lifetime, a normal RBC traverses the circulation thousands of times, enduring tremendous mechanical and metabolic stress with each passage. The smallest capillaries have an internal diameter that is smaller than the diameter of the RBC; thus the blood cells must deform to squeeze through the capillaries and then return to their normal shape as they enter distal venules. During their rapid transit, the RBCs must endure tremendous fluctuations in pH, Po_2, and osmotic pressure. The lipid bilayer that forms the cell membrane is the site of numerous biologic functions mediated by integral proteins. It also is the attachment site for the proteins of the cytoskeleton, which confer the shape and stability necessary for proper membrane function. Some abnormalities in the membrane-cytoskeleton unit result in morphologic defects of RBCs (Fig. 79.6). Because abnormally shaped RBCs are removed from the circulation by the reticuloendothelial system, many of these defects cause some degree of hemolytic anemia. Analysis of these congenital defects has led to an understanding of the erythrocyte membrane and cytoskeleton. The more common erythrocyte cytoskeletal defects originally were described by morphologic and clinical criteria. With better understanding of the cytoskeleton at a molecular level, it became clear that various mutations in genes coding for a few structural proteins are responsible for a family of inherited hemolytic anemias with overlapping morphologic, clinical, and genetic features. Mutations in the genes encoding α-spectrin, β-spectrin, ankyrin, protein 4.1, glycophorin C, protein 4.2, and band 3 have been reported in patients with hereditary defects of the red blood cell membrane/cytoskeleton.[17,91] Inherited hemolytic anemias caused by RBC membranopathy, enzymopathy, and hemoglobinopathy are generally diagnosed by using conventional methods, including RBC morphology, membrane protein analysis, Hb electrophoresis, and measurement of RBC enzyme levels. In the genetic era, Sanger sequencing has been useful for detecting genetic mutations that cause inherited hemolytic anemias. Sanger

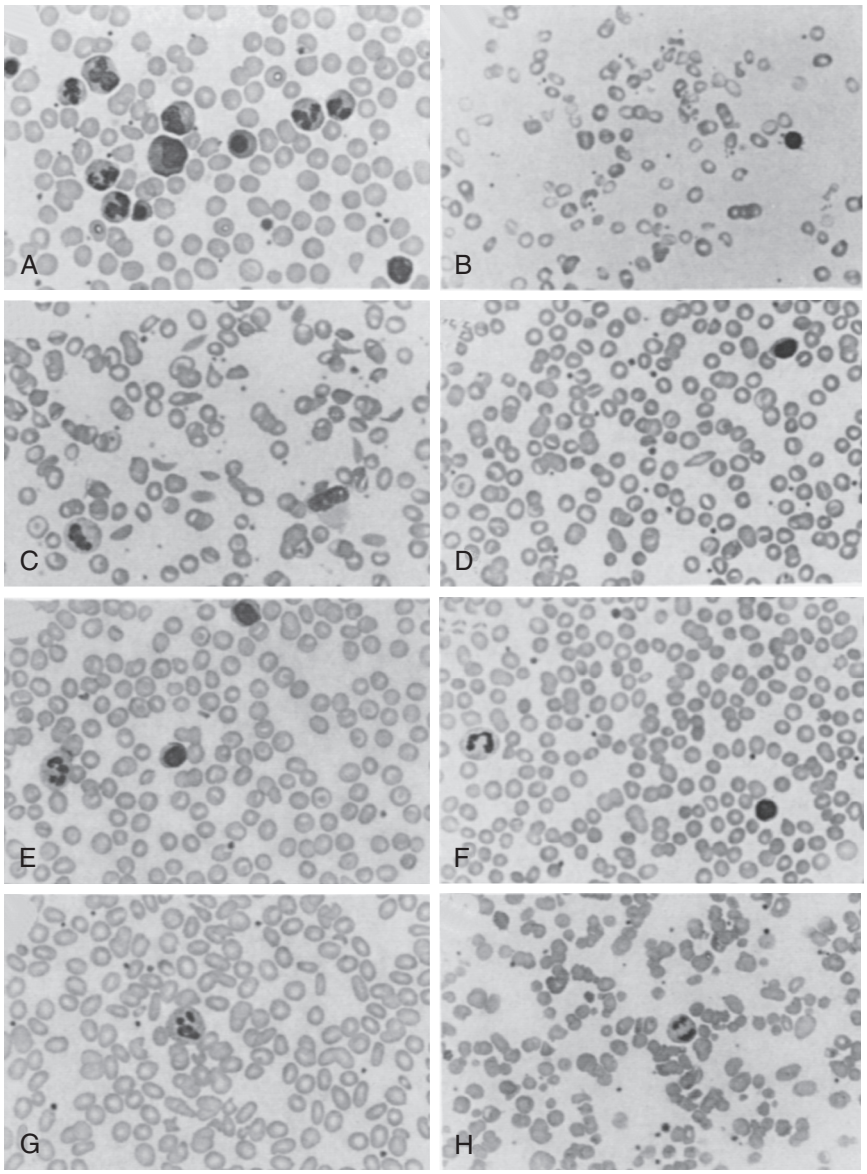
• **Fig. 79.6** Molecular origins of hereditary spherocytosis (HS) and hereditary elliptocytosis-pyropoikilocytosis (HE/HPP) based on the hypothesis of vertical and horizontal defects. Vertical interactions are those needed to stabilize the attachment of the spectrin lattice to the lipid bilayer. Abnormalities in this attachment result in destabilization of the lipid bilayer, membrane loss during splenic conditioning, and HS. Horizontal interactions reversibly hold spectrin dimers and tetramers together, allowing stretching and distortion of the red blood cell membrane during circulation. Weakening of these interactions results in loss of elasticity. GP, Glycoproteins. (Adapted from Palek J. Red cell membrane disorders. In: Hoffman R, et al., eds. *Hematology: basic principles and practice*. New York: Churchill Livingstone; 1991:472.)

sequencing is widely applied to identify disease-causing mutations in cases where traditional testing has failed or when a patient has been extensively transfused, leading to confounding biochemical and other testing findings caused by mixed RBC populations. Recent advances in genetic technology using next generation sequencing have enabled better identification of various genetic mutations that can cause these conditions.[60]

Membrane defects associated with hemolytic anemia may present in the neonate with hepatosplenomegaly, hyperbilirubinemia, and hemolytic anemia. Aplastic crisis, attributed to drugs or an infectious agent such as parvovirus B19, or splenic sequestration, may cause life-threatening anemia in patients with hemolytic anemia. The more severe cases of hemolytic anemia can require splenectomy, although surgery generally is delayed beyond the first few years of life.



Hereditary Spherocytosis. Hereditary spherocytosis (HS) is characterized by the appearance of spherocytes on the peripheral blood smear, accompanied by a hemolytic anemia of varying severity and splenomegaly. Hereditary spherocytosis occurs predominantly in those of Northern European ancestry. Inheritance usually is autosomal dominant, but autosomal recessive and autosomal dominant inheritance with reduced penetrance also have been reported. Spontaneous mutations account for about one-fourth of HS. The defects alter the vertical stability of the cytoskeletal attachment to the lipid bilayer so that pieces of untethered membrane are removed in the spleen. Defects

or deficiency in ankyrin are the most common, although defects in spectrin, band 3, and protein 4.2 also occur. Nondeformable spherocytes with a decrease in the surface area are more susceptible to lysis with exposure to the metabolic and deformation stresses of the splenic sinuses or with incubation in hyposmolar solutions. The osmotic fragility test exposes the suspected cells and normal control cells to progressively more hypotonic solutions and compares their ability to resist lysis.[16,18]

Hereditary Elliptocytosis and Hereditary Pyropoikilocytosis. The findings on the peripheral blood smears in hereditary elliptocytosis and hereditary pyropoikilocytosis are distinct (Fig. 79.7). Hereditary elliptocytosis (HE) is an autosomal dominant condition characterized by elliptical RBCs called ovalocytes, which is more common in people of African and Mediterranean origin. In hereditary pyropoikilocytosis (HPP), the RBC morphology is bizarre, marked by fragments, elliptocytes, and spiculated cells. The disorders are caused by defects in cytoskeletal proteins, most commonly α- or β-spectrin, which weaken the horizontal interactions necessary for cytoskeletal stability and reversible deformability (see Fig. 79.6). The deformed RBCs are prematurely cleared by the reticuloendothelial system. Hemolysis in HE generally is milder than in hereditary spherocytosis. The majority of those with HE are symptomatic. Hereditary pyropoikilocytosis is caused by homozygous or compound heterozygous defects.[16,18] Some neonates with HE may exhibit hemolysis with HPP morphology on blood smear, but later in life their red blood cells will appear as typical elliptocytes. Hereditary pyropoikilocytosis is associated with more severe hemolysis and hyperbilirubinemia, often requiring exchange transfusion or phototherapy in the neonatal period. Examination of blood smears from each parent may be helpful in making this diagnosis.

Southeast Asian ovalocytosis (SAO), or stomatic elliptocytosis, is a mild hemolytic variant of HE, which is common

in Southeast Asia, likely because it confers malaria resistance. Defects in band 3 are the most common.[16,18]

Spherocytic elliptocytosis, characterized by spherocytes and elliptocytes and a mild hemolysis, occurs in those of European ancestry.[16,18]

Membrane Lipid Defects

Membrane lipid abnormalities can be inherited but most often are acquired. Their presence, detected by morphologic abnormalities on the peripheral blood smear, is most important as the signal of an underlying disease. Target cells form when the surface-to-volume ratio of the red blood cell increases, either because of poorly hemoglobinated cells (iron deficiency, thalassemias, Hb C) or because lipids are added to the RBC membrane (liver disease with intrahepatic cholestasis, lecithin-cholesterol acyltransferase deficiency). Acanthocytes form when the membrane lipid composition between the inner and outer leaflets of the bilayer is altered, as in liver disease and abetalipoproteinemia.

Inherited Enzymatic Defects

The mature RBC, lacking a nucleus, polyribosomes, and mitochondria with which to carry out protein synthesis, must circulate through extremes of pH, Po_2, and osmotic gradients while maintaining deformability and integrity. Red blood cells metabolize glucose through the Embden-Meyerhof pathway and hexose monophosphate shunt to provide energy for maintaining ionic pumps, to reduce methemoglobin, and to synthesize small molecules such as adenine, guanine, pyrimidine nucleotides, glutathione, and lipids. The most commonly defective enzyme, glucose-6-phosphate dehydrogenase (G6PD), has been extensively evaluated at the clinical, biochemical, and molecular level. Many other enzymatic defects have been reported, but the rarity of the disorders has hindered investigation. Enzymatic defects of the RBC known to be associated with hemolytic anemia are listed in Box 79.3. A few of the enzyme deficiencies cause abnormalities in other tissues. The end result of these defects is hemolytic anemia of varying severity, sometimes called *hereditary nonspherocytic anemia*. The RBCs may be morphologically normal and usually produce normal results on osmotic fragility testing, but they have a shorter life span. The milder cases cause little difficulty in the neonatal period. Some defects are associated with chronic and/or severe hemolysis, necessitating intermittent or chronic blood transfusions.

Glucose-6-phosphate dehydrogenase deficiency is the only common defect of RBC enzymes and can be associated with severe hemolysis, anemia, and hyperbilirubinemia in the neonate, although many are asymptomatic. This enzymatic defect is common in infants with bilirubin encephalopathy. Occasionally, the hyperbilirubinemia is severe, because of an interaction of G6PD deficiency with the $(TA)_7$ promoter polymorphism of the UDP-glucuronosyltransferase 1A1 (UGT1A1) bilirubin-conjugating enzyme.[57] The prevalence among some ethnic groups suggests a selective advantage, because deficient cells are resistant to malaria. As an enzyme in the pentose phosphate pathway, G6PD supplies NADPH, and by producing hydrogen ions, promotes reduction of glutathione. Deficiency limits the cell's ability to recover from oxidative stress. The gene is inherited as an X-linked recessive. Males are affected most commonly. Females may also be affected, either because of homozygosity or compound heterozygosity, or in cases in which X-inactivation is unbalanced. In the United States, African-American males are the most commonly affected. The A-minus variant, common in Africans, results in a mild reduction in both catalytic activity and stability. The B variant, common among Mediterranean, some Asian, and Ashkenazi Jewish populations, involves a severe reduction of enzyme activity, resulting in chronic, moderate-to-severe hemolytic anemia that could prove fatal in the face of severe oxidant challenge. In affected patients, the oldest RBCs are most deficient, resulting in a normal or minimally shortened erythrocyte life span, but exposure to oxidant drugs and toxins or a febrile episode can precipitate severe hemolysis. Hemolysis occurs within 24-48 hours of exposure and is accompanied by abdominal pain, vomiting, diarrhea, low-grade fever, jaundice, splenomegaly, hemoglobinuria, and anemia.

Neonates may present with hemolytic anemia and hyperbilirubinemia within 24 hours of life and are susceptible to developing methemoglobinemia. Management involves

avoidance of precipitating agents, hydration, phototherapy and, if needed, transfusion (partial volume exchange or simple). Common drugs to be avoided or used with caution in this disorder include antimalarials, sulfonamides and sulfones, nitrofurans, anthelminthics, ciprofloxacin, methylene blue, acetaminophen, aspirin, and vitamin K analogues. An excellent resource for complete food and drug lists, as well as family education, is at https://www.g6pd.org (accessed May 4, 2018). Enzyme levels are highest in younger cells. Evaluation immediately after a hemolytic episode could be inconclusive because the older, abnormal cells have been destroyed. Repeat quantitative testing at a later time, as well as evaluation of maternal enzyme levels, can be useful. Some states and countries include GPD deficiency screening as part of their newborn screening program, using biochemical qualitation, biochemical quantitative assays, and DNA-based PCR screening for common mutations.[57,93]

Vitamin E Deficiency

Vitamin E is a fat-soluble antioxidant that reduces the peroxidation of polyunsaturated fatty acids by reactive oxygen species during oxidative enzyme activity. Preterm infants and infants with low birth weight have low serum and tissue levels of this vitamin. Patients who have chronic fat malabsorption are the most likely to develop symptomatic vitamin E deficiency. A deficiency state in preterm infants and those with very low birth weight has been described, characterized by hemolytic anemia, reticulocytosis, thrombocytosis, chronic lung disease, intracranial hemorrhage, and retinopathy of prematurity. However, present evidence does not support routine supplementation with intravenous or high-dose vitamin E in neonates.

The Thalassemias

The thalassemias are a group of hereditary anemias that arise from quantitative defects in the synthesis of globin chains. In their milder forms, thalassemias are among the most common heritable disorders. The α-thalassemias are most common in the Chinese subcontinent, Malaysia, Indochina, and Africa. β-Thalassemia is common in Mediterranean and African populations but also has a higher incidence in China, Pakistan, India, and the Middle East. Hemoglobin E is common in Southeast Asia. The four α-thalassemia syndromes (silent carrier, α-thalassemia trait, Hb H disease, and hydrops fetalis) are caused by diminished production of α-globin protein because of deletion in one, two, three, or four of the α-globin genes, respectively. Although only two genes for β-globin production are inherited, there are four clinical classifications for β-thalassemia: silent carrier, β-thalassemia trait, thalassemia intermedia, and thalassemia major. The blood smear shows hypochromic microcytes, target cells, and nucleated RBCs. Bizarre RBC shapes and fragments are seen in more severe disease. The clinical outcome in this disease is a result of complex interactions involving the type of genetic defect, the degree of β-globin production, and the ratio of α-globin chains produced relative to the number of β-globin chains (Table 79.11). Abnormal hemoglobin tetramers can accumulate in the bone marrow and reticuloendothelial system, resulting in ineffective erythropoiesis. Mutant hemoglobins can precipitate to form inclusion bodies that adhere to cell membranes, promote oxidative damage to the membrane, diminish cell deformability, and shorten RBC survival. Coinheritance of α- and β-globin defects may result in a less severe thalassemia, because the ratio of α- to β-globin chains is rebalanced.

Prenatal diagnosis strategies are available for both α- and β-thalassemia. If evaluation of the parents' RBCs provides evidence of thalassemia, molecular detection strategies can be used. Fetal tissue from chorionic villus sampling (10-12 weeks' gestation) or amniocentesis (15-20 weeks) can be analyzed by a number of DNA-based methodologies (see Chapter 10). After 18-20 weeks' gestation, fetal reticulocytes may be tested for globin chain biosynthetic ratios, although sampling carries higher risks.

α-Thalassemia

Because the production of α-globin chains predominates from midgestation onward, defects in synthesis can be

detected at birth. Before the debut of molecular analysis, the various α-thalassemia syndromes were assigned according to clinical criteria (Table 79.12). Hydrops fetalis, the most severe and rarest form of α-thalassemia, occurs when an infant inherits deletions of both α-globin genes from each of the parents (see Chapter 23). Such an infant produces small quantities of Hb Portland to maintain in utero viability. The excess γ and β chains form tetramers with themselves, resulting in functionally useless Hb Barts (γ_4), present in the newborn, and Hb H (β_4) present in the older infant. The fetus with four α-globin gene defects experiences congestive heart failure in utero secondary to severe anemia and, in the absence of fetal transfusion, becomes grossly hydropic (hydrops fetalis). There is evidence of extensive extramedullary hematopoiesis and placental hypertrophy. Most are stillborn at 30-40 weeks' gestation or die shortly after delivery. Infants with hepatosplenomegaly, jaundice, and a moderate hypochromic, microcytic hemolytic anemia should be evaluated for deletion of three α-globin genes, Hb H disease. At birth, large amounts of Hb Barts may be seen as well as some Hb H. Incubation of the RBCs with brilliant cresyl blue reveals many small inclusions. Treatment is supportive and includes supplementation with folic acid, avoidance of oxidant drugs, transfusion of RBCs, and attention to iron hyperabsorption and transfusional iron overload. Hypersplenism,

characterized by leukopenia, thrombocytopenia, and worsening anemia, may necessitate splenectomy, although this usually is deferred beyond the first few years of life and is associated with infectious risk as well as increased thrombosis.

α-Thalassemia trait is characterized by a mild anemia with microcytosis, hypochromia, and erythrocytosis. Hemoglobin Barts is mildly elevated at birth. After the neonatal period, there is no simple laboratory evaluation that is diagnostic for α-thalassemia trait. Alpha globin gene analysis can be ordered to confirm clinical suspicion. The diagnosis usually is made in an iron-replete patient with a normal hemoglobin electrophoresis and appropriate family history for α-thalassemia. As the name implies, silent carriers of α-thalassemia could have slightly microcytic RBCs but usually are asymptomatic. Several states now use molecular testing for *HBA1* and *HBA2*, the genes coding for α_1- and α_2-globin, respectively.

β-Thalassemia

β-Thalassemia is not usually diagnosed at birth unless blood loss or RBC destruction has created an unusually high demand for replacement of fetal RBCs with adult. The disease generally manifests after 6 months of age, when a microcytic anemia persists beyond the time course for physiologic anemia. The more severe manifestations of the disease traditionally were called *Cooley anemia*, but these have been separated into *thalassemia major* and *thalassemia intermedia* (see Table 79.12). Affected patients exhibit splenomegaly, poor growth, microcytic hemolytic anemia with ineffective erythropoiesis, target cells on the peripheral blood smear, and extramedullary expansion of erythropoiesis. An abnormal hemoglobin analysis reveals elevations of Hb F and Hb A_2 and a decrease in Hb A.

Patients are categorized as having thalassemia intermedia if they are able to maintain a hemoglobin level greater than 7 g/dL without routine transfusion. Thalassemia major patients require regular transfusions and iron chelation therapy to maintain a hemoglobin value adequate for growth and development. Iron overload is a significant cause of morbidity and mortality starting in the second decade of life. Evidence of hypersplenism may necessitate splenectomy. Bony deformities from expansion of extramedullary hematopoiesis occur in incompletely transfused patients.

β-Thalassemia trait is characterized by abnormalities on the blood smear: microcytosis, hypochromia, erythrocytosis, and the appearance of elliptocytes and target cells. Hemoglobin analysis reveals a mild elevation of Hb A_2 and Hb F, although this is not observed if the genetic mutation also interferes with production of δ- or γ-globin or if Hb A_2 and Hb F production are depressed because of coexistent iron deficiency anemia. The silent carrier state of β-thalassemia is associated with normal findings on the peripheral blood smear and hemoglobin electrophoresis and usually is identified through family studies of patients with a more severe β-thalassemia syndrome.

Hemoglobin E

Hemoglobin E causes one of the most common hemoglobinopathies in the world. This thalassemia syndrome, characterized as a qualitative and quantitative hemoglobinopathy, is particularly abundant among people of Southeast Asian ancestry, especially individuals from Laos, Cambodia, and Thailand. Hemoglobin E is generated by a single nucleotide substitution, Glu26Lys, in the coding region of the β-globin gene. The β-globin monomers associate normally with a pair of α-globin proteins to form a functional hemoglobin tetramer with essentially normal stability and oxygen-dissociation characteristics. Persons with Hb E are anemic because the mutation creates a cryptic splice site in the β-globin message. During RNA processing, a portion of the message is spliced into an abnormal, unstable transcript. Consequently, the total level of β-globin messenger RNA is reduced, resulting in a thalassemia phenotype. Hemoglobin E trait results in mild microcytosis. Those who are homozygous for Hb E have chronic, mild to moderate, microcytic anemia but are otherwise well; however, co-inheritance of an Hb E allele from one parent and a β-thalassemia allele from the other produces a moderate to severe anemia that can be transfusion dependent. Hemoglobin levels in these patients range from 2-7 g/dL, and children with this condition can develop hepatosplenomegaly and growth failure. Hemoglobin E-β^0 thalassemia disease now is the most common form of transfusion-dependent thalassemia in the United States and other parts of the world. Hemoglobin E co-inherited with Hb S results in a sickle phenotype.

Inefficient erythropoiesis is the main mechanism underlying the complications in thalassemia major, such as anemia, splenomegaly, bone malformations, and pulmonary hypertension. New knowledge has become available on pathways that contribute to the pathogenesis and clinical manifestations of this disease. Clinical trials with JAK2 inhibitors (ruxolitinib) and TGF-β family member inhibitors, sotatercept and luspatercept, are currently studying the benefits of these agents in decreasing ineffective erythropoiesis and splenomegaly.[7,88,130]

Another modality of treatment for hemoglobinopathies is gene therapy, which is showing its safety and potential efficacy in both preclinical and early clinical studies. Gene therapy is now a reality, with seven patients cured of their β0/βE thalassemia or with significant amelioration from β0/β0 thalassemia and one patient with SCD, while others are showing modest transgene expression.[42,47,73,103]

Qualitative Defects in Hemoglobin: Hemoglobin Variants

In the fetus, switching from one type of globin chain expression to another occurs several times (see Fig. 79.2), and during the first few months of the postnatal period, the final switch to the adult-type hemoglobin occurs. Some hereditary defects in fetal globin gene products can produce a hemolytic anemia that resolves as β-globin gene expression predominates. Similarly, a neonate who is asymptomatic at birth can develop a hemolytic anemia over the subsequent

months as production of β-globin–containing hemoglobin assumes major importance. Because α chains are produced from the fetal period onward, defects in α-globin are present at birth. If the combination of the mutant α- and the γ-globin is more unstable than that of α- and β-globin or α- and δ-globin, the infant experiences a transient hemolytic anemia that resolves as Hb A predominates.

More than 500 structurally different hemoglobin variants have been reported. The clinically important variants are listed in Box 79.4. Most involve a single amino acid substitution in one of the globin polypeptide chains owing to a single nucleotide change in DNA. Other variants are the result of gene deletions or duplications caused by unequal crossover.

Unstable Hemoglobins

Most mutations causing unstable hemoglobin affect β-globin and involve amino acid substitutions in hydrophobic residues around the heme pocket. These amino acid replacements alter the hydrophobic interior of the molecule, predisposing the hemoglobin to instability and precipitation as small round inclusions known as Heinz bodies. Because the amino acid substitutions often involve replacing one neutral amino acid with another, the hemoglobin electrophoretic mobility may not change. Patients usually develop anemia and jaundice in late infancy as β-globin synthesis increases. Mutations in fetal or embryonic globins can cause symptoms at birth but not later in life. The diagnosis is confirmed by supravital staining for Heinz bodies, which are usually present, and hemoglobin analysis after isopropanol precipitation.

Unstable	Hb Hasharon
Decreased solubility	Hb S, Hb C

Sickle Cell Anemia

Sickle cell disease is a common medical problem in the United States, where 1 in 400 newborns is affected. By definition, *sickle cell anemia* refers to the doubly heterozygous inheritance of abnormal genes that code for the substitution of valine in place of glutamic acid at position six in the β chain of hemoglobin (Hb SS). There are also a number of sickle hemoglobinopathies in which one gene coding for Hb S is inherited along with a second abnormal β-globin gene coding for other hemoglobins, such as Hb C, D, O^{Arab}, or β-thalassemia. The clinical course of affected patients may be indistinguishable from, or milder than, those of Hb SS disease. As with the thalassemias, prenatal diagnostic techniques are available. Newborn screening programs have been instituted in many parts of the world, including most of the United States. Samples of cord or capillary blood are subjected to testing, usually hemoglobin electrophoresis, high pressure liquid chromatography, or isoelectric focusing. Infants with abnormal results on the newborn screen are referred for confirmatory testing and disease counseling (Fig. 79.8; Box 79.5).

The clinical hallmark of Hb SS disease is hemolytic anemia with reticulocytosis and the appearance of irreversibly sickled cells on the peripheral blood smear. The onset of signs and symptoms correlates with the decrease in Hb

F levels and increasing expression of the mutant β-globin gene products during the first year of life. Neonates generally are asymptomatic, although older infants are at risk for several disease-related complications. Because of splenic dysfunction, infections with certain bacteria, such as pneumococcus, are a major cause of mortality and morbidity in infants and young children. A suddenly pale, listless infant may be experiencing life-threatening anemia caused by hepatic or splenic sequestration. Aplastic crisis, triggered by infection or drugs, also may occur. Vaso-occlusive crisis of the infant's hands and feet, the hand–foot syndrome (dactylitis), manifests with pain, warmth, and swelling of the hands and/or feet.

Identification of affected newborns through newborn screening programs with enhancements in parent education and supportive care such as penicillin prophylaxis, immunization against *S. pneumoniae* and *H. influenzae*, and early identification of hepatic or splenic sequestration have decreased the death rate for infants and children. The natural history of sickle cell anemia includes painful vaso-occlusive events, acute and chronic lung disease, stroke, overwhelming sepsis from splenic dysfunction, avascular necrosis of joints, retinopathy, and transfusion-related iron overload. The National Heart, Lung and Blood Institute (NHLBI) issued management guidelines for sickle cell disease in 2002, which are available at https://www.nhlbi.nih.gov/files/docs/guidelines/sc_mngt.pdf. Treatment of the sickle hemoglobinopathies has been largely supported using penicillin prophylaxis; vaccinations; blood transfusions with extended RBC phenotyping; cross-matching to decrease the incidence of transfusion-associated alloimmunization; and hydration, narcotics, and nonsteroidal anti-inflammatory drugs for painful crises. Hydroxyurea decreased the number and severity of vaso-occlusive pain events in infants and young children with Hb SS and Hb SB^0 thalassemia in the randomized, placebo-controlled BABY HUG study.[131] Stem cell transplantation, the only established cure for sickle cell anemia, has been limited by the availability of suitable donors and the uncertainty in predicting which children will express a more severe phenotype. Ongoing studies using reduced intensity conditioning regimens and alternative donor options, as well as risk stratification of sickle cell patients, may allow larger number of patients to undergo stem cell transplantation in the future.

Sickle Cell Trait

Heterozygotes for Hb S (sickle cell trait) were thought to be clinically unaffected, but there are reports of hematuria, decreased urinary concentrating ability, and occasional reports of sudden death related to high altitude and extreme exercise. Associations have been made between sickle cell trait and venous thrombosis, renal medullary carcinoma, and a more severe course of diabetes mellitus.

When to Use Molecular Testing for Patients with Hemoglobin Disorders

Patients suspected of having hemoglobin disorders are screened with a CBC and hemoglobin analysis. Depending on the results and whether there are genetic counseling issues to consider, molecular testing for globin abnormalities may be indicated. Patients with ambiguous hemoglobin results or unusual phenotypes are candidates for DNA testing. Couples seeking genetic counseling should be offered DNA testing when both prospective parents are suspected of having *cis* α-globin deletions or both have β-thalassemia traits. In addition, individuals with β-thalassemia trait or hemoglobin E trait may have coincident α-thalassemia trait that is masked by the microcytosis associated with these β-globin disorders. In such cases α-globin DNA testing might be advised to evaluate risk to offspring of hemoglobin Bart's hydrops fetalis. Prenatal genetic testing should be offered to couples at risk for having an offspring with clinically severe hemoglobin disorders.[111]

Anemia Caused by Inefficient Production of Red Blood Cells

Iron Deficiency Anemia

Although the prevalence of iron deficiency anemia is decreasing in the United States, it remains a major cause of anemia in infants and children, and it has been associated with adverse neurocognitive outcomes. Factors associated with the declining rates of iron deficiency anemia include the increasing number of infants receiving breast milk, the use of standard iron-supplemented infant formulas and iron-supplemented baby cereals during the first year of life, and the delay of the introduction of cow milk into the infant diet until after 1 year of age.

Iron is an essential nutrient. Most iron is bound to the heme proteins, hemoglobin, and myoglobin. The storage proteins ferritin and hemosiderin contain most of the rest of the iron. A small percentage is bound in enzyme systems such as cytochromes and catalase. In healthy adults, most of the body's iron is recycled from the breakdown of RBCs. Little iron needs to be absorbed from the intestines, and little is lost through fecal or urinary excretion. Because neonates must rapidly expand muscle mass and blood volume, they require a much higher percentage of dietary iron intake. The amount of iron stored in the neonate's body is proportional to birth weight. Eighty percent of a term infant's iron is acquired during the third trimester.[11] For a full-term infant, this should be sufficient for the first 4-6 months of life. Preterm infants and those born small for gestational age have a much faster rate of postnatal growth and are at risk for iron deficiency within the first 3 months of life (Box 79.6). Infants born anemic and those who have accelerated iron losses from repeated laboratory testing, trauma, surgery, or anatomic abnormalities may also become deficient. Although both breast milk and cow milk contain iron, the bioavailability of the iron in breast milk is much superior. The American Academy of Pediatrics (AAP) Committee on Nutrition updated its recommendations for diagnosing and preventing iron deficiency and iron deficiency anemia in 2010 (Table 79.13).[11] Full-term infants who are breastfed should not require iron supplementation until 4-6 months of age. At 4 months of age, human milk–fed infants should receive iron supplementation until they are eating iron-containing foods. Two daily servings of an iron-fortified cereal will meet this requirement. Infant cereal fortified with iron should be one of the earliest solid foods introduced. After 6 months of age, one daily serving of a vitamin C–rich food should be introduced. Because the protein in cow milk can cause occult gastrointestinal bleeding in the neonate and because of the poor bioavailability of iron in cow milk, it is recommended that babies avoid cow milk until after 1 year of age. In general, preterm infants who are fed human milk require iron supplementation after 1 month of age, either by a supplement added to the breast milk or iron given directly to the infant. An exception may be made for infants who have received multiple blood transfusions and are thus at risk for iron overload rather than deficiency. A thought-provoking, randomized, placebo-controlled trial of daily oral iron supplementation in very low birth weight infants (<1500 g) of less than 32 weeks' gestational age, who were managed on a liberal transfusion strategy, did not demonstrate an increase in the hematocrit, reticulocyte count, or transfusion requirements at week 36 postmenstrual age.[124]

With improved survival in the smallest patients, additional knowledge gaps and opportunities for investigation are identified in diagnosing, treating, and preventing iron deficiency and iron deficiency anemia (Box 79.7). Although severe iron deficiency in children is fairly simple to

• BOX 79.6 Risk Factors for Iron Deficiency Anemia in Infants

- Prematurity
- Small for gestational age
- Anemia at birth
- Fetal–maternal hemorrhage
- Twin–twin transfusion
- Perinatal hemorrhage
- Iatrogenic or other ongoing blood loss
- Insufficient dietary intake or malabsorption
- Early introduction of cow milk
- Erythropoietin use
- Maternal conditions: severe iron deficiency, diabetes

TABLE 79.13 Guidelines for Iron Supplementation for Infants in the First Year of Life

Birth Status	Intake	Minimum Daily Recommendation	How Supplied
Term, healthy	Human milk	1 mg/kg per day after 4 mo of age until addition of complementary iron-rich foods	Iron supplement until addition of complementary iron-rich foods
Term, healthy	>Half human milk	1 mg/kg per day after 4 mo of age until addition of complementary iron-rich foods	Iron supplement until addition of complementary iron-rich foods
Term, healthy	Standard infant formula	1 mg/kg per day after 4 mo of age	Supplied by standard infant formula and/or addition of complementary iron-rich foods
Preterm	Human milk	2 mg/kg per day beginning at 1 mo of age and until 12 mo of age	Supplement added to human milk or given separately until addition of complementary iron-rich foods
Preterm	Standard infant formula	2 mg/kg per day beginning at 1 mo of age and until 12 mo of age	Supplied by full feeds of standard infant formula and/or complementary iron-rich foods

• BOX 79.7 Challenges in the Diagnosis and Treatment of Iron Deficiency and Iron Deficiency Anemia in Neonates

- Optimal lab testing for premature infants
- Optimal formulation of iron supplementation
- Optimal iron preparation
- Optimal dose and interval of supplementation
- Duration of iron supplementation
- Incidence and proper management of adverse effects of iron supplementation

Adapted from Buchanan GR. Paucity of clinical trials in iron deficiency: lessons learned from study of VLBW infants. *Pediatrics*. 2013;131:e582-e584.

diagnose, milder deficiency may not yet have caused anemia or may be difficult to distinguish from other causes of microcytic anemia, especially in patients with chronic or acute illness. The AAP recommends that testing for anemia by hemoglobin estimation should occur at approximately 12 months of age. In addition, there should be an assessment of risk factors for iron deficiency/iron deficiency anemia at that time. Earlier and/or more frequent assessments should occur in situations of high concern. A careful dietary history should be taken, and consideration should be given to special circumstances such as ongoing blood loss, malabsorption, early or excessive cow milk intake, and birth history. In early iron deficiency, the bone marrow stores are depleted and the RBC distribution width increases. Subsequently, the iron transporter levels fall, resulting in lower serum levels of iron, ferritin, and transferrin in the term infant. Finally, erythrocyte production is affected. A hypochromic, microcytic anemia becomes apparent. Screening test results such as serum iron, total iron-binding capacity, ferritin, and transferrin saturation may be inconclusive because of acute or chronic illness. It is unclear what testing is optimal in the premature infant. The AAP favors the reticulocyte Hb concentration (CHr) and the serum transferrin receptor 1 (TfR1), because these tests are not affected by inflammation or infection, but these tests are not widely available. A therapeutic trial of iron for presumptive iron deficiency anemia is a cost-effective strategy. Ferrous sulfate, in a dose of 2-6 mg/kg per day of elemental iron, may be given for 1 month. If the hemoglobin rises by at least 1 g/dL (in the absence of ongoing blood loss), the diagnosis of iron deficiency is made, and the iron supplementation is usually continued for 2-3 more months or until 1-2 months after the hemoglobin is in the normal range. Screening for lead exposure should be done as part of routine well-baby care and particularly considered if a hypochromia and microcytosis are detected.

Iron Transport Proteins and Iron Homeostasis

Our knowledge of iron biology has been enriched substantially by the recent discovery of mammalian iron transport proteins (DMT1, ferroportin, mitoferrin 1, and ZIP14), heme transporters (HRG1and FLVCR1), iron chaperones (PCBPs), ferrireductases and ferroxidases (DCYTB, STEAP3, PrPc, and hephaestin), and the iron-regulatory hormone hepcidin. The physiologic function of these proteins has been studied to a great extent and the implications of their up-and-down regulation.

We have learned in depth the mechanisms through which iron is transported in the gut. Iron is transported out of the enterocyte and into portal blood via ferroportin (SLC40A1) located on the basolateral membrane. Ferroportin transports only Fe2+, whereas transferrin in portal blood will bind only Fe3+. Efficient transfer of iron to portal blood transferrin is thought to involve an oxidation step catalyzed by a ferroxidase. The best characterized intestinal ferroxidase is hephaestin, a membrane-anchored homologue of the plasma ferroxidase, ceruloplasmin.

Iron Metabolism in Erythrocyte Precursors

Greater than 95% of iron in plasma is bound to its circulating transport protein transferrin, which delivers most of its iron to erythrocyte precursors (i.e., erythroid progenitor cells of the bone marrow that differentiate into mature RBCs). Each day, ~25 mg of iron is taken up into these cells to support the daily production of 200 billion new RBCs. Erythrocyte precursors take up iron nearly exclusively from transferrin via transferrin receptor 1 (TFR1). The quantitative importance of this uptake is illustrated by the fact that an estimated 80% of total body cellular TFR1 is located in the erythroid marrow of an adult human. When transferrin binds to TFR1 at the cell surface, the complex is internalized into endosomes, which become acidified, causing iron to dissociate from transferrin. The endosomal ferrireductase STEAP3 (six-transmembrane epithelial antigen of the prostate 3) reduces the liberated Fe3+ to Fe2+, which is subsequently transported into the cytosol via DMT1.[62,96] Despite being the most avid consumers of iron in the body, erythrocyte precursors abundantly express ferroportin at the plasma membrane and are therefore able to export nonheme iron. Systemic iron depletion has been shown to increase ferroportin expression in erythrocyte precursors, leading to the hypothesis that upregulation of ferroportin in iron deficiency serves to provide iron to nonerythropoietic tissues.[63]

The hepatically produced peptide, hepcidin, is an important regulator of iron homeostasis. It inhibits the transport of iron across the gut mucosa as well as the transport of iron out of macrophages. Hepcidin is an acute-phase reactant: in inflammation, increased hepcidin results in decreased iron absorption. Overexpression of hepcidin in genetically modified mice results in iron deficiency anemia. This has led to interest in human defects of hepcidin overexpression that may result in the inability to absorb iron (i.e., refractoriness to oral iron).[69] Conversely, the intestinal hyperabsorption of iron in thalassemias is associated with low hepcidin levels.

Physiologic Anemia of Infancy and Physiologic Anemia of Prematurity: The Role of Erythropoietin

The physiologic anemia of infancy can be exaggerated in the sick or premature infant by frequent blood sampling: the

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

smaller the infant, the proportionally greater the volume of blood that is withdrawn for laboratory testing. Most RBC transfusions in neonates occur within the first 3-4 weeks of life, with the majority being in the first 2 weeks. Physiologically lower levels of EPO in neonates provided the rationale for the pharmacologic use of erythropoietin to reduce the volume and risks of blood transfusions. Recombinant erythropoietin products are commercially available and have been used for decades in the treatment of adults with renal disease and in cancer-associated anemia. The Food and Drug Administration (FDA) mandated black box warnings for EPO because of increased risks of death, myocardial infarction, stroke, venous thrombosis, and cancer progression in adult patients. These complications have not been seen in neonates. Two approaches to EPO therapy have been systematically reviewed in neonates and reported in a 2017 Cochrane database systematic review.[2,97] The early approach, defined by the use of EPO before day 8 of life, has been shown to reduce (but not eliminate) RBC transfusions and donor exposures but did not impact morbidity and mortality measures. The later use of EPO (on day 8 of life or after) resulted in a reduction in the number of blood transfusions but not the total volume of blood, per infant, so that meaningful clinical outcomes were not affected by the use of EPO. Because most infants received RBC transfusions very early and before being enrolled in the clinical trials evaluating this question, the authors concluded that the critical effort should be aimed at preventing donor exposures in the very first few days of life.[2,97] Stable and larger preterm infants have a better response to EPO therapy when compared with ELBW infants. Erythropoiesis requires iron. Even though EPO administration has been shown to reduce hepcidin levels, thereby increasing intestinal iron absorption, ferritin levels have been reported to drop with EPO use. Supplementation of between 1 mg/kg per day and 10 mg/kg per day elemental iron has been used to lessen the risk of iron deficiency.[2,97]

Transient Erythroblastopenia of Childhood

Transient erythroblastopenia of childhood (TEC) is an acquired, transient, normocytic, hypoplastic anemia with a peak incidence at ages 2-3 years. It is exceedingly rare in neonates. The etiology of TEC is unknown but may be the result of viral injury to erythroid precursors. Familial cases have been reported. The degree of anemia can range from moderate to severe. Transient erythroblastopenia of childhood is a diagnosis of retrospect. Treatment consists of supportive measures, including RBC transfusion if needed, until bone marrow recovery. Most patients recover in 1-2 months. The condition may be confused with Diamond-Blackfan anemia and parvovirus-induced anemias.

Parvovirus-Induced Anemia

Parvovirus B19, which proliferates in human erythroid precursors, causes several diseases. The majority of adults in the United States have antibodies to the virus. The virus produces fifth disease. The rash and joint symptoms associated with this generally minor illness are caused by vascular deposition of antibody complexes generated in response to the infection. In patients with underlying hemolytic anemias, parvovirus infection can cause a transient, severe aplastic crisis. It can also cause chronic anemia from a persistent infection in erythroblasts in immunocompromised hosts. Chronic parvovirus anemia responds to administration of intravenous immunoglobulin. The virus binds to blood group P-antigen on the surface of erythroid precursors, is internalized, and then replicates, disrupting normal erythroid differentiation. Endothelial cell P-antigen is postulated to participate in placental transmission of the virus. This antigen is also found on fetal cardiomyocytes, a finding consistent with the fact that the fetus infected with parvovirus can develop myocarditis. Infection rate during pregnancy is estimated to be in the 3% range. Parvovirus infection during pregnancy can result in anemia, hydrops fetalis, fetal loss, or congenital infection. The rate of transplacental transmission of the virus has been estimated at 33%. Initial reports of high rates of stillbirth and fetal loss have been modified; it is recognized that most of the mortality occurs during the first 20 weeks of gestation.[40] Severe thrombocytopenia occurs in more than one-third of cases and can complicate intrauterine transfusion. Parvovirus-induced hydrops can be detected by ultrasound, and treatment of suspected hydropic infants includes intrauterine RBC transfusion. Parvovirus infection of the fetus may persist after birth as a cause of congenital RBC aplasia.

Diamond-Blackfan Anemia

Diamond-Blackfan anemia (DBA) is a rare, autosomal dominant bone marrow failure syndrome of congenital macrocytic anemia with reticulocytopenia. Bone marrow examination reveals normal cellularity with decreased numbers of erythroid precursors and abnormal erythroid maturation. Serum EPO levels are elevated as a compensatory response to inefficient RBC production by the marrow. Erythrocyte adenosine deaminase (eADA) levels are elevated, as is fetal hemoglobin. Patients with DBA often have one or more physical anomalies, such as low birth weight, short stature, abnormal facies, skeletal abnormalities (including abnormal thumbs), and visceral anomalies. The median age of diagnosis is 2 months. Although the phenotypes of DBA and Fanconi anemia overlap, several features distinguish these syndromes. Patients with DBA are usually anemic from birth, whereas those with Fanconi anemia generally develop reticulocytopenia later in life. Laboratory evaluation reveals increased chromosome fragility in Fanconi lymphocytes but not in DBA. The other macrocytic bone marrow failure syndrome that presents at birth is Pearson syndrome (Table 79.14). Several genes have been identified whose mutations together account for about 45% of patients with DBA. All mutations identified affect proteins of the small (RPS) or large (RPL) ribosomal subunit, suggesting that this is a disorder of ribosome biogenesis. Heterozygous mutations in *RPS19* are evident in 25% of cases.[129]

TABLE 79.14 Bone Marrow Failure Syndromes in the Neonate

Inherited Bone Marrow Failure Syndrome	Inheritance	Genetics	Testing	Treatment
Diamond-Blackfan anemia	Autosomal dominant	RPS19 RPS24, RPS17, RPL35A, RPL5, RPL11, RPS10, RPS26, RPS7 Many unknown	Erythrocyte adenosine deaminase high	20% improve by adulthood Prednisone ± Stem cell transplant
Fanconi anemia	Autosomal recessive X-linked	FANCA, FANCC, FANCD1, FANCD2, FANCE, FANCF, FANCG, FANCI, FANCJ, FANCL, FANCM, FANCN FANCB	Chromosomal breakage assay	Stem cell transplant, reduced intensity conditioning regimen Transfusion Androgens
Pearson syndrome	Maternal inheritance	Mitochondrial DNA deletion	Mitochondrial DNA sequencing	Pancreatic enzyme replacement Vitamins ADEK Transfusion
Shwachman-Diamond syndrome	Autosomal recessive	SBDS	Serum trypsinogen low, pancreatic isoamylase low, fecal elastase low, fatty pancreas by ultrasound	Pancreatic enzyme replacement Vitamins ADEK, G-CSF Transfusion Stem cell transplant, reduced intensity conditioning regimen

About two-thirds of patients with Diamond-Blackfan anemia respond to glucocorticoid therapy with an increase in Hb concentration and the reticulocyte count. Nonresponders to steroids are managed with chronic RBC transfusion therapy, with the long-term complication of iron overload. Stem cell transplantation from an HLA-matched unaffected sibling is a consideration for transfusion-dependent patients, but this is complicated by the fact that about 20% of patients will enter remission by adulthood and also that the sibling donor may have a mutation not detectable by current genetic screening. Despite advances in medical therapy, patients with Diamond-Blackfan anemia have a shortened expected life span. As is true for other congenital bone marrow failure syndromes, Diamond-Blackfan anemia is associated with an increased risk for aplastic anemia, myelodysplastic syndrome, acute leukemia, and other malignancies later in life.[129]

Fanconi Anemia

Although Fanconi anemia (FA) is not a cause of pure anemia in the neonate, this congenital bone marrow failure syndrome is discussed here in the context of congenital morphologic abnormalities and bone marrow failure syndromes. Originally characterized as familial aplastic anemia with birth defects, the condition has been extended to include patients with characteristic chromosome fragility, with or without aplastic anemia and with or without birth anomalies. Hematologic abnormalities other than macrocytosis usually are not evident in infants with FA. The condition often is not recognized until the onset of aplastic anemia, at a mean age of 8 years, or after diagnosis of a rare cancer at an early age. Many physical anomalies associated with FA have been reported. Only a minority of Fanconi patients have radial ray anomalies, the birth defect traditionally associated with this condition. A high incidence of cancers is associated in affected patients. Lymphocytes from patients with FA exhibit increased chromosome breakage in response to certain alkylating agents, and this now is the basis of diagnostic testing for this condition.

Pearson Syndrome

Pearson syndrome is characterized by early-onset cytopenias, macrocytosis, exocrine pancreatic dysfunction, acidosis, sepsis, and hepatic and renal failure with early death. A sideroblastic anemia is present in most patients in the first 6 months of life, but it often resolves. The bone marrow will show vacuolated precursor cells and ringed sideroblasts. This maternally inherited disorder of mitochondrial DNA is diagnosed by mitochondrial DNA sequencing. Fatty replacement of the pancreas on ultrasound is found in Pearson syndrome but also in Shwachman-Diamond syndrome.

Congenital Dyserythropoietic Anemias

Patients with these rare disorders have congenital anemia with ineffective, morphologically abnormal erythroid production. The degree of anemia can range from moderate to severe and can be macrocytic, normocytic, or microcytic. Type II is the most common of the three described types. Bone marrow examination shows multinucleated RBC precursors and asynchrony in the maturation of erythroid nuclei and cytoplasm. Defects in glycosylation of erythroid

precursor surface glycoproteins and glycolipids have been associated with some cases. Congenital dyserythropoietic anemias (CDA) often remain undiagnosed in the neonatal period, although many patients are noted to have anemia and jaundice early on. Dysmorphic features can be associated with the anemia. Management includes transfusion and chelation of iron excess. Stem cell transplantation has been attempted in severe cases.[54,55]

Other Erythrocyte Disorders

Methemoglobinemia

Methemoglobinemia results when methemoglobin production is increased or when the ability to reduce methemoglobin is decreased. For hemoglobin to reversibly bind oxygen, the heme iron must be in the ferrous (Fe^{2+}) state. As the RBC circulates and is exposed to various oxidants, the oxyhemoglobin is slowly oxidized to methemoglobin in the ferric (Fe^{3+}) state. Partial oxidation of hemoglobin markedly increases the oxygen affinity of the other hemes in the tetramer and decreases oxygen delivery to tissues. Reduction of methemoglobin in the RBC depends largely on two electron carriers, cytochrome-b_5 and nicotinamide adenine dinucleotide (NADH), as well as the enzyme cytochrome-b_5 reductase. An alternate pathway using G6PD to generate nicotinamide adenine dinucleotide phosphate (NADPH) in the hexose monophosphate shunt can be driven by the addition of electron carriers such as methylene blue. It is estimated that methemoglobin accumulates in adults at a rate of 2%-3% per day, but RBCs with an intact cytochrome-b_5 reductase system contain less than 0.6% methemoglobin.[77] Neonates and premature infants have a transient enzymatic deficiency and lower cytochrome-b_5 levels for the first few months of life. Ingestion of nitrates, usually from contaminated well water, and their subsequent conversion to oxidizing nitrites by gut bacteria is the leading cause of acquired methemoglobinemia in infants. There is an association between diarrheal illness in infants and methemoglobinemia even when toxin exposure has not been detected. Xylocaine and its derivatives and dapsone are the most common drugs precipitating methemoglobinemia.

Congenital methemoglobinemia is due either to a defect in the cytochrome-b_5 reductase system or to inheritance of one of the M hemoglobins (Hb M), which have an alteration in either the α or β chain, resulting in preferential binding of ferric iron. Inheritance of the Hb M variants is autosomal dominant, whereas defects in the cytochrome-b_5 reductase system are inherited in an autosomal-recessive fashion. Homozygotes and compound heterozygotes usually are affected, but heterozygotes can become symptomatic after exposure to oxidant drugs or toxins. Patients with congenital methemoglobinemia may be cyanotic but otherwise asymptomatic. Similarly, patients with chronic methemoglobinemia, with methemoglobin levels of up to 40% or 50%, may be physiologically well compensated and exhibit minimal symptoms. Acute methemoglobinemia with levels above 20% produces the signs and symptoms of hypoxia. Levels greater than 70% can result in coma and death, although there are reports of neonates who survived levels as high as 85%. The onset of symptoms in patients with one of the M hemoglobins corresponds with expression of the affected globin chains. Patients with cytochrome-b_5 reductase deficiency type I are asymptomatic other than cyanosis; the more rare type II disease presents with cyanosis, failure to thrive, and a severe neurologic phenotype. Many with type II disease die in infancy.[77] The cyanosis is unresponsive to oxygen therapy. Blood is a characteristic chocolate-brown color. A fresh sample of blood is analyzed by co-oximetry to detect absorbance in the 630-nm range. False-positive test results may be caused by the presence of other pigments that absorb near the same wavelength, such as sulfhemoglobin and methylene blue. Confirmatory testing of positive results should be performed. Both quantitative and qualitative tests are available for evaluating defects in the cytochrome-b_5 reductase system.[59,77]

Therapy is initiated for symptomatic patients with cytochrome-b_5 reductase deficiency and those with methemoglobin levels greater than 40%. The usual treatment is oral methylene blue. If the patient does not show a good response within 1 hour, the treatment may be repeated, although consideration should be given that the patient could be deficient in G6PD. Patients with G6PD deficiency should not be treated with methylene blue, because it is often not beneficial, and it also causes oxidant stress and hemolysis. Alternative therapy with ascorbic acid may be used with caution because of concerns about calcium kidney stone formation. High-dose ascorbic acid also has oxidant potential and can trigger hemolysis in G6PD-deficient patients. No treatment exists for those with Hb M variants.

Polycythemia

Polycythemia is defined as an increase in RBC mass more than two standard deviations above the mean for age and gestation. For a term infant, polycythemia occurs when a peripheral venous blood sample has an Hb greater than 22 g/dL or a hematocrit greater than 65%. Capillary blood samples are generally higher than those drawn from peripheral blood; central venous values are lower still. The real issue is viscosity, which has a linear relationship to the hematocrit up to about 60%. Blood viscosity increases more rapidly at greater than 60% hematocrit but less predictably. Laboratory testing for hyperviscosity is not generally available, so decisions are made using the hematocrit or hemoglobin and clinical symptoms. Symptoms include listlessness, irritability, plethora, acrocyanosis, poor feeding, hypoglycemia, respiratory distress, and systemic thrombosis. Persistent pulmonary hypertension of the newborn can be caused by increased pulmonary vascular resistance. Renal vein thrombosis and cerebral sinovenous thrombosis have been associated with polycythemia. The increased load of RBCs also contributes to hyperbilirubinemia. Symptoms often appear at or after 2 hours of life, when the hematocrit is highest because of fluid shifts. Some patients with excessive

extracellular fluid losses may become symptomatic on day 2 or 3 of life, and although most symptoms are transient, there is concern about effects on neurodevelopmental outcome.

Polycythemia is estimated to occur in 2%-5% of term infants. Conditions that result in transfusion to the fetus such as twin–twin or maternal–fetal transfusion or delayed clamping of the umbilical cord can cause polycythemia. It can also be caused by a compensatory response to intrauterine hypoxia, placental insufficiency, maternal toxemia, or postmaturity. Maternal smoking has been associated with symptomatic polycythemia in infants. Several endocrine conditions are associated with increased RBC production and polycythemia, including maternal diabetes, hyperthyroidism or hypothyroidism, and congenital adrenal hyperplasia. Excessive EPO production and polycythemia also are seen in infants with Down syndrome, some other trisomies, and Beckwith-Wiedemann syndrome. Less commonly, hemoglobin with increased oxygen affinity can cause polycythemia, but most of the cases described involved β-chain defects that would be expected to manifest later in infancy. Hereditary defects in the EPO receptor associated with polycythemia also have been reported.[36] Management remains supportive for most infants, because exchange transfusion is associated with the usual transfusion risks as well as increased risk for necrotizing enterocolitis. There is no evidence of long-term neurodevelopmental benefit from partial exchange transfusion; rather, outcome is postulated to be associated with the underlying cause of the polycythemia.[36]

White Blood Cells

Human myelopoiesis begins in the embryo at about 8 weeks. Hematopietic stem cells (HSCs) develop during embryogenesis. This process takes places in different anatomical sites: the yolk sac and the aorta-gonad-mesonephros region. HSCs colonize the bone marrow at birth.[81] By 20 weeks of gestation, neutrophils demonstrate partial functional activity. Neutrophils are derived from a common stem cell progenitor, which also gives rise to mature erythrocytes, megakaryocytes (and ultimately platelets), eosinophils, basophils, and monocytes (see Fig. 79.1). Leukocytes serve as major effector cells for host defense against invading organisms. Neutrophils circulate in the blood until they encounter specific chemotactic signals that promote adhesion to the vascular endothelium and migration through (diapedesis) and movement to the sites of microbial invasion (chemotaxis). Mononuclear phagocytes (monocytes, macrophages) function primarily as cells resident within certain tissues, such as the spleen, lungs, and peritoneum, where they interact closely with lymphocytes to generate a local immune response. Both neutrophils and mononuclear phagocytes, as members of the innate immune system, take up opsonized targets (internalization, phagocytosis). The targets are then destroyed within intracellular vacuoles by the release of hydrolytic enzymes and reactive oxygen intermediates (respiratory burst activity).

Neonatal leukocytes demonstrate impaired adhesion and chemotaxis. Defects in phagocytosis are debated. Neutrophil survival appears to be decreased. A variety of recently identified growth factors and cytokines regulate proliferation and differentiation along neutrophilic lineage (see Table 79.2). Granulocyte colony-stimulating factor (G-CSF) has been used in patients with low neutrophil counts.

Number and Kinetics of Phagocytes

The circulating blood neutrophil pool reflects a dynamic equilibrium among several compartments. Within the bone marrow are the dividing (or mitotic) pool, the differentiation (or maturation) pool, and the storage pool. Outside the bone marrow are the circulating pool, the vascular marginated pool, and the peripheral tissue pool. Neutrophils transit the circulating pool only during a brief 5- to 6-hour period before arrival in tissues. Thus, changes in the WBC count or differential reflect rapid changes in a relatively small yet highly fluctuant pool. Estimates suggest that the peripheral blood neutrophil count represents less than 5% of total neutrophils. About 20% are in the marrow neutrophil precursor pool, 75% are in the marrow storage pool, and 3% are in the marginated vascular pool (Table 79.15). Neutrophils have a residence time of 9 days in marrow, 5-6 hours in blood, and 1-4 days in peripheral tissues.

Neutrophil counts at birth depend on birth weight and gestational age. For term and near-term infants absolute neutrophil count (ANC) increases at birth, followed by sharp three- to fivefold increase (up to ANC of 1500) in next 18 hours of life and later. It gradually decreases after this but is elevated for the first 2 months of life (Table 79.16).[76] ANC values are lower in very low birth weight infants.[89] ANC is the product of the total white blood cell (WBC) count and the percentage of mature neutrophils plus bands:

$$\text{ANC} = \text{WBC} \times (\%\ \text{neutrophils} + \%\ \text{bands}) \times 0.01$$

Neutropenia is defined as ANC value that is two standard deviations below the mean or lower than the fifth percentile. Based on Manroe et al., such value is an ANC less than 1800/μL, whereas Mouzinho charts would suggest an ANC less than 1000/μL.[71]

Neutrophilia is an elevation of the blood neutrophil count greater than two standard deviations above the mean or value above the 95th percentile.[92]

Phagocyte Abnormalities

Neutropenia

Neutropenia is a common finding in the NICU, particularly during the first week of life and in lower birth weight and ill infants. Neutropenia results from a decline in neutrophil production or from accelerated destruction, as well as from changes in the relative distribution of neutrophils between the circulating pool and the marrow and peripheral tissue pools. Most cases are caused by acquired defects,

TABLE 79.15 Adult Blood Neutrophil Pools and Kinetics

Pool	Definition/Calculation	Mean Pool Size ($\times 10^7$/kg)	95% Limits
Total blood neutrophil pool (TBNP)	All neutrophils in the circulation	70	14-160
Circulating neutrophil pool (CNP)	Blood neutrophil concentration multiplied by blood volume	31	11-46
Marginal neutrophil pool (MNP)	Total blood neutrophil pool less circulating pool (MNP = TBNP – CNP)	39	0-85
Kinetics	**Definition/Calculation**	**Mean Value**	**95% Limits**
$t_{1/2}$ (Blood clearance half-time)	Disappearance time of half of the labeled neutrophils from circulation	6.7 hr	4-10 hr
Neutrophil turnover rate (NTR)		163 × 10^7/kg per day	50-340 × 10^7/kg per day

Adapted from Beutler E, et al. *Williams' hematology.* 5th ed. New York: McGraw-Hill; 1995.

TABLE 79.16 Polymorphonuclear Leukocyte and Band Counts in the Newborn during the First 2 Days of Life*

Age (hr)	Absolute Neutrophil Count (per µL)	Absolute Band Count (per µL)	Band-to-Neutrophil Ratio
Birth	3500-6000	1300	0.14
12	8000-15000	1300	0.14
24	7000-13000	1300	0.14
36	5000-9000	700	0.11
48	3500-5200	700	0.11

*Normal values were obtained from the assessment of 3100 separate white blood cell counts obtained from 965 infants; 513 counts were from infants considered to be completely normal at the time the count was obtained and for the preceding and subsequent 48 hours. There was no difference in the normal ranges when infants were compared by either birth weight (whether more or less than 2500 g) or gestational age.
Data from Manroe BL, Rosenfeld CR, Weinberg AG, et al. The differential leukocyte count in the assessment and outcome of early-onset neonatal group B streptococcal disease. *J Pediatr.* 1977;91:632-637.

• BOX 79.8 Etiologies of Early-Onset Neutropenia

- Congenital infection
- Prematurity
- Sepsis
- Birth asphyxia
- Maternal hypertension
- Intrauterine growth restriction
- Bone marrow failure syndromes
- Bone marrow infiltration
- Congenital neutropenias

many of which are transient. Persistent neutropenia, particularly in an infant with dysmorphic features, should be investigated (Box 79.8). Laboratory investigation begins with a CBC and evaluation of the peripheral blood smear, looking for defects in the other cell lines as well as leukocyte morphology. Serial CBCs are often appropriate before bone marrow aspiration and biopsy. Strong consideration should be made as to whether the neutropenia could be part of an immunologic defect such as severe combined immunodeficiency disorder; absolute lymphocyte count, lymphocyte subsets, serum immunoglobulins, and specific testing of B and T lymphocyte function may be needed. Bone marrow morphologic examination and assessment of cellularity, myeloid maturation, and presence of fibrosis can be performed. Bone marrow cytogenetics, FISH for suspected genetic defects or myelodysplasia, and iron staining can also be performed. Rarely, ancillary testing such as electron microscopy of the bone marrow, fetal hemoglobin levels, and pancreatic enzymes may be ordered.

Severe neutropenia is defined by an ANC less than 500/µL. *Very severe neutropenia* requires ANC less than 200/µL. *Moderate neutropenia* occurs at ANC less than 1000/µL. Neutropenia can be central or peripheral depending on whether or not the bone marrow is depleted in mature progenitors. Central neutropenia carries a higher infection risk.[39] Infectious risk depends on the duration of neutropenia and on whether the remaining neutrophils function normally. Bacterial and fungal infections are most common in neutropenia. Typical organisms include staphylococci, streptococci, enterococci, pneumococci, *Pseudomonas*, gram-negative bacilli, *Candida*, and *Aspergillus*. The skin, mucous membranes, nasopharyngeal region, and lungs are most commonly infected.

Extrinsic Defects of Phagocyte Function

Sepsis and Postinfectious Neutropenia. Infection is the most common cause of neutropenia in the neonate.

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

Neutropenia is a risk factor for infection and sepsis, but it can also occur as a result of overwhelming sepsis. Neonates are particularly at risk for this complication, because their neutrophil storage pools are smaller. Neutrophil counts are sometimes unmeasurable in the peripheral blood if the bone marrow neutrophil pool is exhausted. Both increased vascular neutrophil margination and vascular-to-tissue neutrophil movement are associated with circulating neutropenia during sepsis. Among hospitalized infants, neonatal sepsis continues to be a major cause of morbidity and mortality. Neonates with very low birth weight are most vulnerable and are prone to early- and late-onset sepsis.[43] Cytokines such as G-CSF have been used without clear benefit in preventing or treating sepsis in neonates. They are used more commonly, empirically, in neutropenic neonates with serious infection or sepsis. Granulocyte transfusions are discussed in Chapter 80.

Neonatal Alloimmune Neutropenia. Neonatal alloimmune neutropenia (NAN) is a rare cause of neutropenia with an incidence between 0.1% and 0.81%.[1,24,136] However, it can present as severe infection with a mortality rate up to 5%.[136] The cause is analogous to Rh hemolytic disease of the newborn. The neutropenia, which can be severe, is caused by maternal sensitization to paternally inherited human neutrophil antigens (HNA). If maternal IgG crosses the placenta and coats the fetal neutrophils, they will be destroyed by opsonization. Isolated neutropenia (<1000/μL) with normal maternal neutrophil count should trigger suspicion. The diagnosis depends on detection of maternal antineutrophil antibodies in the serum of mother and baby. Most common antibodies are directed against HNA-1 antigens 1a, 1b, and 1c. Human neutrophil antigen typing of the mother and father confirms the diagnosis. If the father is homozygous, the risk for future alloimmune neutropenia is 100%. Affected newborns often develop fever in the first few days of life with associated cutaneous infections, omphalitis, pneumonia, otitis media, necrotizing enterocolitis, and sepsis. Treatment consists of supportive care with antibiotics and sometimes G-CSF or IVIG. As expected for the half-life of maternal IgG, infant neutrophil counts generally return to normal within the first 1-3 months of life.[1]

Autoimmune Neutropenia of Infancy (Chronic Benign Neutropenia). In this case, antibodies are developed by the infant against his own neutrophils. Antineutrophil antibodies have been detected in the serum of infants in the first months of life, although very rarely. It is usually diagnosed between the ages of 5 and 15 months, often discovered during evaluation of fever or infection. A peripheral monocytosis or eosinophilia may be present. Most common is the primary autoimmune neutropenia (not associated with an underlying disorder), severe infection is uncommon, but central neutropenia raises the risk. Secondary neutropenia that is associated with autoimmune disease, infections, or drugs may be more severe.[41] Because neutropenia masks signs and symptoms of severe infection and also increases infectious risk, medical evaluation is recommended for moderate to high fever, and empiric antibiotic coverage is often instituted when the ANC is less than 500/μL. Autoimmune neutropenia is self-limited, with resolution in the first 2-3 years of life. Confirmatory testing demonstrates antineutrophil antibodies in the serum most often against the FcRγIIIb receptor or CD16.[41] If a bone marrow analysis is performed, there may be a paucity of neutrophils and myeloid progenitor cells depending on the specificity of the antibody for mature or progenitor cell antigens. The overall bone marrow cellularity may be normal or hypercellular.[39] Therapy for autoimmune neutropenia depends on the severity of the neutropenia-associated symptoms (e.g., recurrent fevers requiring frequent medical evaluations and/or severe infection). Often no treatment is needed. Supportive care with antibiotics either for brief empiric coverage in the setting of severe neutropenia or to treat infection is important. Granulocyte colony-stimulating factor has been used in the setting of severe infection with neutropenia and also for prevention of recurrent symptomatic severe neutropenia.[41]

Neonatal Iso-immune Neutropenia. This is noted in infants whose mothers have autoimmune disease with passive passage of maternal antineutrophil antibodies to the fetus. In such cases, both mother and infant are neutropenic. Usually neutropenia is transient and asymptomatic.[72]

Drug-Induced Neutropenia. An enormous number of agents have been implicated as causes of neutropenia (Box 79.9). The mechanisms include direct bone marrow suppression or immune-mediated destruction. Anti-inflammatory drugs, semisynthetic penicillins, antiseizure medications, and a host of other drugs commonly used in the newborn nursery can cause neutropenia. Recovery from marrow toxic effects generally begins within several days after the offending agent is discontinued. As with recovery from chemotherapy-induced neutropenia, recovery of peripheral neutrophil counts is ushered in by a rise in circulating monocytes and immature neutrophils in the peripheral blood.

Therapeutic Uses of Granulocyte Colony-Stimulating Factor and Granulocyte-Macrophage Colony-Stimulating Factor

The cytokines granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) are members of a family of hematopoietic growth factors that stimulate production of mature WBCs in the bone marrow. These two cytokines also enhance neutrophil and monocyte functions, such as neutrophil oxidative metabolism, chemotaxis, and phagocytosis. Both are normally present at low concentrations in serum. Granulocyte colony-stimulating factor levels are about threefold higher in the cord blood of premature infants than in term infants in the first 3 days of life. Granulocyte colony-stimulating factor levels peak at 7 hours of life, followed by a rise in the neutrophil count at about 13 hours of life.[45] Whether preterm and full-term infants are capable

of mounting an appropriate cytokine response to infection or sepsis and whether neonatal cells respond adequately to cytokines are still under investigation. The first randomized trial reported 5-year follow-up outcomes of children who received GM-CSF as very small-for-gestational-age preterm babies. It reported that GM-CSF raised neonatal neutrophil counts but did not reduce the prevalence of neonatal sepsis or other neonatal morbidities, nor affected neurodevelopment later in childhood.[78] The utility of these growth factors in the treatment and prevention of sepsis in non-neutropenic infants, however, has not been clearly demonstrated.[25,43] However, based on limited studies there might be utility of growth factor use when systemic infection is accompanied by severe neutropenia as it may reduce mortality.[25] On the other hand, clinical trials using pharmacologic doses of G-CSF have shown benefit in patients with congenital neutropenia by reducing infectious morbidity and mortality and improving quality of life.[33] It is also effective in correcting immune-mediated neutropenias when patients present with infections and an ANC less than 500/μL.

Inherited Disorders Associated with Neutropenia

Congenital Neutropenias

The congenital neutropenias are a group of disorders that persist at least 3 months, whether intermittent or permanent, severe or mild, with or without extrahematopoietic findings, and that are caused by a constitutional genetic defect. About half of the genetic defects reported in neutropenia registries are in the neutrophil elastase gene *ELA2*, which can cause permanent or intermittent (cyclic) neutropenia. The risk of infection correlates with the severity of the neutropenia and increases with dysfunction of the neutrophils or other components of the immune system. Treatment is supportive, with antibiotics and antifungal prophylaxis and sometimes G-CSF. Stem cell transplantation is indicated for some syndromes.[39]

Congenital Neutropenia with Primarily Hematopoietic Abnormalities

Severe Congenital Neutropenia. Kostmann syndrome was the first severe congenital neutropenia described. In the first several months of life, infants manifest severe neutropenia (ANC <200/μL) with recurrent infections (e.g., omphalitis, skin abscesses, respiratory tract infections, sepsis). Bone marrow examination reveals a paucity of myeloid cells and arrest at the promyelocyte or myelocyte stage. Defects are in the *ELA2*, *HAX-1*, and less commonly, in the genes coding for the G-CSF receptor. Inheritance may be autosomal dominant, autosomal recessive, or sporadic. Antibiotic and antifungal prophylaxis, aggressive treatment of infections, and high-dose G-CSF treatment in responsive

patients has improved morbidity and mortality, but early death is still common. Patients who survive early childhood are at risk for myelodysplastic syndrome and acute myeloid leukemia. Stem cell transplantation is an option for selected patients. Later neurologic manifestations of developmental delay and seizures are seen in patients with *HAX-1* mutations.[39]

Cyclic Neutropenia and ELA2 Mutations. Cyclic neutropenia is diagnosed later than Kostmann syndrome, often in the second year of life or later. Patients present with fevers, mouth ulcers, and infections during the nadir of the ANC, which is documented by two to three CBCs per week for 6 weeks, to cycle neutrophil counts approximately every 21 days plus or minus 3 days. Autosomal dominant *ELA2* mutations are the most common and severe. Sporadic inheritance is also described. Supportive care for fevers and infection and possible use of G-CSF to modulate the nadir are common management strategies.[39]

Congenital Neutropenia with Extrahematopoietic Abnormalities

The most common congenital neutropenias with extrahematopoietic defects in neutropenia registries are *HAX-1* mutations, Shwachman-Diamond syndrome, and the glucose-6-phosphatase complex disorders. Many rare congenital neutropenia syndromes have been described clinically, and some have associated genetic defects identified. Deficits in neutrophil function as well as a myriad of dysmorphic defects are associated with these syndromes, although it is important to realize that not all defects are present in the neonatal period, and not all defects appear in a particular patient. The reader is referred to an excellent review of congenital neutropenia by Donadieu and co-workers for more details.[39]

Shwachman-Diamond Syndrome (SDS). Once believed rare, but now accounting for about one-fourth of patients in neutropenia registries, Shwachman-Diamond syndrome (SDS) is characterized by pancreatic exocrine dysfunction, failure to thrive, neutropenia of varying degrees, neutrophil chemotactic dysfunction, and many other dysmorphic features presenting at various times over the life of the patient. Bony abnormalities, rash, cytopenias, mental retardation, and failure to thrive are among the most common features. Shwachman-Diamond syndrome is often included as part of the differential diagnoses with Pearson syndrome and cystic fibrosis. Hematologic manifestations include intermittent neutropenia, cytopenias, aplastic anemia, myelodysplastic syndrome (mutations in chromosome 7), and leukemic transformation. Autosomal recessive inheritance is described, often with defects in the *SBDS* gene on 7q11 with resultant defect in ribosomal function affecting multiple organ systems.[20] Diagnostic testing may include radiographic demonstration skeletal abnormalities, evidence of pancreatic insufficiency (decreased fecal elastase and low serum trypsinogen), as well as hematologic changes. Finding of typical mutation is diagnostic. Supportive care with pancreatic enzyme replacement, G-CSF for neutropenia or severe infection, antibiotics, and antifungals are recommended. Monitoring for malignant transformation is important. Hematopoietic stem cell transplantation is indicated for severe cytopenia, myelodysplastic syndrome, or acute myeloid leukemia.[33]

Glucose-6-Phosphatase Complex Disorders: Glycogen Storage Disease Type 1b and G6PC3. Hepatic glycogen can be dephosphorylated by G-6-P to produce glucose as an energy source. Two of the three proteins that comprise the G-6-P complex on the endoplasmic reticulum are associated with congenital neutropenia: the translocase SLC37A4 and the catalytic protein G6PC3. G6PC3 disorders are characterized by severe, permanent neutropenia with myeloid arrest, thin skin, genitourinary abnormalities, cardiac disease, and myopathy.[39]

GSD1b is characterized by hypoglycemia at birth, lactic acidemia, hepatomegaly with hepatic glycogen accumulation, Crohn-like colitis, neutropenia, and variable neutrophil dysfunction. Diagnosis is based on constellation of symptoms and genetic testing. Patients respond to G-CSF, although in GSD1b, patients may develop worsening splenomegaly. AML has been reported in GSD1b.[33]

Congenital Neutropenia with Defective Immune System

As part of the innate immune system, neutrophils participate in development of the adaptive immune system, and there are some shared receptors and proteins among lymphocytes and neutrophils. Neutropenia may be an early presenting feature of a more global and lethal immunologic defect, with or without autoimmune phenomena. Young age at presentation, failure to thrive, lymphopenia, eczema, and serious infections should be signals that a comprehensive evaluation of innate and adaptive immunity should be undertaken.

X-linked Neutropenia/Myelodysplasia

An X-linked mutation of the Wiskott-Aldrich syndrome gene protein presents with neutropenia but without the classic WAS phenotype.

Cartilage-Hair Hypoplasia. Cartilage-hair hypoplasia is a rare autosomal recessive disorder characterized by short-limbed dwarfism, fine hair, hyperextensible digits, increased susceptibility to infection, lymphopenia, impaired cellular immunity, and chronic neutropenia. This autosomal recessive disease is caused by mutations in *RMRP*, a noncoding RNA gene involved in mitochondrial DNA replication, ribosome biogenesis, and ribosomal RNA processing.[39]

Dyskeratosis Congenita. Dyskeratosis congenita is characterized by neutropenia (and other cytopenias), abnormal skin pigmentation, nail dystrophy, and mucosal leukoplakia. Other features include immunodeficiency, fragile bones, tooth decay, short stature, alopecia or premature graying, gonadal hypoplasia, urethral abnormalities, pulmonary fibrosis, liver cirrhosis, esophageal strictures, mental retardation, and a predisposition to cancers of the skin, gastrointestinal tract, and other sites.

Other Related Syndromes Discussed under Immune Deficiencies

Bone Marrow Failure Syndromes

See Diamond-Blackfan anemia, Fanconi anemia, and Shwachman-Diamond syndrome.

Congenital Neutropenia with Inborn Errors of Metabolism

Isovaleric, methylmalonic, and propionic acidemias; hyperglycinemia; and tyrosinemia are associated with neutropenia.

Neutrophilia

Neutrophilia is the specific elevation of the ANC more than two standard deviations above the mean. Infection is the most common. Other causes include stress, birth asphyxia, and hypoxia.

Leukemoid Reaction

Newborns sometimes mount an exaggerated response to infection. As in older children, the circulating neutrophil count increases, and a left shift occurs (band forms, myelocytes, and metamyelocytes increase in the peripheral circulation). A significant increase in early neutrophil precursors in the peripheral blood, as well as an increase in the white blood cell count (generally exceeding 50,000/μL), is considered a leukemoid reaction. A normal newborn in the first 2 days of life displays a neutrophilia. Immature myeloid forms and even blasts can be seen in the first day or two, and these are especially common in premature infants. A leukemoid reaction associated with severe infection in the newborn often is accompanied by neutrophil cytoplasmic vacuoles and toxic granulations. A rare, autosomal dominant hereditary neutrophilia has been described. Infants with Down syndrome can have a type of leukemoid reaction or even a leukoerythroblastic picture called transient abnormal myelopoiesis.

Down Syndrome Hematologic Abnormalities and Transient Abnormal Myelopoiesis. Hematologic abnormalities are common in Down syndrome (Table 79.17). The American Academy of Pediatrics recommends ordering a CBC for newborns with Down syndrome to screen for hematologic problems. About 10% of infants who have Down syndrome develop a transient clonal myeloproliferative disorder now called *transient abnormal myelopoiesis* (TAM). This process also sometimes occurs in a phenotypically normal child with trisomy 21 mosaicism, including an isolated clone of trisomy 21 bone marrow cells. Transient abnormal myelopoiesis is characterized by a leukoerythroblastic picture with megakaryoblasts in the peripheral blood, variable thrombocytopenia, and hepatosplenomegaly.[110] Abnormalities of all three hematopoietic cell lineages have been described. It is believed that mutations in the megakaryocyte transcription factor GATA1 occur during the period of fetal liver hematopoiesis. There are no clinical, hematologic, or cytogenetic parameters that can predict if the newborn has TAM, which resolves, or acute leukemia. The median age at diagnosis of TAM is 3-7 days. Almost all cases are diagnosed by 2 months of age and resolve by 3-6 months. Transient myeloproliferative disorder can be life threatening or fatal from complications of hepatic fibrosis/liver failure, hydrops fetalis, or hyperleukocytosis (Box 79.10).[38] At least half of infants with TAM show no associated clinical symptoms (silent TAM). About 10%-20% of infants with TAM will develop myeloid leukemia of Down syndrome (ML-DS). Somatic mutations in *GATA1* have been reported in nearly all cases of TAM and ML-DS. In the absence of leukocytosis greater than 100,000 WBC/μL, refractory DIC, massive organomegaly, respiratory compromise, renal dysfunction, or impending liver failure from hepatic fibrosis, pediatric oncologists adopt a wait-and-see approach in managing TAM. Infants with organ infiltration or a severe leukocytosis can be managed with low-dose cytarabine.[13]

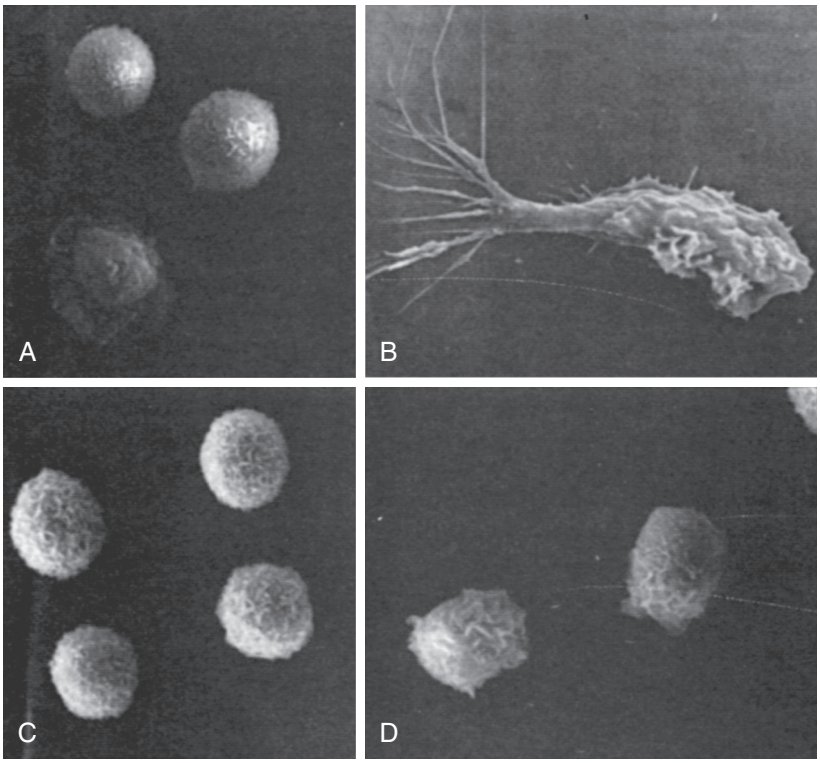
Neutrophil Functional Defects



These conditions are rare; however, neonatologists need to be aware. Below are conditions most commonly seen in infancy.

Oxidative Killing Disorder: Chronic Granulomatous Disease. Chronic granulomatous disease (CGD) is a rare, genetically heterogeneous disorder characterized by

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

inherited defects in generation of the respiratory burst by NADPH oxidase in neutrophils, monocytes, and macrophages. Some patients are mildly affected, whereas others develop severe, recurrent bacterial and fungal infections of skin, mucous membranes, liver, lung, spleen, and lymph nodes in the setting of increased or normal neutrophil counts. Catalase-positive bacteria and *Aspergillus* species are common pathogens. Most patients manifest symptoms within the first year of life. Inadequate neutrophil killing or ingestion is associated with a chronic inflammatory response that culminates in the formation of macrophage-containing granulomas throughout the gastrointestinal and urinary tracts. Because four distinct gene products are required for functional NADPH oxidase activity, defects in any one of these components can lead to this disorder. Chronic granulomatous disease is usually X-linked in inheritance, associated with the gp91 protein, gp91phox, but autosomal recessive forms are associated with defects in p22phox, p47phox, and p67phox. Diagnosis is made by spectrophotometric measurement of superoxide production or by measurement of reactive oxygen species production by flow cytometry, fluorometry, or chemiluminescence. Genetic analysis of affected patients can identify the specific genetic defect. Therapy involves prophylactic antibiotics and antifungal agents. Recombinant interferon-γ-1b prophylaxis has also been effective in reducing the incidence of infections. Hematopoietic stem cell transplantation is an option for severe disease.[116]

Adhesion Disorders: Leukocyte Adhesion Deficiencies Types I and II. Leukocyte adhesion deficiency (LAD) includes a rare group of autosomal recessive disorders characterized by persistent leukocytosis, delayed separation of the umbilical cord, and recurrent infections. LAD-I is characterized by the impairment of the respiratory burst generation of complement-opsonized microorganisms and is associated with defects in neutrophil adhesion and chemotaxis (Fig. 79.9). The clinical picture varies depending on the relative deficiency of CD18, the β2 subunit of integrin. Leukocyte adhesion deficiency should be suspected in any infant who has unusually severe bacterial infections accompanied by normal to increased blood leukocyte counts. There is a striking absence of pus at the site of infection, because neutrophils do not migrate from the vasculature to sites of inflammation within tissues. Diagnosis is made by flow cytometric analysis demonstrating deficiency of CD18 or CD11b/CD18. Carriers can be identified by the expression of about 50% normal CD18 on circulating neutrophils. In addition to persistent leukocytosis and recurrent bacterial infections, the autosomal recessive clinical syndrome LAD-II (Rambam-Hasharon syndrome) described in a few Israeli patients includes short stature, severe mental retardation, and the hh (Bombay) RBC phenotype. The

molecular defect in these patients is a defect of fucosyl transferase, the enzyme responsible for carbohydrate linkages associated with the AB blood groups, specifically the sialyl-Lewis X structure. Sialyl-Lewis X is necessary for the formation of the neutrophil cell surface ligand recognized by the endothelial cell surface E- and P-selectin receptors. Neutrophils from these patients exhibit markedly diminished chemotaxis in vitro but have normal levels of C18.[39]

LAD-III results from mutation in FERMT3, which encodes kindling-3, a protein that binds β integrin tails. Clinically, it is similar to LAD-1; however, patients are also as at risk for bleeding as patients with Glanzmann thrombasthenia. Hematopoietic stem cells are recommended for LAD-1 and LAD-3. LAD-2 patients require supportive care such as fucose supplementation.[37]

Chediak-Higashi Syndrome and Griscelli Syndrome Type 2

Chediak-Higashi syndrome, caused by a defective *CHS1* gene, is an autosomal recessive syndrome featuring oculocutaneous albinism, nystagmus, photophobia, neurodegeneration, neutropenia, giant red inclusions in leukocytes, NK cell dysfunction, recurrent infection, and progression to lymphoproliferative and hemophagocytic disorders. Griscelli syndrome type 2 shares many of these features but lacks the leucocyte inclusions.[39]

Neonatal Immune Deficiencies

It is important for neonatologists to understand primary immune deficiencies, as failure to recognize them early can result in delayed treatment and worse outcomes for these patients. Severe combined immune deficiency (SCID) newborn screen (NBS) using T-cell receptor excision circle (TREC) assay has allowed early detection of T-cell lymphopenia in newborns. As of 2015, this assay is performed in 27 states in the United States, as well as the District of Columbia and the Navajo Nation. Affected infants are reliably being detected and promptly referred to centers that provide immune system restoring treatments. Bone marrow transplantation (BMT) has success rates that vary from 50%-100%.[67] Patients with SCID transplanted within first 3 1/2 months of life have a superior outcome. Population-based screening has determined the incidence of SCID to be 1 in 58,000 births, higher than previous estimates.[68] An infant with recurrent infections and an ALC less than 3000/cmm should warrant immediate referral and further testing of immune system.[80] Absence of a thymic shadow on x-ray is another hint of SCID. Family history is important as well. SCID patients are at risk to succumb to opportunistic life-threatening infections (bacterial, fungal, viral, and mycobacterial). They are also at risk of developing graft-versus-host disease (GVHD) secondary to maternally derived T cells as well as transfusions with nonirradiated blood products. IVIG has a role if B-cell function is impaired.

Primary immune deficiencies can be classified based on immune cells involved (T cell, B cells, NK cells). The majority have an alteration in more than one cellular compartment (combined immune deficiencies). Table 79.18 summarizes most immune deficiencies and defects involved.[67] Below is a brief review of the most recognized diseases.

Humoral Immune Defects

Transient Hypogammaglobulinemia of Infancy. This is caused by a delay in maturation of immunoglobulin production and presents with prolonged hypogammaglobulinemia but is rarely symptomatic. It resolves by 3-4 years of age.[67]

X-linked Agammaglobulinemia. Most common of the agammaglobulinemias, these patients are protected by maternal antibodies in the first months of life. Recurrent infections with encapsulated bacteria or viruses occur later. There is a lack of IgA conjunctivitis; otitis may occur earlier. The mainstay of treatment is IVIG.[67]

Hyper IgM syndrome. This is caused by defects in a CD40 ligand/CD40 interaction. It results in very low levels of IgG, IgA, and IgE but normal or elevated levels of IgM. The immunoglobulin class switch is impaired. Patients can present early in infancy and have neutropenia as well as typical infections characteristic for combined immune deficiencies. BMT is treatment of choice. IVIG infusions are given as well.[67]

Combined Immune Deficiencies

Severe Combined Immunodeficiency (SCID)

Common γ Chain Deficiency (X-linked SCID). Should be considered a pediatric emergency that is fatal if untreated. Patients present within the first few months of life with recurrent sinopulmonary, skin infections, and diarrhea. The infection is bacterial, fungal, viral, and mycobacterial. GVHD from maternally acquired T cells can occur. These patients sometimes present with complete absence of functional lymphocytes. B cells are preserved. The treatment is bone marrow transplantation.[67]

Adenosine Deaminase Deficiency. Adenosine deaminase deficiency is the most common autosomal recessive SCID. Lack of ADA activity allows toxic metabolites to accumulate in immune cells. In addition to complications listed under X-linked SCID, these patients also have ribcage anomalies and osseochondral dysplasia.[67] The treatment is bone marrow transplantation.

Omenn Syndrome (Leaky SCID). Caused by partial deficiency of RAG1 or RAG2, this CID is characterized by splenomegaly, diarrhea, hypereosinophilia, erythroderma, and increased IgE in newborns.

Innate Immune Defects

Wart Hypogammaglobulinemia Immunodeficiency Syndrome

This autosomal dominantly inherited syndrome of bcl-x overexpression is characterized by severe neutropenia with myeloid hyperplasia and degraded precursor cells (myelokathexis) in the bone marrow, recurrent warts, hypogammaglobulinemia, and recurrent infections.[39]

TABLE 79.18 Genetic Defects Linked to Common Immune Deficiencies

Immune Deficiency Group	Condition	Inheritance	Genetic Defect	Affected Cells	Most Common Symptoms
Humoral deficiencies	X-linked agammaglobulinemia	X-linked	BTK	B cells with decreased production in all immunoglobulins	Recurrent infections with encapsulated bacteria, absent lymphoid tissue on exam
	Hyper IgM heavy chain defect	AR	IGHM	B cells with decreased production in all immunoglobulins	Recurrent infections, lymphoid hyperplasia
	Transient hypogammaglobulinemia of infancy	Unknown	Unknown	Low IgA and IgG	Recurrent bacterial and viral infections that resolve by age of 4 years
	CVID	AR, some unknown	ICOS, TNFRSF13B, still learning about new mutations	B cells with decreased production in all immunoglobulins	Chronic sinusitis, bronchiectasis, autoimmune disorders
	Selective IgA deficiency	Unknown		Low IgA	Gastrointestinal, respiratory, urogenital infections
	Immunodeficiency, centromeric instability, facial anomaly (ICF) syndrome	AR	DNMT3B	B cells limited to naïve B cells	Facial anomalies: low set ears, epicanthal folds, flat nasal bridge, hypertelorism, macroglossia Sinopulmonary infections
T-cell and NK-cell deficiencies with intact humoral system	Interferon-γ/IL-12 axis disorders	AR, AD	IL12B IL12RB1 IFNGR1 IFNGR2 STAT1	Macrophages+/- T cells, NK cells	Mycobacterial and Salmonella infections *IFNGR1* gene defects predisposes to atopy, vasculitis, positive rheumatoid factor
	CD16 deficiency	FCGR3A	Unknown	NK cytopenia	Viral (HSV) Abnormal BCG response
T-cell deficiency with B cells present, but not functional	X-linked SCID	IL2RG	X-linked	T-cell lymphopenia, B cells present but nonfunctional, hypogammaglobulinemia	First few months of life: sinopulmonary, skin infections, FTT, diarrhea. Bacteria, viruses, fungals, mycobacteria, and opportunistic organisms. GVHD risk.
	IL-2 receptor α (IL2R α) deficiency	IL2RA	AR	T-cell lymphopenia, B cells present but nonfunctional, hypogammaglobulinemia	Same as X-linked SCID
	IL-7 receptor α (IL7R α)	IL7R	AR	T-cell lymphopenia, B cells present but nonfunctional, hypogammaglobulinemia	Same as X-linked SCID
	Janus kinase-3 (Jak3) deficiency	JAK3	AR	T-cell lymphopenia, B cells present but nonfunctional, hypogammaglobulinemia	Same as X-linked SCID
	CD3δ deficiency	CD3D	AR	T-cell lymphopenia, B cells present but nonfunctional, hypogammaglobulinemia	Same as X-linked SCID
	CD45 deficiency	PTPRC	AR	T-cell lymphopenia, B cells present but nonfunctional, hypogammaglobulinemia Normal γδ T cells	Same as X-linked SCID

TABLE 79.18 Genetic Defects Linked to Common Immune Deficiencies—cont'd

Immune Deficiency Group	Condition	Inheritance	Genetic Defect	Affected Cells	Most Common Symptoms
T-cell deficiency with B-cell deficiency	Adenosine deaminase deficiency	ADA	AR	T-cell and B-cell lymphopenia NK cells present	Same as X-linked SCID May have rib cage anomalies and osseochondral dysplasia
	Recombinase activating gene (RAG) deficiency	RAG1/2	AR	T-cell and B-cell lymphopenia NK cells present	If partial deficiency of RAG1 and RAG2, it will result in Omenn syndrome (see below).
	Artemis deficiency	DCCRE1C	AR	T-cell and B cell lymphopenia NK cells present	Similar to Omenn syndrome. Radiation sensitivity
	Reticular dysgenesis	Unknown	Likely AR	T-cell and B-cell lymphopenia plus neutropenia	Infections characteristic of SCID, plus neutropenia and thrombocytopenia. Deafness reported.
Immunodeficiencies with various T-cell abnormalities	X-linked hyper IgM	TNFSF5		Normal T-cell number, but low IgG, IgA, IgE and high IgM neutropenia	Can present in early infancy with abscesses, autoimmune cytopenias, hepatoma.
	Omenn syndrome	RAG1/2	AR	T-cell oligoclonal, B cells low, hypogammaglobulinemia	Hypereosinophilia, erythroderma, increased IgE, diarrhea in newborns
	MHC I deficiencies	TAP-1, TAP-2, TAPBP	AR	Low CD8, CD4 preserved Normal B cells.	Milder form
	MHC II deficiencies	RFX5, RFXAP, RFXANK, CIIA, ZAP70, p46Lck	AR	Very low CD4 count, CD8 preserved Normal B cells. ZAP70 causes low CD8 and normal but dysfunctional CD4.	More severe than MCH I deficiencies
DNA repair defects	Ataxia-telangiectasia	ATM	AR	Impaired T cells and immunoglobulin production	Oculocutaneous telangiectasia, cerebellar ataxia, bronchopulmonary infections, sensitivity to ionizing radiation and susceptibility to cancer.

AD, Autosomal dominant; AR, autosomal recessive; CVID, common variable immune deficiency; FTT, failure to thrive; GVHD, graft vs host disease; IL, interleukin; MHC, major histocompatibility complex; NK, natural killer; SCID, severe combined immunodeficiency.

IRAK 4 Mutation

Defective expression of the *IRAK 4* gene results in impaired innate immunity caused by defective interleukin 1 receptor-associated kinase 4. Staphylococcal and pneumococcal infections are especially common with moderate neutropenia, which may normalize during infection. Inheritance is autosomal recessive.[39]

Nonmalignant Disorders of Histiocytes

Dendritic Cell Disorders: Langerhans Cell Histiocytosis

Langerhans cell histiocytosis (LCH), the most common disorder of dendritic cells, is defined by accumulation of dendritic cells similar to Langerhans cells in various organs. The disease may be unifocal or multiorgan in involvement. Any organ can be affected, most commonly skeleton, skin, and pituitary. BRAF mutations have been identified in more than half of LCH cases. Diagnosis is made by biopsy of involved tissues and demonstration of Birbeck granules as well as positivity for S-100, CD1a, and Langerin (CD207). Langerhans cell histiocytosis can occur in the perinatal period. The estimated incidence in neonates is one to two per million. The majority (59%) of infants present with multisystem disease (two or more organs involved).[82] The skin is the predominant organ to be involved in infants. The extent of treatment (from observation to systemic chemotherapy) depends on disease status and should be risk adapted according to LCH guidelines.[51]

Congenital Self-Healing Reticulohistiocytosis with Spontaneous Regression

This variant of LCH typically appears at birth or in the neonatal period as multiple crusted papular skin lesions. These lesions tend to resolve spontaneously within weeks to a few months leaving residual hypo- or hyperpigmentation. Extracutaneous presentation is rare. This is diagnosed by skin performing histology of skin lesions.[98]

Hemophagocytic Lymphohistiocytosis

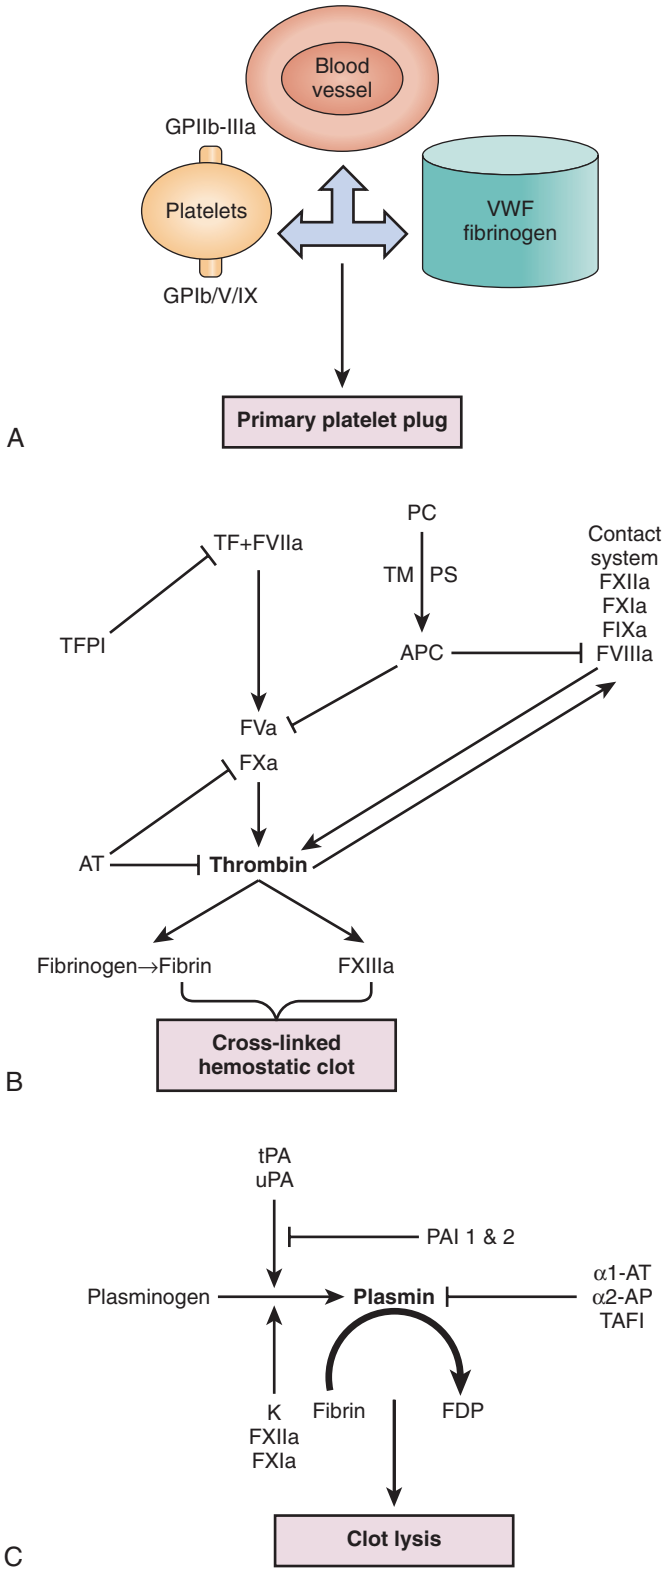
Hemophagocytic lymphohistiocytosis (HLH) is a condition characterized by persistent fever, cytopenia, splenomegaly, hypertriglyceridemia, elevated serum ferritin, elevation in the soluble IL-2 receptor CD25, and hypofibrinogenemia. Familial HLH, a form of primary HLH, is an autosomal recessive disorder that most often presents in infancy. Familial HLH has five subtypes described based on genes involved: one to five correspond to defects in *HPLH1*, *PRF1*, *UNC13D*, *STX11*, and *STXBP2* genes, respectively.[53] Demonstration of a genetic defect is diagnostic but often lags behind fulfillment of clinical criteria and the need to initiate treatment. Management of primary HLH consists of immunomodulatory therapy followed by hematopoietic stem cell transplantation. SCID-associated HLH in neonates has been described. Neonates can also succumb to herpes simplex virus–associated HLH; therefore, prompt initiation of acyclovir is needed.[122]

The Hemostatic System

Overview of Normal Hemostasis

The strategic elements of the hemostatic system are vascular endothelium, platelets, and coagulation proteins. The immediate response to vascular injury is transient arteriolar vasoconstriction caused by reflex neurogenic mechanisms and local secretion of vasoactive factors. This is followed by activation of platelets and coagulation proteins. Finally, once bleeding is controlled, blood vessel patency is restored by the fibrinolytic system. Hence the normal hemostatic response can be viewed to occur in the following three phases (Fig. 79.10):

1. Initiation and formation of the platelet plug (primary hemostasis)
2. Propagation of the clotting process by the coagulation cascade followed by termination of clotting by antithrombotic control mechanisms (secondary hemostasis)
3. Removal of the clot by the fibrinolytic system (tertiary hemostasis)



Vitamin K Physiology in Neonates

Vitamin K is present in a variety of dietary sources and is also produced by intestinal bacteria. Vitamin K is a cofactor for γ-glutamyl carboxylase, an enzyme that performs post-translational carboxylation, converting glutamate residues in proteins to γ-carboxyglutamate residues (Fig. 79.11). These residues facilitate membrane interactions mediated by calcium ions and are necessary for proper function of procoagulant factors (coagulation factors II, VII, IX, and X) and natural anticoagulants (proteins C and S). The newborn infant has a particularly fragile vitamin K status because of limited hepatic stores at birth, limited placental transfer of vitamin K, variable and limited content of vitamin K in breast milk, and an initially sterile gastrointestinal system.[127]

Developmental Hemostasis in the Neonate

Proteins required for hemostasis do not cross the placenta and are synthesized by the fetus. Distinctive, quantitative and qualitative, gestational age–dependent differences involving various components of hemostasis have been well characterized in neonates (Table 79.19).[5,6] These differences are more pronounced in premature infants. Although neonatal platelets are hyporeactive, the concentration and function of von Willebrand factor (VWF) are increased in neonates because of the presence of ultra-large hemostatically potent VWF multimers.[55] Vitamin K–dependent factors II, VII, IX, and X, and contact factors XI and XII, are reduced to about 50% of normal adult values, whereas the levels of the factors V, VIII, and XIII are similar to adult ranges. Although fibrinogen concentration is within normal adult ranges, it exists in a "fetal" form in the first 3 weeks of life. Fetal fibrinogen has a different composition compared to adult fibrinogen (increased sialic acid and phosphorus content) and shows decreased rates of fibrin polymerization,

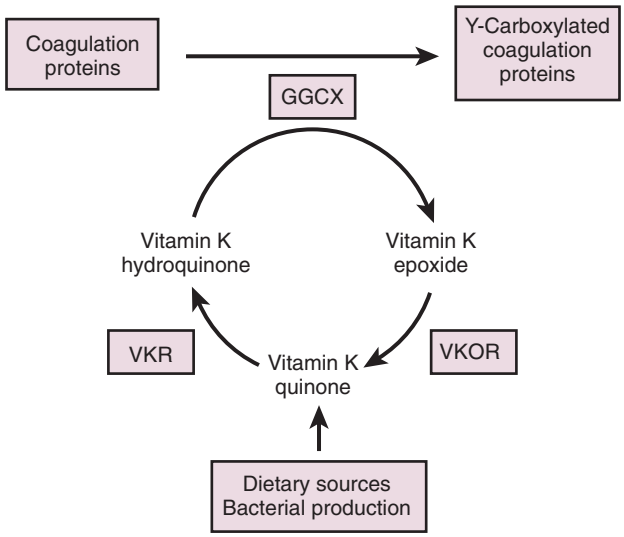
• **Fig. 79.10** Overview of the three phases of hemostasis. **A,** Primary hemostasis is dependent on interactions among platelets, the vascular endothelium, and coagulation proteins (von Willebrand factor [VWF] and fibrinogen). VWF associated with collagen in the exposed subendothelial matrix interacts with platelet GPIb/V/IX complex to mediate "platelet adhesion," whereas VWF and fibrinogen bind platelet GPIIb-IIIa to mediate "platelet aggregation." **B,** Secondary hemostasis involves sequential activation of coagulation factors. Formation of F (factor) VIIa-tissue factor (TF) complex is the major initiating event, which results in the generation of small amounts of thrombin (initiation phase or intrinsic pathway). These amounts of thrombin activate platelets and additional coagulation factors (amplification phase or extrinsic pathway), which results in a burst of thrombin formation so that a stable fibrin clot can be formed. This process is subsequently terminated by three types of natural anticoagulants: antithrombin (AT), which inhibits the activity of thrombin and factors (IXa, Xa, XIa, and XIIa); protein C, which is activated by thrombomodulin (TM), thrombin, and its cofactor protein S, which inhibits factors Va and VIIIa; and TF pathway inhibitor (TFPI), which inhibits FXa and TF/FVII. **C,** Tertiary hemostasis (fibrinolysis) functions to remove formed clots after hemostasis is secured. α1-AT 1 and 2, α1-antitrypsin 1 and 2; FDP, fibrin degradation products; PAI 1 and 2, plasminogen activator inhibitor 1 and 2; tPA, tissue plasminogen activator; uPA, urokinase plasminogen activator.



which results in prolonged thrombin clotting time (TCT) in normal neonates.[141] Similarly, concentrations of antithrombin, protein C, and protein S are significantly lower at birth, and the overall fibrinolytic capacity is decreased in neonates. On the other hand, despite significantly reduced total protein S antigen levels in neonatal plasma, the difference in the concentration of the anticoagulant, active, free form of protein S between infants and adults is much less pronounced, owing to low or undetectable C4b-binding protein in the neonatal period.[115] As a result of all these counterbalanced differences, the neonatal hemostatic system remains physiologically intact in the healthy neonate but lacks adequate reserve under stress conditions. Therefore, the risk of both bleeding and thrombosis is increased in sick neonates and is further increased in premature infants.

General Approach to Neonatal Bleeding Disorders

Bleeding disorders in neonates can be inherited but are more often acquired. It is clinically useful to classify bleeding disorders into those affecting primary hemostasis (blood vessels, VWF, and platelets) and those affecting secondary hemostasis (coagulation proteins). Disorders involving tertiary hemostasis (fibrinolytic system) are exceedingly rare. Acquired bleeding disorders can affect multiple components in the hemostatic system, and these can result in complex hemostatic abnormalities. The evaluation of bleeding disorders in neonates can be challenging because of subtle or nonspecific clinical presentations and difficulties in both obtaining adequate specimen for coagulation testing and interpreting the results of these tests in the context of developmental hemostasis. A systematic approach and the involvement of a pediatric hematologist are vital to

establishing the diagnosis and planning the therapeutic approach to a neonate with a suspected bleeding disorder. A complete history and physical examination is an essential first step that directs further laboratory work-up (Table 79.20). The laboratory evaluation of neonates with suspected bleeding disorders is best carried out in a rational, stepwise fashion (Fig. 79.12). An initial hemostatic screen is performed, and this is followed by additional testing if an abnormality is identified on the initial screen. Additional testing is also indicated if the clinical suspicion remains high despite a normal hemostatic screen. Screening tests do not exclude several less common or milder bleeding disorders

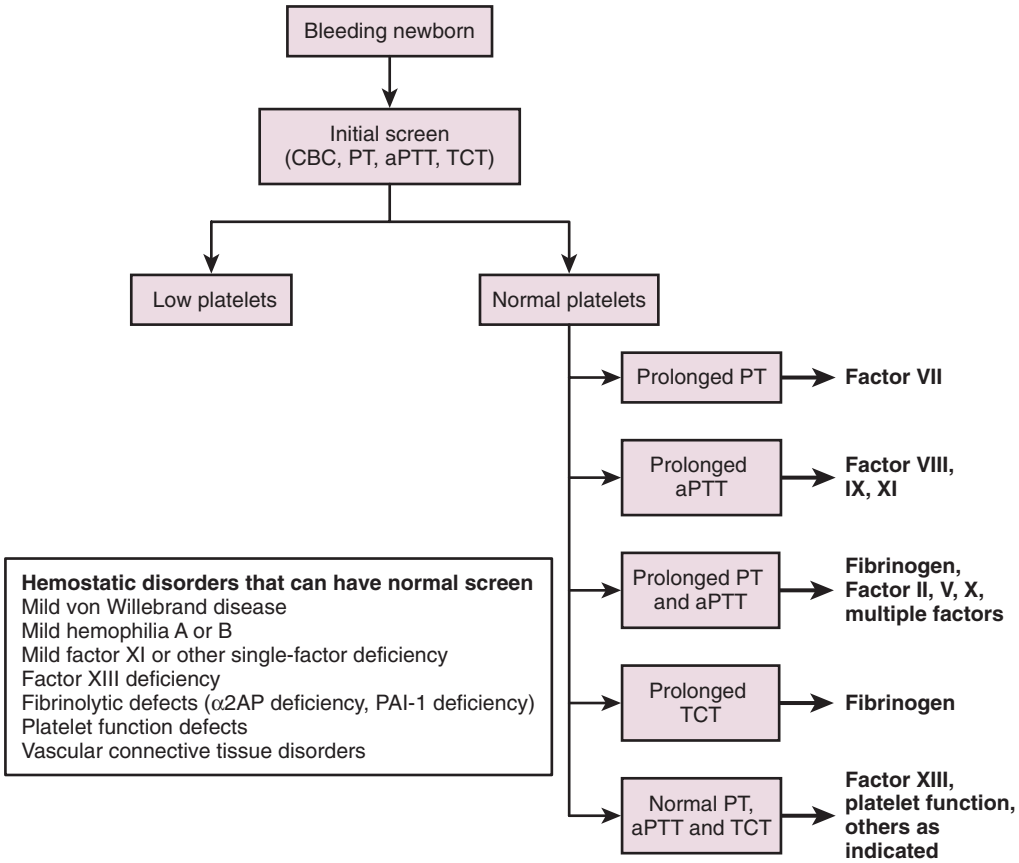
TABLE 79.19 Hemostatic Parameters in the Newborn



Decreased Compared with Adult Reference Ranges	Within Normal Adult Reference Ranges	Increased Compared with Adult Reference Ranges
Factor II	Fibrinogen	Factor VIII (mildly)
Factor VII	Factor V	VWF*
Factor IX	Factor XIII	α2-Macroglobulin
Factor X	α2-antiplasmin	
Factor XI	tPA	
Factor XII	PAI-1	
Pre-kallikrein		
HMWK		
Antithrombin		
Heparin cofactor II		
Protein C		
Protein S		
TFPI		
Plasminogen		

Platelet count and mean platelet volume vary with gestational and postnatal ages with wider intervals than adult reference ranges, prothrombin time (PT) is minimally prolonged, and activated partial thromboplastin time (aPTT) is markedly prolonged. Thrombin clotting time (TCT) is also prolonged. Platelet function studies show shorter bleeding times; shorter closure times by the platelet function analyzer (PFA-100); and decreased platelet aggregation in response to thrombin, ADP, and epinephrine.
HMWK, High molecular weight kininogen; PAI-1, plasminogen activator inhibitor-1; TFPI, tissue factor pathway inhibitor; tPA, tissue plasminogen activator; VWF, von Willebrand factor.
*VWF concentration and function are both increased, and ultra-large molecular weight multimers are present in neonatal plasma.
Data from Andrew M, Paes B, Milner R, et al. Development of the human coagulation system in the full-term infant. *Blood.* 1987;70:165-172; Andrew M, Paes B, Milner R, et al. Development of the human coagulation system in the healthy premature infant. *Blood.* 1988;72:1651-1657.

TABLE 79.20 Pertinent History and Physical Examination Findings in Neonatal Bleeding Disorders

History	• Presentations suggestive of neonatal bleeding disorders include diffuse purpura/ecchymoses, oozing from the umbilical stump, excessive bleeding from peripheral puncture/heel stick sites, large cephalohematomas without significant birth trauma history, prolonged bleeding following circumcision, intracranial hemorrhage in a term or late-preterm infant without history of birth trauma, and unexplained bleeding in a very low birth weight infant. • Bleeding in a well neonate is suggestive of an inherited coagulation disorder or an immune-mediated thrombocytopenia, whereas a sick preterm neonate is more likely to have acquired hemostatic disorder. • Vitamin K administration. • Maternal and obstetric history, including history of prior pregnancies and their outcomes, maternal medications (e.g., anticonvulsants can cause neonatal vitamin K deficiency), and maternal immune thrombocytopenia, which can cause neonatal thrombocytopenia. • Family history, including parental ethnic background and consanguinity, and family history of bleeding.
Physical examination	• The finding of purpura, petechiae, ecchymoses, and mucosal bleeding in neonates is suggestive of a primary hemostatic defect. • The presence of dysmorphic features/congenital anomalies may suggest an underlying genetic defect as some genetic syndromes are associated with a congenital bleeding tendency, most commonly involving platelets.

(see Fig. 79.12). Moreover, several potential pitfalls should be kept in mind regarding laboratory evaluation of hemostasis in neonates (Table 79.21).[84] Although many of these issues can be overcome, the major challenge in hemostatic testing in neonates remains the establishment of appropriate neonatal reference values that are analyzer- and reagent-specific and, at the same time, are clinically relevant (i.e., reference ranges that can accurately distinguish "disease" from "normal").[84]

Neonatal Platelet Disorders

This group of disorders results when platelets are either decreased in number (thrombocytopenia), functionally defective (thrombocytopathy), or both. Typical manifestations include petechiae (singly or in crops), bruising, and hemorrhage from mucosal surfaces. Bleeding from a heel stick puncture is often the first clinical indicator of an issue. Although generally rare, serious bleeding can complicate some of the more severe platelet defects.

Neonatal Thrombocytopenia (Quantitative Platelet Disorders)

Thrombocytopenia in a neonate of any viable gestational age was traditionally defined as a platelet count of less than 150×10^9/L.[108,109] However, recently, gestational and postnatal age-specific reference intervals for platelet counts have been described that should be considered when investigating thrombocytopenia in premature neonates.[134] Thrombocytopenia is one of the most frequent hematologic disorders encountered in the sick neonate.[108,109] This is evidenced by a fairly high incidence among neonates admitted to the neonatal intensive care unit (NICU) (22%-35%) compared with a relatively low overall incidence (0.7%-0.9%).[120] The incidence is inversely proportional to gestational age and/or birth weight.[30,31] Severe thrombocytopenia (platelet count $<50 \times 10^9$/L) is less common, affecting 5%-10% of all neonates and 14% of extremely low birth weight (ELBW) infants.[9,109] The predisposition of neonates to develop thrombocytopenia in response to illness is likely a result of the limited ability of the neonatal megakaryopoietic axis to increase platelet production in response to platelet consumption.[119] Although a large number of disease processes have been associated with thrombocytopenia in neonates, impaired platelet production is the prevailing mechanism in most cases of neonatal thrombocytopenia; consumption and/or sequestration underlie thrombocytopenia in 25%-35% of cases.[107] The differential diagnosis, and consequently diagnostic evaluation, of neonates with thrombocytopenia is usually based on onset (early onset ≤72 hours and late onset >72 hours), overall presentation, and

TABLE 79.21 Special Considerations in Neonatal Hemostatic Laboratory Testing

Variable	Sources of Error	Possible Solution(s)
Preanalytical	Insufficient sample volume and underfilling of collection tubes Heparin contamination (sample collected from indwelling catheters or into a preheparinized syringe) Specimen activation	Establishment of standard protocols, techniques for specimen collection, and transport and microtization of assays
	High hematocrit at birth (required citrate-to-blood ratio of 9:1 may not be achieved using standard collection tubes)	When the hematocrit exceeds 0.55 (55%), the reduced plasma volume requires a decrease in the volume of anticoagulant used to maintain the ratio of 9:1 using the following formula: $C\ (mL) = 1.85 \times 10^{-3} \times (100 - Hct\ [\%]) \times V\ (mL)$ C = mL of 3.2% sodium citrate anticoagulant; Hct (%) = hematocrit of the patient in %; and V = mL of whole blood in tube
Analytical	Elevated levels of bilirubin or lipids and hemolysis in neonates can interfere with optical density measurements used to determine end points of some coagulation tests.	Additional centrifugation of the sample
Postanalytical	Defining appropriate reference ranges for neonates	Use of age-related reference ranges specific for analyzer-reagent combination used in the coagulation laboratory

natural course (Table 79.22). Although the most common identifiable causes are chronic fetal hypoxia in early-onset thrombocytopenia and sepsis and necrotizing enterocolitis (NEC) in late-onset thrombocytopenia, no etiology is identified in a significant proportion of thrombocytopenia among ELBW neonates.[31]

Neonatal Thrombocytopenic Disorders Requiring Special Attention

Immune-Mediated Thrombocytopenias

Fetal and Neonatal Alloimmune Thrombocytopenia

Fetal and neonatal alloimmune thrombocytopenia (FNAIT) is the most common cause of severe neonatal thrombocytopenia and of intracranial hemorrhage (ICH) in term neonates.[21,23] Fetal and neonatal alloimmune thrombocytopenia occurs at an estimated incidence of 1/1000 to 2000 live births.[34] Fetal and neonatal alloimmune thrombocytopenia results from transplacental passage of maternal antibodies, which adhere to fetal platelets expressing paternal antigens that the mother lacks. Fetomaternal incompatibility involving certain human platelet antigens (HPAs) specifically expressed by fetal platelets leads to the production of a maternal IgG alloantibody in response to exposure to fetal blood. Maternal IgG crosses the placenta, often in early pregnancy, and binds to fetal platelets. The fetal platelets are cleared in the reticuloendothelial system, resulting in fetal and neonatal thrombocytopenia. Genetic incompatibility to platelet antigens is necessary but not sufficient for FNAIT, because the observed frequency of the clinical syndrome is far lower than what would be expected based on genetic frequency alone.[21,23] Thus other factors, including genetic immune response modifiers and HLA alleles, must be important in the pathophysiology.[139] The frequency of significant bleeding in FNAIT is striking compared with other thrombocytopenic disorders such as immune thrombocytopenia (ITP). Alloantibody-mediated secondary effects, such as platelet dysfunction and megakaryocytic damage resulting in prolonged thrombocytopenia and endothelial injury, may be responsible for the high incidence of severe bleeding (e.g., HPA-1a antigen is expressed by endothelial cells).[8,10] Human platelet antigen frequencies vary among different ethnic groups; the severity of FNAIT can correlate with the specific HPA incompatibility identified.

Fetal and neonatal alloimmune thrombocytopenia should be strongly considered in one of two clinical scenarios: (1) in an otherwise healthy neonate, born after an uneventful pregnancy and delivery, exhibiting petechiae or widespread purpura within 24-48 hours of birth associated with severe thrombocytopenia (platelet count $<50 \times 10^9$/L); or (2) in cases in which intracranial hemorrhage (ICH), porencephaly, or ventriculomegaly is discovered during fetal life. About 10%-20% of clinically recognized cases have ICH, which is asymptomatic (discovered radiographically) or symptomatic. Fifty to seventy-five percent of ICH occurs in utero. It can be fatal in one-third of cases, and in the rest can result in significant neurologic sequelae. Confirmation of a clinical diagnosis of FNAIT requires two laboratory approaches: (1) platelet antigen incompatibility is demonstrated by genotyping (PCR techniques) and phenotyping (flow cytometry, various immunoassay methods), and (2) there is evidence of maternal alloantibody directed against the identified alloantigen (various immunoassays such as ELISA and using maternal serum tested against paternal

TABLE 79.22 Causes of Neonatal Thrombocytopenia

Classification	Causes	Presentation
Early-onset (≤72 hours)	Chronic fetal hypoxia/placental insufficiency (PIH, IUGR, diabetes)	Slowly evolving, mild–moderate thrombocytopenia, nadir at days 4-7; resolution by day 10
	Aneuploidy (trisomies 18, 13, 21, isochromosome 18q, triploidy, Turner syndrome)	Dysmorphism, congenital anomalies
	Perinatal asphyxia	Sick neonate with severe thrombocytopenia
	Early neonatal sepsis (*E. coli*, GBS, *H. influenza*)	
	DIC	
	Immune-mediated thrombocytopenias (FNAIT, autoimmune thrombocytopenia from maternal ITP)	Well full-term neonate with severe thrombocytopenia
	Kasabach-Merritt syndrome	Severe thrombocytopenia, DIC, enlarging cutaneous or visceral vascular tumor
	Thrombosis (renal vein thrombosis, aortic thrombosis, portal vein thrombosis, CSVT)	Unexplained thrombocytopenia, clinical features of organ dysfunction (e.g., renal insufficiency in renal vein thrombosis, seizures in CSVT)
	Thrombotic microangiopathies (congenital TTP, familial atypical HUS)	Hemolysis, hyperbilirubinemia, multiorgan dysfunction
	Congenital infections (CMV, toxoplasma, others)	Stigmata of congenital infections
	Bone marrow failure syndromes or replacement (congenital leukemia, metastatic neuroblastoma, storage disorders)	Pancytopenia, additional systemic manifestations
	Inborn errors of metabolism (organic acidemia)	Associated clinical features
	Inherited thrombocytopenias	Persistent unexplained thrombocytopenia, associated congenital anomalies
Late-onset (>72hours)	Late-onset sepsis (bacterial/fungal)	Rapid onset severe thrombocytopenia with slow recovery
	NEC	
	Autoimmune thrombocytopenia from maternal ITP	History of maternal thrombocytopenia/SLE
	Congenital infection (CMV, toxoplasma, others)	As above
	Kasabach-Merritt syndrome	
	Inborn errors of metabolism	
	Inherited thrombocytopenias	
	Drug-induced thrombocytopenia (β-lactams, vancomycin, indomethacin, ibuprofen, H_2-blockers, heparin)	Resolution upon withdrawal of offending drug

CMV, Cytomegalovirus; CSVT, cerebral sinovenous thrombosis; DIC, disseminated intravascular coagulation; FNAIT, fetal and neonatal alloimmune thrombocytopenia; GBS, group B Streptococcus; HUS, hemolytic uremic syndrome; ITP, immune thrombocytopenia; IUGR, intrauterine growth restriction; PIH, pregnancy-induced hypertension; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.
Data from Roberts I, Stanworth S, Murray NA. Thrombocytopenia in the neonate. *Blood Rev.* 2008;22:173-186.

platelets and/or platelets from normal donors with known platelet alloantigen phenotypes).[21,23] Neuroimaging of all neonates with suspected FNAIT is recommended, because some will have asymptomatic central nervous system bleeding requiring more aggressive treatment measures.

Autoimmune Thrombocytopenia in Infants Born to Mothers with Immune Thrombocytopenic Purpura

Neonatal ITP caused by transplacental passage of maternal IgG antiplatelet autoantibodies occurs in up to 25% of mothers who develop primary or secondary (owing to systemic lupus erythematosus) ITP during pregnancy.[109,132] The risk of severe thrombocytopenia and ICH in affected neonates is significantly lower compared with FNAIT (<15% and <2%, respectively). Maternal platelet counts during pregnancy cannot reliably predict the risk of neonatal thrombocytopenia; however, a maternal platelet count less than 50×10^9/L at delivery and a history of severe thrombocytopenia in a previous neonate may be useful indicators of the likelihood of significant neonatal thrombocytopenia complicating the current pregnancy.[56,126] Typically, the nadir platelet count in affected neonates is observed between days 2 and 5 after birth with resolution by day 7; however, some neonates may continue to have thrombocytopenia secondary to maternal ITP for months, necessitating long-term monitoring. Evaluation of affected neonates should include serial platelet counts and screening transcranial ultrasonography (if platelet count is $<50 \times 10^9$/L).

Inherited Thrombocytopenias

Inherited thrombocytopenias are a rare, heterogeneous group of disorders with highly variable bleeding tendency (Table 79.23). Although far less common than acquired forms, inherited thrombocytopenias should be considered in neonates with persistent unexplained thrombocytopenia

TABLE 79.23 Inherited Thrombocytopenic Syndromes that Can Present in the Neonatal Period

Syndrome	Genetics	Hemostatic Features	Additional Findings
Large/Giant Platelets, MPV >11 fl			
MYH9-related thrombocytopenia (May-Hegglin anomaly and Fechtner, Epstein, and Sebastian syndromes)	AD (22q11)	Mild bleeding tendency Mild–moderate thrombocytopenia with mild platelet dysfunction	Neutrophil inclusions, ± sensorineural hearing loss, ± nephritis, ± cataracts
Bernard-Soulier syndrome	AR (17pter-p12; 22q11.2; 3q21)	Severe bleeding tendency Variable thrombocytopenia with defective platelet adhesion	None
X-linked thrombocytopenia with dyserythropoiesis	XL (Xp11.23)	Severe bleeding tendency Severe thrombocytopenia with defective platelet function	Microcytic anemia, dyserythropoiesis, thalassemia, splenomegaly
11q terminal deletion disorder (Paris-Trousseau thrombocytopenia/ Jacobsen syndrome)	AD (11q23)	Mild bleeding tendency Severe neonatal thrombocytopenia that resolves over time, and persistent platelet dysfunction	Developmental delay, growth restriction, dysmorphism, and multiple congenital anomalies (Jacobsen syndrome)
Normal-Sized Platelets, MPV 7-11 fl			
Congenital amegakaryocytic thrombocytopenia	AR (1p34)	Severe bleeding tendency Severe neonatal thrombocytopenia	Marrow failure during second decade
Thrombocytopenia and absent radii	AR (?)	Severe bleeding tendency Severe neonatal thrombocytopenia	Shortened/absent radii bilaterally. Bleeding tendency and thrombocytopenia improve after infancy.
Thrombocytopenia and radial synostosis	AD (7p15-p14.2)	Severe bleeding tendency Severe neonatal thrombocytopenia	Fused radius, incomplete range of motion, other skeletal defects, and sensorineural hearing loss Thrombocytopenia usually does not improve with time.
Small Platelets, MPV <7 fl			
Classic Wiskott-Aldrich syndrome	XL (Xp11.23-p11.22)	Severe bleeding tendency with significant risk of bleeding Severe neonatal thrombocytopenia	Immunodeficiency, autoimmunity, eczema, lymphoma
X-linked thrombocytopenia	XL (Xp11.23-p11.22)	Severe bleeding tendency with significant risk of bleeding Severe neonatal thrombocytopenia	Manifestations besides microthrombocytopenia are uncommon.

AD, Autosomal dominant; AR, autosomal recessive; MPV, Mean platelet volume; XL, X-linked.

since birth; bleeding tendency disproportionate to the platelet counts; family history of thrombocytopenia; typical congenital anomalies/dysmorphism; or suggestive blood smear abnormalities (consistently large or small platelets, abnormal platelet granules, or neutrophil inclusions called Döhle bodies). Except for Wiskott-Aldrich syndrome and X-linked thrombocytopenia (XLT), in which increased consumption of platelets in addition to defective production is implicated, thrombocytopenia in these disorders is caused by impaired production. Platelet dysfunction, identified in many inherited thrombocytopenias, is responsible for the significant bleeding tendency that is out of proportion to the measured platelet count and is characteristic of some of these disorders (e.g., Bernard-Soulier syndrome). The diagnostic evaluation of these disorders can be challenging. Testing should be conducted by a clinician with expertise and directed by clinical manifestations, physical examination findings, and initial lab results. Platelet function testing is imperfect, labor intensive, and requires relatively large volumes of blood for immediate processing. Some tests are available only in research laboratories. Genetic and/or molecular studies are needed to confirm the diagnosis in some inherited platelet disorders (such as Wiskott-Aldrich syndrome/X-linked thrombocytopenia).

Platelet Function Disorders (Qualitative Platelet Disorders)

Qualitative platelet disorders include a large number of abnormalities, which are either inherited or acquired (Box 79.11). These disorders pose diagnostic challenges, because the tests needed to fully evaluate platelet function can be complex, requiring a great deal of expertise, and are often restricted to specialized coagulation and/or research laboratories. As a group, these disorders present as primary hemostatic defects of variable severity characterized by mucocutaneous bleeding (bruising, petechiae). Although congenital platelet function defects rarely cause pathologic bleeding in the neonatal period, the severe platelet function disorders such as Glanzmann thrombasthenia and Bernard-Soulier syndrome can present in neonates (Table 79.24). Some of these congenital disorders are associated with thrombocytopenia, while others cause isolated platelet dysfunction with normal platelet counts. For more information about these disorders, the reader is referred to excellent reviews by Bolton-Maggs and co-workers and Nurden et al.[17,95]

Management of Platelet Disorders in Neonates

Besides treating the underlying cause, platelet transfusions are the mainstay therapy for most neonates with platelet disorders. In neonatal thrombocytopenia, platelet transfusions can be given therapeutically in those with active bleeding or, in most cases, prophylactically to prevent serious bleeding events, particularly intracranial hemorrhage and intraventricular hemorrhage (IVH) in preterm infants. Although the correlation between platelet count and the risk of a clinical hemorrhage is poor, the risk of bleeding is likely higher in neonates with FNAIT, sepsis, or

• BOX 79.11 Causes of Platelet Function Defects

Acquired

- Uremia
- Liver disease
- Extracorporeal membrane oxygenation and cardiopulmonary bypass
- Disseminated intravascular coagulation
- Medications (indomethacin, ibuprofen, nitric oxide, others)
- Hypothermia

Inherited

- Primary platelet function defects
- Defective platelet adhesion (platelet-type VWD, Bernard-Soulier syndrome)
- Defective platelet aggregation (Glanzmann thrombasthenia)
- Defective receptor interactions and abnormal signal transduction
- Receptor defects (thromboxane A2 receptor defect, purinergic receptor defects for ADP and ATP, collagen receptor defects)
- Arachidonic acid pathway defects (cyclooxygenase-1 deficiency and thromboxane synthase deficiency)
- Signal transduction defects (defects in G-protein activation, defects in phosphatidylinositol metabolism, defects in calcium mobilization, and defects in protein phosphorylation)
- Defective granule storage and secretion
- Deficiency of α granules (Gray platelet syndrome, Quebec platelet disorder, arthrogryposis-renal dysfunction-cholestasis syndrome)
- Deficiency of δ granules (idiopathic δ-storage pool disease, Chediak-Higashi syndrome, Hermansky-Pudlak syndrome)
- Deficiency of α and δ granules (11q terminal deletion disorder)
- Defective procoagulant function (Scott syndrome)
- Secondary platelet function defects
- VWD
- Congenital afibrinogenemia

ADP, Adenosine diphosphate; ATP, adenosine triphosphate; VWD, von Willebrand disease.

TABLE 79.24 Glanzmann Thrombasthenia versus Bernard-Soulier Syndrome

	Glanzmann Thrombasthenia	Bernard-Soulier Syndrome
Epidemiology	International frequency data are unknown. Increased incidence in certain ethnic groups (South Indian Hindus, Iraqi Jews, French gypsies, and Jordanian nomadic tribes) and families with consanguinity	Estimated prevalence <1 in 1,000,000
Pathophysiology	Defective platelet aggregation caused by quantitative or qualitative defect of platelet GpIIb/IIIa (fibrinogen receptor)	Defective platelet adhesion due to quantitative or qualitative defects of platelet GPIb-IX-V receptor complex (von Willebrand factor receptor)
Inheritance	Autosomal recessive	Autosomal recessive
Thrombocytopenia	No	Yes (of variable severity)
Aggregation studies	Absent platelet aggregation in response to all agonists except ristocetin	Failure to aggregate with ristocetin, normal aggregation response to other agonists
Diagnosis	Flow cytometric studies of platelet surface glycoprotein expression, GpIIb/IIIa	Flow cytometric studies of platelet surface glycoprotein expression, GpIb/IX

TABLE 79.25 Platelet Transfusion Thresholds in Neonates (Platelet Counts $\times 10^9$/L)

	Nonbleeding					
	Preterm					
Published Guidelines	Stable	Unstable	Term	Bleeding	Before Invasive Procedure	ECMO
Most restrictive	<20	<30	<20	<50	<50	<100
Least restrictive	<50	<100	<30	<100	<100	

ECMO, Extracorporeal membrane oxygenation.
Data from Blanchette VS, Hume HA, Levy GJ, et al. Guidelines for auditing pediatric blood transfusion practices. *Am J Dis Child.* 1991;145:787-796; Gibson BE, Todd A, Roberts I, et al. Transfusion guidelines for neonates and older children. *Br J Haematol.* 2004;124:433-453.

necrotizing enterocolitis, particularly those with extreme prematurity.[29,35,143] Because of the paucity of evidence-based guidelines, considerable variability exists in practice as well as in published guidelines (Table 79.25).[14,46] Some recommendations are, however, more restrictive, accepting lower platelet triggers for transfusions because of recognition that the clinical condition is an important determinant of the risk of bleeding and because of concerns regarding the risks of platelet transfusions (e.g., transfusion-related acute lung injury, bacterial contamination, alloimmunization).

Treatment of infants with suspected FNAIT should be initiated promptly and without awaiting definitive test results. The mainstay of therapy is platelet transfusions, which should be given in nonbleeding, well neonates if the platelet count is less than 30×10^9/L and in neonates with intracranial hemorrhage or other major bleeding events if the platelet count is less than 50 to 100×10^9/L.[21,46] Human platelet antigen-1a/5b negative platelets are compatible in greater than 90% of cases with FNAIT, or washed, irradiated maternal platelets are used as the platelet products of choice because they result in higher and longer-lasting platelet count increments.[21] If, however, matched platelets are not immediately available, random donor platelets should be given instead.[8] Intravenous immunoglobulin (IVIG) and corticosteroids can also be used as adjuvant therapies.[21] Antenatal management of pregnancies at risk for FNAIT is complex, requiring a multidisciplinary approach. Standard medical treatment consists of weekly IVIG in early pregnancy with or without systemic corticosteroids. Intrauterine platelet antigen-negative platelet transfusions are reserved for medical treatment failures and for prophylaxis of acute hemorrhage at the time of fetal blood sampling.[22] Early cesarean delivery has also been advocated to decrease the risk of intracranial hemorrhage, although evidence is lacking.

Recommended management of neonatal ITP consists of close observation in those with platelet counts between 20 and 50×10^9/L at delivery and IVIG in neonates with clinical hemorrhage or platelet counts less than 20×10^9/L.[101] Cesarean section, unless otherwise indicated for obstetric reasons, and intrapartum fetal platelet count measurements are not recommended.[94]

In neonates with significant bleeding because of congenital platelet disorders or acquired platelet dysfunction, fibrinolytic inhibitor drugs (epsilon aminocaproic acid and tranexamic acid), and recombinant activated factor VII can be used as adjuvant to or, in some cases, in place of platelet transfusions. Patients with Bernard-Soulier syndrome or Glanzmann thrombasthenia are at increased risk of isoimmunization and/or alloimmunization from platelet transfusion therapy, which can result in platelet transfusion refractoriness rendering future platelet transfusions largely ineffective.[117] For certain inherited platelet disorders, such as congenital amegakaryocytic thrombocytopenia and Wiskott-Aldrich syndrome, hematopoietic stem cell transplantation from suitable donors can be curative.

Neonatal Coagulation Disorders

This group of disorders results in impairment of secondary hemostasis resulting in bleeding that is typically delayed and in deep tissues. As for platelet disorders, inherited or, more commonly, acquired mechanisms are involved. In this section, coagulation disorders are described that can present in neonates.

Inherited Coagulation Disorders

Inherited coagulation disorders usually present with abnormal bleeding in an otherwise healthy neonate. Although a positive family history can confirm the diagnosis, an inherited bleeding disorder in the absence of family history is still possible in cases arising as a result of new mutations or inherited in an autosomal recessive fashion.

Hemophilia

Hemophilia, the most common inherited bleeding disorder to present in the neonatal period, is caused by deficiency of factor VIII (hemophilia A) or, less commonly, factor IX (hemophilia B). Hemophilia is classified according to severity on the basis of plasma procoagulant concentrations. Patients are categorized as having mild hemophilia (>5% but <40% normal factor [<0.05-<0.40 IU/mL]); moderately severe hemophilia (1%-5% normal factor

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

[0.01-0.05 IU/mL]); and severe hemophilia (<1% normal factor [<0.01 IU/mL]). The annual incidences of hemophilias A and B in the United States are 1 in 5000 and 1 in 30,000 male births, respectively. In all, 60% and 44% of these new cases, respectively, have severe phenotype. In both disorders, thrombin generation is markedly decreased, which leads to delayed formation and poor stability of the hemostatic clot.

Both are X-linked recessive disorders caused by a variety of gene mutations. It is estimated that up to thirty percent of mutations in hemophilia A are de novo (new) mutations. Hemophilia A and B are clinically indistinguishable, and clinical manifestations early in life are almost always confined to boys. Greater than 50% of hemophilia patients are diagnosed as neonates, of whom up to one-third have clinically significant bleeding.[32] The pattern of bleeding in newborns with hemophilia differs significantly from that in older children and adults. Iatrogenic bleeding is the most common hemorrhagic manifestation, typically presenting as significant oozing or hematoma formation following venous or arterial puncture, heel stick, intramuscular vitamin K injection, or circumcision. Extracranial hemorrhage (ECH) including subgaleal hemorrhage and cephalohematomas, as well as ICH, can also occur in neonates with hemophilia. The incidence of ICH in neonates with severe hemophilia is 1%-7%.[64,65,123] Intracranial hemorrhage is more common than ECH, and the most frequent site of hemorrhage is subdural.[66] Risk factors for cranial bleeding include forceps/vacuum instrumentation during delivery, severe phenotype, and preterm delivery. Intracranial hemorrhage can have dramatic (seizures, focal deficits) or subtle presentations or can be asymptomatic or "silent." Extracranial hemorrhage also demands attention because it can cause massive blood loss in neonates with hemophilia. Finally, umbilical, musculoskeletal, and GI and other organ bleeding are infrequently encountered in hemophilic neonates.[27,28]

The diagnosis of hemophilia in neonates requires laboratory confirmation. Isolated prolongation of the aPTT is usually found on routine coagulation testing. The definitive diagnosis of hemophilia requires measurement of factor levels in uncontaminated cord blood or neonatal venous blood samples. Although it is usually possible to confirm a diagnosis of hemophilia A of any severity in the neonatal period, irrespective of the gestational age, confirmation of mild hemophilia B is problematic. Unlike factor VIII, factor IX levels are reduced at birth and are further reduced in preterm infants. It is, therefore, possible to make a diagnosis of severe and moderate hemophilia B at birth, but for mildly affected neonates, confirmation requires repeat testing at 6 months of age or molecular analysis if the genetic defect is known.[27,28] Controversy exists regarding role, timing, and optimal technique for radiologic assessment of ICH in neonates with hemophilia. The British Committee for Standards in Hematology has published guidelines that recommend screening cranial ultrasound in all neonates with severe or moderate hemophilia before discharge and cranial MRI or CT scan in symptomatic neonates even if the ultrasound is normal, owing to the low sensitivity of ultrasound for the detection of subdural bleeding.[26]

The management of neonatal hemophilia can be summarized as follows.[26]

Management during Delivery

The optimal mode of delivery remains unclear and may be best determined on an individual basis, taking into account obstetric and hemostatic factors.[70] Vacuum extraction, forceps, and invasive monitoring procedures, such as placement of fetal scalp electrodes and fetal scalp blood sampling, should be avoided.

Management in the Postnatal Period

Intramuscular vitamin K should be withheld until hemophilia is excluded. Oral vitamin K can be given instead if there is a delay in diagnosis or if hemophilia is confirmed. Following confirmation of diagnosis, short-term prophylactic replacement therapy (with specific factor concentrates) may be given to neonates following traumatic, instrumented, or preterm delivery or a prolonged second stage of labor. The benefits of factor replacement must be weighed against the risk of inhibitor development, although a recent report from the CDC demonstrated no difference in inhibitor rates with neonatal factor exposure.[65]

Management of Clinically Significant Bleeding in Neonates

Before confirmation of diagnosis, fresh frozen plasma (15-25 mL/kg) should be given. After confirmation of diagnosis, recombinant factor VIII or IX concentrates should be given with close monitoring, as neonates may require higher doses to achieve desired factor levels and may demonstrate a shortened factor half-life. Although extended half-life factors are now available for use in hemophilia, use in neonates and previously untreated patients is not yet recommended outside of a clinical trial.[74]

von Willebrand Disease

Despite being the most common inherited bleeding disorder overall, initial presentation and identification of most forms of von Willebrand disease (VWD) in neonates is rare, owing to physiologically increased VWF concentration and function in neonates compared to adults. The classification of VWD consists of type 1 disease, which is a partial quantitative deficiency in VWF; type 2 disease, which is characterized by various qualitative (functional) defects in VWF; and type 3 disease, which is owing to a total quantitative deficiency of VWF. More recently, a subtype of type 1 VWD, Vicenza variant, with features of increased clearance of VWF has been identified.[104] Although most types of VWD are inherited in an autosomal dominant fashion, type 3 is recessively inherited as homozygous or compound heterozygous. Laboratory tests in VWD usually include measurements of plasma VWF antigen (VWF:Ag), VWF function by VWF ristocetin cofactor assay (VWF:RCo),

FVIII coagulant activity (FVIII:C), and assessment of the circulating plasma VWF (VWF multimers). Two types of VWD can present in neonates.

Type 2B VWD is characterized by increased affinity for VWF to platelets leading to the formation of circulating platelet aggregates that are reversibly sequestered in the microcirculation. Neonates with this type can present with moderate thrombocytopenia and bleeding. This rare type of VWD should be considered in the differential diagnosis of unexplained neonatal thrombocytopenia.

VWD type 3, the most severe form, represents less than or equal to 1% of all VWD cases but is the type most likely to present in neonates. Bleeding manifestations are variable. Mucosal bleeding is more common than in hemophilia A, whereas ICH is almost unheard of in type 3 VWD. This may be attributed to low, but residual, factor VIII activity.[133] On coagulation testing, type 3 VWD is characterized by prolonged aPTT, undetectable VWF:Ag and VWF:Rco, very low factor VIII:C (<1 IU/mL), and absent VWF multimers.

Because of the clinical and laboratory overlap with severe hemophilia A, testing for type 3 VWD should be considered in neonates with suspected severe hemophilia A, particularly when the gender, clinical course, or laboratory data are not typical. Management of bleeding in VWD requires factor replacement using plasma-derived VWF-containing factor VIII concentrate for moderate to severe bleeding. In older children who present with mild VWD (type 1 and some type 2), desmopressin (DDAVP) is used to increase VWF levels. Because of the risk of hyponatremia, desmopressin (DDAVP) should not be used in the treatment of neonatal VWD.[137]

Rare Inherited Coagulation Disorders

Rare inherited coagulopathies comprise less than 5% of all inherited deficiencies of coagulation. They are generally transmitted as autosomal-recessive traits. Unlike hemophilia, causative mutations, identifiable in 80%-90% of patients, are private (i.e., unique for each affected kindred).[75] Because of their rarity, data on clinical manifestations and management are relatively limited, but it is clear that a number of these disorders are associated with a severe bleeding tendency, which may manifest itself in neonates (Table 79.26).[27] Typical manifestations in neonates include soft tissue bleeding, umbilical stump bleeding, and post-circumcision bleeding. Intracranial hemorrhage is also a relatively common feature of these disorders.[27] These disorders should be suspected in neonates with bleeding tendency and prolonged clotting times. A prolonged PT with a normal aPTT is indicative of factor VII deficiency, whereas a prolonged aPTT with a normal PT is indicative of factor XI deficiency, provided that VWD and hemophilia have been ruled out. The prolongation of both tests should point to the possible deficiencies of factor X, factor V, prothrombin, or fibrinogen; dysfibrinogenemia; or combined factor deficiencies. Factor XII, prekallikrein, and high molecular weight kininogen, if deficient, will prolong the aPTT but are not associated with clinical bleeding. Factor XIII deficiency is an exception in that both PT and aPTT are normal. Quantitative factor XIII assays are preferred over the urea clot stability assay for diagnosis of this factor deficiency. Confirmation of diagnosis is achieved by specific factor coagulant activity assays and, rarely, antigen assays. Although DNA mutation analysis is rarely performed, results can be useful for prenatal diagnosis.[75]

TABLE 79.26 Rare Inherited Coagulation Disorders that Can Present in the Neonatal Period

Disorder	Estimated Prevalence*	Treatment

Combined vitamin K–dependent coagulation factor deficiency§	0.5	Vitamin K (oral or parenteral), FFP

*Per 1 million population.
†Inherited fibrinogen disorders can manifest as quantitative defects (afibrinogenemia and hypofibrinogenemia) or qualitative defects (dysfibrinogenemia). Neonatal presentation is usually seen in afibrinogenemia, which is characterized by the complete deficiency of plasma fibrinogen.
‡In addition to bleeding tendency, affected neonates can have impaired wound healing.
§Severely affected neonates may also exhibit features that resemble "warfarin embryopathy," including nasal hypoplasia, distal digital hypoplasia, epiphyseal stippling, and mild conductive hearing loss attributed to dysfunction of other vitamin K–dependent proteins (osteocalcin and matrix Gla proteins).
FFP, Fresh frozen plasma; PCC, prothrombin complex concentrate.

Acquired Coagulation Disorders

Acquired deficiency or impairment of coagulation is a frequent complication in sick neonates. In the next section, three important acquired coagulopathies in neonates are reviewed: vitamin K deficiency, DIC, and coagulopathy of liver disease.

Vitamin K Deficiency

As discussed, vitamin K is a critical cofactor required for posttranslational modification of coagulation proteins II, VII, IX, and X. In the absence of vitamin K, these proteins are dysfunctional and are released into the circulation in a decarboxylated form known as proteins induced by vitamin K absence (PIVKA). The presence of PIVKA without coagulation deficit indicates subclinical vitamin K deficiency.[127] The recommended dietary intake of vitamin K is 1 μg/kg body weight/day.[127] Vitamin K deficiency can be idiopathic or secondary. Secondary causes include the following:

1. Inadequate intake, which can occur in infants exclusively receiving unsupplemented breast feedings, infants on broad-spectrum antibiotics that eliminate intestinal vitamin K–producing bacteria, or infants who are receiving total parenteral nutrition without vitamin K supplementation.
2. Poor absorption or fat malabsorption state caused by cholestatic liver disease, pancreatic insufficiency, or intestinal disorders (e.g., short bowel syndrome).
3. Poor utilization, as seen in significant liver disease.
4. Vitamin K antagonism due to warfarin therapy.

Vitamin K deficiency bleeding (VKDB) is a rare but potentially life-threatening bleeding disorder, which presents in three different patterns (Table 79.27). Isolated prolongation of the PT is the earliest laboratory evidence of vitamin K deficiency, followed by prolongation of the aPTT. The diagnosis is confirmed by correction of these parameters by vitamin K administration or by assays of the specific factors. Other confirmatory tests, such as measurement of decarboxy prothrombin (PIVKA-II) and measurement of vitamin K concentrations, are rarely able to return a result in real time, limiting their clinical utility for routine laboratory use.[137]

Treatment of VKDB requires parenteral vitamin K administration by slow IV infusion or subcutaneously if venous access cannot be established. For neonates who are bleeding, fresh frozen plasma should also be given. Prothrombin complex concentrates (PCC) should be considered in the presence of life-threatening hemorrhage or ICH when it is necessary to rapidly normalize the levels of the depleted coagulation factors.[137] In the United States, prevention of VKDB by administration of a single intramuscular injection of vitamin K soon after birth is the current standard practice and has been almost universally effective. A single oral dose of vitamin K is ineffective for long-term protection.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a clinicopathologic syndrome that is characterized by systemic activation of coagulation and fibrinolysis, consumption of platelets and coagulation factors, and generation of fibrin clots that can lead to ischemic organ damage or failure. Disseminated intravascular coagulation represents a continuum in severity with definable phases characterized by initial localization and compensation (nonovert or compensated DIC) that progresses into widespread dysregulation of coagulation and fibrinolysis (overt or decompensated DIC).

Although the risk of developing DIC is believed to be highest in neonates, accurate data on the epidemiology of DIC in neonates are lacking because of difficulties in establishing the diagnosis and, consequently, underestimation of the true frequency of this disorder.[128] Disseminated intravascular coagulation in neonates can be triggered by a variety of pathologic conditions (Box 79.12). The cardinal manifestations of overt DIC are caused by excessive bleeding and microvascular thrombosis. Hemorrhagic symptoms include petechiae and bruising, oozing from venipuncture sites, bleeding from traumatic and surgical wounds, and in severe cases, bleeding involving internal organs. Thrombosis typically manifests as biochemical and/or clinical evidence of end-organ dysfunction. Kasabach-Merritt syndrome (KMS) represents a localized form of DIC seen in association with cutaneous or occasionally visceral congenital vascular lesions such as kaposiform hemangioendothelioma and tufted angiomas.[50] The pathophysiology of KMS is

TABLE 79.27 Vitamin K–Deficiency Bleeding Presentations in Neonates

Presentation	Bleeding Sites	Etiologies
Early (first 24 h)	Scalp, subperiosteal, skin, intracranial, intrathoracic, intra-abdominal	Maternal drugs (e.g., warfarin, anticonvulsants)
Classical (days 1-7)	Gastrointestinal, umbilical, skin, nose, circumcision	Mainly idiopathic, breastfeeding (low milk intake)
Late (≥day 8; peak 3-8 weeks)	Intracranial, skin, gastrointestinal	Idiopathic or secondary, exclusive breastfeeding in the absence of vitamin K administration, undiagnosed cholestasis often present. Secondary cases from malabsorption resulting from underlying disease (e.g., biliary atresia, α-1-antitrypsin, cystic fibrosis) or chronic diarrhea. Antibiotic therapy sometimes implicated.

• BOX 79.12 Common Causes of Disseminated Intravascular Coagulation in Neonates

- Sepsis
- Perinatal hypoxia-ischemia (perinatal asphyxia, placental abruption)
- Necrotizing enterocolitis
- Severe hepatic dysfunction
- Respiratory disorders (RDS, MAS)
- Metabolic disorders (galactosemia, others)
- Vascular anomalies (Kasabach-Merritt syndrome)
- Hematologic disorders (purpura fulminans caused by protein C or S deficiency, erythroblastosis fetalis)

MAS, Meconium aspiration syndrome; RDS, respiratory distress syndrome.

generally presumed to be that of platelet trapping by abnormally proliferating endothelium within the vascular anomaly. This results in the activation of platelets with a secondary consumption of clotting factors. The diagnosis of DIC, particularly in the early stages, can be problematic because there is no single laboratory test that can establish or rule out DIC. Hence, the diagnosis is often made on the basis of an appropriate clinical suspicion supported by laboratory evidence of procoagulant and fibrinolytic system activation coupled with anticoagulant consumption. Laboratory abnormalities seen in DIC include thrombocytopenia, elevated fibrin degradation products (FDP) or D-dimers, prolonged PT, prolonged aPTT, prolonged thrombin clotting time, and a low fibrinogen. Serial testing may be necessary for the diagnosis, given the dynamic nature of DIC and that fibrinogen is an acute-phase reactant; plasma fibrinogen can remain well within the normal range despite ongoing consumption.

Successful treatment of DIC relies largely on reversal of the underlying condition and supporting adequate blood flow and oxygen delivery. Blood component transfusions (platelets, fresh frozen plasma, and cryoprecipitate) are an important part of supportive treatment in DIC. In cases of DIC in which thrombosis predominates, such as arterial or venous thromboembolism or severe purpura fulminans, therapeutic anticoagulation with unfractionated heparin may be considered. Except for the use of protein C concentrates in purpura fulminans owing to protein C deficiency, anticoagulant concentrates (protein C, antithrombin), recombinant factor VIIa, and recombinant tissue plasminogen activator are not generally indicated for the routine treatment of DIC.

Coagulopathy of Acute Liver Disease

Acute liver disease affects hemostasis in several different ways. Hemostatic abnormalities associated with acute liver failure include thrombocytopenia and thrombocytopathy, decreased production of coagulation factors, vitamin K deficiency, reduced vitamin K-dependent γ-carboxylase activity, acquired dysfibrinogenemia, decreased fibrinolytic activity, and DIC. The net result is a complex bleeding diathesis of variable severity. Although spontaneous bleeding is rare, serious bleeding after invasive procedures can occur.

Coagulation testing often shows prolonged PT and aPTT, thrombocytopenia, decreased fibrinogen level, and decreased concentrations of factors VII and V. A normal or elevated factor VIII concentration distinguishes primary liver disease from DIC. Conventional coagulation assays do not fully reflect the hemostatic status and do not predict risk of bleeding. Hence, there is no benefit to correcting coagulopathy in nonbleeding neonates. Treatment of active hemorrhage includes blood product transfusions (FFP, cryoprecipitate, platelets) and vitamin K administration. Recombinant factor VIIa has also been used successfully to maintain hemostasis, although there is an increased risk of thrombosis in this setting.[113,140]

Neonatal Thrombotic Disorders

Neonates, particularly those who are critically ill, have a significantly increased risk of developing thrombotic events. This increased risk can be explained by the presence of risk factors unique to this period of time that can promote thrombosis (sepsis, inflammation, hypotension, hypoxia, and the use of intravascular catheters in small-caliber vessels), as well as the developmental hemostatic differences in neonates discussed earlier.[105] Acquired and inherited prothrombotic conditions including factor V Leiden and prothrombin gene mutation; deficiencies of protein C, protein S, and antithrombin; elevated factor VIII, lipoprotein (a), and homocysteine; and antiphospholipid antibodies are known risk factors for thrombosis. However, the contribution of neonatal, and especially maternal, prothrombotic conditions in the causation of thrombosis in neonates is not well characterized. Data from various registries, which likely underrepresent the true frequency of thrombotic complications in newborns, have reported incidences of up to 5.1 per 100,000 live births and 2.4 per 1000 NICU admissions with 45%-55% of these events affecting preterm infants.[12] Common neonatal thrombotic events include thrombosis of upper/lower venous system, portal veins, renal veins, or cerebral venous sinuses, as well as peripheral and CNS arterial thrombosis. The most common trigger for neonatal thrombotic events is an indwelling vascular access device.

Neonatal Deep Vein Thrombosis of the Upper/Lower Venous System

Almost all cases of deep vein thrombosis (DVT) of the upper and lower venous system in neonates are associated with indwelling central venous lines such as an umbilical venous catheter (UVC), peripherally inserted central catheter (PICC), or Broviac catheter. Manifestations are highly variable and include catheter dysfunction, limb or face swelling, discoloration of the skin and/or distention of the superficial veins, persistent chylous effusion, and superior vena cava (SVC) syndrome. Some cases are asymptomatic and are identified incidentally on radiologic studies.

Diagnosis is most commonly established by compression Doppler ultrasound. For thrombosis involving the upper central venous system (proximal subclavian vein, brachiocephalic vein, SVC), Doppler ultrasound has lower sensitivity, and other imaging modalities such as echocardiography or venography (magnetic resonance, computed tomography, or conventional) are often required to make the diagnosis of DVT in this location. In general, the recommended management of acute and symptomatic central venous line–related DVT includes anticoagulation therapy, usually with low molecular weight heparin (LMWH), for a total of 6-12 weeks. The central venous line should be removed if no longer required or if it is nonfunctioning. Anticoagulation therapy 3-5 days before the central venous line removal is recommended. If the central venous line is still required and is functioning, it may be left in place. If the central venous line is still in place on completion of therapeutic anticoagulation, a prophylactic dose of LMWH should be given to prevent recurrent thrombosis until such time as the central venous line is removed. The management of radiologically detected asymptomatic central venous line–related DVT is less clear. If central line access is still required, management options include either anticoagulation in the absence of contraindications or close clinical and radiologic monitoring.[106]

Neonatal Portal Vein Thrombosis

Neonatal portal vein thrombosis (PVT) is an underrecognized thrombotic event that is most commonly encountered in association with UVC placement. The reported incidence of UVC-related PVT is highly variable, ranging from 1.3% up to 43%.[138] A large, single-center retrospective study reported an overall estimated incidence of at least 3.6 per 1000 NICU admissions.[86] Risk factors include both UVC-related factors, such as inappropriate UVC placement (low or intrahepatic), and prolonged catheterization and transfusion through the UVC, as well as patient-related factors, including low birth weight, low-flow state, hypoxia, infection, sepsis, congenital malformations, and gestational diabetes mellitus. Portal vein thrombosis is often associated with subtle, nonspecific, or absent clinical and laboratory signs. Unexplained thrombocytopenia may be an initial manifestation in a proportion of cases.[86] Diagnosis is usually established by Doppler ultrasound. Management is similar to any central venous line–related DVT, although it is not clear if anticoagulation improves outcome. Long-term complications of PVT include portal hypertension and hepatic lobar atrophy, which is usually asymptomatic. As such, PVT is the major cause of extrahepatic portal hypertension and gastrointestinal bleeding in childhood.[138]

Neonatal Renal Vein Thrombosis

Neonatal renal vein thrombosis (RVT) is the most prevalent non-catheter-related thrombotic event during the neonatal period, accounting for up to 20% of all thrombotic events in newborns.[19] Risk factors include a history of perinatal asphyxia, gestational diabetes mellitus, prematurity, dehydration, infection, and congenital heart disease.[19] Involvement of renal veins may also be seen in the context of central venous line–related thrombosis of the inferior vena cava (IVC). Males are more commonly affected than females, representing 67.2% of cases.[19] Approximately 70% of neonatal RVT cases are unilateral, with a left-sided predominance. Most neonates with RVT will manifest with one or more of the three cardinal clinical features of macroscopic (or microscopic) hematuria, palpable flank mass, and thrombocytopenia.[19] Other manifestations include acute renal injury, which can be present in a significant number of cases, distant embolization, and hypertension. Diagnosis is confirmed by Doppler ultrasonography. Current management guidelines recommend either supportive care with radiologic monitoring for extension of thrombosis or anticoagulation for 6-12 weeks for unilateral RVT in the absence of renal impairment or extension into the IVC; anticoagulation for 6-12 weeks for unilateral RVT that extends into the IVC; and anticoagulation alone for 6-12 weeks or initial thrombolytic therapy with tissue plasminogen activator, followed by anticoagulation for 6-12 weeks for bilateral RVT with evidence of renal impairment.[83] Acute complications of RVT include adrenal hemorrhage and distant embolization. Long-term complications include chronic renal insufficiency and hypertension.[19]

Neonatal Arterial Thrombosis

The majority of cases of arterial thrombosis in neonates are caused by indwelling arterial catheters. Neonatal aortic thrombosis is a potentially life-threatening arterial thrombotic event that is most commonly associated with use of umbilical arterial catheters but has been reported to occur spontaneously. Affected neonates can be asymptomatic or present with irritability, absent/diminished peripheral pulses, and coldness or duskiness of extremities. Additional manifestations include catheter dysfunction, hypertension, acute renal injury, mesenteric ischemia, and signs of heart failure.[90] Diagnosis is confirmed by Doppler ultrasound. Management typically includes immediate removal of the indwelling arterial catheter and anticoagulation therapy for 5-7 days. Thrombolytic therapy or surgical thrombectomy should be considered for limb, organ, or life-threatening arterial ischemia.[83]

Neonatal Stroke

See Chapter 53.

Neonatal Purpura Fulminans

Neonatal purpura fulminans (PF) describes a clinicopathologic entity characterized by dermal microvascular thrombosis, DIC, and perivascular hemorrhage, occurring in the

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

newborn period.[100] Inherited cases are most commonly caused by homozygous deficiency of protein C or S. Acquired causes are more common and often are associated with severe infection, most commonly group B streptococcus causing a consumptive coagulopathy and a relative deficiency of protein C and/or S.[100] Neonatal PF usually presents with a rapid onset of cutaneous purpuric lesions shortly after birth and DIC. The skin lesions initially appear dark red and then become purple-black and indurated. They occur at previous sites of trauma (e.g., intravenous cannula insertion sites), and they may initially be mistaken as bruising. There is a predilection for the limbs, although buttocks and thighs are often affected. In time, the areas may become necrotic and gangrenous, resulting in loss of extremities.[100] Other manifestations include thrombosis of the cerebral vasculature, vitreous hemorrhage, and retinal detachment that may result in partial or complete blindness, and large vessel venous thromboses such as RVT.[100] Diagnosis is based on typical clinical presentation. Confirmation of inherited forms requires demonstration of undetectable levels of protein C or protein S, a heterozygous state in the parents, and, if possible, identification of the molecular defect.[100] Treatment should be initiated promptly and includes replacement therapy with fresh frozen plasma (or protein C concentrate for patients with protein C deficiency), followed by indefinite anticoagulation for inherited cases. For acquired cases, the mainstay of therapy is aggressive treatment of the underlying cause and supportive therapy.[100]

Neonatal Antithrombotic Therapy

Antithrombotic agents, which include anticoagulants and thrombolytics, are increasingly used in neonates for treatment of thromboembolism and for prevention of thrombosis in neonates with congenital heart disease and those requiring mechanical circulatory support. The immaturity of the hemostatic system in neonates leads to differences in the pharmacokinetics of commonly used antithrombotic agents and increased risk of bleeding.[142]

Anticoagulants

In neonates, unfractionated heparin (UFH) and low molecular weight heparin (LMWH) are the two most commonly utilized anticoagulants. Both agents function as an anticoagulant by potentiating the inhibitory effects of antithrombin on thrombin and factor Xa. Low molecular weight heparin, which is derived from UFH, has a more profound inhibitory effect on factor Xa than on thrombin.[142] Because antithrombin levels are significantly decreased in neonates, higher initial doses are required to achieve the target anticoagulation levels. Low molecular weight heparin has more stable pharmacokinetics and thus more predictable responses than UFH.[142]

Unfractionated heparin is most often used for the treatment and prevention of thromboembolic events, prevention of thrombosis during cardiac catheterization, and for maintaining the patency of venous and arterial catheters and extracorporeal circuits in cardiopulmonary bypass and extracorporeal life support. Unfractionated heparin in pediatrics is administered as an intravenous infusion. The therapeutic dose recommended for treatment of thromboembolic events in neonates is 28 units/kg per hour, administered as a continuous intravenous infusion and titrated to a target aPTT or antifactor Xa activity level. A bolus dose of 75 units/kg IV, administered over 10 minutes, may be given immediately before initiating the maintenance infusion to accelerate achievement of target anticoagulation.[83] The prophylactic dose of UFH is 10 units/kg per hour, administered as continuous intravenous infusion.[83] The standard concentration for UFH infusion in neonates is 50 units/mL, and it is important that this concentration be stocked for the NICU and for use in infants to avoid dosing errors.

The activated partial thromboplastin time (aPTT) and the antifactor Xa activity are the two assays commonly used to monitor UFH. Target levels for therapeutic anticoagulation for thromboembolic events are an aPTT of 1.5-2.5 times the control aPTT, usually 60-85 seconds, or an antifactor Xa activity of 0.35-0.7 units/mL.[83] Although the antifactor Xa assay, which is generally considered a more reliable measure of the anticoagulant effect, may be preferred to the aPTT in neonates, neither test is ideal. Monitoring of UFH in neonates remains challenging, with a high degree of inter- and intrapatient variability in dosing, leading to difficulty in maintaining target levels.[142] Antithrombin supplementation, either with fresh frozen plasma or antithrombin concentrate, is sometimes used for neonates in whom therapeutic heparinization has been difficult to achieve despite dose escalation.

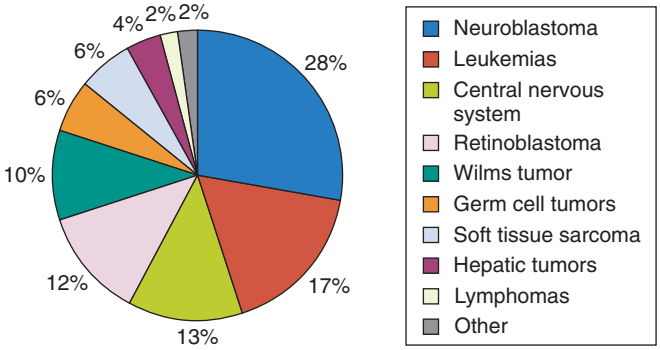
The most important adverse effect of anticoagulation is bleeding. Heparin-induced bleeding in neonates as a result of accidental overdose, owing to drug error in which a higher heparin infusion concentration is erroneously dispensed and administered, is a common serious and avoidable problem in hospitals. Because UFH is used for a variety of clinical indications other than therapeutic and prophylactic infusions (e.g., line flushes), a variety of heparin concentrations are available on hospital formularies, potentially leading to these kinds of errors.[83] Treatment of bleeding owing to UFH includes immediate termination of the infusion and administration of protamine sulfate (if rapid reversal is required). Heparin-induced thrombocytopenia, a very serious adverse event that can lead to severe thrombotic complications, can affect up to 1% of neonates, particularly those with congenital heart disease.[142]

The most frequently used LMWH in pediatrics is enoxaparin. In neonates, LMWH (enoxaparin) has replaced UFH as the anticoagulant of choice in the initial treatment of thromboembolism because of more predictable pharmacokinetics and ease of administration and monitoring. Low molecular weight heparin is also the preferred agent for long-term anticoagulation in neonates. Nevertheless, in neonates at risk for bleeding, UFH is still preferred because of its

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

shorter half-life and complete reversibility with protamine sulfate. The traditionally recommended therapeutic dose of enoxaparin for treatment of thromboembolic events in neonates is 1.5 mg/kg per dose, administered subcutaneously every 12 hours.[83] However, a higher initial dose (1.8-2 mg/kg/dose) administered subcutaneously every 12 hours is commonly employed at major pediatric thrombosis centers, based on data that suggest a higher final dose requirement in this patient population, especially in preterm infants.[83] The recommended prophylactic dose of enoxaparin in neonates is 0.75 mg/kg per dose, administered subcutaneously every 12 hours.[83] Low molecular weight heparin is monitored by the anti-factor Xa assay. A common ordering error occurs when providers request a factor X activity assay rather than the antifactor Xa activity assay. Some laboratories have renamed the antifactor Xa activity assay as a LMWH activity assay to avoid this problem. The target antifactor Xa activity, measured 4-6 hours after dose administration, is 0.5-1 units/mL for therapeutic anticoagulation and 0.1-0.3 units/mL for prophylactic anticoagulation.[83] Adverse effects such as bleeding and heparin-induced thrombocytopenia are infrequent. Protamine sulfate can be administered in serious bleeding but does not completely reverse the anticoagulant effects of LMWH.

Thrombolytics



Alteplase, recombinant tissue plasminogen activator (tPA), is the thrombolytic agent of choice. The main indication for thrombolysis is life-, organ-, or limb-threatening thromboembolism. An important consideration in neonates is that plasminogen levels are significantly lower in newborn infants, which may result in reduced clinical efficacy. Plasminogen supplementation with fresh frozen plasma infusion should be considered before administration of alteplase in neonates to enhance the thrombolytic effect. Thrombolytic therapy is contraindicated in any clinical situation with serious bleeding or increased bleeding risk, including prematurity (<32 weeks' gestation).[83] The recommended dose of alteplase is 0.5 mg/kg per hour, infused for 6 hours. Lower doses of 0.06-0.1 mg/kg per hour have also been successfully used and may be associated with lower bleeding risk. Prophylactic UFH (i.e., 10 units/kg per hour) is typically administered concurrently with alteplase infusion, which is then followed by therapeutic heparinization after discontinuation of thrombolytic therapy.[83] Close clinical and laboratory monitoring (PT, aPTT, fibrinogen, D-dimer, and platelet counts) is required. In patients receiving thrombolytic therapy, fibrinogen levels should be kept greater than 100 mg/dL and platelets should be kept at 100,000/μL to reduce bleeding risk.[83] A screening head ultrasound, CT scan, or brain MRI is commonly obtained in neonates before initiation of thrombolytic therapy to confirm the absence of intracranial hemorrhage (ICH) at baseline. The major adverse event is bleeding, including serious and life-threatening hemorrhages. Intracranial hemorrhage has been reported in up to one-fourth of neonates receiving thrombolytic therapy.[83] Major bleeding is treated by stopping the infusion of the thrombolytic agent and anticoagulant; administering cryoprecipitate (usual dose of 1 unit/5 kg or 5-10 mL/kg), an antifibrinolytic agent (e.g., aminocaproic acid or tranexamic acid), or both; and administering other blood products as indicated.[83]

Neoplasms in the Neonate

Infant Cancer

The annual incidence of cancer in the first year of life, 234 per million infants, is the highest for all of childhood (<15 years of age) according to the National Cancer Institute's Surveillance, Epidemiology and End Results (SEER) statistics for the years 1992-2007. This represents 10% of all childhood malignancies. The first year of life is the only period in childhood when the incidence of cancers is not higher in males than females.[99] Neonatal tumors comprise 2% of all childhood malignancies.[85] The majority of neonatal tumors are solid and can be picked up by a perinatal ultrasound. Teratoma, a germ cell tumor presenting most often on prenatal ultrasound in the sacrococcygeal area, is the most common neoplasm in infancy but is usually surgically excised as a nonmalignant (i.e., noncancerous) tumor. Fig. 79.13 provides a graphic summary of infant cancer incidence by common types.

In adults, cancer is thought to occur after a long interplay between environmental triggers and genetic predisposition. In infancy, especially in the neonatal period, the normal, genetically programmed protections against unregulated growth of cells fail very early. In infancy, embryonal tumors such as neuroblastoma, Wilms tumor, medulloblastoma, hepatoblastoma, and retinoblastoma are more common compared to older ages. The association between congenital abnormalities and certain tumors is well established.[85] The 5-year overall survival for all neonates (age <1 month) was 60.3%. Neonates with solid tumors had the highest 5-year overall survival (71.2%), followed by leukemia (39.1%) and CNS tumors (15%). Except for neuroblastoma, all of the neonatal tumors showed significantly inferior outcomes

• **Fig. 79.13** Comparative incidence of infant cancers. (Data from Pereira GA, Ribeiro KB, Rodriguez-Galindo C, et al. Changes in incidence of infant cancer: analysis of SEER data 1992-2007. *J Clin Oncol.* 2011;29[Suppl]; abstr 9542.)

compared to that in older patients.[3] The inferior survival rates for similar histologic tumors is likely attributable both to differences in the tumor biology and also to altered drug metabolism and increased toxic effects of therapy in infancy.[49] Treatment protocols for infant cancers include elimination or reduction of radiation therapy and age- and weight-based decreases in chemotherapy doses.

Neuroblastoma

Neuroblastoma, an embryonal tumor of neural crest origin arising anywhere along the sympathetic chain, is the leading malignant tumor of the perinatal period and the second most common solid tumor in childhood. About half of infant neuroblastomas are diagnosed within the first 4 months of life, with many being detected as an adrenal mass in utero. Survival of infants with neuroblastoma detected before birth is better that those diagnosed after birth.[52] Other common sites of presentation are cervical and thoracic. Neurologic signs and symptoms of spinal cord compression prompt urgent diagnosis and management with steroids and chemotherapy in about 20% of neonatal neuroblastomas. Many neuroblastoma tumors secrete catecholamines. Urine homovanillic acid and vanillylmandelic acid levels are commonly used diagnostic tests. Mass infant screening programs using these urine tests in Japan, Quebec, and Europe have increased the detection of good-prognosis tumors but have failed to change the mortality rate from high-risk neuroblastoma. Familial neuroblastoma with germline mutations in *PHOX2B* or *ALK* account for 1% of childhood neuroblastoma.[94]

The most important prognostic variables for infant neuroblastoma are the patient age at diagnosis, the stage of the tumor, DNA index, and *MYCN* amplification. Tumor hyperdiploidy (DNA index <1) is a favorable prognostic indicator, whereas *MYCN* amplification is associated with more aggressive disease. Infants with neuroblastoma have a better prognosis than older children, with an overall 5-year survival of about 88% (versus 45% for those >1 year at diagnosis). Infants with localized tumors have a 5-year survival rate of 95%. Expectant observation of babies younger than 6 months of age with small adrenal masses has reduced surgical morbidity and mortality while maintaining excellent event-free survival rates.[94] Observation or surgery, with or without low-dose chemotherapy, is recommended for lower-risk neuroblastoma in infants. High-dose chemotherapy with peripheral blood stem cell rescue, radiation therapy, cis-retinoic acid, and immunotherapy are treatment modalities for infants with high-risk, *MYCN*-amplified disease.

A unique stage of neuroblastoma is 4s. These patients have to be less than 1 year of age, have localized primary tumor with disease dissemination to skin and liver, and have <10% of bone marrow involved with negative metaiodobenzylguanidine (MIBG) in bone marrow. Stage 4s accounts for 7%-10% of the cases of neuroblastoma.[114] This subgroup of infants has the unique, poorly understood characteristic of spontaneous tumor regression. Infants with 4S disease require chemotherapy only if they develop threatening symptoms or progressive disease.[114]

Leukemia

Leukemia is the second most common cancer in infancy. Infant leukemias tend to present toward the second half of the first year of life. Approximate incidence rates per million infants include acute lymphoblastic leukemia (ALL) 20 per million, acute myelogenous leukemia (AML) 10 per million, and juvenile myelomonocytic leukemia (JMML) at 2 per million. Neonatal or congenital leukemia, estimated to occur in 1-5 per million infants, is diagnosed in the first 30 days of life and carries a particularly grave prognosis. Acute myelogenous leukemia is more common than ALL in neonatal leukemia. Rearrangements of the mixed lineage leukemia (*MLL*) gene at chromosome 11q23, MLL-r, are common in congenital and infant ALL and AML. Prenatal MLL-r events promote rapid development of additional mutations or "hits" resulting in early leukemia presentation. If a monozygotic twin is diagnosed with leukemia in the first year of life, intrauterine transfer of the mutation results in an almost 100% concordance for the other twin, with a brief lag time of weeks until the other twin's leukemia diagnosis.[125]

There are many genetic syndromes associated with increased leukemia risk. Bone marrow failure syndromes, primary and secondary immunodeficiencies, defects in DNA repair, and genetic defects impacting tumor suppressor genes are associated with leukemogenesis as well as oncogenesis. Down syndrome (ALL, AML), Noonan syndrome (JMML, AML), and neurofibromatosis type 1 (ALL, AML, JMML) have strong associations and early leukemia presentations.

The differential diagnosis for congenital leukemia includes transient abnormal myelopoiesis, leukemoid reaction, congenital infections, hypoxia or hemolysis, hemophagocytic lymphohistiocytosis, and stage 4s neuroblastoma. Langerhans cell histiocytosis can also present in infants with pancytopenia, organomegaly, and cutaneous extramedullary hematopoiesis.

Infant Acute Lymphocytic Leukemia

A number of clinical features that have been associated with a poorer prognosis are common in neonates and infants with acute lymphocytic leukemia (ALL): a large tumor cell burden (hyperleukocytosis), massive hepatosplenomegaly, involvement of the central nervous system, leukemic skin infiltrates (leukemia cutis), and hypogammaglobulinemia. The leukemic blasts in infant ALL often are CD10 negative, express myeloid antigens, and have cytogenetic abnormalities involving the *MLL* gene, which carries worse prognosis. Strategies to intensify therapy have improved survival for infants with ALL but not for the ones with *MLL* rearrangement.[48] A small percentage of these leukemias are biphenotypic (i.e., express characteristics of both ALL and AML). Neonates experience significant toxicities both from

chemotherapy and central nervous system irradiation. The especially poor prognosis for infant ALL is owing to the high incidence of bone marrow and extramedullary relapse. Infants <90 days of age at diagnosis have worse outcomes.[48] Progressively more intensive chemotherapeutic regimens and bone marrow transplantation have been used in these patients, but the event-free survival rate at 5 years is only in the 30% range.[125]

Infant Acute Myelogenous Leukemia

Neonates with acute myelogenous leukemia (AML) have similarly poor remission and disease-free survival rates indistinguishable from those for older children. Distinctive features of AML in the infant include very high incidences of cutaneous involvement (leukemia cutis) and central nervous system disease, hepatosplenomegaly, hyperleukocytosis, and an unusually high number of cases with blasts of the monoblastic (M5%-50%) or myelomonocytic (M4%-10%) type. Leukostasis syndrome, a complication of severe hyperleukocytosis more commonly seen in AML than in ALL, is characterized by white blood cell plugs in the microvasculature, causing central nervous system events such as stroke and respiratory and cardiac failure. Cytogenetic abnormalities in the blasts are exceptionally common and usually involve *MLL* gene rearrangement, such as t(11;19)(q23;p13) and t(9;11)(p21;q23). Infants with Down syndrome who are diagnosed with AML have a superior survival rate compared with others with AML, because they tend to develop the acute megakaryocytic leukemia subset of AML (AMKL or M7) and have a very high response rate to therapy. Approximately one-third of infants who experience transient abnormal myelopoiesis will develop AMKL. Most other infants with AMKL have a t(1;22)(p13;q13) aberration, which confers a poor prognosis.[125]

Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia (JMML, formerly juvenile chronic myelogenous leukemia) is classified as a myeloproliferative neoplasm/myelodysplastic syndrome that accounts for less than 1% of pediatric leukemias. Ten percent of cases are diagnosed before 3 months of age, and the majority are diagnosed by 2 years of age. Clinical manifestations include splenomegaly, rash, lymphadenopathy, failure to thrive, leukoerythroblastosis, monocytosis, thrombocytopenia, and elevated fetal hemoglobin. The abnormal growth of JMML cells has been linked to a dysregulated transduction signal through the pathway that involves GM-CSF, the GM-CSF receptor neurofibromin, and Ras.

About 10% of children with JMML have neurofibromatosis type 1 (NF1). Neurofibromatosis type 1–activating mutations and *RAS* family oncogene mutations are seen in the leukemic cells of JMML patients. Patients with Noonan syndrome, a disorder associated with gain-of-function mutations in *PTPN11*, the gene encoding the protein tyrosine phosphatase SHP-2, are at increased risk for developing JMML. SHP-2 mutations are present in the leukemia cells of one-third of JMML cases. Mutations of the E3 ubiquitin ligase CBL are now identified in up to another 10%. Monosomy 7 is also seen in a subset of JMML. Patients diagnosed before 3 years of age and those with Noonan syndrome have a better prognosis. Although a variety of therapies have been employed to treat JMML, allogeneic bone marrow transplantation is the only curative treatment.[125]

Many entities (e.g., retinoblastoma [see Chapter 95], Wilms tumor [see Chapter 93], and sacrococcygeal teratoma [see Chapter 13]) are discussed elsewhere.

Teratomas and Other Germ Cell Tumors

Most infant germ cell tumors (GCTs) are diagnosed before the age of 2 months. GCTs comprise a wide range of benign and malignant tumors. They originate from preinvasive precursors that transform into overt tumors during infancy, adolescence, or young adulthood. Whereas 90% of GCTs diagnosed during adult life are gonadal, two-thirds of neonatal and childhood GCTs are extragonadal, with sacrococcygeal teratoma being most prevalent.[112] Serum markers used to help in diagnosis of GCTs are α-fetoprotein (AFP) and β-human chorionic gonadotropin (β-hCG). It is important to note that AFP levels are high at birth and decrease to adult values only by 812 months of age.[112] See Table 79.28 for age-adjusted AFP values.

Most neonatal germ cell tumors, irrespective of location, are benign. The term *teratoma* describes both benign and malignant tumors composed of haphazardly intermixed tissues that originate from pluripotent stem cells and that are foreign to the anatomic site in which they arise. Traditionally, tissue components from all three embryonic germ layers—endoderm, mesoderm, and ectoderm—should be represented in a teratoma. However, it is now generally accepted that tumors that are foreign to the site where they arise and consist of more than one embryonic layer can be classified as teratomas. Sacrococcygeal teratomas are frequently detected prenatally or at birth as a mass in the region of the sacrum or buttocks, sometimes accompanied by obstruction of the rectum or urinary tract. Vertebral anomalies can be seen in patients with sacrococcygeal teratomas. The mainstay of therapy for germ cell tumors is surgical resection. Typically, teratomas have an excellent outcome. Immature teratomas have a prognosis comparable to mature teratomas, provided the tumor can be totally excised. In the case of sacrococcygeal teratomas, prematurity, perioperative hemorrhage, and other postoperative events result in a 10%-20% risk for mortality. Endodermal sinus tumors of the infant testis have a better prognosis than those at later ages and other locations, including the ovary.

Soft Tissue Sarcomas

Infant soft tissue sarcomas account for about 7% of infant cancers and are the fifth most common malignancy in the first year of life. About one-third of these are rhabdomyosarcoma. Rare non-rhabdomyosarcoma tumors of soft tissue

TABLE 79.28 Postnatal Serum Concentrations of α-Fetoprotein in Preterm and Term Infants

Age	α-Fetoprotein Concentration (μg/L)* 10th Percentile	Median	90th Percentile
Preterm Infants (27-35 Weeks' Gestational Age)			
Birth	149,700	252,125	335,375
1 wk	43,825	96,510	234,500
1 mo	21,825	41,975	66,460
2 mo	3,100	16,000	36,900
3 mo	560	1,250	10,140
4 mo	75	162	621
6 mo	22	67	170
9 mo	6	20	54
12 mo	5	10	28
Term Infants (38-42 Weeks' Gestational Age)			
Birth	17,200	30,875	44,350
2 mo	88	206	412
4 mo	16	77	127
6 mo	11	30	67
9 mo	5	12	27
12 mo	4	7	17

*1 μg/L AFP = 1.09 IU/mL.
Data from Lahdenne P, et al. Biphasic reduction and concanavalin A binding properties of serum alpha-fetoprotein in preterm and term infants. *J Pediatr.* 1991;118:272.

that have increased incidence in infancy include infantile fibrosarcoma (25%), malignant rhabdoid tumor (15%), and infantile hemangiopericytoma (4%). Although the prognoses for infantile fibrosarcoma and infantile hemangiopericytoma are excellent, in general, infantile soft tissue sarcomas have a worse outcome than in older children. Radiation therapy is less likely to be used in infants, and vulnerability to acute and late effects of chemotherapy requires dose reductions and careful monitoring for toxicity.[121]

Rhabdomyosarcoma

Rhabdomyosarcoma is a tumor of striated muscle accounting for about half of infant soft tissue sarcomas. Neonatal rhabdomyosarcoma commonly occurs in the genitourinary area or trunk rather than appearing as masses in the head and neck region, as in older infants, and in head/neck and extremities, as in older children. The prognosis depends on both the histologic type (embryonal or alveolar in best to worst order of prognosis) and the extent of tumor resection. Both radiation therapy and chemotherapy are important adjuvants to surgical resection, with infants being less likely to receive radiation and more likely to have local recurrence.[121]

Infantile Fibrosarcoma

Infantile fibrosarcoma is a spindle cell tumor of the soft tissues. It usually presents before the age of 2 years. Surgery is the mainstay of therapy, which, coupled with good response to chemotherapy, results in excellent prognosis. A novel chromosomal translocation, t(12;15)(p13;q25), which gives rise to an *ETV6-NTRK3* fusion transcript, is present in these tumors as well as in congenital mesoblastic nephroma.[121]

Neonatal Brain Tumors

The incidence of neonatal brain tumors is low, accounting for <1% of pediatric CNS malignancies. Histology differs from older children: teratomas, astrocytomas, embryonal tumors, gangliogliomas, etc. It can be diagnosed using antenatal ultrasonography (macrocephaly, hydrocephaly, or other changes suggestive of intracranial tumor). Postnatally infants present with increased head circumference, signs of increased intracranial pressure, bulging fontanelles, hypotonia, irritability, seizures, and neurologic deficits. MRI is the choice of imaging.[15] For infants with suspected germ-cell tumors, checking the AFP and β-hCG values may help in diagnosis. Treatment is reserved to surgical resection and chemotherapy if indicated. Radiation should not be used. Survival in neonates with CNS tumors is poor because of inability to perform aggressive resection, avoidance of radiation, and high-grade pathology. Also, these patients have a very high incidence of endocrine, neurologic, and cognitive deficits later in life.[15]

Acknowledgments

The authors would like to acknowledge the contributions of Drs. Yaser Diab and Lori Luchtman-Jones, who were authors of this chapter in previous editions, portions of which remain unchanged.

Key Points

- Hematopoiesis is a complex process tightly regulated by a multitude of growth factors and chemokines.
- Red blood cell disorders are common in the neonatal period, and their management differs depending on the inheritance pattern and severity of manifestations.
- DNA-based tests are readily available for diagnosis of inherited red blood cell defects when conventional tests have failed, or there is concern for confounding biochemical results caused by previous transfusions.

- Our knowledge and experience have expanded significantly in the recent years in several areas such as iron metabolism, regulation of erythropoiesis, and gene therapies for hemoglobinopathies.
- Gene therapy is emerging as a treatment for hemoglobinopathies and is showing its safety and potential efficacy in both preclinical and early clinical studies. Gene therapy is now a reality, with seven patients cured of their β0/βE thalassemia or with significant amelioration from β0/β0 thalassemia and one patient with SCD, while others are showing modest transgene expression.
- Supplementation of between 1 mg/kg per day and 10 mg/kg per day elemental iron is a clinically important strategy used to lessen the risk of iron deficiency.
- Neutropenia is a common finding in the NICU, particularly during the first week of life and in lower birth weight and ill infants, but persistent neutropenia, particularly in an infant with dysmorphic features, should be investigated.
- About 10% of infants who have Down syndrome develop a transient clonal myeloproliferative disorder now called *transient abnormal myelopoiesis* (TAM).
- An infant with recurrent infections, an absolute lymphocyte count less than 3000/cmm, should warrant immediate referral and further testing of the immune system.
- Hemophilia is the most common inherited bleeding disorder to present in the neonatal period.

Blood Component Therapy for the Neonate

CYRIL JACQUOT, YUNCHUAN DELORES MO, AND NAOMI L. C. LUBAN

Special Considerations for Transfusion Therapy in the Neonate

Neonates constitute one of the most heavily transfused patient groups in the hospital. In a Canadian study, over 50% of infants at less than 30 weeks' gestation and more than 80% of infants with a birth weight of less than 1000 grams received at least one red blood cell (RBC) transfusion during their initial hospitalization.[86] Neonatal transfusion practices differ substantially from adult and pediatric transfusion practices because of unique differences in neonatal physiology. Neonates have small blood volumes when compared with older children and adults but high blood volume per body weight. Their immature organ system function predisposes them to metabolic derangements from blood products and additive solutions and to the infectious and immunomodulatory hazards of transfusion such as transfusion-transmitted cytomegalovirus (TT-CMV) infection and transfusion-associated graft-versus-host disease (TA-GVHD). Neonates undergo rapid growth but have a limited capacity to expand their blood volume. In addition, passive transfer of maternal antibodies to the immunologically naïve newborn creates unique compatibility scenarios not commonly seen in children or adults. Their responses to stresses, including hypothermia, hypovolemia, hypoxia, and acidosis are dependent on gestational age, birth weight, and co-morbidities. These considerations necessitate special approaches to transfusion therapy in the neonate.[98,196,197]

Risks of Transfusion Therapy

Advances in donor recruitment, blood screening, and processing have decreased the risks associated with blood transfusion. As part of patient blood management, current transfusion considerations and guidelines focus on reducing both transfusion number and donor exposures. Nevertheless, hematologic, immunologic, infectious, cardiovascular, and metabolic complications can occur. Many of these risks exist for transfusion recipients of any age, whereas others pose a greater threat to the neonatal recipient. These potential risks affect the choice and processing of blood products. Parents must be advised of the risks, benefits, and alternatives to transfusion, and informed consent should be documented in the medical record along with the indications for, and results of, the prescribed transfusion.

Metabolic Complications

Neonates, especially extremely premature infants, are more susceptible to metabolic alterations caused by the immaturity of many of their organ systems. Glucose imbalances, hyperkalemia, and hypocalcemia are the most common metabolic derangements related to transfusion, owing to the inability of the infant to efficiently metabolize and/or excrete elements intrinsic to blood and blood components, including anticoagulants, preservative solutions, and other solutes that accumulate during refrigerated storage.

Hypoglycemia

Hypoglycemia (see Chapter 86) can result from the combination of decreased glucose infusion rates during transfusion and impaired glycogenolysis and gluconeogenesis within the liver of the preterm neonate. Continuous glucose infusion rates of greater than 3-4 mg/kg per minute are often required in preterm infants; if maintenance fluids are suspended during transfusion, glucose infusion rates can decrease to approximately 0.2 mg/kg per minute for citrate-phosphate-dextrose-adenine (CPDA-1) preserved RBCs and 0.5 mg/kg per minute for the RBC additive Adsol® (AS-1) preserved RBCs. In neonatal intensive care units, holding feeds during blood transfusions, particularly for premature infants, has become a common practice to decrease the risk of neonatal enterocolitis (NEC).[39] In a previous report of 31 fresh (<5 days old) small-volume RBC transfusions in 16 preterm infants (mean birth weight and gestational age: 863 grams and 26 weeks, respectively), 15% of infants receiving AS-1-preserved RBCs and 64% of infants receiving CPDA-1-preserved RBCs required supplemental dextrose infusions during the transfusion owing to hypoglycemia (blood glucose <40 mg/dL or symptoms of

Abstract

Neonates constitute one of the most heavily transfused patient groups in the hospital. Neonatal transfusion practices differ substantially from adult and pediatric transfusion practices because of unique differences in neonatal physiology. Neonates have small blood volumes when compared with older children and adults but high blood volume per body weight. Their immature organ system function predisposes them to metabolic derangements from blood products and additive solutions and to the infectious and immunomodulatory hazards of transfusion such as transfusion-transmitted cytomegalovirus (TT-CMV) infection and transfusion-associated graft-versus-host disease (TA-GVHD). Of recent concern has been the emergence of Zika virus (ZIKV), which can be transmitted by blood products and is associated with abnormalities in fetal development. Neonatal responses to stresses, including hypothermia, hypovolemia, hypoxia, and acidosis, are dependent on gestational age, birth weight, and co-morbidities. These considerations necessitate special approaches to transfusion therapy in the neonate. This chapter also discusses transfusion thresholds and indications for different blood components.

hypoglycemia).[62] Subsequent analysis has shown similar frequency of transfusion-associated hypoglycemia when older (5-21 days old) AS-1-preserved units were used. Furthermore, reported incidences of hypoglycemia in neonates either during or after exchange transfusions range from 1.4%-3.6% with no difference in incidence when group O whole blood or reconstituted whole blood was used. Hypoglycemia occurring after exchange transfusion is believed to be caused by intraprocedural hyperglycemia, which causes rebound hypoglycemia from insulin secretion.[55] Preventive measures for transfusion-associated hypoglycemia include recognizing those infants at risk for developing glucose homeostatic imbalances, continuing the infusion of maintenance fluids rich in dextrose (albeit at a slower rate) to maintain an adequate glucose infusion rate during simple transfusions and close monitoring of blood glucose during both small and large volume transfusions. To minimize the risk of RBC hemolysis and/or agglutination, dextrose-rich fluids should be infused in a separate intravenous line from the blood transfusion.[84]

Hyperkalemia

The risk of transfusion-induced hyperkalemia is directly related to the magnitude of the K^+ load delivered with RBC transfusion, which depends on the age, plasma volume, and plasma concentration of K^+ of the unit, and the rate at which K^+ is delivered (potassium infusion rate). Potassium infusion rates greater than 0.01 mEq/kg per minute may pose a potential risk of transfusion-associated hyperkalemia and have been shown to result in cardiac arrhythmia/arrest in neonates.[55] As stored red blood cells age, potassium leaks out into the plasma and raises the extracellular potassium level within the component. Units of RBCs in extended-storage media (AS-1, AS-3, AS-5) have a hematocrit (Hct) of approximately 60%, and RBCs stored in CPDA-1 have an Hct of approximately 70%. Furthermore, some pediatric transfusion centers centrifuge RBC aliquots before transfusions for neonates to further reduce the plasma component to 20% (e.g., RBC unit: Hct >80%). Such an approach helps reduce the content of potassium, mannitol, and RBC microvesicles in irradiated RBC aliquots stored up to 21 days.[157] After 42 days of storage, K^+ levels in the plasma of an AS-1-preserved RBC unit approximate to 0.05 mEq/mL. Therefore, infusing 15 mL/kg over 3 hours would yield a potassium dose of 0.33 mEq/kg and a potassium infusion rate of 0.002 mEq/kg per minute (e.g., 1-kg infant receiving 15 mL RBC and 6 mL plasma). Conversely, after 35 days of storage of CPDA-1-preserved RBCs, potassium levels in the plasma approximate to 0.08 mEq/mL. Transfusing 15 mL/kg of the CPDA-1-stored product over 3 hours would yield a potassium dose of 0.36 mEq/kg (e.g., 1-kg infant receiving 15 mL RBC and 4.5 mL plasma) at a potassium infusion rate of 0.002 mEq/kg per minute.[55] Given that daily potassium requirement is approximately 2-3 mEq/kg, simple RBC transfusions infused slowly over 2-4 hours (2-5 mL/kg per hour) do not pose a threat for hyperkalemia (Table 80.1).

It has been shown in multiple studies that transfusing dedicated RBC units to their expiration dates does not cause hyperkalemia even in extremely preterm infants.[55,76,100,178]

TABLE 80.1 Dose and Infusion Rate for Potassium in Small-Volume and Large-Volume Transfusion

	CPDA-1 (35-Day)	Additive Solution* (42-Day)	Additive Solution* (20-Day)
Unit hematocrit	70%-75%	57%-60%	57%-60%
Plasma (K+)	0.080 mEq/mL	0.050 mEq/mL	0.030 mEq/mL
15 mL/kg over 3 hours (0.08 mL/kg/min)			
K^+ dose	0.36 mEq/kg	0.33 mEq/kg	0.20 mEq/kg
K^+ infusion rate	0.002 mEq/kg/min	0.002 mEq/kg/min	0.001 mEq/kg/min
25 mL/kg over 3 hours (0.14 mL/kg/min)			
K^+ dose	0.60 mEq/kg	0.54 mEq/kg	0.32 mEq/kg
K^+ infusion rate	0.003 mEq/kg/min	0.003 mEq/kg/min	0.002 mEq/kg/min
25 mL/kg over 1 hour (0.42 mL/kg/min)			
K^+ dose	0.60 mEq/kg	0.54 mEq/kg	0.32 mEq/kg
K^+ infusion rate	0.01 mEq/kg/min†	0.009 mEq/kg/min	0.005 mEq/kg/min
25 mL/kg over 30 min (0.84 mL/kg/min)			
K^+ dose	0.60 mEq/kg	0.54 mEq/kg	0.32 mEq/kg
K^+ infusion rate†	0.02 mEq/kg/min†	0.018 mEq/kg/min†	0.011 mEq/kg/min†

*AS-1, AS-3, or AS-5 RBC units.
†Potassium infusion rate may pose a potential risk of transfusion-associated hyperkalemia, which may result in cardiac arrhythmia/arrest, especially if given through a central line.

Therefore, the routine practice of washing older RBCs is unnecessary for most small-volume RBC transfusions (10-20 mL/kg) in infants, including those with birth weights less than 1.5 kg.[55] Irradiation of RBC components damages the erythrocyte membranes, causing K^+ leakage and a linear increase in plasma potassium concentration over time. Irradiation substantially increases plasma K^+ compared with nonirradiated RBC components, both within the first 24 hours after irradiation (twofold increase) and for the life of the RBC component. The difference was detectable as early as 2 hours after irradiation.[189,194]

Large-volume RBC transfusions (>25 mL/kg), particularly if infused rapidly, may pose a significant risk to the neonate. There have been reports of hyperkalemia-induced electrocardiac abnormalities and cardiac arrest when RBC transfusions (fresh and old) have been administered via rapid infusion (10-20 mL/kg over 10-15 minutes) to neonates with concurrent low cardiac output states when the RBCs were irradiated more than 24 hours prior to infusion and/or when they were given via central line directly into the inferior vena cava.[13,164,189] Whenever possible, fresh RBC units (<7-10 days) should be issued for large-volume RBC transfusions. When fresh RBC units are unavailable, they should be volume reduced or washed and transfused as soon as possible after washing to minimize K^+ re-accumulation. Previously irradiated and stored (≥24 hours) units may have plasma K^+ levels unsafe for large-volume transfusion to neonates, especially if administered rapidly. Therefore, they should be issued immediately postirradiation or volume-reduced or washed to remove extracellular K^+ that accumulates after processing.[100,196] In emergent circumstances of unexpected massive bleeding, when neither fresh nor washed nor volume-reduced RBC units are available, infusion rate should not exceed 0.5 mL/kg per minute.[176]

Special considerations should be taken when RBCs need to be transfused rapidly and should be coordinated with the transfusion center so that proper preparation can be performed to avoid hyperkalemia. Measures to reduce the risk of transfusion-associated hyperkalemia leading to cardiac arrest include anticipating and replacing blood loss before significant hemodynamic compromise occurs, using larger-bore (>23-gauge) peripheral intravenous catheters rather than central venous access, checking and correcting electrolyte abnormalities frequently, and using fresher RBCs for massive transfusion.[97] For patients on extracorporeal membrane oxygenation, prebypass ultrafiltration helps normalize the electrolyte balance of the circuit prime and may reduce the risk of hyperkalemia-related cardiac arrest.[45] In-line potassium adsorption filters have been shown to remove extracellular K^+ in stored AS-3 RBC units to minimal levels *in vitro*.[199] A small randomized clinical trial in adults (>18 years of age) showed that the transfusion of one irradiated RBC unit with a potassium filter was as safe and efficacious as transfusion of one irradiated RBC unit with a standard blood infusion set.[38] However, the use of potassium filters in neonatal RBC transfusions requires more extensive study.

Hypocalcemia

Infants, especially premature infants, are particularly susceptible to hypocalcemia (see Chapter 87) within the first week of life, owing to multiple factors. Because of the immaturity in neonatal liver and kidney function, and small skeletal muscle mass, transfusion of citrate-enriched blood can result in hypocalcemia from citrate toxicity. The amount of citrate infused into a neonate during a small-volume transfusion (10-15 mL/kg) is very unlikely to cause hypocalcemia; however, the citrate load during an exchange transfusion can reach very high levels and lead to symptomatic hypocalcemia. In a retrospective review of neonatal exchange transfusions, symptomatic hypocalcemia was one of the most common side effects along with bleeding associated with thrombocytopenia, catheter-related complications, apnea, bradycardia, and other metabolic disturbances. Adverse events were generally higher among ill neonates (i.e., presence of co-morbidities besides indication for exchange) when compared to healthy ones and complication frequency increased with decreasing birth weights.[112] Because clinical manifestations of hypocalcemia are often subtle and/or variable in premature infants, many recommend monitoring ionized calcium levels and/or QT intervals throughout exchange transfusion procedures, in addition to minimizing potentiating factors such as hypomagnesemia, hyperkalemia, alkalosis, and hypothermia in high-risk (ill) patients. Insufficient evidence is currently available in the literature to support or reject the continual use of prophylactic intravenous calcium infusions in neonates receiving exchange transfusions.[123]

Effect of Plasticizers *(See Also Chapter 14)*

The toxicity associated with the use of the plasticizer di-(2-diethylhexyl) phthalate (DEHP) in blood storage bags has been debated in the transfusion medicine community for over 50 years. DEHP is added to polyvinylchloride plastic storage blood bags to increase bag flexibility, RBC survival, and oxygen permeability for platelet storage. DEHP also stabilizes RBC membranes, which prevents hemolysis and alteration during refrigerated storage. Because of its desirable structural properties, it is also widely used in medical plastics as well as in food storage and household products.[159] Critically ill neonates exposed to endotracheal tubes, orogastric tubes, intravenous tubing, and blood products can have DEHP exposures that exceed safe levels by 3-5 orders of magnitude.[101]

However, there is evidence that DEHP exerts detrimental effects on the endocrine system by acting as an androgen antagonist and an estrogen agonist. While DEHP is broken down in the gastrointestinal tract to some extent, transfusions bypass this protection. At particular risk for toxicity are neonates receiving high-volume transfusions, such as neonatal RBC exchange, during extracorporeal membrane oxygenation (ECMO), and during massive transfusion.[151]

Manufacturers have attempted to find suitable alternatives to DEHP. For example, butyrul-n-trihexyl-citrate

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.
For personal use only. No other uses without permission. Copyright ©2019. Elsevier Inc. All rights reserved.

leaches from the plastic at a slower rate, exhibits lower toxicity, and provides similar antihemolytic effects.[167] Other DEHP-free storage containers are at various stages of development throughout the world. However, a recent survey identified barriers to widespread implementation, including decreased quality of blood products stored in non-DEHP plastics, higher price, shorter shelf-life, and ongoing debate about the evidence of DEHP toxicity.[185]

Immunologic Complications

Transfusion Reactions

Transfusion reactions are less common in neonates than in older children or adults. Nevertheless, whenever a patient is transfused, he/she should be closely monitored for symptoms and signs of a reaction. Often, potential reactions are noted by a change in vital signs or a rash early in the transfusion, but they may occur at any point. The Joint Commission recommends that vital signs be measured pretransfusion, within 15 minutes of initiation and within 1 hour of transfusion end.[48] Hospital policies are based on these guidelines but may differ with respect to each other. In addition to vital signs, it is important to also assess the patient for cutaneous changes (e.g., rash, hives), respiratory distress, discomfort, or pain.

When an acute transfusion reaction occurs, it is crucial to discontinue the transfusion immediately, maintain intravenous access, and verify that the correct unit was transfused while treating the patient's symptoms. Notifying the transfusion service for further laboratory evaluation of the reaction is essential to properly classify the reaction so that the patient can be managed appropriately.[47] Since a single blood donation often results in several different blood products, there may be untransfused co-components that must be quarantined until the investigation is complete.

Hemolytic Transfusion Reactions

Acute hemolytic transfusion reactions occur when RBCs are transfused to a recipient with preformed antibodies to antigens on the transfused RBCs. Almost all acute hemolytic transfusion reaction fatalities are the result of transfusion of ABO-incompatible blood because of clerical errors and misidentification; however, nonimmune causes of acute hemolysis may also occur. These include hemolysis from shear and/or heat stress imposed on erythrocytes by extracorporeal circuits, infusion devices, filters, blood warmers, or phototherapy light exposure. These reactions are characterized by fever, chills, diaphoresis, abdominal pain, hypotension, and hemoglobinuria with potential progression to disseminated intravascular coagulation (DIC) and acute renal failure. When a hemolytic transfusion reaction is suspected, the transfusion should be immediately stopped, blood cultures (from patient and blood component[s]) should be obtained, and the transfusion service should be notified. A clerical check of all labels, blood component inspection, posttransfusion hemolysis check, and direct antiglobulin test (DAT) should be completed by the transfusion service. The patient's hemoglobin/hematocrit, serum bilirubin, lactate dehydrogenase (LDH), and urobilinogen should be monitored, and intravenous fluids should be administered to offset hypotension and ensure adequate urine output. Mannitol may be administered to force diuresis, but osmotic diuresis in neonates is controversial because of concerns about alterations in cerebral microcirculation and risk of intraventricular hemorrhage. Although infants less than 4 months old have an absence of A and B hemagglutinins and other RBC alloantibodies, maternal IgG antibodies can cross the placenta, causing hemolysis of transfused RBCs and, therefore, should be considered when transfusing infants.[44]

Delayed hemolytic transfusion reactions (DHTRs) occur 3-10 days following RBC transfusion and manifest as unexplained anemia, hyperbilirubinemia, and abdominal pain. As with acute hemolytic reactions, the diagnosis is confirmed by a positive DAT, identification of a new RBC antibody, hyperbilirubinemia, and a reduction in hemoglobin.[29] DHTRs are extremely rare in neonates because of the immaturity of the immune system. Even though there have been case reports of anti-E and anti-Kell formation in infants as young as 18 days of life, the majority of reports have supported the infrequency of RBC alloimmunization and DHTRs in infants less than 4 months of age.[55] A cohort study of 1641 neonates and children up to the age of 3 years found no alloimmunization cases within the first 6 months of life. The authors conclude that after initial testing, repeat antibody screening and cross-matching during the first 4 months of life can be safely omitted.[184]

Febrile Nonhemolytic Transfusion Reactions

Febrile nonhemolytic transfusion reactions (FNHTRs) are characterized by fever, chills, and diaphoresis. These reactions are believed to result from the release of pyrogenic cytokines by leukocytes within the plasma during storage. The incidence of FNHTRs has decreased dramatically since the implementation of prestorage leukoreduction of RBCs and platelet products in 1999. Whereas FNHTRs occurred in approximately 10% of transfusions in the past, the incidence for all products since the introduction of leukoreduction is now 0.1% to 3% (approximately 0.2% for prestorage leukoreduction).[89,130] When FNHTR is suspected, the transfusion should be stopped and more serious reactions ruled out. A sample of blood from the patient may be sent for DAT, plasma hemoglobin quantification, serum lactate dehydrogenase, and bilirubin level to ensure that the patient is not experiencing a hemolytic transfusion reaction. The transfusion service may repeat the crossmatch between the RBC unit and a post-transfusion patient sample to ensure there is no new unexpected incompatibility. Bacterial contamination should be assessed via cultures of the transfused product and the patient's blood; empiric antibiotic therapy may be warranted. Most FNHTRs respond to antipyretics, and meperidine may be used for rigors.[87,154]

Allergic Transfusion Reactions

Allergic transfusion reactions (ATRs) are marked by urticaria and itching but can include flushing, bronchospasm, and anaphylaxis in severe cases. For mild or localized cases, transfusion can be continued once symptoms have subsided; however, severe allergic reactions (anaphylactoid or anaphylactic reactions) may require treatment with corticosteroids and/or epinephrine. The same blood unit should never be restarted in severe cases, even after symptoms have abated. Leukoreduction does not decrease the incidence of ATRs as it has for FNHTRs.[130] Premedication with antihistamines with or without steroids is recommended for ATRs. Because these reactions are caused by an antibody response in a sensitized recipient to soluble plasma proteins within the blood product, washed RBCs and platelets may be used for severe or recurrent ATRs nonresponsive to medication. Severe ATRs leading to anaphylaxis can be caused by the development of anti-IgA antibodies in recipients who are IgA-deficient. In these instances, IgA-deficient plasma products may be obtained but require the use of rare donor registries.[188] In patients of Asian descent, haptoglobin deficiency may also be associated with severe ATRs.[160]

The use of platelets in additive solution (PAS) resulted in decreased incidence of ATRs and FNHTRs in one adult study, presumably because of decrease in donor plasma content in the blood products.[40] Since neonates represented only 1.8% of the study population, the effect of PAS platelets in neonates requires further study.

Transfusion-Associated Graft-Versus-Host Disease

Transfusion-associated graft-versus-host disease (TA-GVHD) occurs when an immunosuppressed or immunodeficient patient receives cellular blood products, which contain immunologically competent lymphocytes.[95] The transfused donor lymphocytes are able to proliferate and engraft within the immunologic incompetent recipient because the recipient is unable to detect and reject foreign cells. The degree of similarity between human leukocyte antigens (HLA) of donor and recipient also increases the likelihood of developing TA-GVHD. As an example, in the setting of directed donation from a first-degree relative, donor lymphocyte homozygosity for an HLA haplotype for which the recipient is haploidentical predisposes to recipient tolerance, donor lymphocyte engraftment, and alloreaction leading to TA-GVHD.[54]

The clinical signs and symptoms of TA-GVHD include fever; generalized, erythematous rash that may progress to desquamation; watery diarrhea; mild hepatitis to fulminant liver failure; respiratory distress; and pancytopenia, which is unusually severe because hematopoietic progenitor cells are preferentially affected. Onset is from 3-30 days following transfusion of lymphocyte-replete cellular blood components in older children and adults; however, there may be a longer latency period before the onset of clinical manifestations of TA-GVHD and a longer course of disease before death in neonates. In a literature review of 27 cases of TA-GVHD in neonates in Japan, the median interval of clinical manifestations was 28 (fever), 30 (rash), and 43 (leukopenia) days, and death occurred in all affected patients at a median interval of 51 days. Prolonged latency of clinical manifestations and death is believed to result from thymic and/or extrathymic semi-tolerance for allogeneic cytotoxic T lymphocytes.[127]

Neonates at "high risk" for TA-GVHD include those with impaired cellular immunity, such as severe combined immunodeficiency (SCID) or Wiskott-Aldrich syndrome, those receiving intrauterine transfusions and/or neonatal exchange transfusion, and those receiving cellular blood components from family members or those who are genetically similar to the recipient. Extremely premature neonates are also considered by many to be at significant risk for TA-GVHD.[74,175]

No effective therapy is available to treat TA-GVHD except for hematopoietic stem cell transplantation, and owing to bone marrow hypoplasia, the mortality rate is 90% in the pediatric population. Fortunately, this complication can be prevented by pretransfusion gamma or X-ray irradiation of cellular blood components at a dose of 2.5 Gy, which effectively abolishes lymphocyte proliferation.[95] The shelf life of irradiated red blood cells is 28 days; however, no data currently exist on the safety in the neonatal population of gamma-irradiated or X-ray-treated RBCs that are stored for this amount of time. Because potassium and free hemoglobin increase after irradiation and storage of RBCs, it is preferable to irradiate cellular blood products close to administration time for neonates, who may not be able to tolerate high potassium loads.[194] Irradiation of RBCs also fosters the release of cell membrane microparticles, which may be associated with thrombotic risk.[30] There exists no "standard of care" regarding irradiation of blood products for otherwise non-high-risk infants. Many transfusion services irradiate all cellular blood products given to preterm infants born weighing 1.0-1.2 kg or less, whereas some irradiate all cellular blood products for infants less than 4 months of age, citing the lack of clinical studies on the incidence of TA-GVHD in the neonatal population and the concern for failure to recognize an infant with an undiagnosed congenital immunodeficiency. When an infant requires irradiated blood components, all cellular blood components for that infant should be irradiated; however, it is not necessary to irradiate acellular blood components, such as fresh frozen plasma (FFP) and cryoprecipitate. The known and presumed indications for irradiation of blood components for neonates are listed in Box 80.1.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is an uncommon, potentially fatal acute immune-related transfusion reaction, which typically occurs within 4-6 hours of transfusion and presents with respiratory distress caused by noncardiogenic pulmonary edema (normal central venous pressure and pulmonary capillary wedge pressure), hypotension, fever, and severe hypoxemia.[29] Differentiation from transfusion-associated circulatory overload (TACO), an

• BOX 80.1 Indications for Administering Irradiated Blood Components to Neonates

- Transfusion to a premature infant with birth weight <1200 g
- Intrauterine transfusion
- Known or suspected congenital cellular immunodeficiency
- Hematologic malignancies or solid tumors
- Significant immunosuppression related to chemotherapy, radiation, or immunosuppressive treatment
- Transfusion of a cellular blood component obtained from a blood relative
- Transfusion of an HLA-matched or platelet-cross-matched product
- Granulocyte components

Guidelines for assessing appropriateness of pediatric transfusion. *Transfusion*. 2002;42:1398-1413.

acute, nonimmune transfusion reaction that presents with respiratory distress, cardiogenic pulmonary edema, and hypertension caused by volume overload, is important because treatments differ. Furthermore, transient leukopenia, which is commonly seen with TRALI but is absent in TACO, can aid in differentiation of these reactions. Symptoms of TRALI usually improve within 48-96 hours; however, three-fourths of patients require aggressive respiratory support. Treatment is mainly supportive, including fluid and/or vasopressor support in the face of hypotension. Whereas aggressive diuresis is often required in TACO, this should be avoided in TRALI.[94]

Although the exact mechanism of TRALI remains uncertain, it is generally believed to be caused by the passive transmission of HLA and/or neutrophil antibodies directed against recipient leukocyte antigens. These antibodies activate and sequester recipient neutrophils within the endothelium of the lungs, ultimately leading to the production of vasoactive mediators and capillary leak. Plasma products (such as FFP, plasma frozen within 24 hours of collection [FP24], and apheresis platelets) account for the majority of severe TRALI cases, and multiparous women are the most commonly implicated donors.[94,152] Because of these findings, various preventative measures have been adopted in the United States and elsewhere. These include the use of male-only, high-volume plasma products (FFP, FP24, platelets), or the selection of donor products from donors who have a low likelihood of being alloimmunized via pregnancy or prior transfusions or who are negative on HLA antibody screen.[129] Although there have been no definitive cases of TRALI documented in the neonatal population, TRALI has been well-documented in the pediatric population. A case has been reported of a 4-month-old girl who experienced respiratory distress, hypoxemia, hypotension, and fever within 2 hours of completion of an RBC transfusion from her mother. HLA antibodies were identified in the mother's serum, demonstrating the possible role of HLA antibodies in the pathogenesis of TRALI in the setting of a designated blood transfusion between mother and infant.[152,202]

T-Antigen Activation

"T-activation" is a phenomenon that can cause immune-mediated hemolysis in neonates, ranging from minor to fulminant and fatal. Removal of N-acetyl neuraminic (sialic) acid residues from the O-linked oligosaccharides on glycophorins (A, B, and C) on RBC membranes by neuraminidase-producing bacteria, particularly *Clostridium bacteroides* and *Streptococcus pneumoniae*, results in exposure of the normally masked Thomsen-Friedenreich (T) cryptantigen on the RBC surface of the neonate. Transfusion of adult blood products containing plasma with naturally occurring anti-T antibodies into neonates with T-activation can produce intravascular hemolysis following transfusion or unexplained failure to achieve an expected post-transfusion hemoglobin increment. Alternatively, T-activation may be detected in the laboratory without any evidence of clinical hemolysis, making broad-based screening impractical. T-activation has been reported mainly in neonates with necrotizing enterocolitis, especially in those with severe disease requiring surgical intervention but also in septic infants with other surgical problems.[146]

The incidence of T-activation has been reported in 5%-35% of infants with necrotizing enterocolitis (NEC).[107] The rate of T-activation is higher in infants with more severe disease (e.g., multiple cultures positive for Clostridia, presence of intestinal perforation, need for surgical intervention). In a retrospective report, laboratory evidence of T-antigen activation was detected by lectin agglutination testing in 9% of 43 Taiwanese infants with stage II/III NEC but did not result in hemolysis regardless of whether washed or unwashed RBC units were administered or contribute to an increase in NEC-related mortality.[191] A more recent publication reported that transfusion-associated hemolysis is often not seen in T-activated infants when transfused with donor anti-T-containing plasma. The authors concluded that the use of plasma-containing blood products is not contraindicated in NEC patients with coagulopathy or requiring hemostatic factors, even if T-activation is present.[107] However, others have shown that infants with confirmed NEC and laboratory evidence of T-activation had more frequent and severe hemolysis, hyperkalemia, renal impairment, and hypotension than those without T-activation.[128]

Routine cross-matching techniques may not detect the polyagglutination owing to T-activation when monoclonal ABO antiserum is used. Minor cross-matching of neonatal T-activated red blood cells with donor anti-T-containing serum may show agglutination, but this is not performed routinely. Infants with discrepancies in forward and reverse blood typing and those with evidence of hemolysis on smear

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

should be suspected of T-activation. The diagnosis is confirmed by specific agglutination tests using peanut lectin *Arachis hypogea* and *Glycine soja*. Further hemolysis may be prevented by using washed RBCs and platelets and low-titer anti-T plasma if available.[55] Exchange transfusion with plasma-reduced components may be necessary for infants with severe ongoing hemolysis. Alternatively, hemolysis associated with T-activation may occur independently of transfusion with anti-T-containing serum, and may be the result of sepsis or disseminated intravascular coagulation and cannot be prevented.

Transfusion-Associated Dyspnea (TAD)

TAD is defined as acute respiratory distress occurring within 24 hours of cessation of transfusion. Diagnosis requires ruling out other types of transfusion reactions associated with respiratory symptoms such as ATR, TACO, and TRALI.[29] In some cases, TAD may represent allergic reactions without the full complement of cutaneous and hemodynamic manifestations.

Transfusion-Related Sepsis

Septic transfusion reactions generally present with fever, hypotension, shock, and acutely ill appearance. Platelets are most frequently implicated since their storage at room temperature can foster growth of bacterial contaminants. Based on the inoculum of the pathogen, the onset may be earlier or later in the transfusion. However, the diagnosis can be challenging since such symptoms may also present as part of other transfusion reactions or as a manifestation of the patient's underlying disease.[138]

If a septic transfusion reaction is suspected, the transfusion should be stopped immediately. It is important to maintain venous access by running normal saline through the intravenous line. The remaining blood bag should be sent to the transfusion service for visual inspection, clerical check, possible culture, and placement of co-components into quarantine. If the clinical suspicion for sepsis is high, antibiotic therapy should be started immediately. Cultures of the patient and/or blood product may take some time to turn positive.

Transfusion-Related Necrotizing Enterocolitis (NEC)

NEC is a devastating gastrointestinal emergency that primarily afflicts premature infants but can occur in at-risk term gestation infants as well. Severity and treatment can range from full recovery with conservative medical management to intestinal perforation and bowel necrosis requiring surgical intervention. NEC-related morbidity and mortality remains quite high, with up to 30% of affected infants succumbing to the disease, many with an acute presentation followed by rapid deterioration and death. For full description of clinical presentations, pathophysiology, diagnosis, and treatment of NEC, refer to Chapter 85.

Although the exact mechanism of NEC is not completely elucidated, ischemic insult to the gastrointestinal tract has been proposed as one major contributor to NEC. Some hypothesize that even subtle reductions in blood flow and subsequent reperfusion occurring in response to hypoxia may contribute to bowel injury. It has been demonstrated that high vascular resistance of the superior mesenteric artery determined by Doppler flow velocity on the first day of life in preterm infants is associated with an increased risk of NEC.[111] Furthermore, the stressed newborn has been shown to exhibit abnormal regulation of intestinal vasomotor mediators (i.e., nitric oxide, endothelium, substance P, norepinephrine, and angiotensin), resulting in compromised intestinal flow.[24,121] It has been proposed that anemia may impair blood flow to the intestine, with subsequent transfusion of RBCs leading to reperfusion injury. This phenomenon may be exacerbated by abnormalities associated with stored RBCs, including reduced erythrocyte deformability, increased erythrocyte adhesion/aggregation, and decreased nitric oxide stores.[147] This last effect may predispose to vasoconstriction and further ischemic insult owing to transfused RBCs acting as a nitric oxide sink within the intestinal microvasculature.[32] Similarly, stored platelets accumulate proinflammatory factors over time. One of these, neuropeptide Y, has splanchnic vasoconstrictor effects, enhances neutrophil adhesion to endothelial cells, induces histamine release, and stimulates macrophage phagocytosis.[131a] The use of near-infrared spectroscopy has gained popularity in recent years with its ability to measure regional tissue saturations. A prospective study to examine potential alterations in mesenteric tissue oxygenation demonstrated wide fluctuations and decreases in mesenteric oxygenation patterns in infants who developed transfusion-related NEC.[104] Proposed, but unproven, pathologic mechanisms for transfusion-associated NEC include: a transfusion immunologic injury to the intestine similar to what is seen in transfusion-related acute lung injury (TRALI) and/or transfusion-related ischemia/reperfusion injury as described previously.

Several retrospective studies have demonstrated a temporal association between RBC transfusion and neonatal NEC. They report that 25%-38% of NEC cases occur within 48 hours of RBC transfusion and that the risk of transfusion-associated NEC increases with decreasing gestational age of the infant.[12,18,80,135] Blau et al. found a convergence of transfusion-associated NEC at 31 weeks' gestation,[18] the age of presentation of O_2 toxicity and other neovascularization syndromes. In another retrospective report, Singh et al. displayed a strong association of transfusion and NEC within 24 hours (OR = 7.60, $p = .001$), a significant albeit decreased association for transfusion within 48 hours (OR = 5.55, $p = .001$), and a statistically insignificant (absent) association for transfusion within 96 hours (OR = 2.13, $p = .07$) in their multivariate analysis.[163] Although attempts were made to minimize the confounding effects of multiple

variables, the effect of infants' nadir hematocrit level on the risk of developing NEC remained statistically significant, making it impossible to separate the influence of hematocrit and RBC transfusion.

However, other studies suggest that RBC transfusions may be an epiphenomenon with respect to NEC rather than a contributor to the pathogenesis of disease. Bednarek et al. reported that there was no significant difference in the incidence of NEC between high versus low hematocrit threshold transfusion practices among six NICUs,[14] and the Premature Infants in Need of Transfusion (PINT) (NCT00182390) trial did not show a difference in the incidence of NEC between the low versus high hematocrit transfusion threshold groups.[90] In a meta-analysis of the published literature on transfusions and NEC, increased RBC transfusions were associated with lower rates of NEC; the direction of effect of RBC transfusions on NEC in randomized trials was opposite to that seen in observational studies.[91] Keir and colleagues performed a separate systematic review and did not find an association between transfusions and NEC.[85] One recent prospective study of 598 very low birth weight infants found that severe anemia (hemoglobin <8 g/dL), but not RBC transfusion, was associated with an increased risk of NEC. Thus, prevention of severe anemia may be more important than avoidance of RBC transfusion alone.[132] The temporal relationship observed between RBC transfusion and neonatal NEC may represent reverse causation, whereby clinical instability from evolving NEC leads to RBC transfusion prior to the formal diagnosis of NEC.

A prospective, multicenter observational cohort study of infants with birth weight less than or equal to 1250 g is underway to investigate the associations between RBC transfusion, product irradiation, anemia, intestinal oxygenation, and injury that lead to NEC.[104a]

Transfusion-Related Intraventricular Hemorrhage (See Also Chapter 53)

A newly postulated risk of transfusions among VLBW neonates has emerged based on an association between RBC transfusion and the development of, and progression to, severe intraventricular hemorrhage (IVH), which has been observed in retrospective case control reports. In a six-site prospective study, Bednarek et al. found a trend toward a higher incidence of severe IVH (adjusted for birth weight and illness severity) in NICUs administering RBC transfusions "liberally," compared with other NICUs using transfusions in a more restricted fashion.[14] Subsequently, a retrospective analysis of 155 VLBW neonates with normal head ultrasounds during the first week of life indicated an association between RBC transfusion and the risk of developing a severe IVH within the first month, independent of hemoglobin level, initial pH, sepsis, ventilation, coagulation studies, or severe thrombocytopenia. During the first 72 hours of life and when the head ultrasound was normal, 67% of those neonates who later developed severe IVH versus 31% who did not develop IVH received one or more RBC transfusions ($p < .001$).[10] Additionally, each subsequent RBC transfusion during the first week was determined to double the risk of a severe IVH (each transfusion increased relative risk 2.02; 95% CI 1.54-3.33). In another report by the same investigators, Baer et al. retrospectively compared 55 VLBW neonates in whom a grade I IVH evolved into a grade II or higher IVH to 362 VLBW neonates matched for demographic, level of illness, and coagulation parameters, who had a grade I IVH that resolved completely with no extension to a higher grade. On logistic (and Lasso-fit) regression analysis, an association was found between RBC transfusion up to and on the day of the grade I IVH and extension of the IVH (OR 2.92; 95% CI 2.19-3.90).[11]

However, these associations do not necessarily indicate a cause-and-effect relationship because of inherent limitations in retrospective studies such as failure to recognize confounding variables and susceptibility to bias. Furthermore, no difference in risk of IVH (all grades, or ≥ grade III) was seen in those infants randomized to liberal versus restrictive transfusion practices in either the multi-institutional Canadian PINT study[90] or the Bell study.[15] A meta-analysis similarly did not identify increased rates of IVH in association with transfusions.[85] Additional studies are needed to determine if early RBC transfusion plays any pathogenic role in IVH development or extension.

Infectious Complications

Many infectious agents can be transmitted by blood or blood component transfusion (Table 80.2). These include viruses, bacteria, protozoa, and other pathogens. Current transfusion-transmitted disease testing for allogeneic blood donation includes hepatitis B virus surface antigen (HBsAg), hepatitis B core antibody (anti-HBc), anti-hepatitis C antibody (anti-HCV), antibody to HIV-1 and HIV-2 (anti-HIV-1/2), antibody to human T-lymphotropic virus (HTLV-I and HTLV-II), serology for syphilis and *Trypanosoma cruzi*, and nucleic acid testing (NAT) for HIV-1, HIV-2, HCV, HBV, West Nile virus (WNV), and Zika virus (ZIKV).[173,193]

Cytomegalovirus Infection

The prevalence of human cytomegalovirus (CMV) is 30%-70% in blood donors, varies based on demographic differences within areas of the United States, and increases with age. This DNA virus remains latent within the leukocytes of immune persons and can be transmitted by transfusion of cellular blood components into seronegative recipients. Primary CMV infection occurs in a seronegative recipient from a blood component from a donor who has either active or latent infection. There is wide variation in clinical sequelae from transfusion-transmitted CMV (TT-CMV), ranging from asymptomatic serologic conversion to significant morbidity and mortality from CMV-related pneumonia, cytopenias, and hepatic dysfunction.

TABLE 80.2 Transfusion-Transmitted Infections[16,67,82,174,193,203]

Infectious Agent	Infectious Risk
Bacterial contamination risk	
Platelets	1 in 2500
RBCs	1 in 38,500
Septic transfusion reaction risk	
Platelets	1 in 100,000-200,000
RBCs	1 in 250,000
Hepatitis A	1 in 10 million
Hepatitis B	1 in 750,000-1 million
Hepatitis C	1 in 1.9 million
HIV	1 in 2.1 million
Cytomegalovirus	Unknown
Human T-lymphotropic virus	1 in 2,993,000
West Nile virus	Extremely low
Chagas disease (*T. cruzi*)	Extremely low
Syphilis	Virtually nonexistent
Malaria	1 in 4 million
Babesiosis (*Babesia microti*)	Extremely low*
Creutzfeldt-Jakob disease	No cases reported in United States
Zika virus	Approximately 1 in 93,000 tested donations†

*May be as high as 1 in 1800 in highly endemic areas (northeast United States and upper Midwest).
†Based on sample of 466,834 donations tested between September 19 and November 30, 2016.

Premature, seronegative neonates less than 1250 grams, fetuses receiving intrauterine transfusions, severely immunocompromised individuals, and recipients of hematopoietic stem cell and solid-organ transplants are recipient groups at increased risk for post-transfusion CMV-related morbidity and mortality.[98] Infants born to seropositive mothers apparently have decreased risk for acquiring TT-CMV, but perinatal infection with a different strain of CMV has been reported infrequently.

Because the prevalence of CMV seropositivity among blood donors limits the availability of seronegative components, supplementary strategies can be used to minimize the risk of TT-CMV infection in high-risk infants. Use of third-generation leukoreduction filters at the time of collection of cellular products has been recommended for recipients at risk for TT-CMV. The American Association of Blood Banks states that "leukoreduced" blood products must contain fewer than 5×10^6 total WBCs per unit.[169] Current third-generation leukocyte reduction filters consistently provide WBC reduction in accordance with these standards, with some filters yielding less than 1×10^6 per product. European standards maintain a more stringent definition of leukoreduced as less than 1×10^6 total WBCs per unit.[98]

Leukocyte reduction has been shown to be effective in preventing CMV infection in neonates, among other groups; however, whether leukocyte reduction is as efficacious as the use of CMV-seronegative blood has been disputed widely. In one study, equivalent rates of post-transfusion CMV infection in allogeneic hematopoietic stem cell transplant patients were found for CMV-seronegative units and leukoreduced units (1.4% vs. 2.4%, respectively).[20] A subsequent study demonstrated similar rates of TT-CMV for leukoreduced and CMV-seronegative platelet products but not for RBC products.[117] A prospective observational study of 23 allogeneic hematopoietic stem cell transplant recipients in CMV-negative donor-patient paired individuals were transfused a total of 1847 leukoreduced cellular blood products from CMV "untested" donors and demonstrated no CMV DNA within the blood or CMV-associated clinical complications in the patients greater than 100 days post-transplant despite anti-CMV IgG seroconversion in 17 of 23 patients.[181] These reports support the notion that leukoreduced blood products are "CMV safe" and some experts have argued that leukocyte-reduction alone is sufficient.[177] However, no formal consensus on the debate of equivalency has been developed,[1] leading many to advise against the elimination of "dual inventories" of blood products for CMV-seronegative and seropositive units. Nonetheless, variable strategies for preventing TT-CMV currently exist depending on the number of high-risk patients treated at a given center, the regional donor demographics, and product availability. A prospective multicenter birth cohort study revealed that transfusion of leukoreduced, CMV-seronegative blood products effectively prevented transmission of CMV to very low birth weight infants. In fact, acquisition of CMV in the patient population was primarily through maternal breast milk.[77]

Hepatitis A Virus

Post-transfusion hepatitis A infection is an infrequent complication of transfusion because of the short period of viremia and the lack of an asymptomatic carrier state associated with the hepatitis A virus.[51] The risk of hepatitis A transmission increases when the transfused product is derived from a pool of products, such as cryoprecipitate and plasma-derived clotting factors. Since they rely on solvent/detergent disruption of lipid membranes, purification processes used to treat derivatives of human plasma are ineffective against nonenveloped viruses such as hepatitis A.[71] The virus has demonstrated varying susceptibility to pathogen reduction technologies.

Hepatitis B Virus

Acute infection with hepatitis B virus (HBV) is symptomatic in about 50% of adults, and 5%-10% of those infected become chronic carriers.[51] In contrast, HBV infection acquired in infancy and early childhood is often asymptomatic, yet 70% of those infected become chronic

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

carriers. Elimination of paid blood donors, uniform screening of blood donations for HBV surface antigen (HBsAg), and routine immunization for hepatitis B have reduced the estimated incidence of transfusion-transmitted HBV (TT-HBV) to 1 in 250,000-350,000 units transfused.[51] Initiating donor HBV nucleic acid testing (NAT) has further reduced the estimated incidence of TT-HBV to levels close to HIV and HCV by shortening the window period (time interval between infection and laboratory test positivity when viral markers are too low for detection).

Hepatitis C Virus

Hepatitis C virus (HCV) is a well-known cause of transfusion-associated hepatitis. Acute HCV infection is often asymptomatic and anicteric, but the likelihood of developing chronic hepatitis exceeds 60%. Approximately one-third of those with untreated chronic hepatitis will develop hepatic fibrosis and cirrhosis within 2 decades; those with cirrhosis have a 1%-5% risk of hepatocellular carcinoma 20 years after cirrhosis is diagnosed.[98] Long-term outcome is dependent upon the route of transmission, age when infected, gender, and coexisting morbidities. A retrospective study of 31 adults with transfusion-associated HCV acquired at birth (35 years earlier) described a milder disease with slower progression to hepatic fibrosis in perinatally acquired HCV than those who acquire HCV in early adulthood.[28,99] In a look-back study involving previously transfused infants and children, 88% of those with silent infection (positive anti-HCV enzyme immunoassay) had persistent HCV viremia at 10 years post transfusion. This is in contrast to previously reported pediatric HCV clearance rates of 45% and 42% at 19.5 and 35 years post-transfusion, respectively, which indicated that pediatric patients, unlike adults, may clear HCV over time.[99] The current standard treatment of chronic HCV infection in children ages 3 or older is pegylated-interferon-alpha and ribavirin. However, because of adverse effects (e.g., constitutional symptoms, bone marrow suppression, neuropsychiatric complications, hypothyroidism, and inhibited growth), therapy is often held until later in life. In adults, these medications have been largely supplanted by direct-acting antivirals (DAA) because of improved side effect profile and sustained virologic response. Pediatric clinical trials with DAA are underway.[201]

Since the advent of NAT for HCV in the late 1990s, the incidence of TT-HCV has decreased to 1 in 1.9 million within the United States. This is because of shorter window periods from time of acute infection to laboratory markers of infection (8 days) within the donor population.[98,203]

HIV-1 and HIV-2

The retroviruses HIV-1 and HIV-2 are the agents responsible for acquired immunodeficiency syndrome (AIDS). In the United States, the vast majority of AIDS cases are related to HIV-1. Approximately 1.9% of all reported cases of AIDS have been attributed to HIV-1 transmission by blood components, excluding factor concentrates.[51,98] Factor concentrates were responsible for an additional 0.75% of the more than 339,000 reported transfusion-transmitted AIDS cases. Virtually all of these transfusion-transmitted infections occurred before 1985, when serologic screening for HIV was initiated, and numerous effective methods of viral inactivation for plasma-derived clotting factor concentrates subsequently became available. Today, the risk of HIV transmission from blood transfusion is less than 1 in 2.1 million because of improved donor history screening and the advent of NAT testing in the late 1990s, which decreased the estimated window period to about 9 days.[203]

West Nile Virus

West Nile virus (WNV), a mosquito-borne, single-stranded RNA virus of the *Flaviridae* family, has become a major public health concern since its first detection in the United States in 1999. The first cases of transfusion-transmitted WNV occurred in 2002, with growing numbers of cases through 2004. Infection results in neuroinvasive disease (meningo-encephalitis, spastic paralysis) in roughly 20% of individuals, with more severe sequelae in the elderly and immunocompromised. Donors with WNV virus are commonly asymptomatic, meaning that the donor health questionnaire may fail to identify donors at risk. Despite implementation of pooled blood donor sample WNV NAT testing (with triggered individual donation testing when local disease activity exceeds preset thresholds) in 2003, sporadic cases of TT-WNV in immunosuppressed patients show that rare breakthrough transmissions may still occur in the United States.[173]

Zika Virus

Zika virus (ZIKV) is a flavivirus first discovered in the Zika Forest in Uganda in 1947. For many years, the virus caused sporadic outbreaks in Africa before gradually moving east. Several Pacific Islands were affected in 2013-2014. In 2016, the virus appeared in South America and rapidly spread. The virus is transmitted by the *Aedes* mosquito and, therefore, shows more activity during the summer months. Transfusion-transmitted infection has been documented.[137]

Unlike other flavivirus, ZIKV has been associated with microcephaly and other fetal abnormalities when placental transmission occurs in an acutely infected pregnant woman and is currently under intense study.[161] Of concern for blood supply safety, about 80% of infected patients are asymptomatic. Thus, there was a great risk of a viremic blood donation and transmission to a susceptible donor without suitable laboratory detection. Blood collections were temporarily halted in areas with local virus transmission (e.g., Puerto Rico). In the fall of 2016, NAT screening of all donations in the United States was implemented under an investigation new drug (IND) protocol. During a period of about 2 months, 5 of 466,834 donations tested for ZIKV RNA were found to be positive.[193] The FDA cleared the first approved ZIKV detection test based on viral RNA in the plasma of blood donors in October 2017.

Emerging Pathogens

Transmission of babesiosis and malaria has been reported in neonates within endemic areas such as the northeast United States and Africa, respectively.[59,162] Healthy patients transfused with *Babesia microti*–contaminated blood often do not get sick; however, transfusion-transmitted Babesia can be a significant cause of transfusion-related morbidity and mortality, especially for premature infants. Neonatologists in endemic areas should have a high index of suspicion for babesiosis in premature infants exposed to blood transfusions, because infection is minimized but not eliminated through current blood bank practices.[162] At this time, blood products collected in United States regions with high prevalence of the disease (e.g., Minnesota, Wisconsin, Massachusetts, and Connecticut) are tested for Babesia by a nucleic acid detection test.[109] However, implementation of nationwide testing has not been mandated because of cost-effectiveness considerations.[60]

Continuous attention is being paid to emerging infections such as chikungunya, dengue fever, Ebola, *Trypanosoma cruzi*, variant Creutzfeldt-Jakob disease, and malaria, among others. Despite extensive donor screening and laboratory testing, infections can still be transmitted through blood products. Pathogen reduction/inactivation offers the advantage of eliminating the risk of infection with any nucleic acid–containing agent, which includes viruses, bacteria, protozoa, and fungi (prions excluded). However, current pathogen reduction/techniques using nucleic acid–inactivating agents are still under investigation, because no single technique has proved to be effective for all blood components.[141]

Pathogen Reduction

Current screening approaches are reactive in nature and depend on pathogen identification, characterization of infectious markers, and development of detection assays. While this iterative approach has provided very high blood supply safety, it does require some time to implement for each emerging pathogen.

Pathogen reduction (PR) is an all-encompassing term for a variety of methods (e.g., photochemical activation or solvent detergent treatment) that may be applied to blood following collection in order to confer broad protection against multiple infectious agents by countering proliferation and contamination.[141] Many of these technologies target DNA or cell membranes and are effective across different classes of pathogens (e.g., viruses, bacteria, and parasites), offering the ability to interdict agents that are known to be transfusion-transmissible as well as emerging pathogens that pose uncertain risks to the blood supply.

The appeal of pathogen reduction is that it is a proactive approach to blood safety that inactivates pathogens instead of only screening for their presence. Although developed to complement current testing, PR could ultimately prove to be an alternative to testing. If widely effective, PR could reduce the number of donor deferrals due to disease risk factors. Since PR inactivates white blood cells, it may provide additional benefits such as TA-GVHD prevention and alloimmunization reduction.[37,92] However, concerns remain that PR's detrimental effect on platelet and plasma function may lead to increased bleeding risk in susceptible patients such as trauma victims.[66]

Two different methodologies of photochemical activation that have been more extensively studied will be briefly described, but others are at various stages of development. Thus far, these technologies have been applied only to platelets and plasma. Platelets are of primary concern since their storage at 20-24°C heightens their risk of contamination. No photochemical activation process is currently in clinical use for RBCs; these present an obstacle due to hemoglobin's absorption.

INTERCEPT® and Mirasol® Systems

The only photochemical activation platform approved by the FDA at the time of this chapter is the INTERCEPT® system (Cerus, Concord, CA). This technique uses amotosalen, which can intercalate between DNA bases. In the presence of activation by UVA light, this molecule irreversibly crosslinks with the DNA, thus preventing DNA transcription and cellular reproduction.[81] After INTERCEPT® treatment, an adsorption step removes excess amotosalen; only a tiny quantity remains.[36]

INTERCEPT® is widely used for platelets and plasma and is approved in the United States and European Union for this purpose.[73,114] The technology is effective against viruses, bacteria, and protozoans. However, breakthrough transmission has been reported with hepatitis A virus (HAV), hepatitis E virus (HEV), parvovirus B19, poliovirus, and certain spore-forming and/or fast-growing bacteria.[64,133,155]

The Mirasol® (TerumoBCT, Lakewood, CO) system uses riboflavin as a photosensitizer compound with UVB light. Riboflavin readily traverses lipid membranes and then intercalates nonspecifically with nucleic acids. Upon exposure to UVB light, intercalated riboflavin-modified guanine residues promote the generation of oxygen radicals.[25,61] Since riboflavin and its byproducts are naturally occurring, no additional steps for removal following treatment are believed to be necessary.[136] Mirasol® has shown efficacy against a wide variety of pathogens that pose a risk of transfusion transmission.[9,61,141,183]

A Cochrane review that evaluated 10 randomized control trials (9 with INTERCEPT®, 1 with Mirasol®) showed no difference in clinically significant bleeding or severe bleeding between recipients of pathogen-reduced platelets compared to control platelets. When evaluated, all-cause mortality, product utilization, and adverse events were also not increased.[6,23] Clinical trials performed with INTERCEPT®-treated plasma have shown no difference in clinical efficacy when compared to standard FFP.[70] A European prospective hemovigilance study of INTERCEPT®-treated platelets

following 19,175 transfusions in 2,441 patients demonstrated a low incidence of acute transfusion reactions and a safety profile in line with conventional platelet components. Forty-six of the patients were neonates (<28 days of age) who received a range of 1-9 platelet transfusions while 242 were children (<18 years of age) who received a range of 1-66 transfusions.[93] Thus, there is relative paucity of neonatal and pediatric safety data.

Donor-Specific Units

Autologous Red Blood Cell Transfusions

Collection of autologous umbilical cord blood was first reported in 1979. Depending on the gestational age of the infant, the umbilical cord contains 75-120 mL of fetal blood, which could serve as an alternative source of RBCs for transfusion. It has been shown that collection of placental blood in both vaginal and cesarean deliveries is possible and that the RBC component is able to be stored for short periods of time (21-28 days) in additive solutions (AS-3, SAGM). However, problems with obtaining sufficient volumes, with clotting or hemolysis within the stored unit, and with bacterial contamination are frequently reported, particularly in those who are most likely to benefit from autologous RBC transfusions (e.g., ELBW neonates).[22,34,179]

In most of the reports to date, autologous RBC transfusions have been shown to replace only a minority of allogeneic RBC transfusions needed by the infants, and the cost of collecting and storing autologous umbilical cord blood for subsequent RBC transfusion did not justify the limited benefits. For example, Khodabux et al. reported that of the 176 attempted autologous umbilical cord blood collections performed in neonates with gestational age less than 32 weeks, 101 (57%) yielded 15 mL/kg or greater, and only 64 (36%) yielded satisfactory units for transfusion.[88] Furthermore, only 17% of umbilical cord blood collections were available for autologous RBC transfusions in infants with birth weights less than 1000 grams, and in those infants who received autologous RBCs, their allogeneic RBC transfusion requirements were reduced by only 15%.[88] It is certainly possible that as better techniques are developed for harvesting, storing, and administering autologous RBCs from the umbilical cord, the benefits of using autologous RBC transfusions may outweigh the cost and risks as a means to reducing the need of allogeneic RBC transfusion in VLBW infants. Recent reports have demonstrated improved techniques for harvesting, storing, and administering autologous umbilical cord RBCs and shown the feasibility of using this autologous blood for open heart surgery and cardiopulmonary bypass priming.[31,56] These cord blood transfusions prevented or reduced the need for intraprocedural allogeneic RBC transfusion in infants undergoing cardiac surgery. However, additional large, randomized controlled clinical trials are needed to validate the safety and efficacy of this process before it can become routine NICU practice.[42]

Delayed Cord Clamping and Cord Stripping

Delayed clamping of the umbilical cord of premature infants has been reported as a successful variation of autologous transfusion. Meta-analysis of 738 preterm infants (analysis of 15 studies) showed that delayed cord clamping (30-180 seconds) is safe and is associated with higher circulating blood volumes during the first 24 hours of life, decreased immediate need of blood transfusions (RR 0.61, 95% CI 0.46-0.81), decreased incidence of intraventricular hemorrhage (RR 0.59, 95% CI 0.41-0.85), and decreased incidence of necrotizing enterocolitis (RR 0.62, 95% CI 0.43-0.90).[145] In a follow-up study from their randomized controlled trial (RCT) of immediate versus delayed cord clamping, Mercer et al. showed that delayed cord clamping at birth may be protective against motor disability in VLBW male infants at 7 months' corrected age.[106] However, in a meta-analysis by Rabe et al., there were no significant differences between groups in mean Bayley II scores at 7 months' corrected age. Additionally, it was found that the peak bilirubin concentration was higher for infants who had received delayed cord clamping compared to infants with immediate clamping.[143]

One limitation with delayed cord clamping is the required delay of 30 seconds or more in neonatal resuscitation during a VLBW delivery. As an alternative, "milking" or "stripping" the cord has been proposed. This is done by holding the placental end of the umbilical cord and gently moving blood within the umbilical vessels toward the neonate. This "stripping" is performed one to four times prior to clamping and cutting the cord. In a randomized controlled trial of 40 VLBW infants (stripping versus immediate clamping), Hosono et al. reported that those infants in the stripped group had higher hemoglobin values and blood pressures at NICU admission, shorter duration of ventilation, lower odds of requiring an RBC transfusion, and lower odds of developing an IVH.[69] Subsequently, Rabe et al. compared delayed cord clamping versus cord stripping in a randomized trial ($N = 58$) and found no differences between the two groups in hemoglobin values, number of RBC transfusions, or morbidities.[144] A Cochrane review in 2012 shows that delayed cord clamping up to 180 seconds or umbilical cord milking versus immediate cord clamping resulted in 39% fewer transfusions for anemia, 41% fewer patients with IVH, and 38% fewer patients with NEC.[33,143] Similarly, a randomized clinical trial in 2017 found that delayed cord clamping reduced anemia at 8 and 12 months in infants at high risk for iron deficiency.[83] The American College of Obstetricians and Gynecologists currently recommends a delay in umbilical cord clamping in vigorous term and preterm infants for at least 30-60 seconds after birth.[2]

A large, recent, randomized Australian study of preterm infants <30 weeks' gestation demonstrated no significant benefit of delayed cord clamping on the combined outcome of death or major morbidity or incidence of chronic lung disease or other major morbidities.[180] When this large trial

was included among other available studies, meta-analysis revealed that delayed cord clamping did reduce overall hospital mortality in infants <37 weeks' gestation, although no differences in randomized groups were observed in major morbidities. Delayed cord clamping did increase peak hematocrit by about 3% and reduced the proportion of infants having a blood transfusion by 10%.[58]

Parental Blood Donation

Concern over transfusion-associated infections has encouraged directed-donor blood programs, including those that allow biologic parents to serve as directed donors for their neonates. No data exist to support the contention that directed-donor programs increase safety. Indeed, a retrospective review at a pediatric institution found that parental donors had higher rates of infectious-disease-testing positivity than community donors.[75] Furthermore, paternal blood products are a poor choice in neonates with immune-mediated hemolysis (hemolytic disease of the newborn, or HDN) or neonatal alloimmune thrombocytopenia (NAIT). In these cases, transfused paternal cells express the antigens to which the mother has been sensitized and are passively transferred via the placenta to the neonate. Maternal plasma may contain alloantibodies directed against paternal RBC, leukocyte, platelet, and HLA antigens. Antileukocyte and antiplatelet antibodies have been found in 16% and 12% of mothers, respectively.[53] Transfusion of any maternal blood component containing plasma exposes the infant to these antibodies, with the potential to cause significant hemolytic, thrombocytopenic, or pulmonary reactions. Given these concerns, when parental-directed donation is considered for an infant, the following recommendation should be reviewed with families and the provider[54]:

- All parental cellular blood components must be irradiated before transfusion to the neonate to prevent TA-GVHD.
- If maternal RBCs or platelets are transfused, they should be given as washed cells or should be plasma reduced and irradiated.
- Fathers are not recommended as RBC donors for their newborns.
- Fathers should not donate granulocytes or platelets to their infants unless maternal serum is shown to lack lymphocytotoxic antibodies.

Blood Products

Red Blood Cell Transfusion

In the first few days of life, full-term infants have an elevated hemoglobin concentration (14-20 gm/dL); however, because of physiologic decreases in erythropoietin (EPO) levels, hemoglobin concentration decreases to a nadir of 10-12 gm/dL at approximately 2-3 months before beginning to rise. This is referred to as the physiologic anemia of infancy. In preterm infants, this anemia is more significant, with mean nadirs of 8 gm/dL in VLBW infants (birth weight:1.0-1.5 kg) and 7 gm/dL in ELBW infants (birth weight: <1 kg). This is the result of lower hemoglobin concentrations at birth, frequent blood sampling, low total blood volume to blood sampling ratio, increased risk for other co-morbidities, and diminished capacity of the premature infant to increase EPO.[54] Normal ranges of hemoglobin and hematocrit have been established for full-term and premature infants; however, guidelines for red blood cell transfusion therapy remain controversial, because there are few randomized controlled studies that address appropriate neonatal transfusion triggers. Recent neonatal and pediatric guidelines recommend transfusion at varying hemoglobin or hematocrit thresholds stratified by postnatal age and clinical condition or in circumstances where the amount of blood loss or removal exceeds 10% of a neonate's total blood volume.[116,196] Infants with significant cardiac or respiratory disease generally receive more aggressive RBC transfusion therapy. Recommended guidelines for replacement transfusion therapy in neonates are given in Box 80.2. Two studies attempted to address high versus low threshold transfusion guidelines based on level of respiratory support in ELBW and VLBW infants. Although very different in design and outcome, neither study clearly established an appropriate hemoglobin target. While the multi-institutional Canadian PINT study[90] (enrolling 451 preterm infants) demonstrated no advantage for liberal transfusion practices, the Bell study[15] (enrolling 100 preterm infants) suggested that restrictive transfusion was associated with more apneic episodes, intraparenchymal brain hemorrhage, and periventricular leukomalacia. The disparate results may be a result of a greater hemoglobin difference in the restrictive/liberal transfusion groups (Bell study: 2.7 gm/dL versus PINT: 1.1 gm/dL) and a higher overall hemoglobin value in the liberal transfusion group in the Bell study compared to the PINT study.

Long-term neurodevelopmental assessments in the Bell study cohort demonstrated that those individuals in the

liberal transfusion group performed poorer than those in the restrictive group on visual memory, reading, and associative verbal fluency measures at school age, in accord with structural findings in a subgroup of the original newborn cohort.[105,120] Conversely, previously enrolled infants from the PINT study who were followed up at 18-21 months' corrected age showed a statistically significant advantage of the liberal transfusion group on post-hoc analysis of cognitive delay defined as Mental Development Index score (MDIC) <85; however, there was no significant difference in cerebral palsy, severe cognitive delay (MDIC <70), severe hearing or visual impairment, or death.[192]

Two currently active clinical trials, the Effects of Transfusion Thresholds on Neurocognitive Outcome of Extremely Low Birth-Weight Infants (ETTNO) (NCT01393496)[72] and the Transfusion of Prematures trial (TOP) (NCT01702805), seek to address the conflicting results of the Bell and PINT studies through enrollment of large, randomized cohorts (ETTNO: 920 neonates; TOP:1824 neonates).[118] These trials are aimed at examining the short- and long-term outcomes in extremely low birth weight infants randomized to liberal or restrictive RBC transfusion thresholds.[72,119]

The debate on whether to adopt liberal versus restrictive transfusion practices in neonates remains unresolved. Some argue for more restrictive transfusion practices because of concerns of a potential causative effect of RBC transfusion on NEC, IVH, retinopathy of prematurity (ROP), and chronic lung disease (CLD), although the largely retrospective nature of these observations leads to difficulty in definitive establishment of causation.[190] Others support a more liberal approach to RBC transfusion, owing to decreasing transfusion-transmitted infection risks and the ability to minimize donor exposures using aliquots from the same donor and a potential neuroprotective advantage with a more liberal transfusion approach. Keir and colleagues recently performed a systematic review of primary and secondary adverse clinical outcomes in neonates exposed to liberal versus conservative transfusion strategies and found no statistically significant differences between the two groups across both randomized and nonrandomized studies.[85] Results from the ongoing clinical trials will hopefully delineate the short- and long-term risks and benefits of each transfusion practice to better guide RBC transfusion support decisions.

Most RBC transfusions in newborns are administered to either replace blood loss or treat anemia of prematurity. Blood loss can result from hemorrhage or phlebotomy. Iatrogenic losses from phlebotomy can be considerable but can be minimized by judicious testing strategies, sampling from indwelling catheters, using microtainers for laboratory assays, and implementing point-of-care testing.

The use of recombinant human EPO has been proposed to decrease neonatal transfusion burden, donor exposure, and anemia of prematurity, as well as other co-morbidities. The 2014 Cochrane review assessing the effectiveness and safety of early initiation of EPO (<8 days of life) showed minimal benefits with regard to donor blood exposure, number of RBC transfusions, and volume of transfusions (mL/kg) in 2209 premature infants.[126] Unlike the previous review in 2012, a statistically significant increased risk of retinopathy of prematurity (ROP) (>stage 3) was not noted in neonates who received early EPO therapy. The most recent review is notable for inclusion of new studies using darbepoetin, an erythropoiesis stimulating agent with a longer half-life requiring less frequent dosing compared to EPO.[124] As in the previous review in 2012 (no new studies were included, although one study was reassigned from the early to late EPO review category), meta-analysis of late EPO use (>8 days of life) involving 1591 preterm infants also failed to demonstrate a clear benefit in terms of significantly decreased donor exposures, nor was there any effect on incidence of co-morbidities aside from a trend toward increased risk of ROP with EPO administration. A significant decrease in donor exposures was not demonstrated, because many infants had received one or more transfusions prior to receiving EPO at study entry.[4] Although late administration of EPO reduced the number of RBC transfusions per infant, the clinical impact of these results was likewise trivial with a reduction of <1 transfusion per infant, and the total volume (mL/kg) of RBCs transfused was not significantly reduced in the neonates who received EPO. Therefore, no conclusive evidence currently exists that either early or late EPO use offers any clear benefit in regard to donor exposure or improvement of morbidity and/or mortality in preterm infants, nor that early EPO use may increase risk of ROP in the VLBW neonatal population. Additional studies utilizing darbepoetin are also indicated to determine its risks and advantages compared to erythropoietin. The use of EPO as a neuroprotectant is currently under investigation in the Preterm Erythropoietin Neuroprotection (PENUT) Trial (NCT01378273).[139] Recent preliminary data are very encouraging for improved neurocognitive outcome.[125]

Pretransfusion Testing

Prior to red blood cell transfusion, a blood sample is obtained for ABO and Rh determination (blood group and type) and to screen for antibodies against blood group antigens. Because antibodies identified in the neonate's blood are most often of maternal origin, maternal blood can often serve as the source of serum/plasma for the antibody screen. A newborn's ABO group is assigned solely on the testing of the patient's RBCs for the A and B antigens (forward typing), because the isohemagglutinins anti-A and anti-B are not present in the serum at birth. The use of cord blood specimens for infant blood type determination is discouraged because of possible contamination with Wharton jelly and because of concerns about proper identification of the specimen.

If the newborn's antibody screen is negative, ABO- and Rh-specific RBCs may be transfused, and the antibody screen does not need to be repeated during the infant's hospitalization during the first 4 months of life. If the

screening identifies passively acquired maternal blood group antibodies, as in Rh hemolytic disease of the newborn, then O-negative red blood cells should be transfused until repeat testing is negative for antibodies reacting against the ABO- or Rh-specific units. When antibodies to other RBC antigens other than D are detected, RBCs selected for transfusion should also be negative for the identified antibody. In cases when reconstituted whole blood is needed for large volume transfusion procedures (i.e., exchange transfusions, cardiopulmonary bypass, extracorporeal membrane oxygenation [ECMO]), the neonate may be given plasma that is ABO compatible with the neonate's RBCs but receive RBCs that are compatible with maternal serum. This may result in disparate ABO group of the RBC and plasma units. An alternative used by some transfusion centers entails the use of low isohemagglutinin titer, group-O whole blood, if available.[54] Infants whose Rh-negative mothers were treated with Rh immune globulin (RhIG) during pregnancy often have a positive DAT because of circulating anti-D antibody from the RhIG. The clinician must distinguish this situation from Rh hemolytic disease of the newborn.

In infants older than 4 months of age, repeat testing for blood group, Rh-type, and antibody screening is performed within 72 hours of each red blood cell transfusion if the patient has received a transfusion during the last 3 months or if the history is uncertain or unavailable. Reverse ABO blood group testing, which detects anti-A and anti-B antibodies, is frequently deferred for the first 4-6 months of life, because this testing is often weak or nonreactive in babies less than 1 year of age.

Red Blood Cell Preparations

Viability and functional activity of RBCs require that they be preserved in additive solutions that support their metabolic demands. All anticoagulant/preservative (AP) solutions contain citrate, phosphate, and dextrose (CPD), which function as an anticoagulant, a buffer, and a source of RBC metabolic energy, respectively. The addition of mannitol and adenine to existing additive solutions has increased the shelf life of RBCs from 21 days (CPD) to 35 days (CPDA-1) and to 42 days for newer AP solutions (Adsol® [AS-1], Nutricel® [AS-3], Optisol® [AS-5]) by stabilizing the RBC membrane and maintaining 2,3-diphosphoglycerate and adenosine triphosphate within erythrocytes. Studies have shown that extended-storage preservative solutions are safe and as efficacious as CPDA-1 RBCs in increasing the hematocrit for neonates receiving small-volume (10–15 mL/kg) RBC transfusions.[76,178] However, there are no clinical studies that have confirmed or refuted the effect of an AP on metabolic abnormalities in massive transfusion (>20 mL/kg) for the neonate. Of particular concern is the potential for adenine-induced nephrotoxicity[178] and intolerable fluid shifts secondary to the diuretic effects of mannitol (present in AS-1, AS-5, and AS-7 but not AS-3)[76] in neonatal patients with limited blood volumes.[196] Therefore, some experts recommend avoiding RBCs stored in extended-storage media (AS-1, AS-3, AS-5) for large-volume transfusions until such data have been published.

TABLE 80.3 Estimated Blood Volumes

Age	Blood Volume (mL/kg)
Premature infant	90-105
Term newborn	82-86
1-7 days	78-86
1-12 months	72-78

Data from Price DC, et al. In: Handmaker H, et al, eds. *Nuclear medicine in clinical pediatrics*. New York: Society of Nuclear Medicine; 1975:279.

Red Blood Cell Dose and Administration

The highest relative blood volumes (mL/kg) are found in neonates. Adult blood volumes on a per-kilogram basis are achieved by 3 months of age (Table 80.3). A typical replacement transfusion is 10-15 mL of RBCs per kilogram. Because infants are so small, many pediatric transfusion centers dispense small aliquots from one RBC unit (300-350 mL) to one or several neonates who require multiple transfusions to decrease donor exposure and to conserve RBC inventory. This practice requires sterile connecting devices to assure that the original RBC unit remains a closed system and transfer packs or syringe sets that permit multiple aliquots to be removed. Studies have shown that CPDA-1 and AS-3-preserved split RBC packs effectively limit donor exposures and are safe for use in neonatal small-volume transfusions after 35 days of storage.[102]

A few small studies have compared the consequences of RBCs on clinical outcomes; however, only one prospective study has been conducted in premature infants to evaluate whether fresh RBCs (≤7 days) decreased morbidity and mortality in VLBW infants compared with standard RBCs. In the Age of Red Blood Cells in Premature Infants (ARIPI) trial conducted in Canada, 188 infants provided with fresh RBC transfusions (mean age of transfused RBCs 5.1 days, SD 2.0 days) did not demonstrate an improvement in a composite outcome measure of major neonatal morbidities (NEC, IVH, bronchopulmonary dysplasia [BPD], and ROP) or death at 30 and 90 days compared with the 189 infants who received standard RBC products (mean age of transfused RBCs 14.6 days, SD 8.3 days) despite having 60% more donor exposures.[57] Although an unblinded, randomized control trial suggested an advantage in clinical outcomes in neonates with congenital heart disease receiving reconstituted fresh whole blood defined as less than 48 hours old when dispensed for cardiopulmonary bypass pump priming and postoperative transfusion support,[63] the role of fresh RBCs for routine transfusion support in premature infants has not shown a clear benefit. ARIPI has subsequently been criticized for insufficient separation of mean RBC storage time between its two cohorts (<2

weeks) and for inadequately addressing the issue of storage lesion in the oldest additive solution units (35-42 days). The use of a relatively liberal transfusion strategy may also have contributed to better clinical outcomes than would be expected with restrictive practices.[118] Although the saline-adenine-glucose-mannitol (SAGM) additive solution used in the study is widely available in Canada and Europe, its restricted distribution in other regions may limit the relevance of its conclusions in countries like the United States where other types of additive solutions are utilized.[187] However, based on the results of this and other recent RCTs in older children and adults such as ABLE,[96] RECESS,[172] TOTAL,[49] and INFORM,[65] recent guidelines for neonatal transfusion do not recommend limiting the age of transfused RBCs to <10 days.[27,182]

Because red blood cell units are stored at 4°-6°C, hypothermia can develop after massive transfusion unless the blood products are first warmed to body temperature. Inline blood warmers should be used for RBC exchange transfusions, and radiant heaters should be avoided because they can result in hemolysis of the RBC component. When phototherapy is in progress, the blood component and tubing should be positioned so as to minimize exposure to phototherapy light, which may also cause hemolysis.[196]

Platelet Transfusion

Indications

As with older children and adults, platelet transfusions are administered to neonates therapeutically or prophylactically to prevent the hemorrhagic complications of thrombocytopenia. Neonates have different risks of bleeding given the same degree of thrombocytopenia. For example, thrombocytopenic neonates with neonatal alloimmune thrombocytopenia purpura (NAIT) have a high risk of major bleeding, whereas those with sepsis or NEC, and those with IUGR, have an intermediate and low risk of major hemorrhage, respectively. Differences in platelet function or concurrent coagulopathy are likely causes for these discrepancies.[17] A historic randomized controlled trial addressing whether platelet transfusions reduce major bleeding in neonates found no benefit of maintaining a normal platelet count (platelets >150,000/μL) in preterm neonates compared with those maintained at greater than 50,000/μL. However, this study did not address bleeding risk or transfusion benefit for neonates with platelet counts less than 50,000/μL.[7] More recent data comparing prophylactic platelet transfusion thresholds of 25,000/μL and 50,000/μL in terms of mortality and major bleeding complications in 660 premature infants (less than 34 weeks), reported results in 2018. Infants randomized to the higher transfusion threshold had higher occurrence of a new major bleeding episode or death than infants randomized to the lower threshold (26% versus 19%, $p = 0.02$).[43]

Neonatal platelet transfusion threshold policies vary widely, both nationally and internationally,[41,79] and are largely based on expert panel recommendations garnered from clinical experience because of the lack of randomized clinical trials addressing absolute bleeding risk in thrombocytopenic neonates caused by different etiologies. Because of the concern for IVH in the sick neonate, many physicians have traditionally adopted a fairly aggressive platelet threshold for transfusion (e.g., platelet count >100,000/μL in high-risk patients). Murray et al. retrospectively studied 53 neonates (44 preterm) with severe thrombocytopenia and concluded that a threshold of 30,000/μL without other risk factors or previous IVH is safe for the majority of neonates.[113] In a cross-sectional observational study of neonatal outcomes with severe thrombocytopenia, Stanworth et al. failed to show a clear relationship between nadir platelet count/degree of thrombocytopenia and major hemorrhage (IVH, pulmonary, intra-abdominal, hematuria). In the 169 neonates studied with severe thrombocytopenia (platelet count nadir <60,000/μL), 154 (91%) did not experience major hemorrhage. Of the 15 (9%) that experienced major hemorrhage, 12 patients (80%) had a platelet count nadir before the hemorrhage of greater than 20,000/μL,[170] and follow-up analysis revealed that thrombocytopenia alone was not a strong indicator of bleeding risk, whereas gestational age (<34 weeks), early onset of postnatal thrombocytopenia (<10 days after birth), and coexistence of NEC were strong clinical risk factors for bleeding in this population.[115] Retrospective studies have also failed to establish a link between the severity of thrombocytopenia and risk of IVH[187] across both liberal and restrictive transfusion practices.[19,186] A recent retrospective study of VLBW infants demonstrated that a restrictive platelet transfusion protocol using platelet count thresholds of 25,000/μL in clinically stable neonates and 50,000/μL in clinically unstable neonates, extremely premature neonates within the first week of life, or neonates at high risk of major bleeding was not associated with an increased risk for IVH compared with a more aggressive transfusion protocol.[19] Nevertheless, in their recent retrospective review, Sparger and colleagues found that a majority of neonatal platelet transfusions in the United States continue to be administered for pretransfusion platelet counts of ≥50,000/μL in VLBW infants despite evidence that platelet transfusion has little appreciable impact on the risk of IVH after adjustment for underlying clinical variables.[168]

Thus, a generally accepted transfusion trigger for platelet count less than 25,000/μL has been endorsed for healthy or stable term and preterm infants without other risk factors, whereas some experts propose a higher trigger (<50,000/μL) for VLBW neonates within the first week of life, clinically unstable neonates, and neonates with NAIT (using HPA-compatible platelet products).[149,150] Current recommended thresholds for neonatal platelet transfusion are listed in Box 80.3. Platelet transfusions are also indicated to treat hemorrhage associated with acquired (i.e., ECMO, cardiopulmonary bypass, uremia) or congenital qualitative platelet abnormalities (i.e., Glanzman thrombasthenia, Bernard-Soulier syndrome), even if the platelet count is within the normal range.

• BOX 80.3 Recommended Thresholds for Neonatal Platelet Transfusion

- Platelet count <25 × 10^9/L
  No bleeding, including neonatal alloimmune thrombocytopenia (NAIT) without bleeding or family history of ICH
- Platelet count <50 × 10^9/L
  Bleeding, current coagulopathy, surgical prophylaxis, or NAIT with a family history of ICH in an affected sibling
- Platelet count <100 × 10^9/L
  Major bleeding or requiring major surgery (e.g., neurosurgery)

Modified from New HV, et al. Guidelines on transfusion for fetuses, neonates, and older children. *Brit J Haematol.* 2016;175:784-828.

Pretransfusion Testing

Platelets express intrinsic ABO antigens but not Rh antigens. They should be ABO-group specific whenever possible because of reports of intravascular hemolysis following transfusion of ABO-incompatible platelets in infants and children.[8] Platelets do not routinely require cross-matching. If ABO-incompatible platelets must be used, plasma removal via volume reduction or washing, or selecting low isohemagglutinin (anti-A, anti-B) titer units, are options.[78] Routine volume-reduction methods for all neonates should be avoided, because approximately 20% of platelets are lost in the final product, which is resuspended in either saline or compatible plasma. Although Rh matching does not affect post-transfusion platelet survival, RBCs are present in small amounts of whole blood–derived platelet concentrate and can cause Rh sensitization in an Rh-negative recipient. Administration of RhIG should be strongly considered for any Rh-negative neonate, especially females, within 72 hours of exposure to Rh-positive RBCs through a platelet transfusion. The recommended dose is 120 IU RhIG per mL of RBCs transfused, administered intramuscularly (90 IU RhIG per mL of RBCs intravenously).[46] When aliquots of apheresis platelets, which are relatively RBC free, are used, there should be limited to no concern for Rh sensitization.

Component Definition and Dosing

A standard unit of platelets, prepared from a single donation of whole blood, contains at least 5.5 × 10^{10} platelets in 50-70 mL of plasma.[169] Apheresis platelets, often called single-donor platelets, contain a minimum of 3 × 10^{11} platelets in approximately 250 mL (range: 200-400 mL) of plasma, the equivalent of an estimated 6 units of whole blood–derived platelets. There are two ways to calculate platelet doses in neonates, based on mL/kg or based on equivalent units/kg. An equivalent unit (EU) is the volume of a platelet aliquot that has a minimum platelet content of 5.5 × 10^{10}. Because one apheresis unit contains at least 3 × 10^{11} platelets, the content of an apheresis platelet unit is equivalent to approximately 6 units of whole blood–derived platelets. The standard dose based on this method is 1 EU/5 to 10 kg with a minimum dose of 1 EU. EU-based dosing offers the advantage of reducing platelet content variability in the transfused product because a minimum platelet content will be administered regardless of its volume. This may be clinically significant in sick neonates with thrombocytopenia.

Platelet components may be volume reduced to 15-20 mL for patients requiring significant volume restrictions, but this is associated with significant platelet loss of 15%-35% and may affect platelet function adversely. Rapid decreases in pH have also been observed for aliquots stored in syringes after volume reduction; for this reason, infusion of these products is recommended within 4-6 hours of processing to avoid induction or exacerbation of acidosis in transfusion recipients.[50] Platelets are stored at 20°-24°C under constant agitation and have a shelf life of 5 days after collection. Transfusion of 10-15 mL/kg of platelets for neonates, or 1 EU/5 to 10 kg for children over 5-10 kg, should yield a platelet increment of 50,000/μL to 100,000/μL if no predisposing risk factors for refractoriness exist. It is important to account for device-related dead space (10-30 mL) when issuing the product, as this can be considerable in relation to the overall platelet dose. The expected rise in the platelet count after transfusion may not be met because of destructive thrombocytopenia such as occurs with splenomegaly, fever, sepsis, DIC, bleeding, or antibiotic therapy. Immune-mediated causes of platelet refractoriness, such as alloantibodies to platelet-specific antigens (e.g., HPA-1a, 5b) in NAIT and autoantibodies to common platelet antigens in idiopathic thrombocytopenic purpura, require consideration in this population so that appropriate management can be initiated.[54]

Despite increasing availability of alternative products such as platelet additive solution (PAS)[40] or pathogen-reduced platelets[93] in the United States, their efficacy and safety in neonates or pediatric patients in general have not been widely published with a few exceptions.[68,200]

Granulocyte Transfusion

Neonates, particularly those with very low birth weights, are susceptible to overwhelming bacterial infection. Many factors contribute to this risk, including disruption of mucosal barriers, hypogammaglobulinemia, and qualitative neutrophil defects. Furthermore, preterm neonates may become neutropenic during sepsis because of a reduced capacity to increase myeloid progenitor cell proliferation with infections. Transfusion of granulocytes has been employed in the treatment of neonatal sepsis; however, the efficacy of such transfusions is controversial. Meta-analysis of the safety and efficacy of granulocyte infusion adjunctive to antimicrobial therapy in the treatment of septic neutropenic neonates failed to show that granulocyte infusions reduce mortality or morbidity, although a reduction in the latter approached statistical significance.[131] The Resolving Infection in Neutropenia with Granulocytes (RING) randomized clinical trial compared standard antimicrobial

therapy alone against daily granulocyte transfusion from donors stimulated with GCSF and dexamethasone in addition to standard therapy and found no difference in survival or microbial response in the granulocyte arm,[140] although secondary analyses indicated that higher doses of granulocytes achieved through GCSF stimulation were associated with better outcomes than lower doses.[103] Although children (defined as <18 years of age) were included in this study, they comprised only a minority of the total number of subjects (6/49 in control arm, 4/48 in granulocyte arm).[140] In spite of the conflicting evidence, granulocyte transfusion may be considered in neonates with qualitative neutrophil defects with severe (or progressive) bacterial or fungal infection who have not responded to appropriate aggressive antimicrobial treatment.[150]

Granulocyte concentrates for neonatal transfusion are prepared by automated leukapheresis of healthy stimulated (dexamethasone ± granulocyte colony-stimulating factor [G-CSF]) donors, and contain 1 to 2×10^9 neutrophils per kilogram in a volume of 10-15 mL/kg. Treatment should be continued daily until clinical improvement or neutrophil count recovery (absolute neutrophil count >3000/μL in first week of life; >1500/μL thereafter). All granulocytes should be gamma or x-ray irradiated and CMV negative since leukodepletion is contraindicated. Because granulocyte concentrates have a significant amount of RBCs (hematocrit: 15%-20%), the component must be ABO/Rh and cross-match compatible with the intended neonatal recipient. Because granulocytes must be transfused within 24 hours of collection, FDA-mandated testing for blood products will not be completed before the product is released for administration; therefore, the risks and benefits of transfusing an untested blood product must be weighed by the medical team and the parents of the infant and documented accordingly in the medical record.[54]

There are unique risks to granulocyte transfusion. They include varying degrees of pulmonary reactions from mild transient respiratory distress to severe pulmonary edema, hypoxia, and acute respiratory distress syndrome (ARDS), as well as a high incidence of febrile transfusion reactions. Pulmonary complications have been reported in 4% of transfused infants,[108] and severe pulmonary reactions resembling TRALI have been reported.[122] Mild to moderate reactions occur in 25%-50% and severe reactions in about 1% of all granulocyte transfusions.[140] Administration of amphotericin B should not be done within 6 hours of granulocytes because of suspected increased risk of severe pulmonary reactions. Polycythemia secondary to granulocyte transfusion is an infrequently reported complication but may be especially relevant in neonates, owing to a relatively large volume of RBCs within the granulocyte product being transfused into an infant with a small blood volume. Given the relatively high RBC volume in granulocyte concentrates (hematocrit 15%-20%), a significant increase in the patient's hematocrit may be observed when granulocytes are given at doses of 15-20 mL/kg for several days in a row.[3]

Although granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor have been used successfully to stimulate neutrophil numbers, and IVIG has been attempted to augment traditional antimicrobial therapy to support septic neonates, data on efficacy are inconclusive.[26,153] Because of the lack of clear consensus on their impact on improving host defense mechanisms and improving outcomes, these adjuncts to standard antimicrobial and antifungal therapy need further investigation.

Fresh Frozen Plasma Transfusion

Plasma can be prepared by either whole blood separation or by apheresis. When the plasma product is frozen to −18°C or colder within 8 hours of collection, it is labeled as fresh frozen plasma (FFP) (approximately 250-300 mL) and can be stored at this temperature for up to 1 year.[54] Plasma frozen within 24 hours of collection (FP24) has a similar shelf life and is considered essentially bioequivalent to FFP with the exception of ARIPI Factor VIII activity, which is typically 15%-30% lower.[52,156] To conserve plasma inventory and limit donor exposures for infants who receive only fractions of an adult-sized unit, plasma can be separated into a system of multiple satellite bags and frozen as aliquots. Once thawed, plasma components can be further subdivided into aliquots for multiple neonates via sterile connecting devices, stored at 1°-6°C for up to 5 days and transfused as "thawed plasma."[196] Although thawed plasma has approximately 40% Factor V and VIII (heat labile factors) activity, effective hemostasis is maintained at this level, making thawed plasma clinically similar to FFP and FP24.

Plasma is used primarily to treat acquired coagulation factor deficiencies as a result of DIC, liver failure, vitamin K deficiency from malabsorption, biliary disease, warfarin therapy, or dilutional coagulopathy from massive transfusion. It can also be used for specific factor replacement in congenital factor deficiencies (e.g., Factors V, X, XI) when specific factor concentrates or recombinant products are not manufactured or unavailable.[54,150,196] However, the optimal role of plasma in neonatal transfusion practice has not been established through evidence-based studies, and a majority of FFP transfusions in patients of all ages appear to be given for prophylactic purposes.[110,171] Recent transfusion guidelines do not recommend routine use of plasma for correction of coagulopathy in neonates without clinically significant bleeds. In contrast, plasma may be of use in neonates with significant bleeding, including those requiring massive transfusion or at high risk for bleeding because of an invasive procedure or significant coagulopathy as evidenced by markedly prolonged PT or aPTT.[66] Plasma is not indicated for volume expansion, enhancement of wound healing, or as first-line treatment for congenital factor deficiencies when either a virally inactivated, plasma-derived factor concentrate or recombinant factor is available.

Plasma transfusions should be ABO-compatible with the neonate's RBCs to avoid passive transfer of

isohemagglutinins from ABO-incompatible plasma, which may result in hemolysis.[196] Because the freezing process renders the frozen-thawed plasma component free of viable leukocytes, plasma products are not screened for CMV antibody, nor are leukoreduction and irradiation necessary for the prevention of CMV reactivation and TA-GVHD, respectively. However, passive administration of antibody to CMV in plasma may cause CMV IgG testing to become positive in the transfused neonate. This does not represent CMV infection, and the antibody disappears in a time course consistent with the 21-day half-life of gamma-globulin.[98,181]

Plasma is typically dosed at 10-15 mL/kg. Assuming that 1 mL of plasma equates to 1 U of factor activity (definition of 100% activity), one can predict the amount of replacement of most factors following plasma transfusion. For example, for a *preterm* infant, the calculations are as follows:

1. 1 U of factor activity = 1 mL plasma
2. TBV (total blood volume) = weight × 100 mL/kg
3. TPV (total plasma volume) = TBV × (1 − Hct)
4. Unit of factor needed = TPV × (desired factor [%] − initial factor [%])

Example: 1-kg preterm infant, with Hct 55%; desired factor activity increment of 30%:

TBV = 100 mL, and TPV = 45 mL
Units of factor needed = 45 × (0.30) = 15 U
Amount of plasma needed = 15 mL (or 15 mL/kg)

Using these calculations for a *preterm* infant, it is evident that 10-15 mL/kg of plasma will replace approximately 10%-30% of most factors immediately following transfusion. It is important for the clinician to know the half-lives of the factor(s), because factor half-lives vary. Furthermore, vitamin K–dependent factors (Factors II, VII, IX, and X, as well as anticoagulant proteins C and S) are lower in neonates, thereby prolonging both the PT and aPTT. Correlation of lab values with gestational age and clinical status is, therefore, important when devising a plasma-dosing schedule for a coagulopathic infant. It is critical that appropriately collected specimens for evaluation of coagulation factors be obtained in advance of plasma transfusion.

Solvent/detergent (S/D) treatment shows great effect against enveloped viruses since it disrupts their lipid-containing membranes. Since the treatment also lyses cells, S/D can only be used for acellular products such as plasma (e.g., Octaplas) or coagulation factors. A limitation of the treatment is that non-enveloped viruses such as hepatitis A and parvovirus are relatively resistant. Octaplas received Health Canada approval in 2005 and FDA approval in January 2013. It has been available in Europe since 1992 and several countries (e.g., Norway, Ireland, and Finland) have entirely converted their plasma supply from FFP to Octaplas. Each lot is prepared from a pool of 630-1520 units of FFP, which provides a more consistent level of coagulation factors. The risk of allergic reactions and TRALI appears reduced because of the process of filtration to remove cellular debris as well as the dilution of individual donor plasma proteins. The product is available in 200-mL aliquots, but these cannot be divided into smaller portions, limiting their use in smaller patients. Octaplas preparation includes affinity ligand chromatography (to remove prions), several filtration steps, and S/D treatment with trinitrobutyl phosphate and Triton X-100. Through such preparation processes, Octaplas is associated with reduced risk of bacterial contamination.[148] In the United States, the shelf-life is 3 years when stored below −18°C (compared to 1 year for FFP or FP24).

Cryoprecipitate Transfusion

Cryoprecipitate is the cold-insoluble precipitate prepared from FFP that has been thawed slowly at 1°-6°C and refrozen at −18°C after removal of the supernatant. Each unit (bag) of cryoprecipitate is derived from a single whole-blood donation and has a shelf life of up to 1 year. A unit (10-15 mL) of cryoprecipitate contains a minimum of 80 units of Factor VIII activity and 150 mg of fibrinogen. There are no standards for the quantity of the other factors; however, there is approximately the same amount of von Willebrand Factor (vWF) and Factor XIII in one unit as 10-15 mL/kg of FFP.[54] Therefore, it is a useful product in infants who require higher concentrations of Factors VIII, XIII, vWF, or fibrinogen levels and who are volume restricted. Cryoprecipitate is indicated in the treatment of bleeding episodes associated with von Willebrand disease and/or hemophilia A only when FDA-licensed recombinant factor concentrates and/or viral-inactivated, pooled plasma-derived factor concentrates are not available. Cryoprecipitate is the treatment of choice for Factor XIII deficiency, congenital afibrinogenemia, dysfibrinogenemia, and severe hypofibrinogenemia (<150 mg/dL) associated with bleeding.[54] In general, an infant should receive 1 bag of cryoprecipitate per 5 kg, which increases the total fibrinogen by about 100 mg/dL.

Factor Concentrates

A variety of human plasma-derived and recombinant factor medications have become more widely available in the last several decades, including short- and long-acting Factor VIII and Factor IX concentrates indicated in the treatment of hemophilia A and B, respectively, and von Willebrand Factor concentrates for von Willebrand disease. Activated Factor VII (Novoseven) is indicated for congenital Factor VIII deficiency and hemophiliac patients with high titer inhibitors but is most commonly used for off-label treatment of refractory bleeding in neonates on cardiopulmonary bypass. There is conflicting evidence as to whether the risk of thrombosis is significantly higher in neonates compared to older children.[142] Prothrombin complex concentrates (PCC) containing three (Factors II, IX, X) or four (Factors II, VII, IX, X) factors are indicated for

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

vitamin K deficiency, especially when plasma is contraindicated because of volume restriction, as well as congenital Factor X deficiency. Newer agents indicated for rare specific factor deficiencies include Factor XIII (Corifact), protein C (Ceprotin), and fibrinogen (RiaSTAP) concentrates. The use of antithrombin concentrates is discussed below under the Extracorporeal Membrane Oxygenation (ECMO) section.

Special Topics in Neonatal Transfusion

Exchange Transfusion

Exchange transfusion is the replacement of most or all of the recipient's RBC mass and plasma with appropriately compatible RBCs and plasma from one or more donors. The amount of blood exchanged generally is expressed in relation to the recipient's blood volume (e.g., as a partial, single, or double volume exchange).

Indications

Neonatal exchange transfusions are most commonly used in infants with hemolytic disease of the newborn (HDN). Double-volume exchange transfusions also are frequently used in newborns with severe jaundice from other causes to prevent kernicterus and other toxicities related to hyperbilirubinemia.[196] Bilirubin levels warranting exchange transfusion are discussed in Chapter 91.

Although a Cochrane meta-analysis demonstrated that IVIG administration (0.5-1 gm/kg) may prevent exchange transfusion for many term infants with HDN, a prospective, randomized control trial showed that prophylactic IVIG (0.75 g/kg) did not decrease the duration of phototherapy, maximum bilirubin levels, or need for RBC transfusion or exchange transfusion in Rh HDN.[5,166] Despite this, IVIG is often considered when serum bilirubin levels continue to rise despite aggressive phototherapy or when the bilirubin level is approaching the exchange level. Exchange transfusion can also be used, albeit infrequently, to remove exogenous (drugs) or endogenous (metabolic) toxins.

The efficiency of exchange transfusion diminishes exponentially as the procedure continues. The kinetics of exchange are very similar, regardless of whether a continuous technique (simultaneous withdrawal and replacement) or discontinuous technique (alternating withdrawal and replacement) is used. The effectiveness of exchange transfusion varies with the component being removed and its relative distribution within intravascular and extravascular compartments. The efficiency is highest for RBC exchange. A double-volume ET results in removal of approximately 85% of the neonate's RBCs; however, the amount of bilirubin or maternal alloantibody removed by exchange transfusion is significantly less (25%-45%) because of equilibrium between the intravascular pool and the extravascular tissues for bilirubin, antibodies, and similar substances.

The optimal volume for an exchange transfusion is twice the infant's blood volume. Little is gained by exceeding two blood volumes. When anticipating the volume needed for double-volume exchange, the total volume required depends on whether the infant is preterm. For example, using two times total blood volume (TBV):

$$2 - \text{volume exchange volume (preterm)} = 100\ \text{mL/kg} \times 2, \text{ or } 200\ \text{mL/kg}$$

$$2 - \text{volume exchange volume (term)} = 85\ \text{mL/kg} \times 2, \text{ or } 170\ \text{mL/kg}$$

To perform the exchange transfusion, aliquots of the reconstituted whole blood product are administered while equal amounts of the infant's blood are withdrawn, with careful attention not to exceed 5 mL/kg or 5% of TBV at a time (over 2-10 minutes).

Choice of Blood Components

Either stored whole blood, if available, or reconstituted whole blood (i.e., RBCs plus plasma) can be used for neonatal exchange transfusion. The RBC component should be group O-negative or ABO/Rh compatible to maternal serum for Rh HDN. Fresh (<5-7 days) CPDA-1 units should be used, because the safety of extended storage media has not been amply studied for neonatal large-volume transfusions. If only older CPD(A) units or extended-storage additive units are available, the RBC units can be washed or the supernatant removed. The RBCs are reconstituted with whole blood or compatible plasma to a final hematocrit of 40%-50%. Furthermore, components should be CMV risk reduced (leukodepletion), gamma irradiated, and sickle negative. Both whole blood and reconstituted whole blood are deficient in platelets. Platelets are not added to reconstituted blood during an exchange, because this could lead to increased microaggregate formation. Infants who are significantly thrombocytopenic (platelet count <30,000/μL) after an exchange transfusion or who are bleeding should receive a platelet transfusion. For infants with HDN caused by other RBC antibodies, the RBC product should be specifically selected to be negative for the offending antibody(ies).

Potential complications of exchange transfusion include: hypocalcemia, hyperglycemia (with subsequent rebound hypoglycemia), hypothermia (typically avoided with use of appropriate in-line blood warmers), dilutional thrombocytopenia, neutropenia, umbilical vein/arterial thrombosis, necrotizing enterocolitis, intracranial pressure fluctuations resulting in IVH, air embolization, and infection.[116,196] The majority of adverse events associated with exchange transfusions reported include hypocalcemia (3%-42%), metabolic acidosis (approximately 24%), hypernatremia (8%), severe thrombocytopenia defined as platelet count <50,000/μL (6%-44%; and up to 63% in neonates receiving exchange transfusion specifically for Rh HDN), and leukopenia/neutropenia (70%). These adverse events may occur as asymptomatic laboratory abnormalities or may be associated with significant exchange-transfusion–related morbidity. Adverse events are more frequent in exchanges

done on preterm infants less than 32 weeks, infants with other significant co-morbidities, and when umbilical catheters are used (in particular, portal vein thrombosis). One unique risk factor associated with exchange transfusion in neonates is subsequent development of invasive bacterial infections, with reported incidence of exchange-transfusion-related sepsis ranging from 0%-11%. It is postulated that the increased risk may result from the use of umbilical vein catheters, the associated exchange-transfusion-related leukopenia, and potentially an immunomodulatory effect of blood transfusion.[74,134,165]

Partial Exchange Transfusion

Approximately 5% of all neonates are born with or develop polycythemia. Infants of diabetic mothers and small-for-gestational-age neonates are at higher risk. Neonatal polycythemia is defined as a venous hematocrit greater than 65% within the first week of life. Partial exchange transfusion effectively lowers the hematocrit and reduces whole blood viscosity in polycythemic neonates who have hyperviscosity. Partial exchange transfusion is also useful for correcting severe anemia without the risk of fluid overload and heart failure.

The long-term benefit of early partial exchange transfusion in polycythemic neonates is controversial, at least partly because the prognosis for such infants depends greatly on the etiology. A hematocrit greater than 65% is generally used as the stimulus for partial exchange transfusion because as the hematocrit rises over this level, blood viscosity significantly increases and oxygen transport diminishes.

A partial exchange is used to normalize the hematocrit to below 60% by removing infant whole blood and replacing with an equal volume of isotonic crystalloid solution. Crystalloid solutions are preferable to plasma to decrease exposure to plasma and because NEC has been associated with the use of plasma as replacement solution.[116] The volume of exchange required can be calculated with the following formula:

$$\text{Volume of exchange (mL)} = \text{TBV (mL)} \times \left[\frac{\text{Observed Hct} - \text{Desired Hct}}{\text{Observed Hct}}\right]$$

For example: 1-kg preterm infant with Hct 68%, desired postpartial exchange Hct 55%

$$\text{Volume of exchange (mL)} = 100\ \text{mL} \times \left[\left(\frac{(68-55)}{68}\right)\right] = \approx 20\ \text{mL of crystalloid exchanged with whole blood}$$

To correct severe anemia, RBCs are used as the replacement fluid for the whole blood withdrawn. The formula used to calculate the volume required for exchange is similar to the one above; however, the hematocrit of the RBC product used must be taken into account. RBCs in CPDA-1 usually have a hematocrit of approximately 70%; thus the formula is:

$$\text{Volume of exchange (mL)} = \text{TBV (mL)} \times \left[\frac{\text{Desired Hct} - \text{Observed Hct}}{\text{Hct of Unit} - \text{Observed Hct}}\right]$$

For example: 1-kg preterm infant with Hct 21%, desired postpartial exchange Hct 45%

$$\text{Volume of exchange (mL)} = 100\ \text{mL} \times \left[\frac{(45-21)}{(70-21)}\right] = \approx 49\ \text{mL of CPDA RBCs exchanged with whole blood}$$

If RBCs preserved in other solutions are used, the equation must be altered to take into account the average hematocrit of the product. The technique of partial exchange transfusion is similar to that used in larger volume exchange. A discontinuous methodology is most often used; aliquots of 5 mL/kg or less should be used for each withdrawal and infusion.

Extracorporeal Membrane Oxygenation

Because of the large volume of transfused red blood cells used for ECMO, RBCs used in the bypass circuit should be less than 7-14 days old to avoid high potassium levels in older blood.[100] In the infant with presumed or suspected cellular immunodeficiency, the blood products should undergo CMV risk reduction (CMV seronegative *or* leukoreduced) and gamma or x-ray irradiation. There is mounting anecdotal evidence that RBCs preserved in extended storage media (AS-1, AS-3) are safe for ECMO. Some ECMO centers use RBC products stored in CPD/CPDA preservatives or reduce the additive prior to use.[196] Hemolysis from mechanical damage and phlebotomy contributes to ongoing red blood cell transfusion requirements. Thrombocytopenia occurs in all patients undergoing ECMO as a result of accelerated platelet destruction. This, coupled with the need for systemic anticoagulation with heparin to prevent clotting within the extracorporeal circuit (see Chapter 79), places infants on ECMO at significant risk for hemorrhage.[21] Platelets should be maintained at greater than 50,000-150,000/μL or higher in infants undergoing major surgery such as diaphragmatic hernia repair while on ECMO. Activated clotting times and other coagulation tests such as thromboelastography, aPTT, and anti-Xa assays are used to measure coagulation parameters, and FFP and cryoprecipitate are often needed to correct laboratory abnormalities.

Management of ECMO Patients Using Factor Concentrates (e.g., Antithrombin III)

Although on-demand dosing of antithrombin concentrates (Thrombate, ATryn) for pediatric patients on ECMO increases antithrombin levels and decreases heparin

requirements for at least 12 hours after dosing, no statistical differences in the number of circuit changes, in vivo clots or hemorrhages, transfusion requirements, hospital or ICU length of stay, or in-hospital mortality were identified compared to controls.[198] Similarly, studies of antithrombin supplementation in children on cardiopulmonary bypass have demonstrated decreased heparin doses without significant impact on clinical outcomes.[142]

Therapeutic Hypothermia

Infants presenting with neonatal encephalopathy as a result of a hypoxic insult are offered neuroprotective therapy with whole body or selective head cooling.[158] Often, these infants have suffered an ischemic insult involving several organs, including the liver. This may predispose the infant to liver dysfunction and result in clinical bleeding or disseminated intravascular coagulation. Hypothermia-associated bleeding has been hypothesized to result from dysregulation of enzymatic function, reduced platelet activity, and/or altered fibrinolysis.[35,195] Therapeutic (induced) hypothermia may worsen baseline coagulopathy in asphyxiated newborns through the above mechanisms. Patients undergoing hypothermia with prolonged INR and aPTT values and lower platelet and fibrinogen levels may have a higher incidence of clinical bleeding. Sites of bleeding may be intracranial, pulmonary, gastrointestinal, and/or genitourinary. These data suggest that maintaining an appropriate INR, platelet count, and fibrinogen level may be important in reducing the incidence of clinical bleeding among this vulnerable group of patients.

Future Directions

Neonatal transfusion practices remain highly variable across institutions because of a paucity of evidence-based guidelines. Cure and colleagues recently identified several key areas requiring additional research,[42] including ideal parameters for assessing the need for transfusion beyond cell counts as well as markers for assessing transfusion efficacy and long-term outcomes, methods of gathering and compiling epidemiologic data on neonatal transfusions, and blood management strategies for neonates, especially with regard to safety of pathogen-inactivated products. The authors propose that additional translational studies and clinical randomized controlled trials are needed to address these questions along with large, centralized repositories for collection and analysis of data.

Key Points

- Leukoreduction, donor selection criteria, and improved infectious disease screening have contributed to a very safe blood supply.
- Nevertheless, transfusions still carry infectious and noninfectious risks and should, therefore, be administered carefully and judiciously. Rapid, large volume transfusions, in particular, can lead to metabolic derangements.
- During all transfusions, patients must be closely monitored for signs and symptoms of transfusion reactions.
- Current neonatal transfusion practices are guided by the gestational age and clinical status of the patient but remain highly variable across institutions due to lack of evidence-based studies for many blood components.
- Recent clinical trials have contributed toward understanding of neonatal transfusion triggers and clinical outcomes, but ongoing and future trials are needed for further clarification of these parameters as well as identification of viable alternatives to blood products.
- Increasing availability of both plasma-derived and recombinant factor concentrates has led to replacement of plasma products in the treatment of certain clinical conditions and additional applications in the management of neonates on extracorporeal life support.

Development of the Neonatal Gastrointestinal Tract

MICHAEL DINGELDEIN

The human gastrointestinal (GI) tract is a complex combination of organs whose primary function is to digest and absorb nutrients. Many important secondary functions are also performed, such as the endocrine function of the pancreas. In fact, what was once considered a simple system of digestion and absorption is now recognized as something much more complex and dynamic. Furthermore, as with the respiratory system, to perform its duties, the GI tract must be in continuity with the environment. This places the additional demand of having mechanisms in place to protect the host from toxins and pathogens. It is remarkable that this tube, open to the outside world at both ends and colonized by bacteria for a significant portion of its length, is tolerated so well and has relatively few complications associated with it. But troubles do occur, and in the neonate, most can be traced to developmental anomalies.

The Beginning

During gestation, the alimentary canal can be simply considered as the folding of endoderm and splanchnic mesoderm into a tube at the end of week 3 and the beginning of week 4.[8] As the head fold forms, the cranial part of the yolk sac becomes enclosed within the embryo and becomes the foregut. Shortly thereafter, the caudal portion of the yolk sac becomes enclosed and forms the hindgut. The midgut resides between the foregut and the hindgut, near the yolk sac, which remains outside the embryo. The midgut remains in communication with the yolk sac until the yolk stalk closes during the 10th week of gestation. Initially the digestive tube ends blindly—cranially at the oropharyngeal membrane and caudally at the cloacal membrane. These membranes, made up of endoderm and ectoderm, break down, with the oropharyngeal going first at the start of week 4 followed by the cloacal at the start of week 6.

Esophagus

The esophagus serves as a complex conduit between mouth and stomach and, at the gastroesophageal junction, functions to avoid reflux of stomach contents back up the esophagus. Although this task sounds simple, the esophagus performs its roles so well that no esophageal replacement has been found that does anywhere near as good a job. All efforts are made to keep a native esophagus, even a severely compromised one, rather than go with any replacement.

The fully developed esophagus extends from the pharynx and cricopharyngeal sphincter in the neck to the lower esophageal sphincter and gastroesophageal junction in the abdomen. The blood supply to the esophagus is segmental, which is a key concept to understand for surgical planning. The upper esophagus is supplied by branches descending from the inferior thyroid artery. The middle and lower thirds of the esophagus are supplied by branches arising directly from the bronchial vessels or the descending thoracic aorta. The abdominal and lower esophagus also receive blood supply from the left gastric and inferior phrenic arteries. The full-term newborn esophagus is 10 cm in length and up to 40 cm in adulthood. There are four areas of natural anatomic constriction of the esophagus: (1) at the level of the cricopharyngeal sphincter, (2) as the aortic arch crosses anteriorly, (3) as the left main stem bronchus crosses anteriorly, and (4) at the level of the lower esophageal sphincter. Foreign bodies in the esophagus tend to lodge at one of these areas of constriction, and burns from caustic ingestion tend to be more severe in these regions.[14]

The esophagus is differentiated from the primitive foregut during the 4th week of gestation.[10,11] A tracheoesophageal septum is evident at this time, initiating the division of the trachea anteriorly from the foregut posteriorly. The septum remains at about the same level in the fetus while the body grows cranially. This leads to elongation of the esophagus, primarily from "ascent" of the pharynx rather than "descent" of the stomach. It reaches its full length, relative to the size of the developing fetus, during the 7th week of gestation. Aberrations during this phase of development result in esophageal atresia and tracheoesophageal fistulas.[4]

The muscular wall of the esophagus is similar to that of the rest of the GI tract, with an outer longitudinal layer and a circular inner layer. The more highly developed longitudinal layer forms during the 9th week of gestation, whereas

Abstract

This chapter reviews the embryology of the gastrointestinal tract with a focus toward clinically relevant information.

Keywords

GI embryology
stomach development
esophagus development
intestinal development

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

the circular layer forms during the 6th week. There is no serosa on the esophagus except in the short abdominal portion. This is clinically important when considering the resection or repair of the esophagus.

The epithelial lining of the esophagus is derived from the primitive endoderm. At the 10th week of gestation, this is ciliated, but a stratified, nonkeratinizing, squamous epithelium begins replacing the ciliated epithelium at about the fourth month of gestation. Some ciliated epithelium along the length of the esophagus may persist until birth. The striated muscle of the upper third arises from mesoderm of the branchial arches, whereas the smooth muscle of the distal two-thirds is derived from splanchnic mesenchyme. Therefore diseases of smooth muscle tend to affect the lower esophagus only.

Small glands of mucus- and bicarbonate-secreting cells with ducts opening onto the surface of the epithelium are scattered throughout the length of the esophagus, particularly in the lower third.

By 8 weeks' gestation, immature neurons are identifiable within the wall of the esophagus. These nerves are derived from both parasympathetic and sympathetic fibers. The cervical sympathetic trunks send fibers along the inferior thyroid artery to the upper third of the esophagus, whereas the middle and lower thirds are supplied by branches from the greater splanchnic nerves. The thoracic esophagus is supplied by branches of the esophageal vagal plexus, arising directly from the vagus trunks in the chest.[8]

The act of swallowing is initiated by impulses from the swallowing center, an area in the reticular formation of the rostral medulla where the nuclei of cranial nerves IX and X are located. The initial event in esophageal peristalsis is stimulation of the longitudinal muscle layer, which is followed by the segmental activation of the circular muscle and relaxation of the lower esophageal sphincter. The peristaltic wave begins in the pharynx and continues through to the gastroesophageal junction without interruption. Whereas primary waves are initiated from the swallowing center, secondary peristalsis is mediated by local intramural pathways to return refluxed material in the lower esophagus to the stomach.

The upper esophageal sphincter corresponds to the cricopharyngeal muscle. There is no morphologic distinction in the muscular wall of the lower esophagus that would identify this sphincter, although clearly one functionally exists. The primary role of this sphincter is to prevent the reflux of gastric contents back into the lower esophagus. The lower esophageal sphincter relaxes as the primary peristaltic wave traverses the esophageal body, and it remains open until the peristaltic wave enters the sphincter and closes it. Disordered lower esophageal sphincter function is thought to be one of the mechanisms for pathologic gastroesophageal reflux.[4]

Stomach

The stomach first appears as a fusiform dilation of the caudal part of the foregut at the end of the 4th week of gestation.[7] At this time, the stomach is suspended between the posterior and anterior body walls by a ventral and dorsal mesentery. During weeks 6 through 10, the stomach undergoes rotation in two planes, as well as growth differentials that lead to the appropriate size and orientation of the organ as seen at birth. One rotation is 90 degrees counterclockwise (viewed from below upward) along the longitudinal axis of the stomach. This brings the dorsal aspect of the stomach toward the fetus' left side, and the ventral aspect now points to the right. The two mesenteries follow this rotation, with the ventral mesentery finally extending horizontally from the stomach to the liver as the lesser omentum. The cranial portion of the dorsal mesentery runs horizontally to the spleen laterally as the gastrosplenic ligament, and it contains the short gastric vessels. A second, lesser rotation, in conjunction with a growth differential favoring greater growth on the dorsal (now left lateral) side of the stomach, leads to the organ's final position. This rotation is clockwise around the body's anterior–posterior axis when viewed from the front and brings part of the now left lateral (formerly dorsal) side of the stomach to point caudally. This part of the stomach still has the caudal portion of the stomach's dorsal mesentery attached, which now grows quite quickly caudally, forming a two-layer fat pad that covers the bowel and extends to the pelvis. The two fat layers fuse to each other and to the colon and become the greater omentum. The space now created behind the stomach is called the lesser sac. It has one entrance, the epiploic foramen (foramen of Winslow), which is located beneath the free edge of the ventral mesentery that now extends from the area of the gastroduodenal junction to the liver.[8]

The final shape of the stomach along with the various epithelial cell types that constitute its mucosal lining create distinct areas: the cardia around the gastroesophageal (GE) junction; the fundus, which projects cephalad from the gastroesophageal junction; the body, which is the vast majority of the gastric reservoir; and the antrum, the portion of the stomach immediately before the pylorus. There are three muscle layers of the stomach: the outer longitudinal, the intermediate circular, and the inner oblique. The three layers permit complex mixing and churning movements that help begin the process of digestion.

The blood supply to the stomach is extremely rich and is derived principally from the celiac axis and superior mesenteric artery. Four major vessels are felt to provide the stomach with blood: the right and left gastric and the right and left gastroepiploic. Also important are the short gastric arteries off the splenic artery. Venous drainage is via the portal system, with the exception of the gastroesophageal junction, which can drain to the systemic system via esophageal veins (critical to the development of esophageal varices). The blood supply to the stomach is so redundant that the organ can survive if three of the four major arteries are divided, which is key in operative planning.

The gastric epithelium is made up of a diverse cell population distributed in a regionally specific manner. The early gastric mucosa is initially a stratified or pseudostratified

columnar epithelium that later becomes cuboidal. This mucus-secreting cuboidal epithelium then becomes peppered with gastric pits that are first observed between gestational weeks 6 and 9. By 20 weeks, the mucosa of the stomach is mature in appearance. At the base of the gastric pits are the gastric glands, which contain the effector and regulator cells of gastric secretion.[8]

The different cell populations of the gastric glands in various regions of the stomach allow the stomach to be histologically and functionally compartmentalized. Parietal cells are found predominantly in the gastric fundus and body and less often in the proximal antrum and can be identified in gastric glands as early as week 10. They produce both hydrochloric acid and intrinsic factor under complicated regulatory control. Chief cells are found principally in the gastric fundus and body, first appearing in gestational week 12. They are located exclusively at the base of the gastric glands, where they synthesize, store, and secrete pepsinogen. Pepsinogen is hydrolyzed to the active proteolytic enzyme pepsin in the acid environment of the stomach.

Enteroendocrine cells are present throughout the stomach, duodenum, and distal intestine. Because of their ability to produce biologically active amines and peptides and to internalize certain precursor molecules, they are referred to as *amine precursor uptake and decarboxylation* (APUD) cells. There are many distinct types of enteroendocrine and neuroendocrine cells found in the gastric mucosa. These cells are among the first to populate the gastric glands, appearing at 8-9 weeks. The most common and well characterized are the G cells, which produce gastrin, and the D cells, which produce somatostatin and amylin. These cells predominate in the gastric antrum. Other enteroendocrine cells are ubiquitous both within the gastric glands and within the duodenal wall. They are responsible for producing such diverse amines and peptides as histamine (from the enterochromaffin-like cells), serotonin, dopamine, vasoactive intestinal peptide (VIP), glucagon, gastric-releasing peptide (GRP), motilin, and ghrelin. Interestingly, the A cells, which produce glucagon, are present only in fetal and neonatal glands. Considered along with the trophic effect of many GI hormones, this suggests a growth and differentiation role for these substances, along with the digestive and regulatory roles they are currently known to have.

All three components of the autonomic nervous system—sympathetic, parasympathetic, and enteric—innervate the stomach. The parasympathetic and enteric predominate. Sympathetic innervation is predominantly inhibitory to GI function and primarily uses the postganglionic neurotransmitter norepinephrine.[5] The parasympathetic pathways mediated by acetylcholine are generally stimulatory. The enteric nervous system (ENS), on the other hand, uses a variety of neurotransmitters, including dopamine, somatostatin, VIP, GRP, ghrelin, and cholecystokinin. The ENS is the largest and most complex compartment of the autonomic nervous system and comprises more than 10^9 resident neurons within the wall of the GI tract. The ENS is anatomically separate from the CNS (i.e., the sympathetic and parasympathetic systems).

Sympathetic innervation originates from cell bodies within the thoracic spinal cord and extends through presynaptic fibers in the greater splanchnic nerve to postsynaptic neurons in the celiac ganglion, whose axonal fibers follow blood vessels into the gastroduodenal wall. Parasympathetic presynaptic nerves originate in the brainstem and follow the vagus nerves to the stomach. ENS precursors differentiate from neuroblasts located in the vagal area of the neural crest and migrate with the vagus nerves to the developing GI tract. These ENS neurons then further differentiate, proliferate, and establish connections to each other, to other autonomic pathways, and to developing gastric secretory and muscle cells. There is significantly more ENS than CNS activity within the GI tract, suggesting a more powerful role for intrinsic (ENS) control than for extrinsic (CNS) control.

The stomach has two distinct functional zones based on motor activity differences. The proximal zone, which includes the fundus and the proximal third of the body of the stomach, serves as a reservoir in which an ingested meal is stored. Its ability to distend without increasing intraluminal pressure is important during bolus feeding. The proximal stomach generates slow, sustained tonic contractions under CNS control via the vagus. This action creates a constant pressure gradient that controls the passage of material through the stomach. Vagotomy significantly impairs this function, causing rapid emptying of fluids.[13]

Motor activity in the stomach distal to the proximal third of the body of the stomach is characterized by spontaneous depolarizations that result in phasic, directional contractions. This gives this portion of the stomach the ability to mix and grind solid food and to empty mixed food particles into the duodenum in a controlled fashion. During the fasting state, gastric activity follows a 90- to 120-minute repetitive pattern called the *interdigestive migrating motor complex*. This four-phase complex runs from mechanically silent to coordinated contractions that empty the gastric lumen of all indigestible materials. The fed state occurs when the migrating motor complex is interrupted by the arrival of ingested food. Now, the stomach begins forceful, nonpropagated contractions in the distal stomach coupled with coordinated contractions of the pyloric sphincter that churn food into small particles. A gastric pacemaker located along the greater curvature at the proximal boundary of the distal zone triggers these contractions at a rate of three to four cycles per minute. When the average particle size reaches 1 mm, chyme is allowed to empty into the duodenum. Complex CNS and ENS coordination permits adequate breakdown of the food and ensures that the rate of gastric emptying is adjusted to provide an isocaloric flow of nutrients into the duodenum over time.

Gastric secretory function evolves early in development. By 10 weeks' gestation, parietal and enteroendocrine cells have begun to differentiate, and by 12-13 weeks, gastrin, hydrochloric acid, pepsin, and intrinsic factor (IF) can all be detected. Mucus and bicarbonate secretion commences

later, at about the 16th week. The gastric luminal pH of full-term newborns is neutral, but it is as low as 3.5 within a few hours. By 48 hours, the pH is between 1.0 and 3.0. Premature infants have a prolonged period of alkalinity—often many days—that is related to the degree of prematurity.

The production and secretion of hydrochloric acid by gastric parietal cells is governed by complex neurocrine, endocrine, and paracrine pathways, with little evidence for a final common pathway. The parietal cell can receive input and respond to a large variety of inputs, making its regulation by medical and surgical treatments difficult. Gastric acid has many functions. One is to facilitate protein digestion, but the lack of malabsorption problems in patients with achlorhydria indicates that this role may not be critical. Normal acid secretion does, however, play an integral role in initiating the digestive process. Gastric acid also creates a barrier to the entrance of bacteria into the GI tract. This not only protects the upper aerodigestive tract but also insulates the bacteria downstream from constant challenges from above. This is consistent with data that acid suppression therapy for gastroesophageal reflux may be associated with a higher incidence of lower respiratory tract infections.[9]

Duodenum, Pancreas, and Biliary System

The duodenum is the short retroperitoneal portion of the GI tract that connects the foregut to the midgut. At its proximal end, it connects to the outlet of the stomach, the pylorus, and it ends a short distance later at the ligament of Treitz, where the GI tract becomes an intraperitoneal organ once again and becomes the jejunum. Like the stomach, the duodenum undergoes a rotational process that brings it to its final C-loop configuration (Fig. 81.1). This 270-degree counterclockwise rotation swings the duodenum under the superior mesenteric artery. During this rotation, the duodenum's dorsal mesentery shortens, which allows the duodenum to become fixed in the retroperitoneal position across the upper abdomen from the pylorus (to the right of midline) to the ligament of Treitz (to the left of midline). This fixation is absolutely critical, because from the ligament of Treitz to the cecum (the next retroperitoneal portion of the GI tract located in the right lower quadrant), the bowel is on a mesentery and free to float about the peritoneal cavity. The bowel thus becomes fixed within the peritoneal cavity at the two most widely separated points available—the ligament of Treitz in the left upper quadrant and the cecum in the right lower quadrant. Because the mesenteric base is, therefore, so broad, it is impossible for the floating, intraperitoneal bowel to twist on its mesentery, thus compromising its own blood supply. However, any failure of proper rotation and fixation of the bowel can lead to the twisting of the bowel on its mesentery (i.e., volvulus) and the subsequent catastrophe of interruption of the flow of blood to the bowel.

The rotation of the bowel occurs during the 6th-10th weeks of gestation. Concurrently, there is a rapid epithelial

• **Fig. 81.1** Normal rotation of the developing gut. Eight weeks' gestation: elongation of the midgut and superior mesenteric artery, herniating into the umbilical stalk. Nine and eleven weeks' gestation: 270-degree counterclockwise rotation of duodenal-jejunal segment and 270-degree counterclockwise rotation of ileo-colic segment. Twelve weeks' gestation: final orientation of the normally rotated gut.

proliferation (along with the rectum and esophagus) that obliterates the hollow lumen and converts the duodenum to a solid, cordlike structure. Vacuoles then appear and gradual recanalization occurs. The distal duodenum does not appear to pass through a solid phase. Defects in this proliferation and recanalization process are believed to lead to the problems of duodenal atresia, web, and stenosis.

The duodenum is divided into four portions corresponding to the curvatures of the C loop. The blood supply is derived from the celiac axis through the superior pancreaticoduodenal branches of the gastroduodenal artery and the superior mesenteric artery through the inferior pancreaticoduodenal branches. Consistent with the location of the original liver bud, this transition from celiac to superior mesenteric blood supply defines the transition from foregut to midgut. A consistent landmark in the medial portion of the duodenum, near the end of the foregut, is the ampulla of Vater, which represents the confluence of common bile duct and pancreatic ducts and their entry into the duodenum.

The liver and biliary system develops within a bud along the free edge of the ventral mesentery, with stomach

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

and bowel rotation bringing them to their final location in the right upper quadrant.[2] Also within this bud is the primordial ventral pancreas. Opposite this ventral pancreatic bud (including liver and biliary primordium) is the dorsal pancreatic bud. During rotation, the ventral pancreatic bud fuses to the dorsal bud and becomes one organ. Failure of this rotation leads to the problem of annular pancreas. The biliary and pancreatic drainage systems also fuse during rotation so that the common bile duct descends in the remnant-free edge of ventral mesentery, along with the portal vein and hepatic artery, then passes behind the duodenum to join with the main pancreatic duct at the ampulla of Vater. This main pancreatic duct is formed from the confluence of the original ventral pancreatic duct with the distal dorsal pancreatic duct. The proximal dorsal pancreatic duct remains as the accessory pancreatic duct. The biliary and pancreatic ductal systems are complete by the 10th-12th gestational week. With so many rotation and fusion requirements to produce the "classic" biliary-pancreatic ductal anatomy, it is no wonder that one sees the "classic" form less than 50% of the time. Blood supply to the gallbladder arises from the celiac artery.[8] The layers of the duodenum are the muscularis, the submucosa, and the mucosa. The muscularis is made up of smooth muscle cells, which are divided distinctly into two separate layers: an outer, longitudinal layer and an inner, circular layer. The submucosa is a band of dense connective tissue lying just under the mucosa. The mucosa is the innermost layer and is composed of three distinct layers: the muscularis mucosa, the lamina propria, and the epithelial cell lining. The most striking feature is the villi, 1.5 mm tall in the duodenum and decreasing in size through to the ileum. Crypts of Lieberkühn surround the base of each villus and average one-third to one-fourth the height of the villi.

Like the rest of the small bowel, the duodenal mucosa is made up mainly of enterocytes, tall, columnar epithelial cells that are responsible for absorption. The duodenum is also richly populated with enteroendocrine cells, along with goblet cells, Paneth cells, and lymphoid aggregates of Peyer patches. The enteroendocrine cells are stimulated by nutritional substrates delivered from the stomach, and they secrete mediators that regulate a variety of digestive processes. Secretin is produced by the duodenal S cells in response to luminal acid, stimulating bicarbonate secretion from the pancreas, liver, and duodenal Brunner glands and mucosal cells. Cholecystokinin, produced by duodenal I cells in response to certain fatty acids and amino acids, stimulates gallbladder contraction and pancreatic exocrine secretion.

The pancreas is a central metabolic organ with key roles in both exocrine and endocrine function.[6] It is the primary source of digestive enzymes: More than 20 different enzymes are synthesized and stored in the secretory acini. The proteolytic enzymes such as trypsin, chymotrypsin, and carboxypeptidase are secreted as inactive proenzymes. They are converted to active enzymes by enterokinase, an intestinal brush border enzyme, when they reach the duodenal lumen. These enzymes, in turn, can activate other proenzymes. Pancreatic amylase and lipase are secreted in their active form. The secretory acinar cells are under complex CNS, ENS, and hormonal regulation. The ducts that drain the acini are lined by cells that secrete water and bicarbonate. Secretin stimulates this fluid and bicarbonate secretion, which raises intestinal pH and thereby facilitates pancreatic enzyme activity.

The pancreas also has an essential role in the hormonal regulation of metabolism and glucose homeostasis. These endocrine functions are provided by the islets of Langerhans, which make up about 1%-2% of the pancreatic mass. These 1-2 million islets are more plentiful on the pancreatic tail and are also under complex CNS, ENS, and hormonal control. There are four distinct cell types within the islets: alpha cells for glucagon production, beta cells for insulin, gamma cells for somatostatin, and PP cells for pancreatic polypeptide.

Small Intestine

The small intestine is the major digestive and absorptive portion of the GI tract. The gut initially herniates out of the fetus's abdominal domain and lengthens rapidly during the 6th-12th weeks of gestation.[1] As described earlier, on reentry into the abdominal cavity, the small bowel undergoes a 270-degree twist around the superior mesenteric artery axis to bring it into its final anatomic position. This positioning is complete by the 20th week. The "small" of small intestine clearly relates only to the circumference of the structure, as its length is anything but small. The small intestine typically measures between 200 and 300 cm at birth in the full-term neonate after doubling its length between 26 and 38 weeks of gestation. After birth, the small intestine continues to grow, finally reaching its maximum length of 600-800 cm after 4 years of age.[12] During this time, and continuing through puberty, there are also increases in intestinal diameter, along with development of the plicae circulares, villi, and microvilli that enlarge the absorptive surface area of the small intestine from about 950 cm^3 at birth to 7500 cm^3 in the adult. The blood supply of the small intestine is provided solely by branches of the superior mesenteric artery running in the mesentery of the small intestine.

The circular muscles of the small intestine appear at 6 weeks of gestation and the longitudinal muscles at 8 weeks. Neuroblasts appear at 7 weeks of gestation, and the myenteric and submucosal plexuses are noted to appear between the 9th and 13th weeks. Although there is some peristalsis noted as soon as the plexuses appear, it is poorly coordinated. The appearance of myenteric muscle contractions at 32-34 weeks leads to more coordinated contractions, but intestinal transit time at this gestation time is as long as 9 hours—nearly twice as long as in the term infant. It is not until about 38 weeks' gestation that the myenteric muscle contractions are fully present and fasting motor activity is mature. Even so, limited feedings can be accomplished in

infants as young as 25 weeks, because they appear to stimulate contractions, albeit immature.

Villi appear during weeks 8-11 and acquire their final, fingerlike shape by week 14. However, the villi remain shorter in the ileum than in the jejunum, leading to a fourfold greater absorptive area in the jejunum. Microvilli appear and the enterocytes are morphologically mature and display a well-organized brush border by 14 weeks of gestation. Endocrine cells appear at 9 weeks and continue to proliferate, with all the various gut peptide hormones and neurotransmitters present by 20 weeks' gestation. These include enteroglucagon, neurotensin, gastrin, pancreatic polypeptide, motilin, and VIP. Although all are present at birth, many of them show remarkable increases in basal levels during the first 2 weeks of life in the fed infant. Interestingly, when feedings are withheld in infants, intestinal growth and functional maturation are delayed and basal levels of the intestinal peptides remain low, suggesting some form of cause-and-effect relationship.

It is generally held that the enteric ganglion cells are derived from vagal neural crest cells. As mentioned, neural crest–derived neuroblasts first appear in the developing esophagus at 5 weeks. They then begin a migration down to the anal canal in a craniocaudal direction during the 5th-12th weeks of gestation. The neural crest cells first form the myenteric plexuses just outside the circular muscle layer. The mesenchymally derived longitudinal muscle layer then forms, sandwiching the myenteric plexus after it has been formed in the 12th week of gestation. Finally, the submucous plexus is formed by neuroblasts, which migrate from the myenteric plexus across the circular muscle layer and into the submucosa and the mucosa. This also progresses in a craniocaudal direction, but it occurs during the 12th-16th weeks of gestation.

Colon, Rectum, and Anus

The colon is a continuation of the intestine with two basic functions: (1) the absorption of water and electrolytes and (2) the storage and elimination of feces. Its absorptive function is significant in that the colon absorbs more than 80% of the water left after passage through the small intestine. The rectum and anus are critical in the complex act of controlled defecation.

The colon is divided into six areas: the cecum, the appendix, and the ascending, transverse, descending, and sigmoid colon. Like the duodenum, the colon also undergoes a 270-degree counterclockwise rotation during the 10th-12th weeks of gestation to bring it into the proper position.[3] Although this is nearly concurrent with the duodenal rotation, the two are not completely codependent. Either one, or both, can go astray, so it is possible to have a nonrotated colon with a properly rotated duodenum and vice versa. If properly rotated, the cecum lies in the right lower quadrant, the ascending colon along the right gutter, the transverse colon from the hepatic flexure to the splenic flexure, and the descending colon along the left gutter; the sigmoid colon connects the descending colon to the rectum approximately at the level of the third sacral vertebrae. The ascending colon and the descending colon are retroperitoneal structures with peritoneum covering only their anterior and lateral surfaces. The cecum is variably fixed—sometimes completely retroperitoneal (along with the appendix) and sometimes on a short mesentery. The transverse and sigmoid colon are on a mesentery. The posterior border of the greater omentum is also attached to the transverse colon.

The blood supply of the colon is supplied by both the superior and inferior mesenteric arteries. The watershed area between the distribution of the two vessels is typically located around the mid transverse colon to the splenic flexure. This also marks the boundary of the midgut and hindgut. The rectum is supplied by the inferior mesenteric artery as well as branches off the iliac arteries.

Although it is developmentally similar to the small intestine in general structure, the colon has unique elements. Most obvious is the concentration of the longitudinal muscle coat into three bands—the teniae coli. The teniae create sacculations, called *haustra*, that permit radiographic differentiation of the small from the large intestine after infancy. The mucosa of the colon is characterized by crypts of Lieberkühn, which are lined with absorptive, goblet, and endocrine cells.

The development of the anorectum requires unique attention, because problems result in a wide variety of anorectal malformations. As mentioned previously, during the 3rd week of gestation, the bilaminar germ disc transforms into a trilaminar disc of ectoderm, mesoderm, and endoderm. At either end of the embryo, the endoderm and ectoderm fuse, excluding the mesoderm from these areas and giving rise to the oropharyngeal and cloacal membranes. The former breaks down in the 4th week to give rise to the mouth, whereas the cloacal membrane does not open until the 8th week. Between weeks 4 and 6, it is widely held that the primitive gut tube at the level of the cloacal membrane gets canalized and partitioned into an anterior urogenital sinus and a posterior anorectum by the cranial-caudal growth of a mesodermally derived partition called the urorectal septum. Eventually, the urorectal septum fuses with the cloacal membrane, and the fusion site is called the *perineal body*. The newly formed anorectal canal remains closed by the posterior aspect of the cloacal membrane, which is now called the *anal membrane*. The ectoderm in this region then goes on to form the anal pit or proctodeum, so the distal third of the anal canal is eventually made up of ectoderm, the proximal two-thirds is made up of mesoderm, and the two cell types are divided by the anal membrane. The membrane breaks down during week 8, and the two cell populations fuse at what is called the *pectinate* or *dentate line*.

Aside from the previously described migration of neural crest cells to form enteric ganglion cells, the anorectum has an important neurologic milestone during the 4th week of gestation. At this time, spinal nerves from sacral levels 2, 3, and 4, which contribute to the peripheral parasympathetic

nervous system, form. In contrast to the motility problems noted with failure of migration and thus the absence of ganglion cells, problems related to the proper development of these spinal nerves during week 4 may lead to the proprioceptive and motility problems associated with anorectal malformations.

Key Points

- Gastrointestinal development requires maturation of various digestive, absorptive, and endocrine functions.
- Sympathetic, parasympathetic, and intrinsic enteric neurons all contribute to the maturation of gastrointestinal motility.
- The fore- and midgut undergo unique rotations during 6th-10th weeks of gestation, which ensure fixation in the peritoneal cavity and prevent twisting and remittent bowel obstruction.
- The colon acquires key absorptive and motility functions. Aberrant anorectal maturation may lead to a variety of anorectal malformations.

Acknowledgments

The author and editors acknowledge the important contributions of David K. Magnuson, Walter J. Chwals, and Robert L. Parry to the previous editions of this chapter, portions of which remain unchanged.

Gastrointestinal Reflux and Motility in the Neonate

ANNA MARIA HIBBS

Definitions

Gastroesophageal reflux (GER) is the physiologic retrograde passage of fluid from the stomach to the esophagus. Gastroesophageal reflux events occur in healthy infants multiple times per day. Gastroesophageal reflux disease (GERD) is the pathologic condition wherein such retrograde flow into the esophagus causes medical complications.[106] Regurgitation and vomiting are common and often nonpathologic complications of GER.[51] A definitive determination of GERD in infants is often elusive. Esophageal complications of GERD are often indirectly suggested because of difficulty in directly visualizing the esophagus in very small patients; for instance, infants who have arching, discomfort, or fussiness may be suspected of having esophagitis. Putative extraesophageal GERD-defining complications in infants, such as apnea or worsening of respiratory disease, are controversial, in large part, owing to lack of strong evidence in the literature.[33] In most cases, no single test can diagnose or exclude GERD, and a comprehensive approach including testing and clinical assessments over time is needed to make the diagnosis.

Physiology of Gastroesophageal Reflux

Upper Gastrointestinal Motility and Physiologic Gastroesophageal Reflux

By as early as 26 weeks' gestational age, esophageal motor function is well developed in infants.[67,68] In both term and preterm infants, swallowing triggers coordinated esophageal peristalsis and lower esophageal sphincter (LES) relaxation.[68] However, the velocity of propagation is significantly slower in preterm compared with term infants.[45] Esophageal activity unrelated to swallowing often takes the form of incomplete or asynchronous waves; this type of nonperistaltic motor activity occurs more frequently in preterm infants than in adults.[68] Infants with functional or anatomic esophageal abnormalities, such as those with repaired esophageal atresia or neuropathy affecting smooth muscle, are at risk for impaired esophageal clearance of fluid.

Gastroesophageal reflux events are part of the normal functioning of the upper gastrointestinal tract. The lower esophageal sphincter, which limits the retrograde passage of air and fluids from the stomach to the esophagus, is made up of intrinsic esophageal smooth muscle and diaphragmatic skeletal muscle.[59] Several manometry studies have documented good LES tone, even in extremely low birth weight infants.[68-70] In both preterm and term infants, just as in more mature patients, transient lower esophageal sphincter relaxations (TLESRs) unrelated to swallowing are the major mechanism allowing GER by dropping lower esophageal pressure below gastric pressure, thereby promoting the retrograde passage of fluid.[20,68,70] Transient lower esophageal sphincter relaxations are frequent in preterm infants, occurring several times per hour, although the majority of TLESR events are not associated with GER.[20] A similar frequency of TLESRs is seen in infants with and without GERD, but a higher percentage of acid GER events during TLESRs occurs in infants with GERD.[20] It has been hypothesized that increased intraabdominal pressure during a TLESR, for instance due to straining, may increase the likelihood of a GER event. Although LES relaxations also occur during normal swallowing, these are less often associated with GER events than isolated TLESR events,[20] presumably owing to the coordinated waves of esophageal muscular activity propelling fluid antegrade during a swallow. The number of GER events and the height the fluid bolus reaches in the esophagus are increased after feeding; refluxate after feeding is less acidic than fluid refluxed before feeding.[93] Other factors also promote GER in infants, particularly patients in a neonatal intensive care unit (NICU). For instance, infants ingest a much higher volume per kilogram of body weight, approximately 180 mL/kg per day, than older children and adults.[80] In the NICU population, preterm and term patients with nasogastric or orogastric feeding tubes may experience more reflux episodes because of mechanical impairment of the competence of the LES.[56,79] Infants with anatomic abnormalities of the structures that comprise the LES, such as infants with congenital diaphragmatic hernia, are at risk for experiencing a higher-than-normal frequency of GER events.

Abstract

Gastroesophageal reflux is a frequently occurring normal physiologic process, primarily associated with relaxations of the lower esophageal sphincter. Gastroesophageal reflux disease is defined as GER that triggers complications or morbidities. Nonpharmacologic therapy, including thickened feeds, is the mainstay of therapy. Because of their underlying developmental trajectories, many infants experience an improvement in symptoms over several weeks. Pharmacologic therapy has not been shown to be safe or effective.

Gastric emptying also plays a strategic role in upper gastrointestinal tract function. Between 25 and 30 weeks' gestational age, gastric emptying time seems to be inversely and linearly correlated with gestational age at birth. Simultaneously decreasing the osmolality and increasing the volume of feeds may accelerate gastric emptying, although changes in osmolality or volume alone did not seem to have a significant effect.[81] Human milk also promotes gastric emptying, but fortification may increase emptying time.[14,26] Unfortunately, although breastfeeding is protective against GERD, mothers whose infants were diagnosed with reflux are more likely to wean.[14] In formula-fed infants, several small studies suggest that prebiotics and probiotics may speed gastric emptying time.[41,42] The literature on the impact of hydrolyzed formulas is mixed.[17,57,96] However, although it seems logical that slower gastric emptying would promote GER because of increased fluid and possibly pressure in the stomach, a study of the relationship between gastric emptying and GER in preterm infants found no association.[25]

Gastroesophageal reflux events are frequent in healthy preterm and term infants. Among 509 healthy asymptomatic infants age 3-365 days, the mean number of acid reflux episodes in 24 hours was 31.28, with a standard deviation of 20.68.[105] The reflux index, the percent of time the esophageal pH was less than 4, ranged from less than 1%-23%, with the median and 95th percentile being 4% and 10%, respectively. Among the neonates in this study, the 95th percentile for the reflux index was as high as 13%. In a smaller study of 21 asymptomatic preterm infants, continuous combined esophageal pH and impedance monitoring detected refluxed fluid in the esophagus by impedance for a median of 0.73% (range, 0.3%-1.22%) of the recording time, and acid exposure detected by pH monitoring for a median of 5.59% (range, 0.04%-20.69%) of the recording time. These studies make it clear that GER events occur frequently in asymptomatic infants, and a wide range of reflux measurements may be seen in healthy preterm infants without GERD.

In a study of infants in general pediatric practice, half of all parents reported at least daily regurgitation at 0-3 months of age.[61] The peak prevalence occurred at 4 months, with 67% reporting regurgitation. Thus benign regurgitation was the norm in the first few months of life. Parents reported regurgitation to be a problem when it was associated with increased crying or fussiness, perceived pain, or back arching. The prevalence of regurgitation perceived as a problem peaked at 23% at 6 months and was down to 14% by 7 months. The majority of these children did not receive treatment for GERD from their pediatrician. Infants who did and did not experience frequent regurgitation between 6 and 12 months of age were followed up a year later.[62] At this time, none of the parents described regurgitation as a current problem. Infants with frequent spitting at 6-12 months of age did not experience more infections of the ear, sinuses, or upper respiratory tract, nor did they experience more wheezing.

It is also important to remember that regurgitation and vomiting are not necessarily caused by GER or GERD. Clinical correlation is needed to determine whether other pathologic processes are present. The differential diagnosis includes gastrointestinal obstruction, motility abnormalities, infection, inborn errors of metabolism, adrenal insufficiency and other hormonal abnormalities, and neurologic abnormalities, including increased intracerebral pressure. Commonly, milk protein allergy may mimic GERD.[51]

The distinction between GER and GERD is important when communicating with families. One study showed that in infants with a label of GERD, families were more likely than those with a GER label to be interested in medications, even when they were told that those medications were likely ineffective.[84]

Gastroesophageal Reflux Disease

Symptoms and Complications

Identifying whether troublesome symptoms are in fact caused by reflux can be challenging in infants.[83,87] Symptoms frequently attributed to GERD in infants include regurgitation, Sandifer posturing, worsening of lung disease, food refusal or intolerance, apnea, bradycardia, crying or fussiness, and stridor. Regurgitation may be a symptom of GERD in infants but in itself is neither necessary nor sufficient to make a diagnosis.[87] Clustering regurgitation with other symptoms may increase the accuracy of diagnosis, as demonstrated by the I-GERQ-R infant reflux questionnaire.[49,87] However, the validity of such questionnaires has not been established in the NICU population, which includes preterm infants and sick term neonates who have multiple other potential reasons for the symptoms frequently attributed to GERD.

Although GERD and bronchopulmonary dysplasia (BPD) seem to be associated, causality has not been determined.[1,27,31,47,87] Patients with increased work of breathing may generate more negative intrathoracic pressures, thereby promoting the passage of gastric contents into the esophagus. Conversely, aspirated refluxate could injure the lungs, thereby promoting chronic lung disease. Finally, immaturity and severity of illness predispose to both conditions, and there may be no causal link in the majority of patients. In addition, part of the apparent association between BPD and GERD may be the result of an increased index of suspicion for GERD in patients with BPD, leading to increased rates of diagnosis.[31]

A similar issue exists for apnea in premature infants. Although in animal models, esophageal stimulation may trigger airway protective reflexes,[95] there is insufficient evidence in human infant patients to confirm that reflux causes apnea.[29,87] In fact, apnea may itself trigger reflux.[48,66] Finally, immature infants are simply prone to both apnea and reflux, and there may be no causal association.[94] In a cohort of infants referred for overnight esophageal and respiratory monitoring for suspicion of GERD-induced

apnea, desaturation, or bradycardia, fewer than 3% of all cardiorespiratory events were preceded by a reflux event.[21] Conversely, 9.1% of reflux events were preceded by a cardiorespiratory event. Thus it was more common for a cardiorespiratory event to precede reflux than for reflux to precede a cardiorespiratory event. Even in this population referred for suspicion of GER-triggering cardiorespiratory events, only a small minority of cardiorespiratory events were in fact preceded by reflux. However, data from small or moderately sized research cohorts cannot rule out the possibility that reflux can trigger the majority of cardiorespiratory events in a small subset of patients. Because bedside recording of apnea events is known to be inaccurate, correlation of apnea with feeding or reflux events in a specific patient requires simultaneous respiratory and esophageal monitoring.

It is unclear what component of the refluxate triggers complications. Acidity is often implicated, but it is not clear which, if any, complications are triggered by acidity.[87,94] The other characteristics of the refluxate that have been postulated to be associated with symptoms include the height of the bolus in the esophagus, the volume of the bolus, or the pressure exerted on the esophagus. One study found an association with acid GER into the middle or proximal esophagus and cough in dysphagic preterm neonates.[91]

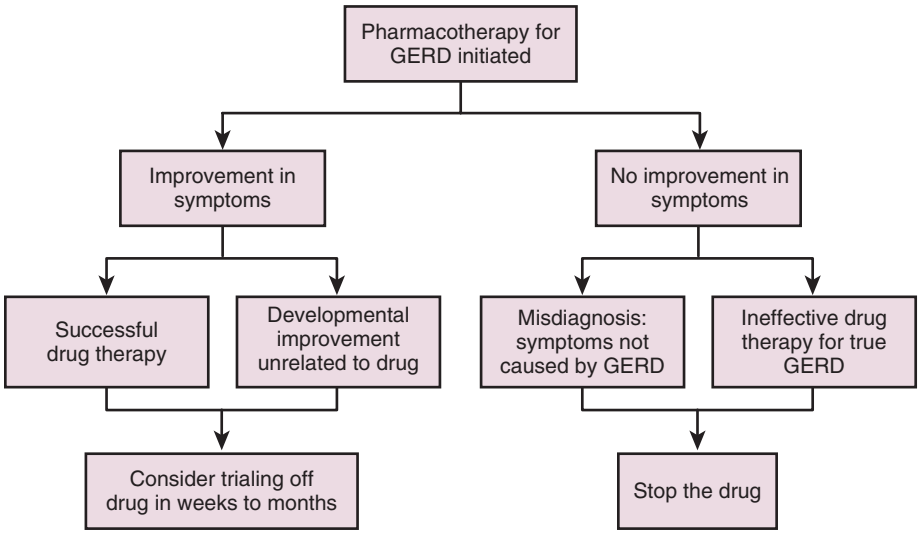
Diagnostic Tools

Numerous tests exist to measure acid and nonacid GER in infants. Because the definition of GERD is based on clinical complications and not physiologic measurements, most available tests for GERD cannot definitively confirm or exclude the diagnosis. Numerous GER events are not sufficiently diagnostic of GERD without evidence of clinical complications. Because the diagnosis of GERD relies on the presence of clinical complications, no physiologic test that only characterizes the frequency or characteristics of GER events in a patient can by itself confirm the diagnosis of GERD. Esophageal monitoring for 12-24 hours gathers the best data on the timing and frequency of GER events. Esophageal pH probes measure acid reflux, and esophageal multichannel intraluminal impedance (MII) measures the presence of fluid in the esophagus regardless of pH. Multichannel intraluminal impedance and pH sensors can be combined in one probe. Esophageal monitoring may be correlated with respiratory monitoring or with the timing of a clinical symptom in order to attempt to temporally correlate symptoms and GER events. However, showing that a GER event preceded a clinical event is not proof of causality.

An upper gastrointestinal radiographic series is a poor measure of the frequency or severity of GER, because it captures only a brief window in time. Capturing a GER event on an upper gastrointestinal series is not informative with regard to either the frequency of GER or the diagnosis of GERD. However, this study may be useful in ruling out anatomic abnormalities that may mimic GERD.

A nuclear medicine scintigraphy study can identify postprandial reflux and aspiration and quantify gastric emptying time. Because of a lack of age-specific norms and the limited focus on postprandial GER, it is not recommended as a routine test for infants suspected of having GERD.[51,106] However, in an infant suspected of chronically microaspirating refluxed fluid, it can document this complication and confirm the diagnosis of GERD. In addition, scintigraphy allows for the calculation of gastric emptying time, which may be useful in infants in whom delayed gastric emptying is part of the differential diagnosis.

Endoscopy with visualization and biopsy of the esophagus can document esophagitis caused by acid or conditions mimicking GERD, such as eosinophilic esophagitis. Unfortunately, many preterm and young term infants are too small for endoscopy to directly assess esophagitis, and so esophageal symptoms can only be inferred from vague symptoms such as food refusal or fussiness.



Treatment

The general categories of interventions available to treat GERD are conservative nonpharmacologic, pharmacologic, and surgical. The natural history of GERD, often with improvement within a few weeks,[73,74,108] must be remembered when interpreting the impact of an intervention. Treatment failures may result from either a failure of the medication to achieve its intended action or from the erroneous application of drugs to symptoms not caused by GERD. Apparent successes may result from either a true drug effect or from the natural resolution of symptoms with maturation (Fig. 82.1). Because the goal of therapy is to treat GERD, not physiologic GER, the gold standard for gauging therapeutic success must be improvement in symptoms or complications, not simply improvement in physiologic measures. The most effective treatment for GERD is time and maturation, and so expectant conservative management is the mainstay of therapy in most cases. With regard to pharmacologic therapy, the American Academy of Pediatrics Section on Perinatal Pediatrics Choosing Wisely campaign advised, "Avoid routine use of anti-reflux medications for treatment of symptomatic gastroesophageal reflux disease (GERD) or for treatment of apnea and desaturation in preterm infants."[37]

Conservative Nonpharmacologic Management

Commonly used conservative interventions for GERD include positioning, thickening feeds, and decreasing the volume while increasing the frequency of feeds. When milk protein allergy is thought to be mimicking or triggering GERD, changing to a more elemental formula may also be appropriate. In the run-in period for a randomized control trial of a pharmacotherapeutic intervention for GERD, the majority of infants seemed to improve over a 2-week period with such a multipronged conservative management strategy, although this effect simply could also be attributed to time and maturation.[74]

• **Fig. 82.1** Approach after pharmacotherapy has been initiated. Gastroesophageal reflux disease (GERD) medications should be discontinued in infants who fail to improve on therapy. Due to rapid maturational changes, even apparently effective medication therapy may only be needed for a limited duration.

Although typical positioning precautions for an infant with a diagnosis of GERD include elevating the head of the bed, there is not an advantage to supine upright versus supine flat positioning.[13] Prone positioning seems to be associated with fewer GER events than supine but is generally contraindicated because of the increased risk of sudden infant death.[3,13] Lateral positioning with the right side down results in more frequent reflux events than left lateral positioning, but it is not clear whether this results in more symptoms.[71]

Thickening feeds has been shown to decrease episodes of clinical vomiting, although it does not seem to decrease physiologic measures of GER.[13,24,38] Feeds may be thickened by adding a thickening agent or using a prethickened commercially available formula. Common thickeners include rice, carob, cornstarch, and locust-bean gum. Rice and some prethickened rice-based formulas require gastric acidity to fully increase their viscosity, so their action may be impaired by drugs that block gastric acidity.[107] An insufficient number of large trials have been conducted to assess the safety of thickening agents in infants, and concerns have been raised about the potential for various thickening agents to cause diarrhea, increased cough, poor growth, and nutrient malabsorption.[38] The efficacy and safety of thickened feeds have not been well studied in preterm infants. A US Food and Drug Administration (FDA) warning cautioned against the use of one brand of commercial thickener in preterm infants because of reports of late-onset NEC.[103] In addition, concerns about the arsenic content in infant rice cereals have raised concerns about their use as thickeners.[11,46]

Drugs That Increase Gastric pH

Histamine-2 (H_2) receptor antagonists and proton pump inhibitors (PPIs) decrease gastric acidity. These drugs were developed to treat esophagitis and prevent Barrett's esophagus in adults. Increasing the pH of refluxate is thought to decrease esophageal mucosal damage and its associated discomfort. Proposed complications of reflux in NICU patients, such as food refusal, arching or fussiness, and pharyngeal or vocal cord edema, could theoretically stem from the effect of acid on the esophagus or airway. Because of either a limited capacity to produce acid or frequent buffering of gastric contents by milk feeds, many infants may experience less acidic GER(D) than older patients. Acid GER predominates preprandially, and nonacid GER predominates postprandially.[15,93] In fact, the majority of GER events in infants are nonacid.[15,93] However, at least some preterm infants are able to experience significant acid GER, as measured by an esophageal pH of less than four for more than 10% of the time.[22] However, it remains unclear if acidity is the mechanism by which reflux causes complications in infants.[87,94]

Pharmacologically increasing gastric pH raises some potential safety concerns. Gastric acidity seems to play a role in defense against infection. The use of H_2 receptor antagonists in preterm infants has been associated with an increased risk of necrotizing enterocolitis,[34] although it is not clear if this is a causal relationship. However, one small study did show that gastric acidification decreases necrotizing enterocolitis.[12] Infants treated with ranitidine have been demonstrated to have higher rates of gastric colonization with bacteria or yeast, although an increase in infection was not seen in this study.[18] Ranitidine was associated with increased late-onset sepsis in NICU patients in a cohort study; however, confounding by indication or severity of illness cannot completely be excluded as the cause of this association.[8] In older patients, an association between acid suppression and lower respiratory tract infections, including ventilator-associated pneumonia, has been proposed but remains controversial.[4,6,10,16,50,58,86,98,112]

Histamine-2 Receptor Antagonists

Examples of H_2 receptor antagonists include ranitidine, cimetidine, and famotidine. They block the H_2 receptor in acid-producing gastric parietal cells. Parietal cells continuously produce a baseline amount of HCl, even when they are not stimulated by histamine. Histamine-2 receptor antagonists suppress HCl production below physiologic

basal secretion rates and also decrease meal-triggered acid production. In addition, this class of drugs impairs the ability of other substances that stimulate acid production, such as acetylcholine and gastrin to trigger acid production.

There are few randomized clinical trials of H_2 receptor antagonists assessing their impact on the symptoms of GERD in term or preterm infants. In one small double-blind study, infants age 1.3-10.5 months were randomized to a higher or lower dose of famotidine and then a placebo-controlled withdrawal.[75] Infants receiving both doses experienced less emesis than those receiving placebo. Infants on the higher dose also demonstrated decreased crying time and volume of emesis. However, famotidine was also noted to be associated with agitation and a head-rubbing behavior that was attributed to headache.

In another randomized trial of H_2 receptor antagonists, very low birth weight (VLBW) infants were randomized to cimetidine or placebo, with the hypothesis that cimetidine could decrease CYP-mediated oxidative injury in the lung.[19] The goal of this study was not treatment of GERD, but it is one of the few studies in which VLBW infants were randomized to an H_2 receptor antagonist early in life. The trial was stopped by the data safety monitoring committee for increased death and intraventricular hemorrhage in the treatment group. The mechanism of these apparent adverse effects is unknown.

Finally, in a small crossover trial of combined ranitidine and metoclopramide therapy in preterm infants with bradycardia attributed to GERD, infants on therapy experienced significantly more bradycardic events than those receiving placebo.[108] This is biologically plausible, because histamine receptors are present in the heart, and ranitidine has been associated with bradyarrhythmias.[2,36,40,60,72,99,110] Of course, the lack of effect found in this study could also have been the result of misidentification of bradycardia as a symptom of GERD, an association that is not well supported by the literature. Even if reflux causes cardiorespiratory events in some infants periodically, the majority of cardiorespiratory events in preterm infants are not temporally related to GER, so bradycardia is likely to have poor specificity for the identification of GERD, and treatment of GERD is unlikely to impact the majority of cardiorespiratory events.[21]

Proton Pump Inhibitors

Proton pump inhibitors irreversibly block the gastric hydrogen/potassium adenosine triphosphatase that secretes hydrogen ions into the gastric lumen. Examples of PPIs include omeprazole, lansoprazole, dexlansoprazole, esomeprazole, pantoprazole, and rabeprazole. PPIs continue to be frequently prescribed for infants, despite a poor safety and efficacy profile.[5,9,92]

Proton pump inhibitors have not been shown to be effective in infants.[104] For instance, in a trial of outpatient infants who had failed a run-in period of nonpharmacologic management to lansoprazole or placebo, there was no difference in efficacy between the groups, with slightly more than half of the infants in each group experiencing improvement in symptoms.[73] However, there was a significant increase in serious adverse events in the lansoprazole group; among these adverse events, a nonsignificant increase in lower respiratory tract infections was seen.

The FDA released a class labeling change for PPIs based on findings that adults on high doses or prolonged courses of PPIs may experience more fractures.[101,102] The impact of acid suppression by PPIs or H_2 receptor antagonists on bone health in healthy neonates or preterm infants with osteopenia of prematurity is unknown. Acid suppression has also been associated with *Clostridium difficile* infection in some adults, with PPIs seeming to have a higher risk than H_2 receptor antagonists.[39,52] The relationship between PPI use and pathogenic or colonizing *Clostridium difficile* in infants has not been reported.

Drugs to Improve Motility

Drugs to promote gastrointestinal motility are thought to decrease GER by increasing gastric emptying or by improving esophageal motility and lower esophageal sphincter tone. The primary motility agents currently available in the United States are metoclopramide and erythromycin. Cisapride was removed from the market owing to the risk of serious cardiac arrhythmias and QT prolongation.[109] Domperidone is used in some countries but is not approved in the United States owing to concerns about arrhythmia, and studies have shown that oral domperidone can increase the QT interval in neonates.[23]

Metoclopramide

Metoclopramide is an antagonist of the dopamine D2 receptor subtype. A systematic review of metoclopramide therapy for GERD in infants found insufficient evidence for either efficacy or safety in this population.[35] Published after this, the previously described placebo-controlled crossover study of combined therapy with ranitidine and metoclopramide found an increase in bradycardia in the treatment group, although this finding is not necessarily attributable to metoclopramide.[108]

Metoclopramide acts on central dopamine receptors. Its ability to cross the blood–brain barrier also allows for neurologic side effects. Reported complications of metoclopramide in infants include irritability, drowsiness, oculogyric crisis, dystonic reaction, apnea, and emesis.[35] In 2009, the FDA issued a black-box warning about the risk of tardive dyskinesia with prolonged or high-dose metoclopramide exposure.[100] Tardive dyskinesia may persist after the drug is stopped and has no known treatment. Whether neonates or preterm infants are at greater or lesser risk of tardive dyskinesia than older patients has not been established. Metoclopramide has also been reported to cause lactation and gynecomastia in neonates.[54,78]

Erythromycin

Erythromycin is a high-affinity analog of the hormone motilin, which is normally produced by duodenal and jejunal enterochromaffin cells.[28,43,44] Stimulation of the

Downloaded for Anonymous User (n/a) at Egyptian Knowledge Bank from ClinicalKey.com by Elsevier on August 29, 2019.

motilin receptor promotes gastrointestinal migrating motor complexes. Infants with a gestational age greater than 32 weeks may be better able to respond to stimulation of the motilin receptor.[63,77] Prokinetic doses are typically lower than antimicrobial doses.

The majority of studies of erythromycin as a prokinetic in preterm infants have focused on improving feeding intolerance and not specifically on treating GERD.[63,77] In a masked randomized trial of erythromycin to promote feeding intolerance in 24 preterm infants, measuring GER as a secondary end point, erythromycin did not decrease the time to attain full enteral feeds, and there were no changes in GER as measured by esophageal pH probe.[65] Gastroesophageal reflux disease symptoms were not addressed in this study. In a review of 10 studies using erythromycin as a prokinetic to promote feeding tolerance, erythromycin seemed to promote the establishment of enteral feeding and was not associated with any adverse events, including pyloric stenosis or arrhythmia. However, rare or long-term adverse events had not been fully studied.[64]

Like cimetidine, erythromycin is an inhibitor of CYP3A.[82] It has been implicated in arrhythmias and QT prolongation when co-administered with cisapride, but also has a direct proarrhythmic effect by itself. Erythromycin blocks the rapidly activating component of the cardiac delayed rectifier potassium current, thereby prolonging repolarization in a manner similar to some antiarrhythmic drugs.[90] This action may prolong the QT interval and predispose the patient to torsades de pointes. Although cardiac adverse events have not been reported in the trials of erythromycin for feeding intolerance in preterm infants,[63] caution should be used in infants at risk for arrhythmia or in infants on other CYP3A inhibitors, such as cimetidine, methadone, and some protease inhibitors.[90]

Fundoplication

Several open and laparoscopic gastric fundoplication techniques may also be considered for infants with severe or life-threatening GERD when other attempts at management have failed and symptoms have not improved over time.[51,106] Fundoplication acts by artificially augmenting LES pressure. Very high rates of complications and recurrence of GERD symptoms have been reported.[32,53,55,76,85,88] In addition, infants with medical co-morbidities, such as neurologic, cardiac, or pulmonary disease, are also those at highest risk for morbidity and mortality associated with the procedure. A great deal of regional variability exists in the use of fundoplication to treat GERD.[89] While some centers routinely evaluate children referred for gastric tube placement for fundoplication, this practice is not supported by the literature, as concomitant fundoplication increased morbidity and does not seem to decrease the use of reflux medications or reflux-related complications.[7,30,111] In addition, in neurologically impaired children, fundoplication has not been shown to decrease reflux-related rehospitalization rates compared to gastrojejunal feeding.[97]

Summary

Because of limitations in the safety and efficacy of pharmacologic and surgical interventions for GERD, and a natural history of improvement over time, conservative expectant management is the mainstay of GERD management in infants. None of the medications commonly used to treat GERD in the NICU has been demonstrated to be safe and effective, and many have the potential to cause harm. Fundoplication also has a high rate of failure and complications and should be considered judiciously.

Key Points

- GER is a frequent normal physiologic process.
- GERD is defined as GER that triggers complications or morbidities.
- Pharmacologic therapy for GERD is common, but the literature does not support its safety or efficacy in infants.
- Conservative nonpharmacologic management is the mainstay of therapy.

Disorders of Digestion in the Neonate

CATHERINE LARSON-NATH, BHASKAR GURRAM, AND GISELA CHELIMSKY

Chronic and prolonged diarrhea is a symptom complex with a variety of underlying etiologies. This chapter focuses on the approach to infants with protracted diarrhea and is a review of recent literature on infantile diarrheal illnesses.

Intractable diarrhea is a term developed many years ago by Avery to describe chronic, unexplained diarrhea in young children.[85] This phrase describes a symptom complex rather than a discrete disease entity and is not favored by many experts. *Protracted diarrhea* has been used more recently to describe infants with loose and frequent stools of sufficient severity to require nutritional support in the form of parenteral alimentation. This emphasis on adequate support of total caloric intake and nutritional rehabilitation has dramatically improved the survival of affected infants.

Diarrhea is classified as either secretory or osmotic; however, in several cases both mechanisms may be involved.[140] A strategic problem in these diarrheal disorders is the presence of fluid and electrolyte secretion into one or more segments of the small intestine, large intestine, or both. Secretory diarrhea is the result of either impaired absorption of NaCl from villous enterocytes or increased chloride secretion from crypt cells, secondary to exogenous toxins from bacteria or viruses or endogenous substances (hormones, neurotransmitters, or cytokines), or from inherent defects in the sodium or chloride channels. The secretory diarrhea usually presents as a large volume of watery stools and does not improve with fasting. Osmotic diarrhea results from nonabsorbable substances in the intestinal lumen, which increases the osmolality of the luminal contents. This results in either retention of fluid or secretion of fluid into the intestinal lumen, therefore leading to diarrhea. In contrast to secretory diarrhea, osmotic diarrhea typically improves with fasting. Osmotic diarrhea can be distinguished from secretory diarrhea by measuring the electrolyte concentration in the stool and the osmotic gap. In osmotic diarrhea, there is a significant osmotic gap (>50 mOsm/kg) between the stool osmolality and twice the concentrations of sodium and potassium in the stool (Table 83.1). However, in clinical practice, usually the diagnosis is made by a trial of fasting to determine if there is improvement in the stool output. Some diarrheal disorders may have a secretory and osmotic component, as is sometimes seen for example in celiac disease.[13] In the absence of carbohydrate malabsorption in a patient with osmotic diarrhea, it is essential to determine whether steatorrhea is present (Table 83.2). Although diarrhea alone may be responsible for an increase in fat excretion of up to 11 g per day (normally <7 g fat/day is excreted by persons consuming 100 g fat/day), when larger amounts of fat are found in the stool the patient should be evaluated for a disorder of fat absorption. Based on the description of diarrhea as osmotic or secretory or mixed osmotic and secretory components, infantile diarrheal etiologies can be distinguished, as shown in Box 83.1.

Disorders of Carbohydrate Absorption

The enterocytes in the small intestine have at their apical surface brush border various enzymes responsible for the digestion of carbohydrates.[194] These carbohydrate hydrolases convert disaccharides and oligosaccharides into simple monosaccharides that are absorbed easily through transport proteins that exist on the intestinal surface.[125] These proteins include maltase-glucoamylase,[194] sucrase-isomaltase (SI), and lactase-phlorhizin hydrolase.[124] The clinical symptoms of carbohydrate malabsorption occur either because of the deficiency of a particular enzyme (e.g., congenital sucrase-isomaltase deficiency) or because of an abnormality in a transport protein involved with the absorption of digestion product (e.g., glucose-galactose malabsorption). Obtaining a detailed feeding history may yield a correlation between the age the diarrhea started and the particular food that was introduced into the baby's diet (Table 83.3) and give clues to the etiology of the diarrhea.

Patients with carbohydrate malabsorption disorders, regardless of the cause, present with severe watery diarrhea, which results from osmotic action exerted by the malabsorbed oligosaccharide[194] (lactose or sucrose) in the intestinal lumen. The malabsorbed sugars are then fermented by colonic bacteria, producing a mixture of gases (e.g., hydrogen, methane, carbon dioxide)[194] and short-chain fatty acids.[151] In normal digestion, the short-chain fatty acids are absorbed via the colonic epithelium, providing energy and decreasing the colonic osmolality. In the presence of a large carbohydrate load, these protective mechanisms become overwhelmed, causing diarrhea.[194] The increased volume

Abstract

Protracted diarrhea of infancy describes infants with loose or frequent stools of sufficient severity to require nutritional support in the form of parenteral nutrition. When evaluating for diarrhea, it is critical to determine if the diarrhea is secretory, osmotic, or has a component of both. Secretory diarrhea usually presents as a large volume of watery stools and does not improve with fasting. Osmotic diarrhea results from nonabsorbable substances in the intestinal lumen, which increases the osmolality of the luminal contents. This results in either retention of fluid or secretion of fluid into the intestinal lumen, therefore leading to diarrhea. In contrast to secretory diarrhea, osmotic diarrhea typically improves with fasting. Osmotic diarrhea can be distinguished from secretory diarrhea by measuring the electrolyte concentration in the stool and the osmotic gap. In osmotic diarrhea, there is a significant osmotic gap (>50 mOsm/kg) between the stool osmolality and twice the concentrations of sodium and potassium in the stool. This chapter reviews the presentation and causes of diarrhea in infants based on carbohydrate, fat, protein, and bile acid malabsorption. We have also included diarrhea due to disordered villous architecture, allergic colitis, food protein-induced enterocolitis (FPIES) and autoimmune enteropathy, and immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome.

Keywords

protracted diarrhea
osmotic diarrhea
secretory diarrhea
carbohydrate malabsorption
fat malabsorption
protein malabsorption
allergic colitis
autoimmune enteropathy

associated with low pH will stimulate gut motility, decreasing intestinal transit time.[85] In this kind of disorder, the diarrhea resolves when oral feeds are discontinued.

Disaccharidase Deficiencies

Congenital Sucrase-Isomaltase Deficiency

Congenital sucrase-isomaltase deficiency (CSID) is the most common congenital disorder of carbohydrate malabsorption.[112] CSID is most common in native Canadians, Inuits, and Greenland Eskimo populations (3%-10%). The prevalence in North American populations is around 0.05%-0.2%.[183]

Etiology

Congenital sucrase-isomaltase deficiency leads to reduced activity of the brush border enzyme sucrase-isomaltase and an inability to metabolize specific carbohydrates like sucrose, maltose, and starch.[149] It is transmitted in an autosomal

TABLE 83.1 Differentiating Osmotic From Secretory Diarrhea

	Osmotic	Secretory
Stool volume	Small	Large
Response to fasting (72 hours)	Improves	Unchanged
Stool sodium	<70	>70
Stool osmotic gap (290-2[stool Na+stool K])	>50	<50

TABLE 83.2 Clues to Distinguish Osmotic Diarrhea From Carbohydrate Versus Fat Malabsorption

	Isolated Carbohydrate Malabsorption	Isolated Fat Malabsorption
Stool character	Loose and watery Non-foul-smelling	Bulky large stool Foul-smelling Oil droplets visible
Perianal rash/skin erosion	+	+
Signs of fat soluble vitamin deficiency	±	+
Stool pH	Acidic (usually <6)	Alkaline
Stool reducing/nonreducing substances	+	–

+, Present; –, not present; ±, may or may not be present.

TABLE 83.3 Age of Onset of Different Carbohydrate Malabsorption Syndromes

Age of Onset	Disorder
