**Notices**

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

# PREFACE

The purpose of this book is to provide the definitive advanced reference text on the diagnostic utility of echocardiography in clinical practice. Put simply, this book reflects our role as clinicians caring for patients with cardiovascular disease. The clinical information in this book will be of value to all cardiovascular specialists, not just those focused on cardiovascular imaging. This book also will be of interest to cardiology fellows, cardiovascular anesthesiologists, and other health care providers using echocardiographic approaches in the clinical setting, including radiologists, interventional cardiologists, electrophysiologists, emergency medicine physicians, and internists with an active interest in cardiovascular disease. Cardiac sonographers, cardiovascular technologists, physician assistants, nurse practitioners, and nursing professionals who wish to go beyond the basics in echocardiographic imaging also will find this book valuable. For the clinical researcher, there are eight chapters dedicated to newer advanced echocardiographic modalities, and this information is integrated into subsequent chapters throughout the book.

Echocardiography is a key component in the evaluation of patients with suspected or known cardiovascular disease. As this technique has evolved and matured, the role of the echocardiographer has shifted from simply providing a description of the images to integrating the echocardiographic findings with other clinical data and finally to providing a diagnosis or therapeutic recommendation. Often, echocardiography supplies all the data needed for clinical decision making. When additional information is needed, the echocardiographic findings help define other imaging modalities that may be helpful. In effect, echocardiography has become a specialized type of cardiology consultation.

The information now requested by the referring physician includes not only the qualitative and quantitative interpretation of the echocardiographic images and Doppler flow data, but also a discussion of how this information may affect clinical decision making. Specific examples include decisions regarding interventional procedures (e.g., suitability for a transcatheter aortic valve implantation), medical or surgical therapy (e.g., treatment of endocarditis, surgery for aortic dissection), optimal timing of intervention in patients with chronic cardiac diseases (e.g., valvular regurgitation, mitral stenosis), prognostic implications (e.g., heart disease in pregnancy, heart failure patients), and the possible need for and frequency of periodic diagnostic evaluation (e.g., congenital heart disease, the postoperative patient). In addition, echocardiography is critical in choosing the optimal therapy for each patient (e.g., selection of patients for intracardiac defibrillator implantation) and has become essential for monitoring percutaneous interventions and the effects of medical or surgical therapy.

The clinical practice of echocardiography no longer is restricted to the full diagnostic examination performed in an imaging laboratory. Instead, echocardiography has become so integrated into cardiovascular care that specialized instruments are now used in the intensive care unit, emergency department, interventional laboratory, and operating room, as well as during electrophysiology procedures. As instruments become smaller, less expensive, and easier to use, the clinical applications of this imaging modality likely will continue to expand.

Each chapter in this book provides an advanced level of discussion, written by an expert in the field, building upon the basic material in my *Textbook of Clinical Echocardiography, Fourth Edition*. In contrast to the *Textbook,* the primary focus of this book is the role of echocardiography in clinical decision making and the impact on clinical outcomes. Emphasis is also placed on the principles of optimal data acquisition, quantitative approaches to data analysis, potential technical limitations, and areas of active research. In addition, the strengths and limitations of alternate diagnostic approaches are reviewed to put the role of echocardiography into the context of clinical practice. Detailed tables, color illustrations, echocardiographic images, Doppler tracings, and figures with key data from published outcome studies are used to provide clarity and depth. To complement the printed text, multiple choice questions at expertconsult.com provide an opportunity for readers to test their knowledge or quickly review the core material. Some highlights of the fourth edition include new chapters on echocardiographic guidance of structural heart disease interventions and echocardiographic evaluation of cardiac assist devices.

It is hoped that this book will provide the needed background to support and supplement clinical experience and expertise. Of course, competency in the acquisition and interpretation of echocardiographic and Doppler data depends on appropriate clinical education and training, as detailed in accreditation requirements for both physicians and technologists and as recommended by professional societies, including the American Society of Echocardiography, the American College of Cardiology, and the American Heart Association. I strongly support these educational requirements and training recommendations; readers of this book are urged to review the relevant documents.

Advances continue to be made both in the technical aspects of image and flow data acquisition and in our understanding of the clinical implications of specific echocardiographic findings. This book represents our knowledge base at one point in time; readers will wish to consult the current literature for the most up-to-date information. Although an extensive list of carefully selected references is provided with each chapter, the echocardiographic literature is so robust that it is impractical to include all relevant references; the reader can conduct an online medical literature search if an all-inclusive listing is desired.

Additional resources for the reader interested in achieving mastery in echocardiography include *Echocardiography Review Guide, Second Edition*, which I wrote with Becky Schwaegler and Rosario Freeman, and which provides a quick summary and self-evaluation questions for my *Textbook of Clinical Echocardiography, Fourth Edition*. These books are now complemented by the new Otto Practical Echocardiography series, all published by Elsevier and available in electronic format and online at expertconsult.com. The Practical Echocardiography series includes *Intraoperative Echocardiography*, edited by Don Oxorn; *Echocardiography in Heart Failure*, edited by Susan Wiegers and Martin St. John Sutton; *Echocardiography in Congenital Heart*

*Disease*, edited by Mark Lewin and Karen Stout; and *Advanced Echocardiographic Approaches*, which I edited with Linda Gillam. All four of these books also offer online clinical cases and video clips to enhance the learning experience.

Little time investment is needed to acquire basic skills in echocardiographic image acquisition and interpretation; the challenge lies in transitioning these skill sets from "basic" to "expert." As echocardiography becomes fully integrated into the practice of medicine in every clinical setting, each of us should be aware of our own limitations, scope of practice, and clinical practice needs. The concentrated educational content and cumulative clinical experience contained in the Otto series of textbooks and online cases not only provides a solid foundation upon which to learn the practice of echocardiography, but can also accelerate the learning curve for those who wish to challenge themselves to become a master of echocardiography.

# ACKNOWLEDGMENTS

My deepest gratitude is due the many individuals who made this book possible. Primary recognition goes to the chapter contributors who provided scholarly, thoughtful, and insightful discussions and integrated the clinical and echocardiographic information into a format that will benefit our readers. The support staff at each of our institutions deserves our appreciation for assisting with manuscript preparation and providing effective communication. The many research subjects who contributed to the data on which our current understanding is based certainly are worthy of acknowledgment as well. The cardiac sonographers at all our institutions are owed thanks as our partners in the clinical practice of echocardiography and as the individuals who acquired most of the images shown in this book. In addition, gratitude is due Natasha Andjelkovic, Delores Meloni, Agnes Byrne, Joanie Milnes, Louise King, and the entire editorial and production teams at Elsevier. Finally, my sincere thanks go to my colleagues in Cardiology at the University of Washington and to my family for their constant encouragement and support.

**Catherine M. Otto**

# GLOSSARY

| | |
|---|---|
| **2D** | two-dimensional |
| **3D** | three-dimensional |
| **A-long** | apical long-axis |
| **A-mode** | amplitude mode (amplitude versus depth) |
| **A** | diastolic ventricular filling velocity with atrial contraction |
| **A′** | diastolic tissue Doppler velocity with atrial contraction |
| **A2C** | apical two-chamber |
| **A4C** | apical four-chamber |
| **ABD** | automated border detection |
| **ACHD** | adult congenital heart disease |
| **ACS** | acute coronary syndrome |
| **AcT** | acceleration time |
| **AF** | atrial fibrillation |
| **AIH** | aortic intramural hematoma |
| **AMVL** | anterior mitral valve leaflet |
| **ant** | anterior |
| **Ao** | aortic or aorta |
| **AQ** | acoustic quantification |
| **Ar** | pulmonary vein atrial reversal velocity |
| **AR** | aortic regurgitation |
| **ARVD** | arrhythmogenic right ventricular dysplasia |
| **AS** | aortic stenosis |
| **ASD** | atrial septal defect |
| **ATVL** | anterior tricuspid valve leaflet |
| **AV** | atrioventricular |
| **AVA** | aortic valve area |
| **AVC** | aortic valve closure |
| **AVR** | aortic valve replacement |
| **AVSD** | atrioventricular septal defect |
| **BAV** | bicuspid aortic valve |
| **BMV** | balloon mitral valvotomy |
| **BNP** | B-type natriuretic peptide |
| **BP** | blood pressure |
| **BSA** | body surface area |
| **c** | propagation velocity of sound in tissue |
| **CABG** | coronary artery bypass graft |
| **CAD** | coronary artery disease |
| **CCTGA** | congenitally corrected transposition of the great arteries (*see* L-TGA) |
| **CCU** | coronary care unit |
| **CFR** | coronary flow reserve |
| **CO** | cardiac output |
| **COPD** | chronic obstructive pulmonary disease |
| **CPB** | cardiopulmonary bypass |
| **CRT** | cardiac resynchronization therapy |
| **CS** | coronary sinus |
| **CSA** | cross-sectional area |
| **CT** | computed tomography |
| **CTEPH** | chronic thromboembolic pulmonary hypertension |
| **CW** | continuous wave |
| **Cx** | circumflex coronary artery |
| **D** | diameter |
| **DAo** | descending aorta |
| **DCM** | dilated cardiomyopathy |
| **DICOM** | Digital Imaging and Communications in Medicine |
| **DORV** | double-outlet right ventricle |
| ***dP/dt*** | rate of change in pressure over time |
| **DSE** | dobutamine stress echocardiography |
| **DT** | deceleration time |
| **D-TGA** | complete (D or dextro) transposition of the great arteries |
| **E** | early diastolic peak velocity |
| **E′** | early diastolic tissue Doppler velocty |
| **ECG** | electrocardiogram |
| **ED** | end-diastole |
| **EDD** | end-diastolic dimension |
| **EDP** | end-diastolic pressure |
| **EDV** | end-diastolic volume |
| **EF** | ejection fraction |
| **endo** | endocardium |
| **EOA** | effective orifice area |
| **epi** | epicardium |
| **EPSS** | E-point septal separation |
| **EROA** | effective regurgitant orifice area |
| **ES** | end-systole |
| **ESD** | end-systolic dimension |
| **ESPVR** | end-systolic pressure-volume relationship |
| **ESV** | end-systolic volume |
| **ETT** | exercise treadmill test |
| **FDA** | Food and Drug Administration (USA) |
| **FL** | false lumen |
| **FPV** | flow propagation velocity |
| **FS** | fractional shortening |
| **FSV** | forward stroke volume |
| **HCM** | hypertrophic cardiomyopathy |
| **HCU** | hand-carried ultrasound |
| **HF** | heart failure |
| **HFpEF** | heart failure with preserved ejection fraction |
| **HOCM** | hypertrophic obstructive cardiomyopathy |
| **HPRF** | high pulse repetition frequency |
| **HR** | heart rate |
| **HRrEF** | heart failure with reduced ejection fraction |
| **HV** | hepatic vein |
| **IABP** | intraaortic balloon pump |
| **IAS** | interatrial septum |
| **ICD** | implanted cardiac defibrillator |
| **ICE** | intracardiac echocardiography |
| **ICU** | intensive care unit |
| **ID** | indicator dilution |
| **IE** | infective endocarditis |
| **inf** | inferior |
| **INR** | international normalized ratio |
| **IPAI** | intraaortic phased-array imaging |
| **IV** | intravenous |
| **IVC** | inferior vena cava |

**IVCT** isovolumic contraction time
**IVRT** isovolumic relaxation time
**IVUS** intravascular ultrasound

**JA** jet area

***L*** length
**LA** left atrium
**LAA** left atrial appendage
**LAD** left anterior descending coronary artery
**LAE** left atrial enlargement
**lat** lateral
**LBBB** left bundle branch block
**LCC** left coronary cusp
**LCx** left circumflex coronary artery
**LIPV** left inferior pulmonary vein
**LMCA** left main coronary artery
**LPA** left pulmonary artery
**LSPV** left superior pulmonary vein
**L-TGA** L-transposition of the great arteries (*see* CCTGA)
**LV** left ventricle
**LVAD** left ventricular assist device
**LVEDP** left ventricular end-diastolic pressure
**LVH** left ventricular hypertrophy
**LVID** left ventricular internal dimension
**LVOT** left ventricular outflow tract

**M-mode** motion display (depth versus time)
**MAC** mitral annular calcification
**MAIVF** mitral-aortic intervalvular fibrosa
**MCE** myocardial contrast echocardiography
**MFS** Marfan syndrome
**MI** myocardial infarction
**MPA** main pulmonary artery
**mPAP** mean pulmonary artery pressure
**MPI** myocardial performance index
**MR** mitral regurgitation
**MRI** magnetic resonance imaging
**MS** mitral stenosis
**MV** mitral valve
**MVA** mitral valve area
**MVL** mitral valve leaflet
**MVP** mitral valve prolapse
**MVR** mitral valve replacement

**NBTE** nonbacterial thrombotic endocarditis
**NCC** noncoronary cusp
**NPO** nothing by mouth
**NYHA** New York Heart Association (classification for heart failure symptoms)

**OM1** first obtuse marginal branch
**OM2** second obtuse marginal branch

**Δ*P*** pressure gradient
**PA** pulmonary artery
**PACS** Picture Archiving and Communications Systems
**PAH** pulmonary arterial hypertension
**pAn** pseudoaneurysm
**PAP** pulmonary artery pressure
**PAPVR** partial anomalous pulmonary venous return
**PASP** pulmonary artery systolic pressure
**PCI** percutaneous coronary intervention
**PCWP** pulmonary capillary wedge pressure
**PDA** patent ductus arteriosus or posterior descending artery (depends on context)
**PE** pericardial effusion
**PEP** preejection period
**PESDA** perfluorocarbon exposed sonicated dextrose albumin
**PET** positron-emission tomography
**PFO** patent foramen ovale
**PH** pulmonary hypertension
**PHT** pressure half time
**PISA** proximal isovelocity surface area
**PLAX** parasternal long-axis
**PM** papillary muscle
**PMVL** posterior mitral valve leaflet
**post** posterior (or inferior-lateral) ventricular wall
**PPM** patient prosthesis mismatch
**PR** pulmonic regurgitation
**PRF** pulse repetition frequency
**PRFR** peak rapid filling rate
**PS** pulmonic stenosis
**PSAX** parasternal short-axis
**PCI** percutaneous coronary intervention
**PV** pulmonary vein
**PVC** premature ventricular contraction
**PVOD** pulmonary venoocclusive disease
**PVR** pulmonary vascular resistance
**PW** pulsed wave
**PWT** posterior wall thickness

**RA** right atrium
**RAE** right atrial enlargement
**RAO** right anterior oblique
**RAP** right atrial pressure
**RCA** right coronary artery
**RCC** right coronary cusp
**RF** regurgitant fraction
**RIPV** right inferior pulmonary vein
**RJ** regurgitant jet
**ROA** regurgitant orifice area
**RPA** right pulmonary artery
**RSPV** right superior pulmonary vein
**RSV** regurgitant stroke volume
**RT3DE** real-time three-dimensional echocardiography
**RV** right ventricle
**RVAD** right ventricular assist device
**RVE** right ventricular enlargement
**RVH** right ventricular hypertrophy
**RVOT** right ventricular outflow tract
**RWT** relative wall thickness

**SAM** systolic anterior motion
**SAS** subaortic stenosis
**SC** subcostal
**SD** standard deviation
**SEE** standard error of the estimate
**SHD** structural heart disease
**SPECT** single photon emission computed tomography
**SPPA** spatial peak pulse average
**SPTA** spatial peak temporal average
**SR** strain rate
**SSN** suprasternal notch
**STE** speckle tracking echocardiography

**STJ** sinotubular junction
**STVL** septal tricuspid valve leaflet
**SV** stroke volume or sample volume (depends on context)
**SVC** superior vena cava
**SVR** systemic vascular resistance

**TAPSE** tricuspid annular plane systolic excursion
**TAPVR** total anomalous pulmonary venous return
**TAVI** transcatheter aortic valve implantation
**TDI** tissue-Doppler imaging
**TEE** transesophageal echocardiography
**TGA** transposition of the great arteries
**TGC** time gain compensation
**TIA** transient ischemic attack
**TL** true lumen
**TN** true negatives
**TOF** tetralogy of Fallot
**TP** true positives
**TPV** time to peak velocity
**TR** tricuspid regurgitation
**TS** tricuspid stenosis
**TSV** total stroke volume
**TTE** transthoracic echocardiography
**TV** tricuspid valve

**V** volume or velocity (depends on context)
**VAD** ventricular assist device
**VAS** ventriculo-atrial septum
**$V_{cf}$** velocity of circumferential shortening
**$V_{max}$** maximum velocity
**VR** ventricular contraction
**VS** ventricular septum
**VSD** ventricular septal defect
**VTI** velocity-time integral

**WPW** Wolff-Parkinson-White syndrome

***Z*** acoustic impedance

| *Symbol* | *Greek Name* | *Used For* |
|---|---|---|
| α | alpha | frequency |
| γ | gamma | viscosity |
| Δ | delta | difference |
| θ | theta | angle |
| λ | lambda | wavelength |
| μ | mu | micro- |
| π | pi | mathematical constant (approx. 3.14) |
| ρ | rho | tissue density |
| σ | sigma | wall stress |
| τ | tau | time constant of ventricular relaxation |

**Units of Measure**

| *Variable* | *Unit* | *Definition* |
|---|---|---|
| Amplitude | dB | Decibels = a logarithmic scale describing the amplitude ("loudness") of the sound wave |
| Angle | degrees | Degree = (π/180)rad. Example: intercept angle |
| Area | $cm^2$ | Square centimeters. A two-dimensional measurement (e.g., end-systolic area) or a calculated value (e.g., continuity equation valve area) |
| Frequency (*f*) | Hz<br>kHz<br>MHz | Hertz (cycles per second)<br>Kilohertz = 1000 Hz<br>Megahertz = 1,000,000 Hz |
| Length | cm<br>mm | Centimeter (1/100 m)<br>Millimeter (1/1000 m or 1/10 cm) |
| Mass | g | Grams. Example: LV mass |
| Pressure | mm Hg | Millimeters of mercury, 1 mm Hg = 1333.2 $dyne/cm^2$, where dyne measures force in $cm \cdot g \cdot s^{-2}$ |
| Resistance | $dyne{\cdot}s{\cdot}cm^{-5}$ | Measure of vascular resistance |
| Time | s<br>ms<br>μs | Second<br>Millisecond (1/1000 s)<br>Microsecond |
| Ultrasound intensity | $W/cm^2$<br>$mW/cm^2$ | Where watt (W) = joule per second and joule = $m^2 \cdot kg \cdot s^{-2}$ (unit of energy) |
| Velocity (*v*) | m/s<br>cm/s | Meters per second<br>Centimeters per second |
| Velocity-time integral (VTI) | cm | Integral of the Doppler velocity curve (cm/s) over time (s), in units of cm |
| Volume | $cm^3$<br>ml<br>L | Cubic centimeters<br>Milliliter, 1 mL = 1 $cm^3$<br>Liter = 1000 mL |
| Volume flow rate (Q) | L/min<br>mL/s | Rate of volume flow across a valve or in cardiac output<br>L/min = liters per minute<br>mL/s = milliliters per second |
| Wall stress | $dyne/cm^2$<br>$kdyn/cm^2$<br>kPa | Units of meridional or circumferential wall stress<br>Kilodynes per $cm^2$<br>Kilopascals where 1 kPa = 10 $kdyn/cm^2$ |

# 1 Transesophageal Echocardiography

IAN G. BURWASH, MD | KWAN-LEUNG CHAN, MD

**Performance of Transesophageal Echocardiography**
- Preparation of Patient
- Esophageal Intubation
- Image Format

**Standard Imaging Planes**
- Basal Views
- Four-Chamber Views
- Transgastric Views
- Aortic Views

**Three-Dimensional Imaging**

**Doppler Examination**
- Left Atrial Appendage Flow
- Pulmonary Vein Flow

**Indications for Transesophageal Echocardiography**
- Native Valve Disease
- Prosthetic Valves
- Infective Endocarditis
- Suspected Cardioembolic Event
- Atrial Septal Abnormalities
- Cardiac Tumors
- Acute Aortic Syndromes
- Atrial Fibrillation
- Congenital Heart Disease
- Coronary Artery Disease
- Pericardial Disease
- Critically Ill Patient in the Intensive Care Unit
- Monitoring During Surgical and Interventional Procedures

**Contraindications to Transesophageal Echocardiography**

**Complications of Transesophageal Echocardiography**

The role of transesophageal echocardiography (TEE) in the diagnosis and management of patients with suspected and overt cardiac disease has evolved with time as a result of refinements in technology and the addition of three-dimensional (3D) TEE.[1,2] The portable nature of the technique allows the examination to be performed in a diverse array of clinical settings that include the outpatient ambulatory clinic, intensive care unit, catheterization laboratory, and operating room. Currently, TEE accounts for approximately 5% to 10% of all echocardiography studies performed.

## Performance of Transesophageal Echocardiography

Transesophageal echocardiography is a semi-invasive procedure that should be performed only by a properly trained physician who understands the indications and potential complications of the procedure. Both technical and cognitive skills are required for the competent performance and interpretation of TEE studies (Box 1-1), and guidelines on training have been published.[2] The physician should be assisted by an experienced sonographer whose tasks are to ensure that optimal images are obtained by adjusting the controls of the echocardiographic system and to ensure safety by monitoring the responses of the patient during the procedure. Although family members or friends are usually not allowed in the room when the procedure is being performed, there are situations in which their presence can be helpful. The presence of a parent can have a calming effect when one is dealing with an apprehensive teenager. A friend or relative who speaks the same language can relieve anxiety when dealing with an anxious patient who is not fluent in English.

Transesophageal echocardiography should be performed in a spacious room that can comfortably accommodate a stretcher. The room should be equipped with an oxygen outlet and suction facilities. A pulse oximeter should be available, to be used mainly in cyanotic patients and patients with severe lung disease. The TEE probe should be carefully examined before each use. In addition to visual inspection, it is important to palpate the probe, particularly the flexion portion, to ensure that there is no unusual wear and tear of the probe.[3] Stretching of the steering cables may result in increased flexibility and mobility of the probe tip with buckling of the probe tip within the esophagus.[4] This phenomenon is associated with a poor TEE image and resistance to probe withdrawal. The probe should be advanced into the stomach and straightened by retroflexion of the extreme antiflexed probe tip. We have also detected perforation of the TEE probe sheath by a ruptured steering cable and recommend inspection of the casing for any protruding wires before probe insertion.[3] The flexion controls need to be tested on a regular basis. Anterior flexion should exceed 90°, and right and left flexion should approach 90°.

### PREPARATION OF PATIENT

Patients should be contacted at least 12 hours before the procedure and instructed to fast for at least 4 hours before the procedure. They are informed that they should be accompanied, because they will not be able to drive or return to work for several hours owing to the lingering effect of sedation. On the day of the study, the procedure is explained in detail, and informed consent is obtained. Patients are told to expect mild abdominal discomfort and gagging following the insertion of

Box 1-1

**COGNITIVE AND TECHNICAL SKILLS REQUIRED FOR THE PERFORMANCE OF TRANSESOPHAGEAL ECHOCARDIOGRAPHY**

**Cognitive Skills**

- Knowledge of appropriate indications, contraindications, and risks of TEE
- Understanding of differential diagnostic considerations in each clinical case
- Knowledge of physical principles of echocardiographic image formation and blood flow velocity measurement
- Familiarity with the operation of the ultrasonographic instrument, including the function of all controls affecting the quality of the data displayed
- Knowledge of normal cardiovascular anatomy, as visualized tomographically
- Knowledge of alterations in cardiovascular anatomy resulting from acquired and congenital heart diseases
- Knowledge of normal cardiovascular hemodynamics and fluid dynamics
- Knowledge of alterations in cardiovascular hemodynamics and blood flow resulting from acquired and congenital heart diseases
- Understanding of component techniques for general echocardiography and TEE, including when to use these methods to investigate specific clinical questions
- Ability to distinguish adequate from inadequate echocardiographic data and to distinguish an adequate from an inadequate TEE examination
- Knowledge of other cardiovascular diagnostic methods for correlation with TEE findings
- Ability to communicate examination results to patient, other health care professionals, and medical record

**Technical Skills**

- Proficiency in performing a complete standard echocardiographic examination, using all echocardiographic modalities relevant to the case
- Proficiency in safely passing the TEE transducer into the esophagus and stomach and in adjusting probe position to obtain the necessary tomographic images and Doppler data
- Proficiency in correctly operating the ultrasonographic instrument, including all controls affecting the quality of the data displayed
- Proficiency in recognizing abnormalities of cardiac structure and function as detected from the transesophageal and transgastric windows, in distinguishing normal from abnormal findings, and in recognizing artifacts
- Proficiency in performing qualitative and quantitative analysis of the echocardiographic data

From Pearlman AS, Gardin JM, Martin RP, et al: Guidelines for physician training in transesophageal echocardiography: recommendations of the American Society of Echocardiography Committee for Physician Training in Echocardiography. *J Am Soc Echocardiogr* 5:187-194, 1992.

the probe and are reassured that these responses are transient. A 20-gauge intravenous cannula is then inserted for administration of medications and contrast agents, if necessary. Lidocaine hydrochloride spray is routinely used for topical anesthesia, which should cover the posterior pharynx and tongue. We usually use diazepam 2 to 10 mg intravenously for sedation.[5] Midazolam at 0.05 mg/kg, with a total dose between 1 and 5 mg, can also be used.

Sedation is used in about 85% of our patients and should be more sparingly used in elderly patients, because they tend to be more stoic and the effect of sedation tends to be more prolonged. On the other hand, sedation is essential in young, anxious patients and when the study is expected to be protracted. We aim for light sedation so that at the end of the procedure the patients are awake and can leave with an escort. Heavy sedation is needed in situations in which blunting the hemodynamic responses to the procedure is desirable, as with a patient undergoing TEE for suspected aortic dissection.[6]

It has not been our practice to use anticholinergic agents such as glycopyrrolate to decrease salivation. In rare circumstances in which there is excessive salivation, it is usually adequate to simply instruct the patient to let the saliva dribble onto a towel placed under the chin, or remove the saliva by intermittent suction. Bacteremia is not a significant risk in TEE, and we do not use antibiotic prophylaxis to prevent endocarditis even in patients with prosthetic valves.[7,8]

## ESOPHAGEAL INTUBATION

We perform the TEE study with the patient in the left decubitus position. The physician, sonographer, and echocardiographic system are all positioned on the left-hand side of the patient.[5] Artificial teeth or dentures are routinely removed. The flexion controls should be unlocked to allow for maximum flexibility of the probe when it is being inserted. The patient's head should be in a flexed position. The tip of the probe is kept relatively straight and gently advanced to the back of the throat. It should be maintained in a central position, because deviation to either side increases the likelihood that it may become lodged in the piriform fossa. (See Fig. 2-2) The operator can facilitate this process by inserting one or two fingers into the patient's oropharynx to direct the path of the probe. Gentle pressure is exerted, and the patient is instructed to swallow. The swallowing mechanism helps guide the probe into the esophagus. In older patients, cervical spondylosis with prominent protrusion into the posterior pharynx can create difficulty with passage of the probe.[5] Manually depressing the back of the tongue provides more room, allowing the TEE probe to assume a less acute angle and facilitating intubation of the esophagus. If significant resistance is encountered when the probe is advanced, it is prudent to withdraw the probe and then initiate a new attempt. In experienced hands, the rate of failure of esophageal intubation should be less than 2%.[5,9]

A bite guard should always be used, except in edentulous patients. Our practice is to put it between the patient's teeth before the TEE probe is passed into the oropharynx and esophagus because patients with a sensitive pharynx may close their mouths involuntarily during esophageal intubation. The patient is instructed to keep the guard between the teeth throughout the procedure, and regular checks are made to ensure that it is in the proper position to prevent damage to the probe or injury to the patient.

Even when the probe is inserted without difficulties, it is not uncommon for the patient to develop nausea with or without mild retrosternal or abdominal discomfort. We find it useful to pause for 10 to 15 seconds to allow these symptoms to subside before proceeding with echocardiographic imaging. Our practice is to start with images acquired from the esophagus before advancing the probe into the stomach for the gastric views. The gastroesophageal sphincter is usually reached when the probe is advanced 40 cm from the teeth. Gentle pressure is all that is

required to advance the probe through the gastroesophageal sphincter. The patient may again experience nausea and mild discomfort, and it may be advisable to pause momentarily for these symptoms to subside. Imaging of the proximal descending thoracic aorta and aortic arch is generally reserved for the end of the study, because the probe needs to be positioned in the upper esophagus, and the patient is generally more aware of the probe at this position and tends to have more discomfort and gagging.

Inadvertent passage of the probe into the trachea can occur, particularly in deeply sedated patients. The development of stridor and incessant cough should alert the operator of this possibility. Furthermore, it would be difficult to advance the probe beyond 30 cm from the teeth, and the image quality is usually poor.[5]

In patients on mechanical ventilation, esophageal intubation is more difficult. We usually introduce the probe with the patient lying supine, because the airway is protected and aspiration is unlikely. The probe is positioned behind the endotracheal tube and gently advanced. It is helpful to have the patient's mandible pulled forward when the probe is being advanced. If there is undue resistance at about 25 to 30 cm from the teeth, slight deflation of the endotracheal tube cuff can be considered to ease passage of the probe. We do not usually remove the gastric tube, which can be used as a guide to help in proper positioning and passage of the TEE probe. In a minority of intubated patients, successful esophageal intubation may be achieved only with direct laryngoscopy.

### IMAGE FORMAT

There is no general agreement on how the imaging planes should be displayed. Our preference is to orient the images such that the right-sided structures are on the left side of the screen and the left-sided on the right. The apex of the imaging plane with the electronic artifact is at the top of the screen. Thus, in longitudinal views, superior structures are to the right of the screen and the inferior to the left.[10]

## Standard Imaging Planes

The TEE probe should be capable of multiplane imaging and preferably also real-time 3D imaging. The imaging plane is steered electronically from 0° to 180° by means of a pressure-sensitive switch, providing views that are unobtainable using monoplane and biplane probes. The following discussion focuses only on standard imaging views routinely performed at the University of Ottawa Heart Institute using multiplane TEE (Table 1-1). These views are considered "standard" because they have important clinical relevance and can be obtained in most patients with specific imaging planes. Further advances in image quality and image analysis of 3D TEE will likely facilitate the rapid acquisition of these imaging planes.

Four basic maneuvers are used to obtain specific tomographic views with TEE.[11] The first relates to the positioning of the probe by advancement or withdrawal of the probe. Although this is a simple maneuver, it is the most crucial, and the imaging views can be conveniently categorized according to the location of the TEE probe within the esophagus or stomach into four groups: basal, four-chamber, transgastric, and aortic views (Fig. 1-1). The second maneuver involves rotation of the probe from side to side. This is particularly useful when using longitudinal imaging planes, which provide a better demonstration of the continuity between vertically aligned structures such as the superior vena cava and the arch vessels (Fig. 1-2).[10,11] Steering the imaging plane using the pressure-sensitive switch is the third maneuver to obtain different tomographic views (Fig. 1-3). The accompanying images in Figures 1-1, 1-2, and 1-3 represent the typical images obtained with one of the basic maneuvers and provide the starting points for further adjustment of the imaging plane to obtain optimal long- or short-axis views of specific structures. This may be achieved using the fourth maneuver, which involves manipulation of the anterior-posterior and right-left flexion control knobs. The availability of a steerable imaging plane has drastically reduced the need to use the flexion knobs, but there are situations in which these knobs play a crucial role in obtaining proper tomographic views.[11] These maneuvers provide an almost infinite number of imaging planes. Table 1-1 summarizes the standard imaging planes and the cardiac structures evaluated in these four groups of views.

**TABLE 1-1 Standard Imaging Planes with Multiplane Transesophageal Echocardiography***

| *Imaging View* | *Standard Imaging Plane* | *Angle of Imaging Array (°)* | *Main Cardiac Structures* |
|---|---|---|---|
| Basal | Aortic valve | 0-60 | Aortic valve, coronary arteries, LA appendage, pulmonary veins |
| | Atrial septum | 90-120 | Fossa ovalis, superior vena cava, inferior vena cava |
| | Pulmonary bifurcation | 0-30 | Pulmonic valve, main and right pulmonary arteries, proximal left pulmonary artery |
| Four-chamber | LV | 0-180 | LV (regional and global function), RV, tricuspid valve |
| | Mitral valve | 0-180 | Anterior and posterior mitral leaflets, papillary muscles, chords |
| | LV outflow tract | 120-160 | Aortic valve, ascending aorta, LV and RV outflow tracts, pulmonic valve, main pulmonary artery |
| Transgastric | LV | 0-150 | LV, RV, tricuspid valve |
| | Mitral valve | 0-150 | Anterior and posterior mitral leaflets, papillary muscles, chords |
| | Coronary sinus | 0 | Coronary sinus, tricuspid valve |
| Aortic | Descending thoracic aorta | 0 | Entire descending thoracic aorta |
| | Aortic arch | 90 | Aortic arch, arch vessels, left pulmonary artery |

*At the University of Ottawa Heart Institute.

### BASAL VIEWS

The basal group of views is obtained with the TEE probe located in the midesophagus. The base of the heart, particularly the aortic valve, is well seen. The relationship of the two great arteries can be very well defined and followed cephalad to at least the level of the pulmonary bifurcation. Beyond this level, the interposing trachea makes imaging impossible. Three tomographic planes are found to be particularly useful and are routinely performed at our laboratory.

#### *Aortic Valve*

A short-axis view of the aortic valve can be obtained with the probe at about 30 to 35 cm from the teeth. The left coronary cusp often appears to have nodular thickening if the aortic valve

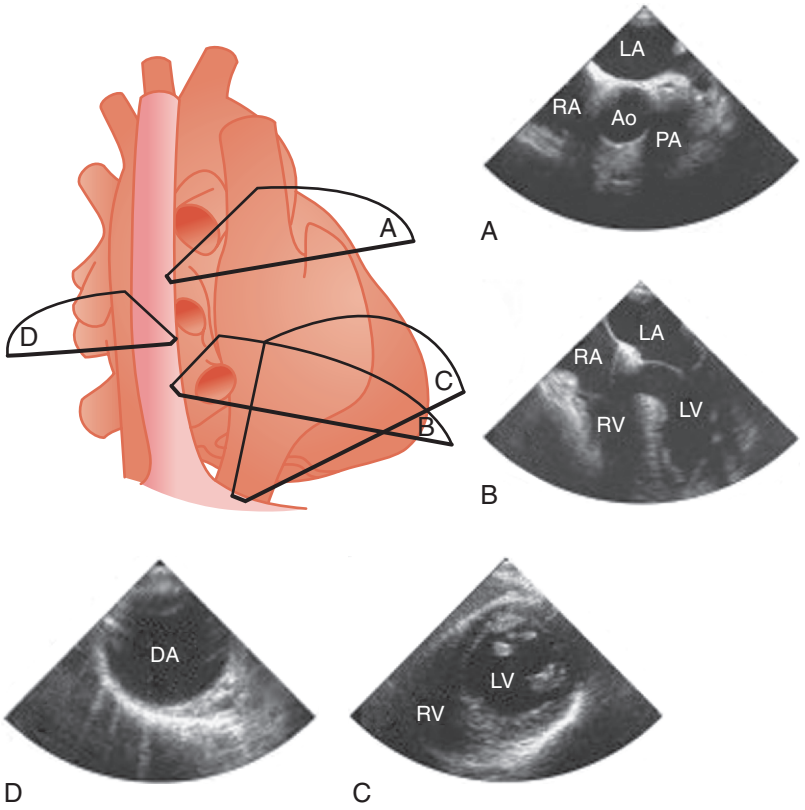

**Figure 1-1** Diagram showing the transesophageal echocardiography transducer locations for the four standard imaging views: basal (**A**), four-chamber (**B**), transgastric (**C**), and aortic (**D**). *Ao*, Aorta; *DA*, descending aorta; *PA*, pulmonary artery.

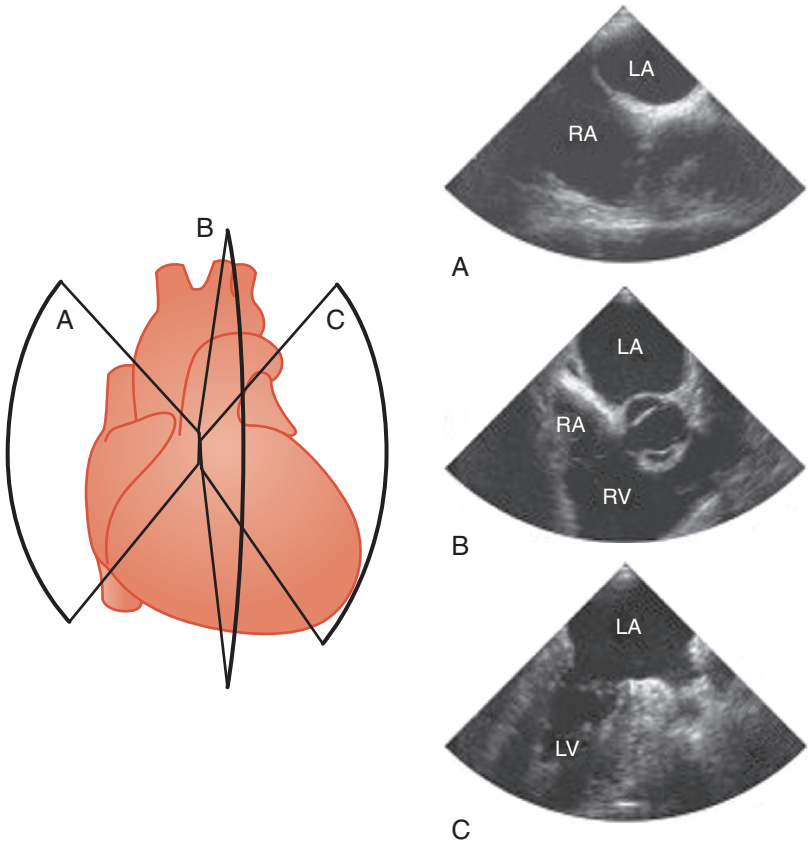

**Figure 1-2** Diagram showing the transesophageal echocardiography longitudinal imaging planes obtained by rotation of probe: atrial septum (**A**), RV outflow tract (**B**), and two-chamber view (**C**).

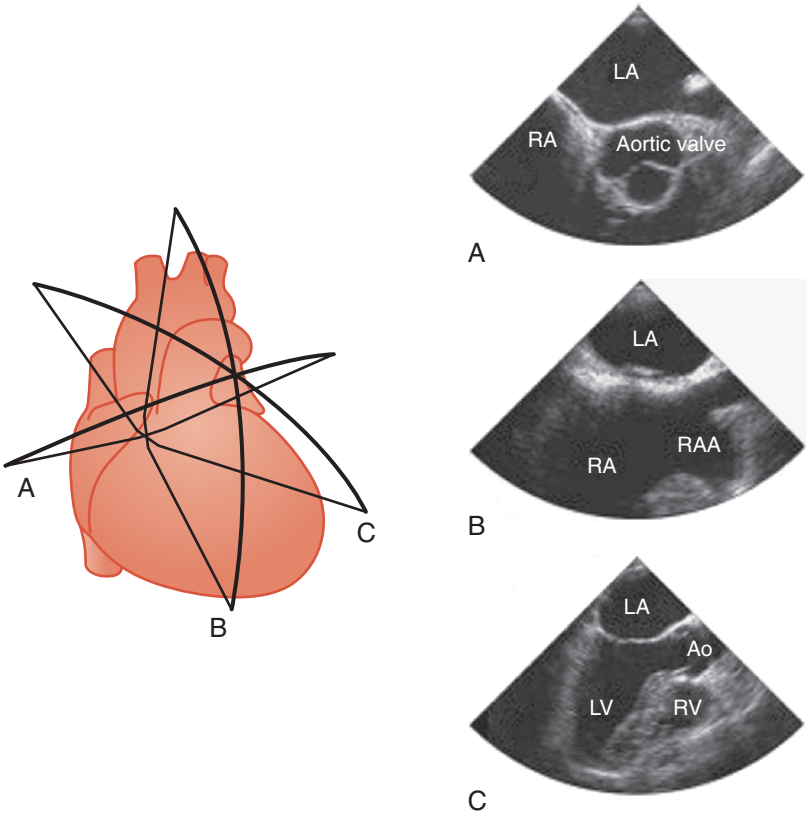

**Figure 1-3** Diagram showing the transesophageal echocardiography rotational imaging planes (0°-180°): aortic valve (**A,** 40°), superior vena cava (**B,** 100°), and LV outflow tract (**C,** 140°). *RAA*, Right atrial appendage.

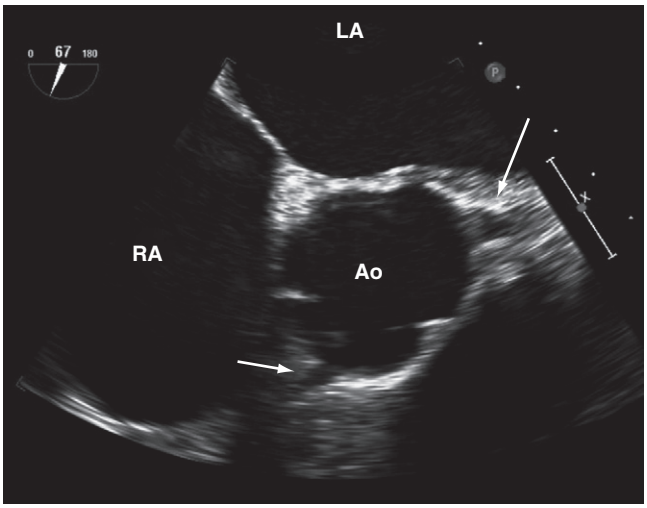

**Figure 1-4** The right (*short arrow*) and left (*long arrow*) coronary arteries can be imaged. The latter can frequently be followed to the bifurcation such that the proximal portions of the left anterior descending and the circumflex arteries can also be imaged. *Ao*, Aorta.

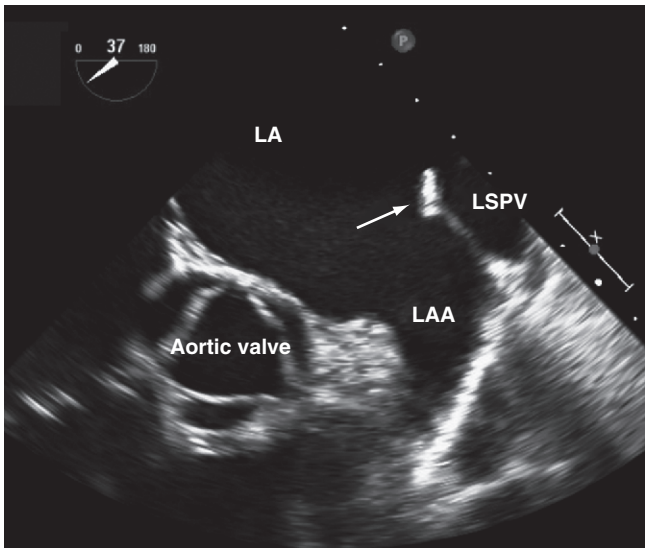

**Figure 1-5** The bulbous partition (*arrow*) between the left upper pulmonary vein and the left atrial appendage (*LAA*) is demonstrated. *LSPV*, Left superior pulmonary vein.

is cut obliquely, which is often the case at 0°.[10] Steering the imaging plane to 30° to 60° should eliminate this artifact by providing an optimal short-axis view of the aortic valve (see Fig. 1-3, *A*).[11] A slight pull-back of the transducer should allow visualization of both the left and right coronary arteries (Fig. 1-4). The left coronary artery can be followed to its bifurcation into the left anterior descending and circumflex arteries. The right coronary artery is more difficult to display, and only the proximal 2 to 3 cm is usually seen. Other structures well seen in this view are the left atrial appendage and left pulmonary veins. The partition between these structures can be quite bulbous and should not be confused with an abnormal intracardiac mass (Fig. 1-5).[12] Rotating the probe to the right should reveal the right pulmonary veins.

We like the horizontal plane in imaging the four pulmonary veins. The left and right pulmonary veins are imaged separately. When one pulmonary vein is identified, a slight translational movement of the probe should bring out the other, because the orifices of the superior and inferior pulmonary veins are in close proximity. The inferior pulmonary veins run horizontal

to the imaging plane, whereas the superior veins are more anterior and at an obtuse angle, making them more suitable for Doppler assessment. It is feasible to image the superior and inferior pulmonary veins, left or right, in the same view using the vertical plane and imaging can be facilitated with the use of color flow imaging (Figs. 1-6 and 1-7). The right and left atrial appendages wrap around the great arteries anteriorly. The left atrial appendage is more prominent and can consist of multiple lobes (Fig. 1-8).[13]

A comprehensive interrogation using multiple imaging planes should be performed to exclude left atrial appendage thrombus in the appropriate clinical setting. The right atrial appendage is smaller and triangular in shape (see Fig. 1-3, *B*). The endocardial surfaces of both appendages are corrugated and should not be confused with small thrombi.[12] A long-axis view of the aorta can be achieved with the imaging plane at about 120° (Fig. 1-9). A more rightward imaging plane, such as 150°, may be needed if the ascending aorta is dilated and tortuous. This view allows the visualization of a longer length of the ascending aorta and thus significantly reduces the blind spot caused by the interposing trachea.

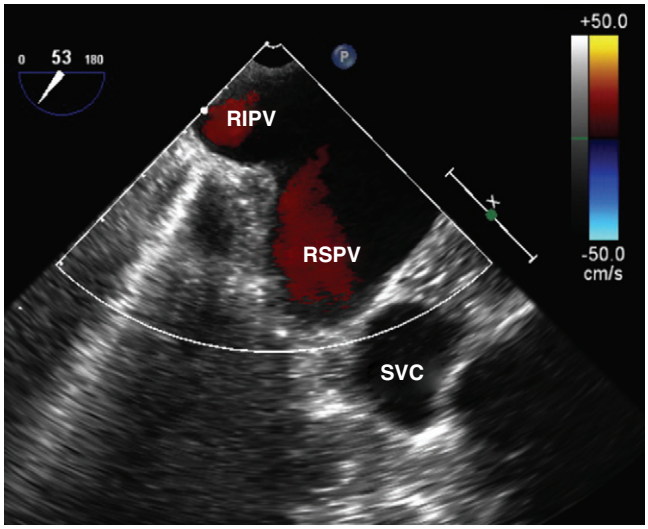

**Figure 1-6** The two right pulmonary veins are demonstrated using the longitudinal plane, and their identification can be facilitated by color flow imaging. The superior vein provides better Doppler spectral signal due to its parallel alignment with the ultrasound. *RIPV*, Right inferior pulmonary vein; *RSPV*, right superior pulmonary vein; *SVC*, superior vena cava.

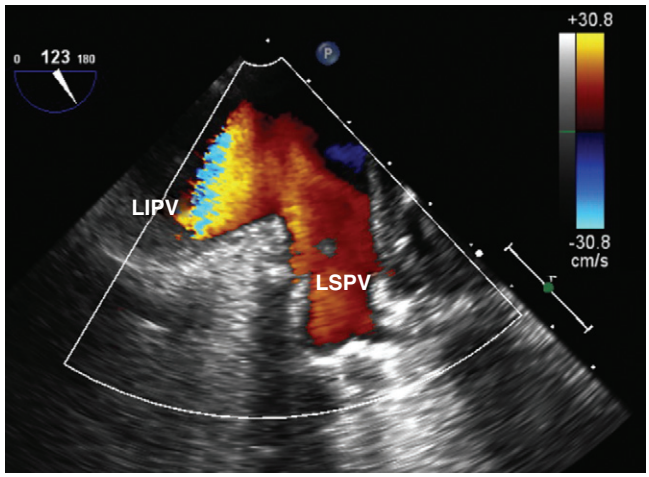

**Figure 1-7** The two left pulmonary veins are demonstrated using the longitudinal imaging plane. As with the right-sided counterparts, the superior vein is preferred for Doppler interrogation. *LIPV*, Left inferior pulmonary vein; *LSPV*, left superior pulmonary vein.

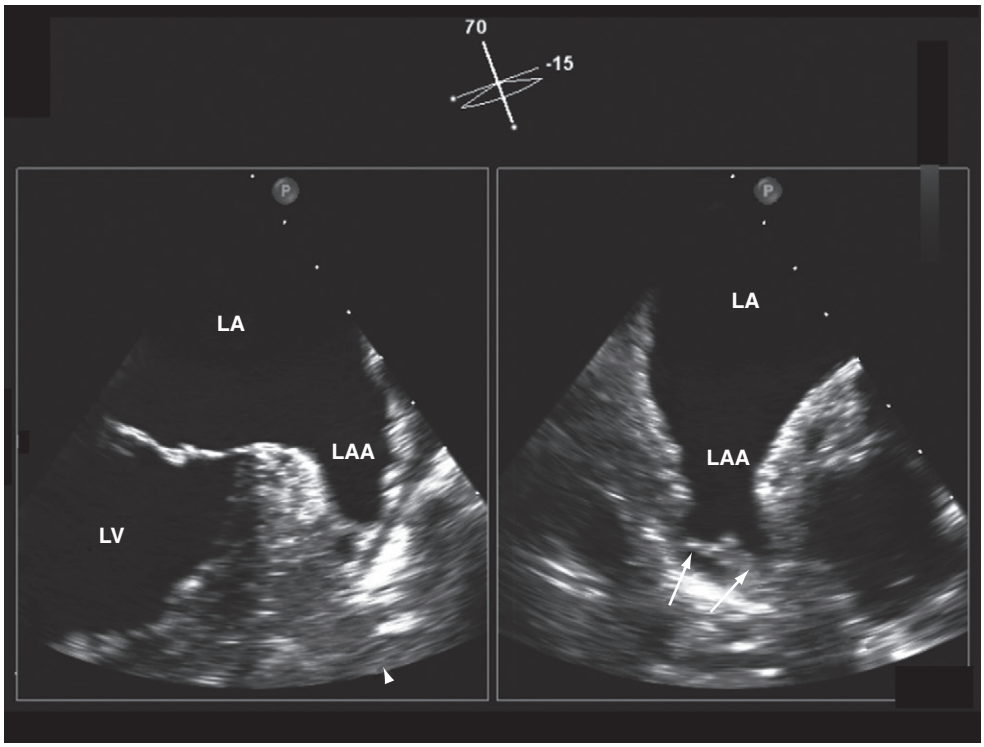

**Figure 1-8** The left atrial appendage (*LAA*) can have multiple lobes that can be readily assessed using X-plane imaging with the 3D transesophageal probe. Two lobes (*arrows*) are demonstrated at –15° (and not at 70°).

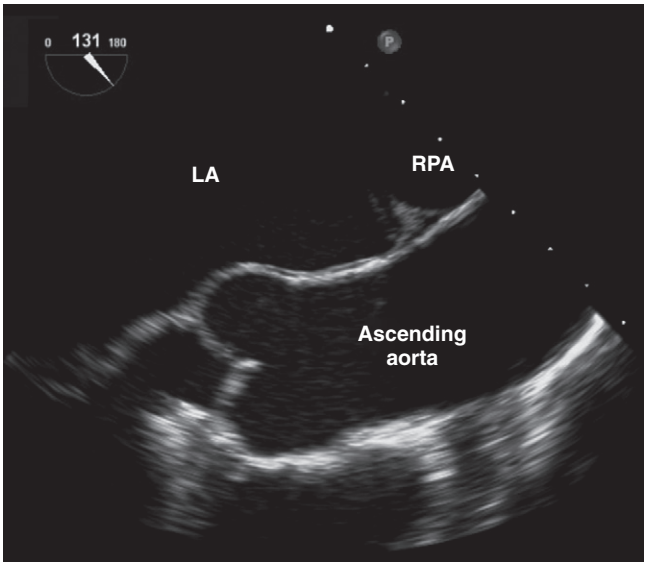

**Figure 1-9** Slight withdrawal of the probe relative to the probe position used to acquire the image shown in Figure 1-3, C, shows the right pulmonary artery (*RPA*) in short axis and more of the ascending aorta.

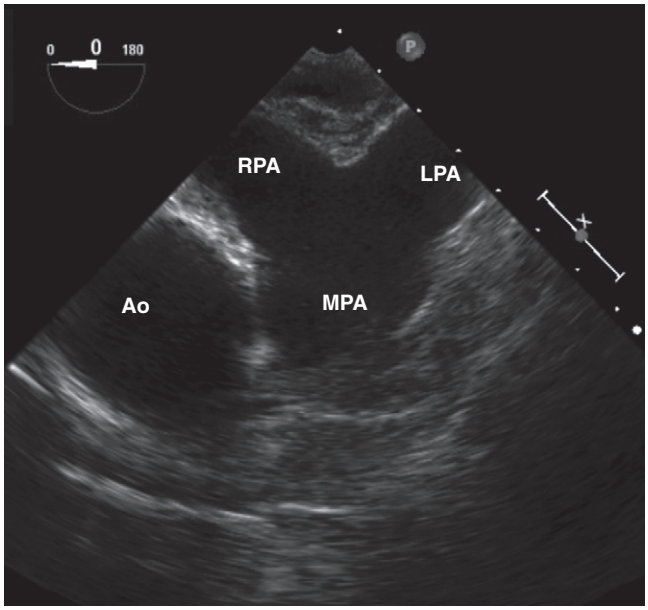

**Figure 1-10** The bifurcation of the main pulmonary artery (*MPA*) into the right (*RPA*) and left (*LPA*) pulmonary arteries is shown using the transverse plane. *Ao*, Aorta.

### *Atrial Septum*

We prefer to image the atrial septum using the longitudinal plane at 90° to 120°. The fossa ovalis, which is the thinnest part of the atrial septum, and the continuity of the superior vena cava with the RA are very well demonstrated in this view (see Fig. 1-3, *B*). This view is particularly valuable in demonstrating the sinus venosus atrial septal defect, which is usually located just inferior to the entrance of the superior vena cava.[14,15] The foramen ovale, if present, is located at the superior aspect of the fossa ovalis and is readily seen in this view. It is important to advance the probe to the level of the inferior vena cava so as not to neglect the inferior aspect of the atrial septum.[16] Careful sweep of the atrial septum with left-right rotation is needed to visualize the entire atrial septum. Continuous rotation from right to left will sequentially demonstrate the left ventricular (LV) outflow tract and the right ventricular (RV) outflow tract (see Fig. 1-2, *B*).

### *Pulmonary Bifurcation*

The pulmonary bifurcation view is achieved by withdrawal of the probe with the imaging plane at 0°. The pulmonic valve and main pulmonary artery are best seen slightly superior to the aortic valve (Fig. 1-10). The pulmonic valve is thinner than the aortic valve and is usually difficult to image in true cross section. Further slight withdrawal allows imaging of the pulmonary bifurcation. The entire length of the right pulmonary artery, but only the very proximal portion of the left pulmonary artery, can be seen. The right pulmonary artery can usually be followed to its first bifurcation by rotation of the probe rightward, but this maneuver is better performed with the longitudinal plane at 90°. Gradual rotation from left to right provides good visualization in cross section of the entire right pulmonary artery and its first bifurcation. This is an important view in the detection of proximal pulmonary emboli.[17,18]

## FOUR-CHAMBER VIEWS

Four-chamber views are obtained with the transducer within the middle to lower esophagus (see Fig. 1-1, *B*). It is difficult to image the left ventricle in its true long axis. Excessive anterior flexion should be avoided to prevent foreshortening of the ventricles. Indeed, to optimize visualization of the left ventricle, it is advisable to withdraw the probe slightly and at the same time attempt gentle retroflexion while maintaining adequate contact between the imaging surface and the esophagus. In the setting of a dilated and unfolded aorta, rotating the imaging plane to about 20° to 30° may be necessary to obtain the four-chamber view without the aorta obscuring the tricuspid valve and part of the RV.

### *Left Ventricle*

The inferior septum and anterolateral wall are usually seen in the four-chamber view (see Fig. 1-1, *B*). The LV apex is difficult to visualize, particularly in patients with a dilated LV. In addition to retroflexion, rightward flexion can often be helpful to minimize foreshortening of the LV. Far-field imaging can be improved by decreasing the transmission frequency or by using harmonic imaging. A continuous sweep from 0° to 180° should be performed to examine the different left ventricular segments so as to have a comprehensive assessment of left ventricular global and regional function (see Fig. 1-2, *C*).

### *Mitral Valve*

The mitral valve is well seen using the four-chamber view, but the depth of the imaging plane should be reduced to enhance the resolution of the image (see Figs. 1-1, *B*, and 1-2, *C*). To identify the individual scallops of the anterior and posterior mitral leaflets, a careful sweep from 0° to 180° should be made. The technique of visualizing specific scallops of the mitral leaflets has been published,[19] but patient-to-patient variation should be kept in mind. The presence of a good long-axis view of the aortic valve and proximal ascending aorta, usually at 120°, is a good indication that the middle scallops of both the anterior and the posterior mitral leaflets are imaged and provides the internal reference for the analysis of the other imaging planes. Both papillary muscles can be imaged, but usually not in the same plane. The subvalvular chords are seldom completely imaged because they are frequently obscured

by the mitral leaflets. The morphologic information obtained from this view should be corroborated by the short-axis view of the mitral valve obtained from the transgastric view, which also allows a better assessment of the subvalvular structures, including the papillary muscles and chords. Four-chamber views are ideal for the assessment of mitral regurgitation in relation to the number of regurgitant jets, the direction of the jets, and the severity of regurgitation.[20,21]

### *Left Ventricular Outflow Tract*

We like to image the left ventricular outflow tract at 120° to 160°, because the outflow tract has a horizontal alignment in this plane that may allow optimal imaging even in the setting of a prosthetic aortic valve (see Fig. 1-3, *C*). The opening and closing of the aortic valve as well as the presence or absence of aortic regurgitation can be well visualized. The proximal ascending aorta is present in this view. A slight withdrawal of the probe will allow more of the ascending aorta to be visualized (see Fig. 1-9). A slight rotation to the left will show the RV outflow tract with the thin pulmonic valve. The motion of the pulmonic valve and the presence or absence of pulmonic regurgitation can be adequately assessed using this view.

## TRANSGASTRIC VIEWS

There is slight resistance during the passage of the TEE probe through the gastroesophageal junction, and the appearance of the liver is a clear indication that the probe is in the stomach. Anterior flexion, often with leftward rotation and flexion, is required to achieve good contact between the imaging surface and the gastric wall. Extreme anterior flexion with further advancement of the probe can sometimes produce images similar to the five-chamber view obtained from the subxiphoid surface approach.

### *Left Ventricle*

Multiple cross sections of the LV can usually be obtained using the transgastric approach (see Fig. 1-1, *C*, and Fig. 1-11). These are the views commonly used in the intraoperative assessment of LV function.[19] Optimization of the short-axis views of the left ventricle can be achieved with leftward rotation accompanied by leftward flexion. To visualize the LV apex, gentle advancement of the probe is required together with slight retroflexion. In our experience, the short-axis view of the LV apex can be obtained in about 60% of cases. Another way to visualize the LV apex is to use the longitudinal plane at about 90° (see Fig. 1-11). Careful lateral rotation can be used to obtain comprehensive regional assessment of the LV. Leftward rotation of this imaging plane can yield a good alignment with the LV outflow tract and aortic valve to allow accurate measurement of the transaortic pressure gradients in the setting of aortic stenosis (Fig. 1-12).[22] The RV can be seen with rightward rotation of the probe. Both short- and long-axis views of the tricuspid valve are achievable, although the tricuspid valve and its papillary muscles are better assessed with the long-axis plane.

### *Mitral Valve*

The mitral valve can be best assessed using the horizontal imaging plane with the transducer brought up to near the gastroesophageal junction (Fig. 1-13). Anterior flexion and leftward flexion are usually required to optimize this view. Adjusting the imaging plane to about 20° will help to bring out the lateral commissure. This view provides unambiguous assessment of the individual scallops of both the anterior and posterior mitral leaflets and thus should be attempted in all patients with myxomatous mitral valve degeneration. In our experience, this view is achievable in about 70% of patients. Both papillary muscles and chords can be demonstrated, and the continuity between these structures and the mitral leaflets is best seen in the long-axis plane.

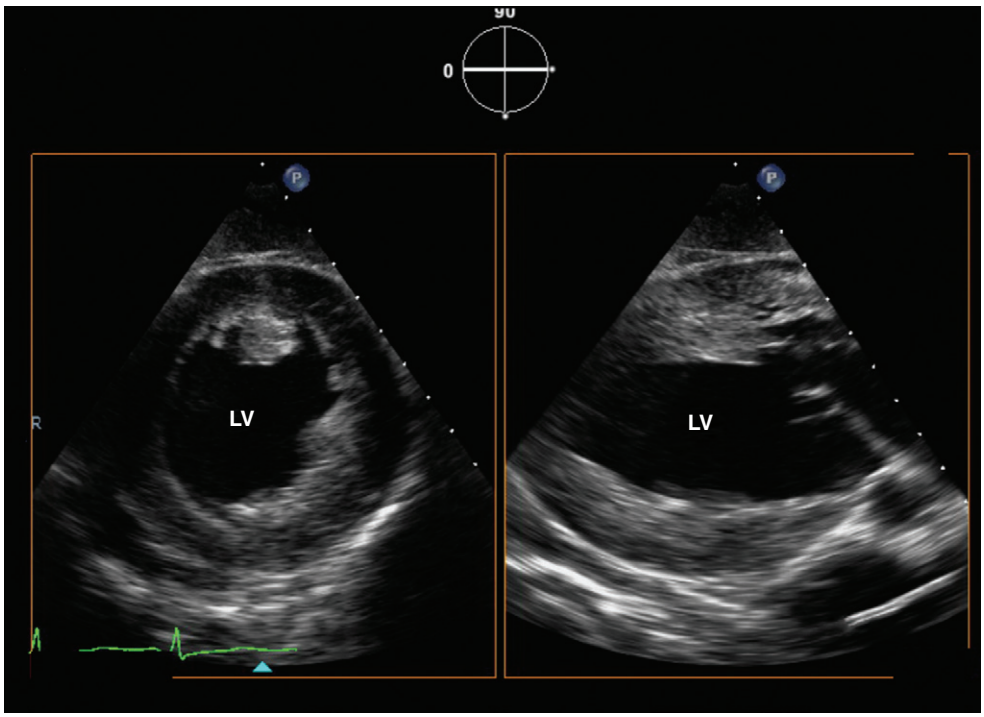

**Figure 1-11** The short- and long-axis views of the LV are demonstrated using X-plane imaging from the transgastric window.

### *Coronary Sinus*

The coronary sinus comes into view when the probe is withdrawn to near the gastroesophageal junction and the flexion knobs are in relatively neutral positions (Fig. 1-14). This view can also be achieved by retroflexion with the probe in the lower esophagus. The coronary sinus is seen as a vascular structure located posterior to the LV at the atrioventricular groove draining into the RA. The tricuspid valve can be visualized to the right and anterior. A dilated coronary sinus should raise the possibility of the presence of a persistent left superior vena cava, which is the most common cause. Leftward rotation while following the coronary sinus may sometimes demonstrate this anomalous vein.[23] In the esophageal views, the left superior vena cava is usually sandwiched between the left atrial (LA) appendage and left superior pulmonary vein.[24]

## AORTIC VIEWS

The thoracic aorta is well assessed by TEE because of its close proximity to the esophagus.

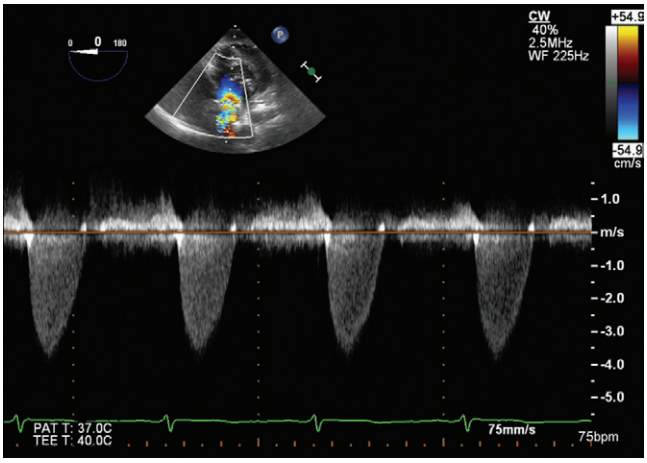

**Figure 1-12** Transgastric window is used to assess the severity of aortic stenosis using CW Doppler echocardiography.

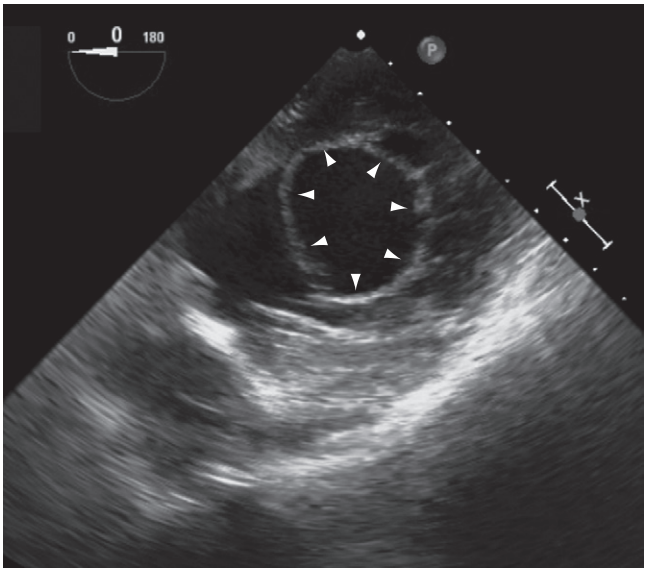

**Figure 1-13** Transgastric view of the mitral valve (*arrowheads*) in the short axis showing the circular orifice of the mitral valve in early diastole.

### *Descending Thoracic Aorta*

The best way to assess the descending thoracic aorta is to use the horizontal imaging plane with the transducer rotated leftward and posterior, followed by slow withdrawal from the level of the diaphragm to the aortic arch (see Fig. 1-1, *D*).[12] Because of the relationship between the esophagus and aorta, slight rotational adjustment is required to visualize the entire circumference of the aortic wall as the probe is slowly withdrawn.[24] If the aorta is dilated or tortuous, proper short-axis views of the descending aorta will require adjustment of the imaging plane by 0° to 90°.

### *Aortic Arch*

The longitudinal imaging plane at 90° is preferred in imaging the aortic arch because it allows visualization of the entire circumference of the aorta (Fig. 1-15).[24] Anterior rotation of the longitudinal plane should visualize the entire aortic arch, but the proximal aortic arch may not be visualized when the aortic arch is unfolded. The transducer will need to be withdrawn slightly to image the arch vessels, which course superiorly. In

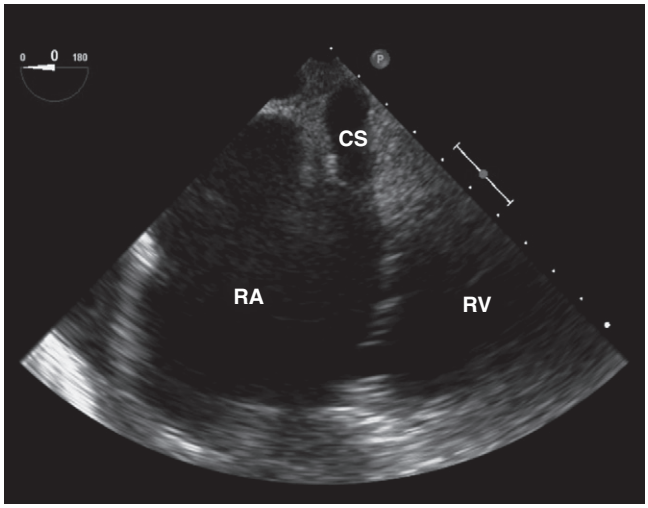

**Figure 1-14** The coronary sinus (*CS*) is demonstrated with the probe at the gastroesophageal junction.

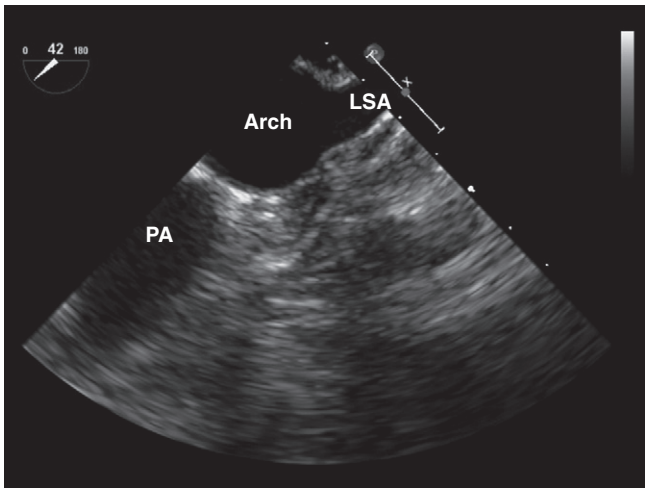

**Figure 1-15** The aortic arch is imaged using the longitudinal plane, showing the origin of the left subclavian artery (*LSA*). *PA*, Pulmonary artery.

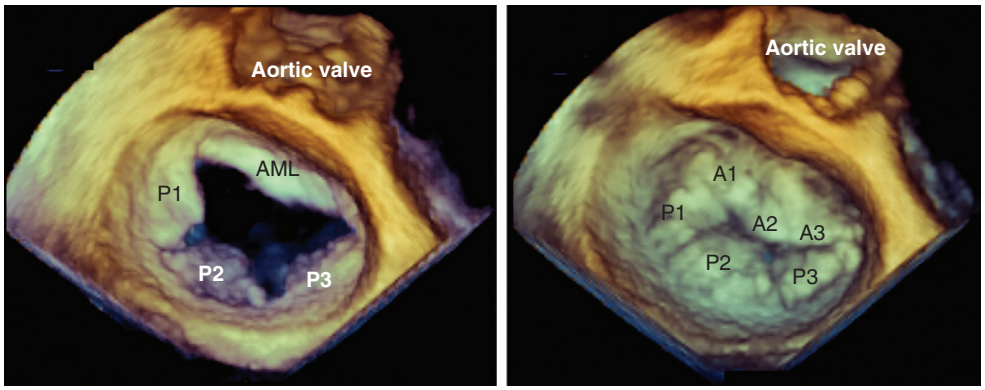

**Figure 1-16** The individual scallops of the anterior (*A1*, lateral scallop; *A2*, middle scallop; *A3*, medial scallop) and posterior mitral leaflets (*P1*, lateral scallop; *P2*, middle scallop; *P3*, medial scallop) in diastole (*left* panel) and systole (*right* panel) are shown using the 3D zoom mode. *AML*, Anterior mitral leaflet.

one third of patients, all three arch vessels can be imaged, but in the other two thirds of patients, only the two distal arch vessels can be imaged. It is rare not to be able to image at least one arch vessel. As a rule, the brachiocephalic artery, which is anterior and more rightward, is the most difficult to image because of the interposing trachea. The transverse plane in a more superior location may sometimes show the three arch vessels in their short axis. Advancing the probe by 1 to 2 cm so that the imaging plane is just inferior to the aortic arch can frequently image the proximal left pulmonary artery. It is sometimes possible to follow it to the first bifurcation. This view should be sought in patients suspected of having pulmonary embolism.

## Three-Dimensional Imaging

Advances in transducer technology have enabled the incorporation of real-time 3D-imaging capacity into the commercially available TEE probe, such that 3D imaging can be readily performed during a conventional two-dimensional (2D) TEE study providing unique anatomic perspectives in a number of clinical situations.[25-32] (See Chapter 4.) The current clinical indications of 3D TEE are summarized in Table 1-2, and the indications are likely to increase with time. In our opinion, 3D TEE imaging should be routinely performed in patients with mitral valve disease and congenital heart disease (Fig. 1-16).

The currently available 3D TEE probe can perform 3D imaging in several modes: 3D full volume, 3D zoom, 3D live, 3D color-flow imaging, and X-plane imaging. We find 3D zoom and X-plane imaging to be the most useful. To acquire 3D full volume, the full pyramidal volume is obtained by stitching together four subvolumes gated to the R-wave of the electrocardiogram. To minimize the stitch artifact between the subvolumes, it is best to acquire the images during a breath hold (Fig. 1-17). In this mode, frame rates are relatively low. Although analysis of the volumetric data set can be performed online, it is frequently performed offline so as not to prolong the study. In the full-volume mode, the semiautomatic multiple parallel slice display can be a quick and useful format in the assessment of LV topography, such as in patients with regional wall motion abnormalities or ventricular aneurysms.

In the real-time live 3D mode, the 3D data set is displayed in real time. It is important to minimize the sector angle so as to increase the frame rate, which is considerably reduced compared to 2D imaging. We find the 3D zoom mode to be the most

**TABLE 1-2 Common Indications for Using Real-time Three-Dimensional Transesophageal Echocardiography**

| *Cardiac Structure* | *Information from 3D TEE* | *Clinical Situations* |
|---|---|---|
| Mitral valve | En-face view of mitral valve | Assessment of the location of prolapsing or flail mitral leaflet scallops for potential mitral valve repair; intraoperative assessment of mitral valve clip repair. |
| Prosthetic valve | Number, size, and location of perivalvular regurgitant jets | Preoperative and intraoperative assessment for device closure of perivalvular regurgitation |
| Atrial septum | Number, size, and location of atrial septal defect | Preoperative and intraoperative assessment for device closure of atrial septal defect |
| Intracardiac baffle or conduit | Better anatomic perspective of intracardiac abnormalities | Assessment of naïve and postoperative complex congenital heart disease |

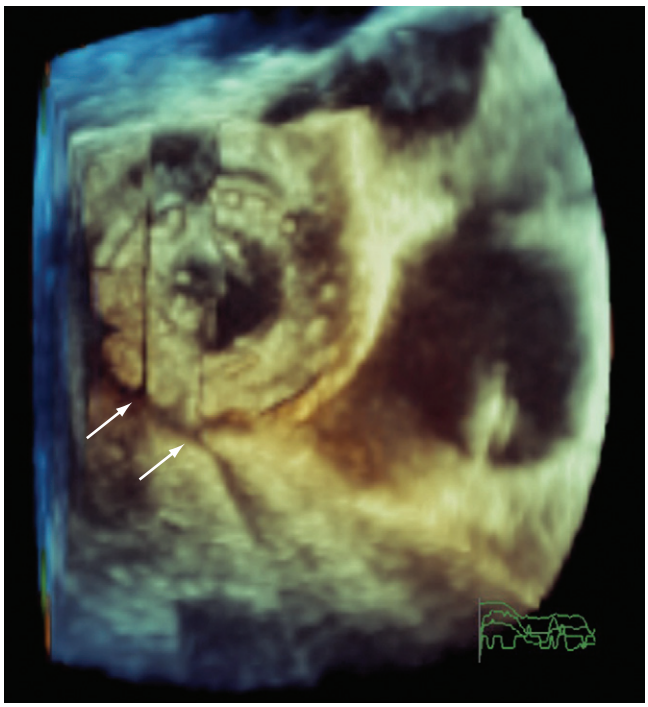

**Figure 1-17** Transesophageal 3D view of the bioprosthetic mitral valve in the full volume mode shows the stitch artifact (*arrows*) between the subvolumes.

versatile. In the 3D zoom mode, the area of interest is identified and encompassed by the zoom box, generally in two orthogonal planes. The height and width of the zoom box are adjusted to include the entire area of interest and at the same time streamlined as much as possible in order to enhance the frame rate. Indeed, the 3D zoom mode is our preferred display format when using the 3D live mode. The availability of the X-plane is a very welcome addition to TEE imaging. It allows the simultaneous display of an additional plane during standard 2D imaging. The orientation of the additional plane is usually orthogonal but can be easily adjusted to any specific orientation. The availability of the X-plane provides a quick and comprehensive assessment of complex structures. One example is the LA appendage, which frequently has multiple lobes (see Fig. 1-8). The use of the X-plane allows rapid assessment of the multiple lobes. Similarly, when multiple mitral regurgitant jets are present, X-plane imaging can readily identify the number and orientations of the regurgitant jets.

Real-time 3D color flow imaging can also be performed to provide a 3D assessment of the color flow jet, but the volume of interest is small, and the frame rate is quite limited in this mode.[33,34] In vitro and early clinical studies have suggested that 3D color flow imaging gives a more accurate assessment of the shape and size of the vena contracta and flow convergence, both of which are important measures of mitral regurgitation severity. Its clinical usefulness, however, remains unclear.

In order to obtain a high-quality 3D image, the 2D image needs to be optimized in terms of gain and compression settings. A slightly higher gain setting generally provides better 3D images. In both the 3D zoom and 3D live modes, the zoom box should be streamlined to focus on the area of interest to maximize the frame rate. Because the best 3D imaging is obtained with the structure close to the transducer and orthogonal to the ultrasound beam, the TEE transducer should be manipulated to achieve these two objectives. For instance, the transgastric window is superior to the transesophageal window in 3D imaging of the LV papillary muscles. The mitral valve is well suited for 3D TEE imaging precisely for these reasons (see Fig. 1-16). On the other hand, it is much more difficult to obtain a good 3D image of the aortic valve because the valve plane is frequently parallel to the ultrasound beam.

## Doppler Examination

Transesophageal echocardiography can be used to assess the flow patterns across the four cardiac valves, but it does not provide additional information to transthoracic echocardiography (TTE). Furthermore, good ultrasound beam alignment with the transvalvular flow may not be feasible because of the anatomic confines of the esophagus. However, accurate Doppler assessment of aortic stenosis can often be obtained from the transgastric window (see Fig. 1-12).[22] On the other hand, intracardiac flows such as pulmonary vein flow and LA appendage flow are better and more consistently obtained by TEE and provide important insight into intracardiac hemodynamics.

### LEFT ATRIAL APPENDAGE FLOW

The LA appendage can be imaged from the midesophagus aortic valve short-axis view (30° to 60°) or the midesophagus two-chamber view (80° to 100°). LA appendage flow should be recorded by positioning the color flow sector over the LA appendage and placing the pulsed-Doppler sample volume at the site of maximal flow velocity. This usually occurs in the proximal or middle third of the LA appendage. Velocity recordings from the distal third of the LA appendage frequently have wall motion artifacts and are usually unsatisfactory. Wall filters should be set low, because low-velocity flow may be present.

The pattern of LA appendage flow is dependent on cardiac rhythm.[35,36] In atrial fibrillation, a regular atrial contraction wave is absent. (See Chapter 42.) In atrial flutter, the velocity waves are more regular and tend to be of greater velocity because of the slower atrial rate. The normal LA appendage velocities are as follows: contraction, 60 ± 14 cm/s; filling, 52 ± 13 cm/s; and early diastolic filling, 20 ± 11 cm/s.[35,37]

The potential clinical utility of measuring LA appendage velocities relates to their association with LA spontaneous echo contrast and LA thrombus.[35,36,38,39] Patients with atrial fibrillation and a LA appendage emptying velocity less than 20 cm/s are more likely to have LA thrombus and have a 2.6-fold greater risk of ischemic stroke compared to patients with a velocity greater than 20 cm/s.[38,39] Lower LA appendage velocities have also been observed in stroke patients in normal sinus rhythm.[40] LA appendage velocities may predict successful cardioversion of atrial fibrillation[41] and the maintenance of sinus rhythm at 1 year.[35,36,42]

### PULMONARY VEIN FLOW

Pulmonary venous flow patterns provide unique and ancillary information for evaluating LV diastolic function, measuring LV filling pressure, assessing mitral regurgitation severity, differentiating constrictive pericarditis from restrictive cardiomyopathies, and identifying pulmonary vein stenosis after radiofrequency ablation of atrial fibrillation.[43-45] TTE can obtain pulmonary vein flow in up to 90% of patients; however, TEE allows a more consistent and reliable acquisition of high-quality laminar Doppler signals.[43,46]

The pulmonary veins are imaged from the midesophagus, and flow is evaluated by placing the pulsed-Doppler sample volume 1.0 to 2.0 cm into the pulmonary veins. The ultrasound beam can be aligned parallel to flow in the left and right superior pulmonary veins; however, this alignment is often not achievable with the inferior pulmonary veins.

## Indications for Transesophageal Echocardiography

In general, TTE should be the initial diagnostic investigation, because it is noninvasive and imparts no risk to the patient. However, patient factors (i.e., obesity, emphysema, chest deformities, or subcutaneous emphysema) and the clinical setting (i.e., surgical bandages, mechanical ventilation, or traction) frequently limit ultrasound penetration or proper patient positioning, resulting in a nondiagnostic TTE. TEE can provide excellent cardiac visualization in these situations and should be considered to obtain the necessary diagnostic information.

TEE can also visualize cardiac structures not usually seen by TTE (i.e., the superior vena cava, pulmonary veins, and descending thoracic aorta) and can provide improved anatomic and spatial resolution to both diagnose cardiac pathology and guide patient management. Common clinical indications for TEE are listed in Box 1-2.

Box 1-2

**COMMON INDICATIONS FOR TRANSESOPHAGEAL ECHOCARDIOGRAPHY**

Nondiagnostic transthoracic echocardiogram
Evaluation of native valve disease
Evaluation of prosthetic valves
Evaluation of suspected and definite infective endocarditis
Evaluation of a suspected cardioembolic event
Evaluation of cardiac tumors or masses
Evaluation of an atrial septal abnormality
Evaluation of an acute aortic syndrome or aortic disease
Atrial fibrillation (TEE-guided strategy for "early" cardioversion)
Evaluation of naïve and surgically corrected congenital heart disease
Detection of coronary artery anomalies and coronary artery disease
Evaluation of postoperative cardiac tamponade and pericardial disease
Evaluation of the critically ill patient
Intraoperative monitoring
Guidance of interventional procedures

## NATIVE VALVE DISEASE

The close proximity of the mitral valve to the posteriorly positioned TEE transducer allows excellent visualization of the mitral annulus, leaflets, chordal structures, and papillary muscles. (See Chapters 18 and 19.) Ruptured chordae tendinae can be visualized, and prolapsing or flail scallops can be localized, to predict the potential for successful mitral valve repair.[20,47-49] Abnormalities of the papillary muscles, such as a partial or complete rupture, are better visualized by TEE than TTE.[50] 3D TEE provides superior delineation of the mitral valve anatomy and can more precisely characterize and localize mitral valve pathology compared to 2D TEE.[26,30,31,51]

The severity of mitral valve regurgitation can be quantified by TEE using the same methods employed for TTE[52]; however, color Doppler regurgitant jet areas tend to be larger on TEE than on TTE.[53] 3D color Doppler imaging provides additional information on the mechanism and severity of mitral regurgitation that may not be apparent from 2D TEE.[33,51,54,55] Pulmonary vein flow can be assessed in nearly all patients and provides a valuable measure of mitral regurgitation severity.[43,56] The vena contracta width and regurgitant orifice area, derived by the proximal flow convergence method, can be measured using TEE and can provide prognostic information in patients with asymptomatic mitral regurgitation.[57-59] The accuracy of these latter measures to quantify mitral regurgitation severity can be improved using 3D TEE.[33,55]

In mitral stenosis, TEE can assess valve mobility and leaflet thickening, but subvalvular disease and calcification may be underestimated in the esophageal views due to a shadowing effect from the thickened and calcified mitral valve leaflets and annulus.[60] (See Chapter 21.) Effective orifice area can be derived by the pressure half-time method, proximal flow convergence method, or orifice planimetry.[61,62] Accurate orifice planimetry requires a tomographic cut of the distal, most narrowed portion of the mitral orifice. Optimal alignment of the image is frequently not possible using 2D TEE, but may be achievable by 3D TEE.[31] The suitability of a patient for percutaneous balloon mitral valvuloplasty usually incorporates a TEE evaluation of the LA chamber and appendage to identify thrombus, an assessment of the mitral valve morphology score, and an evaluation of mitral regurgitation severity. Mitral valve morphology on TEE is predictive of the prognosis of patients following percutaneous balloon mitral valvuloplasty; however, TTE is preferred to evaluate valve morphology because of the limitations of TEE in evaluating calcification and subvalvular thickening.[60,63] TEE can be used during transcatheter mitral commissurotomy to guide the transseptal puncture and balloon placement and to identify potential procedural complications (i.e., severe mitral regurgitation, cardiac tamponade, or significant atrial septal defect).[64] (See Chapter 5.) 3D TEE may provide incremental information during the procedure by confirming the coaxial trajectory of the balloon through the stenotic mitral valve and by better evaluating commissural opening postdilation.[65,66]

Subaortic membranes frequently require TEE for definitive diagnosis.[67] Anatomic valve area of a stenotic aortic valve can be measured using multiplane TEE by planimetry of the maximum systolic orifice area in the esophageal short-axis (30° to 60°) view.[22,68] Proper transducer position should be confirmed by rotating to the longitudinal plane and verifying that the leaflet tips are being imaged. However, dynamic movements of the aortic valve can cause misalignment of the imaging plane with the narrowest cross-sectional area and result in an inaccurate measurement of the anatomic valve area. 3D TEE can avoid this potential pitfall.[69] Unfortunately, valve calcification can affect the accuracy of TEE-measured orifice areas using either 2D or 3D techniques.[70]

TEE is rarely necessary to evaluate aortic regurgitation severity. The standard methods used during TTE to quantify aortic regurgitation severity can be used during TEE.[52,71] Color jet areas on TEE tend to be larger than those obtained during TTE.[53] Vena contracta width on TEE correlates well with the regurgitant fraction and regurgitant volume.[72] Aortic regurgitation severity can also be quantified using the proximal flow convergence method.[73] Holo-diastolic flow reversal in the descending aorta can be detected by TEE using pulsed Doppler.[74]

The tricuspid and pulmonic valves can be visualized on TEE; however, TTE generally provides better visualization because of the anterior position of these valves. 3D TEE appears to be of limited value in evaluating these valves. In one study, 3D TEE provided optimal visualization of the tricuspid valve in only 11% of patients.[75] However, TEE may provide clinically relevant information about the tricuspid and pulmonic valves in patients with poor TTE images.

## PROSTHETIC VALVES

TEE is more sensitive for detecting abnormalities of bioprosthetic and mechanical prostheses when compared to TTE.[76] (See Chapter 25.) Leaflet thickening and calcification, flail leaflets, vegetations, thrombi, filamentous strands, and motion of the occluding device are better appreciated on TEE.[76-83] TEE can distinguish pannus from thrombus formation and guide the use of thrombolytic therapy.[84-87] TEE is especially valuable in assessing a mitral prosthesis, because the transducer's posterior position provides excellent visualization of vegetations and thrombi that usually locate on the LA aspect of the prosthesis.[76,78] However, the ventricular aspect of a mitral prosthesis may not be adequately seen on TEE, and TTE should be performed to complete the assessment.[88] 3D TEE can provide excellent visualization of a mitral prosthesis ring, leaflets, or strut (mechanical or bioprosthesis).[27] The aortic prosthesis ring can also be

well seen on 3D TEE; however, visualization of the leaflets can be suboptimal.[27]

TEE should be performed if significant prosthetic mitral regurgitation is suspected clinically, but not seen on TTE. TEE can distinguish normal variant from pathological prosthetic valve regurgitation and determine whether the regurgitation is paravalvular or transvalvular in origin, potentially modifying the surgical procedure.[77-80,89] 3D TEE may provide better delineation of the site and extent of paravalvular regurgitation or mitral prosthesis dehiscence compared to 2D TEE.[27] The incremental benefit of TEE in assessing prosthetic aortic regurgitation severity is less clear, because the regurgitant jet is usually well seen on TTE, and TEE visualization may be compromised by partial shadowing of the regurgitation jet by either the aortic or mitral prosthesis when imaged in the esophageal views.[80]

All bioprostheses and mechanical prostheses are inherently stenotic, the severity dependent on the prosthesis type and size and the presence of associated pathology such as leaflet calcification, pannus formation, or valve thrombosis. In general, TTE is sufficient to assess the hemodynamic severity of a stenotic aortic or mitral prosthesis, but only TEE has sufficient resolution to distinguish these pathologic conditions.[84,85] In patients with an inadequate TTE, TEE can be used to quantify the stenosis severity, as described for native valve stenoses.[22,62,68,90]

## INFECTIVE ENDOCARDITIS

Identification of a vegetation in the clinical setting of suspected endocarditis confirms the diagnosis.[91] Studies comparing TTE and TEE for detecting a vegetation in native valve endocarditis report a sensitivity of 28% to 70% for TTE, substantially lower than the 86% to 100% sensitivity reported for TEE.[92-97] (See Chapter 22.) Smaller vegetations are better detected by TEE because of the improved spatial resolution of this technique.[93] However, TTE and TEE have a similar specificity that exceeds 90% when strict criteria for diagnosing a vegetation are used.[92,93,95,97] Pulmonic valve vegetations are better detected by TEE than TTE, despite the anterior position of the pulmonic valve.[98] In contrast, TEE has not been reported to have a better sensitivity for detecting tricuspid valve vegetations compared to TTE.[99] However, we would recommend a TEE if there is a clinical suspicion of tricuspid valve endocarditis but the TTE is negative.

Prosthetic valve endocarditis is more difficult to diagnose by either TTE or TEE. The sensitivity of TTE for detecting vegetations ranges from 0% to 43% and increases to 33% to 86% using TEE.[76,94,100,101] Clearly, TEE can identify a vegetation in a significant number of patients with a negative TTE and should be performed in patients with suspected prosthetic valve endocarditis if the TTE does not identify a vegetation.[102]

Although TEE provides a greater sensitivity than TTE for detecting vegetations in native and prosthetic-valve endocarditis, TEE has the greatest impact on diagnosis in patients with suspected endocarditis and an intermediate clinical probability of endocarditis.[102,103] The absence of a vegetation on TEE in this setting makes the diagnosis of endocarditis unlikely (less than 10%), and alternative diagnoses should be considered.[101,104] However, a negative TEE does not supplant a clinical and microbiological diagnosis, because false-negative studies have been reported. Patients with a negative TEE study may benefit from a follow-up TEE in 7 to 10 days if there is a high index of suspicion of endocarditis, a prosthetic valve, or persistent bacteremia.[101-104] TEE is likely not warranted in patients with a low clinical probability of endocarditis, because the diagnostic yield is small.[103]

Complications of infective endocarditis, including abscess formation, leaflet diverticula, leaflet perforation, fistula tracts, mycotic aneurysms, and pseudoaneurysm formation, are significantly better detected by TEE than TTE.[94,105-108] TTE has a low sensitivity (less than 30%) for detecting an abscess,[105] so a patient with a suspected abscess on clinical grounds or persistent bacteremia should undergo TEE despite a negative TTE. TEE can be falsely negative in up to half of patients with an abscess.[108] This often occurs when the abscess cavity is localized on the posterior aspect of a calcified mitral annulus or when a prosthesis is present.[108]

The potential utility of TEE in uncomplicated confirmed endocarditis remains to be defined. Large (greater than 10 to 15 mm) or severely mobile vegetations on TEE are associated with systemic embolization, and vegetation size is an independent predictor of survival.[96,109,110] Furthermore, complications are more likely to occur in patients in whom a vegetation fails to decrease in size with therapy.[111] Although we routinely perform a TTE in follow-up of patients with uncomplicated confirmed endocarditis to reevaluate vegetation size and valve function, we do not routinely perform a follow-up TEE.

## SUSPECTED CARDIOEMBOLIC EVENT

Cardiogenic embolism accounts for approximately 15% to 30% of ischemic strokes and should be considered as a potential cause of cerebral ischemia, especially in those patients without significant cerebrovascular disease.[112] (See Chapter 41.) Potential cardioembolic sources encompass conditions that have a propensity for thrombus formation, intracardiac or intraaortic masses, and potential passageways for paradoxical emboli. Cardiac abnormalities having a strong association with cardioembolic events include atrial fibrillation, LA or LV thrombi, vegetations, intracardiac tumor, mitral stenosis, mechanical valves, recent myocardial infarction, dilated cardiomyopathy, ischemic LV dysfunction (ejection fraction less than 28%), and intraaortic debris.[113,114] Minor risk sources with weaker associations include atrial septal aneurysms, patent foramen ovale, spontaneous echo contrast, mitral annular calcification, mitral valve prolapse, and calcified aortic stenosis.[113-115] Although many of these conditions can be diagnosed clinically, echocardiography is frequently necessary to diagnose anatomic abnormalities.[116] In general, TEE is superior to TTE at identifying major and minor risk sources.

LA thrombus is usually located in the LA appendage, a region poorly visualized on TTE. TTE has a sensitivity for detecting LA thrombi of only 0% to 53%, whereas TEE has a sensitivity of 93% to 100% and a specificity exceeding 95%.[117,118] Care must be taken not to mistake the pectinate muscles for LA appendage thrombus. LA spontaneous echo contrast is rarely appreciated on TTE but is well seen on TEE. LV thrombi can usually be detected by TTE (sensitivity and specificity approaching or exceeding 90%), and contrast echocardiography can improve the diagnostic accuracy.[119] In general, TEE adds no incremental sensitivity unless the TTE is inconclusive, because the apex is located in the far-field position and apical foreshortening is common.[120,121] TEE may better detect small myxomas or papillary fibroelastomas.[122,123] Similarly, TEE is superior to TTE for detecting an atrial septal aneurysm and patent foramen ovale, although the addition of harmonic imaging to TTE has improved the sensitivity of TTE for detecting a patent foramen ovale.[124-126]

The cardioembolic risk of a patent foramen ovale is related to the defect size, which can be better appreciated by TEE.[127,128] Aortic arch atheroma can be detected by TTE; however, TEE is required to adequately assess the extent, degree of lumen protrusion, and morphological features (i.e., mobility, ulceration, calcification) that characterize the potential embolic risk.[38,129-131]

The indication for performing a TEE in a patient with a suspected cardioembolic event is controversial.[113,132,133] Although TEE has a better sensitivity than TTE for detecting potential cardioembolic sources,[134,135] the yield for identifying a major risk source is limited. An analysis of pooled data suggested an overall detection rate for intracardiac masses of only 4% for TTE and 11% for TEE.[113] The yield was greater in patients with cardiac disease (TTE, 13%; TEE, 19%), but small in patients without cardiac disease (TTE, 0.7%; TEE, 1.6%). Of importance, the identification of minor risk source by TEE may not significantly alter patient management. Therefore, TEE should only be performed if the results have a reasonable chance of altering patient management or therapy. In this regard, TEE likely has the greatest potential impact on management when the TTE fails to identify a cardioembolic source in a patient with (1) unexplained cerebral ischemia before 55 years of age, (2) recurrent events or events in multiple cerebrovascular territories, (3) occlusion of a large peripheral or visceral artery, or (4) suspected endocarditis.

## ATRIAL SEPTAL ABNORMALITIES

Atrial septal defects, atrial septal aneurysms, and patent foramen ovale are identified more frequently by TEE than TTE.[14,124,126] Sinus venosus defects and associated anomalous pulmonary venous drainage are easily detected on TEE, but frequently missed on TTE.[14,15] Therefore, a TEE should be considered in a patient with unexplained right heart dilation despite a negative TTE for intracardiac shunting. (See Chapter 44.) TEE can delineate the morphological details of an atrial septal defect and patent foramen ovale, determine the size of the defect and severity of left-to-right shunting, determine the potential for percutaneous closure, and assist with proper device placement during percutaneous closure.[32,127,128,136,137] The en-face view of the atrial septum using 3D TEE and multiplanar reconstruction provides a better appreciation of the defect (i.e., size, presence of multiple defects, septal rim length) and spatial relationships among the defect, occluding device, and surrounding cardiac structures such as the mitral valve and aortic root.[32,75,138,139]

## CARDIAC TUMORS

The sensitivity of TTE and TEE for detecting atrial myxomas has been reported to be 95% and 100%, respectively.[140] (See Chapter 46.) Similar high sensitivities have been reported when detecting nonmyxomatous intracardiac tumors.[140] However, the sensitivities of TTE and TEE are dependent on tumor size and may be as low as 62% and 77%, respectively, for detecting papillary fibroelastomas smaller than 2 mm.[123] TEE is superior to TTE for characterizing features of an intracardiac tumor that are important for diagnosis and management, such as the involvement of multiple chambers, site of attachment, presence of multiple tumors, infiltration of adjacent structures, and presence of tumor calcification or cyst formation.[122,140] TEE can be used to guide percutaneous biopsy of an intracardiac tumor.[141] 3D TEE may provide incremental information relevant to deciding the optimal surgical approach.[142]

Pericardial or paracardial tumors are better detected using TEE than TTE.[140] TEE appears especially valuable for detecting tumors located at the base of the heart, adjacent to the great vessels, or adjacent to the right heart.[122,140] However, the size and extent of paracardial involvement is not usually well delineated using TTE or TEE. Magnetic resonance imaging and computed tomography have a wider field of view and provide a superior evaluation of extracardiac involvement.

## ACUTE AORTIC SYNDROMES

Aortic dissection can be detected by TEE with a high degree of accuracy and is the diagnostic investigation of choice for suspected aortic dissection in many institutions.[143] (See Chapter 36.) The presence of an intimal flap is diagnostic of aortic dissection and can be distinguished from reverberation artifacts commonly seen in the ascending aorta by using M-mode echocardiography.[144] A small segment of the superior ascending aorta may not be visualized by TEE because of the interposition of the air-filled trachea and bronchus. Multiplane TEE has a sensitivity of 98% to 100% and a specificity of 94% to 95%[145] and can be performed at the bedside of hemodynamically unstable patients. TEE can determine the extent of the dissection and involvement of arch vessels or coronary arteries, differentiate the true and false lumen, identify thrombus within the false lumen, locate the site of the intimal tear, detect signs of rupture, and evaluate for aortic valve involvement and the potential for valve repair.[143,146] TEE can also guide stent graft implantation for descending thoracic aorta dissections and identify complications following surgical repair.[147,148]

Intramural hematoma and penetrating aortic ulcers have a similar presentation to aortic dissection.[149,150] TEE has a sensitivity and specificity that exceed 90% for identifying intramural hematoma[145] and can be performed serially to assess for hematoma regression or progression or the development of classic dissection.[151] The diagnostic accuracy of TEE for detecting penetrating aortic ulcers is unclear; however, one study reported a sensitivity of 83%.[152] The presence, depth, and diameter of a penetrating ulcer are predictive of disease progression and prognosis.[153]

Traumatic aortic rupture and blunt aortic trauma can be diagnosed by TEE with a sensitivity of 63% to 100% and a specificity of 84% to 100%.[130,154] TEE can guide the acute management and triage patients for conservative therapy, immediate surgery, or postponed surgical repair.[155] However, TEE cannot consistently visualize the superior ascending aorta and aortic arch branch vessels, a frequent site of traumatic injury.

## ATRIAL FIBRILLATION

Atrial fibrillation predisposes the LA to contractile dysfunction, chamber dilation, and thrombus formation in approximately 13% of patients with nonrheumatic atrial fibrillation of more than 2 days' duration.[156] TEE is clearly superior to TTE for detecting LA thrombus and has a sensitivity ranging from 93% to 100% and a specificity greater than 95%.[117,118] In addition, LA appendage velocity less than 55 cm/s on TEE identifies patients at increased risk for thrombus formation.[157] The presence of LA thrombus, spontaneous echo contrast, LA appendage velocity below 20 cm/s, or complex aortic atheroma on TEE identifies patients with atrial fibrillation at higher risk of thromboembolism.[38,158]

A TEE-guided strategy can be used in patients with atrial fibrillation of more than 2 days' duration to permit "early" cardioversion without a preceding 3 weeks of therapeutic anticoagulation.[159] (See Chapter 42.) This approach provides a therapeutic option for patients at increased risk of a hemorrhagic complication with anticoagulation therapy or who are not tolerating their atrial fibrillation. In the TEE-guided approach, LA thrombus is ruled out by TEE and followed by "early" cardioversion. The TEE-guided strategy had a similar incidence of embolic events, stroke, or transient ischemic attack, but fewer hemorrhagic events, compared to the conventional management strategy.[159] The costs of the two strategies are similar.[160]

LA appendage velocity may predict the likelihood of maintaining sinus rhythm post cardioversion[41,42]; however, we do not perform TEE studies in patients with atrial fibrillation solely for this purpose.

## CONGENITAL HEART DISEASE

The potential indications for TEE in patients with congenital heart disease are extensive and encompass the preoperative, interventional, intraoperative, and postoperative management of these patients.[161-163] (See Chapters 43-45.) TEE better appreciates abnormalities of the atrial septum and pulmonary veins.[14,15,32,75,137,162] The atrioventricular valves and site of chordal insertion are better visualized using TEE if surgical valvuloplasty is being considered for an atrioventricular canal defect.[164] TEE can better appreciate a baffle stenosis or leak, or complication of a Fontan procedure such as obstruction or thrombosis.[165,166] TEE can characterize outflow tract obstructions[67,162] or abnormalities of the aorta, such as aortic coarctation or a patent ductus arteriosus.[167,168] 3D TEE provides incremental information beyond 2D TEE, including a better delineation of the shape of an intracardiac defect, anatomic position, extent of an atrial rim, and potential presence of multiple or fenestrated defects.[32,139,169,170]

## CORONARY ARTERY DISEASE

Stress echocardiography with TTE imaging is a widely used technique for evaluating patients with suspected or confirmed coronary artery disease, and the addition of a contrast agent can improve the diagnostic accuracy when endocardial definition is limited.[171,172] (See Chapters 15 and 16.) In specific clinical situations, TEE can be used to diagnose coronary artery disease by either (1) visualizing coronary stenoses in the proximal vessels, or (2) detecting stress-induced regional wall motion abnormalities.

The left main coronary artery can be visualized in more than 85% of patients using TEE. The proximal left anterior descending artery and left circumflex artery can also be visualized in most patients. The proximal right coronary artery is more difficult to visualize but may be seen in more than 50% of patients. In patients with visualized vessels, TEE has a sensitivity and specificity of greater than 90% for identifying a significant left main coronary artery stenosis.[173,174] The sensitivity of TEE for detecting significant proximal disease in the left anterior descending artery, left circumflex artery, or right coronary artery is 78% to 100%, 50% to 89%, and 82% to 100%, respectively, but significantly decreases when nonvisualized segments are included in the analysis.[173,174] However, TEE should not replace coronary angiography in the diagnosis of proximal coronary artery disease, but rather should be potentially used when an angiographic stenosis of the left main or left anterior descending artery is of questionable severity and intravascular ultrasound is unavailable.[175]

Stress TEE can be performed using either transesophageal atrial pacing or pharmacologic stimulation with dobutamine or dipyridamole infusion. These techniques are accurate in detecting and risk-stratifying patients with coronary artery disease and can be performed safely in morbidly obese patients.[176-179] However, TEE is an invasive procedure with potential risks and should be reserved for patients with poor TTE images.

Additional applications of TEE include the detection of anomalous coronary arteries, coronary artery aneurysms, and coronary artery fistulas.[173]

## PERICARDIAL DISEASE

Cardiac tamponade can be challenging to diagnose early after cardiac surgery. (See Chapter 29.) Localized compression of a cardiac chamber (usually the RA) may not be apparent on TTE because the thrombus is located posteriorly; image quality is poor because of suboptimal patient positioning, surgical bandages, and drainage tubes; and the findings of RA or RV diastolic collapse are frequently absent. TEE circumvents many of these problems and can better detect extracardiac compression.[180] In constrictive pericarditis, TEE with respiratory monitoring can be helpful in patients with a nondiagnostic TTE.[181,182] Pericardial thickening, pericardial metastases, intrapericardial thrombus, and pericardial cysts are better seen by TEE than TTE.[180,183] However, computed tomography and magnetic resonance imaging are better techniques for evaluating pericardial thickness, pericardial calcification, localized pericardial abnormalities, and tissue characterization of a pericardial mass.[182]

## CRITICALLY ILL PATIENT IN THE INTENSIVE CARE UNIT

TTE image quality in an intensive care unit is frequently inadequate, and in this setting TEE can provide rapid access to diagnostic information that alters patient management.[184,185] TEE can evaluate myocardial function, valve function, volume status, hemodynamics, and intracardiac shunting, which are critical components for the diagnosis and management of patients with unexplained hypotension, pulmonary edema, or hypoxia.[17,18,184-187]

## MONITORING DURING SURGICAL AND INTERVENTIONAL PROCEDURES

A comprehensive intraoperative TEE can evaluate global and segmental LV function; detect intraoperative myocardial ischemia; monitor hemodynamics including cardiac output, LV filling pressures, and volume status; determine the potential cause of hemodynamic disturbances; and evaluate the adequacy of surgical repairs, replacements or reconstructions before leaving the operating room.[188] (See Chapter 2.) The American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists recently updated their guidelines on the use of perioperative TEE, recommending that intraoperative TEE be used in all open heart and thoracic aorta surgical procedures and be considered during coronary artery bypass graft surgery.[163] Intraoperative TEE was recommended during noncardiac surgery when the patient has known or suspected cardiovascular pathology that might result in hemodynamic, pulmonary, or neurologic compromise.[163]

TEE is routinely used during percutaneous closure of an atrial septal defect or patent foramen ovale to exclude multiple defects, size the defect, guide positioning of the occluding device, and determine the presence of residual shunting.[137,170] (See Chapter 5.) 3D TEE can provide additional information relevant to the procedure.[32,170] Percutaneous closure of a ventricular septal defect is usually performed under 2D or 3D TEE guidance.[32,170] During percutaneous mitral valvuloplasty, TEE can direct the transseptal puncture, assist with proper balloon placement, evaluate the result, identify any complications, and shorten procedure and fluoroscopy times.[189] For transcatheter aortic valve implantation, TEE can guide proper prosthesis positioning and identify periprocedural complications.[190] During transcatheter closure of a periprosthetic valve leak, TEE can delineate the precise location and extent of any paravalvular jets.[170] 3D TEE can improve spatial appreciation of the regurgitant jets (i.e., number, location, extent), better identify complications, and improve procedural efficiency.[27,33] TEE can assist with the proper positioning of a LA appendage occluding device, which is essential to avoid complications.[32] TEE has also been used to guide catheter ablation of arrhythmias, alcohol septal ablation for hypertrophic cardiomyopathy, and biopsy of the RV or an intracardiac mass.[32,141]

## Contraindications to Transesophageal Echocardiography

There are few absolute contraindications to performing a TEE (Box 1-3); however, relative contraindications are more frequently encountered in clinical practice. Thus, a critical analysis of the risk-benefit ratio is required based on available information and potential discussion with the attending physician.

An elective TEE should be postponed if the patient has not been fasting for 4 to 6 hours before the procedure because of the risk of vomiting and aspiration. However, an urgent TEE can be performed with minimal risk of vomiting and aspiration if only clear fluids were taken up to 2 hours before the procedure.[191] TEE should not be performed in an uncooperative patient who is not heavily sedated or paralyzed to minimize the chance of injury. Patients with a tenuous cardiorespiratory status should be intubated and ventilated to avoid decompensation during the procedure. TEE should not be attempted in a patient with an esophageal obstruction (stricture or mass) because of the potential for esophageal rupture. Upper endoscopy should be considered before performing a TEE if the patient has a history of dysphagia or odynophagia. An esophageal diverticulum is a relative contraindication to TEE because the probe can potentially enter and perforate the diverticulum. Fluoroscopic balloon guidance or a fiberoptic endoscope and overtube can be used to allow a TEE examination in the presence of a Zenker diverticulum.[192] TEE should not be performed in patients with an unrepaired tracheoesophageal fistula, esophagectomy, perforated viscus, or active gastrointestinal bleed. A history of esophageal varices is not an absolute contraindication to TEE; however, the small risk of major bleeding needs to be weighed against the potential for important incremental information. A severe coagulopathy is a relative contraindication to TEE; however, TEE can safely be performed in patients on anticoagulation therapy. Severe cervical arthritis or dislocation of the atlantoaxial joint, where neck flexion is severely limited, is a relative contraindication.

**Box 1-3**

**CONTRAINDICATIONS TO TRANSESOPHAGEAL ECHOCARDIOGRAPHY**

**Absolute**
Uncooperative patient
Severe respiratory depression
Tenuous cardiorespiratory status
Esophageal obstruction (stricture, mass)
Esophagectomy or esophagogastrectomy
Tracheoesophageal fistula
Perforated viscus
Active upper gastrointestinal bleed

**Relative**
Esophageal diverticulum
Esophageal varices
Previous esophageal surgery
History of dysphagia
Recent upper gastrointestinal bleed
Severe cervical arthritis with restricted mobility
Atlantoaxial joint disease with restricted mobility
Severe coagulopathy

## Complications of Transesophageal Echocardiography

TEE is a relatively safe procedure with a low risk of serious complications. In up to 1.9% of TEE studies, the esophagus cannot be successfully intubated.[193] Procedural complications occur in up to 3.5% of patients and predominantly involve the gastrointestinal, cardiovascular, or respiratory systems.[193] The vast majority of complications are minor (Box 1-4), with approximately 0.2% to 0.5% of patients suffering a major complication.[5,9,193,194] TEE-related mortality has been estimated at less than 0.01%.[194] A recent review of 17 studies encompassing 42,355 patients identified four TEE procedural deaths.[193]

**Box 1-4**

**PROCEDURAL COMPLICATIONS WITH TRANSESOPHAGEAL ECHOCARDIOGRAPHY**

**Major Complications**
Death
Esophageal rupture/perforation
Upper gastrointestinal bleed (Mallory-Weiss tear, mucosal laceration/ulceration, etc.)
Laryngospasm or bronchospasm
Congestive heart failure or pulmonary edema
Sustained ventricular tachycardia

**Minor Complications**
Excessive retching or vomiting
Sore throat
Hoarseness
Minor pharyngeal or lip bleeding
Nonsustained or sustained supraventricular tachycardia/atrial fibrillation
Nonsustained ventricular tachycardia
Bradycardia or heart block
Transient hypotension or hypertension
Angina
Transient hypoxia
Tracheal intubation
Dental injury (loose/chipped tooth)

Perforation of the esophagus and major upper gastrointestinal bleeding are serious gastrointestinal complications that occur in up to 0.01% and 0.03% of TEE studies, respectively.[194] Minor gastrointestinal complications include lip and pharyngeal bleeding due to mucosal trauma and excessive retching or vomiting that can require premature termination of the examination.[9] Dental injuries occur in up to 0.03% of patients.[194] A minor sore throat may be present for 24 hours after the procedure. Approximately 0.1% of patients have persistent odynophagia that requires further investigation.[194]

Cardiac complications are rare and include nonsustained and sustained supraventricular tachycardias or atrial fibrillation, nonsustained and sustained ventricular tachycardia, bradycardia, transient hypotension or hypertension, angina pectoris, congestive heart failure, and pulmonary edema.[193,194]

Respiratory complications include laryngospasm (less than 0.02%), accidental tracheal intubation, transient hypoxia, and blood-tinged sputum.[193,194]

Adverse reactions may occur from intravenous sedation or topical anesthesia. Intravenous sedation can cause respiratory depression, hypoxia, hypotension, or paradoxical reactions. Topical anesthesia with benzocaine or lidocaine can cause acute toxic methemoglobinemia, a rare but potentially lethal condition that manifests clinically in approximately 0.115% of TEE studies.[195] In this condition, the topical anesthesia agent oxidizes hemoglobin and prevents oxygen delivery to the tissues, potentially resulting in cyanosis, lethargy, tachycardia, dyspnea, and death.[195-197] Methylene blue administration is indicated if the methemoglobin levels are above 30%, or if the patient has cyanosis, central nervous system depression, or cardiopulmonary compromise.[195]

Intraoperative TEE has a morbidity rate of 0.2% to 1.2%, similar to that reported in the nonoperative setting.[194] The complication rates for TEE in pediatric patients are variable.[194] The largest case series of predominantly intraoperative TEE reported a complication rate of 2.4% (excluding failed intubations).[198]

## KEY POINTS

- TTE and TEE are complementary modalities with distinctly different advantages and limitations for the evaluation of patients with suspected cardiac disease.
- TEE is a relatively safe semi-invasive procedure with a small but definite risk of gastrointestinal, cardiac, and respiratory complications.
- The performance of a TEE requires the echocardiographer to have knowledge of cardiac anatomy and pathology, as well as proficiency in manipulating the transducer imaging plane and ultrasound machine image controls.
- TEE is an essential component of the pre- and perioperative evaluation of the patient being considered for mitral valve repair.
- TEE is a valuable modality to detect and quantify prosthetic mitral valve dysfunction.
- TEE has a high sensitivity and specificity for identifying a vegetation in patients with suspected endocarditis. Alternative diagnoses should be considered if the TEE is negative.
- TEE should only be performed in the patient with a potential cardioembolic event if the results will alter management. The greatest impact of TEE on management resides in the young patient with unexplained cerebral ischemia, recurrent events, or events in multiple vascular distributions.
- TEE can be considered the diagnostic investigation of choice for the diagnosis of thoracic aortic dissection.
- A TEE-guided strategy can be used in patients with atrial fibrillation of more than 2 days' duration to allow "early" cardioversion without a preceding 3 weeks of therapeutic anticoagulation.
- TEE has an integral role in monitoring patients undergoing open heart or aortic surgery and guiding catheter-based intracardiac procedures.
- 3D TEE currently provides important incremental information in the evaluation of patients with mitral valve disease, prosthetic valve regurgitation, atrial septal defects, and congenital heart disease. The applications of 3D TEE will likely continue to expand with technological refinements.

Epicardial/Epiaortic Echocardiography
**Transesophageal Echocardiography as a Monitor of Intraoperative Ventricular Function: Impact on Postoperative Outcomes and Cost-Effectiveness**

In this chapter, the focus is on the use of transesophageal echocardiography (TEE) in the assessment of cardiac function in the setting of both cardiac and noncardiac surgery. In addition, the impact intraoperative TEE has had on the quality of perioperative care is discussed. Intraoperative assessments of valvular function, chamber size, masses, and great vessels are covered in other sections of the book. The milieu of the operating room is unique and is not always conducive to obtaining TEE images of high quality. Dim the lights in the room as much as possible to avoid the necessity for "overgaining." Try to get the important parts of the study completed before the surgical incision is made. Set the loop cycle to a time-based rather than a beat-based mode, as this will prevent premature looping when electrocautery is used. The TEE probe is placed under general anesthesia so that the patient is not able to complain if insertion is too forceful; this makes the understanding of the difficulties of probe insertion and manipulation especially important (Figs. 2-1, 2-2, and 2-3).

## Evaluation of Intraoperative Ventricular Function

### LEFT VENTRICULAR FILLING

Using TEE, the clinician can assess left ventricular filling with Doppler estimation of left atrial (LA) pressure, and two-dimensional (2D) measurement of left ventricular (LV) cross-sectional area, calculation of LV volume, and assessment of diastolic function.

#### *Left Atrial Pressure*

LA pressure can be estimated with Doppler TEE by several methods. If mitral regurgitation is present, measurement of the peak velocity of the regurgitant jet and application of the modified Bernoulli equation allows calculation of the left ventricular to atrial pressure gradient; in the absence of aortic stenosis, subtraction of this number from the peak systolic blood pressure yields LA pressure. Certain mitral inflow and pulmonary venous variables also correlate with LA pressure; in patients undergoing cardiovascular surgery, Kuecherer and colleagues[1] found that changes in the systolic fraction of the pulmonary venous tracing correlated inversely and strongly with pulmonary capillary wedge pressure and theorized that this related to decreased atrial compliance. Nomura and associates[2] found that in patients with ejection fractions less than 35%, the deceleration time of the early velocity of mitral inflow correlated with pulmonary capillary wedge pressure and that a deceleration time greater than 150 msec was strongly predictive of a pulmonary capillary wedge pressure of less than 10 mm Hg. Arguing that the aforementioned Doppler parameters were overly influenced by loading conditions, Kinnaird and colleagues[3] proposed that examining the deceleration slope of the diastolic component of pulmonary venous flow allowed the left atrium to be treated as a receiving chamber in its own right and showed that this deceleration time was inversely correlated with LA pressure. The ratio of early to atrial LV diastolic filling velocity (E/A ratio) has also been used to predict fluid responsiveness in cardiac surgical patients. Patients with higher E/A ratios tended to have a more rightward position on the diastolic pressure volume curve (Fig. 2-4) and thereby were less likely to increase their cardiac output with an infusion of colloid.[4]

There are a number of caveats related to the intraoperative estimation of LA pressure with TEE. Patients with a rhythm other than sinus or with valvular regurgitation were excluded in most studies; these are the patients in whom preload estimates are often crucial. In suitable patients, correlations but not absolute values of LA pressure are usually yielded. Use of the mitral regurgitation jet to calculate LA pressure dictates that mitral regurgitation must be present. Finally, an estimate of LA pressure, whether obtained by Doppler echocardiography or by

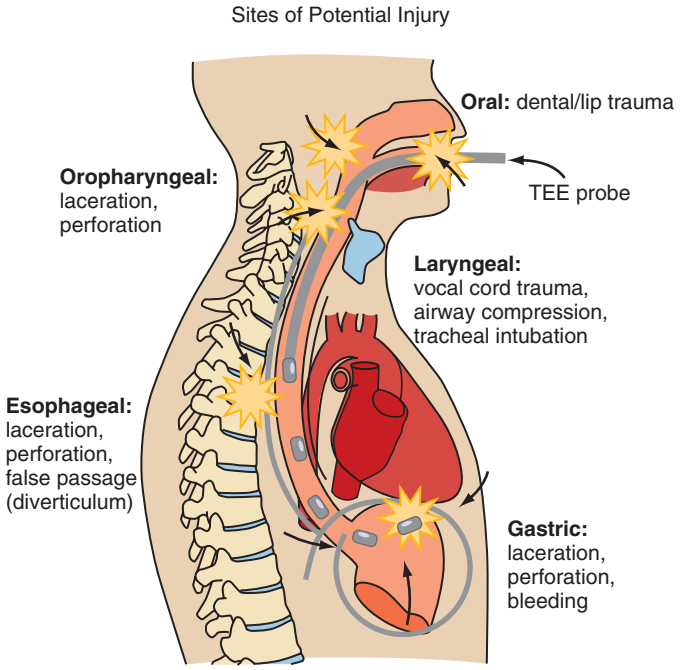

**Figure 2-1** Sites of potential injury with TEE probe placement. *(From Hilberath JN, Oakes DA, Shernan SK, et al: Safety of transesophageal echocardiography.* J Am Soc Echocardiogr *23:1115-1127, 2010.)*

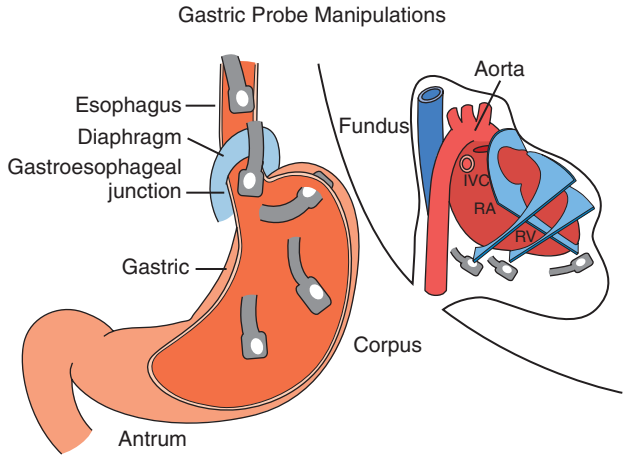

**Figure 2-3 Gastric probe manipulations.** Gastric injury typically occurs in the gastric fundus during deep transgastric probe manipulation, especially when requiring extreme anteflexion to bring the probe inline and in contact with the apex of the heart (e.g., deep transgastric aortic outflow view). The gastroesophageal junction is a vulnerable zone because probe manipulation at this level may place the relatively fixed tissues under considerable tension. *(From Hilberath JN, Oakes DA, Shernan SK, et al: Safety of transesophageal echocardiography.* J Am Soc Echocardiogr *23:1115-1127, 2010.)*

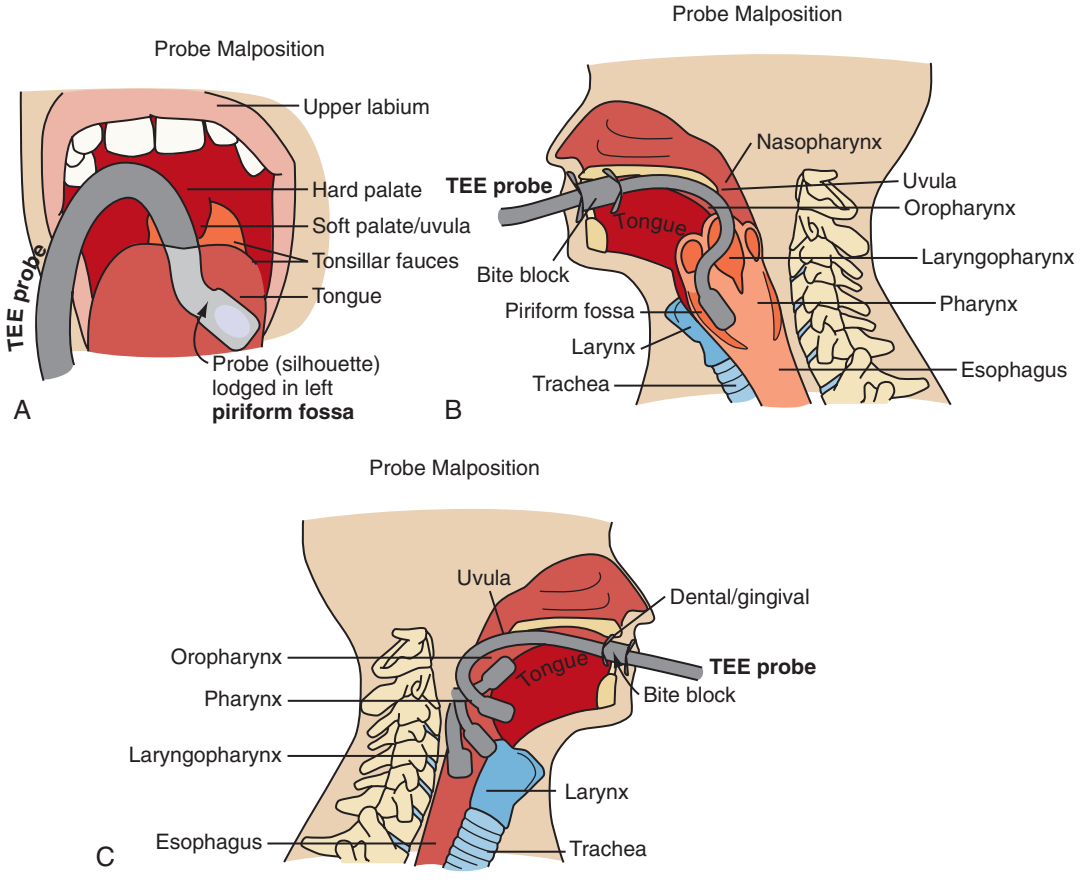

**Figure 2-2 Probe malposition. A** and **B,** Difficulty during probe insertion can be encountered if the TEE probe is lodged into one of the pyriform sinuses. **C,** In addition to causing mucosal injury to the oropharynx, the TEE probe can occasionally become distorted in extreme flexion. Attempts to withdraw a TEE probe in this configuration before advancing into the stomach and unfolding the kink can lead to severe esophageal injury. *(From Hilberath JN, Oakes DA, Shernan SK, et al: Safety of transesophageal echocardiography.* J Am Soc Echocardiogr *23:1115-1127, 2010.)*

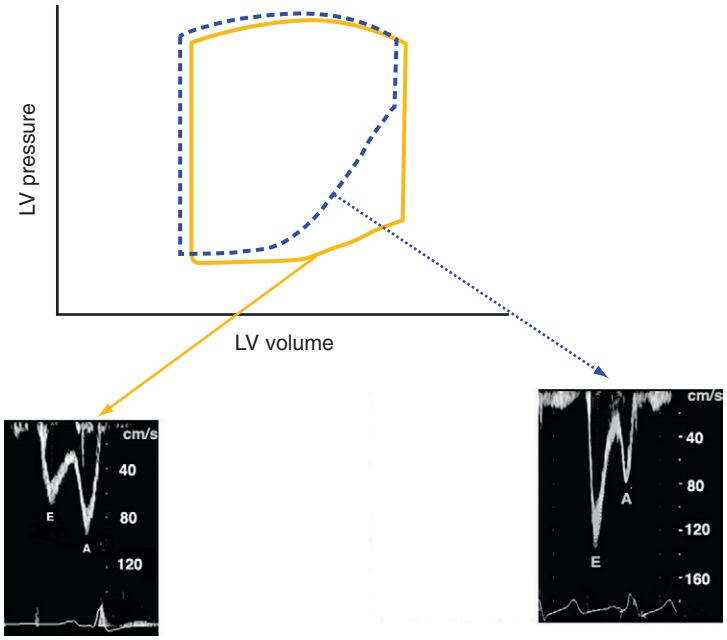

**Figure 2-4 Schematic representation of the pressure/volume relationship of the left ventricle.** Measurement of the E/A (E and A waves of the transmitral flow) ratio gives information on the position of the diastolic pressure/volume curve of the left ventricle. Lower ratios suggest a leftward position on this curve, and higher ratios, a rightward position, in which left ventricle compliance is reduced. Patients with low E/A ratios are more likely to increase cardiac output after volume infusion than patients with high E/A ratios.

pulmonary artery catheter, may still yield inaccurate estimates of preload in patients with decreased ventricular compliance[5]; this is the case in many patients following cardiopulmonary bypass.[6]

Measurements of LA size and volume by TEE are underestimates of the values obtained by transthoracic echocardiography (TEE)[7] but are most accurate when obtained using Simpson's biplane technique.[7]

### *Left Ventricular Diastolic Function*

In patients with impaired diastolic function, LV filling in the period following separation from cardiopulmonary bypass is especially tenuous as both systolic and diastolic function are further reduced.[8-10] In addition to the standard parameters of mitral inflow and pulmonary venous flow velocities, newer techniques may be used to better define problems with ventricular filling.

Tissue Doppler imaging of the mitral annulus has been proposed as a descriptor of LV relaxation that is less affected by changes in loading conditions and ventricular function than more traditional Doppler parameters.[11] The E′ velocity relates directly to LV relaxation; thus this parameter has been used to correct for LV relaxation and render the E wave of mitral inflow more accurate in the estimation of LV filling pressure (E/E′ ratio). There is a paucity of data, however, regarding the usefulness of tissue Doppler of the mitral annulus in the intraoperative setting. Many factors other than LA pressure influence the E/E′ ratio,[12] and in reality many of these conditions are present in the intraoperative population, limiting the usefulness of this parameter.

Color M-mode flow propagation velocity is another less load-dependent measure of diastolic function and is attractive in that it examines simultaneous pulsed-wave (PW) Doppler measurements throughout the LV cavity (Fig. 2-5). Djaiani[13] has shown that in patients undergoing coronary artery bypass graft, a value less than 50 cm/sec identifies abnormal diastolic function.

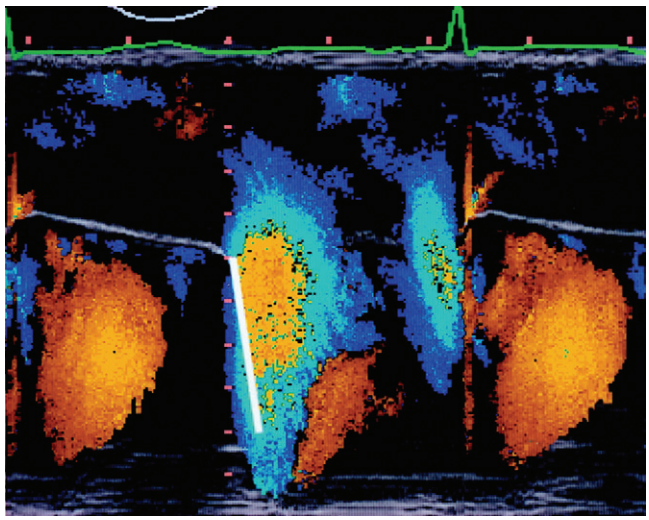

**Figure 2-5** Color M-mode propagation velocity shown as the slope of the first aliasing velocity during early filling of the ventricle. *(From Djaiani GN, McCreath BJ, Ti LK, et al: Mitral flow propagation velocity identifies patients with abnormal diastolic function during coronary artery bypass graft surgery.* Anesth Analg *95:524-530, 2002.)*

### *End-Diastolic Area and End-Systolic Area*

The American Society of Echocardiography's guidelines and standards committee have published recommendations for chamber quantification by both TTE and TEE. The normal ranges for dimension and volume are comparable between the two techniques.[14]

A number of authors have examined the intraoperative relationship between end-diastolic area or end-systolic area measured at the transgastric midpapillary level and cardiac volume status. In a classic paper, Cheung and associates[15] performed an elegant study examining the effect of graded hypovolemia produced by autologous blood collection on hemodynamic- and TEE-derived indices of LV preload in patients undergoing

coronary artery bypass surgery. Patients with valvular insufficiency, rhythms other than sinus, and overt congestive heart failure were excluded. End-diastolic area, end-systolic area, pulmonary capillary wedge pressure, and measures of end-diastolic and end-systolic wall stress decreased linearly as blood volume was reduced by 0% to 15% in all patients; however, in patients with impaired LV function, only the TEE-derived indices maintained linearity. As the authors acknowledge, estimation of ventricular volume in the patient with asymmetric ventricular dysfunction may be problematic, because hypokinetic or akinetic areas may not be represented in the area of the 2D cut.

It must also be remembered that the presence of a small end-diastolic area or end-systolic area does not always reflect decreased intravascular volume. Small LV volumes can be seen with restrictions to filling, as in pericardial disease, or decreased right-sided heart function (Fig. 2-6), for example, owing to right ventricular (RV) infarction or a large pulmonary embolus. Other causes of a small LV volume include increased inotropy or redistribution of blood out of the thoracic cavity.

### *Left Ventricular Volumes*

The generally accepted method for volume measurement is the biplane method of disks (Simpson's rule). Smith and colleagues[16] found that measurement of LV volume was underestimated by TEE when compared to ventriculography and attributed this to underestimation of ventricular length; more recent studies using multiplane probes[17] have shown that volumetric data obtained by TTE and TEE show minor or no differences. Notwithstanding its accuracy, this technique is rarely used in the intraoperative setting because of the high frequency and rapidity of hemodynamic shifts.

The use of real-time three-dimensional (3D) TEE in the operating room has increased dramatically. Although real-time 3D TTE assessment of LV volume has shown promise, this experience has not been replicated with real-time 3D TEE[18] and cannot be recommended for routine use in the operating room.

### *Conclusion*

The assessment of preload with intraoperative TEE is in most cases a semiquantitative estimate based on visual inspection of end-diastolic area and end-systolic area and supported by an array of Doppler indices. Confounding conditions, such as RV failure, vasodilation, or the administration of inotropic agents, must be considered.

## GLOBAL SYSTOLIC FUNCTION

### *Cardiac Output*

Doppler TEE has the potential to be used in the intraoperative setting for the continuous measurement of cardiac output. These methods use the concept that the cross-sectional area of a conduit within the cardiovascular system multiplied by the Doppler-derived time-velocity integral yields the stroke volume through that conduit. When the result is multiplied by heart rate, the product is cardiac output.

Several important assumptions are inherent to this approach. Valid area formulas must be applicable to the anatomic site being analyzed. The velocity profile across the valve must be flat and devoid of skew.[19,20] Whichever anatomic area is chosen, the ability to consistently obtain the image and to interrogate parallel to flow is mandatory.

### Transesophageal Doppler Technology

With this technique, Doppler data is obtained and used to calculate hemodynamic parameters in a fashion similar to the techniques described later.[21] Because no 2D imaging is used, the probe is considerably smaller than a standard TEE probe, can be placed orally or nasally, and can be left in for longer periods of time. The probe is placed in the esophagus in order to measure velocities in the descending thoracic aorta. A number of assumptions are inherent in the technique, and they may be violated in the intraoperative setting; these include the diameter of the aorta at the point of Doppler interrogation, the presence of a flat velocity profile, and the angle of insonation. Perhaps most importantly, the technique assumes that the amount of blood flowing in the descending aorta as a fraction of total cardiac output is constant. This may be a reasonable assumption in clinically static situations[22]; however, in the dynamic environment of cardiac surgery, this may not be the case.[23] At the present time, trending of hemodynamic variables appears possible, although reliance on esophageal Doppler for the absolute determination of hemodynamic variables does not appear to be justified.[24]

### Left Ventricular Outflow Tract

This Doppler technique has been extensively studied and found to be extremely accurate when applied to a group of patients before and after cardiopulmonary bypass.[25] With the probe in the stomach, turned leftward, in the flexed position, and at low imaging frequency, the aortic valve and LV outflow tract can

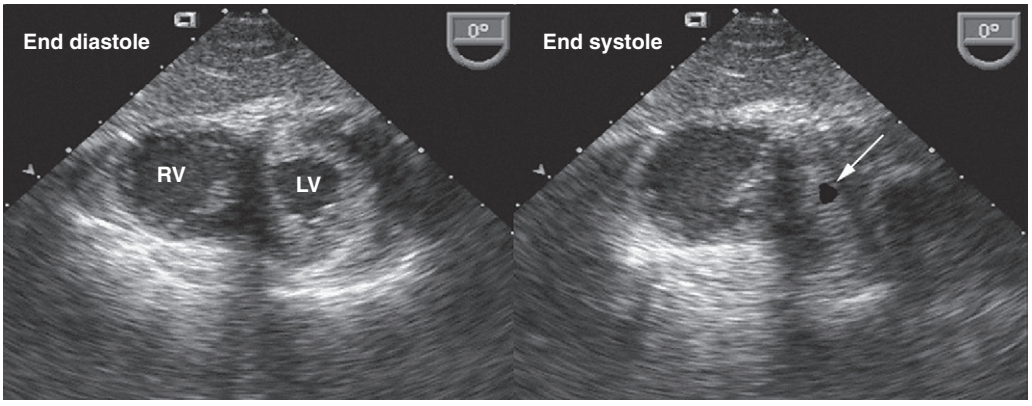

**Figure 2-6** Transgastric image of a transesophageal echocardiography scan obtained in a patient with pulmonary hypertension secondary to cystic fibrosis. Although the end-systolic area of the left ventricle is exceedingly small (*arrow*), this was secondary to right-sided heart failure and not absolute hypovolemia.

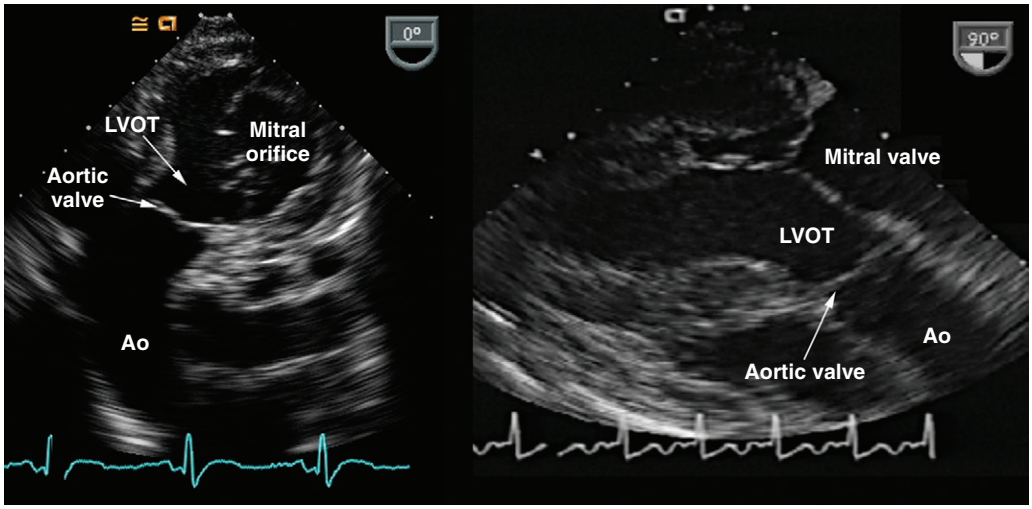

**Figure 2-7** Transesophageal echocardiography imaging from the stomach allows parallel alignment with the ascending aorta (*Ao*). *Left* panel, the deep transgastric long-axis view; *right* panel, the transgastric long-axis view. *LVOT*, Left ventricular outflow tract.

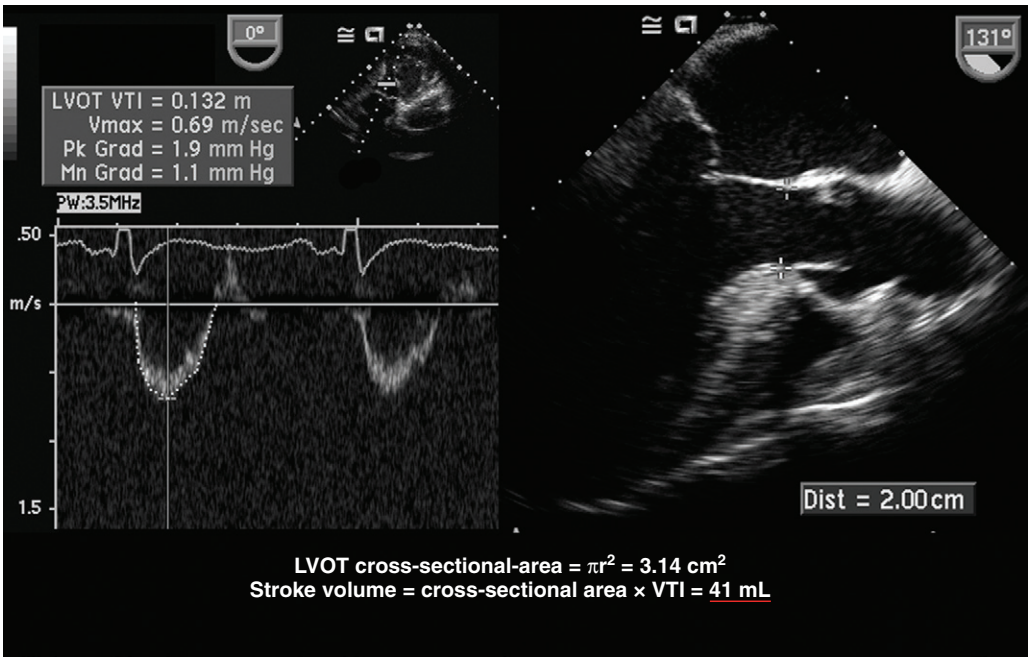

**Figure 2-8** Transgastric imaging of the left ventricular outflow tract (*LVOT*). The ascending aorta is well visualized, and the Doppler intercept angle is small. Pulsed-Doppler velocity time integral and diameter measurement (obtained in a mide sophageal long axis) are used to calculate stroke volume. *Mn Grad*, Mean gradient; *Pk Grad*, peak gradient; *Vmax*, maximum velocity; *VTI*, velocity time integral.

usually be imaged between 0° and 140° (Fig. 2-7). Imaging from the stomach allows parallel pulsed-Doppler interrogation of the LV outflow tract; its diameter can be obtained from either the stomach or the midesophageal long-axis view. Calculation of the cross-sectional area and cardiac output follow the standard formula (Fig. 2-8). To avoid contamination of the Doppler signal by the region of flow acceleration adjacent to the aortic valve orifice, the sample volume must be placed precisely in the LV outflow tract. In the presence of outflow tract obstruction, the validity of the measurement may be compromised.

### Pulmonary Artery

With the probe at 0° and retroflexed, the main pulmonary artery and pulmonic valve can be imaged at the base of the heart (Fig. 2-9). In a study by Gorcsan and colleagues[26] using both PW and continuous-wave (CW) methodologies, pulmonary artery diameter was measured just distal to the pulmonic valve. Interobserver variability was low in all studies, and correlation with thermodilution was strong. Alternatively, the main pulmonary artery may be imaged at 60° to 90° using the aortic arch as a window (Fig. 2-10).

### Right Ventricular Outflow Tract

From the transgastric approach, the probe is turned rightward and flexed to image the RV outflow tract at a rotation angle between 0° and 120°. Imaging frequency must usually be reduced to ensure optimal penetration. Maslow and colleagues[27] found excellent correlation between cardiac output calculated with PW Doppler and thermodilution. Patients with pulmonary hypertension, significant tricuspid

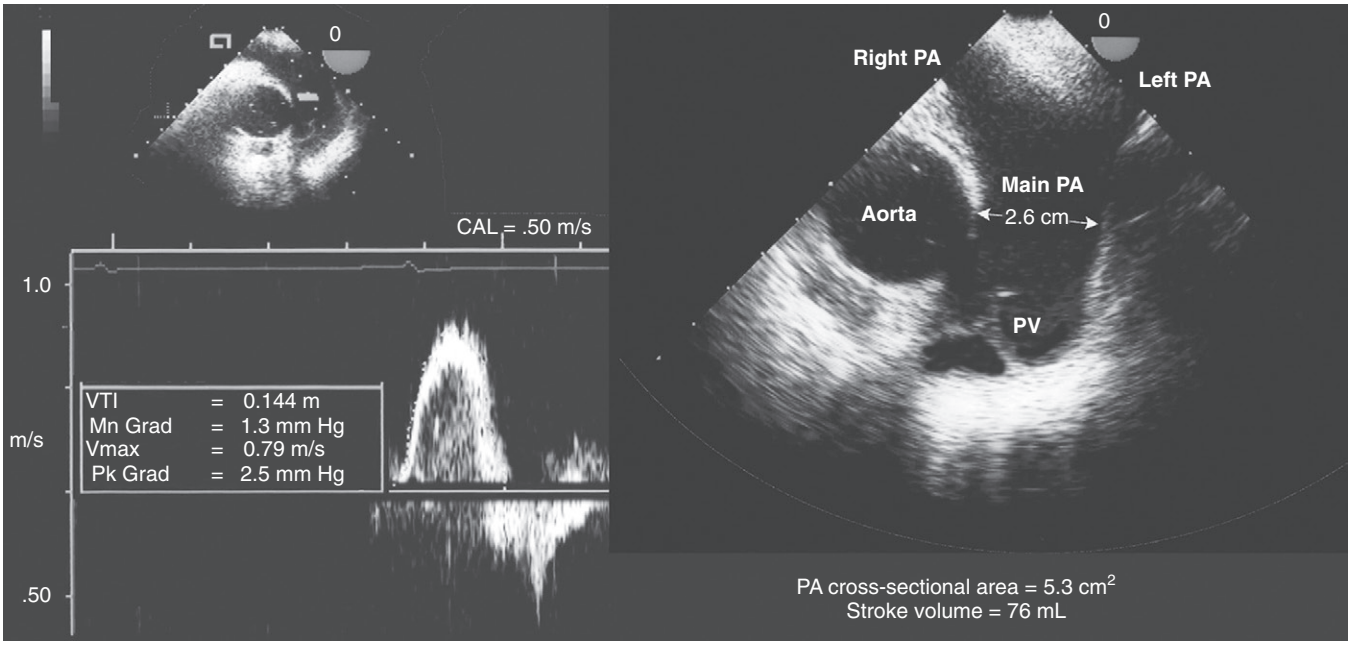

**Figure 2-9** Imaging at the base of the heart of the main pulmonary artery (*PA*) and its branches. Pulsed-Doppler velocity time integral (VTI) and diameter measurement are used to calculate stroke volume. *Mn Grad*, Mean gradient; *Pk Grad*, peak gradient; *PV*, pulmonary valve; *Vmax*, maximum velocity.

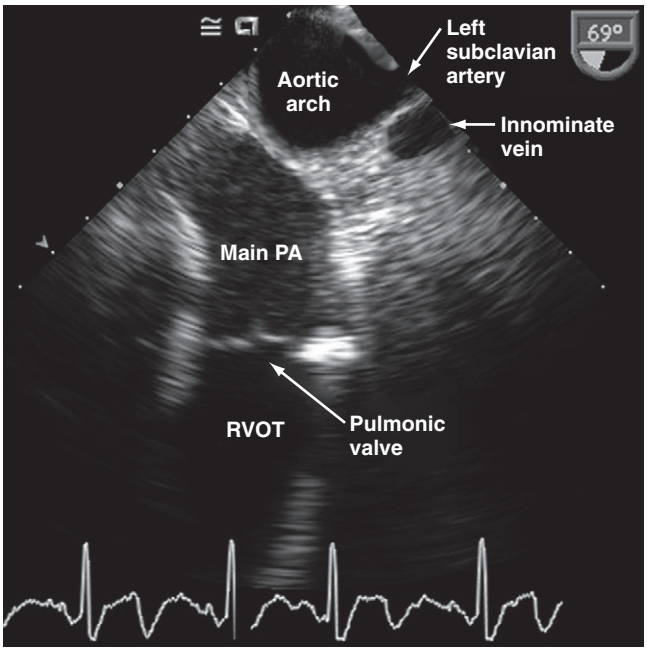

**Figure 2-10** Using the aortic arch as a window, the high esophageal aortic arch short-axis view is obtained. regurgitation, and nonsinus rhythms were excluded. In a significant percentage (16%) of patients, the 2D image was not suitable.

## Mitral Valve

Using the mitral valve for calculation of cardiac output has the advantages of consistent imaging and parallel Doppler alignment. However, the saddle shape of the mitral annulus makes the area measurement unpredictable, and the cross-sectional velocity skew is of concern when using PW Doppler.

## Practical Considerations

For intraoperative transesophageal Doppler calculation of cardiac output, the LV outflow tract method is the most reproducible. Adjustments in the degree of probe flexion and imaging angle should be made to ensure that the aortic valve and ascending aorta are clearly visualized and that the Doppler intercept angle is small (see Fig. 2-8). Several measurements should be made and averaged, this being especially important when dealing with rhythms other than sinus. In practical terms, Doppler measurement of cardiac output is used when a pulmonary artery catheter is not in place or when conditions, such as severe tricuspid regurgitation, render thermodilution inaccurate. When right- and left-sided outputs are obtained simultaneously, shunt fraction may be calculated. There is a need for further validation of this approach in patients with a spectrum of cardiovascular diseases.

### *Ejection Fraction and Stroke Volume*

Although it is somewhat load dependent and therefore not a pure index of "contractility," ejection fraction is often assumed to reflect ventricular contractility. During intraoperative TEE, the fractional area of change measured at the transgastric midpapillary level is often used interchangeably with ejection fraction, although gauging volume in a potentially asymmetric chamber based on a measure of area has obvious limitations. In an elegant study, Royse and colleagues[28] demonstrated that fractional area of change when corrected for afterload was closely related to preload recruitable stroke work, a relatively load-independent measure of contractility. $dP/dT$ was more load dependent and less reliable. The patient group was quite diverse in terms of overall ventricular function. As mentioned previously, the most common and generally accepted method for volume measurement is the biplane method of disks, Simpson's rule (Fig. 2-11).

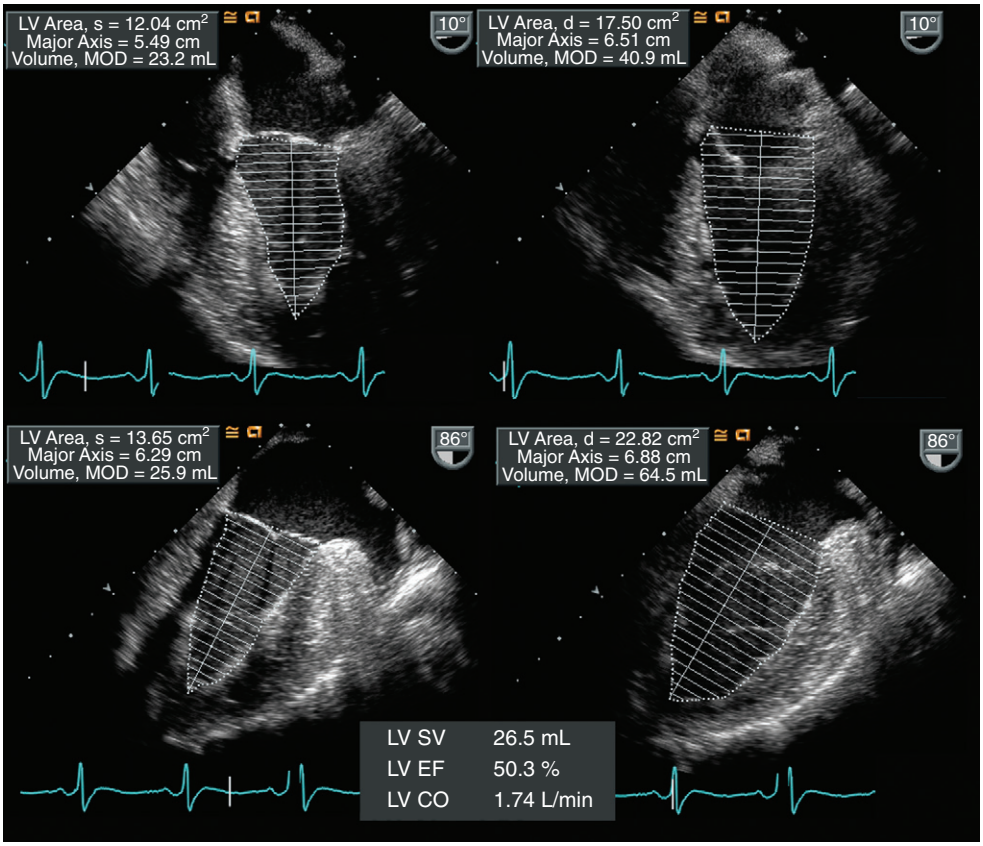

**Figure 2-11** Measurements of systolic (*s*, left) and diastolic (*d*, right) area made in the four-chamber (*upper* panels) and two-chamber (*lower* panels) views are used to obtain volumetric data by the method of disks (*MOD*). From these measurements, stroke volume (*SV*), ejection fraction (*EF*), and cardiac output (*CO*) can be calculated.

Practically, intraoperative ejection fraction is still most often visually estimated or is measured by single plane fractional area change. Concern remains that fractional area change underestimates ejection fraction in patients in whom hypokinetic areas are not represented in the measurement. The use of TEE-derived volumetric data to estimate ejection fraction is more accurate, though manual tracing is tedious; however, software that comes with many TEE machines allows rapid calculation. Real-time 3D TEE, although seemingly attractive, does not at present have a routine place in the intraoperative assessment of ventricular volumes and ejection fraction.

### *Contractility*

Ejection fraction and myocardial thickening, although largely affected by contractility, are not independent of the influence of loading conditions. The end-systolic pressure-volume relationship and resultant end-systolic elastance defines contractility in a load-independent fashion as described in the classic paper by Sagawa.[29] At present, however, the methods for intraoperative data analysis that involve a number of surrogates for invasive measurements are prohibitively complex.

## *Other Indices of Left Ventricular Function*

### Tissue Doppler Imaging

The use of tissue Doppler imaging in the assessment of diastolic function has already been described. Systolic myocardial velocity at the lateral mitral annulus is a measure of longitudinal systolic function that correlates with ejection fraction.[30] One of the major limitations of this technique is that lack of movement of myocardial tissue secondary to tethering is not readily distinguished from hypokinesis owing to ischemia. In order to circumvent this issue, the use of strain and strain rate imaging has been extensively studied and is discussed in several excellent reviews.[31,32] (See Chapter 10.) In essence, strain rate represents the local rate of myocardial deformation and is estimated by spatial velocity gradients obtained by tissue Doppler imaging. Because Doppler is used, the angle of insonation is a limitation; however, strain rate may also be measured by the Doppler-independent technique of speckle tracking.[31] By acquiring high-quality 2D echo images and identifying unique acoustic markers in the image to track specific areas of myocardium over time, strain rate can be calculated.

Simmons and colleagues[32] showed the feasibility of using TEE to obtain radial and longitudinal LV wall velocities; there was consistency between TTE and TEE measurements, and regional reduction in S′ correlated with decreased regional wall motion. Skarvan and colleagues[33] used tissue Doppler imaging of the anterior wall as a complement to visual assessment of systolic wall thickening.

More recently, several authors have done feasibility studies of intraoperative strain analysis using both tissue Doppler imaging[34] and speckle tracking[35] (Fig. 2-12). Intraoperative strain analysis shows promise for the analysis of global and regional systolic function.

### *dP/dt*

The rate of pressure rise at the onset of ventricular contraction (*dP/dt*) is a load-dependent index of systolic performance. Measurement of dP/dt using CW Doppler of the mitral regurgitation jet has been validated against measurements in the cardiac

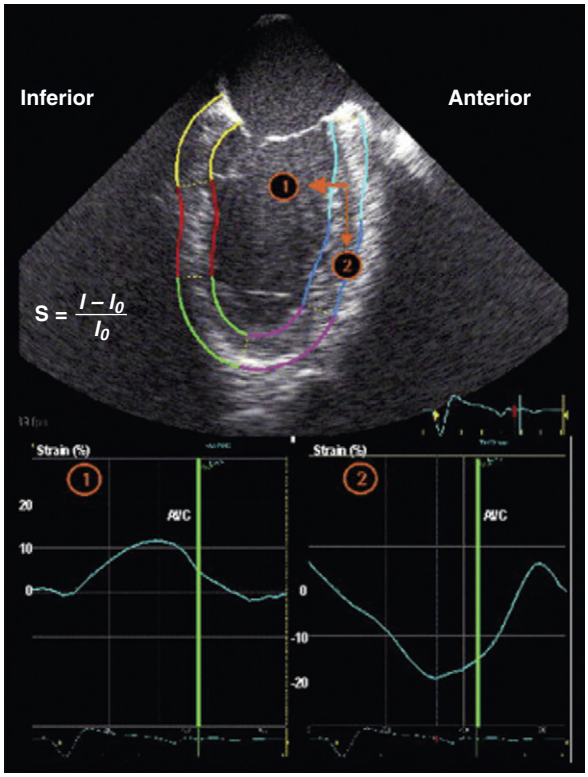

**Figure 2-12** *Top:* Midesophageal two-chamber view of the LV with the anterior (*right*) and inferior wall (*left*). The different colors indicate the separation into, from top to bottom, basal, mid, and apical segments. *Bottom*: Radial (*1*) and longitudinal (*2*) strain from the anterobasal segment in this view. *AVC*, Aortic valve closure; *l*, instantaneous length; $l_0$, original length; *S*, strain. *(From Kukucka M, Nasseri B, Tscherkaschin A, et al: The feasibility of speckle tracking for intraoperative assessment of regional myocardial function by transesophageal echocardiography.* J Cardiothorac Vasc Anesth *23:462-467, 2009.)*

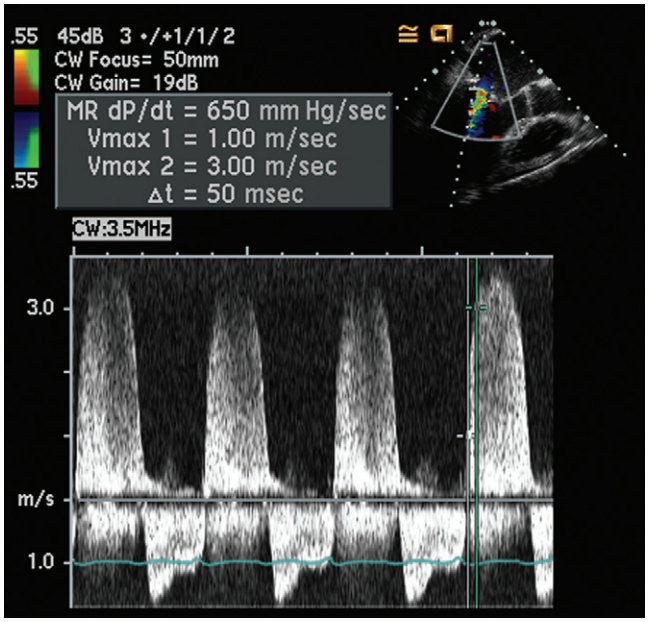

**Figure 2-13** Measurement of *dP/dt* is taken from the mitral regurgitation jet obtained by CW Doppler. The duration of time required for the velocity to increase from 1 to 3 m/sec (or the pressure to rise from 4 to 36 mm Hg) is measured. *MR*, Mitral regurgitation; *Vmax*, maximum velocity.

catheterization laboratory.[36] The time in seconds required for an increase of the pressure gradient from 4 to 36 mm Hg (or an increase of velocity from 1 to 3 m/sec) is divided by the pressure difference of 32 mm Hg for calculation of dP/dt. Normal values are 800 to 1200 mm Hg/sec (Fig. 2-13).[37] The presence of mitral stenosis contraindicates the technique. It has not been adequately tested in the intraoperative environment.

### *Right Ventricular Function*

In the setting of cardiopulmonary bypass, the evaluation of RV function is important. RV dysfunction often occurs secondary to the inadequate delivery of cardioplegia[38] and to the embolization of intracardiac air down the right coronary artery following separation from cardiopulmonary bypass (Fig. 2-14). The triangular shape of the right ventricle makes its global function hard to quantitate with TEE, although the modified method of disks has been used in offline analysis in the setting of coronary bypass grafting.[39] The abnormal septal motion often seen following cardiopulmonary bypass makes analysis more difficult. Standards for the measurement of RV volumes with TEE have been published.[14]

Tricuspid annular velocity measurement by tissue Doppler imaging has been used to quantitate RV function, with excursions less than 1.5 cm associated with poor prognosis in a variety of cardiovascular diseases.[40] The technique is feasible during cardiac surgery using modified transgastric imaging.[40]

Right ventricular speckle tracking was shown to be feasible in the operating room[41] and compared well with other indices such as tricuspid annular plane systolic excursion and fractional area of change. The technology is complex and at present is still in evolution.

TEE assessment of intraoperative RV function is best accomplished by visual inspection and semiquantitative assessment in both the transgastric and the four-chamber views.

## REGIONAL WALL MOTION

The link between perioperative myocardial ischemia and cardiac morbidity[42] has led to an intensive search for accurate methods of its intraoperative detection (Fig. 2-15). Visual inspection of the electrocardiogram for ST segment changes has been the foundation on which the newer technologies of automated ST analysis and TEE detection of regional wall motion abnormalities have been added. There are several points on which to judge the merits of TEE: applicability, accuracy, reproducibility, cost, expertise required for interpretation, and prognostic importance.

Segmental analysis is most frequently undertaken using the 16-segment model first proposed by Schiller and colleagues[43] and later modified for TEE by Shanewise and co-workers.[44] In 2002, a 17th segment, the apical cap, was added.

The recognition that coronary occlusion leads to the immediate development of regional wall motion abnormalities[45] and their frequent regression following revascularization[44] has prompted investigators to examine the usefulness of intraoperative TEE as a monitor of ischemia. The paucity of contraindications to TEE means that it can be used in most patients undergoing general anesthesia. The midpapillary view is generally easy to obtain and demonstrates areas of myocardium subtended by the three major coronary arteries. Interpretation is

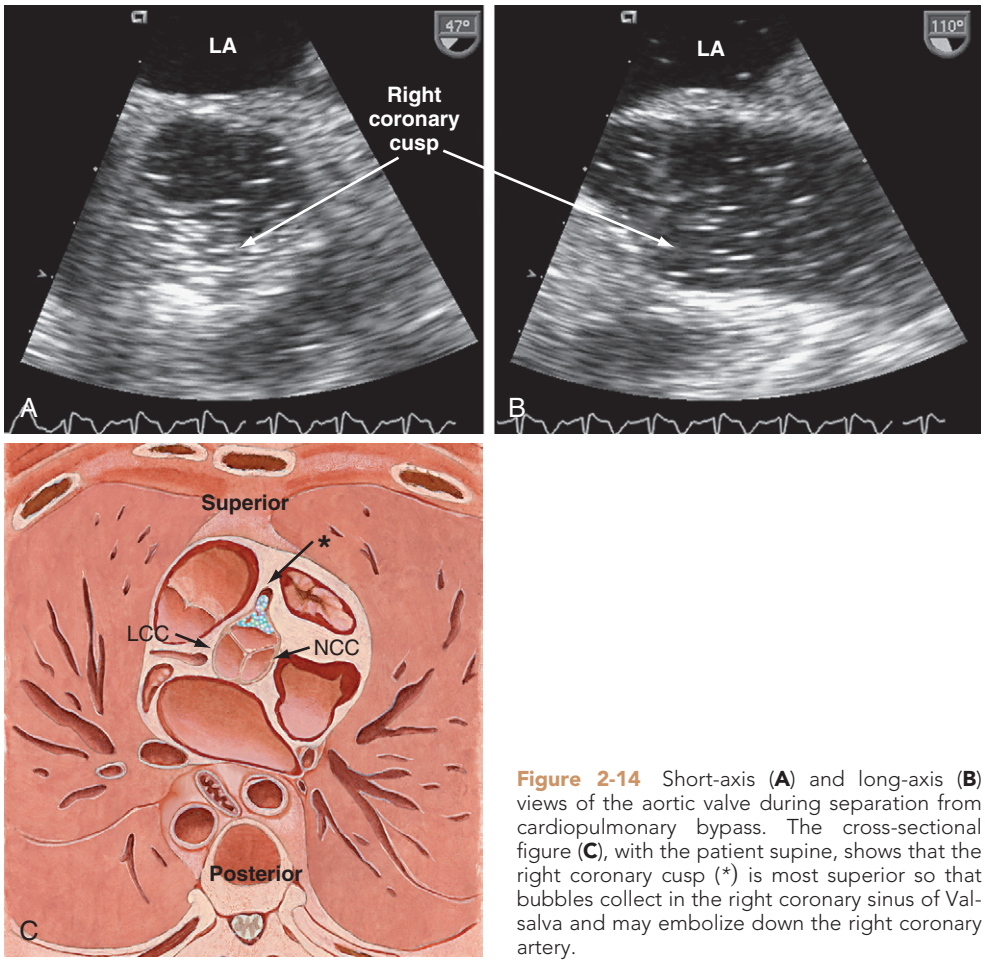

**Figure 2-14** Short-axis (**A**) and long-axis (**B**) views of the aortic valve during separation from cardiopulmonary bypass. The cross-sectional figure (**C**), with the patient supine, shows that the right coronary cusp (*) is most superior so that bubbles collect in the right coronary sinus of Valsalva and may embolize down the right coronary artery.

rarely confounded by rhythm disturbances, as is the case for automated ST analysis. TEE cannot be used, however, in patients receiving regional anesthesia, and because the probe is not inserted until after anesthetic induction, it cannot detect changes during this vulnerable period.

Conflicting studies regarding the prognostic importance of regional wall motion abnormalities were subsequently published. In a study by London and colleagues,[46] 156 patients undergoing noncardiac surgery who were at high risk for coronary artery disease were studied. Specific clinical, electrocardiographic, or hemodynamic events prompted analysis of stored images. The number of new wall motion abnormalities detected was low, and discordance with electrocardiographic findings was significant . The number of postoperative cardiac complications was low. In the study by Leung and associates,[47] patients undergoing coronary artery bypass were examined with electrocardiography and TEE. Although prebypass ischemia was rare, postbypass ischemia was more common, and postoperative cardiovascular complications were associated more closely with TEE findings than with electrocardiography alone.

It is now accepted that regional wall motion abnormalities, although often the result of myocardial ischemia, also may result from hypovolemia, tethering of nonischemic myocardium, and myocardial stunning after cardiopulmonary bypass. Abnormal interventricular septum abnormalities are seen after cardiopulmonary bypass, with right-sided chamber overload, ventricular pacing, and bundle branch blocks. Off-line analysis has been employed in most of the large-scale studies involving comparison of TEE with other methods of ischemia detection, but extrapolation to the accuracy of real-time TEE analysis should not be assumed. Regional wall motion abnormalities that subtend the anatomic distribution of coronary artery flow are more often a result of ischemia than those that do not.

Comunale and colleagues[48] also documented the poor concordance between the TEE and electrocardiography and attributed this finding to the lack of standard definitions of significant regional wall motion abnormalities and ischemic ST changes, the exclusion of longitudinal TEE views, and the use of different models of segment nomenclature.

TEE is the most sensitive test for intraoperative myocardial ischemia and has therefore been adapted by many practitioners as cutting-edge technology in this regard. Conditions that lead to its lack of specificity, as mentioned, must be taken into account. The ability to monitor additional tomographic planes; the use of cine loops for comparison; and the advent of new technologies, such as tissue Doppler imaging and speckle tracking with strain imaging and real-time 3D TEE, should improve accuracy. Regional wall motion abnormalities precede electrocardiographic changes,[49] and once ischemia is diagnosed, TEE can be used to directly monitor the effects of intervention.

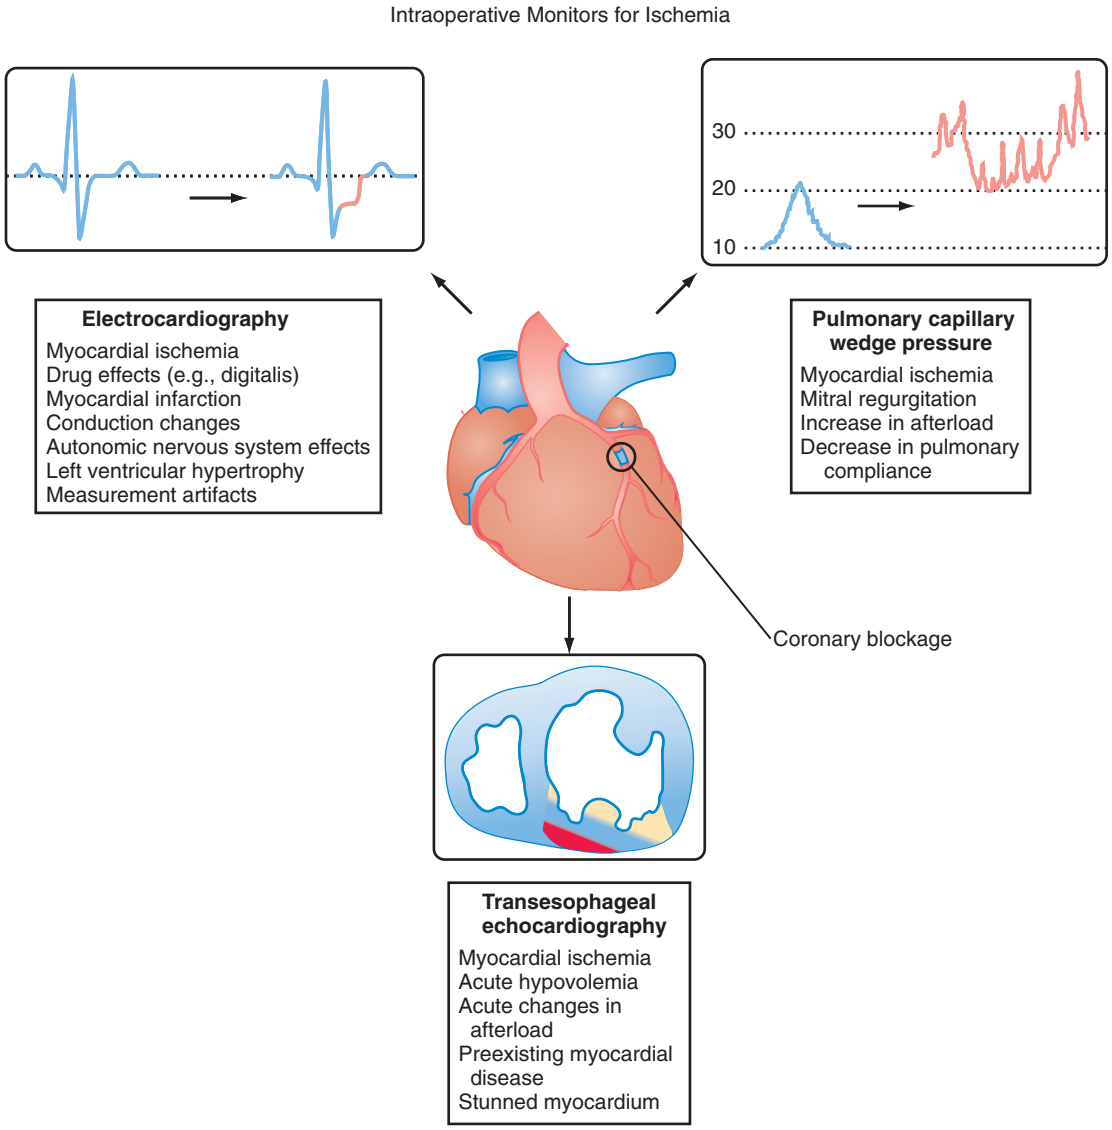

**Figure 2-15** Causes of ischemic changes on intraoperative monitors. *(From Fleisher LA: Real-time intraoperative monitoring of myocardial ischemia in noncardiac surgery.* Anesthesiology *92:1183-1188, 2000.)*

## Use of Transesophageal Echocardiography to Monitor Intraoperative Cardiac Function in Specific Clinical Entities

The use of TEE has improved our ability to intelligently manage post–cardiopulmonary bypass instability. It has allowed us to understand the intraoperative changes that occur during some of the newer techniques in coronary revascularization and can guide us in placement of numerous intracardiac and intravascular devices. Its use in monitoring cardiac function during noncardiac surgery is most advantageous in the diagnosis of sudden and unexplained hemodynamic instability.

### SEPARATION FROM CARDIOPULMONARY BYPASS

At the time of separation of the patient from cardiopulmonary bypass, the use of TEE may guide the anesthesiologist in the use of pharmacologic and nonpharmacologic therapies and can maximize the likelihood of a smooth transition.

#### *Intracardiac Air*

Left-sided intracardiac air is ubiquitous following procedures in which left-sided chambers have been open to atmosphere and is identified by its characteristic "firefly" appearance. Air is often seen entering the left atrium from the pulmonary veins or enmeshed in the mitral subvalvular apparatus (Fig. 2-16). Echocardiographic inspection is carried out in the four-chamber and transgastric long-axis views. Careful evacuation by the surgeon is important and involves suctioning on the aortic root vent or needle aspiration of the LV apex to evacuate trapped pockets. In addition to guiding evacuation, TEE is useful in diagnosing the consequences of embolization through the right coronary ostium, which results in ventricular dysfunction in a right coronary distribution (see Fig. 2-14).

#### *Cardiac Output*

There are a number of potential causes of low cardiac output immediately following cardiopulmonary bypass: perioperative infarction,[50] coronary air emboli, metabolic abnormalities, hypovolemia, LV outflow tract obstruction, and inadequate myocardial protection. It seems intuitive that the

yield of TEE, when it is used during hemodynamic instability during and after cardiac surgery, would be high. Two published series have demonstrated the myriad diagnoses that have been made and the ability to intervene on many patients (Table 2-1).[51,52] No attempt was made to compare TEE with other diagnostic modalities, although the speed with which information is made available appears hard to supersede. The prebypass TEE-derived wall motion score index was found to independently predict the need for postbypass inotropic support.[53]

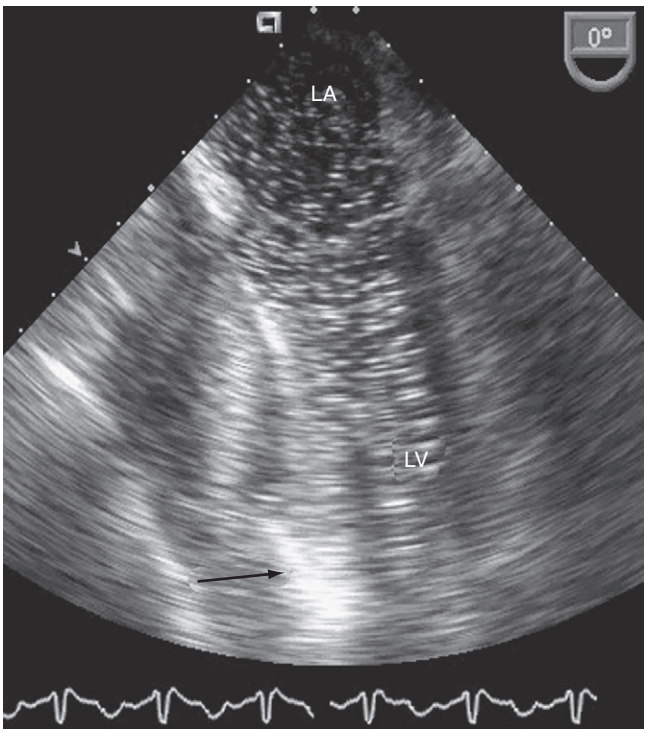

**Figure 2-16 Four-chamber midesophageal view.** As the patient is being separated from cardiopulmonary bypass, a pocket of air enmeshed in the left ventricular subvalvular apparatus is noted (*arrow*), with numerous bubbles emanating from it.

## OFF-PUMP CORONARY BYPASS SURGERY

One of the major controversies in cardiac surgery is the performance of coronary revascularization without cardiopulmonary bypass, the off-pump bypass or "beating heart" operation. The major criticism is that incomplete revascularization leads to repeat interventions, and in addition, coexistent pathology such as mitral regurgitation cannot be dealt with. Shroyer's[54] pivotal study showed that at 1 year, the off-pump strategy led to worse composite outcomes, although the accompanying editorial emphasized that in certain patient subsets benefits may still exist,[55] such as in those with atheromatous disease of the aorta.[56]

Hemodynamic instability can occur both from intraoperative ischemia and from cardiovascular deformation by the device used to stabilize the heart during coronary anastomoses (Fig. 2-17).[57] Although the number of readable myocardial segment decreases during cardiac displacement, TEE can adequately detect regional wall motion abnormalities in most patients.[58] and may help guide revascularization strategy.[59] It has been suggested that displacing the heart with a saline bag posteriorly aids in transgastric image quality.[60]

## CARDIAC FUNCTION IN NONCARDIAC SURGERY

The most recent guidelines published jointly by the American Society of Anesthesiologists and Society of Cardiovascular Anesthesiologists Task Force on Transesophageal Echocardiography[61] and by the European Association of Echocardiography[62] are summarized in Table 2-2.

Regardless of the type of noncardiac surgery being undertaken, the greatest diagnostic yield for intraoperative TEE is obtained when sudden and unexplained hypotension occurs.[60] Memtsoudis and colleagues[63] examined the use of TEE in cardiac arrest during noncardiac surgery. In 18 of 22 patients, the etiology was detected by TEE and helped guide subsequent management.

As the use of intraoperative TEE for cardiac surgery continues to proliferate, so will its use in unstable patients undergoing noncardiac surgery.[64]

**TABLE 2-1 Relevant Intraoperative Transesophageal Echocardiographic Findings Categorized by Indication**

| | Indication, *n* | | | | |
|---|---|---|---|---|---|
| *Finding* | *Hemodynamic Instability* | *Surgical Planning* | *Trauma* | *Hypoxemia* | *Total Number of Patients* |
| Severe left ventricular dysfunction ± regional wall motion abnormality | 15 | 2 | — | — | 17 |
| Aortic dissection ± aortic regurgitation | 1 | 13 | — | — | 14 |
| Significant mitral regurgitation | 4 | 2 | — | — | 6 |

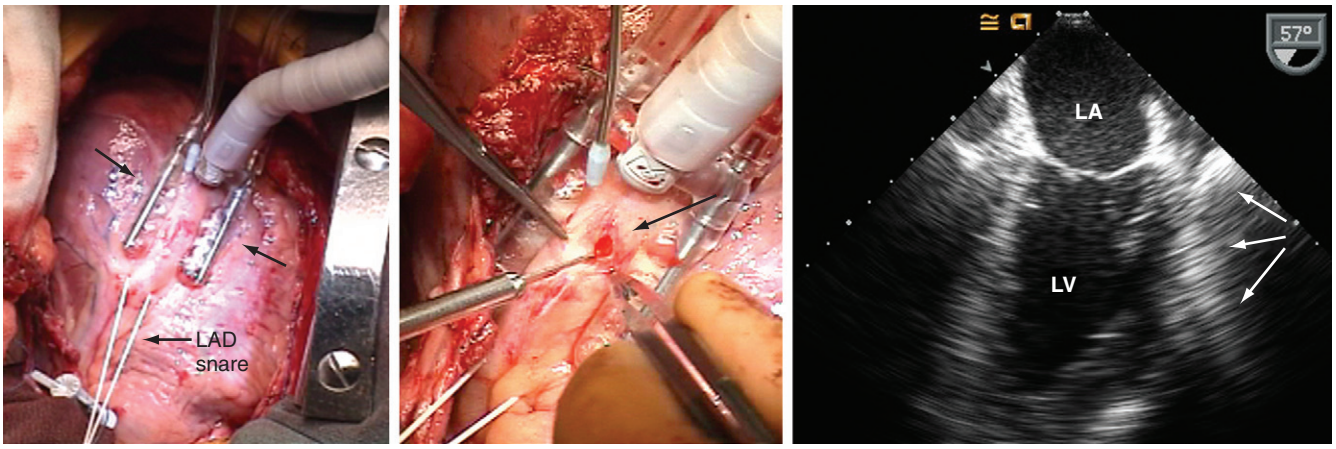

**Figure 2-17** In the *left* panel, the *two arrows* indicate the stabilizing device, which, through suction, lifts and immobilizes a portion of the anterior cardiac wall. The two limbs of the device straddle the left anterior descending artery (*LAD*), which has a snare around it. In the *center* panel, an arteriotomy has been made in the LAD (*arrow*). In the *right* panel, the stabilizer (*arrows*) deforms the anterior wall of the left ventricle.

**TABLE 2-2 Recommendations for the Use of Perioperative TEE in Adults**

| *Clinical Situation* | *Recommendations (ASA/SCA Task Force)*[60] | *Recommendations (European Association of Echocardiography)*[61] |
|---|---|---|
| Cardiac (non-CABG) and thoracic aortic surgery | Should be used in all adults without contraindications to TEE | TEE should be used in adult patients undergoing cardiac surgery or surgery to the thoracic aorta under general anesthesia, in particular, in valvular repair procedures. |
| CABG | Should be considered in CABG surgeries as well<br>• to confirm and refine the preoperative diagnosis,<br>• to detect new or unsuspected pathology,<br>• to adjust the anesthetic and surgical plan accordingly, and<br>• to assess the results of the surgical intervention. | |
| Transcatheter intracardiac procedures | May be used | |
| Noncardiac surgery | TEE may be used when the nature of the planned surgery or the patient's known or suspected cardiovascular pathology might result in severe hemodynamic, pulmonary, or neurologic compromise.<br>• If equipment and expertise are available, TEE should be used when unexplained life-threatening circulatory instability persists despite corrective therapy. | TEE may be used in patients undergoing specific types of major surgery where its value has been repeatedly documented. These include neurosurgery at risk from venous thromboembolism, liver transplantation, lung transplantation, and major vascular surgery, including vascular trauma.<br>TEE may be used in patients undergoing major noncardiac surgery in whom severe or life-threatening hemodynamic disturbance is either present or threatened.<br>TEE may be used in major noncardiac surgery in patients who are at a high cardiac risk, including severe cardiac valve disease, severe coronary heart disease, or heart failure. |
| Critical care | For critical care patients, TEE should be used when diagnostic information that is expected to alter management cannot be obtained by transthoracic echocardiography or other modalities in a timely manner. | TEE may be used in the critical care patient in whom severe or life-threatening hemodynamic disturbance is present and unresponsive to treatment, or in patients in whom new or ongoing cardiac disease is suspected and who are not adequately assessed by transthoracic imaging or other diagnostic tests. |

*CABG*, Coronary artery bypass graft.

## POSITIONING OF INTRAVASCULAR DEVICES

Intraoperative TEE can be used to guide the positioning of a number of intravascular devices.

### *Pulmonary Artery Catheters*

Right heart dysfunction, tricuspid regurgitation, and atrial fibrillation are entities in which proper placement of a pulmonary artery catheter may be challenging. Guidance with TEE helps facilitate passage through the tricuspid valve. It also allows determination of the depth of advancement into the pulmonary artery (Fig. 2-18); this may be important in instances where the pulmonary artery may be transected, such as lung transplantation.

### *Central Venous Pressure Air Aspiration Catheters*

Specialized central venous catheters are often used during sitting craniotomies to aspirate air that has gained access to the venous circulation. Correct positioning is at the right atrial-superior vena caval junction, and imaging is best in the mid-esophagus with rightward rotation and a transducer angle of approximately 90° to 100° (Fig. 2-19).

### *Intraaortic Balloon Pump*

The intraaortic balloon pump is best imaged in the descending aorta in a vertical TEE plane. Correct positioning of the catheter tip is at the inferior border of the transverse aortic arch.[65] Once the tip of the balloon is visualized at a transducer angle of

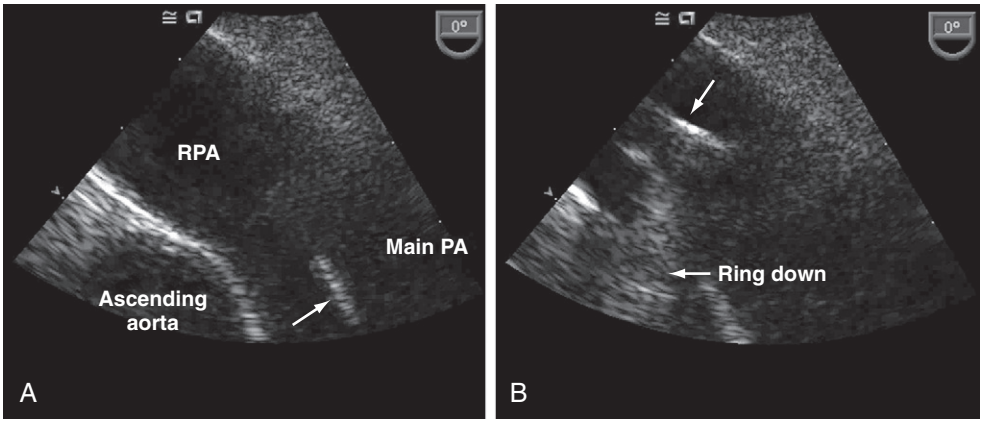

**Figure 2-18** **A,** In this high esophageal short axis, the tip of the pulmonary artery (*PA*) catheter (*arrow*) is seen in the main pulmonary artery. **B,** The balloon is inflated (with resultant ring down artifact) and the pulmonary artery catheter advances into the right pulmonary artery (*RPA*).

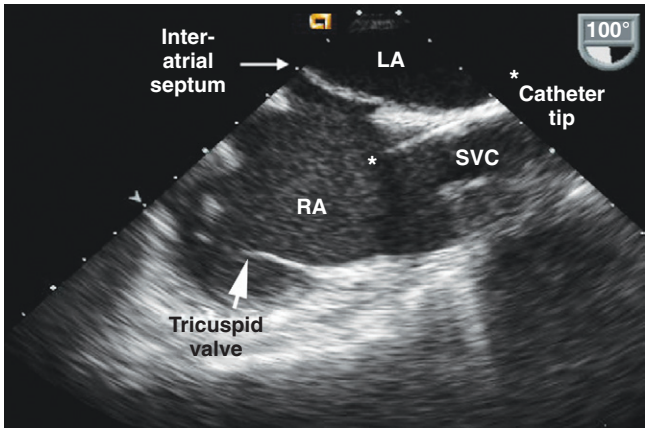

**Figure 2-19** A catheter inserted from the arm is positioned at the junction of the right atrium and superior vena cava (*SVC*) to evacuate any air that gains access to the venous circulation during sitting craniotomy.

approximately 90°, the probe marking at the teeth is noted. The probe is slowly withdrawn until the left subclavian artery orifice is seen; the marking is again noted. The distance between the balloon and the subclavian orifice should be approximately 5 cm (Fig. 2-20).

### *Left Ventricular Assist Device*

As the left ventricular assist device withdraws blood from the left ventricle, LA pressure falls below right atrial pressure. (See Chapter 31.) It is important to determine whether a patent foramen ovale is present, because right-to-left shunting will invariably occur. Any thrombi detected on the left side of the heart must be dealt with before instituting flow through the device. A mechanical aortic valve, even if functional, should be replaced with a bioprosthetic valve to minimize the increased risk of valvular thrombosis and possible embolization. Mitral stenosis, if significant, may limit the ability of blood to be removed to the device by the inflow cannula. The orifice of the

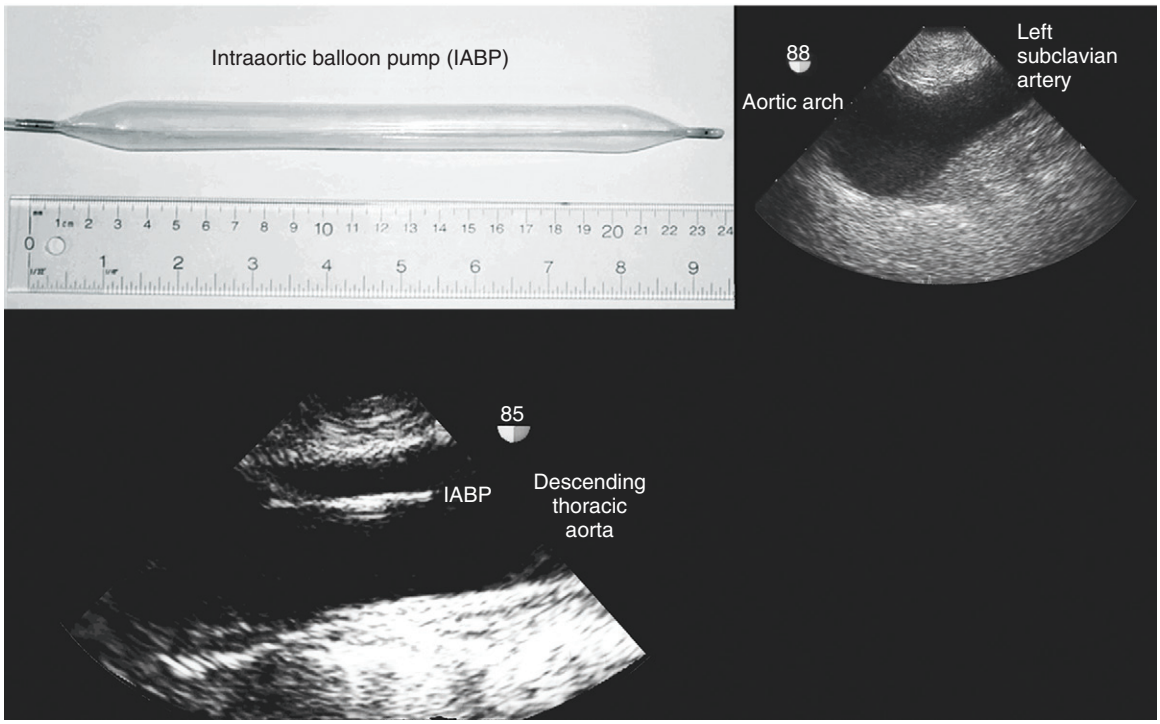

**Figure 2-20** Intraaortic balloon pump (*IABP*) positioned in the descending thoracic aorta. The left subclavian artery is visualized to ensure the IABP does not encroach on the vessel orifice.

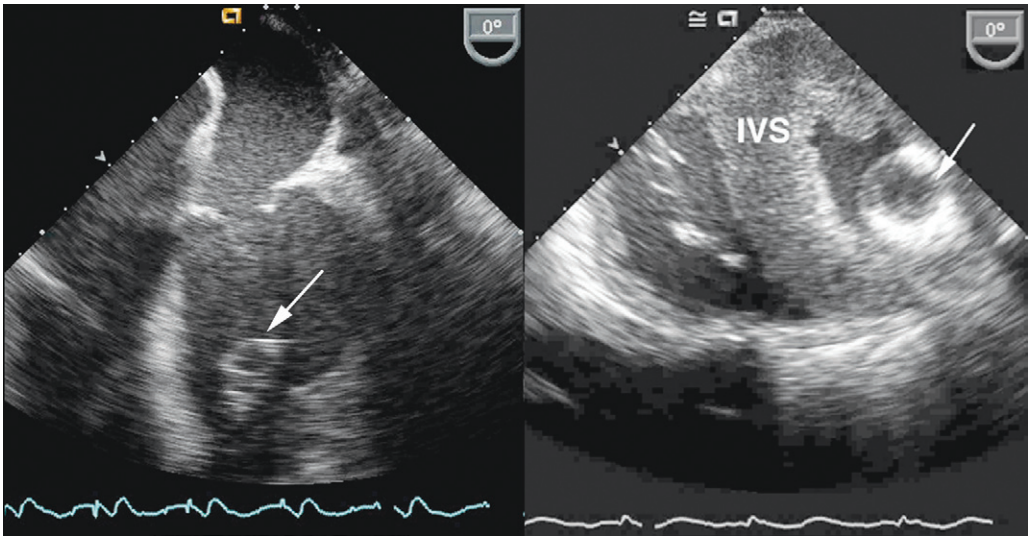

**Figure 2-21** The inflow cannula of the left ventricular assist device (*arrow*) is seen to freely enter the apical region of the left ventricle and not abut the interventricular septum (*IVS*). *Left* panel, four-chamber view; *right* panel, transgastric short-axis view.

ventricular apical cannula (inflow cannula) should be imaged in the four- and two-chamber views, and the lack of obstruction by adjacent walls should be ascertained (Fig. 2-21). On occasion, the inflow cannula is placed in the left atrium via one of the pulmonary veins. Because the outflow cannula terminates in the ascending aorta (Fig. 2-22), it is important to rule out significant aortic regurgitation; this would lead to LV distension during aortic flow. Patients may return to the OR because of left ventricular assist device malfunction. The TEE exam should focus on possible causes: intracardiac thrombi, or problems with the cannulae themselves[66] (Fig. 2-23).

### *Right Ventricular Assist Device*

In positioning the right ventricular assist device, it is preferable to avoid impingement on the tricuspid valve.

### *Coronary Sinus Cannulation*

The coronary sinus is cannulated through blind right atrial puncture for the purposes of administering retrograde cardioplegia. Occasionally, TEE guidance is required, especially in minimally invasive surgical procedures (Fig. 2-24).

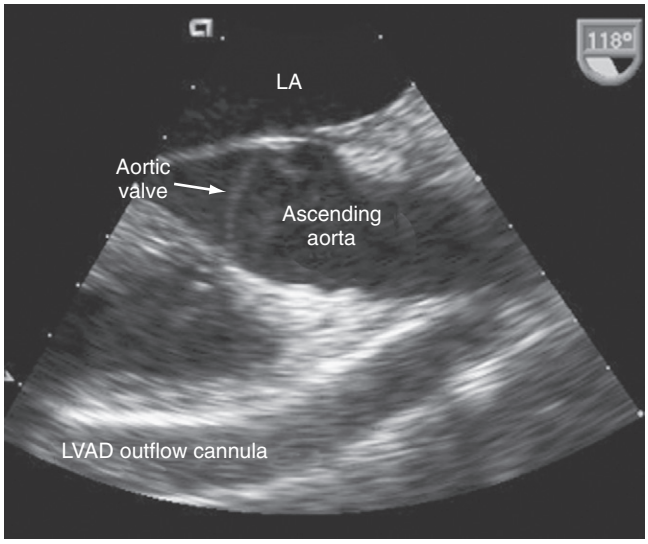

**Figure 2-22** The outflow cannula of the left ventricular assist device (*LVAD*) terminates in the ascending aorta.

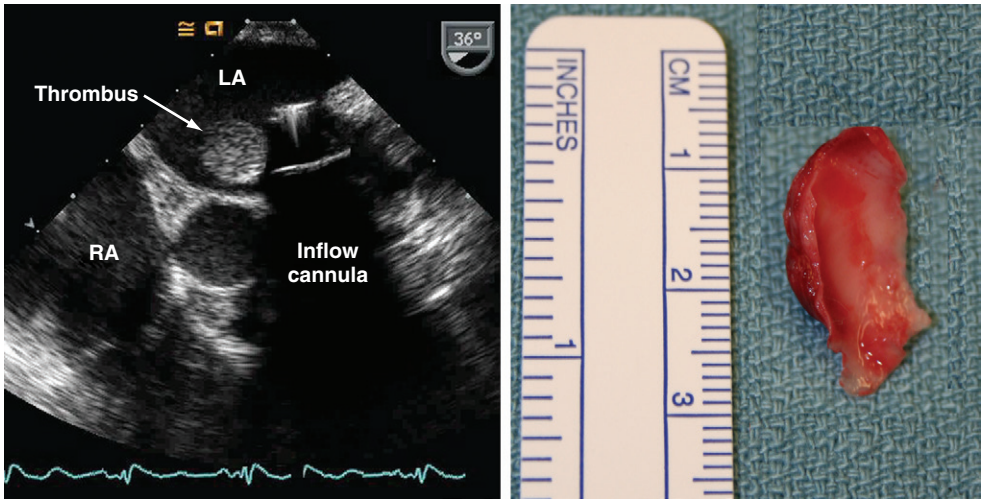

**Figure 2-23** Because of left ventricular assist device malfunction, this patient returned to the operating room for left ventricular assist device exploration. Intraoperative TEE (*left*) revealed a thrombus impinging on the inflow cannula in the left atrium. The surgical specimen is seen at *right*.

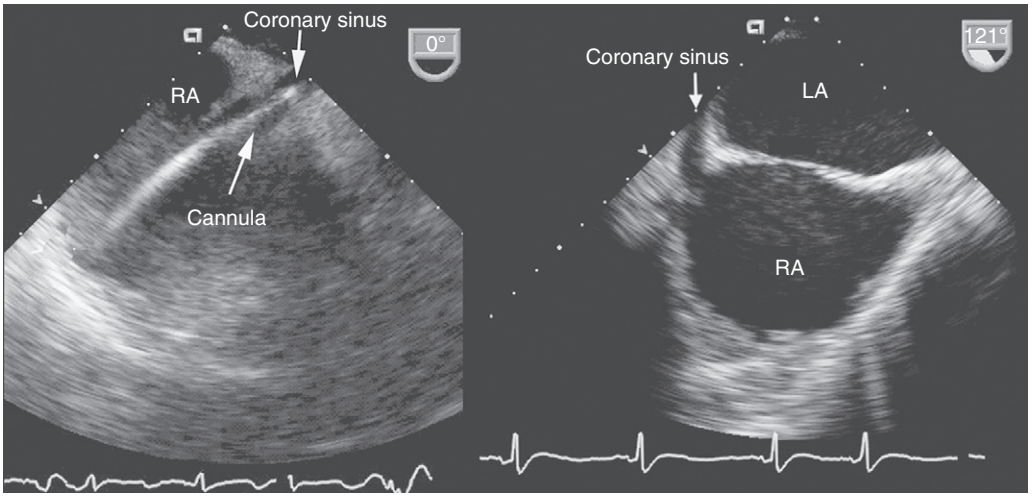

**Figure 2-24** The coronary sinus, visualized in a low esophageal view (*left*) and a bicaval view (*right*). In the left panel, the catheter is seen traversing the right atrium (*RA*) and entering the coronary sinus orifice.

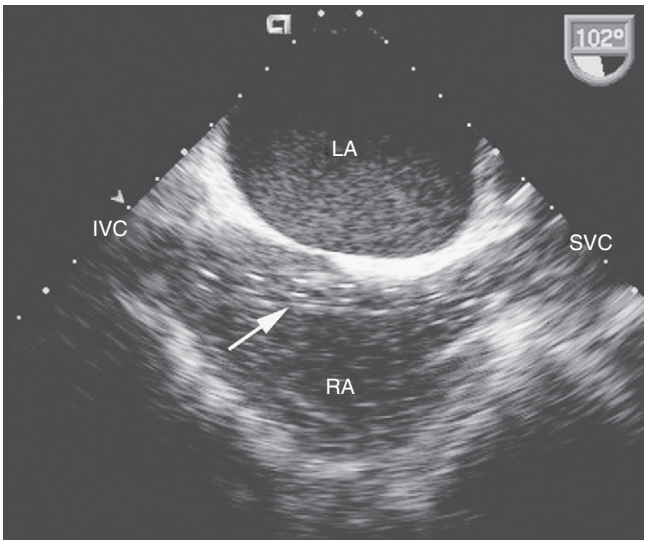

**Figure 2-25** The multiorifice femoral venous cannula is seen entering the right atrium from the inferior vena cava (*IVC*). *SVC*, Superior vena cava.

### *Left Ventricular Vent*

An LV vent is placed through the right superior pulmonary vein into the left atrium and advanced through the mitral valve into the left ventricle to drain excess ventricular volume on bypass.

### *Femoral Venous Cannula*

Occasionally venous drainage on bypass is achieved through femoral venous cannulation with advancement into the right atrium (Fig. 2-25).

## TRANSPLANT SURGERY

### *Heart Transplantation*

TEE is used to examine the native heart for LV thrombi and to assess the function of the donor heart before procurement and after the recipient is separated from cardiopulmonary bypass, when the effects of the ischemic time may become evident. In addition, the anastomoses may be examined if obstruction is suspected, such as in the pulmonary artery anastomosis (Fig. 2-26).

### *Lung Transplantation*

During lung transplantation, the use of TEE has been described in the evaluation of vascular anastomoses. The pulmonary venous anastomoses are generally well seen, and velocities are usually less than 1 m/sec in the absence of significant obstruction.[67,68]

The right pulmonary artery anastomoses (and less likely the left) may be visualized in the midesophageal ascending aortic short-axis view, although the angle of flow usually precludes Doppler interrogation of the anastomosis (Fig. 2-27).

If the recipient's heart exhibits right ventricular hypertrophy, right ventricular outflow tract obstruction may develop when the new lungs are reperfused.

### *Liver Transplantation*

During reperfusion of the transplanted liver, significant right-sided embolization can occur, with resultant hemodynamic instability. TEE can aid in this diagnosis and guide treatment.

# Alternate Techniques

## EPICARDIAL/EPIAORTIC ECHOCARDIOGRAPHY

On occasion there may be contraindications to TEE, or the images obtained may be suboptimal. Using a high-frequency ultrasound probe in a sterile sheath, the cardiac surgeon can image the heart by placing it on the epicardial surface and obtain standard surface echocardiographic images[69] (Fig. 2-28). Similarly, the ascending aorta may be scanned for regions of atheromatous disease, which should be avoided during aortic cross clamping[70] (Fig. 2-29).

# Transesophageal Echocardiography as a Monitor of Intraoperative Ventricular Function: Impact on Postoperative Outcomes and Cost-Effectiveness

The recommendations of the American Society of Anesthesiologists and the Society of Cardiovascular Anesthesiologists task force for the use of perioperative TEE[71] and the European Association of Echocardiography for the use of intraoperative TEE in cardiac and noncardiac surgery[72] are presented in Table 2-2.

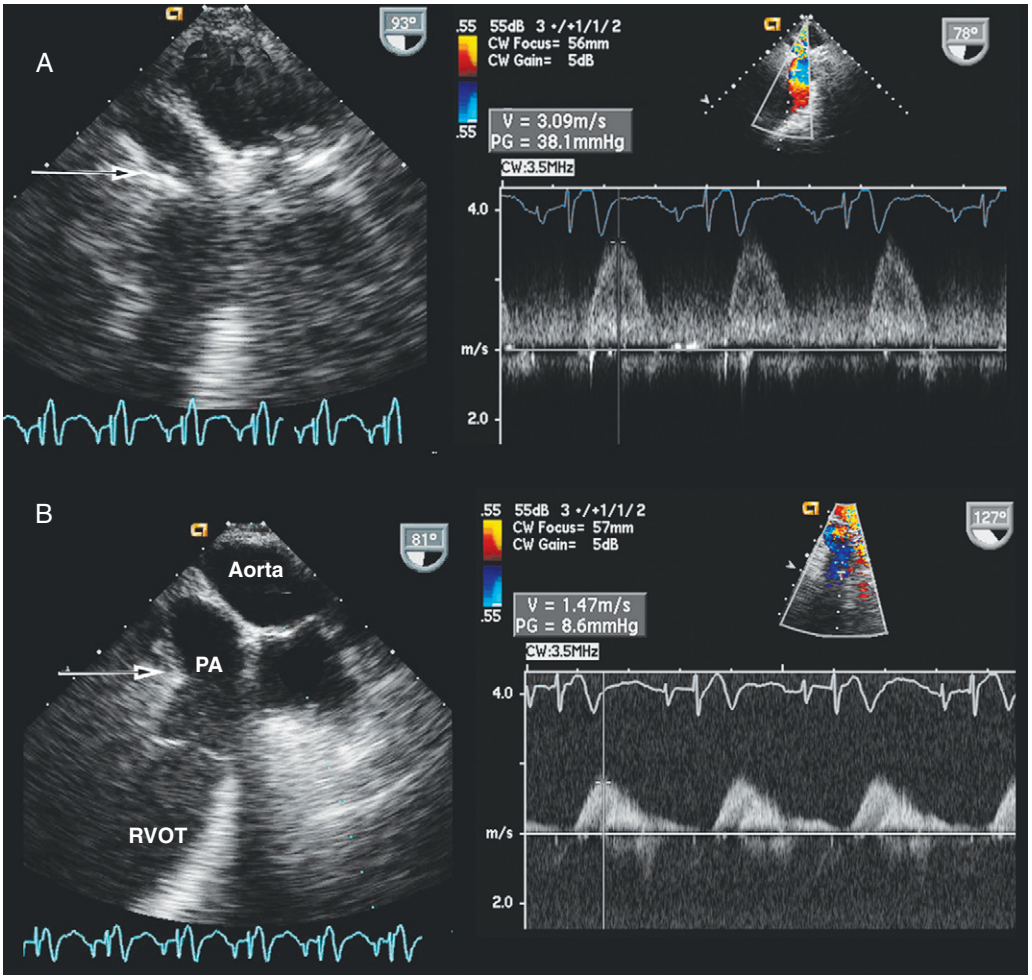

**Figure 2-26** **Images obtained from a high esophageal window. A,** Pressure gradient (*PG*) of 38 mm Hg across the pulmonary artery led to the diagnosis of an anastomotic obstruction (*arrow*). **B,** Anastomosis was revised with resolution of the gradient. *PA*, Pulmonary artery; *RVOT*, right ventricular outflow tract; *V*, velocity.

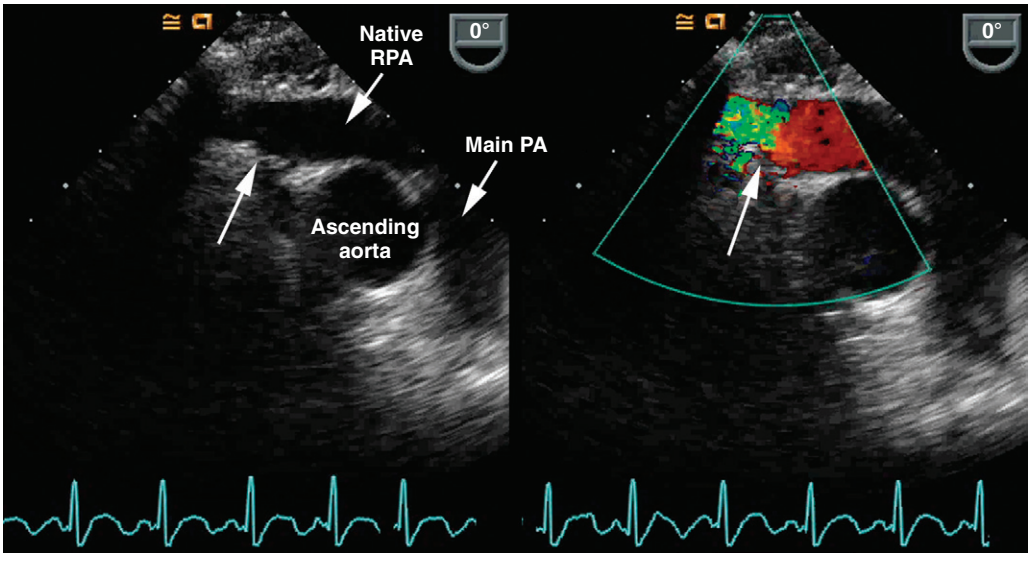

**Figure 2-27** **Midesophageal ascending aortic short-axis view in a patient who received a right-sided lung transplant.** In the *left* panel, the arrow indicates the slight narrowing of the anastomotic site. In the *right* panel, aliasing in the color Doppler signal is seen at the anastomosis. *PA*, Pulmonary artery; *RPA*, right pulmonary artery.

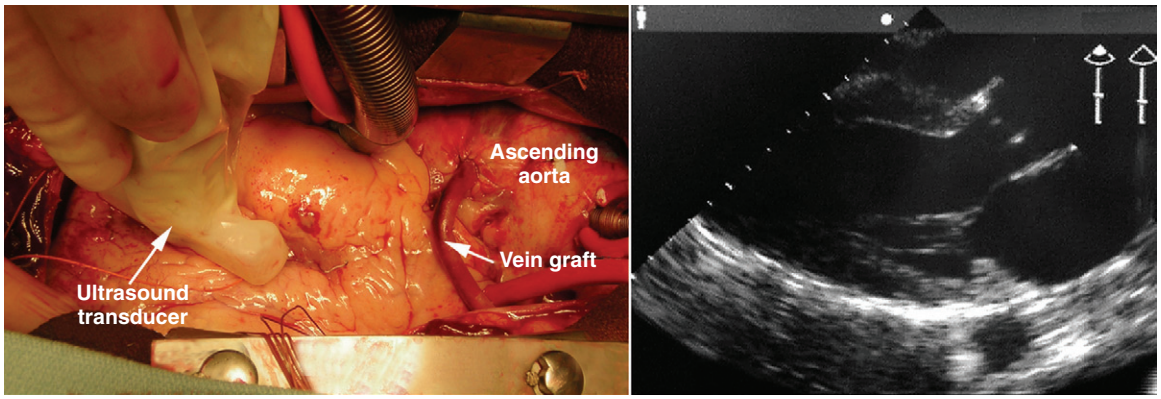

**Figure 2-28** In the *left panel,* the surgeon places an ultrasound probe directly on the epicardial surface after protecting it with a sterile sheath. In the *right panel,* a parasternal long-axis view is obtained.

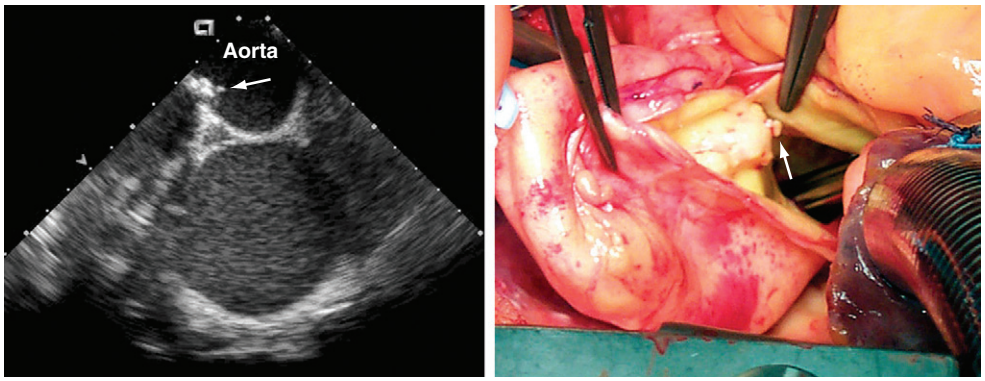

**Figure 2-29** In the *left panel,* epiaortic scanning reveals a mobile atheroma in the ascending aorta, which led to a modification of cannulation strategy. In the *right panel,* the mobile atheroma is seen in the open aortic root (*arrow*).

Several studies have addressed the impact of intraoperative TEE monitoring of ventricular function during coronary bypass surgery. In all instances, benefits must be weighed against the reported complication rate of TEE of approximately 0.2%.[71]

In a study conducted at the Mayo Clinic, Click and colleagues[72] prospectively analyzed the effect of intraoperative TEE on surgical management. TEE use (and thus inclusion in the study) was determined by the treating physicians. Of the 292 patients having coronary artery bypass graft surgery, there were 97 new TEE findings (33% of all cases) prebypass and 24 new TEE findings (8% of all cases) postbypass. This large number probably reflects a selection bias, because more complex cases were more apt to be selected for TEE.

In a series of unselected and consecutive cardiac surgical patients having exclusively coronary artery bypass graft with TEE monitoring, Qaddoura and co-workers,[73] also at the Mayo Clinic, noted new prebypass findings in 52 patients, resulting in alterations of the surgical procedure in 21 of them; the most common occurrence was a previously undiagnosed patent foramen ovale (Table 2-3). Postbypass there were 19 new findings in 15 patients, resulting in 15 surgical interventions in 10 patients (see Table 2-3). In a retrospective review of 2343 unselected patients having cardiac surgery, Forrest and assosiates[74] found a surgical impact of TEE findings of 4.5%. When the data for coronary artery bypass graft patients was analyzed, the surgical impact was 6.7% of high-risk patients versus 2.8% of low-risk patients. What would be difficult to determine given the designs of these two studies is whether the additional procedures performed led to improved outcome. Bergquist and colleagues[75,76] studied the concordance between real-time intraoperative TEE interpretation by five cardiac anesthesiologists and offline analysis by two blinded investigators in the assessment of LV filling, ejection fraction area, and regional wall motion. Results obtained by the two methods were within 10% of each other 75% of the time with respect to ejection fraction and filling. The accuracy of regional assessment was variable: more accurate for normal than for abnormal wall motion and better in anesthesiologists with more advanced echocardiographic training. In the second part of the study, TEE was found to be the most important factor in guiding hemodynamic interventions in 17% of cases examined. What is lacking is a clear demonstration that the TEE assessments were correct and that the same interventions would not have been undertaken if guided by more traditional monitors. Cost and outcome were not examined. Mathew and colleagues[77] demonstrated that cardiac anesthesiologists interpret TEE examinations at a level comparable to physicians whose primary practice is echocardiography.

At the Cleveland Clinic, Savage and co-workers[78] examined the use of intraoperative TEE monitoring in a group of high-risk patients undergoing coronary artery bypass graft. In addition to documenting numerous management changes related to TEE-derived information (Table 2-4), they documented lower short-term morbidity and mortality rates as compared with a

historical group of patients with similar severity scores[79] who were not monitored with TEE (Table 2-5). An individual not part of the anesthetic or surgical team read the TEE scan; it is uncertain whether someone involved in direct patient management would have as readily garnered the information.

In studies from Australia,[80] Europe,[81,82] Canada,[83] and India,[84] the real-time accrual of information with TEE was demonstrated to be of value in the management of hemodynamic perturbations and the planning of the surgical procedure in coronary artery bypass graft and other cardiac surgical procedures (Tables 2-6 and 2-7). No assessment of the effect of intraoperative TEE monitoring on patient outcome was made. These studies and others are summarized in Table 2-8.

Cost effectiveness has been demonstrated by studies of the use of TEE in congenital cardiac surgery,[85] preparation for elective cardioversion,[86] and determination of antibiotic treatment duration in endocarditis.[87] Similar data for routine TEE monitoring in coronary artery bypass graft are lacking.

Fanshawe and colleagues[88] showed substantial savings with the routine use of TEE in cardiac surgical patients but not specifically coronary artery bypass graft. In a number of instances, surgery was either cancelled or newly recommended based on the findings of intraoperative TEE; whether these alterations of treatment were beneficial was not determined in follow-up. The claim of improved patient outcome must be tempered by the fact that most surgical changes involved closure of an asymptomatic patent foramen ovale. Their findings are summarized in Table 2-9.

In the largest series to date of the impact of intraoperative TEE on decision making in cardiac surgery, Eltzschig and colleagues[89] retrospectively examined 12,566 patients. From 1990 to 2004, the frequency with which intraoperative TEE was performed increased steadily (Fig. 2-30). The major findings, presented in Table 2-10, reveal that a large number of procedures were affected by TEE findings both before and after cardiopulmonary bypass. As pointed out in the accompanying commentary,[90] changes in therapeutic management are not, as endpoints, as convincing as morbidity, mortality, and cost, but nonetheless the study and its magnitude were commended as an "excellent resource for the design of future, randomized, controlled trials examining the potential benefits of intraoperative TEE on clinical outcome."

The impact of monitoring of ventricular function during noncardiac surgery has not been studied as closely. In a

retrospective review by Suriani and colleagues,[91] the use of TEE was associated with some alterations in anesthetic and surgical management in most cases. However, the indications for TEE were subjective, and neither the cost effectiveness nor the effect on outcome was studied. Hofer and co-workers[92] prospectively examined patients at "high risk" for myocardial ischemia who were having major noncardiac surgery. A large number of patients had therapeutic changes based on TEE findings (Table 2-11), but outcome data were lacking. Other studies have also described the changes in intraoperative management during noncardiac surgery,[93,94] but cost-effectiveness or outcome data were not provided. The authors acknowledge that randomized controlled clinical trials to evaluate outcome with intraoperative TEE are difficult to perform.

Although data showing improved outcomes is lacking, intraoperative TEE has become an essential tool in the assessment of ventricular function during cardiac surgery and in the monitoring of specific clinical entities, such as device placement and organ transplantation. It must be emphasized that appropriate physician training and quality assurance are crucial to the correct interpretation of data. Numerous technologic advances are on the horizon and may improve intraoperative applicability.

**TABLE 2-11 Preoperative Cardiovascular Diagnoses and Intraoperative Transesophageal Echocardiography: Incidence of Therapeutic Consequences**

| | *Total*, N | *Vasodilator*, n (%) | *Vasopressor*, n (%) | *Fluid*, n (%) |
|---|---|---|---|---|
| CAD | 61 | 36 (59) | 28 (46) | 11 (18) |
| CAD + valve | 13 | 7 (54) | 5 (39) | 5 (39) |
| Valve | 11 | 4 (36) | 3 (27) | 2 (18) |
| SWMA | 28 | 26 (93)* | 20 (71)* | 9 (32) |
| EF <40% | 15 | 8 (53) | 6 (40) | 1 (7) |
| LHF | 10 | 8 (80)* | 3 (30) | 1 (10) |
| PAH | 11 | 8 (73)* | 8 (73)* | 4 (36) |
| RHF | 10 | 7 (70)* | 5 (50) | 2 (20) |
| Total | 99 | 54 (55) | 43 (43) | 24 (24) |

Vasodilator/vasopressor/fluid, new therapy, or changes of therapy with respect to vasodilator/vasopressor and fluid management.

From Hofer CK, Zollinger A, Rak M, et al: Therapeutic impact of intra-operative transoesophageal echocardiography during noncardiac surgery. *Anaesthesia* 59:3-9, 2004.

*CAD*, Coronary artery disease; *EF*, ejection fraction; *LHF*, left-sided heart failure; *PAH*, pulmonary arterial hypertension; *RHF*, right-sided heart failure; *SWMA*, systolic wall motion abnormality; *Valve*, valve diseases.

*$P$ <0.05.

## KEY POINTS

- TEE is an essential tool for monitoring cardiac function in the operating room.
- TEE allows evaluation of ventricular function and filling pressures.
- Doppler-derived cardiac output is best calculated using velocity and diameter obtained from the left ventricular outflow tract.
- Although the calculation of left ventricular contractility using TEE is prohibitively complex, the fractional area of change provides a useful surrogate and is suited to the rapidly changing environment of the operating room.
- TEE assessment of intraoperative RV function is best accomplished by visual inspection and semiquantitative assessment in both the transgastric and the four-chamber views.
- Knowledge of the coronary circulation allows the echocardiographer to inform the surgeon of culprit vessels in the setting of ischemic wall motion abnormalities.
- Using TEE, the echocardiographer can guide the surgeon in placement of the coronary sinus cardioplegia cannula, the intraaortic balloon pump, and other intravascular devices.
- After heart or lung transplantation, TEE is important in the assessment of overall graft function and anastomotic integrity.
- Using TEE, the echocardiographer can guide the surgeon in evacuating air from the left ventricle following cardiopulmonary bypass.
- TEE is particularly useful for in determining the etiology of failure to wean from cardiopulmonary bypass.

# Contrast Ultrasound Imaging: Technical Aspects and Clinical Applications

THOMAS R. PORTER, MD | FENG XIE, MD

**Left Ventricular Ultrasonic Contrast Agents**
Characteristics of Microbubbles
Clinical Contrast Agents
**Perfusion Imaging Techniques**
Harmonic High–Mechanical-Index Intermittent Imaging (Harmonic) Power Doppler
Low–Mechanical-Index Imaging Schemes
**Qualitative and Quantitative Methods of Analysis**
Continuous Infusion Imaging
Technical Equipment, Image Processing, and Artifacts
**Safety of Ultrasound Contrast**
**Clinical Applications of Contrast Enhanced Ultrasound**
Detecting Acute Ischemia/Risk Area in the Emergency Setting
Assessment of Myocardial Viability in the Acute and Chronic Setting
Detection of Coronary Artery Disease
**Other Diagnostic Applications of Microbubbles**
Improved Left Ventricular Cavity Opacification
Doppler Enhancement
Contrast Perfusion Imaging of Other Organs
Molecular Imaging with Contrast Ultrasound
Detection of Carotid Artery Atherosclerosis
**Therapeutic Applications of Ultrasound and Microbubbles**
Drug and Gene Delivery
Thrombolysis

The use of intravenous microbubbles for real-time perfusion imaging is now a reality. There is a consensus throughout the ultrasound community that ultrasound contrast is safe and effective for improving endocardial border delineation and should be used for improving left ventricular (LV) wall motion and detecting LV apical hypertrophy, noncompaction, thrombus, endomyocardial fibrosis, takotsubo, LV aneurysm, or pseudoaneurysm.[1] Furthermore, multicenter studies have demonstrated perfusion imaging with ultrasound contrast is comparable to radionuclide imaging, with the potential to improve spatial resolution, detect subendocardial ischemia, and reduce ionizing radiation exposure to the patient. Single-center studies have consistently demonstrated the incremental clinical benefit of myocardial perfusion imaging during dobutamine, vasodilator, or bicycle stress echocardiography, and in the evaluation of acute coronary syndromes. Intravenous targeted microbubbles also have a potential role in molecular imaging of arteriogenesis and transplant rejection, as well as in the detection of remote ischemia. Ultrasound-mediated microbubble destruction serves as a mechanism for targeting drug and gene delivery. Image-guided targeted microbubble destruction with ultrasound is being used to noninvasively dissolve intravascular and microvascular thrombi in ischemic stroke and acute myocardial infarction animal models either with reduced-dose fibrinolytic agents or in the absence of fibrinolytic agents. The actual clinical role of contrast echocardiography in these areas remains uncertain, but clearly the potential exists for tremendous advances in both the detection of cardiovascular disease and prompt noninvasive therapies.

## Left Ventricular Ultrasonic Contrast Agents

### CHARACTERISTICS OF MICROBUBBLES

Microbubbles must meet numerous physical and chemical standards to reach the LV cavity and myocardium following venous injection. The first requirement is size. Microbubbles greater than 8 μm in diameter are filtered from the pulmonary circulation and will not reach the LV cavity.[2] The scattering cross section of a microbubble is related to the sixth power of its radius, and thus the smaller bubbles that reach the LV are less reflective than the bubbles filtered by the pulmonary circulation. To detect the comparatively weak echoes of the bubbles small enough for transpulmonary passage, imaging modalities have been developed that register the more "microbubble-specific" resonant frequencies. The resonant frequency of a microbubble is inversely related to its diameter.[3]

Another problem arising with the small microbubble size is surface tension. The internal pressure of gases within microbubbles is increased dramatically as the size of a microbubble decreases to less than 7 μm. Therefore, the gases within the microbubbles are at very high concentration and rapidly diffuse into blood. This immediately reduces their size and hence their contrast effect, a limitation that becomes most evident when attempts are made to obtain myocardial ultrasonographic contrast from an intravenous injection. Therefore, a second requirement for intravenous microbubbles is to have a method of preventing dissolution after exposure to blood. The gas composition is one of the most important factors for retention of microbubble size in circulation. First-generation contrast agents

contained room air, which is 78% nitrogen. Because nitrogen rapidly diffuses, these microbubbles survived only seconds.[4] To overcome this problem, slowly diffusing, high–molecular-weight insoluble gases were incorporated into the microbubbles. The diffusivity of a gas is inversely proportional to the square root of its molecular weight (Graham's law). When less soluble gases with a higher molecular weight were incorporated inside the microbubble, the microbubbles became more stable so that myocardial contrast could be visualized following intravenous injections. Perfluorocarbons have the added advantage of preferentially remaining a gas instead of becoming a liquid at higher temperatures (low Ostwald coefficient). Several types of microbubble solutions containing high–molecular-weight gases have been developed for potential clinical use (Table 3-1).

### CLINICAL CONTRAST AGENTS

Optison (GE Healthcare, Princeton, N.J.) was the first perfluorocarbon-containing intravenous ultrasonographic contrast agent approved for use in humans. Its indication was enhancement of LV opacification from intravenous injection. Perfluorocarbon-exposed sonicated dextrose albumin (PESDA) is a contrast agent formulated on-site by sonicating 5% dextrose with 5% human serum albumin (3:1 mixture) after hand agitating this mixture with the perfluorocarbon decafluorobutane. Intravenously injected perfluorocarbon-containing sonicated albumin microbubbles appear to have a rapid transit through the myocardium and do not affect LV function, coronary and systemic hemodynamics, or pulmonary gas exchange. Both PESDA and Optison have proven to be capable of creating consistent myocardial contrast enhancement in animal and human studies when used with newer imaging techniques.[5-7]

Definity (Lantheus Medical Imaging, North Billerica, Mass.) has also received U.S. Food and Drug Administration (FDA) approval for endocardial border detection. Definity is a lipid-coated microbubble that is formed from two components: a long-chain lipid and an emulsifier. This is typically a saturated diacyl phosphatidylcholine and a polyethylene glycol spacer. To create stable microbubbles, this mixture must be activated with a Vialmix device. In Europe, Sonovue (Bracco Diagnostics, Milan, Italy) has been approved as a contrast agent for limited clinical applications. This microbubble has a phospholipid shell surrounding a sulfur hexafluoride gas.

Two recent ultrasound contrast agents sought FDA approval as myocardial perfusion imaging agents. One agent was formulated by altering microbubble shell thickness (CARDIOsphere; Point BioMedical, San Carlos, Calif.). This agent has an albumin and polylactide shell that is of sufficient thickness that it remains stable in the bloodstream even though the encapsulated gas is nitrogen. Although it was never approved by the FDA, multicenter clinical trials were performed with this unique microbubble to detect myocardial perfusion abnormalities during dipyridamole stress echocardiography.[8] Another fluorocarbon-based microbubble, Imagify (Acusphere Inc., Lexington, Mass.) also sought FDA approval for a myocardial perfusion indication, but also was denied despite completing multicenter trials showing accuracy for detecting coronary artery disease equivalent to radionuclide imaging.[9] This agent was used to improve LV opacification and assess myocardial perfusion (Fig. 3-1) and had receiver operator characteristics identical to those of radionuclide imaging in detecting coronary artery disease (Fig. 3-2).

## Perfusion Imaging Techniques

Although high–molecular-weight gases have rendered thin-shelled microbubbles more stable, their detection in the myocardium with echocardiographic equipment is limited with conventional imaging techniques. The development of harmonic imaging, intermittent imaging, harmonic power Doppler, and, more recently low mechanical-index (MI) real-time detection techniques has dramatically enhanced the myocardial contrast produced from intravenously injected microbubbles.

### HARMONIC HIGH–MECHANICAL-INDEX INTERMITTENT IMAGING

Microbubbles in an ultrasonic field have the ability to scatter ultrasound not only linearly but also nonlinearly. At peak incident pressures (above 0.1 megapascals), the microbubbles respond in a nonlinear manner. This physical property is attributable to the fact that gas bubbles are compliant and react to insonation at diagnostic frequencies with compression and rarefaction, thus emitting radial oscillations. However, the magnitude of compression and rarefaction is not the same with each oscillation, and therefore both linear and nonlinear returning waves occur.[10] The nonlinear responses occur in both the fundamental and harmonic frequencies and can be received and filtered by an appropriate echocardiography system. Because tissue and side lobes exhibit a significantly smaller nonlinear response to ultrasound, ultrasonic transducers that selectively receive the nonlinear responses produce a much better signal-to-noise ratio and more sensitive detection of microbubbles than conventional imaging.[11]

Microbubbles are destroyed by real-time ultrasound when it is transmitted at diagnostic intensities (MIs greater than 0.3). Destruction can be reduced by selecting one frame out of every one to several cardiac cycles, usually with triggering the frame to the electrocardiogram. This has been referred to as intermittent imaging. When the intermittent ultrasound impulse is at a

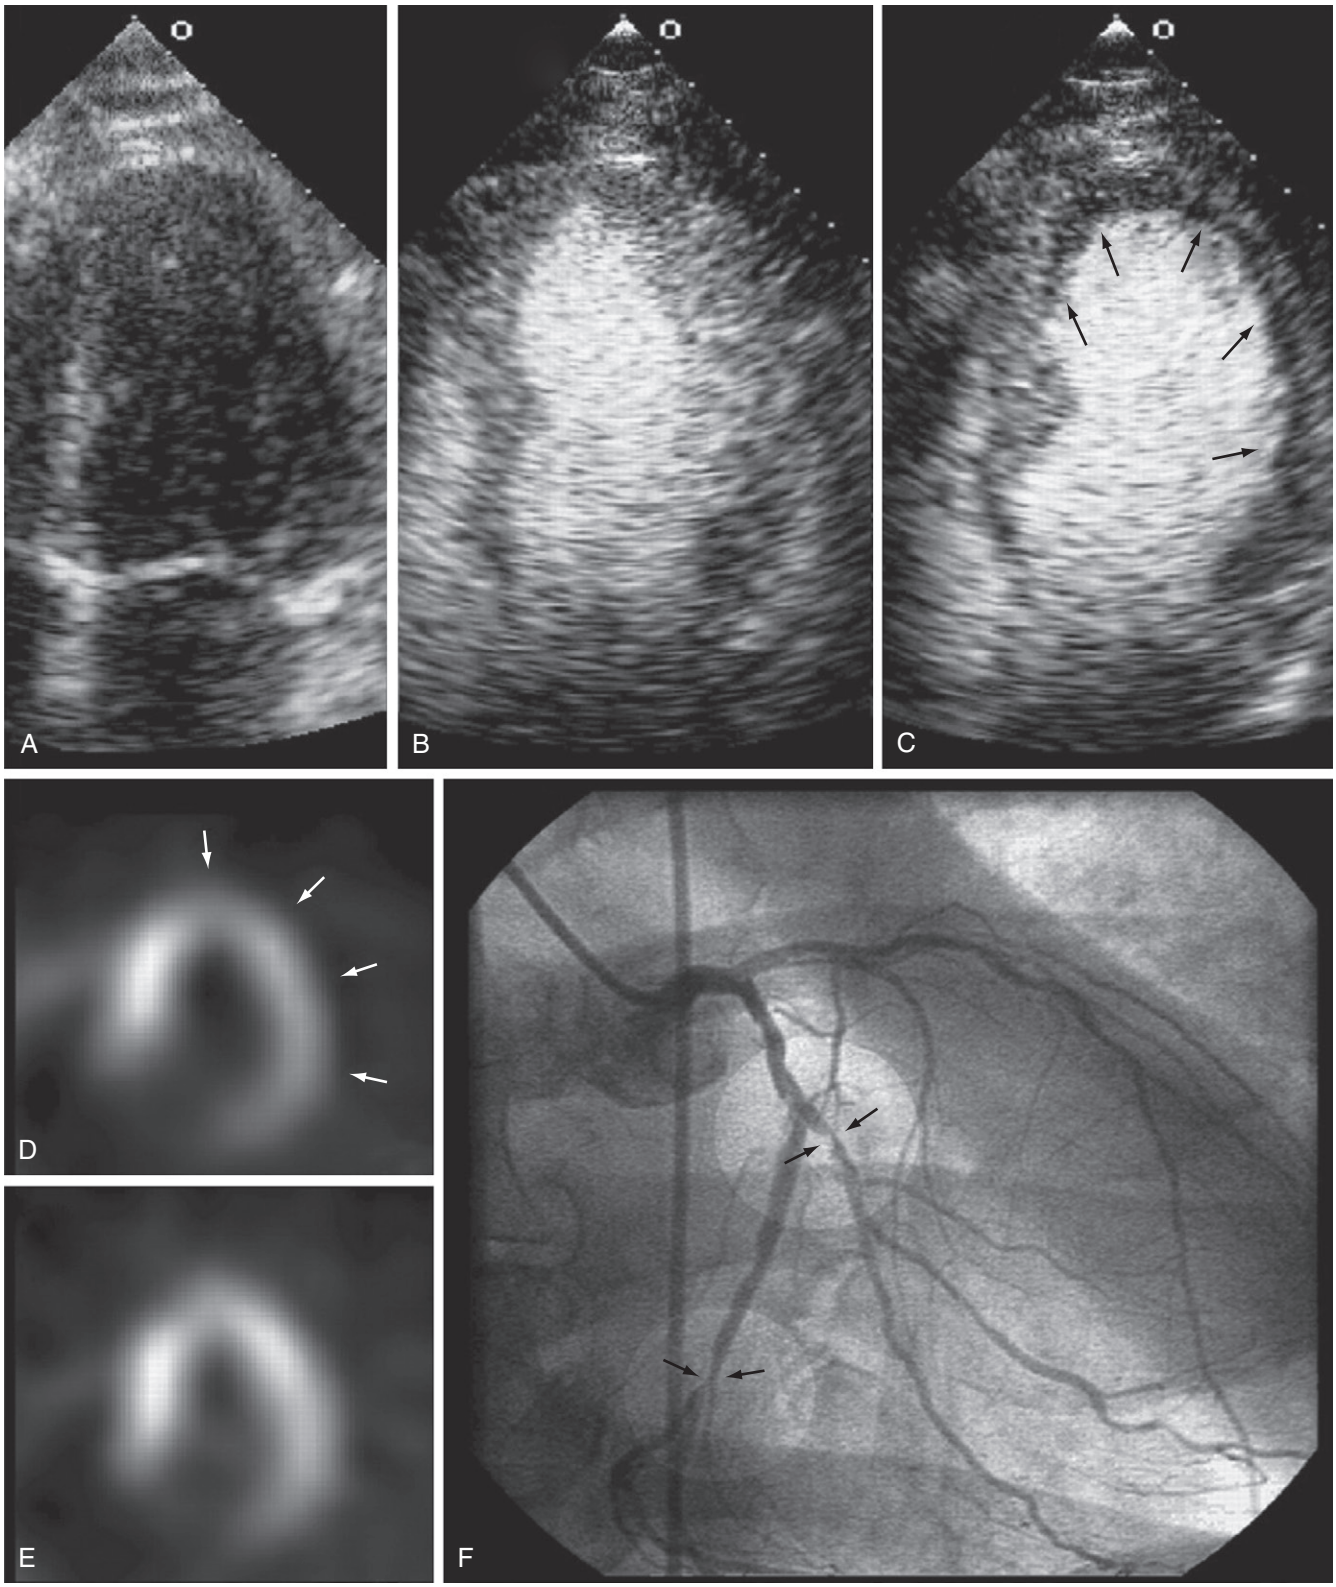

**Figure 3-1 Example of a myocardial perfusion defect.** These images were produced with the Acusphere contrast agent (Imagify) in a multicenter trial, comparing perfusion imaging with real-time perfusion echocardiography precontrast (**A**), at rest (**B**), and with stress (**C**), which shows a decrease in apical and lateral myocardial perfusion (*arrows*), with radionuclide stress (**D**) and rest (**E**) images, which show lateral ischemia, and the corresponding angiogram (**F**) showing circumflex artery stenosis (*arrow*). *(Reprinted, with permission, from Senior R, Monaghan M, Main ML, et al: Detection of coronary artery disease with perfusion stress echocardiography using a novel ultrasound imaging agent: two phase 3 international trials in comparison with radionuclide perfusion imaging.* Eur J Echocardiogr *10:26-35, 2009.)*

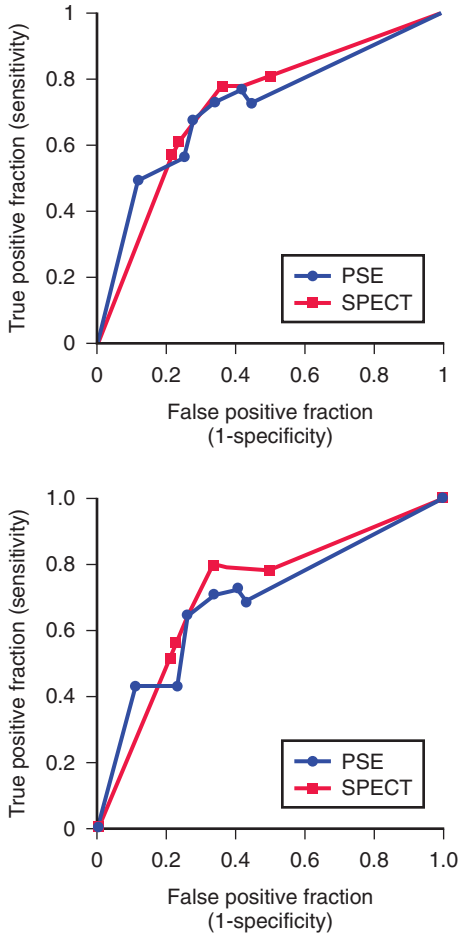

**Figure 3-2** Receiver operator characteristic curve for myocardial perfusion imaging with the Acusphere contrast agent and radionuclide single photon emission computed tomography (SPECT) imaging compared to quantitative coronary angiography in 622 chronic, stable, chest pain patients (*top*) and in the 492 patients without prior myocardial infarction (*bottom*). The points on the curves indicate the results for each reader (4 for SPECT and 6 for PSE). *(Reprinted, with permission, from Senior R, Monaghan M, Main ML, et al: Detection of coronary artery disease with perfusion stress echocardiography using a novel ultrasound imaging agent: two phase 3 international trials in comparison with radionuclide perfusion imaging.* Eur J Echocardiogr *10:26-35, 2009.)*

high intensity (MIs above 0.9), there is a strong and brief nonlinear echo. This transient scattering produces a large contrast signal from the microbubbles.[12,13] Interrupting the high-intensity ultrasound for a short period of time allows for replenishment of microbubbles, which serve to produce contrast enhancement for the subsequent triggered frame. When microbubbles are administered as a continuous infusion and the ultrasound pulsing interval is incrementally varied, the reappearance of bubbles in the myocardium permits the calculation of mean microbubble velocity and plateau (or peak) myocardial signal intensity.[14] Because the background subtracted plateau intensity correlates with capillary cross-sectional area, multiplying the contrast replenishment rate and plateau intensity allows one to quantify myocardial blood flow changes. Therefore, with a combination of second harmonic and intermittent imaging, it has become possible to noninvasively examine myocardial perfusion in animals and humans using a wide variety of intravenous higher molecular-weight microbubbles.[3,15-18]

## (HARMONIC) POWER DOPPLER

Power Doppler images are based on the integrated power in the Doppler signal instead of its mean frequency shift, as used in conventional color Doppler.[19] The amplitude of the Doppler signal is related to the concentration of moving scatterers at a particular location. This amplitude is much greater in the presence of microbubbles when compared with the signal of red blood cells.[20] This type of Doppler signal is more sensitive, not subject to aliasing, and independent of the angle of insonation. Intermittent harmonic power Doppler, therefore, can be used just like intermittent harmonic imaging to examine myocardial blood flow changes. It is, however, subject to flash artifacts, which occur with movement of the heart. Harmonic power Doppler has been successfully employed in animal[21] and human myocardial perfusion studies, showing satisfactory concordance in the comparison between echocardiographic and $^{99m}$Tc-sestamibi single-photon emission computed tomography (SPECT) stress imaging.[22,23]

## LOW–MECHANICAL-INDEX IMAGING SCHEMES

Significant achievements have been made in low-MI real-time visualization of myocardial function and perfusion. Pulse inversion Doppler is a multipulse technique that separates linear and nonlinear scattering using the radiofrequency domain. The concept is an extension of pulse inversion, in which alternating positive and negative pulses of identical amplitude are transmitted into the tissue, the sum signal of which is equal to 0 (Fig. 3-3). The responses of linear scatterers to this kind of pulse, therefore, will be canceled. On the other hand, the signal from nonlinear scatterers (which do not react to positive and negative pressures in the same way) will not be equal to 0 and can be registered as a bubble-specific response.[24] Pulse inversion Doppler overcomes motion artifacts by sending multiple pulses of alternating polarity into the myocardium. This allows one to visualize wall thickening and contrast enhancement simultaneously at very low MIs (less than 0.2) while maintaining an excellent signal-to-noise ratio. Since it can receive only even order harmonics, however, there is significant attenuation, especially in basal myocardial segments in apical windows. Initial studies using this technique in humans have demonstrated brilliant myocardial opacification from very small bolus injections of intravenous Optison.[25,26]

Power modulation is another technique that improves the signal-to-noise ratio at very low MIs. This technique, developed by Philips (Andover, Mass.), is also a multipulse cancellation technique, only here the power of each pulse is varied. The low-power pulses create a linear response, whereas the slightly higher power pulse results in a linear response from tissue but a nonlinear response from bubbles. The linear responses from the two different pulses (the amplified low-power pulse and the slightly higher power pulse) can be subtracted from each other. The transducer then sees only the nonlinear behavior, which emanates exclusively from the microbubbles. Both pulse inversion Doppler and power modulation can be used at very low MIs to assess myocardial contrast in real time with excellent spatial resolution at higher bandwidths.

Contrast pulse sequencing (Siemens Acuson Sequoia; Mountain View, Calif.) extends these multipulse techniques by interpulse phase and amplitude modulation.[27] An example of the excellent myocardial tissue rejection and increased microbubble signal intensity with contrast pulse sequencing in a normal

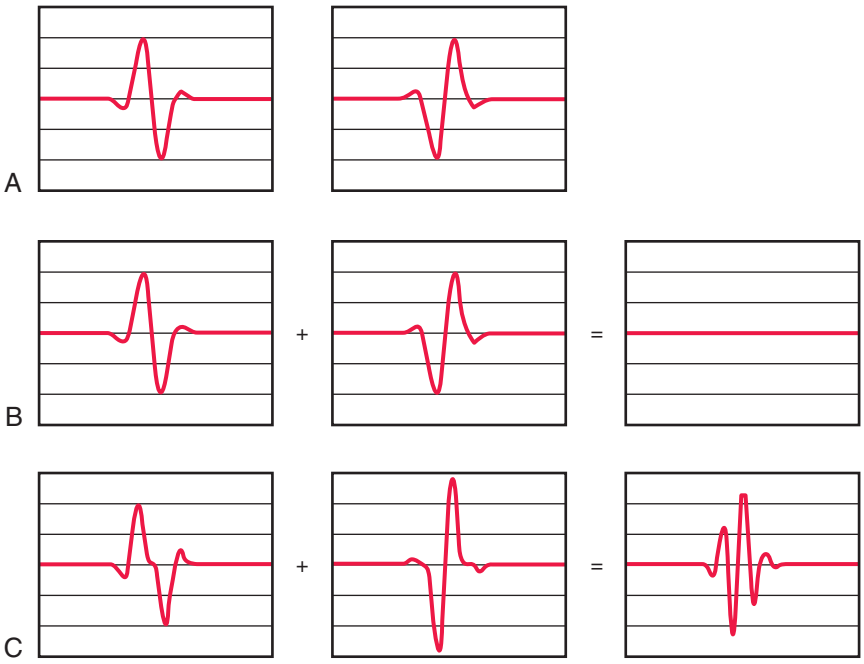

**Figure 3-3 How pulse inversion is used to suppress nonlinear responses from tissue and elicit nonlinear responses from microbubbles.** Pulses of alternating polarity (**A**), when transmitted to tissue, will cancel each other out with the summed response shown in **B**. However, because microbubbles respond nonlinearly to these pulses of alternating polarity, there is actually a nonlinear response (**C**) at twice the transmitted frequency. *(With permission from Rafter P, Phillips P, Vannan MA: Imaging technologies and techniques.* Cardiol Clin *22:181-197, 2004.)*

patient from the apical four-chamber view is displayed in Figure 3-4. Table 3-2 summarizes the various perfusion imaging techniques and lists their advantages and disadvantages.

## Qualitative and Quantitative Methods of Analysis

Regardless of the route of microbubble injection, an accurate definition of microbubble concentration in the myocardium requires that the relationship between concentration and signal intensity be linear. This precondition is fulfilled at low intramyocardial microbubble concentrations; with an increase of the concentration, however, echocardiographic systems normally reach a saturation point, where videointensity is no longer proportional to the microbubble concentration.[28] This becomes a factor with bolus injections of microbubbles, in which transient high concentrations can be reached even in regions with reduced myocardial blood flow, leading to a brief period during which contrast enhancement falsely appears normal in these regions. It is not until microbubble concentration falls during the washout period that differences in microbubble concentration are visually evident. It is during this time period that there is a linear relationship between concentration and signal

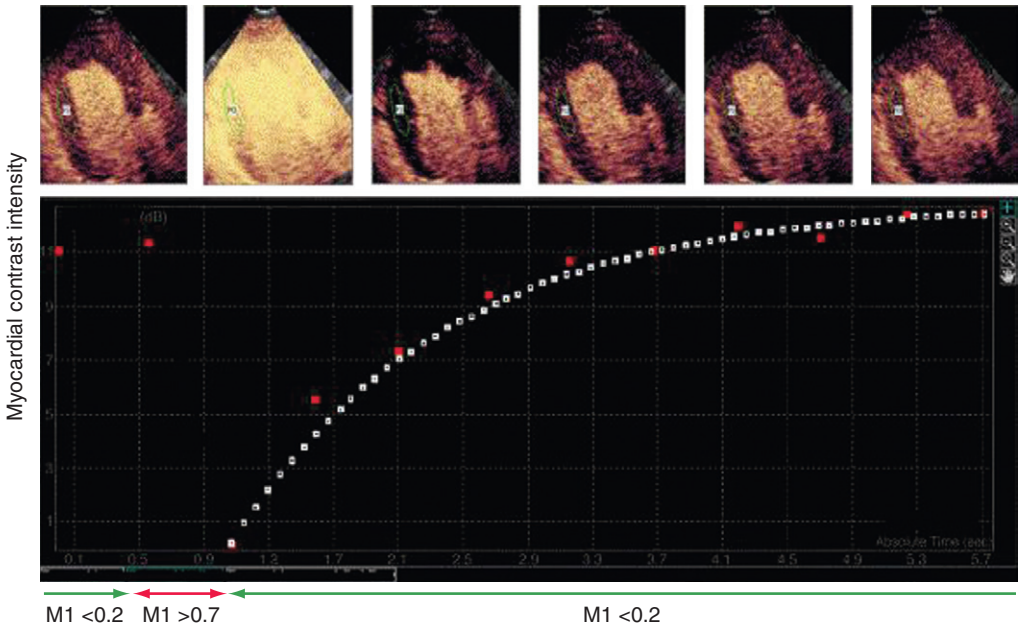

**Figure 3-5 Example of myocardial contrast replenishment.** After a high-mechanical-index (MI) impulse (depicted as the bright flash in the second apical three-chamber image in the *top* panels) the time curve of myocardial contrast intensity is shown (*bottom panel*). using a typical low-MI pulse sequence scheme. Note that after the high-MI impulse, there is replenishment of myocardial contrast while imaging at a low MI (0.2). This can be plotted and fitted to the one-exponential function. *(With permission from Rafter P, Phillips P, Vannan MA: Imaging technologies and techniques.* Cardiol Clin *22:181-197, 2004.)*

intensity. With bolus intravenous injections of microbubbles, the myocardial contrast intensity during this washout period is a reflection of myocardial blood volume. Estimates of myocardial blood flow cannot be ascertained from bolus injections, because mean transit times cannot be obtained from time intensity curves as a result of dispersion of the bolus by intrapulmonary filtering. Therefore, with intravenous injections, myocardial blood volume (peak intensity) can be estimated, but quantification of myocardial blood flow is not possible.

## CONTINUOUS INFUSION IMAGING

The difficulties arising with thresholding effect and saturation point of echocardiography systems can partly be avoided by using a continuous peripheral venous infusion for microbubbles instead of a bolus injection. This method assumes that the input of microbubbles into the myocardium is constant. The practical advantage of a continuous infusion is that attenuation artifacts due to high contrast intensity in the LV cavity can be reduced.[29,30] Moreover, the contrast dosage administered can easily be adjusted depending on the individual imaging conditions of different patients.[31]

Starting from the presumption that a true continuous venous infusion of a constant number of microbubbles can be achieved, a quantitative assessment of myocardial blood flow is possible. The ultrasound beam destroys these microbubbles when a high MI is used, so that insonation at high MIs results in almost complete bubble destruction with every pulse. Triggering ultrasound to one frame timed to end-systole in the cardiac cycle at a sequence of incrementally longer cardiac cycles allows a replenishment of contrast agent corresponding to flow to the given region during that time sequence. The longer the triggering intervals are set, the more microbubbles refill the capillaries and the higher the signal intensity to be registered in the tissue, until finally a plateau phase is reached. Alternatively, if one is imaging at low MI in real time, brief high-MI impulses can be applied to the imaging plane, following which replenishment can be visualized in real time at a low MI (Fig. 3-5). The plateau background-subtracted myocardial contrast intensity of a respective myocardial region is related to the capillary cross-sectional area. The rate at which this plateau stage is achieved (slope) is proportional to the blood flow velocity in that region. Because the peak background-subtracted myocardial videointensity is directly related to capillary cross-sectional area, the slope times peak or plateau myocardial videointensity represents a measure of myocardial blood flow.[13] Although this methodology holds much promise, incomplete destruction of microbubbles in the ultrasound field could lead to significant underestimation of myocardial blood flow abnormalities.[32] Models have been proposed and validated that correct the plateau myocardial signal intensity (which is subject to regional ultrasound beam inhomogeneities) by dividing this value by the adjacent LV cavity intensity (Fig. 3-6). The replenishment versus time curve fits a one-exponential curve function and has been useful for quantifying myocardial blood flow. The normalized plateau intensities multiplied by the rate of contrast replenishment and divided by tissue density are used to compute myocardial blood flow.[33,34] Continuous infusion techniques can be done with infusion pumps or handheld infusions. With either of the commercially available contrast agents, one can mix them at the bedside with saline and infuse them either as a continuous drip or as a handheld infusion.

## TECHNICAL EQUIPMENT, IMAGE PROCESSING, AND ARTIFACTS

Processing and analysis play a major role in the quantitative, reproducible assessment of echocardiographic myocardial perfusion. In most cases, myocardial signal intensity in one or more

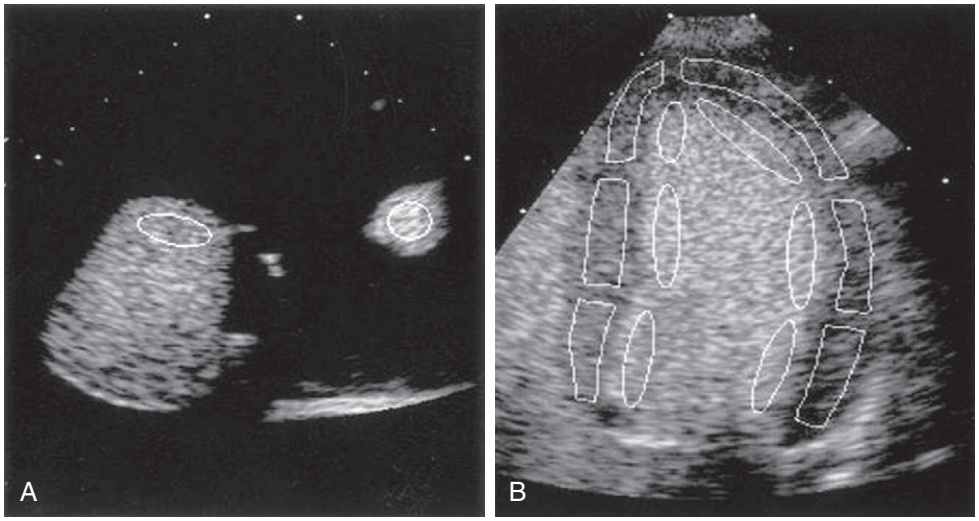

**Figure 3-6 Normalization of myocardial signal intensity for quantitation of myocardial blood flow.** Regions of interest are shown in a perfusion phantom (**A**) and normal human (**B**). Quantification of myocardial blood flow is performed by normalizing each myocardial signal intensity with the adjacent LV cavity to compensate for regional beam inhomogeneities and beam attenuation. *(With permission from Vogel R, Indermuhle A, Reinhardt J, et al: The quantification of absolute myocardial perfusion in humans by contrast echocardiography.* J Am Coll Cardiol *45:754-762, 2005.)*

regions of interest per frame is specified. The regions of interest have to be maintained in a constant position, large enough to provide the highest signal-to-noise ratio, but without including any parts of the brighter endocardial or epicardial border. The alignment, manually or by a computer algorithm, should be performed at or near end-systole, to reduce contributions from contrast in larger intramyocardial arterioles.[35] Regions of interest should also corrected by using background subtraction,[36] performed by subtracting any background intensity post high-MI impulses from contrast-enhanced pictures. If the signal intensity in the regions of interest is measured from video data, it can be displayed in a dynamic range of 256 pixels, the different values related to the pixel that contains the highest signal intensity. Because the ability of the human eye to distinguish among many shades of gray is relatively poor, color coding is a helpful tool for better detection of perfusion abnormalities.[36,37] To prevent the loss of information that comes from analyzing video images, digital intensity obtained from returning signals before postprocessing is more commonly used today. This information is unprocessed and not affected by the postprocessing functions of the imaging chain. All quantitative analyses to date have been shown to be time consuming and technically demanding.[38] Nonetheless, there is general agreement that visual analysis of myocardial perfusion data will be inadequate when quantifying myocardial contrast enhancement from venous infusions of contrast.

Commercially available ultrasound systems and digital review stations are now equipped with quantitative signal intensity systems that can measure contrast intensity as well as myocardial blood flow changes using the one-exponential function. Quantification of myocardial contrast enhancement will require that we understand what normal variations in contrast enhancement exist within different regions. Animal and human studies have demonstrated that there is a regional heterogeneity in myocardial contrast enhancement from microbubbles.[33,34,39] A recent metaanalysis of quantitative stress myocardial contrast echocardiography (MCE) has demonstrated the potential for both the rate of replenishment (beta) and the product of plateau intensity and rate of replenishment (A × beta) to detect coronary artery disease.[40]

Three-dimensional real-time perfusion concepts have been developed, which attempt to quantify myocardial blood flow changes using volumetric acquisition protocols.[41] In this setting, high-MI impulses to destroy microbubbles during continuous infusions of microbubbles cover a volume of interest (as opposed to a single imaging plane). Care must be taken with this approach to prevent LV cavity destruction, and thus maintain a constant input function. The feasibility and accuracy of this approach have yet to be determined.

## Safety of Ultrasound Contrast

In October 2007, the FDA issued a Box Warning regarding the use of Definity and Optison, stating that deaths had occurred within 30 minutes of contrast administration (http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/ucm110260.htm). The echocardiographic community was obviously concerned and perplexed with this warning, as it seemed to be inconsistent with what was observed in routine practice. To study this, several single and multicenter experiences were reported, and no such increase in mortality was observed when compared with an equivalent patient population not receiving contrast (Table 3-3). As can be seen in the table, there was no increased risk associated with contrast use in well over 100,000 patients, including patients in the intensive care setting, patients with potential acute coronary syndromes undergoing resting or stress echocardiography, or patients following acute myocardial infarction.[42-54] A rare anaphylactoid reaction may occur in response to Definity; this is estimated to occur with a frequency of 0.006%.[50] More recent publications focusing on the use of contrast within the first 24 hours of hospital admission have demonstrated that patients receiving contrast may have a reduced mortality rate compared to patients not receiving contrast, suggesting that the increased diagnostic accuracy afforded by the use of contrast may lead to earlier correct diagnoses and

subsequent reduced mortality.[48] These publications have also demonstrated the significant value that contrast has even when just being used for enhancing LV opacification, where more than 35% of patients evaluated had a change in diagnosis when contrast was added to the echocardiographic examination or a change in medications.[55]

Although diagnostic ultrasound MIs do have the potential to disrupt capillaries and induce both hemorrhage and hemolysis, these studies have still only been done in settings where minimal attenuation of the ultrasound beam exists.[56] Much larger human trials using ultrasound and contrast during stress echocardiography have confirmed no significant adverse effects occur.[54,57] High-MI impulses (MI up to 1.9) applied during dobutamine stress echocardiography (DSE) have the potential to elicit isolated ventricular premature depolarizations, but no sustained arrhythmias induced by these transient high-MI impulses from diagnostic transducers have been observed.[58]

## Clinical Applications of Contrast Enhanced Ultrasound

### DETECTING ACUTE ISCHEMIA/RISK AREA IN THE EMERGENCY SETTING

In several animal and human investigations, intracoronary ultrasound contrast injections have successfully delineated the area at risk after acute myocardial infarction, which is defined as the complete transmural extent of the perfusion bed supplied

by an occluded coronary artery.[59-61] These studies have shown that area at risk measured with intracoronary contrast is superior to clinical, electrocardiographic, hemodynamic, or angiographic data in determining actual risk area. Intravenous microbubbles encapsulating high–molecular-weight gases in combination with new imaging techniques have made the rapid noninvasive assessment of risk area possible in an acute setting. In several animal experiments, the spatial distribution of hypoperfusion after coronary artery occlusion and reperfusion has been accurately quantified with intravenous myocardial contrast echocardiography.[5,62-64] Perfusion defects delineated by ultrasound contrast have correlated with the extent of wall motion abnormality in the corresponding myocardial segment and postmortem measurements of risk area.[62] Continuous infusions of microbubbles have been employed to quantify reductions in myocardial blood flow using the destruction-replenishment techniques described previously.[14]

Resting MCE data have been used in the emergency department in a large number of patients with chest pain and nondiagnostic electrocardiograms. In patients with low or moderate clinical risk scores, myocardial perfusion assessed with intermittent high-MI ultraharmonic or harmonic power Doppler imaging provided incremental prognostic information to the clinical assessment of risk (Thrombolysis in Myocardial Infarction [TIMI] Risk Score). Patients with both abnormal regional wall motion and abnormal myocardial perfusion in these single-center studies had a significantly worse event-free survival when compared to patients with abnormal regional function but normal myocardial perfusion.[65]

## ASSESSMENT OF MYOCARDIAL VIABILITY IN THE ACUTE AND CHRONIC SETTING

Identification of patients with the "no-reflow" phenomenon has proven to be an important clinical application for myocardial contrast echocardiography. This phenomenon, described first in an animal setting by Kloner and associates[66] in 1974, is characterized by a lack of recovery in microvascular perfusion, although the occluded coronary artery is successfully reopened by percutaneous intervention or thrombolysis. Ito and co-workers[67] were the first to systematically examine myocardial microvascular perfusion with intracoronary microbubbles in patients with acute anteroseptal myocardial infarction immediately following restoration of antegrade flow in the left anterior descending artery. Using intracoronary sonicated radiographic contrast, they demonstrated that 23% of the patients had persistent contrast defects (i.e., no reflow) in the area at risk after recanalization. The long-term prognosis of these no-reflow patients was impaired, and there was significant deterioration in regional and global systolic function at follow-up. These findings have been confirmed by other investigators. Several investigators have succeeded in detecting the no-reflow phenomenon from intravenous administration of microbubbles in patients with acute myocardial infarction following revascularization. Lepper and colleagues[68] studied myocardial contrast enhancement in patients with acute infarction undergoing angioplasty immediately before and 24 hours after recanalization using intravenous perfluorocarbon-containing microbubbles and intermittent harmonic imaging. An improvement of myocardial perfusion within 24 hours after intervention was predictive of functional recovery verified at 4-week follow-up.[69] In patients undergoing primary coronary stenting, homogenous myocardial contrast enhancement within the infarct zone by continuous infusion intravenous MCE was highly predictive of regional recovery of function.[70] Restoration of microvascular perfusion was most likely to occur if patients demonstrated at least partial perfusion to the risk area before primary stenting. In recent comparative studies between nitroglycerin-enhanced SPECT and MCE, the assessment of myocardial viability by MCE was superior to that by SPECT in predicting patient outcome.[71] Multicenter studies have recently demonstrated that the extent of microvascular damage, assessed on day 1 following reperfusion therapy in acute myocardial infarction, is the most powerful independent predictor of whether LV remodeling will occur.[72] Furthermore, MCE performed during dipyridamole infusion 1 week after acute myocardial infarction in patients receiving primary fibrinolytic therapy has been shown to be useful in both detecting a significant residual stenosis within the infarct vessel and predicting when multivessel coronary disease is present.[73]

Visualization of collateral myocardial blood flow to the risk area before and after revascularization following acute myocardial infarction has been demonstrated with intracoronary contrast. In patients with occluded vessels, injection of ultrasonographic contrast material into adjacent coronary arteries can produce myocardial contrast enhancement in the perfusion bed subtended by the occluded vessel.[74,75] This phenomenon is clinically relevant because it indicates viability of the perfusion bed subtended by the occluded coronary artery.[76] Sabia and associates[77] demonstrated that revascularization of an occluded coronary artery after myocardial infarction resulted in improved function only when myocardial contrast enhancement was observed following ultrasound contrast injection into the opposite coronary artery.[78] The spatial extent of collateral blood flow as defined by contrast echocardiography correlated closely with improvement in regional function within the infarct zone. Table 3-4 summarizes the clinical studies performed evaluating the ability of MCE to detect myocardial viability, both in the post–myocardial infarction setting and in the evaluation for hibernating myocardium.

In patients with chronic coronary artery disease and LV dysfunction, both the visual and quantitative assessment of MCE during a continuous infusion of intravenous microbubbles has provided significant independent data on the effects of revascularization to that segment, exceeding that which can be obtained with radionuclide imaging.[79] In this setting, the product of the slope of myocardial replenishment and plateau myocardial contrast intensity (an index of myocardial blood flow) in dysfunctional segments correlated with contractile reserve by low-dose dobutamine, as well as greater than 60% thallium uptake with radionuclide SPECT. More importantly, this index of myocardial blood flow by MCE was able to identify viable myocardium in segments that did not exhibit contractile reserve by DSE.[80] However, these studies have all had small patient numbers and have yet to be verified in multicenter studies.

## DETECTION OF CORONARY ARTERY DISEASE

### *With Vasodilator Stress Perfusion Imaging*

Until the past few years, radionuclide scintigraphy has been the diagnostic tool to address myocardial perfusion during stress testing. This method, especially when performed with $^{99m}$Tc rather than $^{201}$Tl, provides high sensitivity in identifying patients with coronary artery disease. It is limited, however, by poor spatial resolution and frequent attenuation artifacts. With

intravenous perfluorocarbon contrast agents and nonlinear ultrasonographic techniques, detection of underperfused myocardial segments during stress echocardiography has become feasible. Initial studies deployed intermittent harmonic or power Doppler imaging techniques to detect coronary stenoses during vasodilator stress.[23,81] Real-time perfusion and other lower MI imaging techniques have been applied to vasodilator stress as well. Multicenter studies comparing MCE with radionuclide SPECT during dipyridamole stress have demonstrated a similar sensitivity and specificity between the two techniques, regardless of stenosis severity.[82,83] Prognostically, real-time perfusion during dipyridamole stress has been shown to be superior to SPECT in predicting patient outcome.[84]

Both adenosine and the selective A2A receptor antagonist regadenoson have been used as vasodilator stress agents with real-time perfusion imaging and have demonstrated excellent sensitivity and specificity for detection of coronary artery disease.[85,86] Regadenoson has the advantage that it can be given as a 400-mcg bolus, with immediate real-time perfusion imaging, resulting in a 10-minute stress test. An example of an inducible perfusion defect following a regadenoson bolus injection is demonstrated in Figure 3-7. More recently, adenosine stress real-time perfusion has been compared with 3-tesla cardiac magnetic resonance imaging as a reference standard for the detection of functionally significant coronary artery disease. It was found to have sensitivity of 85% and specificity 74%.[87] Table 3-5 summarizes all recent studies using vasodilator stress MCE to detect coronary artery disease and predict patient outcome.

### *During Dobutamine or Exercise Stress Echocardiography*

Real-time perfusion techniques have been used to detect coronary stenoses during exercise and DSE. In predominately single-center studies, real-time perfusion echocardiography has been shown to increase the sensitivity of the dobutamine stress test

when compared to wall motion analysis[88,89] and to improve the ability of the test to predict death or nonfatal myocardial infarction.[90] Lonnebaken and co-workers[91] has also shown the value of dobutamine-induced perfusion abnormalities at intermediate stress levels in detecting coronary artery disease. The improved detection of coronary artery disease with real-time perfusion over conventional stress echocardiography appears to be due to the induction of perfusion defects in the absence of wall motion abnormalities, but also to the ability of real-time perfusion to delineate subendocardial wall thickening abnormalities that were detectable only because of the coexistent perfusion defect.[92] Examples of inducible perfusion defects within single vessel territories (the left anterior descending and left circumflex) are displayed in Figures 3-8 and 3-9, whereas a multivessel inducible perfusion defect is displayed in Figure 3-10.

Clinical studies have also demonstrated the incremental value of myocardial perfusion assessment using low-MI imaging during exercise testing.[93] Similar to dobutamine stress, the improved detection appears to be related to the ability of real-time perfusion to detect subendocardial ischemia.[94] Prognostically, the addition of perfusion analysis to wall motion during supine bicycle stress has enhanced the power of the test to predict cardiac events.[95] Table 3-6 lists the clinical studies that have been performed in the previous 5 years examining the sensitivity and specificity of MCE in detecting coronary artery disease during dobutamine and exercise stress echocardiography.[8,54,73,93,96-105]

### *Artifacts in Myocardial Perfusion Assessments*

One must be able to differentiate potential artifacts that create the appearance of perfusion defects. The most comment artifact is that due to attenuation. This typically occurs in basal segments and is differentiated from true defects by its location. Attenuation typically masks not only the myocardium but adjacent epicardial and endocardial borders as well. Attenuation is usually present both at rest and during stress, whereas inducible defects are present only during stress and typically involve just the subendocardium. Other potential artifacts are lung shadows, which will often mask an entire region (e.g., the anterior wall in the apical two-chamber view). This can be overcome by purposefully foreshortening these views, cutting out the apex but permitting better delineation of contrast replenishment within the basal to mid segments (Fig. 3-11). A third location where artifacts tend to occur is in the apical region. If the near-field gains (time gain compensation) are set too low, the apex will appear hypoperfused (Fig. 3-12, *A*). Unlike true defects, this can be corrected by increasing the near-field potentiometers (Fig. 3-12, *B*). One must be sure under resting conditions and in the presence of normal wall motion that apical contrast enhancement is similar to basal and mid segments (using adjustment of near-field gain settings) and that the myocardial contrast disappearance is observed after a high-MI impulse so that replenishment can be visualized. Near-field destruction of microbubbles can also cause the false appearance of perfusion defects in the apex. This can be corrected by moving the focus

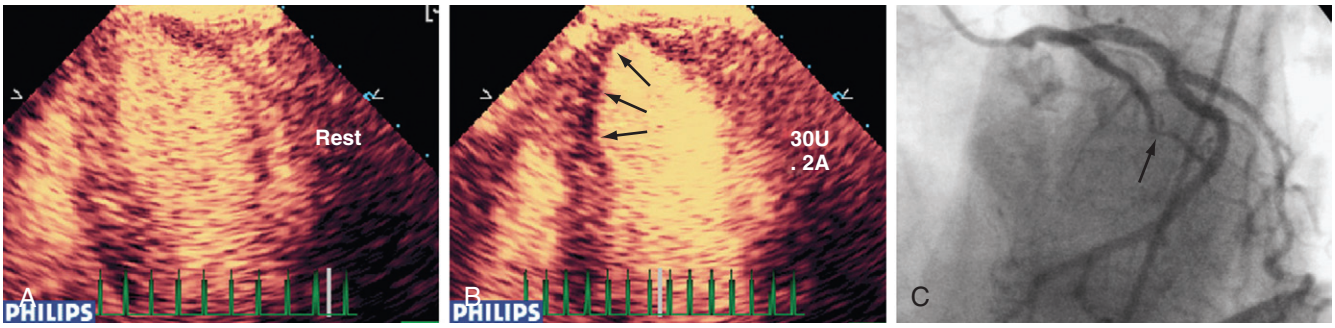

**Figure 3-8 Inducible septal and apical perfusion defect during DSE using real-time contrast echocardiography.** In the apical four-chamber view, resting images (*left*) show normal wall motion and myocardial perfusion. With dobutamine (*center*, 30 mcg/kg per minute plus atropine 0.2 mg), akinesis, and decreased myocardial perfusion of the apical septum is seen (*arrows*). Coronary angiography showed severe stenosis (*arrow*) in the left anterior descending coronary artery.

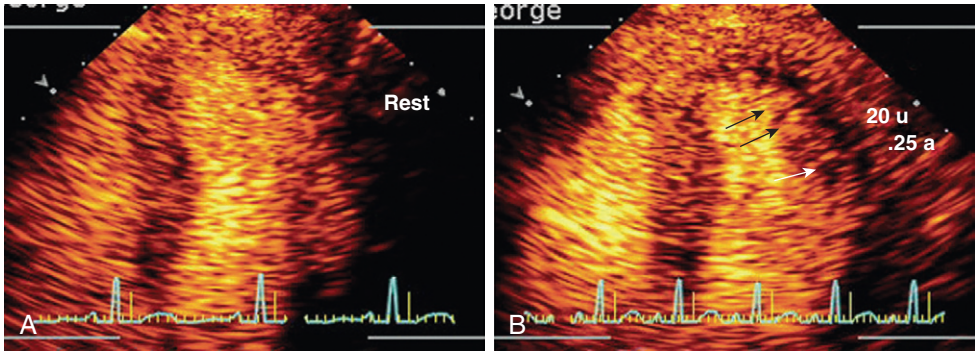

**Figure 3-9 Lateral wall perfusion defect detected with real-time contrast echocardiography during DSE.** Resting images in a four-chamber view (*left*) show normal myocardial perfusion, but with stress (*right*) decreased perfusion in the lateral wall is seen (*arrows*).

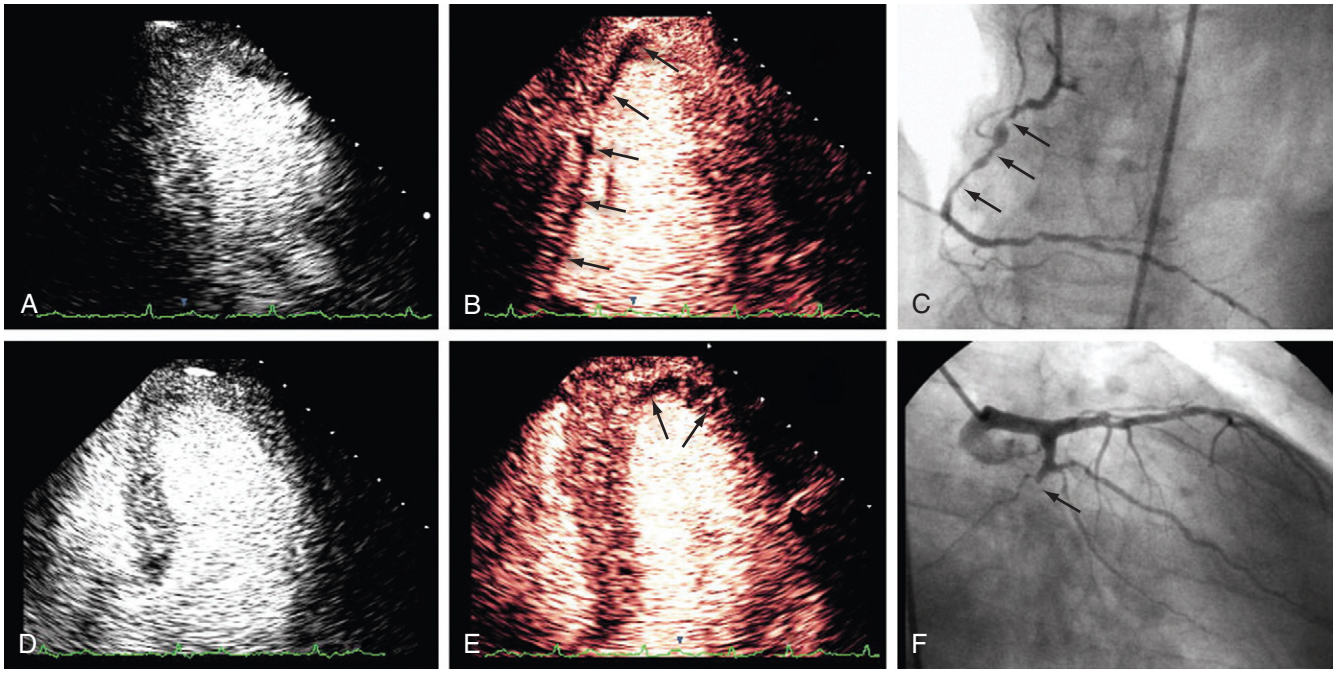

**Figure 3-10 Multivessel pattern of inducible perfusion defect during DSE in which subendocardial defects are seen in multiple coronary artery territories.** At rest, the apical long-axis (**A**) and four-chamber (**D**) views show normal wall motion and myocardial perfusion. With stress, the same views show reduced myocardial perfusion (arrows) in the inferior (**B**) and lateral apical (**E**) walls. Coronary angiography shows right coronary (**C**) and left circumflex (**F**) disease corresponding to the contrast stress study results.

to the near field, which decreases the scan-line density in this region and reduces destruction.

### *Real-Time Myocardial Contrast Echocardiography in Specific Clinical Scenarios*

Patients with left bundle branch block and pacemaker-dependent patients represent clinical scenarios which both the assessment of wall thickening and conventional myocardial perfusion imaging with radionuclide SPECT are not helpful in the detection of coronary artery disease.[106] In these patients, there are difficulties with interpretation of wall thickening in the septum (in left bundle branch block) or, in pacemaker-dependent patients, in the septum and entire apex. In patients with left bundle branch block, perfusion defects in the interventricular septum are seen on radionuclide SPECT despite normal myocardial blood flow with real-time perfusion and no significant coronary artery disease by angiography. The reason for this appears to be the partial volume effect, as the false-positive perfusion defects seen with radionuclide SPECT had a normal perfusion appearance with higher resolution real-time MCE and were independently associated with smaller septal systolic wall thickness measurements.[106] Similar wall thickness abnormalities encompassing a larger territory (the septum and apex) are seen in pacemaker-dependent patients. An example of normal perfusion despite septal and apical hypokinesis and wall thinning due to chronic right ventricular pacing is shown in Figure 3-13.

### *Large Arteriolar Contrast Imaging*

If a higher MI is used in real time, microbubbles within capillaries are destroyed, but those transiting faster through larger arterioles (greater than 300 μm) can still be visualized. These larger arterioles are not involved with autoregulation, and their contrast intensity exhibits a predominately diastolic component under normal conditions. As the smaller arterioles (150 to 300 μm) involved with autoregulation dilate in response to a coronary stenosis, a correspondingly greater concentration of microbubbles from these arterioles is injected retrograde into the larger arterioles during systole. Wei and colleagues[35,107] have demonstrated that this increase in systolic contrast intensity (or increase in the systolic-to-diastolic signal ratio) from these larger arterioles can detect when significant stenoses are present in the left anterior descending artery under resting conditions.

## Other Diagnostic Applications of Microbubbles

### IMPROVED LEFT VENTRICULAR CAVITY OPACIFICATION

The only currently approved indication for the use of ultrasound contrast is to improve LV opacification. Several different intravenous ultrasound contrast agents have demonstrated their ability to improve the diagnostic value of echocardiographic examinations in patients with suboptimal imaging

conditions. In routine ultrasonographic examinations of patients with poor echocardiographic windows, contrast enhancement of the LV cavity provides better delineation of the endocardial border. Clinically, this could give information regarding regional and global systolic function that could not be assessed with routine echocardiography. Tissue harmonic imaging by itself has significantly improved endocardial border definition, often eliminating the need for intravenous ultrasonographic contrast agents filled with room air.[108] During the past few years, however, studies have shown that intravenous perfluorocarbon-containing microbubbles, because of their consistent LV opacification, have improved border definition in the LV of patients with suboptimal tissue harmonic images. Although the use of contrast may increase the costs for routine transthoracic echocardiograms, substantial cost savings could still be achieved in the examination of patients with poor baseline harmonic image quality because contrast would eliminate the need for additional diagnostic studies in these situations.[109] Indeed, recent clinical studies have shown that if contrast were used for suboptimal windows, downstream testing would be reduced by 33%, resulting in an average cost savings of $122 per patient.[55]

Reilly and co-workers[110] studied the effect of intravenous Optison injections in harmonic transthoracic echocardiography in the intensive care unit. Their results indicated a significant increase in interpreter confidence in evaluating myocardial segments that could not be analyzed without contrast application. Furthermore, the ability to estimate LV ejection fraction was clearly improved with Optison. Kurt and associates[55] recently demonstrated that significant changes in patient management occurred when contrast was used in intensive care unit patients, and Main and colleagues[48] discovered that acutely hospitalized patients receiving contrast to enhance LV opacification had 24% lower mortality than patients not receiving contrast. Malhotra and co-workers[111] compared stress echocardiograms performed with both fundamental and harmonic imaging modalities with and without intravenous Optison contrast in 200 patients. They reported that the combination of harmonic ultrasonography with Optison resulted in the most consistent endocardial border delineation, which significantly exceeded the quality of either fundamental contrast imaging or tissue harmonic imaging alone. Interobserver agreement with Optison and harmonic imaging in this study was 95%. A recent multicenter study compared the reproducibility and accuracy of contrast-enhanced cardiac magnetic resonance imaging, contrast-enhanced and unenhanced echocardiography, and cineventriculography in quantifying ejection fraction using biplane methods. The echocardiographic settings for contrast-enhanced imaging were an MI of 0.3, gain settings of 60%, and compression of 15% (Sonos 5500; Philips, Andover, Mass.). These studies demonstrated that the most reproducible method (lowest intraclass coefficient) for quantifying ejection fraction was contrast-enhanced echocardiography.[112] Contrast-enhanced echocardiography also had the highest interobserver agreement for analyzing regional wall motion.[113]

Contrast-induced homogeneous opacification of the LV cavity could also assist physicians in detecting LV thrombi or tumors[114,115] and complications of acute myocardial infarction such as myocardial rupture and LV pseudoaneurysm.[116] This technique has also been used during transesophageal echocardiography to delineate false and true lumen in patients with aortic dissection.[117] Using a continuous infusion of microbubbles, one can examine the replenishment patterns of contrast within cardiac masses following high-MI impulses to differentiate among malignant tumors, stromal tumors, and thrombi.[118]

## DOPPLER ENHANCEMENT

Intravenous microbubbles affect Doppler recordings because the scatter from them is much greater than from red blood cells. Microbubbles therefore can markedly increase the signal strength in a Doppler examination, which may be helpful in patients with suboptimal imaging quality. Von Bibra and associates[119] described a significant enhancement of spectral and color Doppler and an increase in the signal-to-noise ratio in the quantitative assessment of aortic stenosis, pulmonary venous flow, and mitral regurgitation by intravenous injection of Levovist. Transthoracic pulmonary venous flow velocities have been improved by intravenous contrast enhancement to the point that they are comparable to those obtained with transesophageal imaging.[120] Moreover, intravenous microbubble ultrasound contrast was successful in providing a clear spectral signal across stenotic aortic valves in cases in which the echocardiogram would have been nondiagnostic without contrast enhancement.[121] The gradients determined using contrast-enhanced Doppler signals correlated well with catheterization calculations.[121] Okura and colleagues[122] studied the effect of Albunex in 45 patients with prosthetic aortic valves. They found a significant improvement in transvalvular continuous-wave Doppler signal intensity with intravenous Albunex, increasing the frequency of satisfactory Doppler signals from 64% to 93% of patients. More recently, Jeon and co-workers[123] have demonstrated that a 10% air, 10% blood, 80% saline hand-agitated mixture is more optimal than the traditional agitated air-saline mixture in Doppler enhancement of the tricuspid regurgitant jet. They found that brief premixture of the patient's own blood with air and saline produces greater concentrations of small microbubbles, which improved the accuracy of the pulmonary artery pressure measurement.

## CONTRAST PERFUSION IMAGING OF OTHER ORGANS

The replenishment curves following microbubble destruction that have been used to detect myocardial blood flow changes can be applied to solid organs as well. The time versus acoustic intensity curve following ultrasound-mediated destruction of microbubbles has been validated as a method of measuring blood flow changes within the cerebral microcirculation.[124] This has been applied in traumatic brain injury to document the beneficial effect of early decompressive surgery on cerebral microvascular blood flow.[125] Contrast-enhanced ultrasound has also been shown to accurately quantify renal cortical blood flow changes in response to flow-limiting stenoses or during dopamine infusion.[126]

Quantitative measurements with contrast-enhanced ultrasound in skeletal muscle have also been used to demonstrate that physiologic increases in insulin alter microvascular blood volume without altering muscle blood flow.[127] Womack and colleagues[128] used high-resolution contrast-enhanced ultrasound to examine forearm skeletal muscle capillary blood flow responses to hand grip exercise in diabetic patients. A defective capillary blood volume response was observed almost exclusively in the diabetic patients who had developed microvascular disease. Unlike microvascular complications, however, this

defective capillary response was unrelated to the duration of disease. This indicates a potential role for defective capillary blood flow responses in the pathogenesis of microvascular complications in diabetes.

### MOLECULAR IMAGING WITH CONTRAST ULTRASOUND

Several potential applications for attaching ligands to the microbubble shell (polymer, albumin, or lipid) exist. Ligands include monoclonal antibodies, peptides, and glycoproteins,[129] which are typically conjugated to the microbubble shell in a manner that attaches them to a molecular spacer that projects the ligand away from the shell surface.

Lindner and associates[130] hypothesized that during the early inflammatory response after reperfusion, activated leukocytes adherent to the venular endothelial surface may bind microbubbles and therefore may be responsible for their prolonged transit. Using tumor necrosis factor-α injection in an animal setting, they showed that both lipid and albumin microbubbles attach to activated leukocytes. The binding of the albumin microbubbles was mediated by $\beta_2$-integrins, whereas the interaction between leukocytes and lipid microbubbles involved the complement pathway.[130] In a subsequent investigation, the leukocytes involved were identified to be mostly neutrophils and monocytes. Both lipid and albumin microbubbles were phagocytosed by these cells, remained acoustically active for up to 30 minutes, and could be detected in vivo after microbubbles from the blood pool had already vanished.[131]

Microbubbles also can be conjugated with disintegrins, which serves to target the microbubbles to $\alpha_v$ integrins that are expressed on neovascular endothelium.[132] Unlike unlabeled microbubbles that pass freely through the microcirculation, these microbubbles are retained within regions of increased arteriogenesis that occur in response to prolonged hindlimb ischemia.[133] The arteriogenic effects of certain agents, such as fibroblast growth factor-2, used to treat ischemic regions can therefore be assessed noninvasively by measuring signal intensity following intravenous injections of microbubbles targeted to $\alpha_v$ integrins. Similarly, phosphatidylserine has been incorporated into the shells of microbubbles to increase complement-mediated avidity to activated leukocytes. These microbubbles have been shown to be retained within reperfused myocardium, and the signal intensity derived from these microbubbles correlates closely with the severity and extent of postischemic inflammation.[134] The retained signal intensity from microbubbles targeted to activated leukocytes or to upregulated leukocyte adhesion molecules on the endothelial surface has also been used in animal studies to detect rejection following cardiac transplantation.[135,136] Microbubbles targeted to both $\alpha_v\beta_3$ integrins and activated leukocytes have been used to assess the effects of agents that inhibit endothelial integrin and platelet glycoprotein IIb/IIIa receptors in reducing myocardial infarct size.[137]

Microbubble targeting imaging has the potential to image myocardial regions where there has been remote ischemia. P-selectin is externalized by endothelium within minutes of ischemic territories and persists for up to hours. Therefore, it can be detected by microbubbles targeted to P-selectin, and preclinical studies have demonstrated ultrasound contrast retention within recently ischemic myocardium of rats and mice.[138,139] In the setting of heart transplant rejection, microbubbles targeted to intracellular adhesion molecules (e.g., ICAM-1) have been used to detect endothelial activation within the myocardium.[140] Detection of inflammatory plaque has also recently been demonstrated with contrast-enhanced ultrasound. Targeted microbubbles have demonstrated vascular endothelial adhesion molecule (VCAM-1) upregulation in apolipoprotein-deficient mice with differing degrees of plaque inflammation.[141] Early detection of plaque in animal models has been shown with microbubbles targeted to VCAM-1 and P-selectin.[142] One question that remains is whether the sensitivity of current surface ultrasound systems will be able to detect retained microbubbles in larger animal models and humans. Retention fractions need to be improved, which may require that microbubbles be targeted to multiple ligands.

### DETECTION OF CAROTID ARTERY ATHEROSCLEROSIS

Contrast-enhanced ultrasound has been used in two particular areas of carotid imaging. First, it has been used to better define intimal medial thickness as well as severity of plaque stenosis.[143] More importantly, contrast-enhanced ultrasound has been used to detect the adventitial vasa vasorum and intraplaque neovascularization.[144] The presence and extent of vasa vasorum–derived intraplaque neovascularization has recently been correlated with plaque stability and clinical cardiovascular outcome, indicating the potential for the assessment of carotid plaque neovascularity to identify the vulnerable patient.[145]

## Therapeutic Applications of Ultrasound and Microbubbles

A number of studies indicate that ultrasound-mediated microbubble destruction may also be used for therapeutic purposes. These applications include targeted drug and gene delivery, stimulation of arteriogenesis, and thrombus dissolution.

### DRUG AND GENE DELIVERY

The fact that microbubbles are destroyed by the ultrasound beam has led to the study of their potential role in depositing conjugated drugs or genes to an "ultrasound-targeted" organ.[146] Skyba and co-workers[147] studied the intravascular destruction of perfluorocarbon-containing microbubbles and the bioeffects of this process in the isolated spinotrapezius muscle of rats. With just one frame of ultrasound from a diagnostic ultrasound transducer (2.3 MHz at 1.1 MI), microbubble destruction was observed that caused local microvessel rupture. When the bubbles were mixed with colloidal particles, these particles were "microinjected" into the interstitial space. The degree of microbubble destruction and resulting "drug delivery" was directly related to the MI used.[148] Before these observations, it was demonstrated that large quantities of synthetic DNA, in the form of antisense oligonucleotides, adhere to perfluorocarbon-exposed sonicated dextrose albumin microbubbles.[149] These antisense oligonucleotides are synthetic gene products that can be used to inhibit the translation of messenger RNA into proteins and enzymes that regulate pathologic processes such as neointimal hyperplasia following vascular injury. In these studies, external diagnostic ultrasound released the synthetic antisense into the insonified kidney if the antisense oligonucleotide was given intravenously bound to microbubbles. Subsequently, it was shown that recombinant adenovirus containing β-galactosidase

could be conjugated to the surface of intravenously injected perfluorocarbon-containing albumin microbubbles and successfully targeted to the myocardium of rats by diagnostic ultrasound at a high MI (1.5). Postmortem analysis showed β-galactosidase transgene expression in the myocardium after ultrasound antigen delivery, but no expression of the transgene in the control groups that had received microbubbles alone, virus alone, or virus plus ultrasound.[150] Targeted intramyocardial gene delivery has also been reported in vivo with lipid-encapsulated microbubbles.[151] The simultaneous imaging of microbubbles appears to be important in targeted delivery, in that the highest quantity of delivered agent occurs when high-MI delivery impulses are applied only when maximal signal intensity from the microbubbles within the region of interest is present[152] (Fig. 3-14). Current diagnostic transducers are equipped with the ability to switch from sensitive low-MI pulse sequence schemes, which image the microbubbles, to high-MI impulses that destroy drug-carrying microbubbles. Low-frequency, high-MI impulses have been shown to create transient, temporary micropores in the endothelial cells.[153] This has led to the observation of "microinjections" of drugs conjugated to the microbubbles into the subendothelial spaces, even across the blood-brain barrier with transcranial ultrasound.[154] Ultrastructural observations following ultrasound-mediated destruction of microbubbles in the brain has demonstrated increased numbers of intracytoplasmic vacuoles within the brain capillary endothelium following ultrasound-mediated destruction of circulating intracerebral microbubbles.[155] Low-MI pulse sequence schemes, therefore, have the advantage of guiding when to apply high-MI impulses, and thus could significantly reduce unwanted bioeffects of hemorrhage or permanent endothelial injury. Most of these therapeutic effects of diagnostic ultrasound transducers are at peak negative pressures and pulse durations that fall within current FDA guidelines.[156]

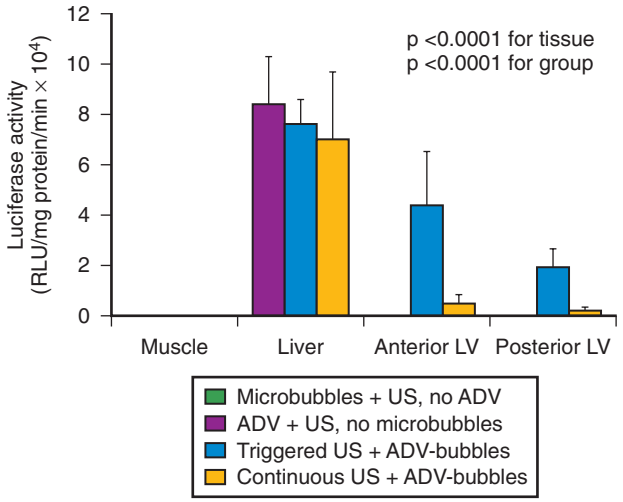

**Figure 3-14 Luciferase activity in the anterior and posterior myocardium following intravenous microbubble injections that are conjugated with the adenovirus (ADV) encoding the luciferase gene.** When diagnostic ultrasound (US) application is in a continuous mode (*yellow bars*), there is minimal deposition of the gene into the myocardium. However, when US is delivered only when a maximum quantity of microbubbles is present (triggered US; *blue bars*), there is a significant increase in gene transfer. The liver uptake is maximal (*purple bar*) when the ADV is administered without microbubbles. Activity is so low with microbubbles but no ADV (absent green bars) that no signal is detected. *(With permission from Chen S, Shohet RV, Bekeredjian R, et al: Optimization of ultrasound parameters for cardiac gene delivery of adenoviral or plasmid deoxyribonucleic acid by ultrasound-targeted microbubble destruction.* J Am Coll Cardiol *42:301-308, 2003.)*

Targeted delivery of genes has been explored as a method to cure type 1 diabetes. Recent work by Chai and associates[157] has demonstrated that a modified rat insulin promoter gene can be specifically delivered to beta cells in the pancreas using guided high-MI impulses from a diagnostic transducer. Specifically, using image-guided diagnostic ultrasound targeted destruction, these investigators have shown that plasmids containing a modified rat insulin promoter (termed RIP 3.1) are more effective than the full-length rat insulin promoter or a cytomegalovirus promoter in delivering the insulin gene to beta and alpha cells of the pancreas. Another area where guided ultrasound targeted microbubble destruction may be effective is in transiently altering blood-brain barrier permeability. Transcranial ultrasound and intravenous microbubbles have been used in mice to target delivery of antibodies directed against the amyloid-beta peptide and specifically remove the amyloid-beta plaques that are considered pathogenetic in Alzheimer disease.[158]

## THROMBOLYSIS

Several investigators have examined the potential of high-energy ultrasound alone to dissolve thrombi in vitro as well as in an animal setting. Transcatheter ultrasound has been shown to reduce thrombus weight and possibly recanalize occluded femoral arteries.[159] Because this process involves cavitation, more recent investigations have focused on whether microbubbles could potentiate this phenomenon. When combined with intravenous perfluorocarbon microbubbles, low-intensity, high-frequency ultrasound significantly increased the thrombolytic effect of urokinase in vitro. Even more importantly, ultrasound plus perfluorocarbon-containing microbubbles (PESDA) alone proved to be equivalent to urokinase in degree of thrombus dissolution. Therefore, it appeared that ultrasound and microbubbles could produce a localized clot lysis similar to a fibrinolytic agent without a systemic lytic state.[160] To demonstrate the potential for this in vivo, acutely thrombosed iliofemoral arteries in 10 rabbits received transcutaneous ultrasound treatment on one side and no ultrasound treatment on the other following intravenous PESDA injections. After ultrasound treatment, all arteries that had received PESDA and ultrasound were recanalized by angiography, but none of the arteries treated with PESDA alone were patent. Ultrasound alone also was unable to recanalize any of the thrombosed vessels.[161]

More recent work has focused on the potential clinical applications of using ultrasound and intravenous microbubbles to recanalize acutely thrombosed arteriovenous grafts, as well as restoring flow in acute intracoronary or intracerebral thrombi.[162-164] Effectiveness may be reduced in the setting of attenuation, but recanalization may still be feasible if platelet targeted microbubbles are used (Fig. 3-15). In a porcine model, the use of guided high-MI impulses from a diagnostic transthoracic ultrasound transducer and both nontargeted and platelet-targeted microbubbles in acute ST segment elevation myocardial infarction improved microvascular recovery and regional wall thickening independent of whether epicardial recanalization occurred.[165] The mechanism for improved microvascular flow in the absence of epicardial recanalization may be related to nitric-oxide–mediated stimulation of collateral flow.[166]

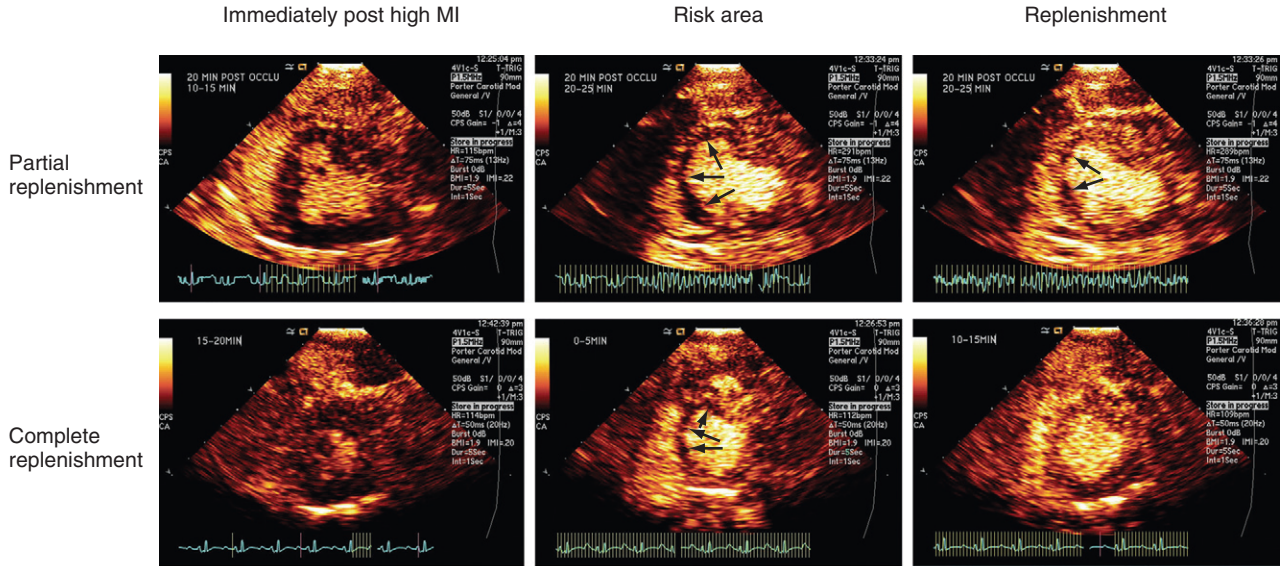

**Figure 3-15** Microvascular flow within the risk area improves following acute left anterior descending artery thrombotic occlusion, when the risk area is treated with a continuous infusion of platelet-targeted microbubbles and guided high-mechanical-index impulses from a diagnostic transducer. Improvements in microvascular flow and regional function were observed even in the absence of epicardial recanalization. *(With permission from Xie F, Lof J, Matsunaga T, et al: Diagnostic ultrasound combined with glycoprotein IIb/IIIa-targeted microbubbles improves microvascular recovery after acute coronary thrombotic occlusions.* Circulation *119:1378-1385, 2009.)*

## KEY POINTS

- Ultrasound contrast agents are produced by electromechanical sonification or as lipid-encapsulated microbubbles.
- High-MI MCE uses intermittent ranging.
- Low-MI MCE uses pulse inversion or power modulation.
- Contrast agents may be given as bolus injections or as a continuous infusion.
- Myocardial contrast imaging can be evaluated in a qualitative or quantitative manner.
- Contrast echocardiographic evaluation of myocardial ischemia has been used to detect acute coronary syndromes.
- MCE can be used to detect myocardial viability.
- MCE demonstrates areas of inducible ischemia during stress testing.
- Intravenous contrast echocardiography also can be used to detect blood flow in other organs and in tumors.
- Thrombolysis and targeted drug delivery may be possible in the future using microbubbles and ultrasound.

Left Ventricular Volume and Function
Left Ventricular Mass
Right Ventricular Volume
Atrial Volume
Valvular Heart Disease
Congenital Heart Disease
Guidance of Intracardiac Catheter-Based Interventions
Other Selected Applications
**Technology Diffusion**
**Future Considerations**
**Summary**

For a full understanding of cardiac structures, the user of two-dimensional (2D) echocardiography must be able to mentally integrate a series of these views in order to understand the three-dimensional (3D) structure of the heart and the spatial relations between its components. For example, when performing 2D echocardiography on a patient with prolapse of a portion of the posterior mitral valve leaflet, the echocardiographer individually examines each portion of the valve from a series of 2D images and mentally reconstructs the entire valve to determine which portion of the valve is prolapsing. To accurately perform this task, one must know the precise relationship of each 2D image to the others. In addition, when quantifying cardiac chamber volumes, mass, or function with 2D echocardiography, one relies on assumptions about the geometry of the chamber to apply specific formulas for calculation of these and other parameters. As chambers become distorted in shape, the geometric assumptions about shape become less accurate, as do the calculated values using these formulas.

3D echocardiography from both transthoracic (TTE) and transesophageal (TEE) approaches eliminates the need for cognitive 3D reconstruction of image planes and the need to use geometric assumptions about shape of structures for cardiac quantitation (Fig. 4-1). This is particularly applicable to complex shapes, such as the right ventricle, an aneurysmal left ventricle, an asymmetrically stenotic or regurgitant valve orifice, eccentrically directed regurgitant jets assessed by color Doppler, valve annuli, and the complex structural relationships observed in congenital heart lesions. The 3D echocardiographic technique has the potential to decrease the time required for complete image acquisition of the heart. Also, the 3D echocardiogram can be viewed from various projections by rotation of the images, and thus an improved appreciation of the relationships between various cardiac structures can be obtained.

Advances in transducer technology and image processing power have helped improve 3D echocardiography acquisition, display, and image quality. Whereas initial 3D echocardiography required transducer locating systems and labor-intensive offline reconstruction, current approaches enable 3D ultrasound (US) imaging in real time.

## Technical Considerations

The 3D US data set can be acquired either (1) as a series of 2D images and then reconstructed into a 3D image (reconstruction technique) or (2) as a 3D volume of US data (volumetric technique). The earliest 3D echocardiograms were obtained using the reconstruction technique[1,2] and required that the precise location and timing of the each image be known to facilitate the integration of the images. Whereas the reconstruction method is time consuming because of image acquisition, spatial registration, offline reconstruction, and image rendering and display, this approach has proven accurate and valuable for quantitation of left ventricular (LV) size and function,[3] right ventricular (RV) size and function,[4] pericardial effusions,[5] and valve disease.[6] In fact, early 3D echocardiographic reconstructions demonstrated that the mitral valve annulus is saddle shaped, and thus prolapse of the leaflets below the low points of the annulus into the left atrium (LA) can only be observed in 2D echocardiographic views that display these low points, typically the anterior and posterior portions of the annulus as seen in the parasternal and apical long-axis views.[6] The 3D reconstruction approach has mostly been replaced by the volumetric 3D techniques that are the focus of this chapter. More detailed information about reconstruction techniques can be found in earlier editions of this textbook.[7]

The volumetric approach requires a specialized transducer to collect a pyramidal (or 3D) volume of image data. The resultant image can then be displayed in many fashions. The surface of the structure can be displayed as a solid object. Alternatively, the volume can be displayed with varying degrees of transparency and shading to show different depths, thus allowing visualization of various structures within the volume (Fig. 4-2).

The development of complex TTE and TEE US transducers has enabled acquisition of 3D volume data sets in real time or "near" real time. To achieve this goal, the transducer elements are typically arranged in a rectangular grid or matrix array, and advanced electronics enable beam steering in multiple directions. To scan a volume of adequate size and at a reasonable frame rate, multiple US pulses must be emitted from this matrix array at the same time and processed in parallel. The earliest

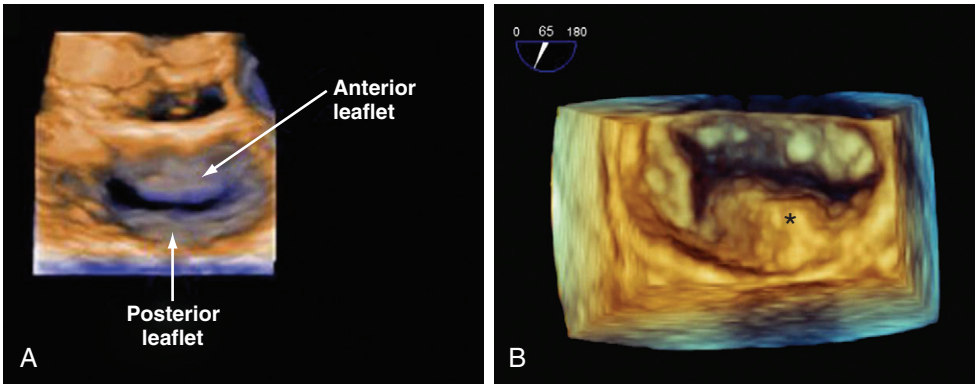

**Figure 4-1** **A,** Diastolic frame of a 3D TTE of mitral valve viewed from the LA demonstrating myxomatous anterior leaflet in a patient with anterior mitral valve prolapse. **B,** Diastolic frame of a 3D TEE of mitral valve viewed from the LA demonstrating myxomatous posterior leaflet (*) in a patient with posterior mitral valve prolapse.

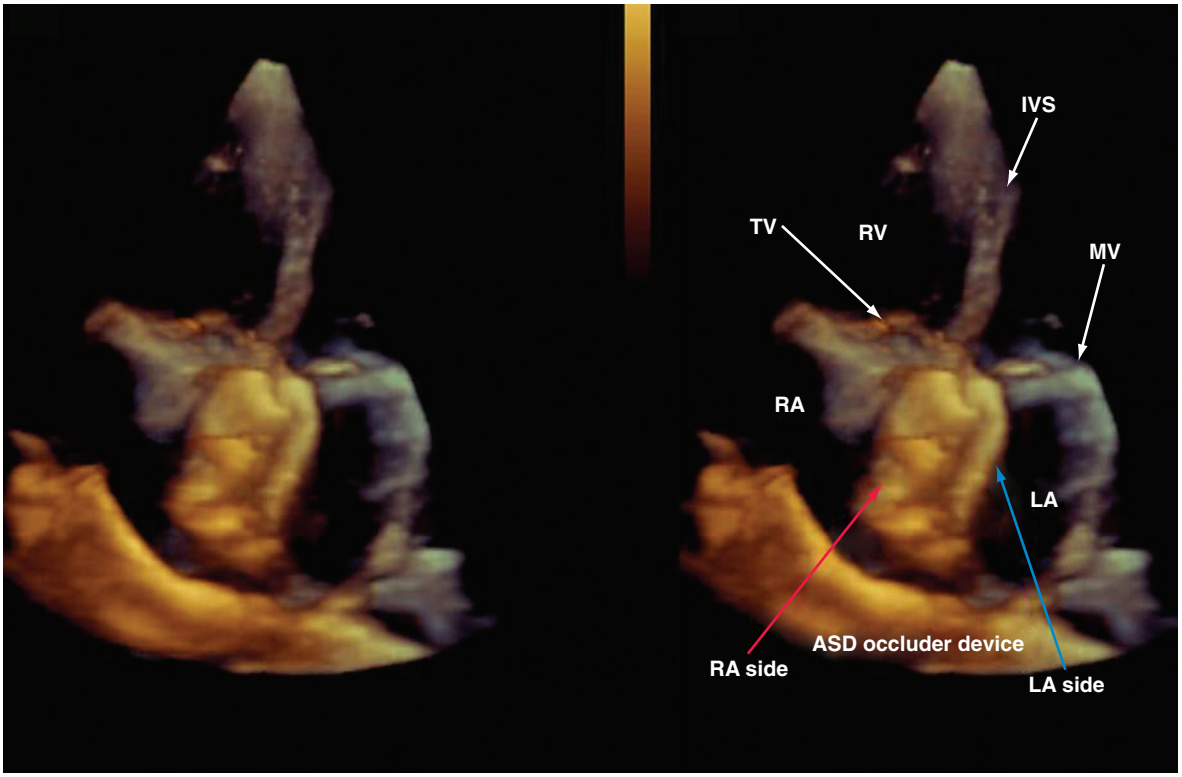

**Figure 4-2** Real-time 3D TTE from an apical view demonstrating an atrial septal defect (*ASD*) occluder device. The 3D depth is depicted by varying degrees of transparency and brightness. Structures closest to the viewer are brightest. *IVS*, Interventricular septum; *MV*, mitral valve; *TV*, tricuspid valve.

device utilized a sparse-array matrix transducer with 256 elements and acquired a pyramid-shaped volume of US data within a single cardiac cycle.[8-10] Although this provided real-time 3D images, the spatial and temporal resolution were not ideal, and volume rendering was not performed on the machine.

Current real-time 3D (RT3D) TTE systems utilize matrix array transducers with approximately 3000 elements, whereas 3D TEE matrix array transducers have a lower number of elements. A pyramid-shaped 3D US volume of about 30° by 50° can be acquired and displayed in real time. With a volume of this size, only a portion of the adult heart can typically be displayed in real time and three dimensions. However, this is large enough to display valves, the RV, complex defects, masses, color Doppler jets, the infant LV, or portions of the adult LV. To optimally visualize this RT3D US image, one rotates the image to view from all perspectives (Fig. 4-3). Display of a larger volume can be obtained from a single-beat acquisition on specific echocardiographic devices. However, for most devices, it typically requires acquisition of component volumes from a series of consecutive cardiac cycles, and these are then combined to yield a 90° by 90° image set. Color Doppler flow mapping by the 3D volumetric technique typically requires acquisition of a larger number of component volumes. To reduce artifacts that may appear in these "fused" images

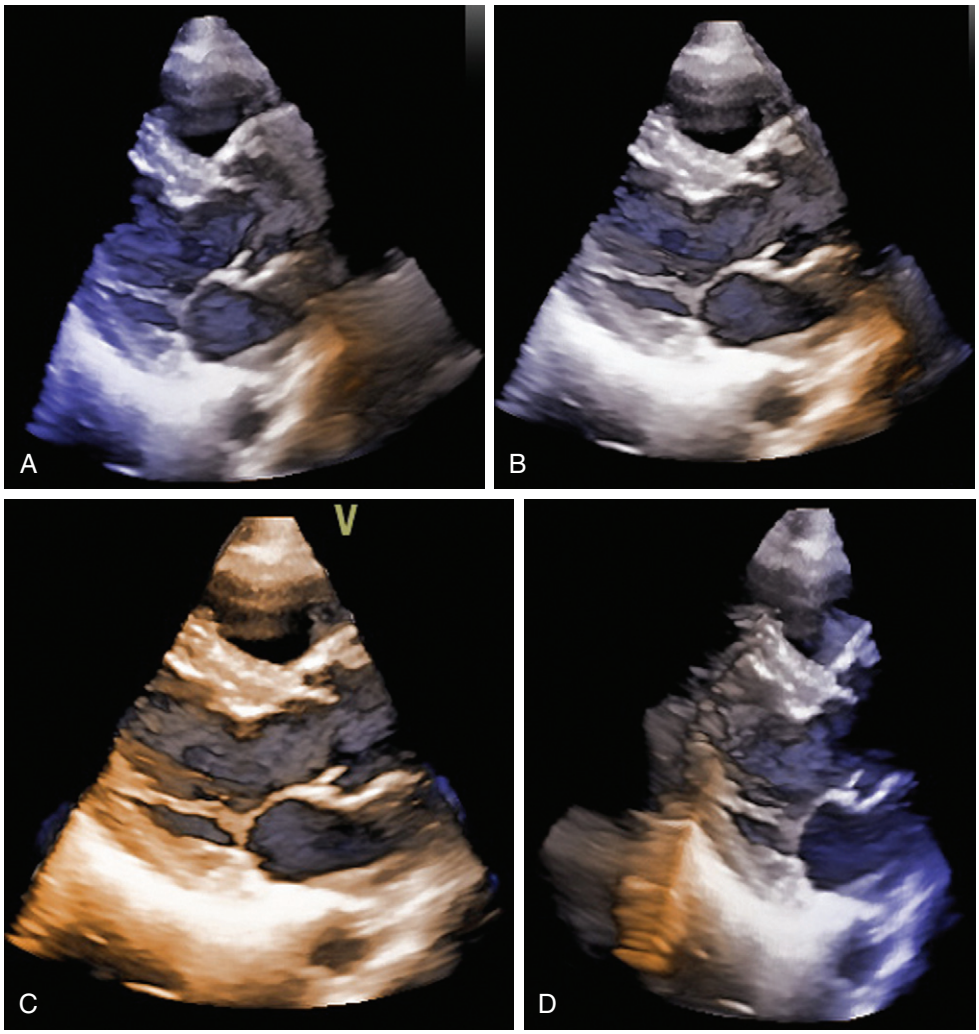

**Figure 4-3** Parasternal long-axis view of a real-time 3D TTE demonstrating that for optimal review, the structures included in the volume can be viewed from various perspectives (**A-D**).

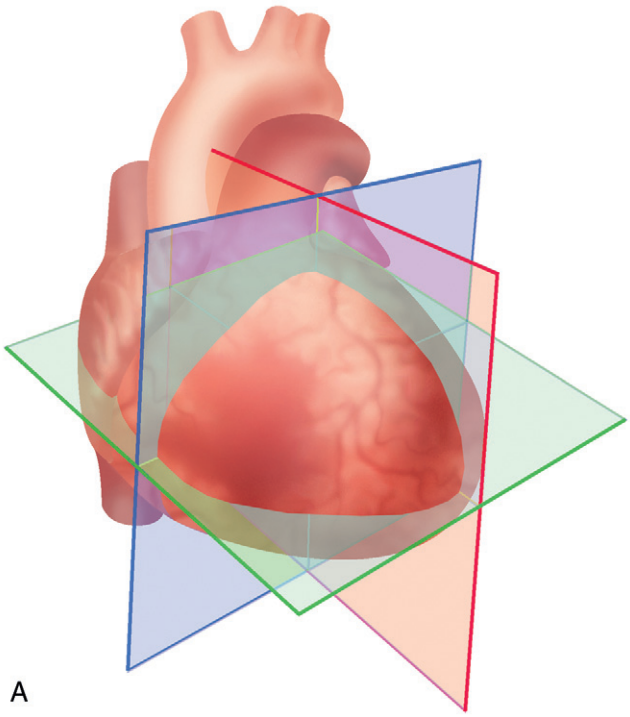
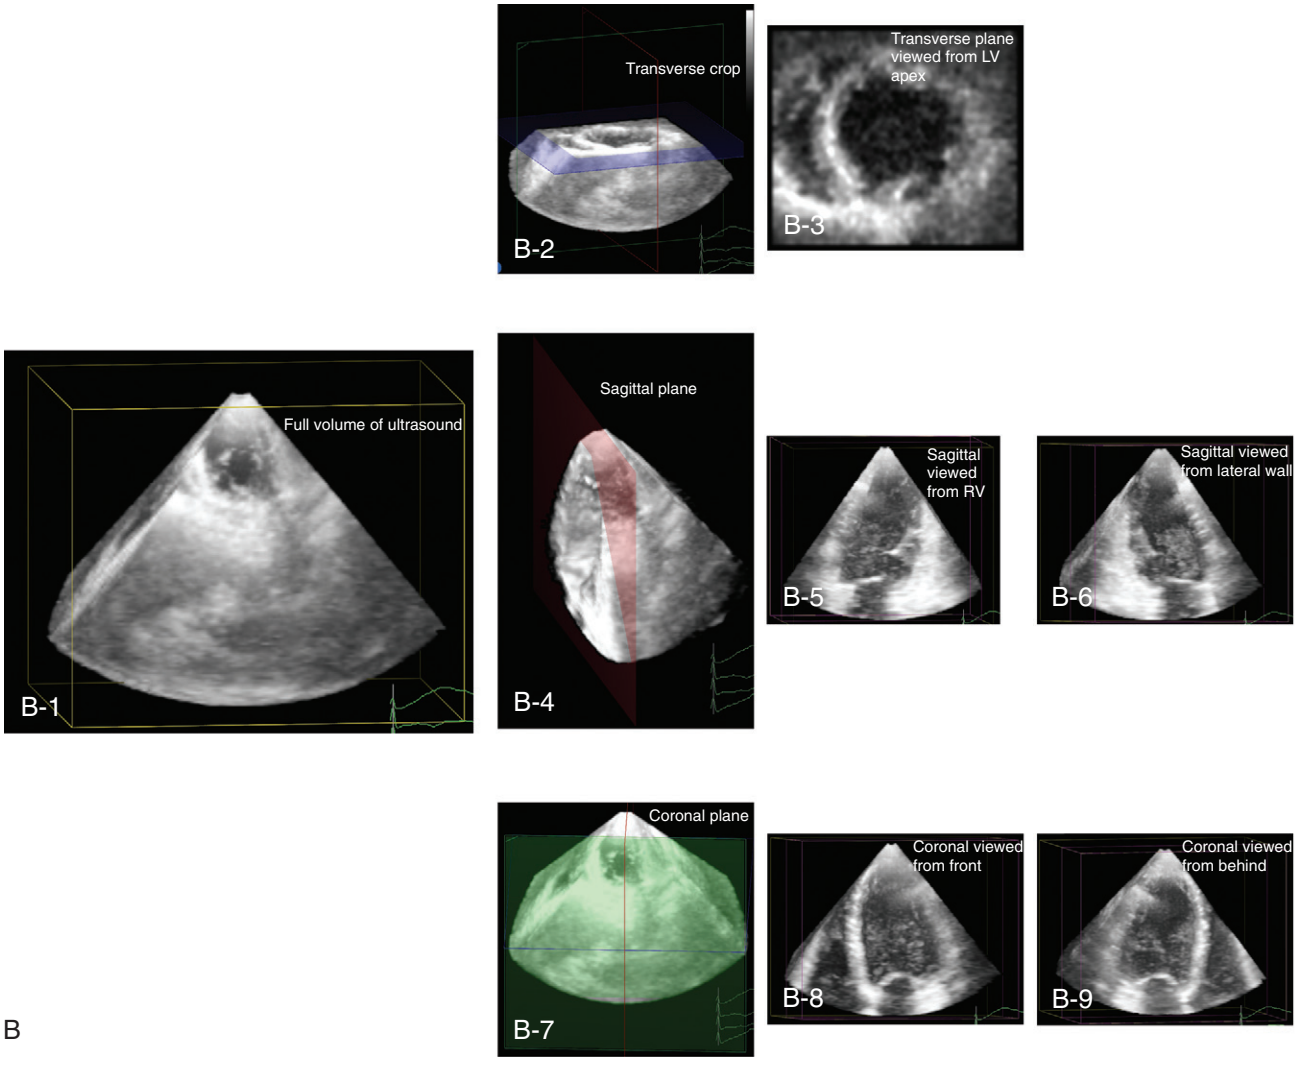


resulting from changes in position of the heart during the image acquisition, it is best if the images are acquired with held respiration. The frame rates at which these "full-volume" images are obtained typically vary from 20 to 40 Hz for both 3D TTE and 3D TEE. The full-volume frame rate will vary as a function of depth and size of the volume. Even though transducer position is more limited for RT3D TEE compared to RT3D TTE, image quality is superior much as 2D TEE image quality is typically superior to 2D TTE, and for similar reasons. In addition to 3D imaging, matrix array transducers can provide unique 2D acquisitions. For example, from a single transducer position, the 2D US plane can be adjusted in a fashion similar to a multiplane TEE transducer so that multiple 2D image planes can be obtained over *multiple* cardiac cycles without moving the transducer. This can be of particular value when tracking the circumferential extent of a prosthetic-valve paravalvular leak.[11] Also, multiple image planes of a structure can be obtained during the *same* cardiac cycle. In this scenario, rather than transmit and receive from the transducer elements to obtain a volume of US data, the pattern of firing of the elements can be configured to transmit and receive a series of 2D planes. This real-time multiplane imaging is of particular interest for quantitation. For example, the endocardial borders from a series of simultaneous apical views of the LV can be automatically or manually traced to calculate the LV volume and systolic function. This is similar to the approach with 3D reconstruction methods, except that all images of the heart are obtained in the same cycle, and the processing is faster. This real-time multiplane approach can be used to ensure that 2D images are on axis. For example, while visualizing a parasternal long-axis view as a guide, a second imaging plane can be directed that is perpendicular to the narrowest opening of the leaflet tips of a stenotic mitral valve.

When the 3D US full-volume image is first displayed on the echocardiographic machine or a workstation, only an outer surface of the pyramidal data set is seen, and it provides little information. To visualize the cardiac structures within this volume, layers of it must be removed—a process referred to as "cropping" (Fig. 4-4). Multiple cropping planes can be created to display structures of interest and the relationship of several structures to one another.



3D color flow Doppler is acquired in a similar fashion with the volumetric technique and displayed in real time simultaneously with the gray-scale images[12,13] (Fig. 4-5).

In general, the RT3D image is used for visualization of structures, whereas the offline cropping of the larger or composite 3D volume sets is used for quantitation or improved resolution of structures.

**Figure 4-4 Cropping of a full-volume ultrasound data set. A,** Schematic of standard cropping in transverse, sagittal, and coronal planes is shown with the colors corresponding to the image planes shown below; however, any 3D cropping plane can be created. **B,** Individual cropping planes through an ultrasound volume collected from the apical transducer position demonstrate cardiac structures from various perspectives. To visualize structures within the 3D ultrasound volume (**B-1**), cropping is performed. The transverse plane in *blue* (**B-2**) yields a short-axis view (**B-3**) viewed from the LV apex; the sagittal plane in *red* (**B-4**) yields either an apical two-chamber view viewed from the RV (**B-5**) or viewed from the lateral wall (**B-6**) or long-axis view depending on depth and angle of the cropping plane; and the coronal plane in *green* (**B-7**) yields an apical four-chamber view viewed from the front (**B-8**) or from behind (**B-9**).

The 3D image is viewed from the LV outflow tract or lateral wall perspective looking "en face" at the defect. Proximal flow convergence area (*short arrow*). *LVOT*, Left ventricle outflow tract.

### ADVANTAGES AND DISADVANTAGES OF THREE-DIMENSIONAL ACQUISITION TECHNIQUES

Compared to the reconstruction technique, image acquisition with the volumetric method is simpler and potentially faster. With the RT3D and the real-time multiplane 2D display, there is no time needed for offline reconstruction and display. For the "near real-time, full-volume" method, offline manipulation (cropping) is required, but typically the amount of time required compared to reconstruction techniques is short. Image quality of the RT3D and full-volume 3D images is a function of matrix array transducer characteristics such as frame rate and number of transducer elements. The image quality, however, continues to improve with advances in transducer technology.

For some of the 3D US methods, quantitation from the 3D image requires transfer to a special workstation. Because both reconstruction techniques and most of the current full-volume method combine multiple images gated to the cardiac and respiratory cycle, accurate image display can be challenging when the heart rate is irregular, such as during arrhythmias and when the patient is breathing at a rapid rate or with varying effort. The motion artifacts that may result will be most apparent in the cropped views that include the interfaces of the combined component images. For example, if the LV imaging volume is acquired by fusing four sequential volume sets from a parasternal short-axis view (medial to lateral) during which the patient coughs, when the images are cropped and viewed from the perspective of the LA or the LV apex, one will see the motion artifact with the appearance that the images are not stitched together well. However, if one crops and views this same image set from the perspective of the ventricular septum to observe a long-axis of the valve (sagittal plane), display of such artifacts would be minimized because the stitch artifact would not be in the plane displayed (Fig. 4-6).

3D color Doppler has some limitations. For example, Doppler interrogation with the volumetric method is subject to low frame rates, although this is improving. Importantly, pulsed-wave and continuous-wave Doppler capabilities have recently become available on some matrix array transducers, allowing all TTE or TEE imaging to be performed with one transducer.

In clinical practice, most 3D TTE and TEE US imaging is performed with matrix array transducers and the volumetric methods. Because quantitation of cardiac structure and function is accurate with the reconstruction approach, it is still used in some research applications with both TTE and TEE modalities. Although dimensions, volumes, and areas can be calculated from cropped 3D US volumes, deriving linear dimensions that extend out of these cropped planes remains a challenge.

## Three-Dimensional Echocardiographic Work Flow

The images obtained and cropped from a 3D US volume should focus on the goals of the imaging. Assessments of ventricular function, aortic valve function, or an atrial septal defect with 3D TTE require reconstructions or volume acquisitions of different parts of the heart. With 3D LV volume quantitation, for example, the 3D volume is obtained from an apical window to ensure that the entire LV is within the volume of acquisition while for a 3D assessment of the aortic valve the 3D volume is obtained from a parasternal window so that the valve is in the near field and frame rate and resolution are optimized. In the past, whether or not the 3D US image set was adequate could only be determined after cropping. Enhancements are now available that display examples of cropped 2D planes during acquisitions of the US volume so that image adequacy can be assessed in real time. Such modifications increase the likelihood that the 3D US volume obtained will contain the structure of interest, be free of artifacts, and be of adequate image quality.

It is likely that in the future, specific imaging protocols will be developed. Ideally this approach will include a rapid acquisition of the 3D US volume, and then the majority of image preparation time will be spent cropping the volume to display and quantify cardiac structures, function, and pathology. This cropping may be standardized to demonstrate all cardiac structures in specific orientations. For example, the cardiac volume can be cropped in planes sagittal (apical two-chamber or

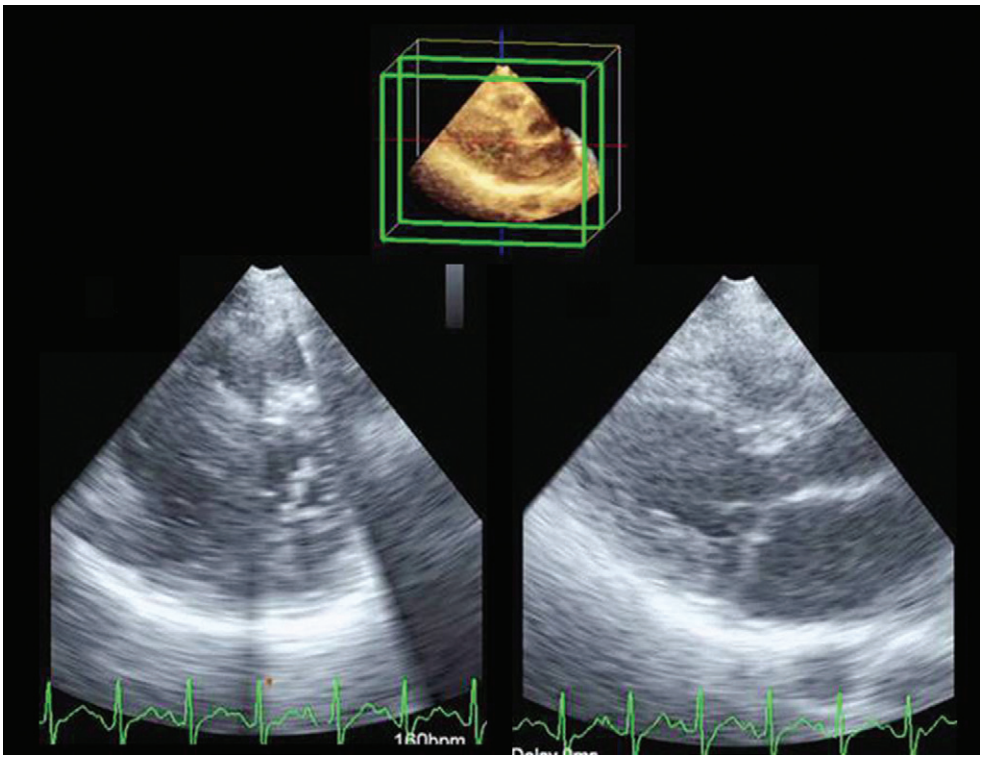

**Figure 4-6** Example of stitch artifact that occurs from patient motion during acquisition of the component subvolumes that are combined for the full-volume 3D ultrasound image. The artifact is noted (*left*) when the cropping plane includes more than one subvolume. If the cropping plane does not include multiple subvolumes (*right*), the artifact is not seen.

long-axis depending on angle and depth of plane), coronal (apical four-chamber), and transverse (short-axis) relative to the heart (Fig. 4-7). Although predetermined or automated cropping planes can be used to rapidly display and quantify structures of interest, in many cases of cardiac pathology the anatomic relationships may be altered, and thus it is critical to individualize the cropping process to optimize the views of each cardiac structure. This is particularly true for color flow Doppler assessment in which the paths of regurgitant jets do not respect standardized planes.

## Evidence-Based Applications of Three-Dimensional Echocardiography

### LEFT VENTRICULAR VOLUME AND FUNCTION

Validation studies using a variety of reference standards have demonstrated the improved accuracy of 3D echocardiography-derived LV volume compared to LV volumes measured from 2D echocardiograms in humans.[14] (See Chapter 9.) Initial 3D echocardiographic studies of LV volume involved the reconstruction method, and more recent studies have utilized the volumetric method. Selected validation studies of 3D LV volume are highlighted in Table 4-1.

3D echocardiography provides a more accurate representation of the LV endocardial surface than the 2D echocardiogram. The volume calculation with 2D echocardiograms relies on assumptions of the symmetry and geometry of the LV, whereas the volume of the LV by 3D echocardiography is calculated from the 3D LV endocardial surface without assumptions of shape. Also, methods used with 2D echocardiography are at risk to yield underestimations if the images used for the quantitation are foreshortened (Fig. 4-8). With 3D echocardiographic data sets transferred to an offline workstation, the volume can be calculated by several methods. First is a method of disks, in which multiple short-axis planes are derived to create a series of component volumes of the LV, which are summed from base to apex. This measurement is more accurate when a larger number of short-axis planes is used. A second method is to directly sum the volumetric picture elements (voxels) enclosed by the endocardial borders of the 3D structure (see Fig. 4-8, *B*). Compared to reference standards, the accuracy of 3D echocardiographic LV volume by the *reconstruction* method is a function of the number of component images used because this determines the extent of interpolation of the endocardial surface between images.[15] The accuracy of the 3D echocardiographic LV volume by the *volumetric* method is a function of the number of elements in the matrix array transducer, the voxel size, and the spatial resolution of the image.

Compared to cardiac magnetic resonance imaging (MRI), both end-diastolic and end-systolic LV volumes of normal subjects and patients with cardiac disease are smaller when calculated from 3D echocardiography regardless of the 3D echocardiographic acquisition technique. Images obtained from the apical transducer position may underestimate the LV cavity slightly because of the US point-spread function and beam width.[16-18] In many of the validation studies, the volume of the 3D echocardiogram was calculated from apical (or long-axis) images, whereas the cardiac MRI used short-axis images; this may account for some differences. Another explanation for

the discrepancy between 3D echocardiography and cardiac MRI is the difference in definition of the endocardial border. For echocardiography, the inner border of the endocardial trabeculations is traced, whereas on MRI the outer border of the trabeculations is commonly traced (i.e., trabeculae are included in the LV cavity), and so a larger volume is measured in the same patient.[19] A multicenter study examining the differences between LV volume by 3D echocardiography and cardiac MRI has shown that a 1-mm difference in the position of the endocardial surface resulted in a 10% difference in volume.[20]

Because the LV volumes calculated from 3D echocardiograms are accurate, it follows that the derivations of LV stroke volume and ejection fraction from these volumes are also accurate.[21] The advantages of this technique for assessment of LV function is most noticeable in subjects with wall motion abnormalities or distorted ventricles such as LV aneurysms.[22] LV volume can be calculated from either manual or automated border tracing throughout the cardiac cycle with the generation of volume-time curves as a measure of systolic and diastolic function.[23,24] Observer variability is low, and change in LV volume, stroke volume, and ejection fraction are also more precisely determined with 3D echocardiography compared to other echocardiographic techniques. Thus, the 3D echocardiographic technique has shown value in clinical situations in which accurate characterization of changes of these parameters is critical, such as heart failure risk stratification in post–myocardial infarction patients[25] and LV volume determination to guide decisions for valve surgery.[26]

The use of contrast enhancement in 3D echocardiography and acquisitions that reduce stitch artifact may further improve volume and ejection-fraction measurements. Contrast-enhanced 3D echocardiography has shown improved agreement with ejection fraction as measured by cardiac MRI.[27] Two-beat acquisitions of the LV volume yield similar LV volumes and ejection fraction as 4-beat acquisitions with fewer artifacts, but the current low temporal resolution of single-beat acquisition underestimates LV end-diastolic volume and LV ejection fraction.[28]

## LEFT VENTRICULAR MASS

LV mass is an important predictor of prognosis. (See Chapter 9.) It is calculated as the product of the volume of the LV myocardium and the myocardial density (g/cm$^3$). The specific gravity of cardiac muscle, a ratio of its density relative to water, is often substituted for density. The myocardial volume is calculated with 3D echocardiography as the space between the epicardial and endocardial borders of the LV. This can be calculated directly

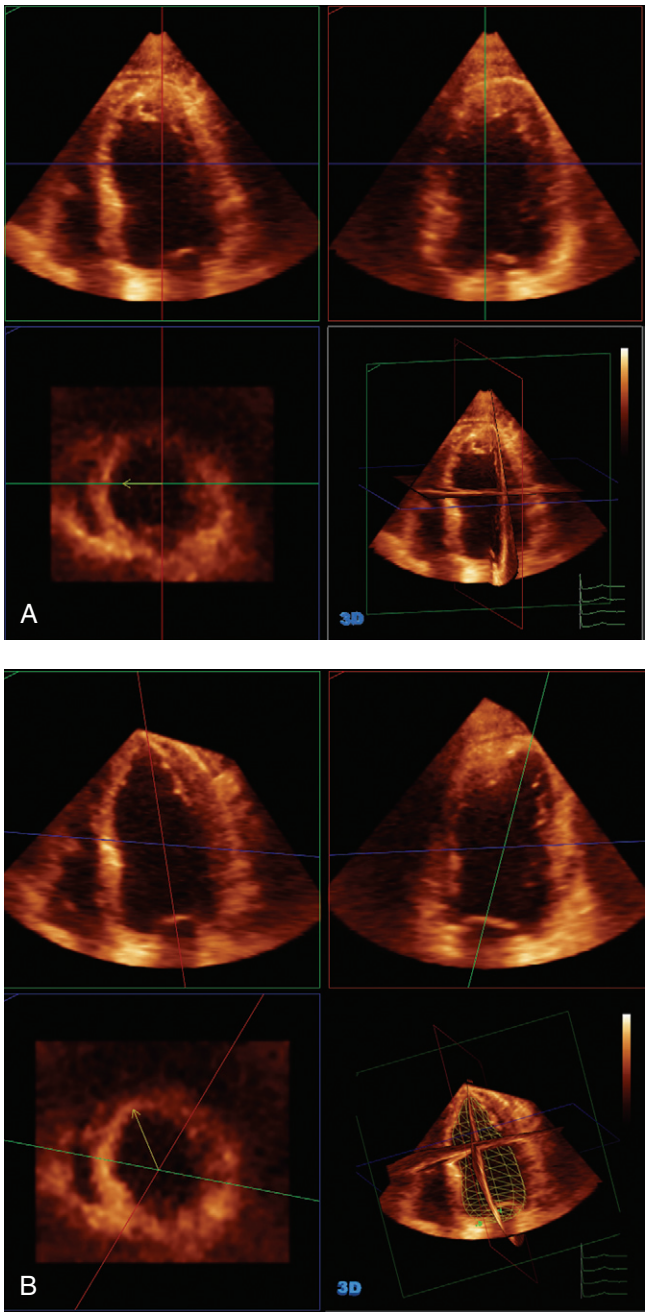

**Figure 4-8** The full-volume transthoracic ultrasound data set enables positioning of cropping planes so that the true length of the left ventricle is visualized and measured. **A,** Typical 2D imaging planes for the four-chamber (coronal plane, *upper left*) and two-chamber (sagittal plane, *upper right*) views fail to include an aneurysm at the anterior apex of the left ventricle. **B,** Coronal (*green*) and sagittal (*red*) cropping planes adjusted through the true long axis of the left ventricle in the same full-volume data set. The endocardial borders are then detected and an accurate left ventricular volume quantified. End-diastolic volume (*yellow shell*) is shown (*lower right*).

as a sum of the voxels in this enclosed space or derived from the difference of the epicardial and endocardial volumes. Initial 3D quantitative LV mass analysis relied on manual tracing of endocardial and epicardial borders or semiautomated border detection of multiple 2D long-axis planes extracted from volumetric data. These processes were time consuming and required geometric modeling to convert the multiplanar area measurements into volumes. Subsequently, the development of rapid algorithms for the detection of the 3D endocardial surface allows for direct quantification of LV volumes and has been applied to the epicardial (in addition to the endocardial) surface to calculate LV mass. Using such algorithms, LV mass is quickly calculated and compares favorably to MRI.[29]

Potential sources of error with 3D echocardiographic measures of LV mass include the need to include the entire epicardial surface of the LV within the image sector and exact tracing of endocardial trabeculations. However, human studies document close correlation of 3D echocardiographic measurements compared to cardiac MRI LV mass measurements (Table 4-2). These studies have been conducted in various patient populations, including left ventricular hypertrophy,[30] various forms of cardiomyopathy,[31] wall motion abnormalities,[32] and congenital heart disease.[33] Furthermore, regression of 3D echocardiographically measured LV mass with pharmacologic therapy has been demonstrated in a small study of hypertensive patients.[34] Because LV mass derived from 3D echocardiography is more accurate, more precise, and less variable than that from 2D echocardiography, it is expected that fewer subjects will be required in clinical trials of LV mass regression using this technique compared to trials that have used 2D echocardiography to measure LV mass change.

## RIGHT VENTRICULAR VOLUME

The RV has a complex geometrical shape, and the RV inflow, outflow, and apex do not all align within a single 2D plane. This makes calculation of total RV area or volume challenging by 2D echocardiography. 3D echocardiography can eliminate the need for geometric assumptions used in the calculation of RV volume. The methods for calculating RV volume from the 3D image are the same as described previously for LV volume. The RV is typically smaller and more heavily trabeculated than the LV surface, and therefore one might expect lower accuracy of volume quantitation compared to the LV. However, initial validation studies for RV volume performed mainly in nonhuman models showed correlation coefficients, standard errors, biases, precision, and percent interobserver variability similar to those for LV volume quantitation.[7] Additionally, the accuracy of RV volume determination in humans is improving as technical factors are optimized[35] and new software programs specific for volumetric analysis are utilized.[36] Selected validation and clinical studies of RV volume assessment by 3D echocardiography are highlighted in Table 4-3. For healthy male and female adults with a wide age range, the normal reference values for indexed RV end-diastolic volume, indexed RV end-systolic volume, and RV ejection fraction by 3D echocardiography are 49 ± 10 mL/m$^2$, 16 ± 6 mL/m$^2$, and 67 ± 8%, respectively.[37]

As measurement techniques and software programs have improved, RV volume assessment with 3D echocardiography is being applied in disease states that affect the RV. Specifically, 3D echocardiographic quantification of RV volume and function has been applied to a small number of patients with arrhythmogenic RV dysplasia/cardiomyopathy.[38] Although the correlations with cardiac MRI are lower than noted in other validation studies, patients with pathologic RVs could be discriminated from normal controls and unaffected family members. 3D echocardiographic quantitation of RV volume has also been used to assess RV remodeling in secondary pulmonary hypertension[39] and has shown that RV volumes are largest and RV ejection fraction lowest in patients with pulmonary hypertension compared to healthy volunteers or patients with other

cardiac disease.[36] In patients with various complex and/or surgically repaired congenital heart diseases, 3D echocardiographic assessment of RV size and function was reproducible and had good accuracy compared to MRI.[40] Further studies in patients with a wider range of conditions affecting the RV are warranted to confirm the results of these initial studies and to define the role of 3D echocardiography in the clinical diagnosis and management of these patients. (See Chapters 32 and 33.)

## ATRIAL VOLUME

LA size is not only a marker of diastolic function but has also been shown to be a predictor of adverse outcomes including atrial fibrillation, stroke, and cardiac events. In these assessments, LA volume has been shown to be a stronger risk factor than LA area or linear dimension,[41] thus LA volume calculations derived from 2D planes are recommended as the standard measurement technique.[42] However, because of lack of symmetry of the atria, 3D echocardiography is better suited for accurate quantitation of left and right atrial volumes, and the methods are similar to that for calculation of ventricular volume by 3D echocardiography. LA volume measurement by 3D echocardiography compares well against traditional 2D echocardiographic measurements,[43] and although the number of studies is limited, accuracy appears comparable to MRI.[44,45] By providing a detailed analysis of the phasic changes of LA volume throughout the cardiac cycle, 3D echocardiography enables the assessment of the reservoir, conduit, and active contraction functions of the LA.[46,47]

3D echocardiographically derived LA volume measurement has been shown to be more sensitive to changes in volume than 2D echocardiographic measurements[48] and is a predictor of cardiac events in patients with severe LV dysfunction.[49] In a study of 178 outpatients, LA minimum volume by 3D echocardiography provided prognostic information for the occurrence of major cardiovascular events.[50] Additionally, 3D echocardiography for LA volume and function has been evaluated in specific clinical contexts, including hypertrophic cardiomyopathy and evaluation of the LA appendage.[51,52]

3D echocardiographic evaluation of the right atrium (RA) has been studied less than that of the LA; however the feasibility of RA volume assessment with 3D echocardiography and its superiority over 2D echocardiographic measurements have been demonstrated.[53] Detailed knowledge of RA anatomic features (i.e., crista terminalis, cavotricuspid isthmus) is of particular interest to electrophysiologists performing catheter ablation procedures, and 3D TEE is being studied for this application.[54] A current limitation of studies of 3D echocardiographically derived atrial volumes is the paucity of comparisons to reference standards such as cardiac MRI and CT imaging.

## VALVULAR HEART DISEASE

3D echocardiography is especially suited for assessment of valve disease because of its ability to image nonplanar valve leaflets, demonstrate the spatial relationships of all components of the valve and surrounding structures, and depict color Doppler flow in three dimensions. Its use is emerging in the preoperative and intraoperative US evaluation of patients being considered for or undergoing repair and replacement of valves.[55] (See Chapter 5.)

### *Mitral Valve*

As previously discussed, since its early development, 3D echocardiographic approaches have been used to understand the complex geometry of the mitral valve (MV) and improve the echocardiographic diagnosis of MV prolapse.[6] The delineation of the nonplanar shape of the mitral annulus has led to identification of imaging planes and 2D echocardiographic views from which it can be seen that the mitral leaflets truly prolapse below the annulus into the LA. Studies suggest that with RT3D TTE, visualization of the MV is feasible in the majority of patients and that the anterior mitral leaflet is visualized better than the posterior mitral leaflet.[56] RT3D TEE has been shown to provide excellent visualization of the MV, as all scallops of both leaflets were visualized in approximately 90% of patients.[57]

### Mitral Stenosis

Characterization of mitral stenosis is a strength of 2D echocardiography. (See Chapter 21.) Whereas planimetry and pressure half-time methods with 2D echocardiography and Doppler typically provide equivalent assessments of the MV area, there are situations, particularly immediately after percutaneous

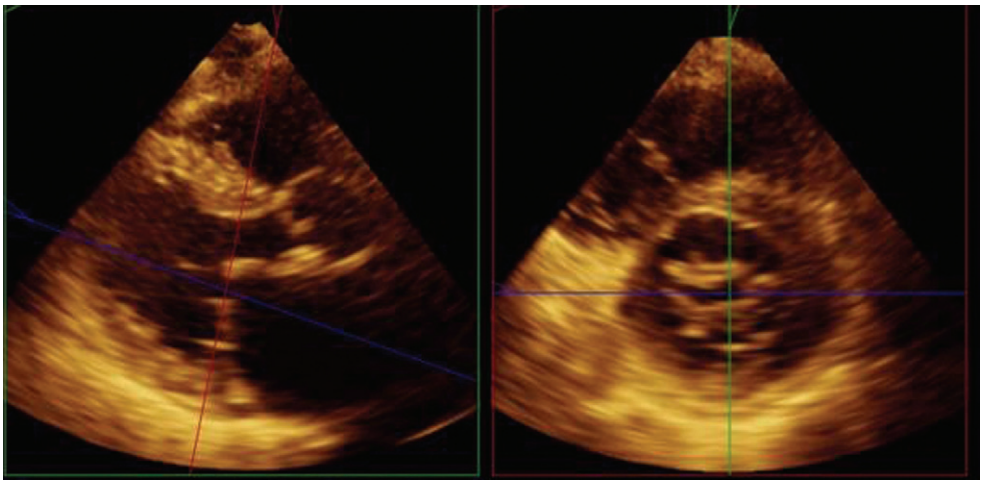

**Figure 4-9 Two images from a full-volume TTE of a patient with mitral stenosis.** Sagittal (long-axis) plane through the middle of the LV (*left*). The stenotic mitral valve is viewed from a lateral perspective. A transverse cropping plane (*red*) is then positioned orthogonally at the smallest mitral valve orifice at the leaflet tips. The resultant short-axis view (*right*) displays the stenotic mitral valve orifice viewed from the LV perspective.

mitral valvuloplasty,[58] in which only planimetry provides an accurate measure. Accurate planimetry of MV area requires a parasternal image plane that is perpendicular to the long axis of the smallest mitral orifice. This is a time-consuming task, especially when the valve orifice is asymmetrically narrowed. Deviations from the ideal image plane positioning will lead to significant overestimations of the valve area.[59] With 3D echocardiographic reconstruction techniques, a series of parallel short-axis planes through the MV is used to identify the smallest MV area for direct planimetry.[60] With the 3D volumetric technique, the best image of the valve can be cropped and rotated to display the best plane for planimetry[61] (Figs. 4-9, 4-10). Because multiple US planes can be created simultaneously with a matrix array probe, another method for planimetry of the MV area is to obtain a long-axis view of the MV and then position a second intersecting imaging plane that is perpendicular to the limiting orifice.[62] Investigations have shown MV area by 3D TTE to be more precise than 2D measures and comparable to that of the pressure half-time technique when compared to invasive measures of valve area.[61] In such comparisons, the 3D measurement frequently changed the classification of mitral stenosis severity. For experienced sonographers, there may not be a significant difference in valve area calculation compared with 2D echocardiography; however, the time required to acquire the view of the MV for planimetry is reduced. The benefits will be observed by less experienced personnel. The Wilkins morphology valve score by the 3D approach demonstrates less interobserver variability than the 2D echocardiographic technique,[61] and efforts are underway to develop novel scoring systems using 3D echocardiography that provide prognostic information that is additive to the Wilkins score.[63] Studies suggest that 3D echocardiography may better quantify the degree of commissural fusion before percutaneous mitral valvuloplasty, the leaflet morphology after the procedure,[64] and the MV area in the period immediately following.[65] The presence of atrial fibrillation, especially when the ventricular response is variable, continues to pose a challenge for the application of 3D echocardiography in mitral stenosis.

## Mitral Regurgitation

3D echocardiography has been used for several different aspects of mitral regurgitation (MR) (Fig. 4-11). First, it can quantify the severity of MR. (See Chapter 18.) Second, it can delineate specific anatomic lesions responsible for MR resulting from degenerative disease, myxomatous valve disease, congenital lesions, or endocarditis. Third, it can provide insights into the mechanisms responsible for functional and ischemic MR. Last, by better understanding the mechanisms of the regurgitation and the shape and anatomical relationships of surrounding supporting structures, such as annulus and papillary muscles, 3D echocardiography can assist in the design of valve repair techniques and prosthetic supports, such as annular rings. (See Chapter 19.)

3D echocardiographic quantification of MR can be performed either by the proximal isovelocity surface area (PISA) method or the vena contracta area method.[13,66,67] For the PISA method, the 3D color Doppler image of the flow convergence zone is examined to find the true shape of this region. The true radius and the convergence angle correction factor are then measured and used in the equations for MR volume and regurgitant orifice area. Alternatively, the true flow convergence area can be quantified free of assumptions of geometry and used in the calculations (Fig. 4-12). This approach is of particular value for quantitation of regurgitation from MV prolapse in which the jet may be eccentrically directed in the LA and the shape of the flow convergence zone may not be a symmetric hemiellipse.[68] In recent studies, both 3D TTE and TEE approaches have demonstrated accurate calculations of regurgitant orifice area and regurgitant volume when compared to MRI.[69,70] For the calculation of vena contracta area, the best image of the vena contracta is obtained, the full-volume color Doppler image set is then cropped in a plane parallel to the leaflets, the image is rotated to view the vena contracta enface, and finally the previously cropped portion of the image is added back until the largest vena contracta area is depicted. With the improved quantification of the complex geometry of the vena contracta and flow convergence areas, it is not unexpected that the 3D technique has produced more accurate measurements than 2D echocardiography[71] and has shown better correlations with invasive measurements of regurgitant severity than 2D echocardiography.[13,66] The direct measurement of the regurgitant orifice area by 3D echocardiography is feasible when image quality permits and may overcome some of the limitations of the calculation of this area by the PISA method.[12]

Another application of 3D echocardiography has been the direct visualization and localization of prolapsed segments of

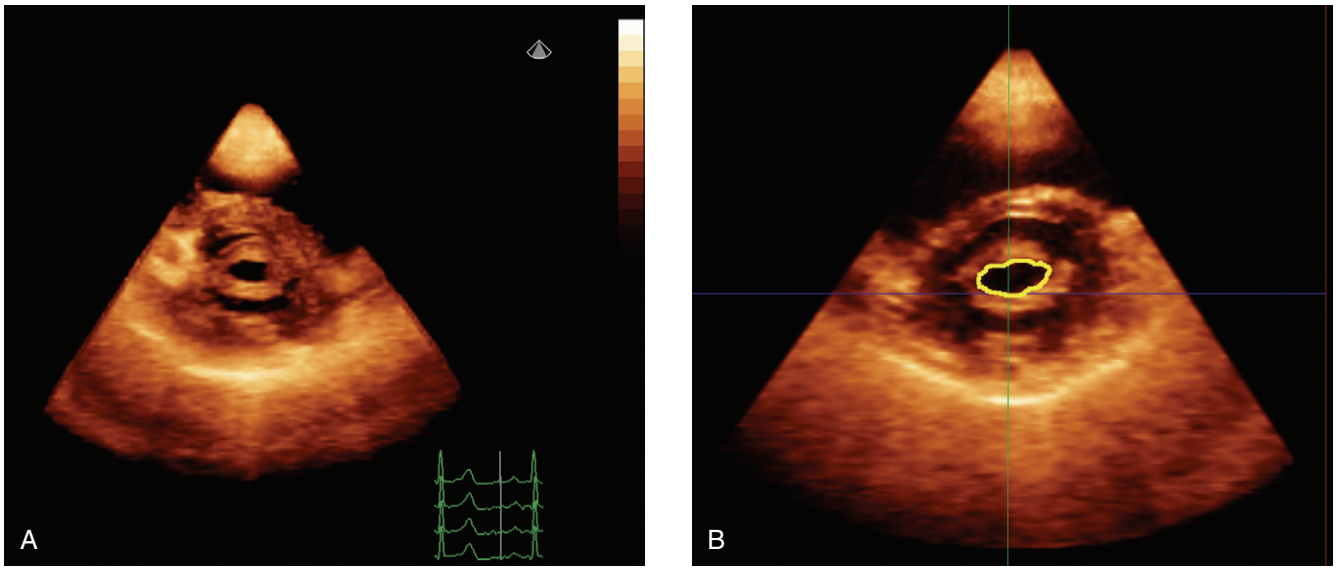

**Figure 4-10 Full-volume 3D transthoracic echocardiography of mitral stenosis. A,** Transverse (short-axis) plane through a stenotic mitral valve viewed from the LA perspective. **B,** Same plane viewed from the LV perspective with planimetry of the orifice in *yellow* (1.5 $cm^2$).

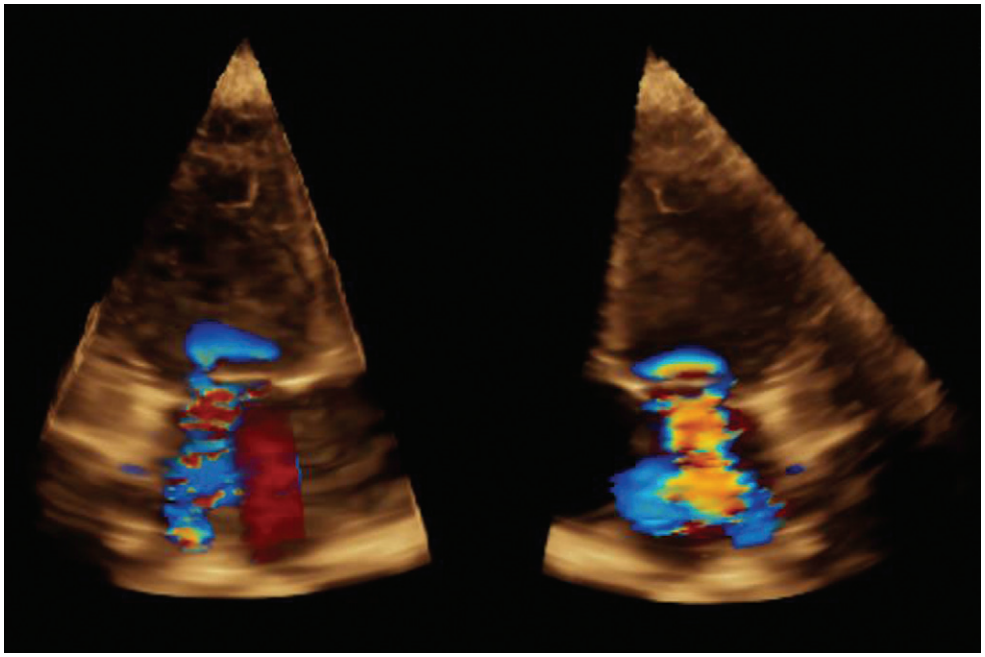

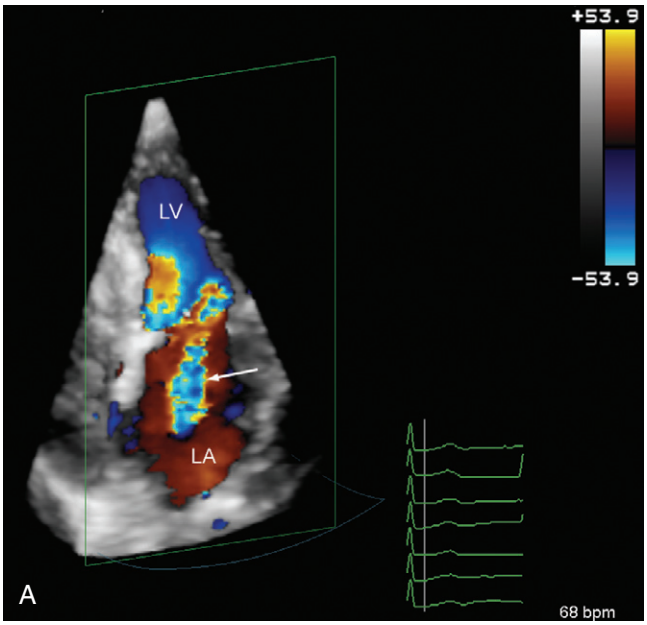

**Figure 4-11 Mitral regurgitation on 3D TTE as seen from cropping planes that best depict the jet direction.** Whereas the mitral regurgitation jet appears central *at right*, which approximates the apical four-chamber view, the eccentric inferior regurgitant jet direction is noted *at left*, which approximates an apical two-chamber view. The asymmetric natures of the proximal flow convergence zone and the vena contracta are also appreciated from the 3D echocardiogram. *(Courtesy Siemens Medical Solutions USA Inc., Ultrasound.)*

mitral leaflets before surgical repair[72,73] (Fig. 4-13). Recent evaluations with 3D TTE have demonstrated a comparative accuracy to 2D TEE for localizing the prolapsing segment.[74,75] A major determinant of this accuracy is image quality. With this technique, the most accurate detection has been for pathology of the central portion of the leaflets. For 3D TTE with current matrix array transducers, the parasternal transducer position typically provides better visualization of the leaflets compared to the apical window: The structure of interest is closer to the transducer, and thus scan line density will be greater and beam spread artifact will be less. 3D TEE improves the detection and localization of prolapsing mitral leaflet segments. In patients undergoing MV repair for MR, 3D TEE was superior to 2D TEE in the diagnosis of bileaflet disease and some specific leaflet portions such as P1, A2, and A3 valve segments.[76] The use of 3D TEE for a systematic characterization of the mitral valve is becoming more common, and protocols for a complete evaluation have been published.[77] Despite the improved performance of both 3D TTE and TEE for the morphologic evaluation of the MV, studies documenting improved patient outcomes with this

technique are required to help establish the clinical role of this modality.

Quantitative analysis of the geometry of the mitral apparatus represents another application of 3D echocardiography. Measurements of annular size by 3D TTE in patients with various forms of cardiomyopathy have been shown to correlate well with MRI.[78] In addition, observations from 3D echocardiography have provided important insights into mechanisms responsible for both functional and ischemic MR.[79-82] 3D echocardiography has shown that as the LV dilates, it leads to displacement of normal papillary muscle position such that the mitral leaflets are apically tethered (increased MV tenting area), and the resulting *functional* MR occurs through incompletely closing leaflets. 3D echocardiography has also shown that, in contrast, regional distortion of wall motion and/or distortion of the wall shape, such as aneurysm formation, adjacent to a papillary muscle will lead to a disruption of the normal spatial relationships between a papillary muscle and MV, resulting in disruption of normal coaptation and *ischemic* MR. 3D TTE quantification of papillary muscle anatomy can also discriminate the pathologies of MR, with preservation of papillary muscle symmetry occurring in functional MR and unequal papillary muscle tethering lengths occurring in ischemic MR.[83] Clinical studies with 3D echocardiography have confirmed prior experimental studies and demonstrated that with

ischemia and infarction, as the mitral annulus flattens, it enlarges predominantly in the anterior-posterior direction and annular motion during the cardiac cycle is reduced, especially compared to that of the posterior segments.[84,85] Based on these observations, repair techniques that reduce anterior-posterior annular diameter,[86] decrease tenting area,[87] restore normal ventricular geometry,[67,88] and reposition papillary muscles[89] have each been proposed for treatment of ischemic MR. In contrast, maneuvers that reduce global LV dilation and enhance reverse LV remodeling are being tested for functional MR.[90]

Experience with 3D echocardiography for evaluation of prosthetic valves is increasing, and the technique appears most accurate for the mitral position.[91] In a study of 18 patients with mitral valve dehiscence, 3D TEE provided additional information about the exact anatomic characteristics of the dehiscence and origin of the MR and was used to help plan the most appropriate corrective intervention.[92] 3D TEE to help guide percutaneous procedures, such as percutaneous valve repairs and paravalvular leak closure, is gaining increased use (See Chapter 5).

### *Aortic Valve*

3D echocardiography may have value in the assessment of aortic valve disease because all aspects of the three leaflets of the aortic valve cannot be visualized in a single 2D plane, and the 2D US imaging plane often is oblique through the stenotic or regurgitant aortic orifice. Direct planimetry of the aortic valve in aortic stenosis, description of valve morphology (i.e., number of leaflets) (Fig. 4-14), localization and description of subvalvular obstruction (both discrete membranes and hypertrophic septum/LV outflow tract [LVOT] obstruction), quantification of aortic regurgitation, and assessment of aortic root pathology have all been demonstrated with 3D echocardiography.[93-101]

#### Aortic Stenosis

Planimetry of aortic valve area by volumetric 3D TTE and by intraoperative 3D TEE (reconstruction technique) compares favorably with both invasive and by 2D TEE valve area measurements.[95,102] Studies of aortic valve planimetry by volumetric 3D TEE suggest similar benefits.[103,104] As noted for mitral stenosis, the advantage of 3D imaging in aortic stenosis centers on its ability to optimally define an imaging plane through the stenotic orifice.[105] As the technique continues to evolve, 3D TEE aortic valve planimetry is likely to have a role in the assessment of aortic stenosis in the operating room, because Doppler methods are more difficult there. However, because planimetry of the aortic valve from standard 2D TEE is accurate in many cases, further studies are necessary to determine in which subsets of patients and clinical situations the 3D approach is of additive value.

The 3D echocardiographic approach for aortic valve area measurement is also expected to be beneficial for continuity equation–based measurements, as a growing body of literature has documented that the LVOT is elliptical in shape.[106] This may be a source of inaccuracy in standard continuity equation–based measurements that assume a circular shape for the LVOT.[107] Additionally, direct measurements of stroke volume derived from 3D LV volumes yield more accurate continuity equation–based measurements of aortic valve area than the traditional 2D approach.[108]

#### Aortic Regurgitation

The vena contracta and PISA methods described for assessment of MR can be applied to aortic regurgitation, though experience is more limited.[109,110] In in vitro models, direct measurement of PISA with 3D TTE has been validated and calculation of aortic regurgitation volumes with 3D color Doppler has been shown to be more accurate than the conventional 2D method that uses the hemispheric assumption of flow convergence.[111] Furthermore, in the absence of other regurgitant valves, aortic regurgitation can also be accurately quantified as the difference in LV and RV stroke volumes calculated by 3D TTE.[112] Aortic valve repair is feasible for certain etiologies of aortic regurgitation.[113] Measurements of the ascending aorta, the sinotubular junction, the perpendicular distance from annulus to coaptation point of the leaflet tips, the distance from annulus to sinotubular junction, and the distance from the sinotubular junction to leaflet

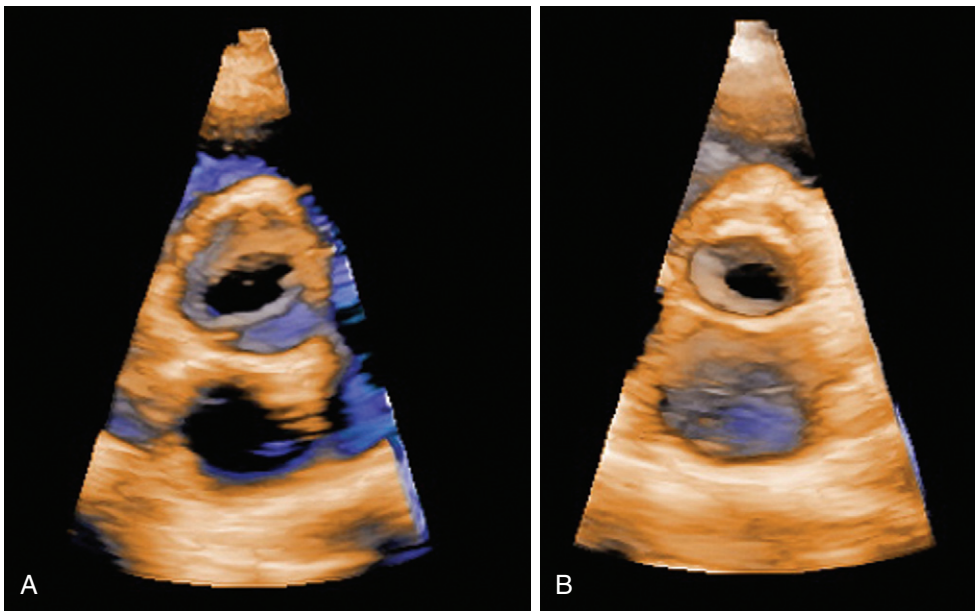

**Figure 4-14** Bicuspid aortic valve on 3D transthoracic echocardiography viewed from the aortic perspective (**A**) and LV perspective (**B**).

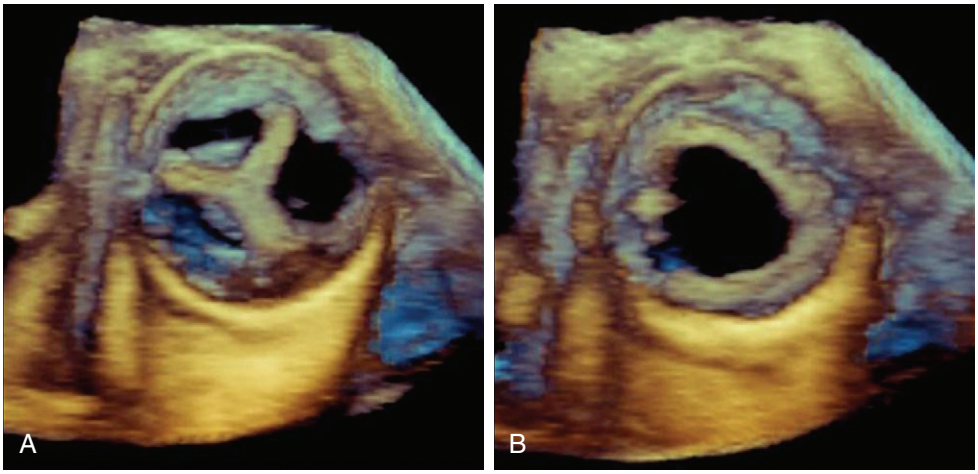

**Figure 4-15** 3D TEE of a pericardial aortic prosthetic valve demonstrating diffuse leaflet thickening, as viewed from the ascending aorta. **A,** Diastole (leaflets closed). **B,** Systole (leaflets open).

coaptation point can provide insights into the mechanisms responsible for aortic regurgitation and incomplete aortic valve closure.[101] These measurements are feasible with 3D TEE and may facilitate the development of new repair techniques and the assessment of the success of aortic valve repair.

### Aortic Prostheses

Similar to the mitral valve, studies investigating the use of 3D echocardiography in the assessment of prosthetic aortic valves are currently limited, although the clinical experience is increasing[114] (Fig. 4-15). The use of 3D TEE for transcatheter aortic valve implantation (TAVI) is evolving[115] (See Chapter 5).

### *Tricuspid and Pulmonic Valves*

The utility of 3D echocardiography for evaluation of the right-sided valves has not been as well-studied as the left-sided valves (Fig. 4-16). Initial reports for 3D echocardiography of the tricuspid valve were in the form of case reports, although a recent study comparing 3D TTE to MRI found that measurements of the tricuspid annulus are comparable between the two techniques.[116] 3D echocardiographic studies have shown that the tricuspid valve annulus is less saddle shaped and more round or oval than the MV annulus.[117] This may have implications for annuloplasty and/or repair of the tricuspid valve.[118] 3D echocardiography has also been used to evaluate the tricuspid valve in pulmonary hypertension,[119] rheumatic disease,[120] carcinoid heart disease,[121] and complex congenital heart lesions.[122] For example, quantitative 3D TTE has shown that following Fontan procedures, bidirectional cavopulmonary shunts, and Norwood procedures, significant tricuspid regurgitation can result from enlarged annular area, reduced systolic annulus area change, systolic annular flattening, and papillary muscle displacement.[123] Observations that the tricuspid regurgitation results predominantly from annular and ventricular abnormalities, rather than from the valve, may facilitate modification of surgical techniques.

Studies of the pulmonic valve are even more limited, but reports are emerging describing the 3D echocardiographic assessment of the anatomy of the RV outflow tract and pulmonic valve,[124] the vena contracta and regurgitant volume in pulmonic regurgitation,[125] and the pulmonic valve in carcinoid heart disease.[126]

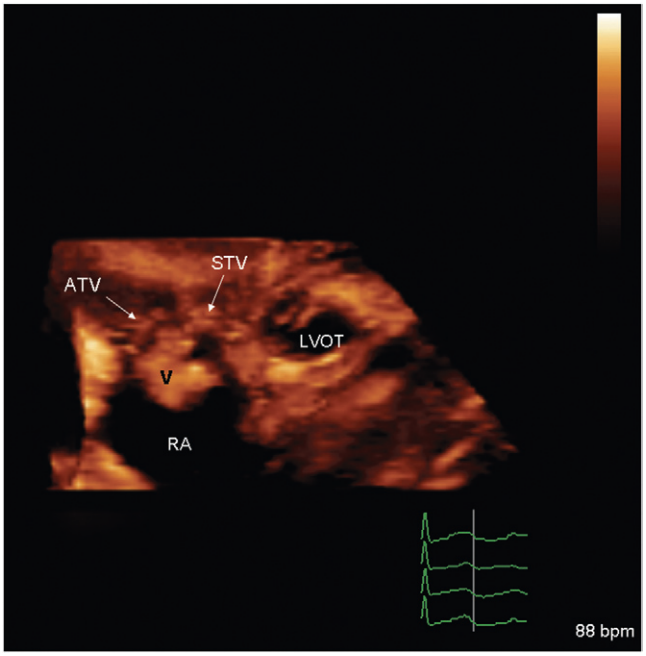

**Figure 4-16 Transverse crop from a 3D full-volume TTE of a tricuspid valve vegetation.** The vegetation is seen to arise from the atrial surface of the septal leaflet. *ATV,* Anterior leaflet of tricuspid valve; *LVOT,* left ventricular outflow tract; *STV,* septal leaflet of tricuspid valve; *V,* vegetation.

## CONGENITAL HEART DISEASE

3D echocardiography has a potential impact on diagnosis and treatment of patients with congenital heart disease because of the ability to define and display the complex spatial relationships seen in many of these pathologies. In addition, the shorter time for image acquisition with volumetric 3D echocardiography improves the probability of complete

cardiac US imaging assessment of children. A study of 75 patients with suspicion of congenital heart defects reported that 3D TTE image sets were obtained in all cases in less than 5 minutes, and sedation of infants and children was never required.[127] In a more recent report of 3D TTE in 70 patients with simple and complex congenital heart disease, improved depiction of cardiac and lesion morphology compared to 2D imaging was noted regardless of the experience level of the echocardiographer.[128] In this study, in at least 30% of the cases, the 3D echocardiogram added new information compared to the 2D imaging. Other investigators have confirmed that in about one third of patients with congenital heart disease, 3D TTE provided anatomic information not seen on 2D echocardiography that was helpful in clinical decision making.[129] This additive benefit was most prominent in patients with atrial septal defect, ventricular septal defect, atrioventricular septal defect, and L-transposition of the great vessels. In another 29% of this population, the 3D technique provided additional information compared to 2D echocardiography, but it was deemed not critical to decision making, and in 36% of the patients the information was equivalent for the two techniques.

Validation studies and evidence supporting the use of 3D echocardiography in congenital heart disease are now available for numerous measures of cardiac structure and function, including LV volume, mass and ejection fraction,[130] RV volume and function,[131] and single ventricle measurements.[132] 3D echocardiography has also been used to evaluate the mechanisms and sites of regurgitation in congenital abnormalities of the atrioventricular valves.[133] Additionally, there are case reports describing the successful use of 3D echocardiography for assessment of cleft MV[134] and Ebstein's anomaly.[135]

The detection and quantification of atrial septal defects is a particular strength of 3D TTE and TEE[136,137] (Fig. 4-17). The area or diameters of the defect can be measured from an enface view from either the RA or LA perspective.[138] Calculation of atrial septal defect shunt volume from 3D TEE reconstructions of Doppler color flow through the defect compares favorably to other methods.[139] Visualization of the extent of septal rim and assessment of the proximity of other structures is necessary when considering if a patient with an atrial septal defect is a candidate for percutaneous closure device, and 3D echocardiography may provide value in this assessment (See Chapter 5). In addition to secundum atrial septal defect, 3D TTE has been utilized to assess sinus venosus defects,[140] unroofed coronary sinus,[141] atrioventricular septal defects,[142] and ventricular septal defects.[143]

Currently the role of 3D echocardiography in patients with congenital heart disease is still being defined. It is likely that a paradigm that integrates 2D and 3D echocardiography in the evaluation and treatment of patients with congenital heart disease will produce the best patient outcomes.[144] Continued refinement of 3D technology, including development of higher frequency TTE matrix array transducers with smaller footprints and faster frame rates, and smaller 3D TEE probes will allow this technique to reach its full potential in this unique patient population.

## GUIDANCE OF INTRACARDIAC CATHETER-BASED INTERVENTIONS

Percutaneous catheter-based noncoronary procedures are gaining acceptance and becoming more commonplace in cardiac catheterization and electrophysiology laboratories.

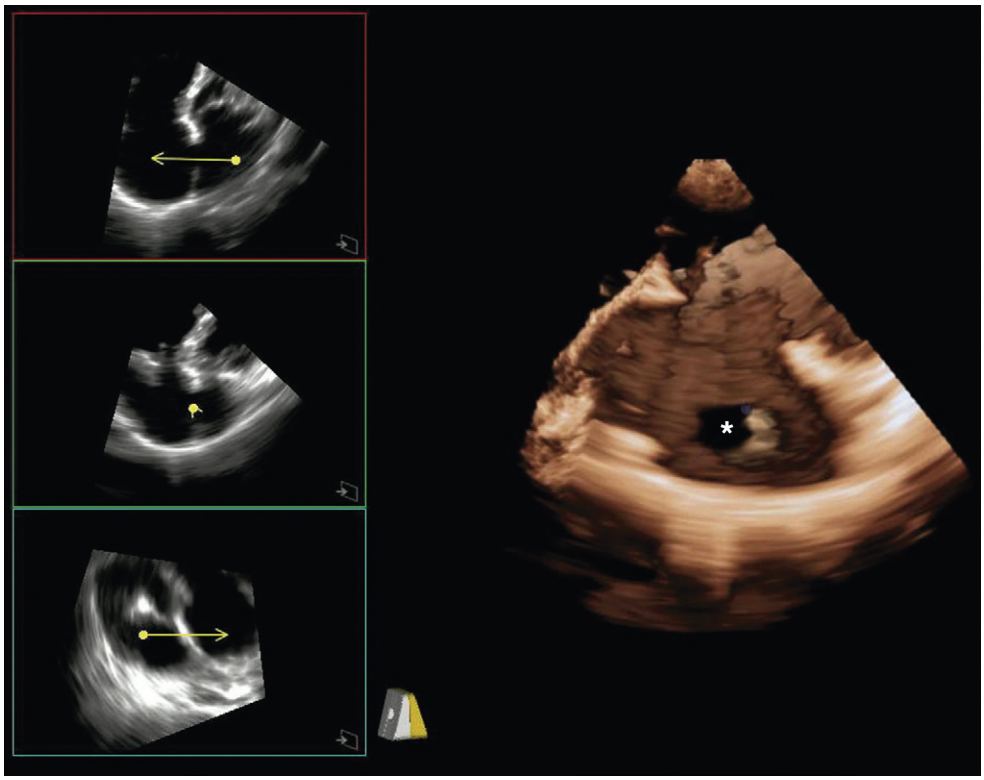

**Figure 4-17 3D TTE of a secundum atrial septal defect.** *Left*, Views from three cropping planes. *Right*, en-face view of the defect from the RA perspective. The 3D en-face view clearly depicts the shape of the atrial septal defect (*) and the adequacy of the surrounding septal tissue. *(Courtesy Siemens Medical Solutions USA Inc., Ultrasound.)*

Imaging guidance of such procedures has traditionally utilized fluoroscopy, which results in radiation exposure and, unless large volumes of radiologic contrast are used, has limited ability to depict complex anatomy and defects. Intracardiac echocardiography and 2D TEE are established modalities to help guide catheter-based procedures, although they have limitations. RT3D TEE has emerged as a powerful imaging tool because it allows the interventionalist a real-time 3D appreciation of cardiac anatomy, location of defects, and position of devices and catheters relative to the defects. Although these can be assessed with 2D TEE, it is easier with 3D imaging to rapidly understand the spatial relationships. The feasibility of 3D TTE and TEE has been demonstrated for closure of secundum atrial septal defect (see Fig. 4-2) and patent foramen ovale (Fig. 4-18), MV repair, mitral balloon valvuloplasty for mitral stenosis, TAVI, closure of prosthetic valve paravalvular regurgitation, closure of ventricular septal defects, LA appendage obliteration, and pulmonary vein ablation for atrial fibrillation.[145-147] In a multicenter evaluation of RT3D TEE for guidance of such catheter-based interventions, several distinct advantages of RT3D TEE were found.[147] Specifically, RT3D TEE allowed for visualization of the entire length of intracardiac catheters, including the tips of all catheters and the balloons and devices they carry, along with clear depiction of their positions in relation to other cardiac structures. Another advantage of RT3D TEE is the ability to demonstrate certain structures in an en face view, allowing appreciation of the exact shape of the lesion undergoing intervention.

Compared with 2D TTE and fluoroscopy, RT3D TTE has demonstrated efficacy in helping to guide RV biopsy, by providing improved visualization and localization of the bioptome tip in the RV.[148]

Recent evaluations support the use of RT3D echocardiography, both TTE[149] and TEE,[150] for guiding closure of atrial septal defects and detection of complications of this procedure, such as a torn interatrial septum.[151] There is also evidence that use of RT3D TEE to assist percutaneous closure of interatrial communications can result in lower radiation exposure for patients.[152] A true representation of atrial septal defect shape with 3D TEE enables more accurate measurement of defect size compared to 2D TEE. This can guide selection of the appropriate closure device and reduce residual shunting.[137]

Catheter-based therapy of valvular heart disease represents another major area where RT3D echocardiography is being utilized. In addition to mitral stenosis, RT3D echocardiography also has uses in guiding the treatment of MR. RT3D echocardiography has been used to evaluate the impact of a coronary sinus-based percutaneous transvenous mitral annuloplasty on dynamic changes of mitral annular geometry, demonstrating a reduction in mitral annular area and dimensions.[153] Percutaneous edge-to-edge repair of the MV to reduce MR is a promising technology, and RT3D echocardiography may guide perpendicular alignment of the therapy catheter to the MR jet and help position devices along leaflet edges.[154] Additionally, RT3D echocardiography may help detect the complications that can occur in the setting of percutaneous MV repair.[155] Paravalvular regurgitation in the setting of prosthetic MV dehiscence is another clinical situation in which RT3D echocardiography is being utilized to select patients and guide percutaneous therapy.[156] In this setting, the imaging requirements include visualization of location and size of the leak, guiding wire position through the leak, and determining of the size and number of devices required to close the leak(s) (Fig. 4-19). The incremental value of RT3D over 2D echocardiography for device closure of paravalvular leak needs to be established.

TAVI has been shown to reduce mortality in patients with severe aortic stenosis who are not suitable candidates for surgery.[157] TEE is relied on during the TAVI procedure to assist in device sizing, device positioning, adequacy of device deployment and function, and identification of complications. As with guidance of other procedures, RT3D TEE provides better display of device and cardiac structures such as the aortic annulus compared with 2D TEE.[158]

Atrial fibrillation is another disease in which RT3D echocardiography is used to guide catheter-based therapies. RT3D TEE can be used to help guide transseptal puncture in patients undergoing atrial fibrillation ablation, allowing for fast and safe transatrial access with a single puncture attempt.[159] For patients with atrial fibrillation who have contraindications to anticoagulation, LA appendage occlusion devices may represent a novel treatment option.[160] In a study of 66 patients, RT3D TEE for visualization and quantitation of LA appendage orifice areas was feasible and correlated well with 64-slice cardiac computed tomography.[52] Thus, RT3D TEE may help select patients suitable for LA appendage occlusion, determine device size, and assess position during deployment. In addition, color Doppler from an en face view of the implanted device as seen from the LA perspective can rapidly identify residual flow around the

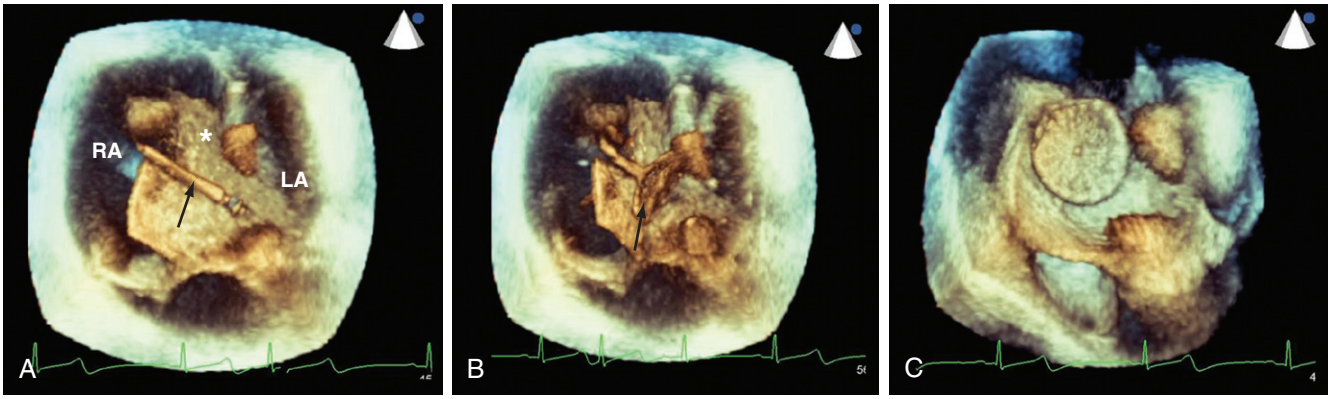

**Figure 4-18** 3D TEE obtained during percutaneous closure of a patent foramen ovale, as viewed from an LA perspective. **A,** Guiding catheter (*arrow*) seen traversing the patent foramen ovale. Interatrial septum viewed en face (*). **B,** LA septal occluder disk opened (*arrow*) and in the process of being pulled against the LA side of the interatrial septum. **C,** LA septal occluder disk apposed to the LA side of the interatrial septum.

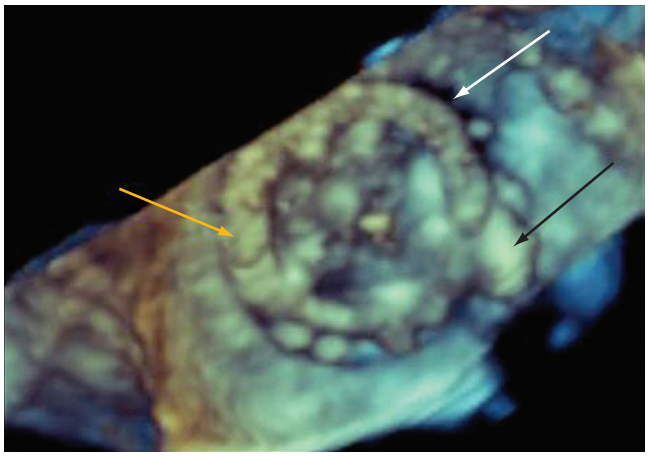

**Figure 4-19** 3D TEE obtained during percutaneous closure of a paravalvular leak associated with a single-tilting disk prosthetic mitral valve. An occluder device (*black arrow*) is positioned in a portion of the gap between valve and cardiac tissue. An area of residual paravalvular leak (*white arrow*) is also seen. The sewing ring of the valve is noted (*yellow arrow*). The highly reflective spot in the middle of the valve is its central strut.

margin of the device, which may prompt repositioning or change in device sizing.

## OTHER SELECTED APPLICATIONS

As would be expected, 3D echocardiography can be applied to almost any current use of 2D echocardiography. Several of these situations are described in this section. When assessing its additive value, important questions include whether the technology provides additional information that alters diagnosis or outcome and whether the information is obtained in a simpler or faster fashion.

### *Stress Echocardiography*

The use of single cardiac cycle multiplane 2D imaging or 3D echocardiography during stress echocardiography offers several advantages over the current practice. First, all ventricular segments are imaged rapidly at each stage, which is particularly important at peak stress, so that all myocardial segments are visualized before reduction in workload and the resolution of transient ischemia-induced wall motion abnormalities (Fig. 4-20). Second, if image acquisition is performed properly, the entire LV is imaged, and the risk of not evaluating the true LV apex due to foreshortening of the 2D view is reduced. Third, function of all myocardial segments is assessed at the same point in time, enabling accurate comparisons. Fourth, cropping of the images enables display and interpretation of image planes that are on-axis, thus reducing errors that occur with interpretation of oblique cuts of the ventricular walls or rotational motion. Last, cropping of the 3D images from each stage allows comparison of reproducible and identical myocardial segments at each stage, even if the heart has changed size or shape. However, if wall motion of all segments of the LV is accurately visualized and interpreted during 2D stress echocardiography, then it is unlikely that 3D imaging will improve the accuracy of the test.

The feasibility of the integration of 3D echocardiography with treadmill and pharmacologic stress echocardiography has been demonstrated.[161-163] Comparisons of 2D and 3D stress echocardiography have shown variable results, with some reporting comparable sensitivity and specificity for the two imaging methods during dobutamine[164] while others reported a lower sensitivity but higher specificity for the 3D stress echocardiogram during treadmill exercise.[165] One study comparing multiplane apical views to multislice short-axis views obtained from 3D TTE during dobutamine stress echo has demonstrated comparable sensitivity but enhanced specificity of the multiple simultaneous short-axis views. The improvement appears to be due to increased specificity for disease of the right coronary artery.[166] The time required to perform the 3D imaging during both pharmacologic and exercise stress has been reported to be approximately 50% shorter than that needed to acquire the comparable 2D images.[164,167]

With present-day 3D echocardiographic systems, several factors may influence test accuracy. The low frame rate of current 3D images might reduce detection of wall motion abnormalities, especially when images of rapidly beating ventricles are obtained. In addition, poor image quality has been noted in up to 9% of the 3D image sets.[165] Several 3D image acquisitions from different transducer positions may be necessary to acquire adequate-quality images of all myocardial segments. For example, 3D volumes from the standard apical transducer position will provide high-resolution images of the apical portions of the LV compared to more basal portions, because the resolution of the structures in the far field is influenced by the increasing scan line separation. However, 3D images from the parasternal transducer position can provide higher-resolution images of those basal portions. The large size of some matrix array transducers has contributed to difficulties in visualizing the anterior and lateral walls of the LV due to variable contact of the entire transducer footprint on the chest wall, thus resulting in a lack of the anterolateral regions of the LV in the volume acquired.[168] However, improvements in the technology are resulting in smaller transducers that should resolve this issue. The limitations of image quality during stress have been reduced with the addition of intravenous contrast for LV opacification.[169] The fusion of component images from multiple cardiac cycles may lead to image artifacts, particularly during stress and recovery when the heart rate is changing and patients are breathing rapidly. These artifacts can lead to the false impression of dyssynchrony or wall motion abnormality.[168]

Although 3D imaging is ideally suited for stress echocardiography, several enhancements are necessary before widespread clinical application. These include increases in frame (volume) rates that enable visualization of ventricular wall motion at the increased heart rates encountered at peak stress and additional methods that allow flexibility in the side-by-side display of cropped images from different stages.

### *Left Ventricular Dyssynchrony*

In randomized trials of advanced systolic heart failure, cardiac resynchronization therapy (CRT) has resulted in a reduction in symptoms and improved survival.[170] Echocardiography, specifically tissue Doppler imaging, has been used to assess LV mechanical dyssynchrony (LVMD) in an effort to select patients and predict response to CRT. (See Chapter 26.) However, results from a multicenter trial highlight the limitations of current tissue Doppler imaging–based measures of LVMD for patient selection for CRT, particularly those due to interpreter variability.[171] Efforts are focused on identifying echocardiographic methods for assessment of LVMD that have

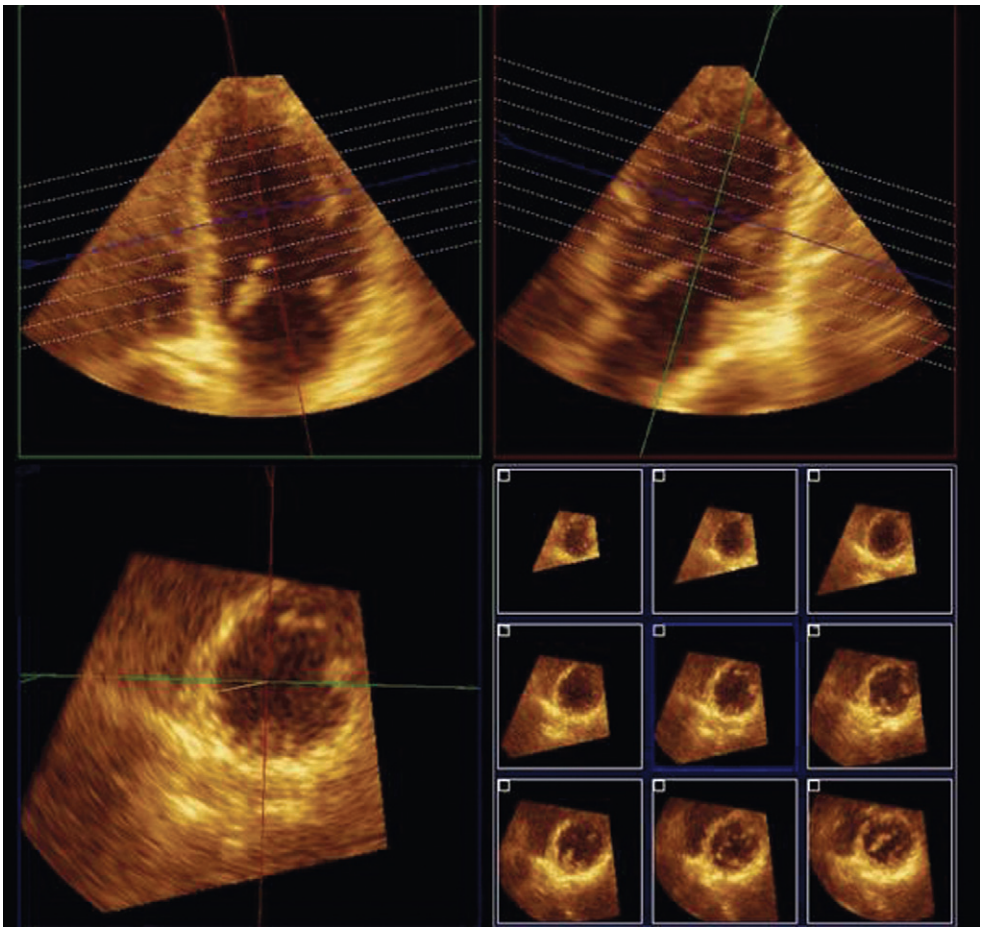

**Figure 4-20 One type of display of full-volume 3D stress echocardiogram.** Nine simultaneous short-axis views (*inset*) from apex (*upper left*) to base (*lower right*) of the LV. The distance between each adjacently displayed short-axis image is equal, and positions of these transverse cropping planes are shown (*white lines*) on the coronal and sagittal crops.

reduced measurement variability. 3D echocardiography is being studied this context.[172-174] The advantages of 3D echocardiography for the assessment of LVMD and the response to CRT in heart failure patients are similar to those noted earlier for stress echocardiography—all segments can be assessed simultaneously. Specifically, a full-volume data set is acquired and is imported into analysis software in which the complete LV endocardial border is tracked through the cardiac cycle. The LV volume is then divided into a series of subvolumes, the change in each subvolume during the cardiac cycle is calculated, and time-volume curves are generated. In LVMD, there is dispersion of the timing of the minimum volume point for all the subvolumes (Fig. 4-21). A systolic dyssynchrony index can be derived by calculating the standard deviation of the time to minimum volume in each of the subvolumes; this index is expressed as a percentage of the duration of the cardiac cycle.[175] In a recent study of 187 patients at two centers, LVMD quantification by 3D TTE was reproducible between centers and systolic dyssynchrony index was a predictor of response to CRT.[176] 3D TTE to quantify LV reverse remodeling and predict response to CRT has also been demonstrated.[177,178] Despite these promising results, limitations of 3D echocardiography for assessment of LVMD do exist.[179] Another potential role for 3D echocardiography is in the creation of color-coded parametric images that provide a spatial display illustrating which LV segments are most delayed.[180] When incorporated with information about coronary venous anatomy, this provides a visual display of how one may position the LV pacing lead adjacent to the most delayed segment. Additionally, techniques such as 3D speckle tracking are beginning to be studied for LVMD.[181]

### *Hypertrophic Cardiomyopathy*

In hypertrophic cardiomyopathy, 3D echo has shown improved identification of systolic anterior motion of the MV, improved localization of the predominant septal hypertrophy,[182,183] and usefulness for measurement of LVOT area and quantification of LVOT obstruction at rest and after provocation.[184] 3D echocardiography may also have value in the identification and quantification of LVOT and septal remodeling after surgical myomectomy and percutaneous alcohol septal ablation.[98]

### *Endocarditis*

Case reports have highlighted the value of 3D echocardiography in infectious endocarditis (Fig. 4-22). These reports suggest that 3D echocardiographic assessment may improve the detection of valve perforations, in addition to identifying the number and location of vegetations on both native and prosthetic valves[185,186] as well as on pacemaker leads.[187] Additional studies suggest that vegetation size measured on 3D TTE is more accurate than on 2D TTE.[188] A recent case series of 13 patients showed that intraoperative 3D TEE provided more information about complications of endocarditis such as

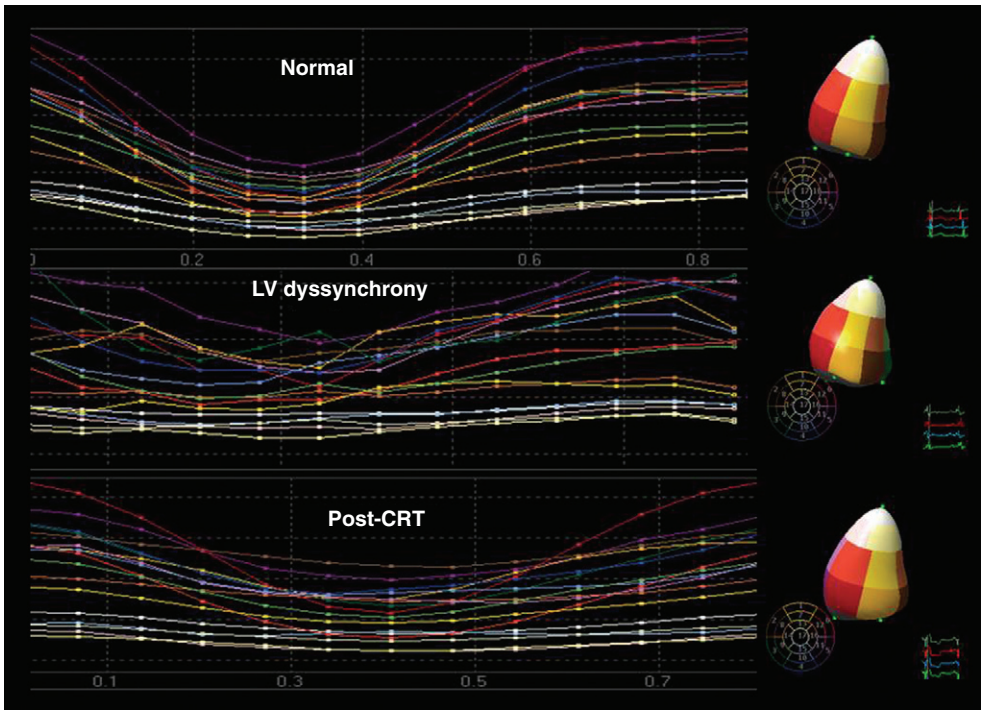

**Figure 4-21** **Intraventricular mechanical dyssynchrony of the LV can be assessed by 3D transthoracic echocardiography.** LV volume throughout a single cardiac cycle (*top*) is derived from a full-volume acquisition. All segments achieve their minimum volume at approximately the same time in the cardiac cycle. The same LV volume calculations in a patient with left bundle branch block and New York Heart Association class III heart failure (*middle*). A wide dispersion of time to minimum volume is observed for the segments representing intraventricular mechanical dyssynchrony. A follow-up 3D echocardiogram was performed 1 month after a cardiac resynchronization device was implanted, and the pattern of LV volume over time (*bottom*) now shows synchronous motion of the LV segments. *CRT*, Cardiac resynchronization therapy.

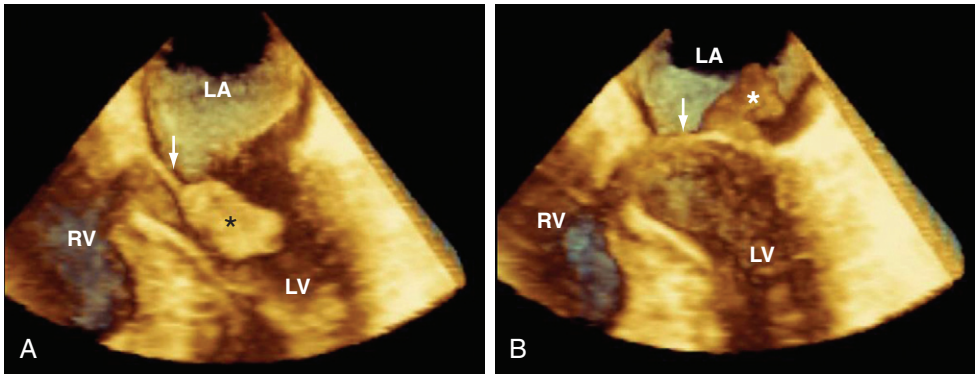

**Figure 4-22** Full-volume 3D TEE of a mitral valve vegetation in a patient with *Enterococcus faecalis* bacteremia. The vegetation (*) is seen to arise from the atrial surface of the anterior mitral leaflet. *Arrow* designates base of anterior mitral valve leaflet. **A,** Valve open in diastole. **B,** Valve closed in systole.

abscesses, perforations, and ruptured chordae and that this information may be helpful in planning the cardiac surgical procedure.[189] Systematic studies comparing 3D echocardiography (TEE and TTE) to the 2D echocardiographic modalities are still required to determine if vegetation detection rate is improved and if 3D echocardiography has incremental value to guide clinical decision making.

### *Aortic Dissection*

Case reports have demonstrated aortic dissection by 3D echocardiography,[190] and a study in a small number of patients suggests that the diagnosis of type A aortic dissection by TTE can be dramatically enhanced with 3D echocardiography.[191] In a more recent study, comparing 3D and 2D TEE, the assessment of entry-site tear size in chronic aortic dissection was enhanced and compared favorably to CT.[192] Case reports suggest that 3D echocardiography can be useful for the imaging follow-up of patients with surgically repaired aortic dissection.[193]

### *Myocardial Perfusion*

3D echocardiographic imaging enables display of myocardial contrast perfusion zones in a single cardiac cycle rather than reliance on a single image plane as is the common practice of 2D myocardial contrast echocardiography. The extent of

perfusion defect and quantification of myocardial perfusion have been demonstrated in both experimental preparations and humans with volumetric 3D echocardiography.[194] 3D myocardial contrast echocardiography has been used to assess subendocardial perfusion abnormalities after percutaneous intervention for myocardial infarction and was more precise than the 2D technique in this setting.[195] A potential impediment to use of RT3D TTE for myocardial perfusion is that the high intensity acoustic power and large number of scan lines that the current matrix array transducers transmit enhance premature microbubble destruction.

### *Pericardial Effusion*

The size of pericardial effusions can be more accurately quantified by 3D echocardiography than by 2D techniques. The 3D technique does not rely on the assumption that the fluid is symmetrically distributed. With the 3D echocardiographic method, the pericardial fluid volume is calculated as the difference between the volume of the outer pericardial sac (parietal pericardium) and the outer surface of the heart. Experimental studies using the reconstruction technique have shown excellent accuracies compared to true volume ($r = 0.98$; SEE 7.7 mL; mean error $1.1 \pm 7.8$ mL),[5] and more recent clinical experiences with volumetric TTE have confirmed its benefits.[196] For accurate quantitation of the fluid, the entire parietal pericardium or outer border of the effusion must be obtained in the image volume.

### *Intracardiac Masses*

The detection of masses, including thrombi and tumors, within the heart by 3D echocardiography has been documented in several case series.[188,197,198] 3D echocardiography may improve the detection of the site of attachment of the mass and the size of the mass. (See Chapter 46.) As image quality improves, it may have the potential to provide additive information over 2D echocardiography to help guide surgical procedures.[199] Studies are required to determine if serial quantification of thrombus volume with 3D echocardiography is an accurate and reproducible method to assess response to therapy.

## Technology Diffusion

Among the impediments to the widespread clinical use of 3D echocardiography are availability and cost of equipment, unfamiliarity with the technique, and image quality. Studies have shown that short, intensive, interactive sessions that incorporate supervised training in the cropping of 3D data sets and the interpretation of 3D echocardiograms lead to significant improvements in user expertise.[200] Thus, in addition to identifying specific indications where 3D TTE and TEE are critical, continued efforts at sonographer and physician "hands-on" training are necessary. Although 3D TTE image quality has not always been comparable to that of 2D TTE, the excellent image quality of 3D TEE has led to its rapid acceptance for specific indications such as assessment of mitral valve disease and guidance of intracardiac catheter-based interventions.

## Future Considerations

The key to the future of 3D echocardiographic imaging is continued technologic enhancements. Enhancements to transducer technology and computer processing will enable higher frame (volume) rate acquisitions with smaller matrix array transducers, and this should lead to improved image quality and color Doppler display. Such advances have already led to larger volume data acquisitions during a single cardiac cycle, and thus the current integration of several cardiac cycles for full cardiac 3D volume display will be a transition phase for the technique. The single cardiac cycle method will remove the artifacts observed with arrhythmias, respirations, and patient motion.

As 3D echocardiographic full-volume data acquisition becomes a routine part of the clinical work flow, there is the potential for shortened image acquisition time because a 3D volume of US containing all cardiac structures should be able to be imaged within just a few cardiac cycles from a few imaging windows. Additional time would then be spent on preparing the image sets for interpretation, mainly by cropping the views into image planes that best display the various cardiac structures. Efforts are now being focused on developing 3D TTE and TEE imaging protocols and standardized image cropping planes, and on training personnel for this image preparation and quantitation. In addition, enhancements to the 3D image display should lead to development of novel ways to view the images and the ability to perform "virtual dissections" through the image set both offline and in real time. Because echocardiography has superior temporal resolution compared to other noninvasive cardiac imaging modalities (some of which have superior spatial resolution), there is the potential to enhance noninvasive diagnostic and therapeutic cardiac imaging through fusion of modalities, such as cardiac MRI, computed tomographic imaging, or angiography with 3D echocardiography[201] (Fig. 4-23).

Clinical investigations comparing 2D echocardiography and 3D echocardiography continue to be required in order to demonstrate where there is incremental value of 3D

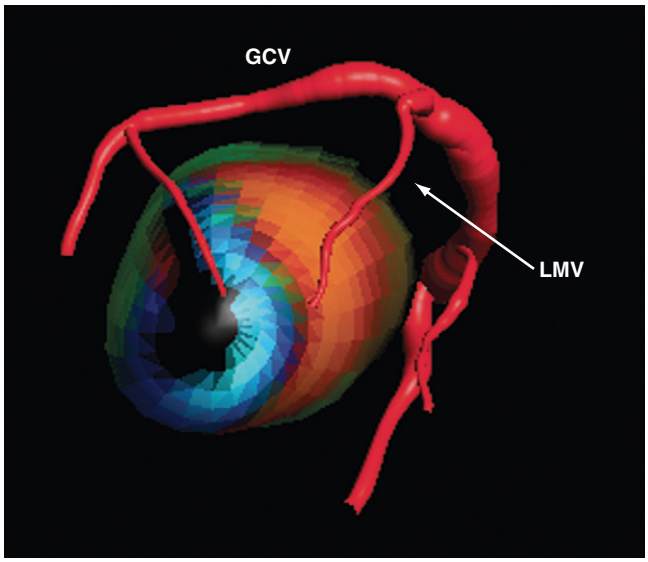

**Figure 4-23** An image integrating 3D TTE and 3D rotational coronary venous angiography viewed from the lateral apex of the LV. This example displays the LV dyssynchrony map (on a 3D echocardiographic volume of the LV) and the coronary venous anatomy before placement of pacing wires for cardiac resynchronization therapy. echocardiography for detection and quantification of specific cardiac pathologies and for improved patient care.

## Summary

3D echocardiography has many advantages over 2D echocardiography, including improved visualization of complex shapes and spatial relations between cardiac structures; improved quantitation of cardiac volumes, mass, and function; improved visualization of color Doppler flow fields; improved display and assessment of valve dysfunction and some structural cardiac lesions; and decreased time for image acquisition. Technical improvements, including enhanced TTE transducer design for better image quality from volumetric data sets and more automation of the image processing (cropping) protocol, are required for its widespread clinical use and for it to replace 2D TTE. 3D TEE by the volumetric method is relatively new, but because its image quality is superior to that of 3D TTE, it is being incorporated into clinical practice. 3D echocardiography continues to undergo dynamic evolution.

## KEY POINTS

- Understanding the complex shapes and spatial relationships of various cardiac structures is enhanced with 3D echocardiography.
- 3D echocardiography eliminates the need to assume a specific geometric shape of the LV or RV when quantifying volume and ejection fraction.
- 3D echocardiography has the potential to reduce the time required for echocardiographic image acquisition.
- 3D US can be acquired as either a series of 2D images requiring reconstruction into a 3D image or more commonly as a 3D volume of ultrasound.
- The volumetric technique requires a rectangular (matrix) array transducer. A small RT3D volume or a larger 3D full-volume composed of component images from several cardiac cycles can be displayed.
- Multiple 2D image planes can be obtained simultaneously with a matrix array transducer.
- 3D echocardiographic quantitation of LV volume, ejection fraction, mass, and RV volume are more accurate than the 2D approaches, and these measurements derived from 3D echocardiography have reduced measurement variability.
- In congenital heart disease, significant benefits of 3D echocardiography compared to 2D echocardiography have been noted in patients with atrial septal defect, ventricular septal defect, atrioventricular septal defects, and L-transposition of the great vessels.
- Continued enhancements to the current 3D technology will include higher volume or frame rate acquisitions to improve image quality and resolution. These are required for broader clinical application of the technology.
- 3D TEE has a role in real-time guidance of intracardiac catheter-based interventions such as patent foramen ovale/atrial septal defect closures, ventricular septal defect closures, LA appendage occlusion, transcatheter aortic valve implantation, and transcatheter mitral valve repair.

Intracardiac Ultrasound
Computed Tomography
Cardiac Magnetic Resonance Imaging
Multimodality Imaging
**The Catheterization Laboratory of the Future**

In the past few years, percutaneous interventions have been developed as alternatives to open heart surgery for the treatment of many structural heart diseases. Cardiac imaging plays a major role in patient selection, procedure guidance, and the short- and long-term follow-up of these patients. Both transthoracic (TTE) and transesophageal echocardiography (TEE) have unique attributes that facilitate their application in the catheterization laboratory, and they have become the main imaging tools in the management of most patients with structural heart disease (SHD).

Guidance of structural heart disease interventions requires that the echocardiographer understand the morphology and physiopathology of the SHD abnormality, be familiar with the catheterization laboratory environment, and recognize the echocardiographic and fluoroscopic appearance of the catheters and devices being used for the intervention. Images are obtained following structured protocols, ensuring completeness of the evaluation and facilitating the flow of the intervention. The echocardiographer must anticipate the imaging needs at each point of the intervention.

Echocardiographic imaging planes are frequently different from the fluoroscopic or angiographic planes used in the catheterization laboratory. Therefore, a common language needs to be established between the interventionalist and echocardiographer to designate directionality of the catheters and devices as they are advanced and deployed.

In this chapter we emphasize the role of echocardiography for guidance of SHD interventions.

## Structural Heart Disease

### DEFINITION

In its broadest definition, SHD refers to all cardiac disorders that are marked by abnormal cardiac structure and function. Thus, SHD encompasses valvular heart disease, congenital heart disease, and acquired disorders characterized by abnormalities of heart chambers, valves, myocardium, and cardiac function such as left ventricular (LV) aneurysm/pseudoaneurysm, pericardial disease, and all forms of myocardial disease[1-5] (Fig. 5-1).

### STRUCTURAL HEART DISEASE INTERVENTIONS

SHD interventions are distinguished from the two other large areas of interventional cardiology: coronary artery intervention (percutaneous coronary intervention, or PCI) and peripheral artery intervention. SHD intervention is a useful grouping for the specialty because these interventions require technical, imaging, and hemodynamic knowledge and skills that are distinctive from PCI and other vascular interventional skills. Training programs in interventional cardiology now describe SHD interventions as a unique component, continuing medical education conferences have separate sessions, and textbooks have emerged that are focused on SHD interventions,[6] all as a consequence of this uniqueness in clinical practice, knowledge base, and interventional skills.

SHD interventions involve image guidance that is fundamentally different from that used in PCI and other vascular

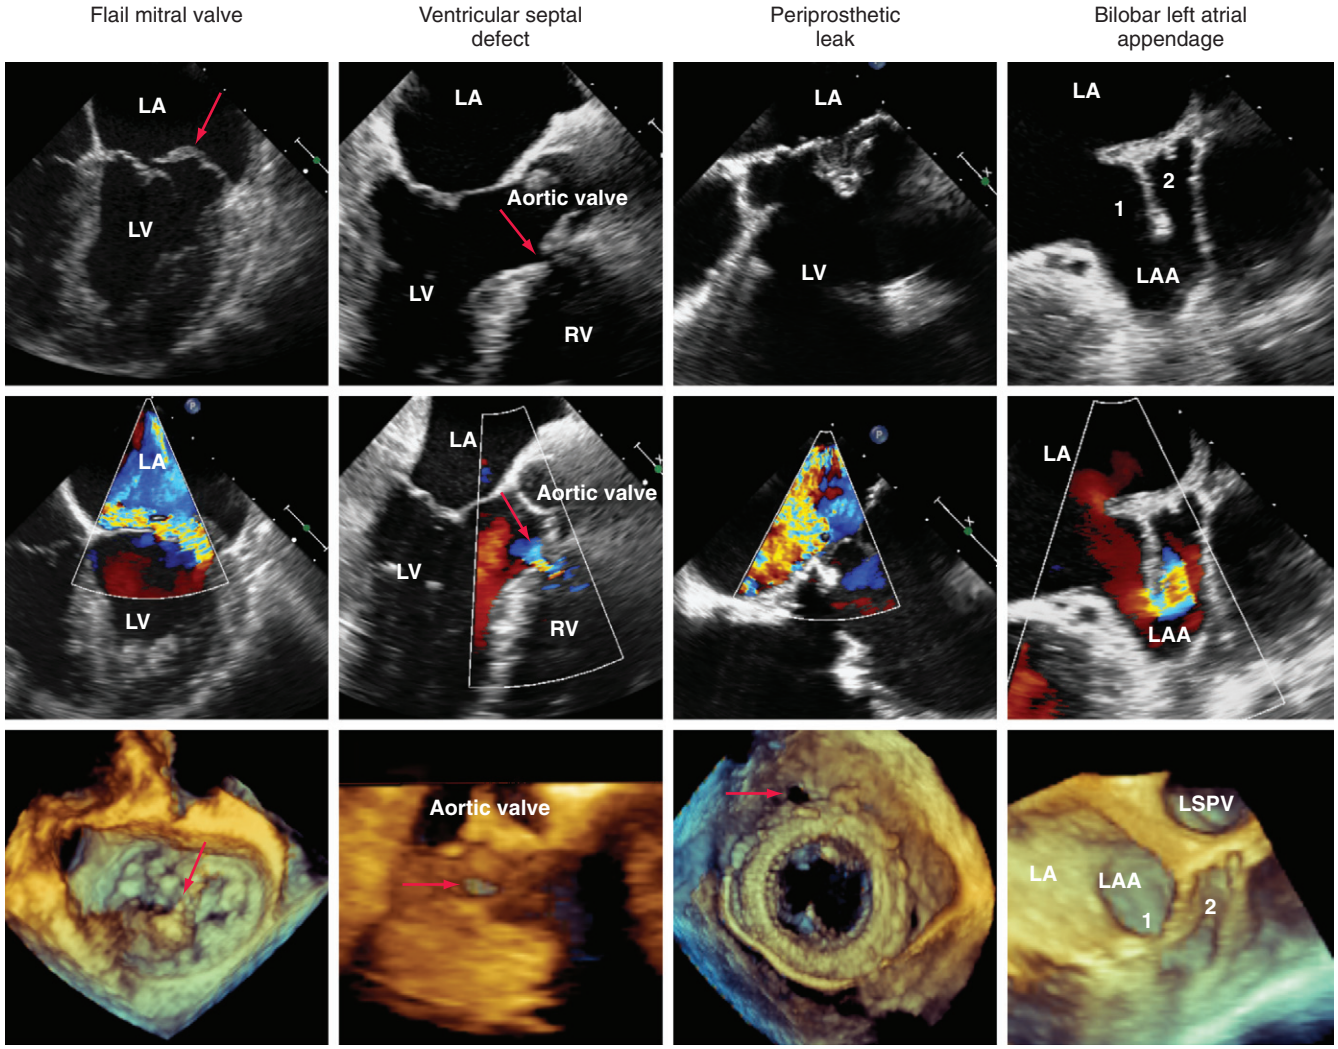

**Figure 5-1 Structural heart disease.** Typical examples of patients with structural heart disease referred for percutaneous interventions. The first patient has a flail posterior mitral leaflet (*arrows*) and was referred for mitral clip repair. The second patient has a perimembranous ventricular septal defect (VSD) (*arrows*) and was referred for percutaneous VSD repair. The third patient has a periprosthetic mitral valve leak (*arrow*) and two prior open heart surgeries and was referred for percutaneous repair. The fourth patient illustrates an anatomic variant of the left atrial appendage (*LAA*), in this case bilobar (*1,* primary lobe; *2,* secondary lobe), this being an important consideration for the use of an LAA occluder. *LSPV,* Left superior pulmonary vein.

interventions. PCI is solely guided by x-ray fluoroscopy and coronary angiography. On the other hand, image guidance of SHD interventions often requires an additional modality—typically cardiac ultrasound (Table 5-1). The form of ultrasound varies by the procedure being performed, but also by local expertise, experience, and the techniques available. TEE and intracardiac echocardiography (ICE) are the two forms of cardiac ultrasound commonly used, whereas TTE is a third form used less frequently in adults because of suboptimal image quality in many patient undergoing SHD interventions.

During an intervention, ultrasound imaging and Doppler hemodynamic assessment are used diagnostically to assess the abnormal structure and function before and after the intervention and assess other relevant structures and physiologic parameters. Both techniques are also critical to manage complications.[7] In the flow of most SHD interventions, imaging makes the transition back and forth from its diagnostic utility to its true image guidance use.

**TABLE 5-1 Cardiac Ultrasound Properties That Promote Its Use in SHD Interventions**

| *Cardiac Ultrasound Properties* | *Importance to SHD Interventions* |
|---|---|
| Excellent temporal and spatial resolution of soft tissue | The target of many interventions is soft tissue (valves, chamber walls), and these are not visualized by x-ray except during angiography, which cannot be repeatedly used. |
| No harmful effects of ultrasound energy | Efforts to minimize the use of ionizing radiation from x-ray are facilitated by substituting ultrasound guidance for various tasks performed during the procedure. |
| Doppler and echocardiographic visualization and quantification of flow abnormalities, chamber function, and valve function are accurate and broadly accepted as gold standards | Intraprocedure assessments of cardiac function, shunts, and valve function are required in most interventions; need to be repeated; and may replace or complement catheter-based pressure measurements, oximetric determination of shunt location and quantification, and thermodilution measurement of cardiac output. |

*SHD,* Structural heart disease.

**TABLE 5-2 Main Imaging Modalities Used to Assist Structural Heart Disease Interventions**

| | *Frequency of Use* | *Advantages* | *Disadvantages* |
|---|---|---|---|
| Fluoroscopy and cineangiography | ++++ | Current gold standard | Radiation<br>No soft tissue characterization |
| Intracardiac echocardiography (ICE) | ++ | No radiation<br>High-resolution soft tissue characterization | Poor resolution in far fields<br>No 3D rendering |
| Transthoracic echocardiography (TTE) | ++ | Noninvasive<br>No radiation<br>Soft tissue characterization | Limited echo windows<br>Adds complexity to procedure<br>Additional personnel required |
| Transesophageal echocardiography (TEE) | +++ | No radiation<br>High-resolution soft tissue characterization<br>3D imaging rendering possible | Semiinvasive<br>Adds complexity to procedure<br>Additional personnel required |

### FLUOROSCOPY AND CINEANGIOGRAPHY

Fluoroscopy is the major real-time imaging modality used in all SHD interventions. Transcatheter or percutaneous interventions of the heart require the interventional cardiologist to first access the circulation via a peripheral artery or vein and then navigate wires, catheters, delivery systems, and other specialized tools to the heart. These procedural tasks are almost exclusively performed with fluoroscopy. Once the heart is reached, image guidance often becomes a multimodality affair for SHD interventions. Fluoroscopy and echocardiography are used together or in an alternating fashion (Table 5-2).

Fluoroscopy remains the major imaging modality for SHD interventions for multiple reasons, starting with its ability to provide global or large-field guidance for the navigation of equipment. With table panning and large field-of-view flat detectors, the interventional cardiologist can track the course of catheters and devices from the distal access point to any place within the heart. In addition, fluoroscopy is essential because all diagnostic and interventional supplies are radiopaque. The design and choice of material for equipment has historically been done to optimize x-ray visualization. Fluoroscopy is also the principal imaging modality because it is so widely available, physicians have been trained and gained extensive experience using it, and the x-ray system has many features and imaging tools that further enhance the utility of x-ray imaging.

As an imaging modality, fluoroscopy has many strong features. It is real time and provides the continuous feedback essential for performing an intervention. It has a high spatial and temporal resolution critical for cardiac work. Although fluoroscopy is two-dimensional (2D) and produces a projection or "shadow" image, in skilled hands it allows the determination of device position relative to anatomic landmarks and interventional targets. Certain SHD targets are in fact apparent on fluoroscopy (e.g., a calcified aortic valve). Finally, it is a modality that is simple to set up and use in the procedure room.

Cineangiography has been used for decades in the diagnosis and quantification of many forms of SHD. Ventriculography, aortography, and other selective chamber/vessel injections have been the first techniques used to diagnose all of SHD. In the era of SHD interventions, cineangiography is still used in a focused fashion but does not have a central role because of several key facts. First, angiographic contrast dye is an acute osmotic load, may be nephrotoxic, and must be injected in large volumes to clearly show the features of SHD. Second, it cannot be repeated numerous times. Third, it produces 2D projection images that often misrepresent the complex three-dimensional (3D) relationships of key structures in SHD.

The focused use of cineangiography is still common in certain interventions such as left atrial appendage occlusion, transcatheter aortic and pulmonic valve implantation, and ventricular septal defect closure. Cineangiography is intertwined with the use of fluoroscopy to perform certain tasks of the intervention. Cineangiographic images provide a road map for fluoroscopic guidance and also help determine the optimal projection that is needed for a specific step of an intervention. Note that this function of cineangiography is not readily replaced by using ultrasound.

Cineangiography is not a static technique, and important developments are leading to a rebirth of angiography in general.[8] Rotational angiography is a new acquisition technique that has now been coupled with 3D reconstruction algorithms. The traditional 2D x-ray tools of fluoroscopy and cineangiography are being supplemented by C-arm computed tomographic (CT) techniques that convert the imaging system into a CT scanner capable of imaging soft tissue. These volumetric 3D data sets or preprocedure acquired cardiac CT scan data can be registered or fused with fluoroscopy to provide a more powerful imaging guidance tool for SHD interventions.[9] These developments have profoundly changed neurointerventions and many interventional radiology procedures.[10] The cardiac applications are emerging later because of the challenge of imaging the heart's rapid motion and the precision needed in interventions within this complex structure.[11]

## Echocardiographic Guidance of Structural Heart Disease Interventions

### ECHOCARDIOGRAPHIC MODALITIES

All of the echocardiographic methods used in the echocardiographic laboratory[7,12-16] can be used in the catheterization laboratory for the guidance of SHD interventions. The approach to obtain this information is through either TTE or TEE. The selection of either approach depends on the intervention to be performed, the need for endotracheal intubation, and the quality of the TTE windows. Because of the increased spatial resolution of TEE, we favor its use for all patients who require endotracheal intubation and in all patients with suboptimal transthoracic windows. The development of real-time 3D echocardiography has opened a new window into the heart and has been particularly useful in the guidance of SHD interventions; currently all of our TEE-guided interventions are performed with 3D TEE. The new 3D TEE technology allows for switching from 2D to 3D and color imaging, which is of great value to obtain all required information immediately preceding the intervention and for procedural guidance (Fig. 5-2).

## Assisting with Access Routes

The initial role of echocardiography in the catheterization laboratory for guidance of SHD interventions is in facilitating the access of guidewires, catheters, and devices into the appropriate vessel and cardiac chamber. Although fluoroscopy is the main imaging tool for this purpose, real-time ultrasound guidance

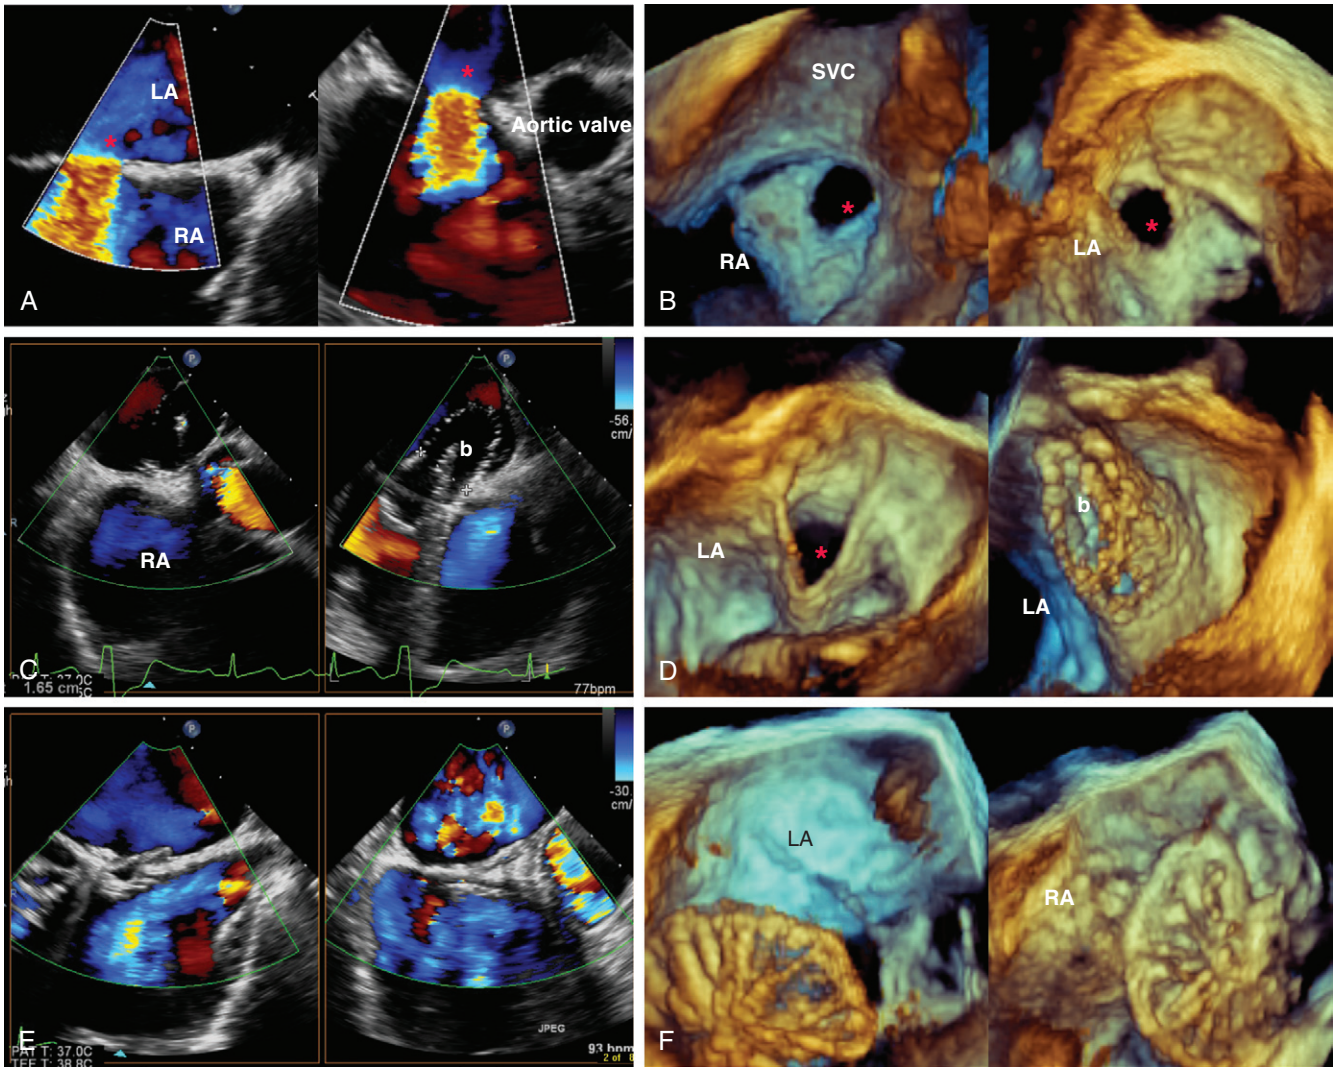

**Figure 5-2 TEE applications in structural heart disease interventions.** With real-time 3D TEE, it is now possible to alternate 2D (x-biplane) and 3D presentations. In this patient undergoing percutaneous closure of a secundum atrial septal defect (*), simultaneous biplane color images are presented in panels **A,** preprocedure, **C,** balloon sizing, and **E,** post–device deployment. Presentations on 3D are illustrated in panels **B,** preprocedure, **D,** balloon sizing, and **F,** post–device deployment. *b*, Balloon; *SVC*, superior vena cava.

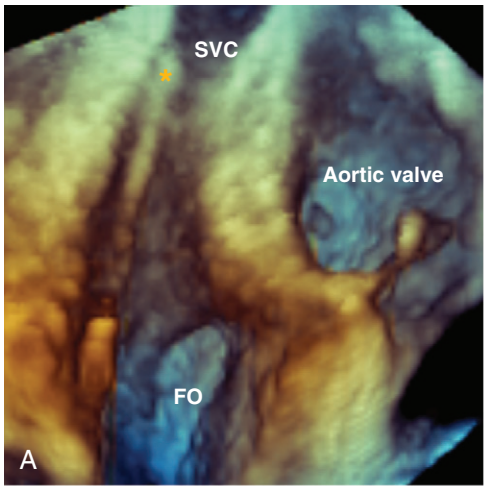
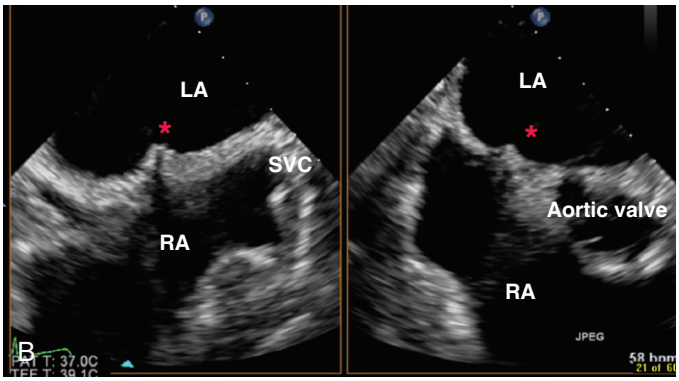
reduces time to access, number of attempts, and complications in central venous access, as well as providing improved common and superficial femoral artery cannulation.[17,18]

## Transseptal Catheterization

Since the original description of transseptal left heart catheterization as a new diagnostic method by Ross[19] more than 50 years ago, transseptal catheterization has become an integral part of SHD interventions.[20,21] The technical aspects on how to perform a successful transseptal catheterization have been well described in the literature[22,23]; the role of echocardiography in assisting this initial step of SHD interventions has also been demonstrated and is illustrated in Figure 5-3.



## Transapical Catheterization



Direct cardiac puncture to access the LV has been traditionally used when operators were concerned about crossing the native aortic or mitral valves,[24] or more recently in the presence of simultaneous mechanical aortic and mitral prosthesis.[25] Patients with SHD who are candidates for transapical catheterization include those undergoing percutaneous aortic valve replacement and those with paravalvular mitral prosthetic leaks.[26]

## Recognizing and Analyzing Catheters and Devices with Echocardiography

The echocardiographer assisting with structural heart disease interventions needs to be familiar with the equipment required for the intervention. A complete description of each piece of equipment required for the performance of SHD interventions is beyond the scope of this chapter; however, a general understanding of the types, function, and fluoroscopic and echocardiographic appearance of these catheters and devices is essential for successfully assisting SHD interventions. Table 5-3 summarizes the main items used in percutaneous SHD interventions, and Figures 5-4 and 5-5 illustrate the fluoroscopic and echocardiographic appearance of selected catheters and devices.

It is also important to recognize pitfalls and common echocardiographic artifacts seen during structural heart disease interventions, as illustrated in Figure 5-6.

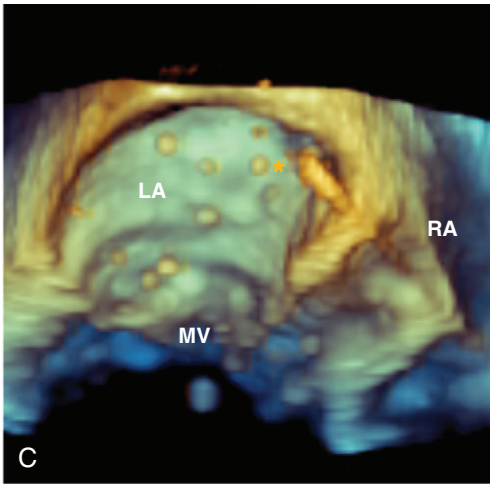


**Figure 5-3 Septal puncture.** Both 2D and 3D methods can be used to provide septal puncture guidance. **A,** 3D TEE view of the interatrial septum as seen from the right atrium. The tip of the guiding catheter (*yellow asterisk*) is in the superior vena cava (*SVC*) and will need to be withdrawn to the level of the fossa ovalis (*FO*). Once in the fossa ovalis, biplane 2D imaging (**B**) permits visualization of the "tenting" (*red asterisk*) and puncture of the membrane of the FO—inferior to the SVC and posterior to the aorta. **C,** 3D imaging illustrates the dilator (*yellow asterisk*) in the LA and microbubbles in the LA cavity, confirming correct positioning of the catheter.

## Specific Structural Heart Disease Interventions

The general classification of structural heart disease interventions, the approval status of different devices in use, and common image guidance modalities are shown in Tables 5-4, 5-5, and 5-6.

**TABLE 5-3 Common Equipment Used in Structural Heart Disease Interventions**

| | |
|---|---|
| Guidewires | Soft J-tipped wires<br>Stiff wires<br>Glide wires<br>Steerable wires |
| Sheath/dilator sets | Introductory sheath/dilator sets<br>Long delivery sheath/dilator sets |
| Diagnostic catheters | Extruded catheters<br>Floating balloon catheters<br>Woven Dacron catheters |
| Transseptal catheterization apparatus | Guidewire<br>Mullins introducer (sheath and dilator)<br>Brockenbrough needle and stylet |
| Balloon dilation catheters | Inoue balloon |
| Endovascular stents | Large vessel stents (>12 mm)<br>Medium size vessel stent (6-12 mm) |
| Closure devices | Amplatzer ASD, PFO, PDA,VSD, and vascular plug (AGA Medical, Plymouth, Minn.)<br>CArdioSEAL, STARFlex and BioSTAR (NMT Medical, Boston)<br>Helex (W.L. Gore Associates, Flagstaff, Ariz.)<br>Premere (St Jude Medical, St. Paul, Minn.) |

*ASD,* Atrial septal defect; *PDA,* patent ductus arteriosus; *PFO,* patent foramen ovale; *VSD,* ventricular septal defect.

**TABLE 5-4 SHD Interventions of Septal Defects**

| *SHD Intervention Category* | *Status 2011* | *Image Guidance Modalities Commonly Used* |
|---|---|---|
| **Interatrial Septum Interventions** | | |
| Secundum atrial septal defect | Approved devices | Fluoroscopy and TEE or ICE |
| Fenestrated atrial septum | Approved device | Fluoroscopy and TEE or ICE |
| Patent foramen ovale | Approved devices OUS, off-label use of approved devices in US | Fluoroscopy and TEE or ICE |
| Atrial balloon septostomy | Off-label use of approved balloon catheters | Fluoroscopy alone or with TEE, TTE, or ICE |
| Transseptal catheterization | Approved catheters, needles, and RF ablation catheters | Fluoroscopy alone or with TEE or ICE |
| **Interventricular Septum Interventions** | | |
| Congenital muscular VSD | Approved device | Fluoroscopy and TEE |
| Congenital perimembranous VSD | Experimental, predominantly preclinical | Fluoroscopy and TEE |
| Post–myocardial infarction VSD | Approved device OUS, IDE device in US available for compassionate use | Fluoroscopy and TEE |

*ICE,* Intracardiac echocardiography; *IDE,* investigational device exemption; *OUS,* outside United States; *RF,* radio frequency; *VSD,* ventricular septal defect.

## CLOSURE OF INTRACARDIAC COMMUNICATIONS

### *Atrial Septal Defects*

The presence of symptoms, echocardiographic findings of right ventricular (RV) volume overload, or the presence of shunt-related pulmonary hypertension are accepted indications for atrial septal defect (ASD) closure.[27,28] Surgical closure is required for patients with ostium primum and sinus venosus ASDs, as well as for patients with secundum ASDs whose anatomy is unsuitable for device closure. (See Chapter 44.)

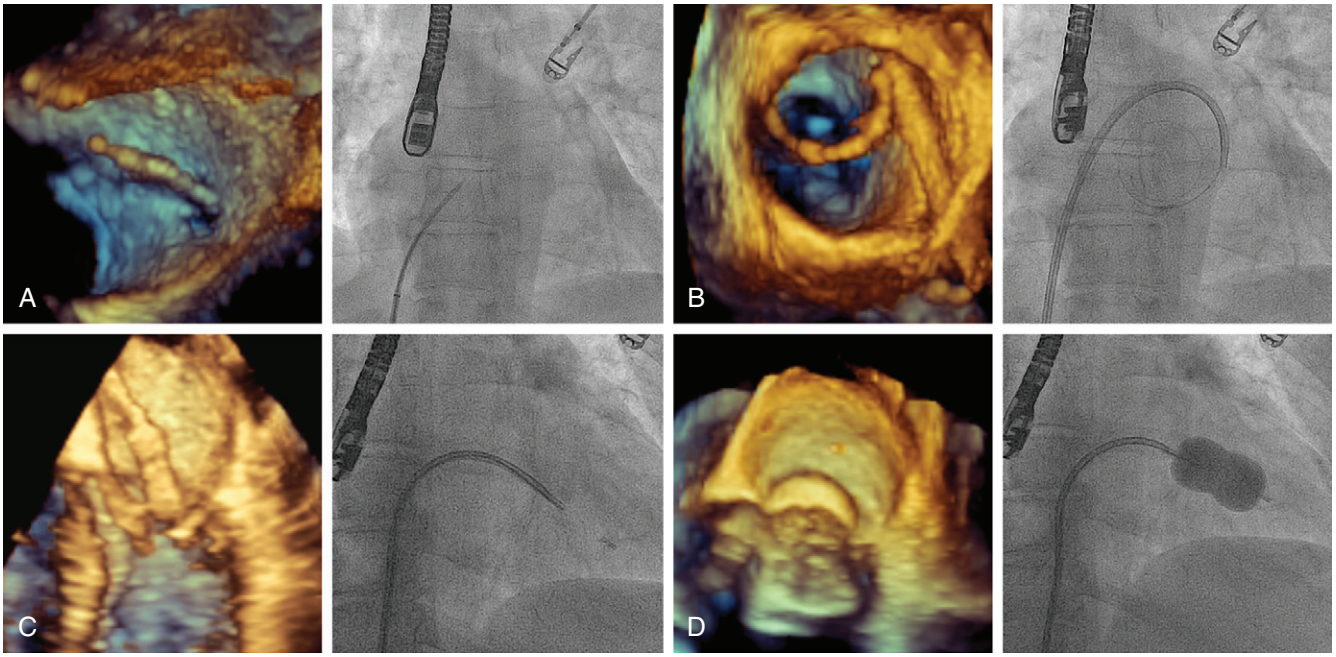

**Figure 5-4 Echo (3D TEE) and fluoroscopic appearance of catheters and devices in mitral valve balloon valvotomy. A,** Guidewire entering the left atrium. Note the lack of soft tissue characterization of the fluoroscopic image. **B,** Delivery catheter and a guidewire have been advanced and rolled into LA. **C,** Deflated balloon is near the orifice of the mitral valve. **D,** Inflated balloon is seen dilating the mitral valve orifice.

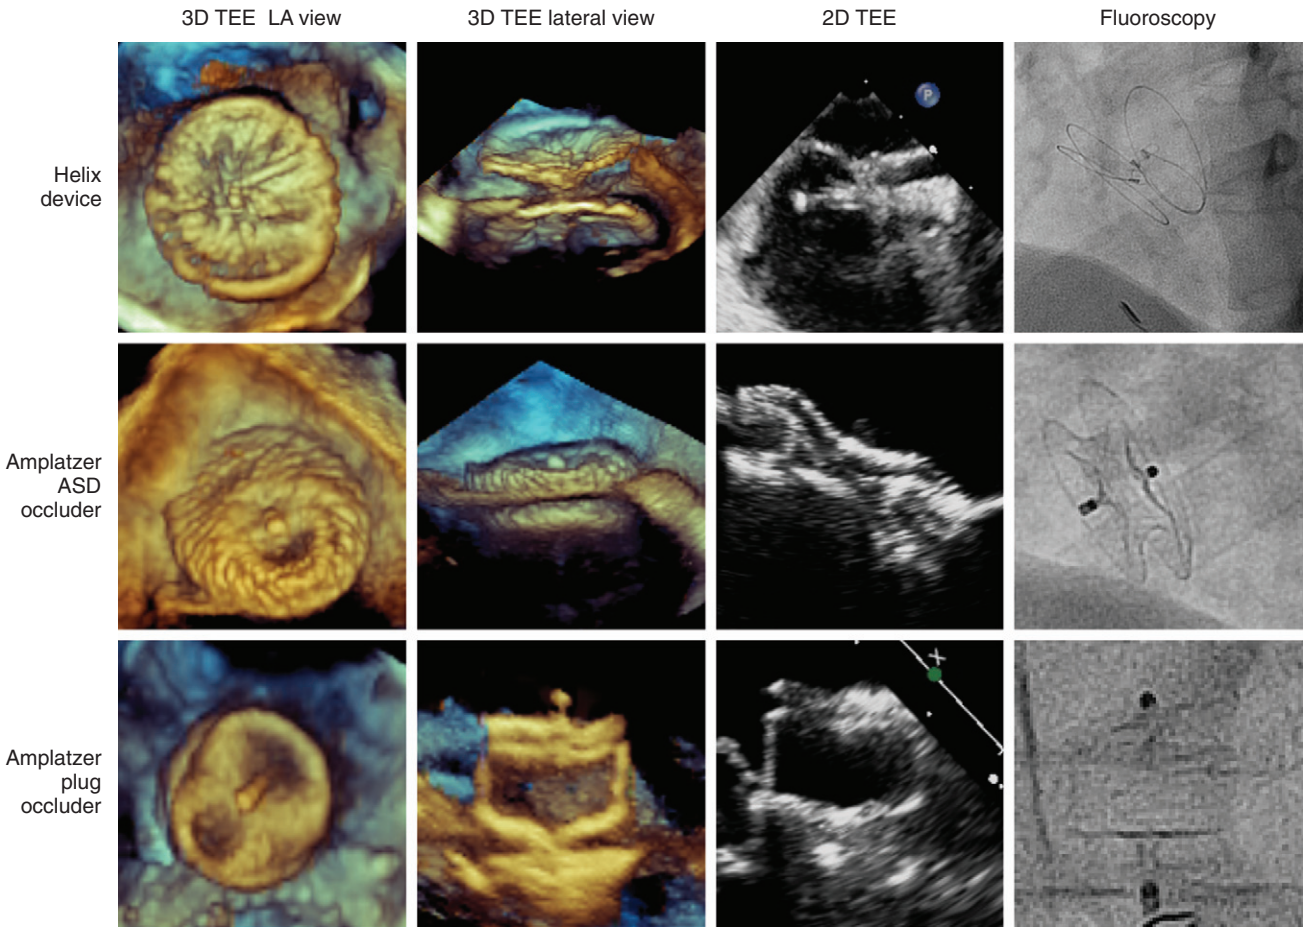

**Figure 5-5 Occluders.** For three different occluder devices, the enhanced spatial resolution of the 3D TEE images is contrasted with the 2D images provided by 2D TEE and fluoroscopy.

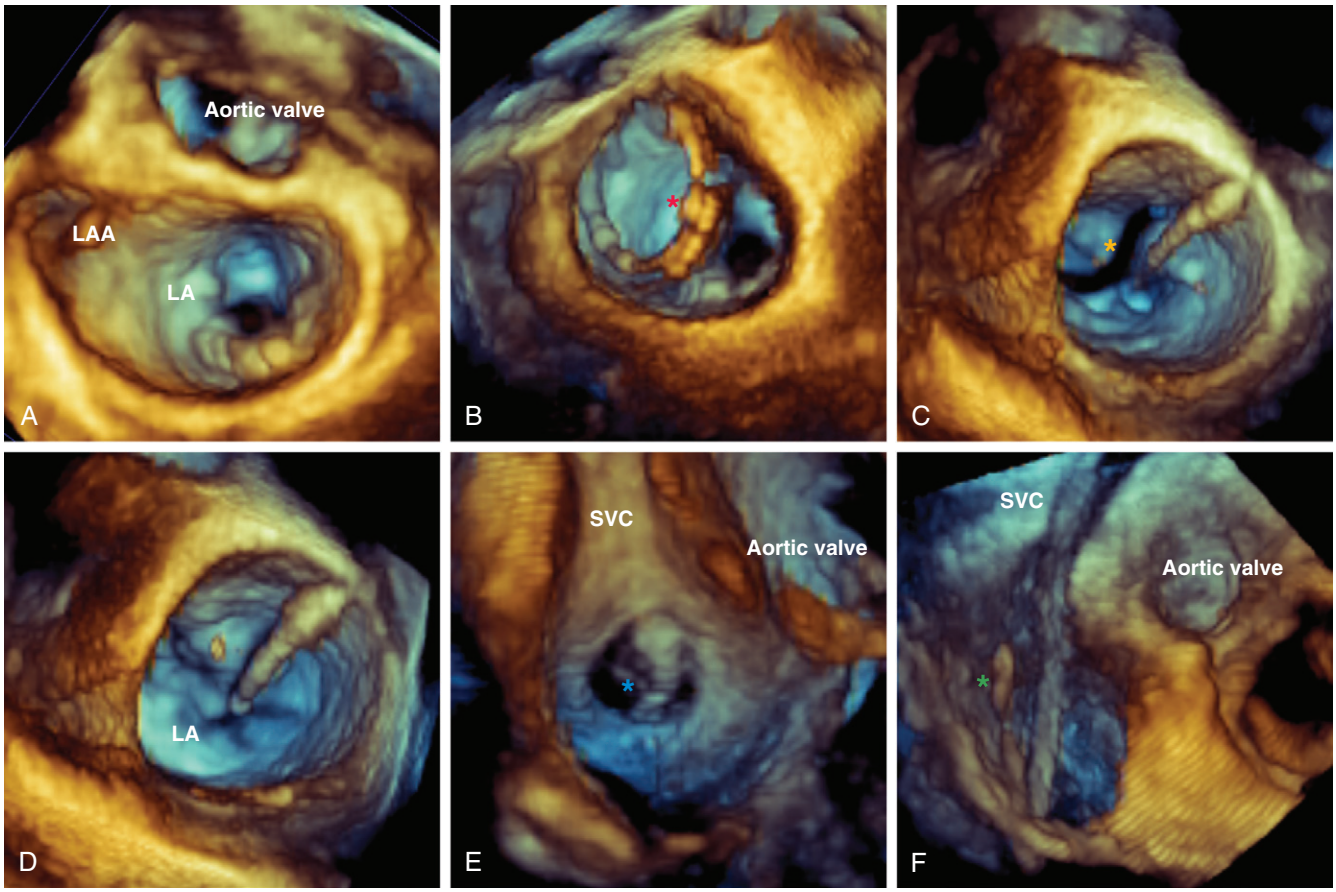

**Figure 5-6** **3D TEE artifacts during structural heart disease interventions. A,** En face view of a stenotic mitral valve. Guidewire in the LA is not seen because it is in a plane superior to the selected plane of view. **B,** By slightly withdrawing the TEE probe, the guidewire comes into view and is easily identified (*red asterisk*). **C,** Black S-shaped line (*yellow asterisk*) that on motion appears as a large fissure in the mitral valve, but in reality represents a shadowing artifact from a catheter in the LA. **D,** A slight rotation of the tomographic plane eliminates the artifact. **E,** The membrane of the fossa ovalis appears to have a hole (*blue asterisk*), giving the illusion of an atrial septal defect when in reality there is none. Changing the gain or looking from a different perspective clarifies the problem. **F,** "Ghost" artifact (*green asterisk*) with the appearance of two catheters in the RA when in reality there was only one. *LAA*, Left atrial appendage; *SVC*, superior vena cava.

The first percutaneous ASD closure was reported by King and colleagues[29] in 1976; this method has now become the preferred treatment for hemodynamically significant secundum-type ASD. Percutaneous ASD closure can be performed safely and with minimal risk even in elderly patients.[30] They profit in terms of symptom reduction, improvement of exercise capacity, and right-heart remodeling.[31]

Echocardiography provides substantial information regarding the characteristics of ASDs.[32] TEE is the favored imaging tool to select patients for percutaneous ASD closure and to guide the intervention. Of particular relevance to ASD closure is the characterization of the ASD rims, defined as the interatrial tissue surrounding the ASD and named after the cardiac structure adjacent to it: superior vena cava rim (superior), aortic rim (anterosuperior), coronary sinus rim (anteroinferior), inferior vena cava rim (inferior), and posterior rim. Inferior rims less than 5 mm in length make patients unsuitable for device closure. Likewise, an ASD more than 35 to 36 mm in diameter has a higher incidence of device embolization, and surgical closure is preferred. ASD sizing is an important aspect of intraprocedural TEE evaluation and is usually accomplished by direct measurement of the defect or by measuring the "waist" diameter of an ASD sizing balloon inflated until the color flow determines absence of shunt.

The TEE protocol we currently use for transcatheter ASD closure guidance include 2D imaging, 2D imaging with color, and 3D imaging. We use the "zoom 3D" mode to guide catheters and the device through the ASD as well as for guidance of the initial deployment of the left atrium hemidisk. For the deployment of the right atrium hemidisk, we use 2D imaging or simultaneous biplane (x-plane) 3D imaging. Color 2D imaging is used to verify absence of residual shunting before releasing the device (Figs. 5-7 and 5-8).

Cardiac CT angiography is an accurate and useful technique for preprocedural assessment of ASDs and may be superior to conventional TEE in large defects that have deficient inferior rims.[33]

### *Patent Foramen Ovale*

A large body of circumstantial evidence, including reports showing an actual embolus traversing the patent foramen ovale (PFO), epidemiologic association, and case-control series, links PFO to cryptogenic strokes.[34] (See Chapter 41.) The echocardiographic diagnosis of PFO and the characterization of "high-risk" subgroups including PFO size and presence of interatrial septal aneurysm and embryonic recesses have been well described in the literature.[35] Recently the added value of 3D TEE to define the morphologic phenotypes of PFO has been

described.[36] A PFO is categorized as "complex" when any of the following findings is present: long tunnel length (8 mm or more), multiple openings into left atrium, atrial septal aneurysm, hybrid defect (PFO and additional defects in the fossa ovalis), thick secondary septum (10 mm or more), presence of a Eustachian ridge or valve, and presence of a Chiari network. If none of these findings is present, the PFO is categorized as "simple."[36] In addition, the importance of a structured and systematic echocardiographic evaluation of the interatrial septum, in patients being considered for percutaneous PFO closure, has been described.[37,38] The percutaneous closure of a PFO can be guided with fluoroscopy, with ICE, or with TTE or TEE. At our institution, most PFO closures are done under fluoroscopic and ICE imaging. In patients with large or complex PFO, TEE is used to define interatrial septal anatomy (Fig. 5-9), to determine the size and type of the device to be used, and to assist with device deployment.

The TEE protocol we use for PFO closure is similar to the one described for ASD closure. Echocardiography also plays an important role in detecting and managing periprocedural complications such as cardiac perforation, device embolization, device thrombosis, device erosion, and arm fracture.[39]

### *Ventricular Septal Defects*

Ventricular septal defects (VSDs) are common congenital heart defects in children and adults. The majority (70% to 80%) involves the membranous septum and the adjacent portion of the muscular septum and are called perimembranous VSDs (see Chapter 44). Muscular VSDs account for 10% to 15% of all VSDs and can be apical, midseptal, anterior, or posterior defects. Although the standard treatment for perimembranous VSD is open heart surgery, catheter-based approaches for their closure have been shown to be an attractive alternative to surgical closure with acceptable mortality and morbidity as well as encouraging results.[40,41] Yang and co-workers recently reported their experience with percutaneous perimembranous VSD closure in 848 patients, 110 of whom were more than 20 years of age.[42] All patients were screened by conventional 2D and color Doppler TTE. These authors noted that although TEE is the imaging modality most frequently used to guide transcatheter perimembranous VSD closure, TEE was used only in the early stages of their experience and was gradually replaced by TTE combined with angiography.

Development of a VSD is a rare (1% to 2%) but serious complication of transmural myocardial infarction. The incidence of post–myocardial infarction VSD has decreased significantly with thrombolytic therapy,[43] yet morbidity and mortality

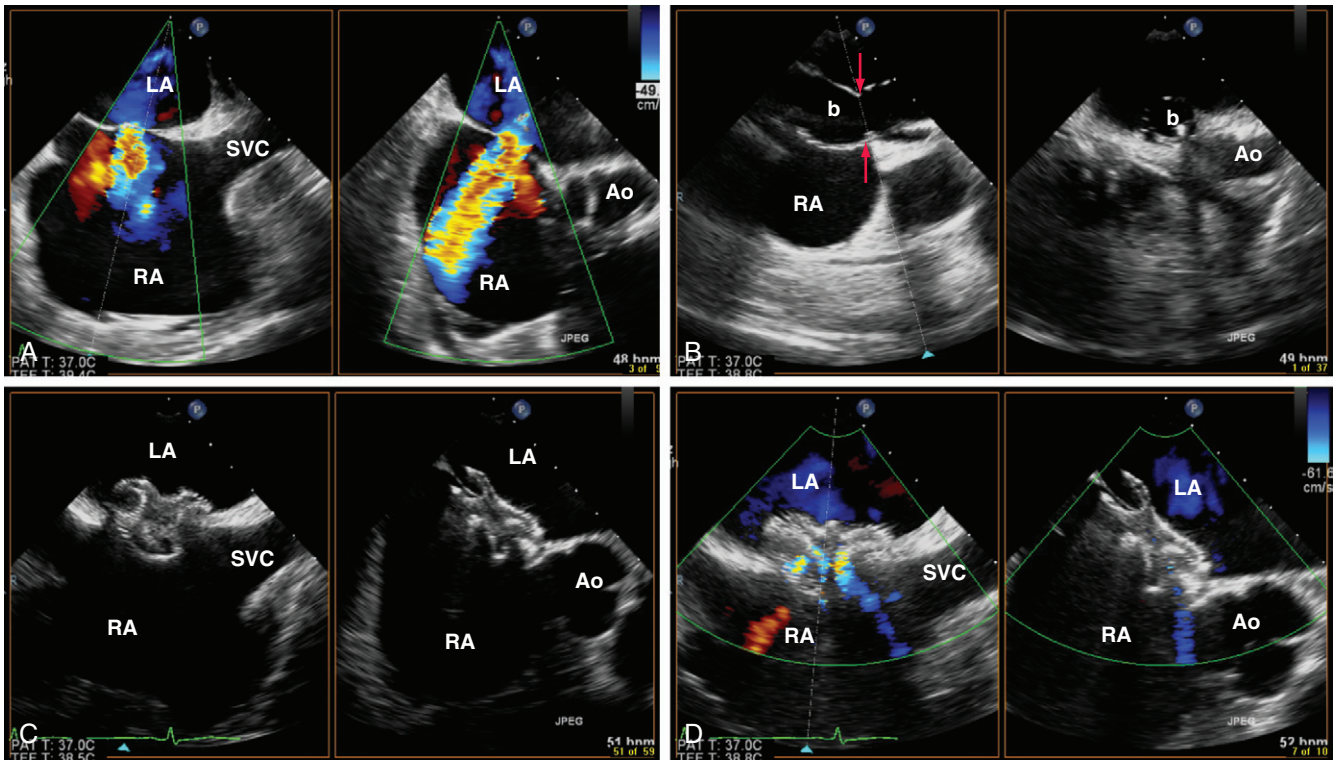

**Figure 5-7 Biplane 2D TEE atrial septal defect device (ASD) closure.** Real-time x-plane TEE (biplane images derived from 3D data sets) during a percutaneous ASD closure. **A,** *Color:* Shunt from the LA to the RA. **B,** The inflated sizing balloon (*b*) is seen in long and short axis with the "waist" marked by *arrows*. This dimension is used to estimate the device size to be used. **C,** Both hemidisks of the Amplatzer device have been deployed. **D,** Color Doppler shows small degree of shunting through the device (normal finding) and absence of peridevice shunt. *Ao*, Aorta; *SVC*, superior vena cava.

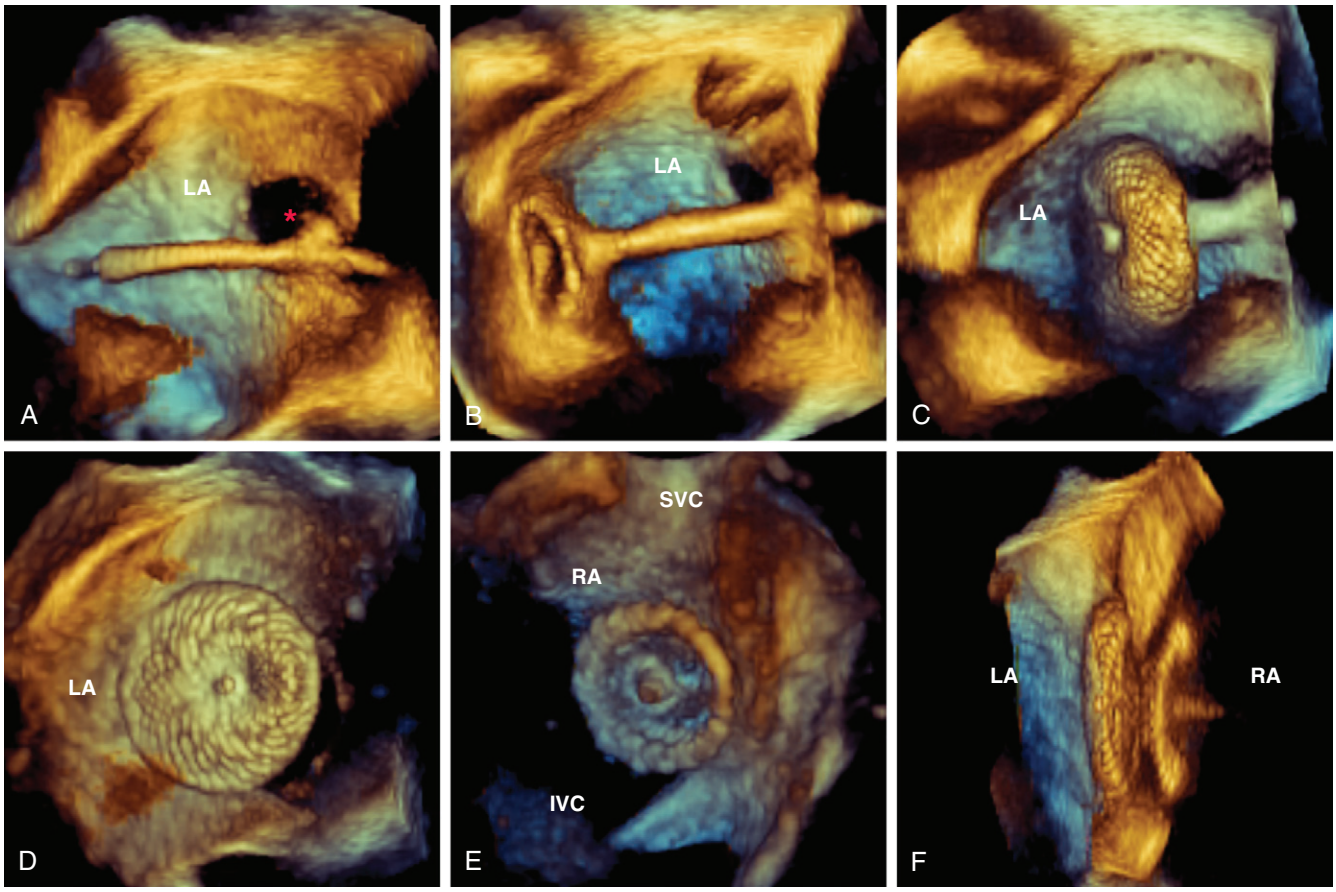

**Figure 5-8 3D TEE guidance of Amplatzer atrial septal defect (ASD) closure device.** All views are zoom 3D images of the interatrial septum as seen from the LA (panels **A** through **D**), from the RA (**E**), or from an anteroposterior perspective (**F**). **A,** Delivery catheter is seen in the LA entering through the ASD (*red asterisk*). **B,** LA disk is being deployed. **C,** LA disk is fully deployed and catheter is pulled back. **D,** Catheter is pulled back until the left hemidisk abuts the interatrial septum. **E,** Right hemidisk is deployed and sits in the RA inferiorly to the superior vena cava (*SVC*) and superiorly and anteriorly to the inferior vena cava (*IVC*). **F,** Device is seen in profile with one hemidisk in the LA and the other in the RA.

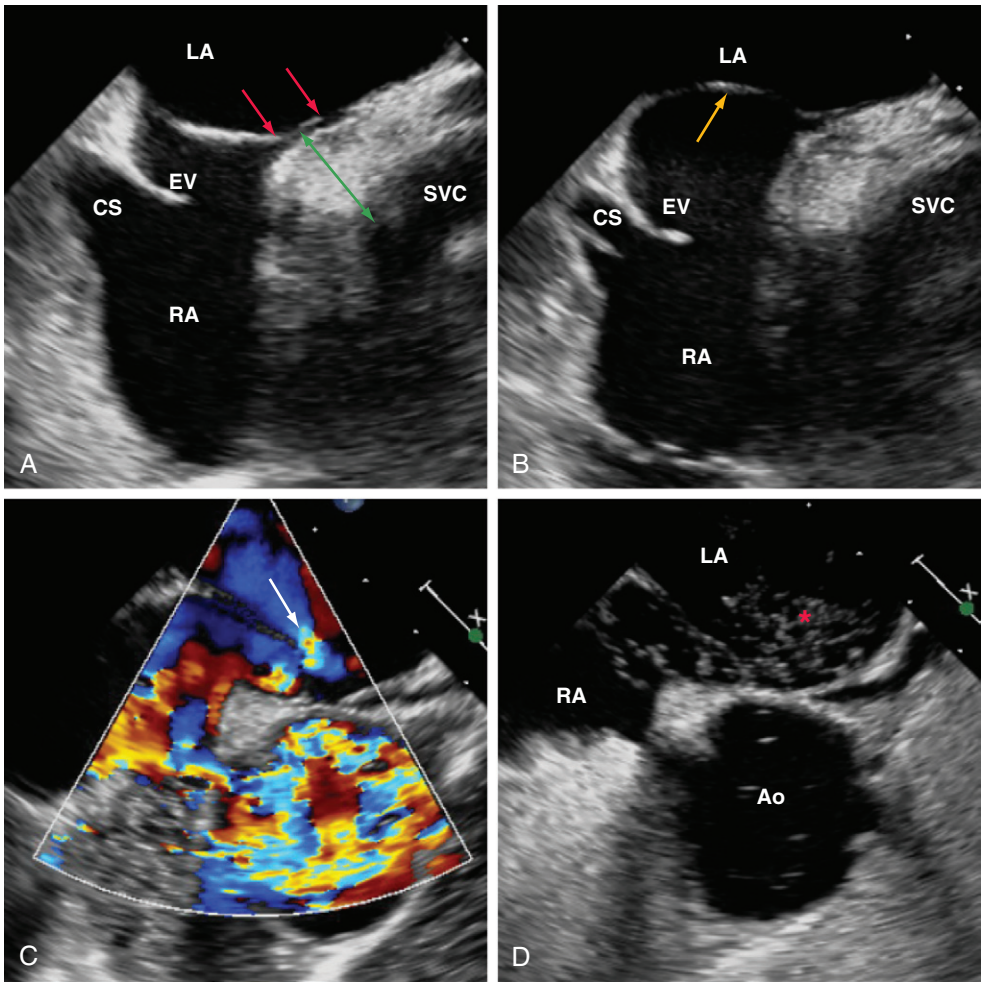

**Figure 5-9 TEE evaluation of patent foramen ovale (PFO).** Key points to be noted in the evaluation of PFOs being considered for device closure. **A,** *Red arrows* demark the length of the PFO tunnel. A thickened septum secundum (*green arrow*) next to the superior vena cava (*SVC*). A prominent Eustachian valve (*EV*) is seen next to the coronary sinus (*CS*). **B**, Interatrial septum (*yellow arrow*) as it moves into the LA. This excessive excursion denotes the presence of an interatrial septum aneurysm. **C,** Interatrial shunt (*white arrow*) as seen with color Doppler. **D,** Microbubbles (*) entering the LA from the RA through the PFO. *Ao*, Aorta.

remain high. (See Chapter 14.) Surgical repair[44] is difficult because of friable and necrotic tissue and can be complicated by persistent shunt or a recurrent VSD. Percutaneous catheter-based closure techniques have therefore been developed and are now frequently used to treat these patients.[45-47] The aim of the percutaneous procedure should be complete closure or at least a major reduction in the left-to-right shunt with normalization of hemodynamics.[48]

The deployment of a VSD closure device requires the creation of an arteriovenous wire loop. A guidewire is introduced in a femoral artery; it is advanced trough the aorta and aortic valve into the LV. Through the VSD, the wire is advanced into the RV and right atrium, and it is finally steered into the superior vena cava and pulled out through the internal jugular vein. TEE complements fluoroscopy in guiding the wire to create the arteriovenous loop and then advancing the delivery catheter and deploying the closure device. TEE is particularly helpful in aligning the closing device parallel to the long axis of the interventricular septum and outside of the VSD tract. We have found that 3D TEE helps clarifying the complex morphology of post–myocardial infarction VSDs and currently is our preferred imaging tool to guide percutaneous VSD closures.

## AORTIC VALVE INTERVENTIONS

### *Balloon Aortic Valvuloplasty*

Surgical aortic valve replacement is the treatment of choice for severe symptomatic calcific aortic stenosis in adults. (See Chapter 23.) However, patients with advanced age, hemodynamic instability, or multiple comorbidities often carry an unacceptably high operative risk and can be considered for balloon aortic valvuloplasty. There are two different approaches to reach the aortic valve for balloon aortic valvuloplasty—the retrograde approach by arterial access through the aorta (most commonly used) and the antegrade approach by venous transseptal access.[49]

Balloon aortic valvuloplasty has long been used as a treatment modality in children and adolescents with valvular aortic stenosis.[50] In addition, in children and young adults, the

systematic use of Doppler echocardiography guidance for balloon aortic valvuloplasty interventions is feasible and is associated with high success and very low complication rates. Compared to historical series of balloon aortic valvuloplasty guided by angiography, patients who undergo balloon aortic valvuloplasty with echocardiographic guidance have a significant reduction of fluoroscopic time and a tendency to a lower incidence of significant aortic regurgitation.[51]

In adults, balloon aortic valvuloplasty is useful as palliative treatment for symptomatic relief in elderly patients with severe calcific aortic stenosis who are deemed inoperable.[52,53] Balloon aortic valvuloplasty can be used as a palliation or bridge to definitive therapy in patients with severe aortic stenosis who are poor candidates for surgery.[54] It is associated with good medium-term outcomes in this very high-risk population group and enables some patients to receive definitive therapy in the future.[55] In these patients, echocardiography provides information regarding preprocedure and postprocedure LV ejection fraction, mean gradients, and presence and severity of aortic regurgitation.

### *Transcatheter Aortic Valve Implantation*

Transcatheter aortic valve implantation (TAVI) is maturing as an interventional technique for the treatment of severe symptomatic aortic stenosis.[56-63] The procedural results continue to improve, in part through the use of multidisciplinary teams, including cardiac surgeons, interventional cardiologists, and cardiac imaging specialists. The anatomy of the aortic valvar complex and its implications for TAVI have recently been reviewed.[64]

Two TAVI systems are currently in use: the self-expandable CoreValve ReValving (CoreValve, Irvine, Calif.) and the balloon-expandable Edwards valve (Edwards Lifesciences, Irvine, Calif.). Retrograde transarterial or antegrade transapical approaches are used to implant the aortic valve. To facilitate passage of the prosthesis through the stenotic native valve, balloon aortic valvuloplasty is performed before valve insertion. With the balloon expandable valve, burst ventricular pacing is used to decrease transvalvular flow and avoid expulsion of the system toward the aorta on deployment.

The central role that echocardiography plays in TAVI has recently been reviewed by Jayasuriya and colleagues.[65] In addition, the usefulness and limitations of echocardiography in optimizing the outcome of percutaneous aortic valve implantation have been recently evaluated by Moss and co-workers.[66] In this study, candidates for percutaneous aortic valve implantation were evaluated with transthoracic echocardiography to assess aortic annular dimension and aortic valve hemodynamics. TTE was found useful in guiding correct device sizing. Fifty consecutive patients were deemed suitable for percutaneous aortic valve implantation. Seventy-four percent (37 of 50) of patients underwent TEE during the procedure. TEE was used for the early detection of paravalvular aortic regurgitation and complemented fluoroscopy in the detection of complications. These authors felt that echocardiography played an important role in case selection, in guiding device placement, and in detecting complications of percutaneous aortic valve implantation. The use of 2D and 3D TEE to aid in the positioning and deployment of TAVI has been recently reported, demonstrating that TEE can be an important adjunct to fluoroscopy for guiding percutaneous aortic valve implantation and, therefore, can improve the safety and efficacy of the TAVI procedure.[67] The use of balloon aortic valvotomy sizing of the aortic annulus has been described as an important adjunct to TEE when selecting valve size.[68]

Masson and colleagues[69] have recently reviewed the clinical experience of multiple centers with different valve implantation systems and techniques and highlighted the recognition and management of potential complications. Echocardiography was found to be of particular use in the identification of aortic dissection, detection of annular and root rupture, recognition of mitral valve injury, and detection of paravalvular regurgitation and acute structural valve failure. Bagur and co-workers recently reported their experience in 100 patients in whom TEE was used as the primary imaging technique to guide transapical aortic valve implantation.[70] They found that TEE provided acute and midterm results similar to those of angiography-guided procedures and significantly reduced use of contrast during the procedure.

## BALLOON MITRAL VALVOTOMY

Mitral stenosis occurs from commissural fusion, leaflet thickening, and chordal shortening and fusion, usually as the result of rheumatic fever. Because mitral stenosis is primarily a mechanical obstruction to forward flow through the mitral valve orifice, the only definitive therapy is mechanical relief of this obstruction. The current procedures that are effective in providing such therapy are balloon mitral valvotomy (BMV) (most commonly used approach), open mitral commissurotomy (rarely used), and mitral valve replacement (used in patients who are not candidates for BMV).[71]

Suitability for BMV is determined by valve morphology and the presence and severity of mitral regurgitation. (See Chapter 21.) Patients with moderate or severe mitral regurgitation are usually not candidates for BMV. The Wilkins score[72,73] addresses the morphologic suitability of the mitral valve for BMV and is useful in patient selection with a lower score (less than 9), predicting a favorable outcome with BMV.

The basic steps for BMV are[74] (1) characterize mitral valve morphology and hemodynamics before BMV (to evaluate the degree and location of commissural fusion, determine presence and severity of mitral regurgitation and measure mean mitral valve gradient); (2) guide the transseptal puncture (see Fig. 5-3); (3) locate and define relationships of atrial appendage and mitral orifice and perform visual biofeedback calibration with catheters while inside the left atrium (catheter navigation); (4) ensure coaxial trajectory orientation while navigating the catheter through the mitral orifice (balloon catheter alignment); (5) perform precise position and exclude subvalvular chordal apparatus involvement before inflation and monitor balloon inflation; (6) inspect postinflation commissurotomy results (commissure splitting, mean mitral valve gradient); and (7) search for potential complications (iatrogenic valvular damage, atrial septal defect at site of septal puncture, or pericardial effusion) (Fig. 5-10).

## MITRAL REGURGITATION

Surgery is currently the standard of care for patients with severe mitral regurgitation. Mitral repair has a distinct advantage over mitral replacement because it preserves LV systolic function, obviates the need for anticoagulation, and improves survival (see Chapter 18). Unfortunately, surgical repair is not always feasible, because of advanced age and comorbidities or lack of local surgical expertise. This has promoted the development of

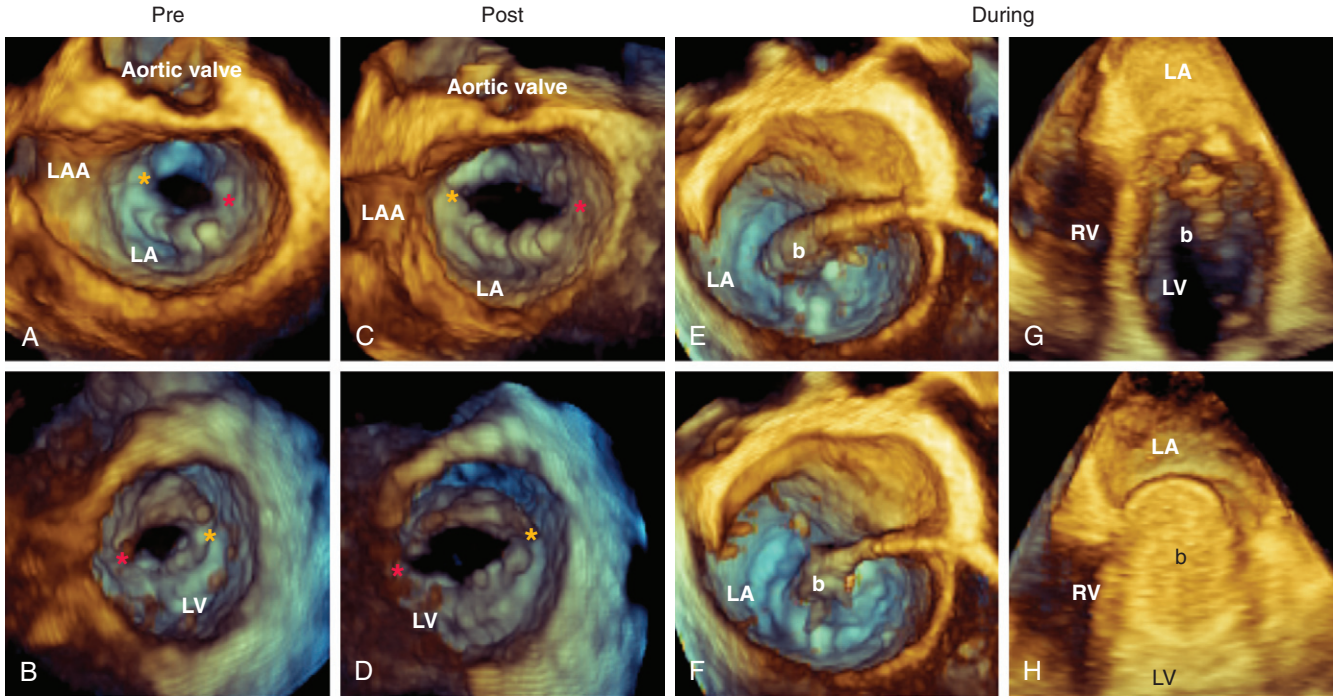

**Figure 5-10** **3D TEE guided mitral valve balloon valvotomy (BMV). A** and **B,** Stenotic mitral valve orifice in a patient with severe mitral stenosis before MVBV. **A,** Mitral valve as seen from the LA. **B,** Stenotic mitral valve as seen from the LV. Fused posteromedial commissure (*red asterisk*); fused anterolateral commissure (*yellow asterisk*). **C** and **D,** Commissural splitting produced by the balloon valvotomy. Note the significant enlargement of the mitral valve area and the splitting of the commissures. **E** to **H,** 3D TEE images obtained during MVBV guidance. **E,** Deflated balloon (*b*) has been advanced through the interatrial septum and is directed to the mitral orifice. **F,** Deflated balloon has been advanced through the mitral orifice into the LV. **G,** Deflated balloon is seen along the long axis of the LV. **H,** Inflated balloon is seen in its longitudinal cross section stretching and splitting the mitral valve commissures. *LAA,* Left atrial appendage.

a variety of transcatheter technologies to treat mitral regurgitation. Echocardiography plays a central role not only in characterizing the cause and severity of mitral regurgitation, but also in determining timing for intervention, providing procedural guidance, and evaluating short- and long-term results. (See Chapter 19.) In addition to fluoroscopy, TEE is the main imaging tool used to assist transcatheter interventions for mitral regurgitation.

### *Percutaneous Edge-to-Edge Mitral Repair*

The Alfieri edge-to-edge mitral repair is a surgical technique to treat mitral regurgitation by approximating the middle scallops of the mitral leaflets, creating a double orifice with improved leaflet coaptation.[75-77] A percutaneous method to create the same type of repair is now available. A transseptal approach is used to deliver a clip device (MitraClip, Abbott Vascular, Menlo Park, Calif.) that grasps the mitral leaflet edges to improve leaflet coaptation and reduce or eliminate mitral regurgitation.[78,79] Echocardiographic and hemodynamic measurements after percutaneous mitral valve repair with this technique show a decrease in mitral valve area, but no evidence of clinically significant mitral stenosis.[80]

TEE plays a central role in guiding the percutaneous edge-to-edge repair. It helps in determining the best site for septal puncture for delivery of catheters to the central area of the mitral valve orifice. TEE permits correct positioning of the clip device over the mitral orifice perpendicular to the line of leaflet coaptation. This step is essential to prevent clip disengagement and to obtain an acceptable reduction in regurgitant severity. The added value of 3D TEE imaging for optimal guidance during the procedure and to evaluate the anatomic result and residual mitral regurgitation has been reported,[81] and 3D TEE is our preferred imaging tool for edge-to-edge mitral valve repair (Figs. 5-11 and 5-12).

The MOBIUS Leaflet Repair system (Edwards Lifesciences) is another catheter-based edge-to-edge technique for the percutaneous treatment of mitral regurgitation. In contrast to the MitraClip, this system uses a catheter to stitch the free edges of the anterior and the posterior mitral leaflets, creating a double-orifice mitral valve. A suction catheter is used to adhere the leaflets together and facilitate stitch placement. This is accomplished under fluoroscopic and echocardiographic guidance.[82,83]

### *Annuloplasty Approaches Using the Coronary Sinus*

In patients with functional mitral regurgitation, the surgical implantation of an annuloplasty ring reshapes the circumference of the annulus and reduces the medial-lateral annular dimension. By moving the posterior annulus and posterior valve leaflet closer to the anterior leaflet, better systolic leaflet coaptation is accomplished.[84] Several biomedical companies are exploring transcatheter approaches that imitate surgical annuloplasty.[85-87] The coronary sinus runs just outside and roughly in the same plane as the posterior mitral annulus; therefore, a device that is placed in the coronary sinus can deform

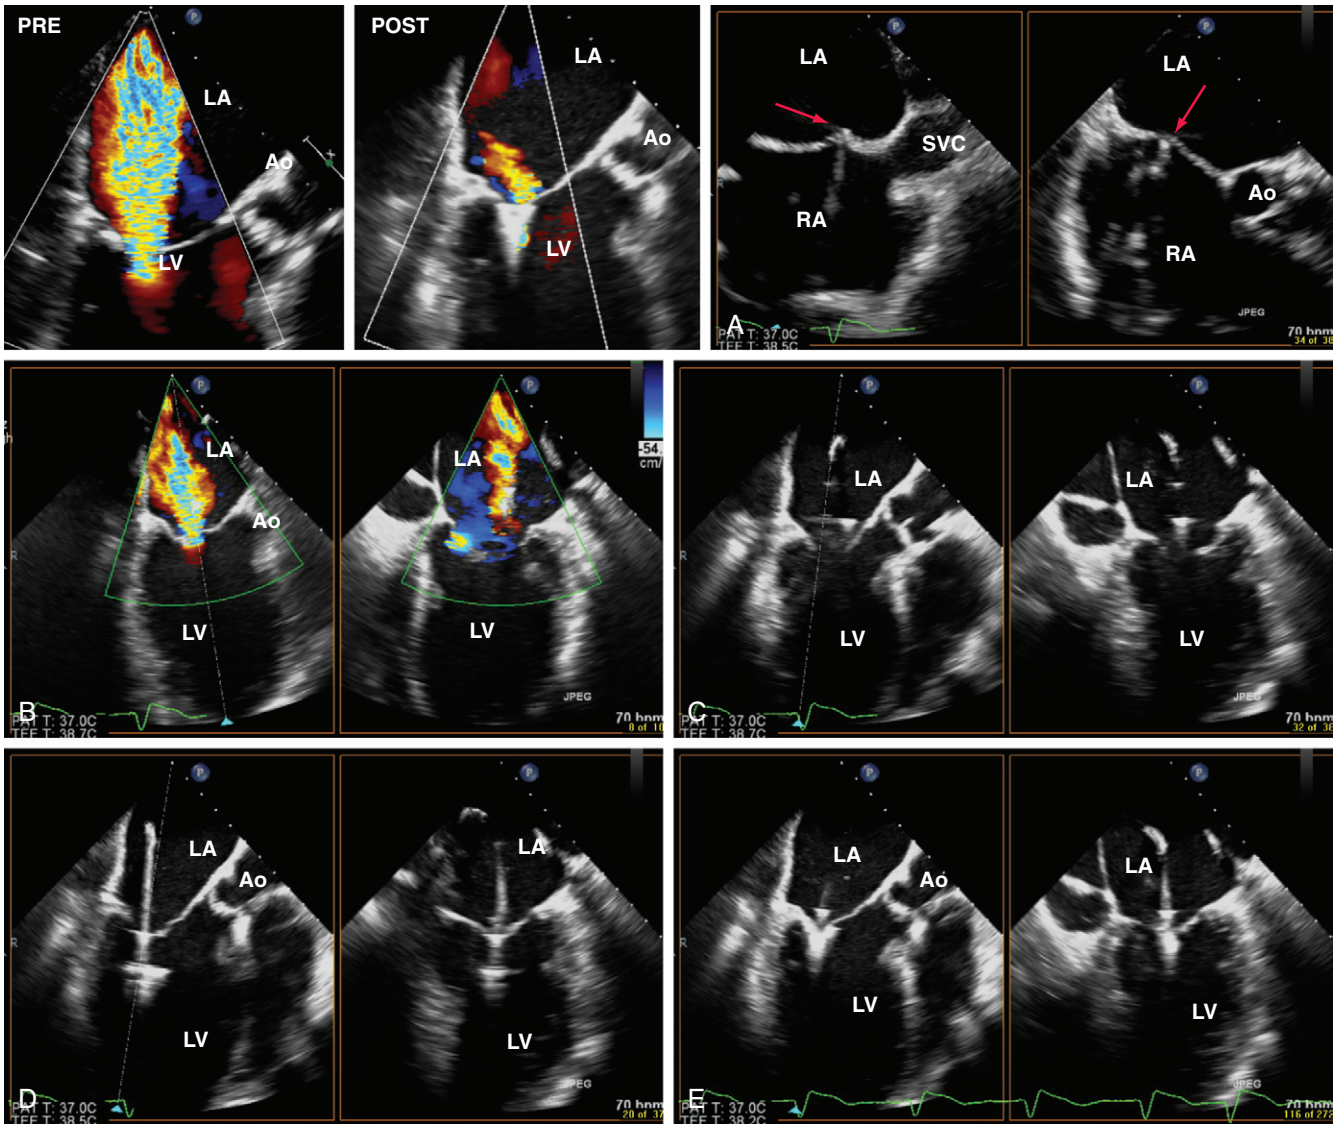

**Figure 5-11** **TEE guidance of mitral clip repair.** (*Top left*) TEE color Doppler images before (*PRE*) and after (*POST*) mitral valve clip repair. Note the presence of severe mitral regurgitation before the procedure and only mild mitral regurgitation after clip repair. **A,** Point of septal puncture, chosen to optimize device delivery. **B,** Guiding catheter and device delivery system are directed to the area of mitral regurgitation by following the mitral regurgitant jet. **C,** Clip approximates the coaptation point of the mitral valve. **D,** Device is advanced into the LV near the tips of the mitral leaflets. **E,** Catheter has been withdrawn, and the clip is grasping the free edges of the leaflets. *Ao*, Aorta; *SVC*, superior vena cava.

the mitral annulus, decrease the intercommissural distance, and, by approximating the mitral leaflets, decrease or obliterate the presence of mitral regurgitation. Currently there are three coronary sinus annuloplasty devices undergoing clinical trials: (1) the Percutaneous Transvenous Mitral Annuloplasty device (Viacor, Wilmington, Mass.), which consists of three straight and rigid nitinol rods seated in a multilumen catheter, which is introduced in the coronary sinus in to the interventricular groove[85]; (2) the Carillon device (Cardiac Dimensions, Kirkland, Wash.), which consists of a curved nitinol arc connecting a proximal and a distal anchor[86]; and (3) the Edwards MONARC system (Edwards Lifesciences), which is a nitinol assembly with a small distal anchor, a larger proximal anchor, and a springlike bridging segment.[87]

In all of these trials, TTE and TEE are used for patient selection and procedural guidance. TTE with 3D imaging is used to characterize the mitral annulus; TEE is used to measure quantitative procedural baseline mitral regurgitation and the septal-lateral annular dimension.

### *Percutaneous Left Ventricular and Mitral Annulus Remodeling*

Current treatments for functional mitral regurgitation, secondary to LV dysfunction, include medical therapy and surgery—consisting of either mitral valve repair or mitral valve replacement. An integrated approach directed to reshape the remodeled LV and annulus to treat functional mitral regurgitation is being developed (Coapsys-Myocor, Maple Grove, Minn.). Coapsys reshapes the ventricle, compressing the mitral annulus and subvalvular apparatus to decrease functional mitral regurgitation.[88] A surgical trial (RESTOR-MV) with this device supports the concept of the ventricular reshaping strategy to reduce mitral regurgitation.[89] Echocardiography was an integral part of the protocol in the RESTOR-MV trial. 2D and 3D TEE provided

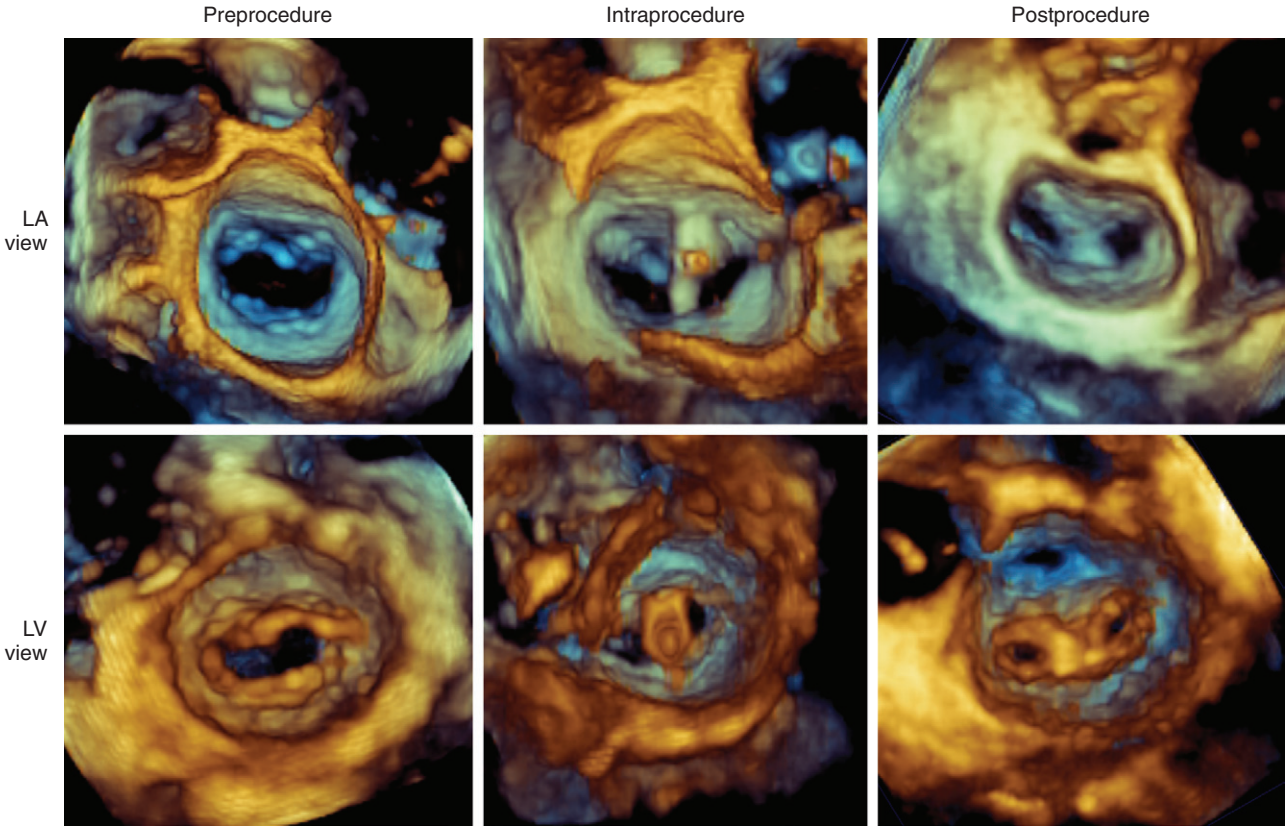

**Figure 5-12 3D TEE guidance of mitral clip repair.** These 3D TEE zoom images depict the mitral valve as seen from the LA and LV before, during, and after mitral valve clip repair. Note how the 3D imaging facilitates placing the device in the center of the mitral valve orifice and perpendicular to the coaptation line. After the device is implanted, a two-orifice mitral valve is noted.

real-time imaging of the LV mitral annulus and presence and severity of existing mitral regurgitation. To further reduce the invasiveness of the procedure, a percutaneous implantation system has been developed [88](iCoapsys, Maple Grove, Minn.). A clinical trial (VIVID: Valvular and Ventricular Improvement via iCoapsys Delivery) has been launched. The implantation has four stages: pericardial access, site identification, device implantation and sizing, and therapeutic evaluation. Echocardiography plays a central role in each of these stages.

## PROSTHETIC VALVES

### *Prosthetic Paravalvular Leaks*

Paravalvular leaks are a rare but serious complication of valve replacement surgery. Most paravalvular leaks follow a benign clinical course, but occasionally, and especially if leaks are large, patients develop heart failure, endocarditis, or hemolysis. (See Chapter 25.) Most clinically significant paravalvular leaks occur in association with prosthetic mitral valves, but prosthetic valves in any position can be affected. Surgical reintervention is associated with high morbidity and mortality; therefore, there has been a compelling interest in developing percutaneous transcatheter closure procedures. Both LV puncture and retrograde transfemoral approaches are used with fluoroscopic and transesophageal guidance. Mahjoub and colleagues[90] have recently described a reference method for TEE and fluoroscopic localization and guidance of mitral paraprosthetic transcatheter leak reduction.

In our laboratory, we use real-time 3D TEE both to define defect anatomy and to guide transcatheter paravalvular leak closure.[91] When combined with the information derived from existing 2D imaging modalities (echocardiography and fluoroscopy), 3D echocardiography enhances catheter navigation by defining the location of the defect relative to surrounding intracardiac structures. With real-time 3D TEE guidance, we facilitate both catheter navigation and defect crossing without the need for time-intensive offline reconstruction. In addition, 3D echocardiography can be used immediately after paravalvular leak closure to assess device stability and interaction with prosthetic valve struts and prosthetic leaflets. The added value of 3D TEE guidance for paravalvular mitral leak closure has also been reported by other laboratories.[92,93]

### *Transcatheter Valve-in-Valve Implants*

The valve-in-valve implant concept is a novel therapeutic option for patients with degenerative failure of bioprosthesis. The transcatheter valve-in-valve implantation does not need reoperation, potentially reducing morbidity and mortality. However, this requires accurate sizing of the transcatheter valve, which is currently available in only two sizes. Therefore, 3D imaging techniques, particularly CT and potentially 3D TEE, are used to provide a more exact sizing of the xenograft ring. Transatrial, transcatheter mitral valve-in-valve implantation has been shown to be feasible off pump in an experimental sheep mode.[94,95] Two recent case reports have demonstrated the feasibility of using this approach in humans.[96,97]

## TRANSCATHETER MITRAL VALVE REPLACEMENT

Several companies are developing percutaneous mitral valve replacement devices. A stent-based bioprosthesis inserted via a transseptal or transapical approach is favored. Lozonschi and co-workers[98] have recently reported an experimental model of a self-expanding valved stent created for transapical replacement of the mitral valve. It houses a trileaflet glutaraldehyde-preserved porcine valve provided with atrial and ventricular fixation systems. Ten pigs underwent transapical mitral valved stent implantation through a lower ministernotomy. The valved stent function was assessed by TEE and contrast left ventriculogram. All animals exhibited normal hemodynamics immediately after mitral valved stent implantation and maintained stability for the entire period of monitoring.[98]

Endovalve (Micro Interventional Devices Inc., Langhorne, Penn.) is developing a mitral valve replacement system with a foldable nitinol structure that attaches to the native valve apparatus with a gripper and is fully valve sparing. Initially this will be used with a minithoracotomy approach. A subsequent truly percutaneous delivery catheter using the same valve design is planned for later development. Again, TEE will likely play an important role in supporting this new technology.

## RIGHT HEART VALVE DISEASE

### *Tricuspid Balloon Valvotomy*

Tricuspid stenosis is usually secondary to rheumatic heart disease and most commonly occurs in association with mitral stenosis (see Chapter 34). Surgical commissurotomy and valve replacement are the standard surgical approaches to correct it. Percutaneous tricuspid balloon valvotomy can now be used to treat tricuspid stenosis in a fashion similar to that used to treat mitral stenosis.

Balloon valvotomy for tricuspid stenosis appears to be effective and associated with low morbidity.[99-102] Thus, in symptomatic patients refractory to medical therapy, balloon valvotomy of the stenotic tricuspid valve should be considered. Echocardiography is used to determine the presence and severity of tricuspid stenosis, as well as to document the degree of associated tricuspid regurgitation. The echocardiographic guidance for tricuspid valvotomy is similar to the one described for BMV.

### *Pulmonic Valvotomy*

Congenital pulmonic valve stenosis comprises 7% to 9% of all congenital heart defects. In the past, surgical valvotomy was the treatment of choice; more recently, balloon valvuloplasty has become the preferred option for the management of congenital pulmonic valve stenosis. Balloon dilatation is usually performed only in patients with a peak-to-peak gradient greater than 50 mm Hg.[103] Echo/Doppler methods play an important role in the diagnosis and determination of pulmonic stenosis severity, as well as in short- and long-term follow-up. Procedural guidance is usually done with fluoroscopy and cineangiography.

### *Percutaneous Pulmonic Valve Implantation*

The most common consideration for percutaneous pulmonic valve implantation is in patients who have previously undergone surgery of the RV outflow tract during repair of congenital heart disease and have symptoms related to RV outflow tract dysfunction.[104]

The RV outflow tract gradient and severity of pulmonic regurgitation are evaluated using standard approaches (see Chapter 34). Echocardiography performed 24 hours after percutaneous pulmonic valve implantation shows a reduction in RV pressure and RV outflow tract gradient along with a significant reduction in the degree of pulmonic regurgitation.[105] Pulmonic valve implantation is usually done with fluoroscopic and angiographic guidance.

## PERCUTANEOUS INTERVENTIONS IN THE LEFT VENTRICLE

### *Alcohol Septal Ablation for Hypertrophic Cardiomyopathy*

Hypertrophic cardiomyopathy is a clinically heterogeneous autosomal dominant genetic heart disease characterized by unexplained LV hypertrophy (see Chapter 27). It is the most common cause of sudden cardiac death in the young and is an important substrate for heart failure disability at any age.

Alcohol septal ablation is an effective method to treat symptomatic hypertrophic cardiomyopathy (HCM) refractory to medical therapy.[106,107] Guidance of the procedure by contrast TTE or TEE facilitates choosing the appropriate septal perforator artery to infuse with alcohol and avoid acute complications that cannot be anticipated by angiography alone.[108] The commonly accepted indications for alcohol septal ablation in patients with HCM include symptoms that interfere substantially with lifestyle despite optimal medical therapy; septal thickness of at least 15 to 16 mm; systolic anterior motion of the mitral valve; LV outflow tract gradient of 30 mm Hg at rest or 50 mm Hg on provocation; accessible septal branch; absence of intrinsic abnormality of the mitral valve; and absence of proximal left anterior descending coronary artery stenosis.

Echocardiographic guidance of septal ablation for HCM starts with characterization of the degree and location of septal hypertrophy, demonstration of systolic anterior motion of the mitral valve leaflet, outlining the degree and direction of the associated mitral regurgitation jet, and measurement of the resting or provocable (amyl nitrite or catheter-induced premature ventricular contractions) LV outflow tract gradient. In general we use TTE guidance unless transthoracic windows are suboptimal, in which case we use TEE. The objective of septal ablation is to safely administer 100% ethanol into the area of septal hypertrophy responsible for outflow obstruction and systolic anterior motion of the mitral valve. Therefore, it is critical to identify the septal branches of the left anterior descending coronary artery that supply the septal myocardium responsible for the obstruction. This is best accomplished by the use of myocardial contrast echocardiography. A wire is passed into the septal perforator estimated to supply the area of septal hypertrophy responsible for outflow obstruction, and then a short balloon is advanced over the wire into the proximal part of the target vessel. The balloon is inflated to completely obstruct the septal artery as demonstrated by the absence of reflux of contrast around the balloon. About 1 mL of a mixture of radiographic contrast agent mixed with blood and agitated saline is injected through the balloon catheter and visualized by TTE showing contrast enhancement in the thickened septum. Multiple views (apical 4, apical 5, apical long-axis view, and short-axis LV views) allow characterization of the extent of the contrast enhancement and permit recognition of undesirable areas of blood supply of the selected septal perforator such as the free wall of the right ventricle and the anterolateral wall of the LV and papillary muscles.

Once the appropriate septal perforator is selected, 1 to 5 mL of alcohol is slowly injected through the central lumen of the

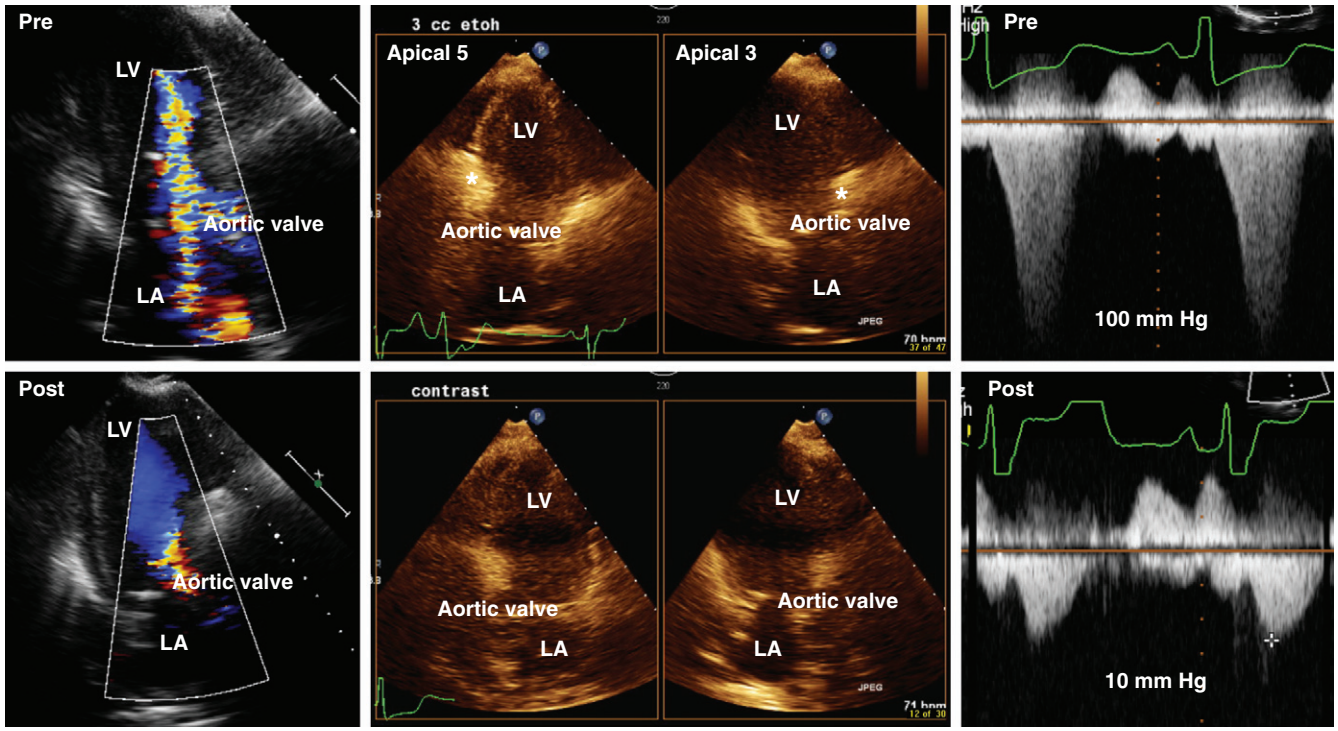

**Figure 5-13 Alcohol septal ablation for hypertrophic cardiomyopathy (HCM).** Resolution of mitral regurgitation (*left panels*) immediately post alcohol septal ablation in this patient with HCM. Drop of left ventricular outflow tract gradient from 100 mm Hg to 10 mm Hg (*right panels*) with alcohol septal ablation. Simultaneous biplane views of the LV (*middle* panels) from the apical 5 and apical 3 chambers. These planes permit visualizing the area of the interventricular septum (*) that is enhanced with the injection of contrast and, later on, alcohol in the appropriate septal perforator.

balloon catheter under echocardiographic guidance. After each milliliter of alcohol is injected, the presence and severity of systolic anterior motion and mitral regurgitation are recorded. In addition, the outflow gradient is measured and the degree of basal septal hypokinesis is noted. It is very important to continuously monitor the entire myocardium with echocardiography to watch for hypokinesis and myocardial enhancement in undesirable areas, which can represent alcohol in those areas. The immediate postinjection Doppler gradient is used to confirm satisfactory results. The goal is to reduce the resting gradient to less than 10 mm Hg or 50% of the preprocedure provocable gradient. If this is not achieved, a second potential septal perforator is searched for and the process is repeated. At the end of the procedure, the presence and degree of systolic anterior motion and mitral regurgitation are noted, and a final resting and post–premature ventricular contraction gradient is recorded (Fig. 5-13).

Echocardiography also plays an important role in detecting and managing potential complications during septal ablation for HCM. In addition to recognizing wall-motion abnormalities in inappropriate locations, echocardiography is ideally suited to detect a new pericardial effusion suggesting cardiac perforation, increased degree of mitral regurgitation suggesting papillary muscle compromise, and the presence of a new ventricular defect suggesting a large transmural septal infarct.

### *Percutaneous Closure of Pseudoaneurysm of Left Ventricle*

LV pseudoaneurysm is an uncommon, often fatal complication associated with myocardial infarction, cardiothoracic surgery, trauma, and, occasionally, infective endocarditis. LV pseudoaneurysms form when cardiac rupture is contained by adherent pericardium or scar tissue (see Chapter 14). LV pseudoaneurysms are not common, the diagnosis is difficult, and they are prone to rupture.[109] Most investigators support surgery as the appropriate treatment for LV pseudoaneurysm,[110] because untreated pseudoaneurysms have a 30% to 45% risk of rupture. However, surgery for repair of LV pseudoaneurysm still carries high morbidity and mortality. There are now several reports of percutaneous closure of LV pseudoaneurysms with encouraging results.[111-113]

## PERCUTANEOUS CLOSURE OF LEFT ATRIAL APPENDAGE

Patients with atrial fibrillation have a fivefold higher risk of stroke, making this the primary cause of long-term disability and one of the leading causes of death in patients with atrial fibrillation. (See Chapter 42.) Antithrombotic therapy to prevent thromboembolism is recommended for most patients with atrial fibrillation, using the CHAD2 guidelines for nonvalvular atrial fibrillation and the ACC/AHA guidelines for management in those with coexisting valve disease.[114]

In patient with atrial fibrillation, most thromboemboli arise from the left atrial appendage (LAA). Percutaneous device LAA closure has now been developed as an adjunct and as an alternative to pharmacotherapy in patients with atrial fibrillation.[115] Encouraging randomized data is available with the WATCHMAN device[116,117] (Atritech, Plymouth, Minn.), and several other devices are in various stages of clinical development. These include the Amplatzer Septal Occluder and cardiac plug (AGA Medical, Plymouth, Minn.), PLAATO (ev3 endovascular, Plymouth, Minn.) and the transcatheter patch (Custom Medical Devices, Athens, Greece). The deployment in all the devices is fairly similar. The left atrium is accessed through a standard septal puncture, the sheath is advanced up to the LAA orifice,

and a pigtail catheter is inserted into the LAA. The morphology of the LAA is characterized by TEE, paying special attention to its orifice shape and size, angulation of the orifice and body of the LAA, and presence and number of lobules. The device is sized, advanced, and deployed into the LAA orifice.[118] After device deployment, TEE is used to determine device stability and presence of any residual flow in the LAA. TEE is also the principal modality to evaluate for procedural complications such as structural damage, pericardial effusion, and residual atrial septal defects.

### PERCUTANEOUS CLOSURE OF AORTIC PSEUDOANEURYSMS

Pseudoaneurysms of the ascending aorta usually follow previous aortic dissection repair, aortic valve replacement, coronary artery bypass graft surgery, and cardiac transplantation. Surgical repair is the standard form of therapy, but it is associated with significant morbidity and mortality. Percutaneous closure of aortic pseudoaneurysms is therefore an attractive alternative, and now there are several reports with successful outcomes using this modality.[119-121] Transthoracic and TEE provide useful imaging guidance for percutaneous closure of aortic pseudoaneurysms.

## Procedures Not Covered in This Chapter

There are several other echocardiographic applications in the catheterization laboratory that we have not covered in this chapter. This is because they are not, strictly speaking, SHD interventions, or they are covered in other chapters of this book. We do provide some references for the interested reader to review. These include use of echocardiography to guide myocardial biopsy[7,122,123]; cardiac electrophysiology–related procedures[7,124-127]; balloon pericardiotomy[128,129]; and uncommon congenital heart disease interventions.[130]

## Limitations and Alternate Approaches

Although echocardiography is the most commonly used imaging technique to supplement fluoroscopy during SHD interventions, it has some limitations that need to be recognized. Image quality may be compromised by having the patient in the supine position instead of the usual left lateral decubitus. This problem can be partially corrected by the use of a rotating table with mild lateral rotation, or by the use of a pillow under the patient's right shoulder. If image quality remains nondiagnostic, an alternative imaging approach, such as TEE or ICE, should be considered. An additional shortcoming of TTE during interventions for SHD is that not all the standard echocardiographic windows are available during the intervention. The easiest window to use is the apical window; the left parasternal, subcostal, and suprasternal windows tend to be less accessible because they interfere with fluoroscopic imaging.

Because of these problems with TTE, TEE is favored in many SHD interventions. Unless general anesthesia is planned for other reasons, TEE can be performed under conscious sedation, with the added complexity and potential for complications this brings to the procedure. To decrease the chances of aspiration, the table needs to be somewhat rotated, and a pillow under the patient's right shoulder is used. Continuous oral suction also decreases the chances of aspiration. In addition to the standard conscious sedation regimen, we favor the use of intravenous antiemetic agents to decrease the gagging and vomiting that can significantly impair the safe performance of an intervention. Although image quality with TEE usually is excellent, suboptimal images may be seen in patients with a large esophagus or with a hiatal hernia that precludes adequate probe-to-esophagus contact. In prolonged procedures, there is also the potential for dryness in the esophageal mucosa and image deterioration. Adding a lubricant to the esophageal probe at 30- to 60-minute intervals decreases this problem.

Another limitation of TEE is the relative narrow field of view, especially in the near-field structures such as the posterior left atrium. Frequently catheters or devices are not visualized because they are out of the imaging field. The probe position can be adjusted as needed to bring the catheters into view, or, if this is not possible, the device or catheter can be advanced under fluoroscopic guidance alone until it comes into the echocardiographic field of view.

### INTRACARDIAC ULTRASOUND

Echocardiographic guidance of SHD interventions has been significantly affected by the development of intracardiac echocardiography.[131,132] ICE is now a standard tool in centers performing catheter therapies for SHD (See Chapter 6). The impact of ICE has been affected by multiple facets, including the unique aspects of the images, the ability of the interventionalist to perform ICE, the special skills needed, the costs and reuse of the catheter, and the vascular access issues (Fig. 5-14). In addition, the list of specific procedures for which ICE has been used continues to grow and includes both diagnostic use as well as image guidance, typically combined in the same procedure. Finally, the future of ICE is likely to include more widespread use, the addition of real-time 3D imaging, enhanced integration into the procedure room, and a variety of new catheter designs.

There are four areas in SHD interventions where ICE has had its greatest impact. These include the performance of transseptal catheterization, closure of interatrial defects (Figs. 5-15 and 5-16), mitral interventions, and atrial fibrillation ablation. ICE provides in-depth understanding of the anatomy, is used during balloon sizing of defects, guides the placement of the device, and then allows conformation of proper device placement, completeness of closure, and absence of complications.[133] ICE guidance in the performance of transseptal catheterization has become routine. With the probe in the right atrium, all key structures are visualized by ICE. This has increased the safety of the procedure, but also allowed the site of transseptal crossing to be more precisely determined.[134] Valvular interventions may also be guided by ICE (Fig. 5-17). Mitral balloon commissurotomy for mitral stenosis can be greatly facilitated by the use of ICE. After guiding the transseptal puncture, ICE can provide unique assessment of the subvalvular apparatus, assess the placement of the balloon, and monitor the result.[135] Atrial fibrillation ablation has been a procedure that has moved ICE into being a necessary technology in the electrophysiology laboratory. ICE provides guidance for the transseptal catheterization, but also for the subsequent visualization of ablation in the left atrium and pulmonary veins.[136]

### COMPUTED TOMOGRAPHY

SHD interventions can often be planned using cardiac CT angiography. Comprehensive fine resolution of cardiac structure and display of 3D relationships to adjacent structures in combination with a full field of view are the strengths of

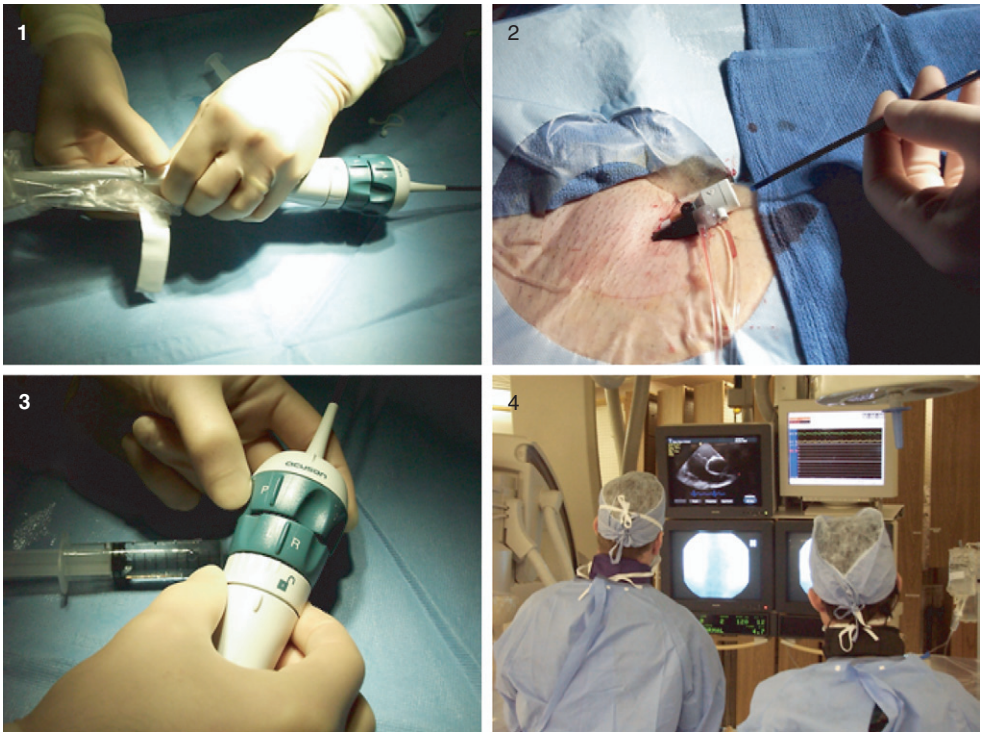

**Figure 5-14 Steps in intracardiac echocardiography (ICE).** The four steps in using ICE to guide structural heart disease interventions. *1*, Preparation of ICE catheter for plug and play. *2*, Insertion into vascular access point and navigation to the heart using fluoroscopic guidance. *3*, Navigation within the heart for visualization of structures of interest for the intervention. *4*, Display and interpretation of images during intervention.

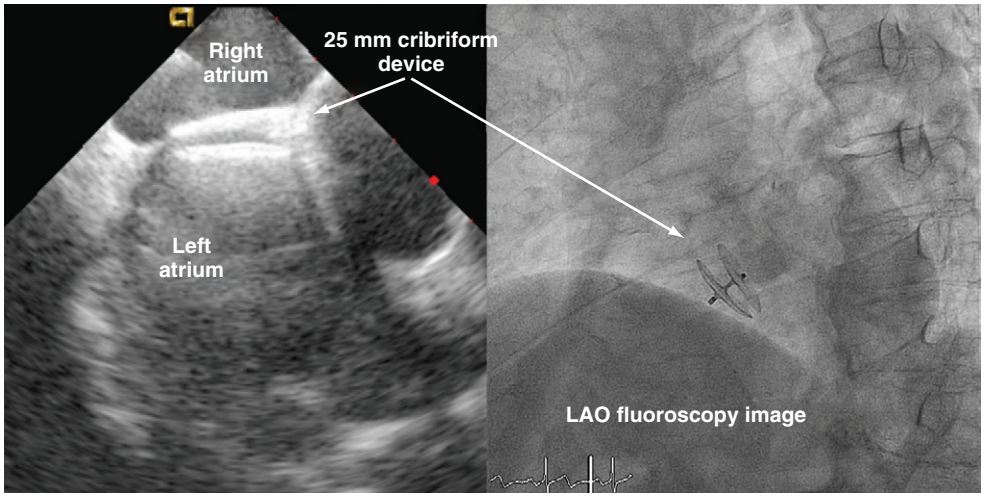

**Figure 5-15 Device visualization using both intracardiac echocardiography (ICE) and fluoroscopy.** Appearance of a nitinol mesh device used to close a multifenestrated atrial septal defect using ICE (*left*) and fluoroscopy (*right*) visualization. *LAO*, left anterior oblique.

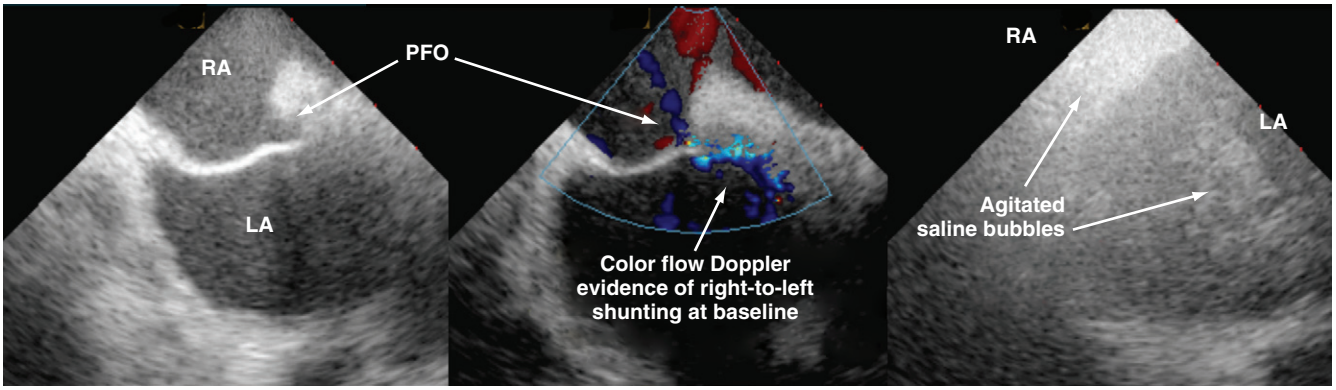

**Figure 5-16 Intracardiac echocardiography (ICE) assessment of patent foramen ovale (*PFO*) immediately before closure.** Intraprocedure assessment of a PFO in a patient with systemic hypoxemia from right-to-left shunting. ICE placement in the RA is straightforward and yields excellent image quality of interatrial septum. (*Left panel*) Visualization of the thin septum primum and septum secundum, which is thick, i.e., lipomatous. The PFO tunnel length and width at any point of the tunnel can be measured. (*Middle panel*) Color flow Doppler visualization of the right-to-left flow in the PFO. (*Right panel*) Dense opacification of both the RA and LA from a peripheral injection of agitated saline that immediately traversed the PFO. These three findings provide the evidence for the need for closure, including the large volume of shunting producing systemic hypoxemia, and the measurements needed for device sizing.

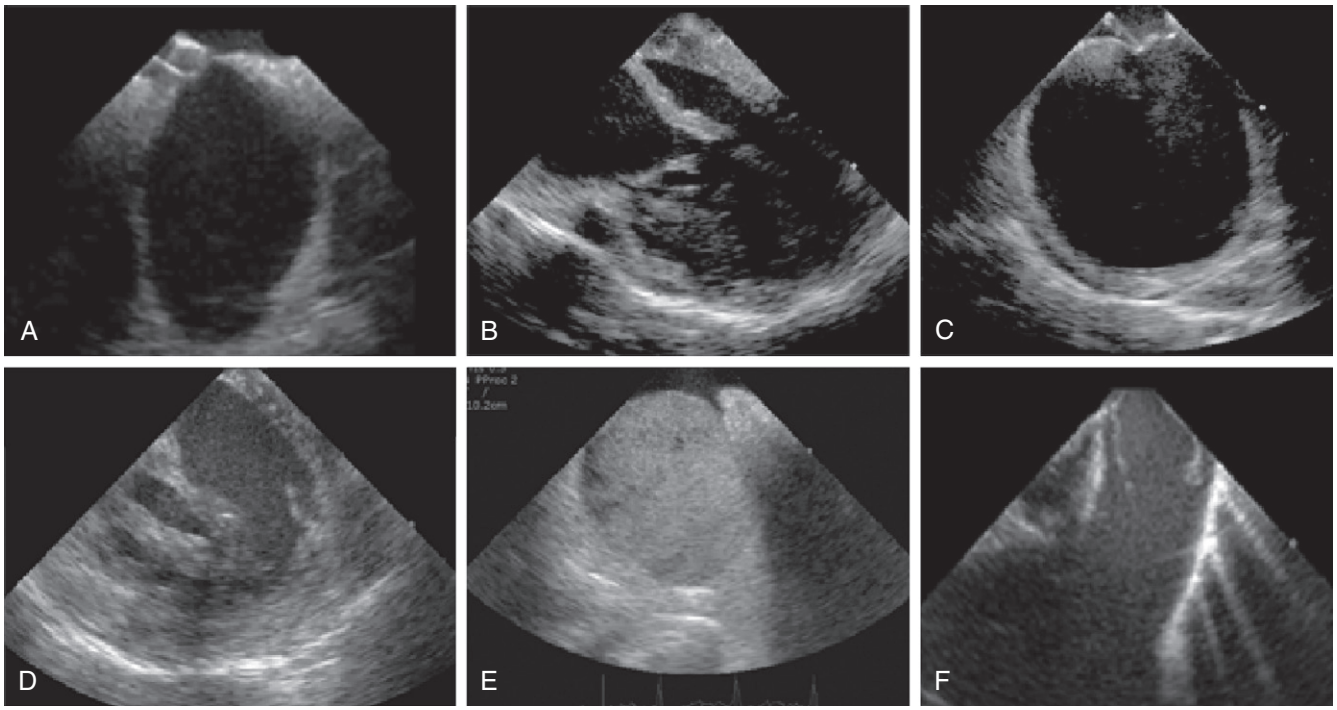

**Figure 5-17 Six panels of intracardiac echocardiography (ICE) findings during structural heart disease interventions. A,** ICE catheter in the RA visualizes the interatrial septum with a "j" wire being navigated to cross a patent foramen ovale before closure. **B,** ICE catheter in the RV visualizes the mitral leaflets during a mitral balloon valvotomy. Note the thickened anterior leaflet. **C,** ICE catheter in the RA visualizes the interatrial septum, showing "tenting" due to engagement of a transseptal catheter before needle puncture. **D,** ICE catheter in the RV visualizes the mitral subvalvular apparatus, which is severely thickened, contracted, and matted. The mitral balloon valvotomy was aborted because of this finding. **E,** ICE catheter in the RA visualizes the LA, which is opacified by bubbles from agitated saline being injected in the left pulmonary artery to document a large pulmonary arteriovenous fistula during a closure procedure. **F,** ICE catheter in the RV visualizes the pulmonic valve immediately after inflation of a balloon in a congenitally stenotic valve. The thin valve leaflets now open widely and no longer dome.

tomographic imaging techniques such as cardiac CT angiography and magnetic resonance. Multislice CT scanners have become useful in SHD intervention because of faster gantry rotation speeds, increased numbers of detectors and dual sources, and improved spatial and temporal resolution. CT angiography can provide the information to describe the target of the intervention, help size the device, and potentially plan the pathway to the target and the needed delivery system. Currently CT angiography is used for planning TAVI,[137] paravalvular leak closure, large ASD closure,[138] and VSD closure, and whenever any other cardiac structural defect is poorly characterized by echocardiography.

### CARDIAC MAGNETIC RESONANCE IMAGING

Cardiac magnetic resonance imaging is a valuable technique used in SHD interventions,[139-143] but less useful than cardiac CT angiography because of the length of acquisition and analysis, the somewhat reduced spatial resolution, and the wider availability of CT angiography. That being said, cardiac magnetic resonance is more common in the pediatric patient population and has the ability to quantify shunts, regurgitant volumes, and many aspects of cardiac function relevant to SHD. Cardiac gating and breath-holding are needed.

### MULTIMODALITY IMAGING

Preprocedure CT angiography and cardiac magnetic resonance can now be imported, segmented, and registered with fluoroscopy in the SHD interventional lab as well as in the hybrid operating room. This advanced multimodality approach requires an image workstation and applications on the workstation that allow the CT angiography and MR images to be manipulated and segmented to optimize their use for the intervention. A new team approach must be developed in hospitals performing SHD interventions that includes physicians with training in advanced imaging modalities and echocardiographers with specialized knowledge and TEE skills specific for image-guided interventions.[3]

Echocardiography joins fluoroscopy and preprocedure CT angiography and cardiac magnetic resonance as the multimodality imaging approaches to SHD interventions. Each brings advantages and disadvantages. The available technologies as well as expertise at an institution often determine which modalities are used. As the new SHD interventions become available, there is a new emphasis on determining the image guidance strategy that is optimal for the intervention. Furthermore, the multiple modalities used include the differing needs of planning for the intervention versus its real-time image guidance.

## The Catheterization Laboratory of the Future

3D imaging has emerged as an important tool to aid in SHD interventions. Not only are the 3D relationships between structures of critical importance to understand before an intervention, but the navigation of delivery systems and the deployment of devices are greatly aided by real-time 3D imaging. New approaches to 3D imaging will include 3D ICE and also the

ability to generate and immediately use 3D images from other modalities.[144,145]

An important technology development relevant to SHD interventions is the C-arm CT approach.[146] The standard flat detector rotating around the patient with or without contrast injection transforms this x-ray machine into a CT scanner capable of soft-tissue visualization. This in-room capability may be especially useful in TAVI in providing annulus measurements for device sizing, root anatomy to avoid coronary obstruction complications during valve implantation, and orientation information for proper device deployment to avoid embolization.

Optimization of image display includes large flat screens with very high resolution to allow the display and manipulation of images from multiple modalities. For preprocedure planning, image display on the monitor has been replaced by the ability of rapid prototyping[147] to take imaging data from CT angiography, cardiac magnetic resonance, or 3D echocardiography and transform images into physical heart models. The physicality of a model allows the interventional team to examine the patient's heart in a unique fashion and simulate the intervention by trying different device sizes, for example.

SHD interventions have stimulated the development of novel devices and interventional techniques, and these unique interventions have also fundamentally transformed medical imaging, including diagnostic imaging, planning for interventions, and the actual image guidance process. This chapter on SHD interventions has emphasized the important role echocardiography plays in procedural guidance and highlights the transformation of echocardiography, both the technology and the echocardiographer, to support these interventions. This has occurred in a short period of time.

## KEY POINTS

- SHD has come into use in the interventional cardiology community to designate a group of disorders potentially amenable to catheter-based therapies, often involving unique devices that act to close defects, plug communications, and modify cardiac function.
- SHD interventions is a useful grouping for the specialty because these interventions require technical, imaging, and hemodynamic interpretation knowledge and skills that are distinct from those required by percutaneous coronary interventions and other vascular interventional skills.
- The main imaging tools to guide SHD interventions include fluoroscopy, cineangiography, intracardiac echocardiography, and transthoracic and transesophageal echocardiography.
- All of the usual echocardiographic methods used in the echocardiographic laboratory, including 2D and 3D echocardiography, spectral Doppler, color Doppler, and contrast echocardiography, are used in the catheterization laboratory to support SHD interventions. Both TTE and TEE approaches can be used.
- Echocardiography plays a central role in guiding structural heart disease interventions by facilitating access to the target vessel or chamber and by assisting with catheter navigation and device delivery.
- The SHD interventions that have benefited the most from echocardiographic guidance include closure of septal defects, alcohol septal ablation for hypertrophic cardiomyopathy, balloon valvuloplasty, edge-to-edge mitral valve repair, closure of paravalvular leaks, left atrial appendage occlusion, and, more recently, transcutaneous aortic valve implantation.
- Advanced imaging modalities to assist in the management of patients with SHD include computed tomography and cardiac magnetic resonance imaging.
- The cardiac catheterization laboratory of the future will have integrated multimodality imaging to assist in SHD interventions.

# 6 Intracardiac Echocardiography

THOMAS BARTEL, MD | SILVANA MÜLLER, MD |
THOMAS KONORZA, MD | RAIMUND ERBEL, MD

Equipment and Handling Procedures
Guiding Device Closure of Interatrial Communications
Monitoring of Percutaneous Left Atrial Appendage Closure
Guiding Radiofrequency Pulmonary Vein Ablation
Monitoring Transcatheter Aortic Valve Implantation
Perioperative and Periinterventional Imaging of the Ascending Aorta
Periinterventional Imaging of the Descending Thoracic Aorta
Periinterventional Imaging of the Mitral Valve
Limitations

During the past decade, intracardiac echocardiography (ICE) has become a standard guiding approach in interventional treatment of structural heart disease,[1] such as in device closure of interatrial communications, percutaneous transluminal septal myocardial ablation, pulmonary vein ablation, percutaneous left atrial appendage closure, and recently in transcatheter aortic valve implantation (TAVI). With the introduction of the 8F AcuNav catheter (Acuson Siemens, Mountain View, Calif.), which is also used for ICE,[2] intraaortic phased-array imaging (IPAI) became feasible. Guidance by fluoroscopy alone is limited because it cannot distinguish soft tissues and does not allow cross-sectional imaging. Consequently accurate positioning of devices can be difficult without echocardiographic guidance.[2a] On the other hand, distant posterior areas are difficult to depict with transthoracic echocardiography, especially when the patient is supine. Although transesophageal echocardiography (TEE) including real-time three-dimensional (3D) imaging is a well established diagnostic tool and provides exceptional high-resolution images, TEE's usefulness for interventional procedures is not always ideal (see Chapter 5). However, evidence that ICE guidance can improve the safety of these procedures is still lacking.

Miniaturized ultrasound-tipped catheter devices were primarily introduced for intravascular use. The first attempts to percutaneously introduce intravenous probes with built-in echo transducers for in vivo intracardiac imaging were reported in the late 1960s. During the following two decades, several intracardiac echocardiographic catheters were developed. Later, intravascular ultrasound (IVUS) was employed to image coronary arteries as well as the aorta and peripheral vessels (see Chapter 7). IVUS-based intracardiac imaging was also used for guiding electrophysiologic procedures. Nevertheless, intracardiac IVUS lacks Doppler capabilities and is further limited by inadequate ultrasound penetration. For current noncoronary percutaneous interventions in structural heart disease, high-quality near-field images as well as Doppler flow analysis are a prerequisite for optimal results and also aid in avoiding and detecting complications. Thus, technical advances led from IVUS to the development of ICE and IPAI. Using these methods as a guiding tool in noncoronary percutaneous interventions is justifiable on the basis of improved procedural success and reduced complications, although costs of the catheter and reimbursement are problematic in many countries. In particular, progress in electrophysiologic ablation is clearly linked to the advances made with ICE.[3] ICE and IPAI are also exciting research tools. Transfer of the methodology from the realm of research to routine clinical use is ongoing, such as in TAVI.[4]

## Equipment and Handling Procedures

Current devices (Acuson, Mountain View, Calif.) are multimodal, phased-array transducer-tipped intracardiac echocardiographic catheters. Nowadays, the 8 F AcuNav catheter has become the tool of choice for ICE. Other devices have been introduced[5] but have gained only limited acceptance (Table 6-1).

Just like conventional echocardiography, the miniaturized AcuNav transducer provides a 90°-sector image. The ICE probe can be connected to standard ultrasound units (Siemens and General Electric) through the SwiftLink Catheter Connector, which attaches to the ultrasound unit like any probe. After the SwiftLink Catheter Connector is covered with a sterile jacket, it is placed into the sterile field at the catheter table, where it is connected to the sterile intracardiac echocardiographic probe. The catheter steering mechanism and the function of the transducer should be checked in a water bath before insertion.

In comparison to the 10-Fr version, the 8-Fr AcuNav catheter has facilitated ICE and increased patient comfort and probably safety as well. After its introduction in pediatric cardiology,[2] the 8-Fr ICE catheter now is also used in adult interventional cardiology. The catheter possesses the unlimited echocardiographic capabilities of its predecessor but is available with more insertable length and in a shorter version. Besides two-dimensional (2D) and M-mode imaging, the ICE catheter also permits functional analysis. It possesses complete Doppler capabilities, including pulsed wave, continuous wave, color flow, and tissue Doppler modalities (Table 6-2).

An access sheath is required for introducing the ultrasound catheter into the femoral vessels or the right jugular vein. The disposable ICE catheter can be navigated through the inferior vena cava (femoral venous access) or the superior vena cava (SVC) (jugular venous access) into the right atrium (RA). This

**TABLE 6-1 Presently Available Intracardiac Echocardiographic Devices**

| *Catheters* | *Company* | *Features* |
|---|---|---|
| UltraICE | Boston Scientific | Rotational, nonsteerable |
| EP Med View Flex | St. Jude Medical | Side-looking, 10 Fr, 2-8 MHz |
| ClearICE | St. Jude Medical | Side-looking, steerable, 3D localization |
| AcuNav | Siemens/Biosense-Webster | Side looking, steerable, 8 Fr and 10 Fr |
| SoundStar | Siemens/Biosense-Webster | Side-looking, steerable, 10 Fr, 3D localization |

**TABLE 6-2 Doppler Imaging Modes and Frequencies of the Intracardiac Echocardiographic Catheter Family**

| | | |
|---|---|---|
| Catheter versions | 10 F | 8 F |
| Insertable length | 90 cm | 90 cm (formerly 110 cm) |
| Steering | Four-way | Four-way |
| 2D imaging frequency | 5.0-10.0 MHz | 5.0-10.0 MHz |
| Color Doppler frequency | 4.0-7.0 MHz | 4.0-7.0 MHz |
| CW Doppler | 5.0 MHz | 5.0-5.2 MHz |
| PW Doppler | 4.0-5.0 MHz | 4.0-5.0 MHz |
| Recommended access sheaths | 11 Fr | 8 or 9 Fr |
| Penetration | 15 cm | 15 cm |

*PW*, Pulsed wave.

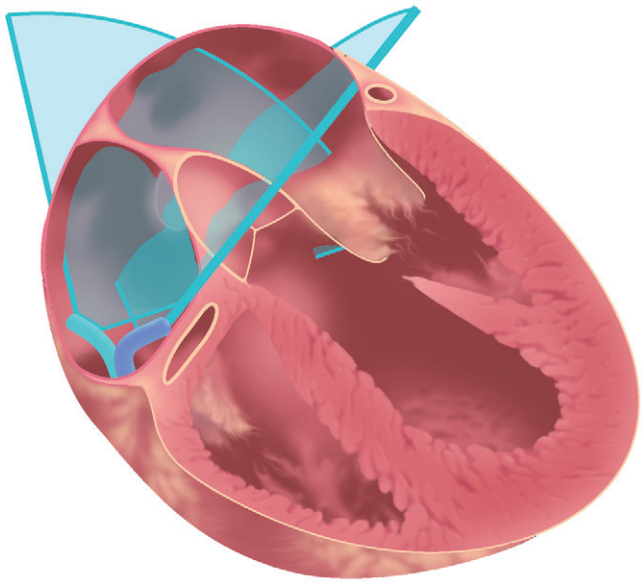

**Figure 6-1 Standard transatrial views for intracardiac imaging are obtained with the catheter tip in the RA.** Two image planes are shown in blue—a short-axis view of the aortic valve and interatrial septum atrium, and a longitudinal view through the interatrial septum.

may present a potential risk, although most patients undergo ICE as part of an interventional procedure, so the additional risk remains minimal. Special caution is needed when navigating the ICE catheter through the pelvic veins. Although the risk of venous injury or perforation is very low, isolated pelvic vein perforation and inferior vena cava dissection have been described. Adequate handling of the catheter device includes use of a long access sheath and fluoroscopy, two recommended precautions that enhance patient safety. The long access sheath in particular spares the examiner problems associated with pelvic vein navigation, thereby increasing patient safety. In addition, it is recommended to infuse saline solution before ICE. This increases venous pressure and dilates the central veins, facilitating venous puncture and insertion of access sheaths and the ICE catheter. Even intracardiac navigation becomes easier if the heart is well filled. The intracardiac probe does not accommodate a guidewire and is therefore fundamentally different from IVUS catheters. These require guidewires and are therefore relatively safe to manipulate. Obtaining arbitrary views may be difficult, however, especially in the near field. Particularly in the vicinity of the RA, the guidewire can restrict full visualization of lumen and wall, and it will frequently not allow adequate views of structures of interest, such as the transition into other chambers or vessel orifices.

## PRACTICAL TIPS

- Use long access sheaths to avoid injuring the pelvic veins during navigation.
- Use fluoroscopy as a precaution to safely advance the bidirectionally steerable (but guidewireless) catheter into the heart.
- Infuse 500 mL saline solution to dilate the veins and to facilitate catheter passage. Added benefit: reduced tendency for vagal responses when both the left and the right femoral veins need to be punctured.

To permit adequate imaging of the interatrial septum and its neighboring structures, two standardized views are used: (1) a transatrial longitudinal view showing the extent of the atrial septum from cranial to its distal margins—this view is seen with the catheter retroflexed inside the RA; and (2) a perpendicular transatrial short-axis view for visualizing the anterior part of the atrial septum and the transition to the aortic valve and the ascending aorta (Fig. 6-1).

The aortic valve is visualized by turning the catheter toward the aorta. One may need to straighten or even slightly anteflect the catheter. The tricuspid valve and the right ventricle (RV) are best displayed in a longitudinal view by anteflexing the probe after positioning the tip in the high RA. The left and right pulmonary veins as well as the left atrial appendage (LAA) are each visualized in a modified transatrial longitudinal view. For depicting the left pulmonary veins and the LAA, the catheter is angulated inferiorly; to visualize the right pulmonary veins, it is turned clockwise and advanced superiorly.

Clockwise rotation of the straightened ICE catheter permits visualization of the smallest anatomic details in the near field as well as to a depth of up to 12 cm. In order to enter the right ventricle, the tip of the probe is positioned in the mid to upper RA with the piezoelectric crystal facing the free wall of the RA, before the probe is gradually deflected anteriorly. From the right ventricle, the transventricular long-axis view of the left ventricle (LV) is obtained, which shows the interventricular septum proximally, the LV outflow tract, and the mitral valve apparatus. When the catheter tip is tilted to the right, the transventricular short-axis view of the LV comes into view (Figs. 6-2 and 6-3).

Interpretation of LV wall motion from transventricular views requires care because the catheter is moving inside the RV. By tilting the catheter tip away from the transventricular long-axis view, the RV outflow tract and pulmonary valve can be visualized as well (Fig. 6-4).

To avoid ventricular arrhythmias, the catheter has to be carefully navigated inside the RV cavity. The catheter should not be advanced beyond the pulmonary valve. When using the SVC

approach, inadvertent catheter passage into the coronary sinus has to be avoided by all means. A certain expertise in intracardiac catheter manipulation is essential to safely advance the catheter into the right heart, to orient oneself inside the heart, to obtain standardized views, and to adequately visualize the cardiac anatomy[6] (Table 6-3; also see Fig. 6-1).

Although the diagnostic potential and limitations of this imaging modality have not been fully evaluated, ICE may find an adequate place in operating rooms and catheterization laboratories for online monitoring of complex intracardiac interventions. Nonsurgical cardiac procedures require real-time, high-quality, and near-field views for optimal results. Moreover, continuous progress in the field of percutaneous interventions warrants more effective imaging guidance without compromise to patient comfort and safety. ICE has been proven an important diagnostic tool for depicting expected or unanticipated aberrant anatomy in patients with congenital heart disease. Tissue motion, intracardiac devices, and their relation to the surrounding structures can be very clearly delineated.

## Guiding Device Closure of Interatrial Communications

Device closure of interatrial communications is performed for treatment of severe left-to-right shunts associated with atrial septal defects (ASDs) (see Chapter 44) and for prevention of recurrent paradoxical embolism in patients with a patent foramen ovale (see Chapter 41). Some complications with closure of interatrial communications are due to suboptimal device performance.[7] Others, however, may be related to discontinuous echocardiographic monitoring, because supine patients do not tolerate continuous monitoring with TEE well unless they are sedated or under general anesthesia. More than 10 years of experience make us believe that some specific complications of transcatheter closure can potentially be avoided with improved echocardiographic monitoring. In that respect, ICE can be recommended as the method of choice for guiding percutaneous device closure, especially of ASDs.

Before passing instrumentation through the interatrial communication, the ICE catheter is advanced through the inferior vena cava into the RA. The transducer is aimed at the left atrium (LA) to obtain the transatrial longitudinal view. As a first step,

adequate position of a long guidewire in the left superior pulmonary vein is demonstrated. The left superior pulmonary veins are depicted by angulating the probe from the longitudinal view inferiorly. The stretched size of ASDs can be adequately measured by ICE; however, sizing balloons must still be used—a mandatory step for estimating the size of the communication before ASD device closure.[8]

Next, the long access sheath required for occluder device application is inserted over the guidewire. Fluoroscopic imaging during that part of the procedure can be reduced to very short intermittent checks because placement of the tip of the sheath into the LA can be primarily guided and documented by ICE. Simultaneous echocardiographic and fluoroscopic viewing is recommended during deployment of the closure device.

## PRACTICAL TIPS

- ICE displays release of the left-sided counteroccluder opening in the LA.
- The whole system including the long access sheath with the delivery cable inside and the opened left-sided counteroccluder is slightly pulled back until the open counteroccluder applies some traction on the atrial septum. ICE depicts the moment when the left-sided counteroccluder is closely aligned with the atrial septum.
- With the delivery cable still under traction, the long access sheath is further withdrawn to release the right-sided counteroccluder. ICE demonstrates release of the right-sided counteroccluder inside the RA and the left-sided counteroccluder remaining on the left side of the septum.
- While monitoring the opening of the right-sided counteroccluder, the delivery cable is carefully pushed forward until the counteroccluder also fits tightly into the atrial septum, but from the right side. Viewing two perpendicular cut planes (transatrial longitudinal and short-axis views) is mandatory to confirm the result and to rule out jamming of one of the counteroccluders in the interatrial communication (Fig. 6-5).

With the occluder device positioned but still connected to the delivery cable, the "wriggle maneuver" is monitored. Aiming to ensure that the counteroccluder cannot tilt or slip to the contralateral side, the occluder device is pushed and pulled before release. This will guarantee that the atrial septum is optimally engaged. Details of this maneuver, which is considered the best technique to avoid unsatisfactory device orientation or embolization, can be nicely shown by ICE. The wriggle maneuver should be visualized in the transatrial longitudinal view and again in the transatrial short-axis view. In the short-axis view, any compression of the aortic bulb by the occluder device can be ruled out. It is sensible to also use ICE for monitoring device disconnection from the delivery cable.

Once it is released, the device lines up with the atrial septum, reaching its definitive orientation. The final position of the device should be visualized to ensure that the counteroccluder completely encloses the rims of the interatrial communication. After device deployment, color flow imaging can depict any residual shunt. During deployment of the occluder device, the device and the intracardiac echocardiographic catheter do not interfere with each other. As a precaution, the intracardiac echocardiographic catheter should be kept at least 1 cm from the occluder device. A closer position would impair optimal imaging of the occluder device. As elucidated, continuous ICE imaging during each stage of the procedure allows optimal device positioning, a prerequisite for safe percutaneous closure of interatrial communications. Real-time 3D ICE imaging will be available soon.

Several investigators demonstrated that ICE can safely guide interventional therapy in interatrial communications and that ICE monitoring is superior to conventional TEE.[9-12] TEE requires general anesthesia with or without endotracheal intubation, whereas ICE permits unlimited echocardiographic viewing in fully conscious and compliant patients. This is of utmost importance, because malposition and migration of the device into the systemic or pulmonary circulation or perforation of the cardiac wall and rapid thrombus formation on the device are known to happen on occasion.[7,13,14] ICE provides better image resolution than TEE and therefore facilitates the procedure, particularly when long continuous or repeated

echocardiographic viewing is required or when complications begin to develop. ICE results in much less procedural stress to the patient, and fluoroscopic and procedural times can be shortened.[9,12] Because many patients with interatrial communications are of reproductive age or younger, reduction of radiation exposure has to be considered a major advantage of ICE. In that respect, patients who undergo ASD closure benefit more from ICE than patients undergoing closure of a patent foramen ovale, because ASD closure is more complex and more time consuming. Employing ICE in the pediatric population is also recommended. Several years' experience show that ICE is a practical and straightforward approach for guiding device closure in children and adolescents.[2,11] The overall risk related to ICE appears to be low. Moreover, it is likely that ICE improves the safety of interventional device closure in interatrial communications. From an economic point of view, savings from shorter procedural time and from avoiding general anesthesia need to be weighed against the cost of the ICE catheter. After a brief learning curve, interventional cardiologists who are familiar with echocardiography can fully benefit from the advantages of ICE.

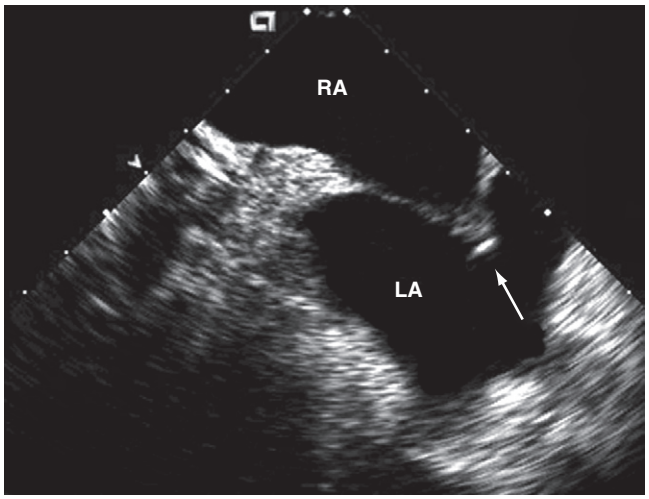

**Figure 6-6** Intracardiac echocardiographic imaging depict "tenting" of the fossa ovalis (*arrow*) while a Brockenbrough needle is advanced from the RA.

## Monitoring of Percutaneous Left Atrial Appendage Closure

ICE guidance for LAA device closure has only been described in a few cases.[15,16] It is an option in patients with atrial fibrillation in whom oral anticoagulation is contraindicated. Anatomical variation of the LAA, exclusion of thrombi, and the diameter of the ostium are usually assessed by TEE, which is also used for intraprocedural monitoring. As in any other percutaneous transseptal catheter interventions, one needs to establish access to the atrial appendage by septal puncture before LAA closure. This is best done under ICE guidance. Before atrial septal puncture, anatomic anomalies should be ruled out. When tenting of the fossa ovalis identifies contact with the transseptal needle, the pressure on the needle can be slightly increased until the needle perforates the atrial septum. For device closure, using novel placement of an intracardiac echo probe via a Mullins sheath in the RV outflow tract and pulmonary artery[16] seems to be advantageous over viewing from the LA. This allows near-field visualization of device deployment in the LAA. This technique may increase the spectrum of patients who benefit from the procedure by decreasing procedure time, fluoroscopy, and procedure-related morbidity (Fig. 6-6).

Transseptal crossover and advancement of the dilator and sheath are adequately imaged and the ostium of the LAA is easily delineated and measured by ICE. Device positioning, release, potential periprosthetic leaks, and especially the spatial relation of the device to the surrounding structures can be continuously monitored in the transatrial longitudinal view. In some patients, the transventricular long-axis view can represent an alternative (see Table 6-3).

## Guiding Radiofrequency Pulmonary Vein Ablation

The rapidly evolving field of interventional electrophysiology creates a demand for guidance by imaging. This is particularly true in view of the fact that currently available techniques, such as fluoroscopy and endocardial ECG, may be helpful but have

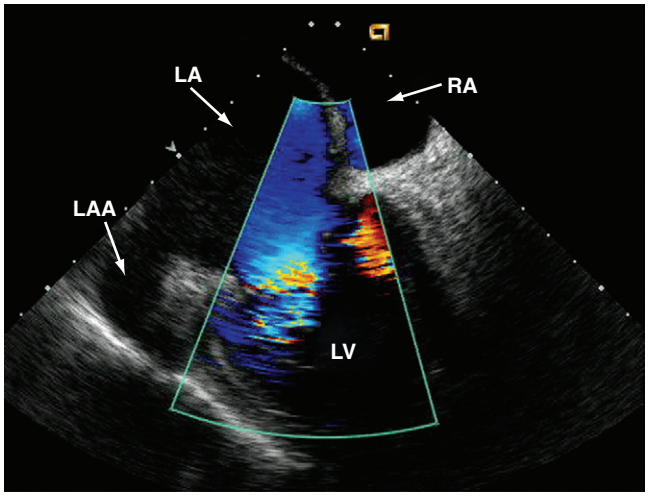

**Figure 6-7 Transatrial longitudinal view.** Left atrial appendage (*LAA*) and transmitral flow into the LV.

certain limitations. In many cases, angiographic guidance of circular mapping catheters is not sufficiently accurate. After initial puncture of the interatrial septum, high-quality images provided by ICE are capable of guiding transseptal pulmonary vein ablation, a treatment option in atrial fibrillation. Delineation of the endocardium and direct visualization of the pulmonary venous ostium facilitate mapping and radiofrequency ablation by depicting the target area, ensuring electrode-tissue contact, and helping with energy titration (Fig. 6-7).

Angiography-guided placement can result in poor contact between the ablation catheter and the endocardial surface. Inadequate contact reduces heat transfer to the tissue and allows convective heat loss into the circulating blood.

In the transatrial longitudinal view, the left pulmonary veins can be imaged by advancing the probe without tension or steering forces. Clockwise rotation of the catheter and insertion into the SVC allows the right pulmonary veins to be visualized in a cross-sectional view. Left or right steering permits longitudinal views of the right pulmonary veins. Thus, accurate anatomical

positioning of the ablation catheter tip in relation to adjacent endocardial structures is supported[17] (Fig. 6-8).

Doppler measurements of pulmonary vein flow velocities before and after ablation are recommended. During the procedure, the ablation zone can be directly visualized, including the evolving tissue injury. Visualization permits assessment of shape, cross-sectional area, wall thickness, and lesion formation[18] and depicts lesion size and continuity.[19] ICE is also useful for monitoring bubble formation during the phase of radiofrequency energy delivery, allowing radiofrequency dose titration to prevent overheating of the catheter tip. After effective ablation, transvenous flow velocities should be interrogated using continuous-wave Doppler in order to identify the potential presence of a gradient,[20] which can occur as a complication. This illustrates that ICE contributes to the safety of the ablation procedure and to prevention or early detection of potential complications associated with electrophysiologic interventions, that is, thrombus formation[21] and development of pulmonary vein stenosis.[20] Periinterventional monitoring depicts each step of the ablation process, improves efficacy, and also reduces early and late complications.[22] As demonstrated for device closure of interatrial communications, ICE can lower fluoroscopy time and shorten the ablation procedure.

## Monitoring Transcatheter Aortic Valve Implantation

Generally, potential alternative sound windows are available for ICE-based intrainterventional assessment in TAVI. These include the transaortic window for viewing from inside the ascending aorta[23] and the transventricular window for transseptal viewing from the right ventricle.[24] Views from inside the aorta are inconvenient because the ICE catheter is prone to interfere with procedural catheters. In many individuals, it is also challenging to keep the ICE catheter stabilized in the RV (transventricular approach) throughout the procedure. However, longitudinal views from the lower SVC and the upper RA supplemented by RA short-axis views seem to be most suitable for continuous guidance, because the catheter position remains stable and the catheter does not interfere with the TAVI procedure[24a] (Figs. 6-9 and 6-10).

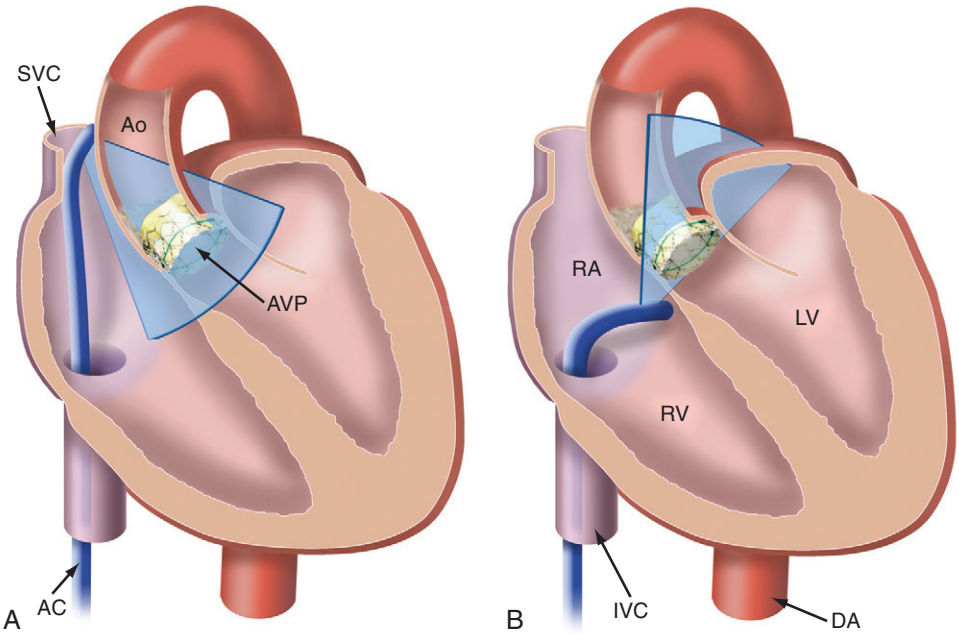

**Figure 6-9** Longitudinal transcaval/transatrial (**A**) and short-axis transatrial (**B**) standard intracardiac echocardiographic views for transcatheter aortic valve implantation. *Ao*, Ascending aorta; *AC*, AcuNav catheter; *AVP*, aortic valve prosthesis; *DA*, descending aorta; *IVC*, inferior vena cava; *SVC*, superior vena cava. *(From Bartel T, Bonaros N, Müller L, et al: Intracardiac echocardiography: a new guiding tool for transcathter aortic valve replacement.* J Am Soc Echocardiogr *24:966-57, 2011).*

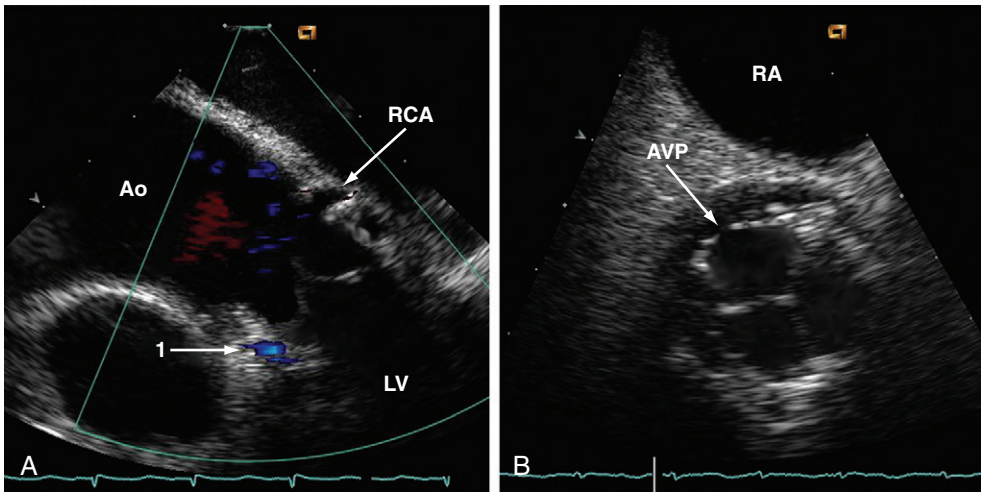

**Figure 6-10** Longitudinal transcaval (**A**) and short-axis (**B**) intracardiac echocardiographic views of aortic valve prosthesis after deployment and at end-diastole. *1*, Minimal paravalvular leak; *Ao*, aorta; *AVP*, aortic valve prosthesis; *RCA*, right coronary artery. *(From Bartel T, Bonaros N, Müller L, et al: Intracardiac echocardiography: a new guiding tool for transcathter aortic valve replacement.* J Am Soc Echocardiogr *24:966-57, 2011).*

Even in asymptomatic patients, aortic stenosis is known to be associated with a poor prognosis.[25] An increasing number of patients cannot undergo surgical aortic valve replacement owing to high perioperative risk due to comorbidities and advanced age.[26] The periinterventional risk of TAVI must be weighed against these facts.[27] Especially in extremely high-risk patients, each step of the procedure can cause life-threatening complications.[28] Although periprocedural echocardiography is regarded as an important means of lowering the rate of complications, and although TEE monitoring is frequently used in those patients exposed to extreme risks to assist with the interventional steps and to detect complications, current guidelines for TAVI do not include any detailed methodologic suggestions for intraprocedural use of echocardiography.[29]

Echocardiography also qualifies as a tool for guiding TAVI with the purpose of increasing its benefit-to-risk ratio.[30] Intraprocedural TEE has become an established method,[29] although it is not necessarily an ideal guiding tool, one reason being the difficulty of aligning the Doppler beam with transvalvular flow in the deep transgastric view. Transgastric measurement of aortic valve blood flow cannot be considered a routine approach and is known to require a significant learning curve. It also may not depict the maximum transvalvular or transprosthetic gradient because the TEE approach results in a non-parallel Doppler angle. In contrast, the Doppler beam can be nicely aligned with transvalvular flow in the transcaval/transatrial longitudinal ICE view, and determination of transvalvular pressure gradients is therefore much easier than with TEE. The gradient not only gives an estimate of the effectiveness of predilatation, but helps to avoid unnecessary additional dilatations. This is meaningful for risk management because each balloon dilatation is associated with the risk of annulus dissection and significant aortic regurgitation.

When positioned at the level of the aortic valve, the TEE probe impedes posterior-to-anterior fluoroscopic viewing, which is mandatory for angiography, balloon dilatation, final adjustment of the prosthesis, and its subsequent implantation. This is another drawback of TEE. The only workaround is repeated TEE probe withdrawal at crucial points of TAVI work flow, subsequent repositioning of the probe, and new alignment to obtain appropriate TEE views. Consequently, TEE provides only episodic monitoring on the one hand. On the other hand, repeated repositioning of the TEE probe may cause several interruptions of TAVI work flow. Although real-time 3D TEE represents a feasible guiding tool and may improve spatial orientation, it nevertheless remains a variant of TEE with all disadvantages inherent in this technique when applied to TAVI.

In contrast to TEE, the ICE catheter can be left in place with the probe aimed at the aortic valve during the entire TAVI procedure. Slight readjustments of the catheter may be occasionally required. Simultaneous and uninterrupted echocardiographic guidance by ICE is an ideal method for assisting predilatation, final adjustment, and deployment of the valve prosthesis; for ruling out potential complications as early as possible; for confirming proper prosthetic valve function without a need for repeated angiography; and for checking LV function immediately after implantation. Decreased use of contrast agents is meaningful, because renal failure has been reported to be the commonest short-term complication after TAVI.[31] In comparison to TEE, ICE provides a more coaxial view of the ascending aorta and may therefore help to improve coaxiality between the valve-balloon system and the ascending aorta. ICE also assists wire crossing of the native valve in the majority of patients and better depicts the coronary ostia than TEE, which helps to rapidly exclude any obstruction by displaced debris from the calcified native valve (Fig. 6-11).

Both ICE and TEE approaches can be considered equivalent with respect to determining annulus size and LV function. Measuring annulus size is particularly critical and essential for selecting the correct size valve prosthesis. The ICE catheter is maneuverable by the interventional operator, who can adjust the transducer as needed and independently from a noninvasive cardiologist or anesthetist, while the ultrasound unit is operated by an ultrasonographic technician. Operated by an interventional cardiologist also experienced in echocardiography and especially in ICE application, this tool has some potential in minimizing procedural risks by avoiding and, whenever possible, detecting TAVI complications[32] at the earliest possible time.

TAVI can also be completed under local anesthesia and moderate sedation,[33,34] provided patients are selected accordingly.

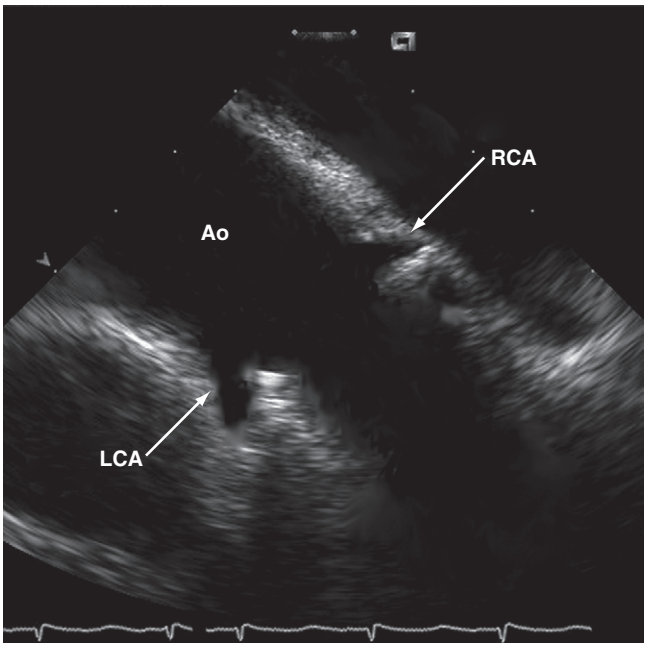

**Figure 6-11** Longitudinal intracardiac echocardiographic view demonstrates both coronary arteries branching off above the opened aortic valve prosthesis. *Ao*, Aorta; *LCA*, left coronary artery, *RCA*, right coronary artery. *(From Bartel T, Bonaros N, Müller L, et al: Intracardiac echocardiography: a new guiding tool for transcathter aortic valve replacement.* J Am Soc Echocardiogr *24:966-57, 2011).*

However, prolonged TEE imaging requires deeper sedation. The availability of ICE as an adjunct for TAVI lets the operator decide whether to use local anesthesia plus sedation or general anesthesia independently of the need for echocardiographic guidance.

## Perioperative and Periinterventional Imaging of the Ascending Aorta

When a high transesophageal image plane—also known as "banana view"—is used, TEE depicts the caudal part of the ascending aorta anteriorly to the right pulmonary artery. Unfortunately, ascending aortic flow is not aligned with the Doppler beam in this plane. For that reason, perioperative functional assessment of the aortic valve and the ascending aorta by TEE is limited to regurgitant flow detection. Perioperative IPAI and ICE from the RA and the SVC may become alternative approaches for complete morphologic assessment of the ascending aorta and functional evaluation of the aortic valve. In order to display the proximal ascending aorta, the ICE catheter is used as described for TAVI. Alternatively, it can be inserted via a jugular venous access and advanced through the SVC into the upper RA. In contrast to transfemoral access, no fluoroscopic guidance is needed with the jugular venous approach because the access sheath guides the catheter sufficiently, making direct catheter navigation superfluous. From the superior RA, the aortic bulb and aortic valve can be displayed in the long-axis view and, after tilting the tip of the catheter, also in a short-axis view. After the catheter is pulled back into the SVC, a longitudinal cut plane of the whole ascending aorta reaching up to the innominate artery can be obtained. In contrast to TEE, systolic flow is mostly aligned with the Doppler beam of the catheter, permitting color flow and pressure gradient recordings of highest image quality. Therefore, ICE might be of clinical interest immediately after aortic valve surgery or surgery of the ascending aorta (Fig. 6-12).

Intraoperative cannulation of the ascending aorta with surgical devices can also be monitored with IPAI views from the SVC. Further development of right-heart assist devices could create another potential application. Nevertheless, clinical experience with the transjugular approach is limited.

## Periinterventional Imaging of the Descending Thoracic Aorta

TEE adds incremental information, improving the safety of stent-graft placement in type B aortic dissection. In addition, IVUS is considered helpful in patients with complex dissection including abdominal extension.[35] With respect to aortic diseases, the main limitation of IVUS is attributable to its inability to perform Doppler analysis. Flow detection by TEE is also limited if the flow is not aligned with the Doppler beam. In consequence, detecting flow from true to false lumen and vice versa by TEE depends on the alignment of the dissection flap. Therefore, TEE has a low sensitivity for detecting small entries and reentries (Fig. 6-13).

On the other hand, sonographic approaches may help lower the current complication rate of percutaneous stent-graft implantation,[36] thus opening up new opportunities for monitoring interventional therapy in aortic diseases using IPAI. In that respect, IPAI not only combines advantages of TEE and IVUS, but adds capabilities.

The descending thoracic aorta cannot be viewed from any venous approach. Periinterventional sonographic diagnostic methods need to clarify which lumen supplies the side branches, a difficult feat with TEE and even with IVUS images. Thus, the need to navigate the aorta with the echocardiographic catheter turns from a disadvantage into an advantage, because the Doppler beam can be aligned with any flow between true and false lumen and with blood flow into small branches. Thus, intraaortic monitoring by IPAI has great potential to become a tool for the effective guidance of aortic stent-graft implantation, in such a manner that all entries are closed. First case reports also suggest that IPAI is capable of safely guiding other diagnostic intraaortic procedures in aortic diseases.[37]

Since the approval of the 8-Fr ICE catheter, its intraaortic use has added to the diagnostic spectrum in aortic disease.[37] For intraaortic employment of the echocardiographic catheter, a very long access sheath is definitely recommended so that only the tip of the catheter with the transducer sticks out of the sheath. Sheath and indwelling catheter are then jointly pulled back while imaging is performed. The catheter can be rotated intermittently and aimed at the region of interest by tilting its tip.

In type B aortic dissection, the echocardiographic catheter is placed into the true lumen and IPAI performed carefully. IPAI provides scans of the dissection flap when the device is rotated and withdrawn. Detection and precise localization of tears in the dissection membrane must be considered important for therapeutic decision making. In most cases, there are obviously more entries than are demonstrable by angiography, IVUS, or TEE. The fact that such data form the basis for optimal stent-graft placement, which aims to close all entries to the false

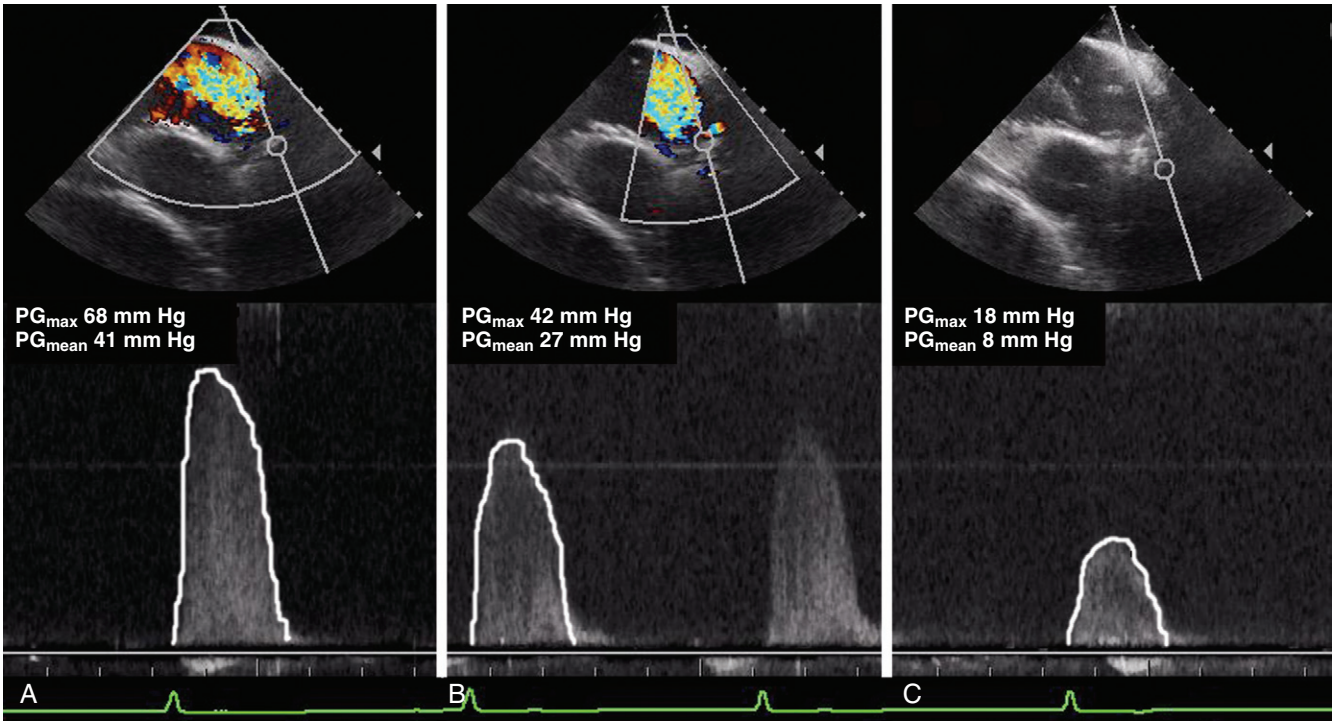

**Figure 6-12** **Aortic valve and ascending aorta seen from the superior vena cava:** measurement of pressure gradients (*PG*) before transcatheter aortic valve replacement (**A**), after predilatation (**B**), and after valve deployment (**C**). This approach allows full intraoperative hemodynamic assessment as well.

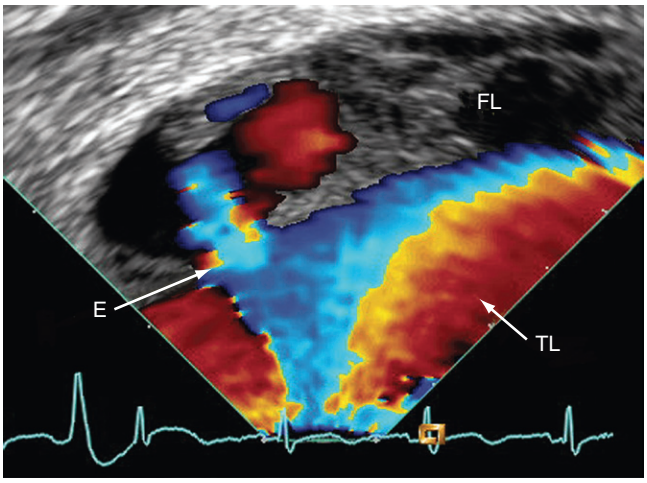

**Figure 6-13** Intraluminal phased-array imaging from the true lumen (*TL*) to the false lumen (*FL*): thrombus formation in type B aortic dissection. *E*, Entry.

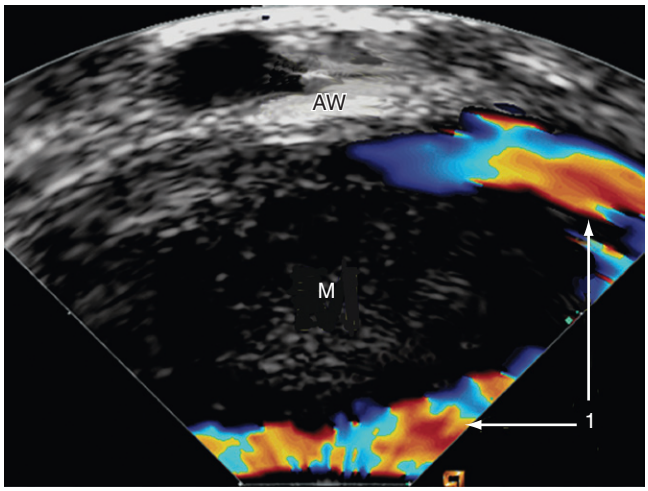

**Figure 6-14** Intraluminal phased-array imaging of an intraaortic mass (*M*). *1*, Flow around the mass; *AW*, aortic wall.

lumen, mandates a detailed analysis of the sensitivity of conventional diagnostic approaches. If overlooked or not properly closed by interventional treatment, even small tears can lead to significant flow into and inside the false lumen, impairing the desired thrombus formation in the false lumen and thereby impeding healing of the dissection. IPAI depicts more entries than one would expect from conventional diagnostics and demonstrates which abdominal vessels originate from the true and the false lumen. Thrombus formation in the false lumen, a result of effective pressure separation between true and false lumen, can be also displayed.

IPAI can also be used to safely guide percutaneous biopsies of intraaortic masses suspected to be tumors. To accomplish that, the transducer is aimed at the mass and the radial-jaw biopsy forceps (Fig. 6-14).

Under continuous ultrasonographic imaging, targeted biopsies are taken from the depth of the mass. Opening, pushing, and closure of the biopsy forceps can be precisely guided and

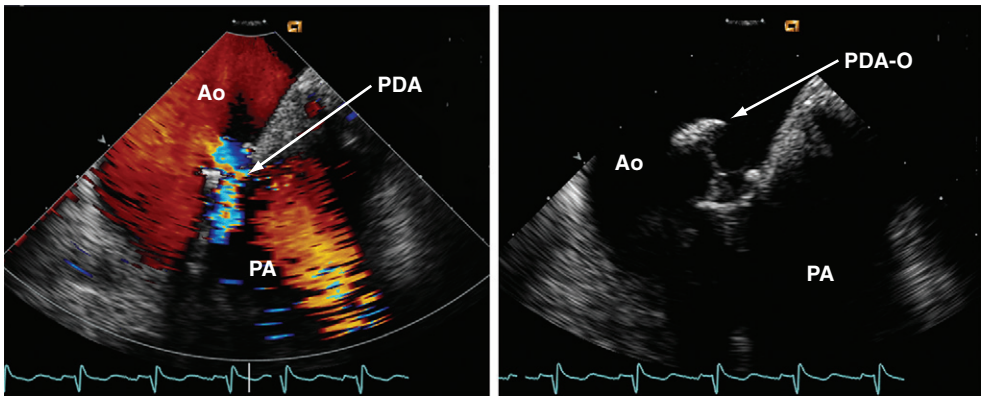

**Figure 6-15** Intraaortic viewing: device closure of patent ductus arteriosus (*PDA*). *Ao*, Aorta; *PA*, pulmonary artery; *PDA-O*, patent ductus arteriosus occluder.

documented.[37] With careful handling, interference between the echocardiographic catheter and the lesion can be avoided. Nevertheless, there is some risk of peripheral embolization during the procedure.

Percutaneous device closure of patent ductus arteriosus is another interventional approach nicely guidable by use of IPAI. It may help to reduce procedural time, limit radiation exposure, and lower the amount of contrast agent administered. It is conceivable that IPAI can contribute to the safety and success of this nonroutine procedure[38] (Fig. 6-15).

## Periinterventional Imaging of the Mitral Valve

Percutaneous transseptal balloon mitral valvotomy (BMV) (see Chapter 21) can be performed in concentric stenosis when the commissures are fused because of rheumatic heart disease without significant calcification and mitral regurgitation. Suitability of mitral stenosis for BMV can be assessed using the Wilkins score and a commissural score. As described for interventional left atrial appendage closure, atrial septal puncture is guided by the ICE transatrial longitudinal view. In that view, tool positioning in the LA can also be monitored. After introduction of a special guidewire into the LA, the transventricular long-axis view of the LV is obtained. Mitral ring diameter and intercommissural distance are measured, and the fused commissures are visualized. A balloon of appropriate size is selected. The same view is also useful for guiding a balloon through the stenotic mitral valve into the LV. Adhering to the double balloon technique, the distal balloon is inflated. Inflation should be monitored with ICE and fluoroscopy simultaneously. The next steps must be completed quickly to avoid prolonged LV inflow occlusion. Simultaneous echocardiographic and fluoroscopic viewing and documentation are recommended to accomplish this goal. The distal balloon is first inflated, and then pulled back toward the stenotic valve. Not until this step is completed is the proximal balloon inflated and valvotomy performed. At this time, ICE demonstrates that the balloon fits tightly into the stenotic valve orifice. The newer single-balloon technique[39] may require even closer echocardiographic guidance to precisely position the cylindrical balloon into the stenosis.

After balloon deflation and withdrawal, immediate two-dimensional and Doppler analyses are recommended to show the split commissures and to exclude any injury of the commissures or the mitral valve apparatus. In addition, the degree of mitral regurgitation is reassessed. Intraprocedural ICE viewing may be considered an optional imaging modality, especially if the transthoracic acoustic window is very poor. It allows analysis of the valvular anatomy and is ideal when enhanced views are required.[40] ICE is capable of providing excellent imaging and guidance, which results in low radiation exposure and minimizes the need for contrast angiography.[15]

One would expect the more sophisticated interventional procedures to derive more benefits from ICE. Thus, there is great potential for ICE in percutaneous valve implantation techniques and other catheter-based "valvular repair" procedures currently under development. Another future application may arise from the increasing importance of minimally invasive and reconstructive mitral valve surgery.

## Limitations

Adequate handling of the ICE catheter requires a learning curve, even for an interventionalist familiar with left and right heart catheterization and IVUS. Additionally, the relatively large probe may limit its use in infants. In addition, the multifrequency probe does not provide harmonic imaging capability. ICE does, however, eliminate the need for general anesthesia and intubation, thereby lowering costs and increasing patient comfort. On the other hand, the high price for one AcuNav catheter remains an important shortcoming. Today, the catheter is no longer a disposable device. The lumenless catheter can be resterilized with gas. Vanguard AG Medical Services for Europe (Berlin, Germany) is an approved CE-certified company licensed to resterilize ICE catheters. Technical and medical safety and compliance with appropriate legal regulations governing health care products are guaranteed. After more than 2 years of experience, we can recommend resterilization as a safe procedure that permits each catheter to be reused approximately three times. Although the image quality may slightly deteriorate from resterilization, each catheter can eventually be used four times, markedly lowering the costs for each use, even when the cost of resterilization is accounted for.

**TABLE 6-4 Usefulness and Effectiveness of Intracardiac and Intravascular Imaging**

| *Procedure* | *Clinical Benefit* |
|---|---|
| Device closure of atrial septal defect | Very high |
| Device closure of patent foramen ovale | Moderate |
| Left atrial appendage closure | Moderate |
| Radiofrequency pulmonary vein ablation | Very high |
| PTSMA | Moderate |
| Transcatheter aortic valve implantation | High |
| Surgery of the ascending aorta | Undetermined |
| Interventional therapy of the descending aorta | Potentially high |
| Balloon mitral valvotomy | High |
| Surgical/interventional mitral valve repair | Undetermined |

*PTSMA*, Percutaneous transluminal septal myocardial ablation.

Finally, the relation between advantages and disadvantages of using ICE and IPAI depends mainly on the expenditure and the risk of the specific interventional procedures. Increasing familiarity of interventional cardiologists with this technique may also affect its use in clinical practice (Table 6-4).

## KEY POINTS

As an alternative to TEE and IVUS and in conjunction with fluoroscopy, ICE can guide a variety of noncoronary percutaneous interventional therapeutic interventions:

| **Interventional Procedure** | **Guidance by ICE** |
|---|---|
| 1. Device closure of interatrial communications | View from the RA |
| 2. LAA occlusion | View from the RA (and RV) |

## Technical Background

### GRAY-SCALE INTRAVASCULAR ULTRASOUND

Gray-scale intravascular ultrasound (IVUS) utilizes one or more miniaturized transducers secured at the end of a flexible catheter that is inserted into arteries for in vivo tomographic visualization of vascular anatomy. Intracoronary ultrasound has become the most commonly used form of intravascular imaging and is regularly employed to delineate plaque morphology and distribution, to assess angiographically ambiguous lesions, to assess atherosclerosis progression and regression, to guide transcatheter coronary intervention, and to assess mechanisms of restenosis (Fig. 7-1).[1-2] The IVUS catheter is attached to either a portable or installed ultrasound machine through an interface that ensures sterility of the catheter and allows for motorized pullback. Motorized pullback of the IVUS catheter (or of the transducer within the catheter) at 0.5 mm/s or 1.0 mm/s allows calculation of lesion length and plaque volumes (necessary for progression/regression studies), ensures adequate time to visualize the lesion, and allows comparison between IVUS "runs" done at different times but with similar pullback speeds.

There are two types of transducers used in IVUS catheters: mechanical and phased array. The mechanical catheter uses a single transducer that is mounted at the tip of the catheter and rotated quickly (at 1800 rotations per minute [rpm]). Because the IVUS transducer is oriented at a 90° angle to the length of the catheter, the images are displayed as cross-sectional views of the artery. The mechanical transducer has the advantage of a simple design and a greater signal-to-noise ratio. These properties account for its high image quality with an overall resolution (with current 40- to 45-MHz transducers) of approximately 100 to 120 μm. The primary disadvantage of mechanical transducers is that they require a central drive shaft to rotate the transducer on the tip of the catheter. This drive shaft decreases catheter flexibility. If a mechanical transducer is placed within a tortuous vessel, the drive shaft may be constricted, resulting in nonuniform rotation of the distal transducer, thus creating an artifact of the image termed nonuniform rotational distortion.

The phased array transducer uses multiple, tiny transducer elements. Each transducer element is permanently mounted around the circumference of the catheter tip and sends and receives ultrasound from a small sector. The multiple imaging sectors are then "added together" to produce a cross-sectional image of the artery. Because the phased array transducer is permanently fixed with no moving parts, it is more flexible and transverses torturous vessels more easily. These transducers do not produce nonuniform rotational distortion artifacts. However, the 20-MHz phased array transducer does require more complex programming to add the sectors together and thus has a lower temporal resolution (a function of computational speed) and lower spatial resolution.

### IMAGE FORMATION

An IVUS image is formed when ultrasound bounces off the multiple layers of the artery and returns to the transducer.[3] The coronary artery is a muscular vessel composed of three basic layers: intima, media, and adventitia (Fig. 7-2). The intima, only a few cells thick at birth, is the site of atherosclerotic plaque accumulation. The intima is directly surrounded by the media, a layer of predominately homogeneous smooth muscle cells that provides the artery with its vascular tone. The outermost layer is the adventitia. Each of these layers tends to have a different acoustic property, allowing each to be visualized separately. When ultrasound encounters the intima, there is a large change in acoustic impedance; and much of it is bounced back

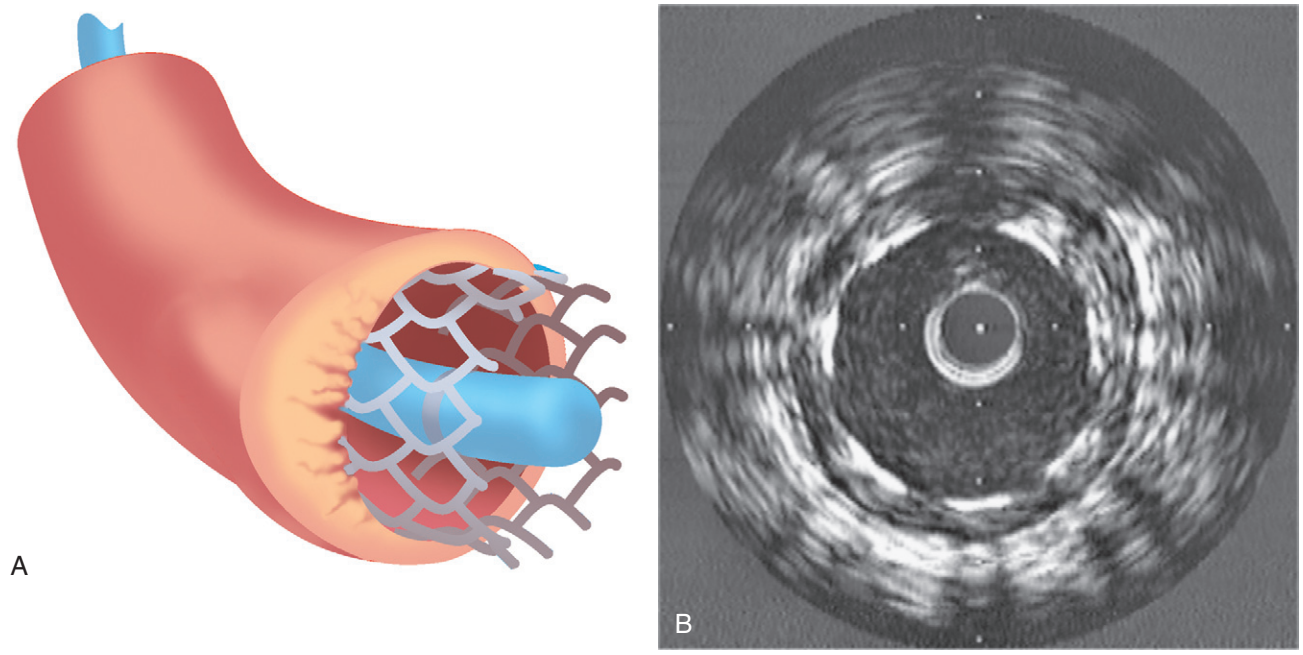

**Figure 7-1** **A,** Pictorial representation of an intravascular ultrasound catheter inserted into a coronary artery after stent deployment. **B,** Actual intravascular ultrasound image of a well-deployed coronary stent.

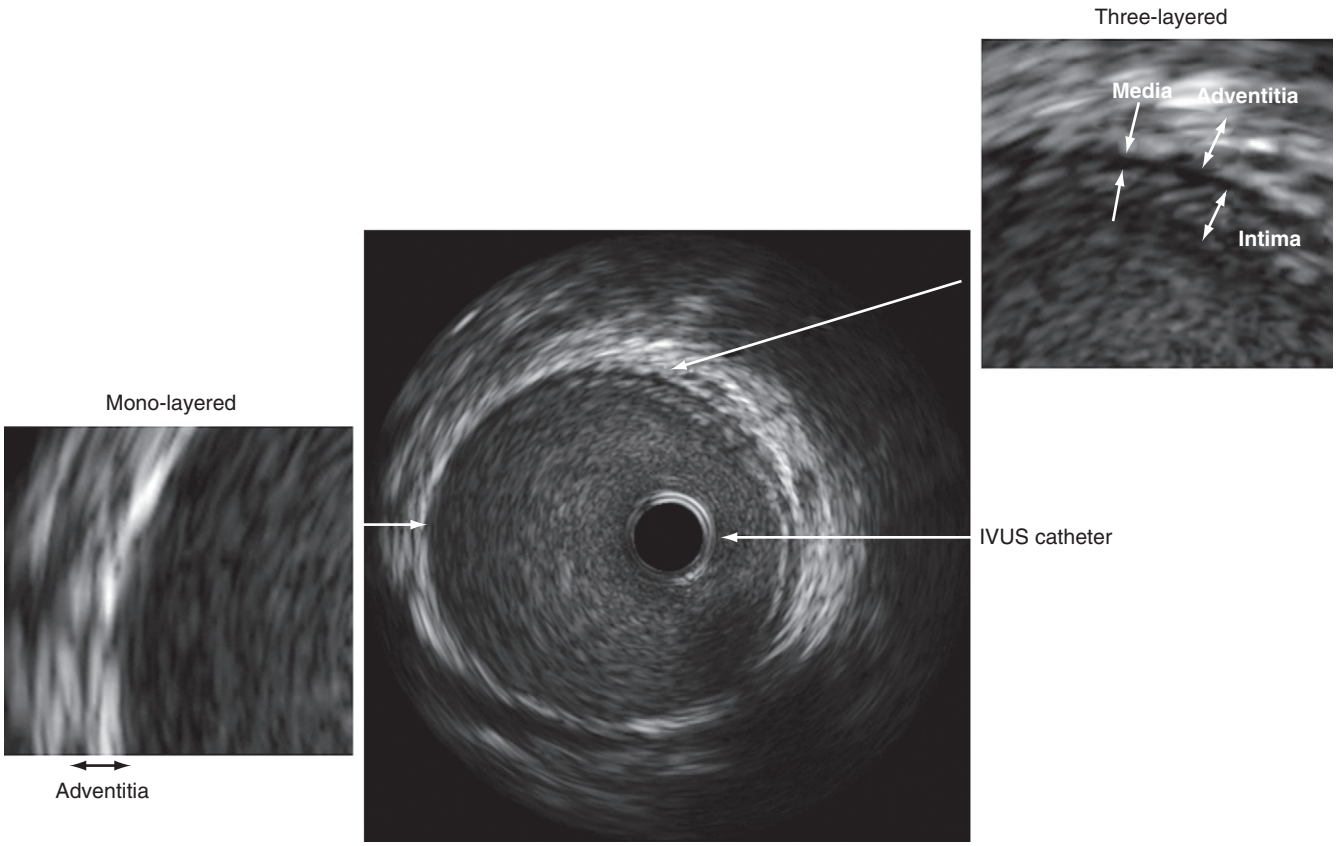

**Figure 7-2** *Center* image was magnified and displayed at right and left. (*Right*) Typical "three-layered" appearance indicating intima, media (dark band), and adventitia. (*Left*) "Mono-layered" appearance indicating very thin intima below intravascular ultrasound resolution, media (not visible), and adventitia.

to the transducer and displayed as a single concentric echo. Unless the intima becomes extremely hard, such as with the formation of a calcified plaque, some ultrasound penetrates through to the media. Because the media is composed of homogeneous smooth muscle cells, it passes through with minimal reflection; thus the media appears as a dark zone devoid of echoes. The adventitia has numerous layers of collagen fibers and therefore is a highly reflective structure that appears bright. As a result of the different acoustic properties of each layer, the normal coronary artery has a three-layered appearance, which

includes (1) a bright echo from the intima, (2) a dark zone from the media, and (3) bright echoes from the adventitia. Because the resolution of IVUS is approximately 100 to 120 μm, the intima has to be at least this thick to be visualized as a distinct structure. In Western society, most patients presenting to the cardiac catheterization laboratory have some diffuse thickening of the intima. But if the intima is truly disease free, as in a newborn, child, or adolescent, then the intima will be much thinner and below the resolution of IVUS so that the artery will appear as a monolayer (see Fig. 7-2).

## IMAGE INTERPRETATION

The interpretation of an IVUS image involves only a few simple steps: (1) identify the IVUS catheter in the center of the screen, keeping in mind that the IVUS catheter is traveling down the blood-filled lumen; (2) identify the dark stripe of the media that tells the size of the artery in the absence atherosclerotic disease; (3) remember that all of the echoes within the media stripe represent intima or intimal (atherosclerotic) disease and (4) all of the echoes outside the media are adventitia (see Fig. 7-2).

The amount of ultrasound that reflects off of tissue depends on the acoustic impedance (density) of the tissue. This property provides IVUS with some ability to differentiate plaque of different compositions. Hard material (calcium or fibrotic plaque) will reflect more ultrasound and appear brighter, whereas soft plaque (fat) will not reflect the ultrasound and will appear dark. Calcium is so dense that no ultrasound penetrates to the deeper tissues and, thus, produces acoustic shadows; shadowing, along with the bright echoes is the hallmark of calcification. A conventional approach is to compare the overall brightness of the plaque to the surrounding adventitia. Plaque is typically characterized as hypoechoic if less dense than the adventitia, hyperechoic if more dense than the adventitia, calcified if bright with acoustic shadowing, or mixed. IVUS can detect dense calcium with high sensitivity and specificity,[4-6] but its accuracy in identifying high-risk lipid rich plaque or even thrombus formation is poor.[7] As shown in Figure 7-3, gray-scale IVUS can also detect two other types of high-risk plaques: (1) noncalcified attenuated plaque (which correlates with fibroatheroma) and (2) calcium nodules (calcium with a convex shape and irregular surface).[8-10]

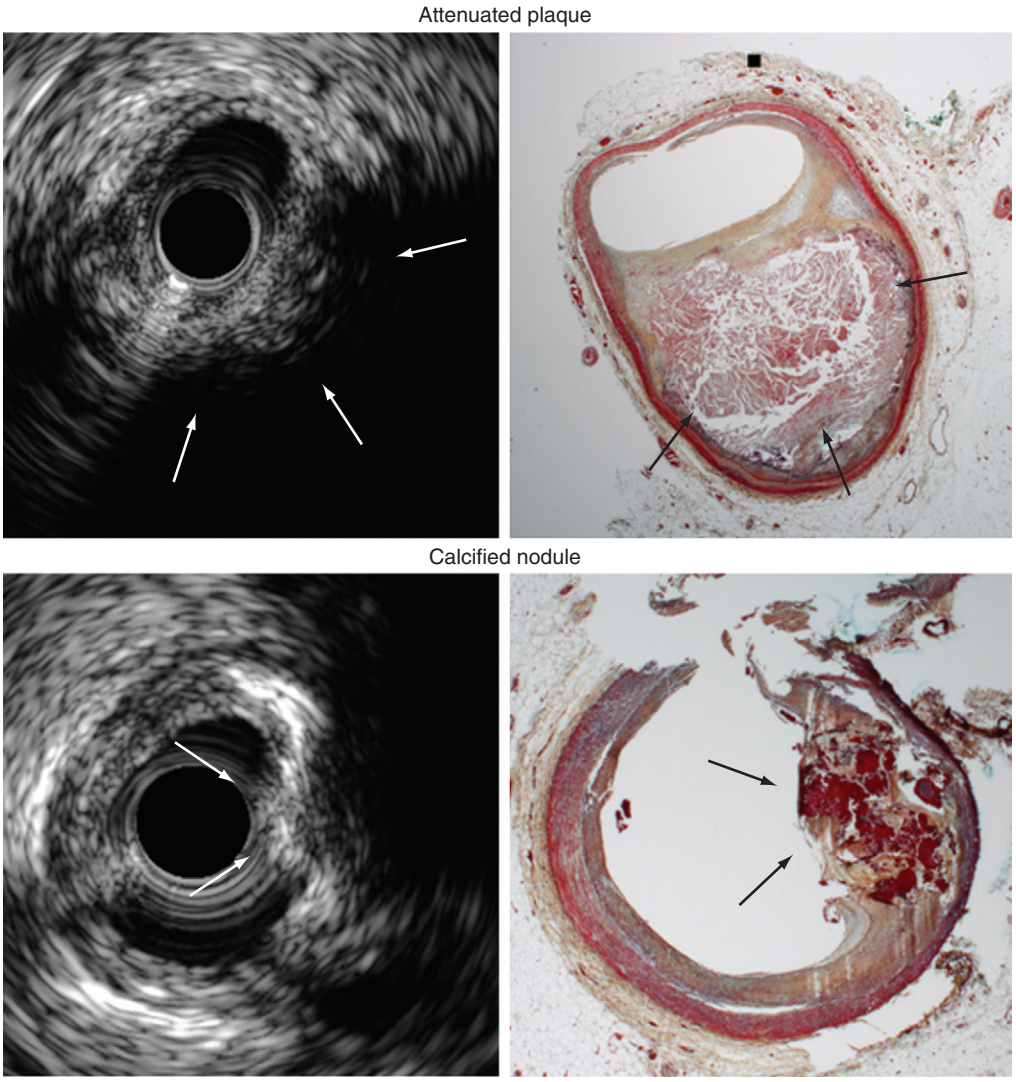

**Figure 7-3** Both intravascular ultrasound (IVUS) and corresponding histology (Russell-Movat's pentachrome staining) are shown. (*Top*) IVUS image shows typical "attenuated plaque"—non-hyperechoic plaque with attenuation. Corresponding histology shows advanced fibroatheroma (*black arrows*). Intravascular ultrasound image (*bottom*) shows "calcified nodule," which has convex irregular surface with acoustic shadow. Corresponding histology shows cluster of calcified nodules (*black arrows*).

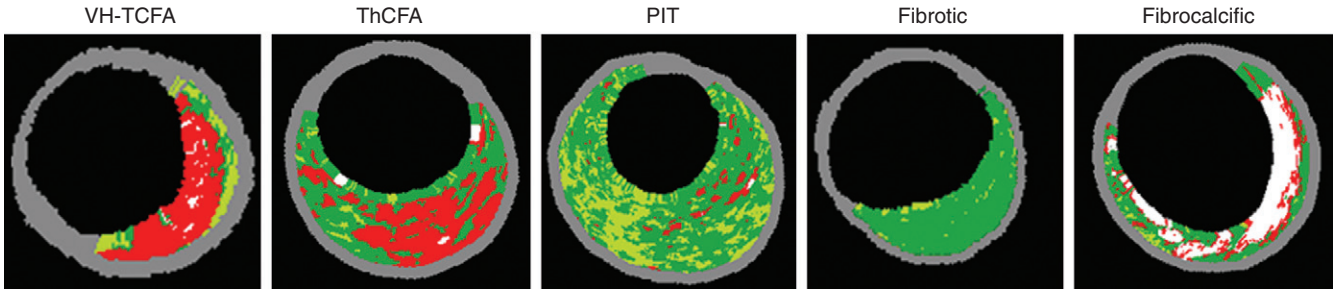

**Figure 7-4 Virtual histology (VH) IVUS classification.** (*red*, necrotic core; *white*, dense calcium; *light green*, fibrofatty; *dark green*, fibrous tissue) *VH-TCFA*, VH thin-cap fibroatheroma; *ThCFA*, thick-cap fibroatheroma; *PIT*, pathologic intimal thickening; fibrotic plaque; and fibrocalcific plaque.

## RADIOFREQUENCY IVUS

Standard gray-scale IVUS is limited, in part, because it uses only the amplitude of reflected ultrasound to formulate the image. In an effort to improve on the qualitative assessment of the reflected ultrasound signal, Kawasaki and coworkers developed a plaque characterization algorithm called integrated backscatter IVUS using time domain information directly from the radiofrequency signal. This process has resulted in improved plaque characterization with a reported in vitro sensitivity of 90% and specificity or 92% for lipid-rich plaque.[11]

In a similar effort to improve plaque characterization, spectral analysis (virtual histology [VH]-IVUS) combines signal frequency and amplitude analysis to create an algorithm that detects fibrous tissue (dark green), fibrofatty (light green), necrotic core (red), and dense calcium (white). Reported sensitivity and specificity of VH-IVUS are 91.7% and 96.6% for identification of the lipid-rich necrotic core.[12-14] However, VH-IVUS cannot detect thrombus (in fact, thrombus appears as either fibrotic or fibrofatty plaque depending on the age of the thrombus) and has not been validated for assessment of stent metal or intimal hyperplasia. VH-IVUS lesion phenotype has been classified as (1) VH thin-cap fibroatheroma, (2) thick-cap fibroatheroma, (3) pathologic intimal thickening, (4) fibrotic plaque, and (5) fibrocalcific plaque (Fig. 7-4). Fibrotic plaque has mainly fibrous tissue with less than 10% confluent necrotic core, less than 10% confluent dense calcium, less than 15% fibrofatty. Fibrocalcific plaque has mainly fibrous tissue with greater than 10% confluent dense calcium, but less than 10% confluent necrotic core. Pathologic intimal thickening has a mixture of all plaque components, but dominantly fibrofatty with less than 10% confluent necrotic core and less than 10% confluent dense calcium. Fibroatheroma (both VH thin-cap fibroatheroma and thick-cap fibroatheroma) has greater than 10% confluent necrotic core. Because the resolution of VH-IVUS is 150 to 250 μm, it is not possible to detect fibrous cap thickness less than 65 μm (the typical pathologic definition of a thin fibrous cap). Therefore, if there is greater than 30° of necrotic core abutting to the lumen in three consecutive slices, the fibroatheroma is classified as VH thin-cap fibroatheroma; otherwise, it is classified as thick-cap fibroatheroma.[15]

## IVUS VERSUS ANGIOGRAPHY

Angiography permits the measurement of only luminal diameters and typically in only two or three views. Because of its tomographic presentation and high resolution, IVUS is far more accurate than angiography in assessing atherosclerotic plaque extent, morphology, and distribution.

To appreciate and apply IVUS in clinical practice, one needs to have a full understanding of how IVUS and angiography differ. Angiography is often referred to as a "shadowogram" of the lumen because a silhouette of the arterial lumen is obtained by injecting radiopaque dye into the lumen and projecting the shadow from the dye on to cineangiographic film. The shadow-o-gram is then used to extrapolate a luminal narrowing to a plaque accumulation. It is common to detect atherosclerosis in an artery that appears "normal" by angiography. Although it may appear to be a discrepancy at first, it is not, and both the angiography and the IVUS studies are providing complementary and accurate information. The primary difference is that angiography is visualizing just the lumen, whereas IVUS visualizes both the lumen and arterial walls. If the assumption is that all angiographic stenoses are from plaque, then it would make sense to conclude that an angiogram displaying a lumen without any narrowing is free of plaque. However, that may not be true (and usually is not). Conversely, an angiogram of an artery can be free of any stenosis, but that artery can still have many areas of plaque. This is true because of three phenomena: (1) atherosclerotic plaque is often diffusely distributed, (2) arteries can undergo vascular remodeling, and (3) complex atherosclerotic plaques are not appreciated by the two-dimensional silhouette.

It has been verified in autopsy studies and other IVUS studies of healthy donors that most people have diffuse atherosclerotic disease throughout their arteries by midlife, and this disease often remains angiographically silent because of its diffuse nature. In addition to diffuse plaque, vascular remodeling is also responsible for the high prevalence of angiographically silent disease. Both pathology and IVUS studies have documented that coronary arteries will enlarge to accommodate focal plaque deposition in an attempt to maintain luminal integrity. Compensatory dilation of the arterial wall occurs in direct response to the accumulation of atherosclerotic plaque. An absolute reduction in lumen dimensions typically does not occur until the lesion occupies approximately 40% to 50% of the area within the internal elastic membrane (40% to 50% cross-sectional narrowing).[16] As a result, most of the atherosclerotic burden is contained within angiographically normal reference segments.[17]

Complex luminal shapes can result from irregular plaques or the disruption of a plaque (from balloon angioplasty). Although such a lesion may appear hazy, it may not demonstrate a luminal stenosis when viewed from only one or two views and projected as a silhouette. This may be similar to an eccentric lesion, which can fool inexperienced angiographers, unless a large number and variety of views are obtained, each displaying a different

severity. However, a lumen with highly irregular borders may not be fully appreciated, even in multiple views. The tomographic images of IVUS are necessary to appreciate the true luminal shape. Therefore, diffuse plaque, vascular remodeling, and irregular plaque can all lead to an inability of angiography to appreciate the plaque that is seen on IVUS. This is predominately because angiography only visualizes the lumen and does so in limited views using silhouettes of the dye.

Finally, angiography may contain areas that are hazy or lesions that are ambiguous. These hazy or ambiguous lesions may result from irregular plaque, a focal area of calcium, a dissection, or an intraluminal thrombus. IVUS is particularly useful for ambiguous lesions because each of the causes (plaque irregularities, calcium, dissection, or thrombus) appear different on IVUS.

## Clinical Applications

The concepts involved in the use of IVUS to guide coronary interventions are not different from the concepts involved in the use of angiography to guide interventional procedures. From a practical standpoint, the primary uses of IVUS are to assess the severity of a coronary artery stenosis including left main coronary artery (LMCA) disease, to measure lesion length, to measure reference vessel size, to identify complications, to optimize final results, and to assess causes of stent failure (including stent underexpansion, stent fracture, and late acquired stent malapposition).

### INTEGRATION INTO PRACTICE

Many practical aspects of IVUS imaging are facilitated by designating specific IVUS technologists who become responsible for all practical aspects of IVUS imaging: (1) equipment and catheter setup, (2) image optimization, (3) proper recording of IVUS imaging runs, (4) accurate voice and onscreen alphanumeric documentation, (5) patient and procedure logs, and (6) equipment maintenance. With time, technologists can be trained to interpret images accurately, to provide the iterative feedback necessary for IVUS-based decision making, and to answer questions posed by the primary operators. Measurements should be made offline (from hard drive after the imaging run is complete), not when the catheter is in the vessel; this saves procedure time and minimizes patient ischemia.

The angiographic (i.e., "road-map") monitors can be "wired" to display IVUS images. Angiographic monitors offer superior resolution, are convenient and readily visible to the operator, and allow the IVUS machine to be placed in a position away from the patient table and out of the way of the nurses providing patient care.

In a busy laboratory with multiple operators, it is important to standardize image acquisition and analysis. The use of a motorized transducer pullback device aids (in fact, enforces) discipline and acquisition standards; there is no question whether the transducer is being advanced or withdrawn. The preferred pullback speed is 0.5 mm/s; this is the fastest rate at which the trained eye can assimilate the information. Standardization of image acquisition facilitates offline image analysis and comparison of serial (preintervention versus postintervention or postintervention versus follow-up) studies; it is essential for multicenter studies.

### STANDARD IVUS ACQUISITION PROTOCOL

IVUS imaging should include careful uninterrupted imaging of (1) at least 10 mm of distal reference, (2) the lesion site(s), and (3) the entire proximal reference back to the aorta. Advantages of motorized pullback are (1) controlled catheter withdrawal so no segment of the vessel is skipped or imaged too quickly by pulling the catheter back too rapidly, (2) the ability to concentrate on the images without having to simultaneously pay attention to catheter manipulation, (3) the ability to make length and volumetric measurements, and (4) uniform and reproducible image acquisition for multicenter and serial studies. Disadvantages of motorized pullback are the following: (1) even at slow pullback speeds, it is possible to skip over focal lesions; (2) not enough attention may be paid to important regions of interest; and (3) it is not possible to have the transducer "sit" at one specific site in the vessel.

However, motorized transducer pullback does not preclude the addition of careful, manually controlled interrogation of the lesion. Manual transducer pullback should be at a slow rate similar to motorized pullback. Advantages are that it is possible to concentrate on specific regions of interest by having the transducer sit at a specific site in the vessel. Disadvantages include the following: (1) it is easy to skip over significant pathology by pulling the transducer back too quickly or unevenly, (2) length and volume measurements cannot be performed, and (3) antegrade and retrograde manual catheter movement can be confusing when the study is reviewed at a later date.

When interrogating ostial lesions, it is important that the guiding catheter be disengaged from the ostium. If not, the true ostial lumen dimensions may not be identified. In all cases, at least one continuous uninterrupted imaging run should be performed from approximately 10 mm beyond the target lesion to the ostial junction of the ostium with the aorta.

### SAFETY

Three large studies have evaluated the safety of IVUS. Other than transient spasm, complications appear to be rare (Table 7-1).[18-20]

### ASSESSMENT OF STENOSIS SEVERITY

Coronary angiography underestimates stenosis severity most markedly in vessels with 50% to 75% plaque burden (plaque area divided by arterial area) at necropsy and in patients with multivessel disease.[21-25] Clinical events are determined by lumen size, not by the amount of plaque. Therefore, it is important to focus on accurate measurement of lumen dimensions and not to be distracted by the plaque burden. Plaque burden in patients with atherosclerosis tends to be large even in the absence of lumen compromise.

**TABLE 7-1 Studies Evaluating the Safety of Intravascular Ultrasound**

| *Study* | *Number of Patients* | *Number of Centers* | *Transient Vessel Spasms* | *Major Complications* |
|---|---|---|---|---|
| Hausmann and colleagues[18] | 2207 | 28 | 2.9% | 0.4% |
| Batkoff and Linker[19] | 718 | 12 | 0.6% | 0.6% |
| Gorge and colleagues[20] | 7085 | 51 | 3.0% | 0.14% |

Data from references 18, 19, and 20.

Figure 7-5 Normal left main coronary artery (LMCA) compared to LMCA with severe disease.

Studies performed more than 10 years ago suggested that an IVUS minimum lumen area (MLA) greater than 4 $mm^2$ was a valid criterion for deferring an intervention based both on comparisons to physiologic measures and on follow-up data.[26-29] This cutoff only applied to major epicardial vessels excluding the LMCA and excluding saphenous vein grafts. However, it was necessary to interrogate the lesion carefully to identify the image slice with the smallest lumen, especially in very focal stenoses. Once the smallest lumen is identified, careful measurement was required. Recently this cutoff has come under criticism for a number of reasons including the size of the vessels (studies were done mostly in large 3.5-mm vessels), the average MLA of the intermediate lesions studied (4 $mm^2$), and the fact that these studies have been misinterpreted to suggest that lesions with an MLA below 4 $mm^2$ justify stent implantation. For this reason, it is recommended that for major epicardial vessels excluding the LMCA, physiologic lesion assessment (using an intracoronary pressure wire and maximum hyperemia with intravenous adenosine to measure the fractional flow reserve) is a complementary approach to assess lesion severity.[30]

## ASSESSMENT OF LMCA DISEASE

A high percentage of patients with angiographically "normal" LMCA with only nonsignificant stenosis have substantial disease by IVUS.[31-34] Reasons for the discrepancy between angiography and necropsy or IVUS assessment of LMCA disease include the following: (1) diffuse atherosclerotic involvement affects the angiographic diameter stenosis (DS) calculation because of the lack of a normal reference segment; (2) a short LMCA also makes identification of a normal reference segment difficult; (3) unique geometric issues exist in LMCA disease (the correlation between angiography and necropsy or IVUS appears to be somewhat better in non-LMCA stenoses); and (4) there is significant interobserver and intraobserver variability in the angiographic assessment of LMCA disease.[35-42] In fact, the LMCA is the coronary arterial segment with the greatest variability in angiographic assessment.

We reported 122 patients who underwent angiographic and IVUS assessment of the severity of LMCA disease, who did not have subsequent catheter or surgical intervention, and who were followed for 1 year.[43] There were three distinct predictors of these cardiac events: diabetes; a major epicardial vessel or bypass graft with a quantitative angiography (QCA) DS greater than 50% that was left untreated; and LMCA lesion site minimal lumen diameter measured by IVUS. An example is shown in Figure 7-5.

Jasti and colleagues reported that an IVUS MLA of 5.9 $mm^2$ or a minimal lumen diameter of 2.8 mm corresponded to physiologic ischemia (fractional flow reserve less than 0.75) in the LMCA.[44] Hernandez and co-workers evaluated 354 angiographically intermediate (diameter of stenosis 25% to 60%) unprotected LMCA lesions by IVUS. Of the patients evaluated, 186 had an MLA of at least 6 $mm^2$, and only 7 patients were revascularized.[45] In 2 years, percentages for survival free of cardiac death (97.7%) and revascularization (96.5%) were very high, suggesting a MLA of 6 $mm^2$ or greater as a safety cutoff to defer the revascularization of LMCA disease.

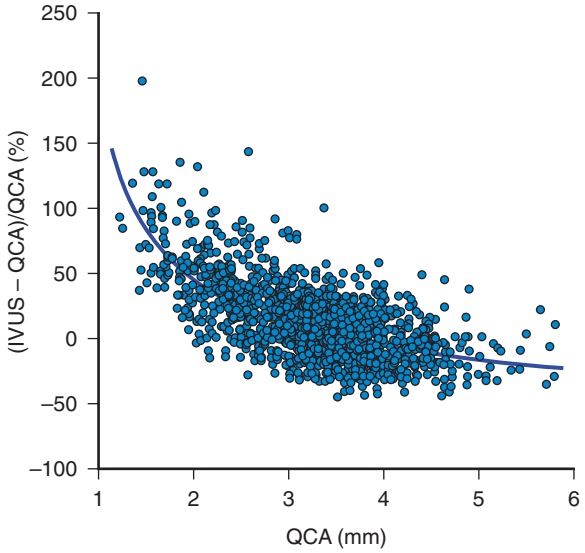

**Figure 7-6 Correlation between reference diameter by quantitative angiography (QCA) and intravascular ultrasound (IVUS).** At smaller vessel sizes, IVUS dimensions are larger than QCA; at larger vessel sizes, the difference is small.

## LESION LENGTH AND REFERENCE DIMENSIONS

The two most important measurements for stent size selection are lesion length and reference dimension. Motorized transducer pullback is essential for length measurements and has been validated in vivo.[46] A comparison of IVUS and QCA reference lumen measurements in 3311 nonostial native coronary arteries or saphenous vein graft lesions showed a QCA proximal reference lumen diameter of 3.05 ± 0.68 mm and an IVUS proximal reference lumen diameter of 3.41 ± 0.62 mm ($p$ less than 0.0001 versus QCA). The difference between the IVUS and QCA measurements was 0.36 ± 0.64 mm or 15 ± 24%. This difference was greatest in the smallest vessels, decreased asymptotically with increasing vessel size, and was zero at a QCA reference of approximately 4 mm shown in Figure 7-6.

This analysis suggests that, especially in the smaller arteries (which have higher restenosis rates), (1) the angiographic assessment of reference lumen dimensions is flawed and (2) an IVUS measurement would indicate that a larger device could be used that could result in larger final lumen dimensions without having to resort to midwall or media-to-media device/vessel sizing.[47,48] Alternatively, some authorities have advocated the use of IVUS "true vessel," "media-to-media," or midwall dimensions for device sizing; however, this should only be done by highly experienced IVUS users because it carries a greater risk of acute complications such as stent edge dissection.

## UNUSUAL LESION MORPHOLOGY

IVUS is useful in understanding lesions with an unusual angiographic appearance including filling defects, haziness, aneurysms, ulceration, myocardial bridge, and spontaneous dissection.[49-53] Examples are summarized in Figure 7-7 and shown in Figures 7-8 through 7-11.

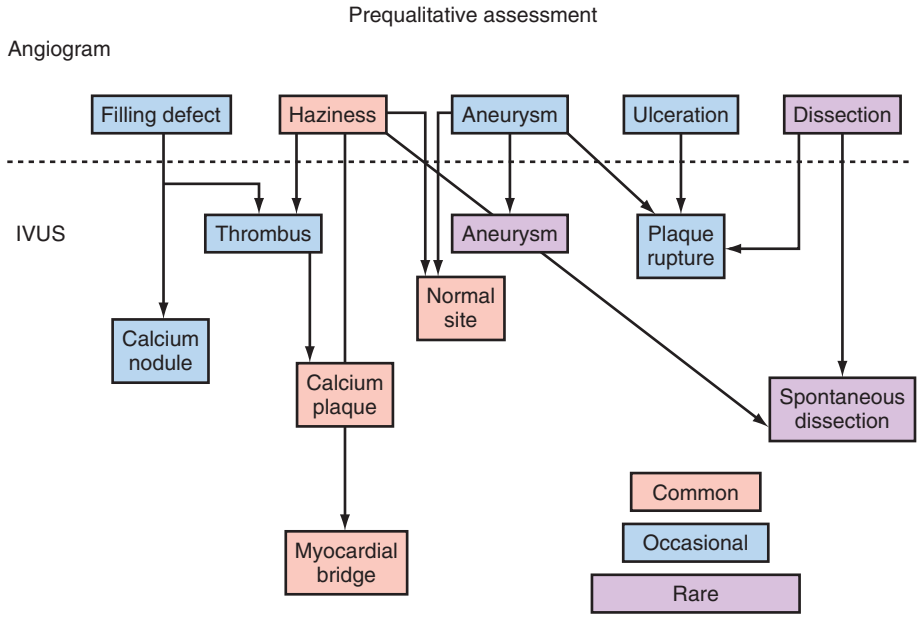

**Figure 7-7** Summary of preintervention qualitative assessment by intravascular ultrasound (IVUS). If the angiogram shows a filling defect, IVUS will show either thrombus or calcium nodule. If the angiogram shows haziness, IVUS will show thrombus, calcified plaque, myocardial bridge, normal site, or spontaneous dissection. Causes of an angiographic aneurysm include true aneurysm, false aneurysm, plaque rupture, or just a normal site that appears aneurysmal.

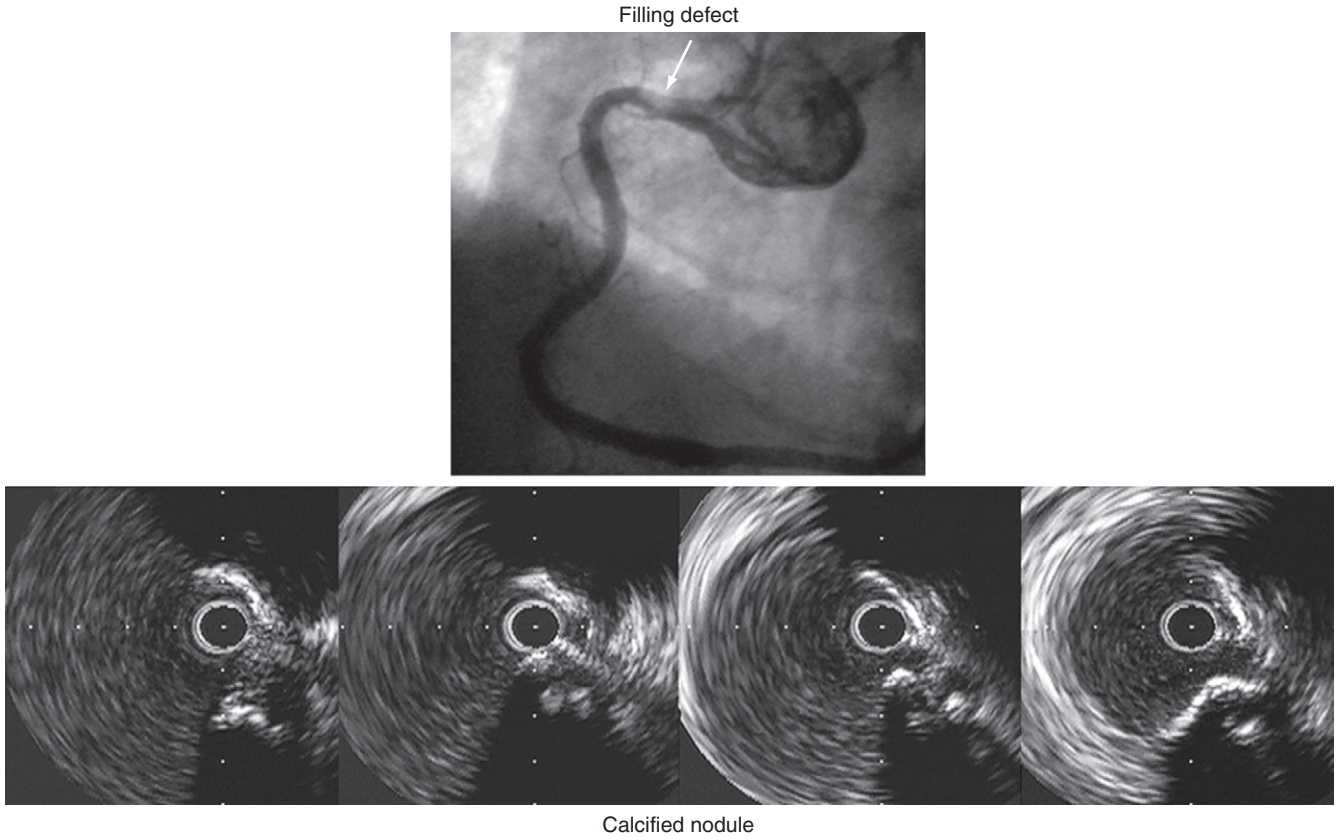

**Figure 7-8 Angiogram shows filling defect in the proximal right coronary artery.** Intravascular ultrasound shows calcified nodule.

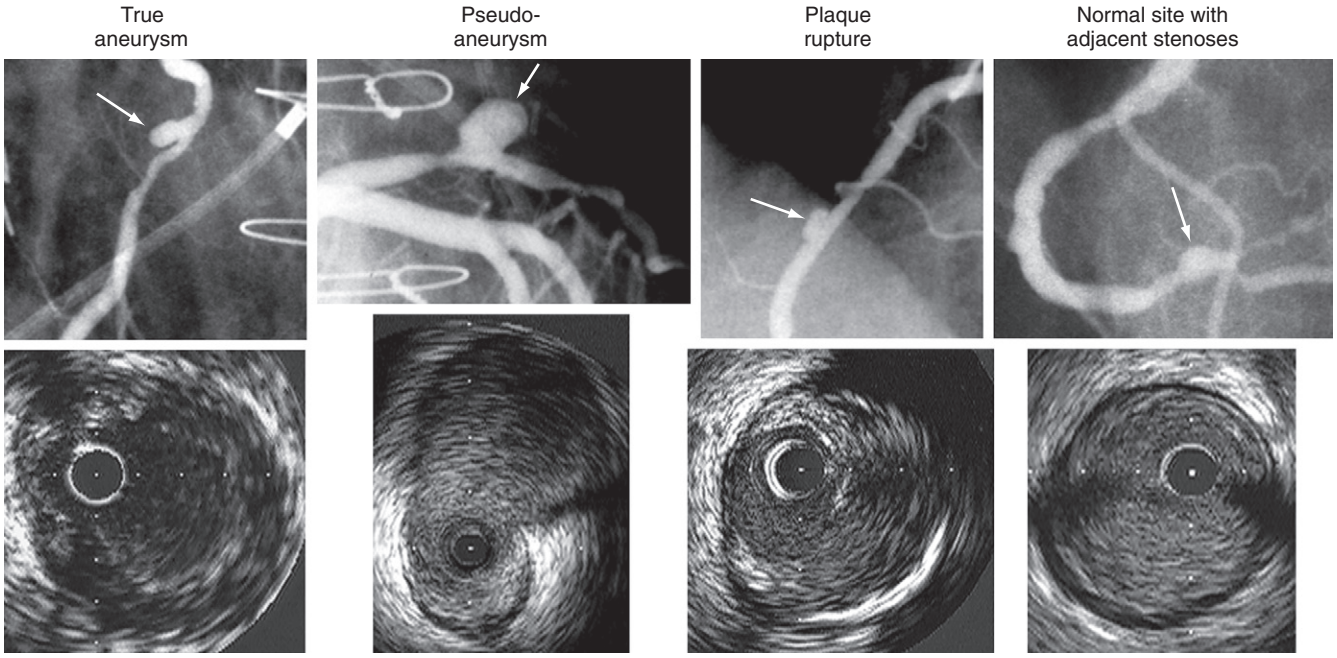

**Figure 7-9 All angiograms have the appearance of an aneurysm.** Intravascular ultrasound can differentiate true (three-layered) or pseudoaneurysm, plaque rupture, or just normal segments with adjacent stenoses.

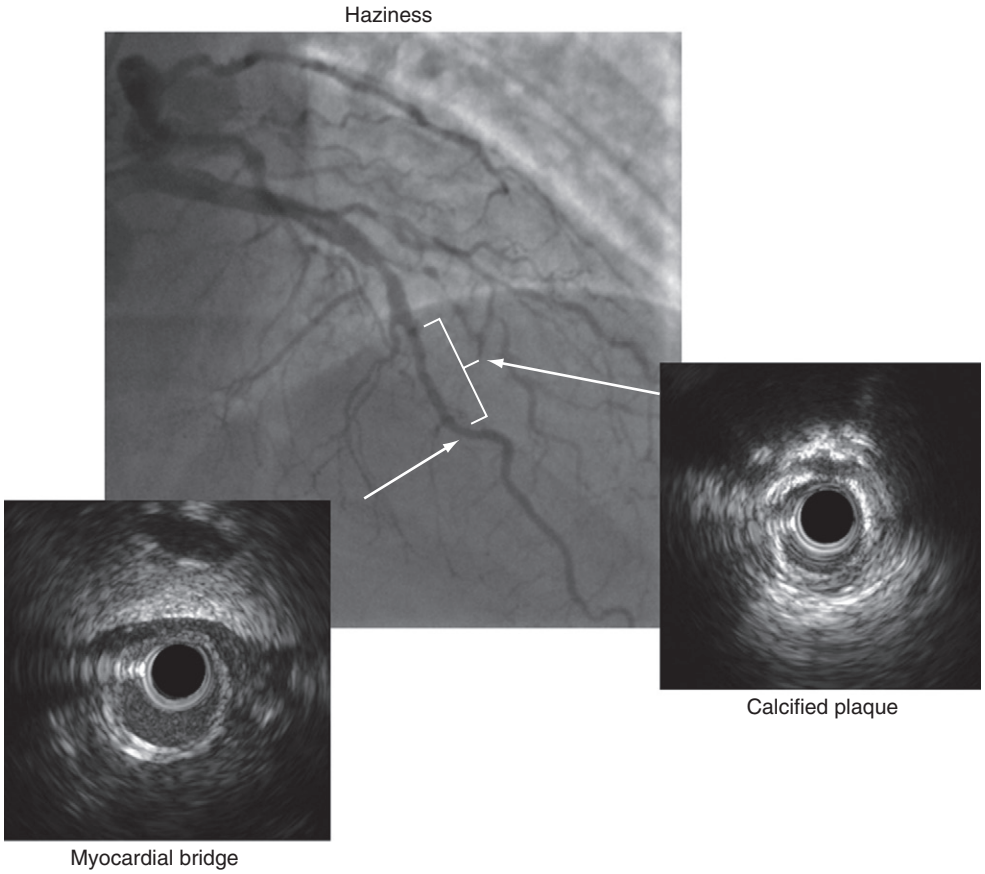

**Figure 7-10 Angiogram shows diffuse stenosis with haziness in mid to distal left descending artery.** Proximal segment of haziness appears as calcified plaque, and distal end appears as myocardial bridge by intravascular ultrasound (surrounded by low echoic band).

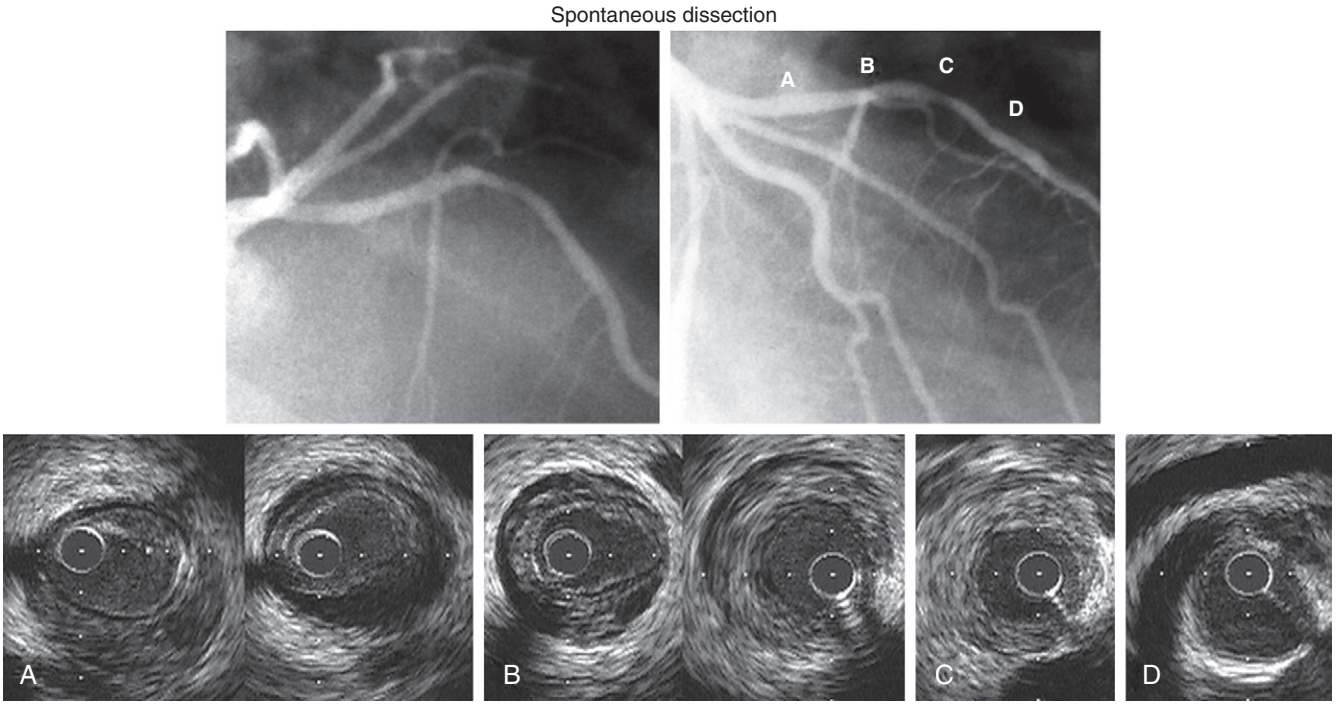

**Figure 7-11** Angiogram shows diffuse mild stenosis in mid to distal left descending artery (*A-D*). Corresponding intravascular ultrasound images shows spontaneous dissection (with intramural hematoma).

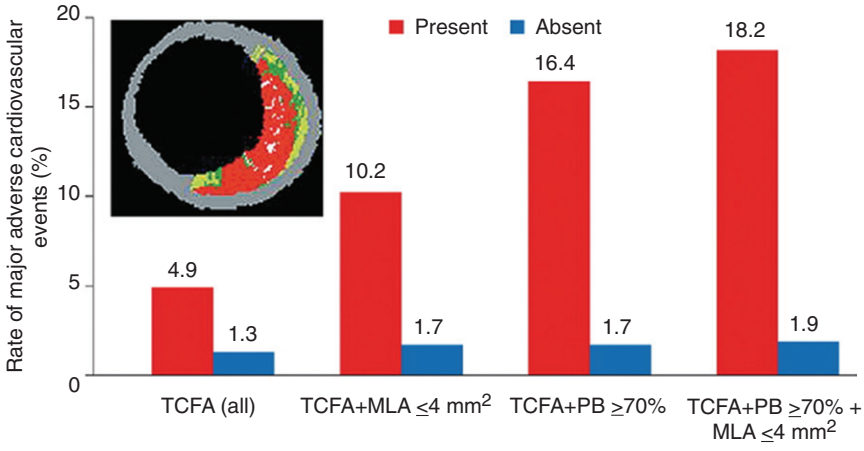
An IVUS classification of angiographic coronary artery aneurysms has also been created.[50] Of 77 aneurysm-containing lesions, 21 (27%) were classified as true aneurysm; 3 (4%) were classified as pseudoaneurysms (all having previous intervention); 12 (16%) were complex plaques; and the other 41 (53%) were normal arterial segments adjacent to one or more stenoses. Examples are shown in Figure 7-9. In a study of 300 consecutive IVUS-defined plaque ruptures, 91% were categorized as complex by angiography: ulceration in 81%, intimal flap in 40%, thrombus in 7%, and coronary aneurysm in 7%.[51] Approximately one quarter of patients had IVUS-detectable myocardial bridges in the LAD coronary artery; only 3% (11 of 331) were diagnosed by angiography. In 13% of cases, IVUS-detectable myocardial bridges appeared as mild (diameter of stenosis less than 25%) fixed lesions and/or angiographic haziness (see Fig. 7-10).[52] Spontaneous dissections are an intramural process that appears as a medial dissection with an intramural hematoma occupying the dissected false lumen without intimal tears and without a communication between the true and false lumens.[53] An example is shown in Figure 7-11.

## ASSESSMENT OF VULNERABLE PLAQUE

PROSPECT (Providing Regional Observations to Study Predictors of Events in the Coronary Tree) was a prospective study of the natural history of coronary atherosclerosis using angiography and VH-IVUS to identify the clinical and lesion-related factors that predicted future coronary events.[15] It was performed at 37 sites in the United States and Europe. Patients with acute coronary syndromes were enrolled after undergoing successful percutaneous coronary intervention of all culprit lesions responsible for the acute event. Angiography was performed of the entire coronary tree followed by gray-scale and VH-IVUS of the proximal 6 to 8 cm of all epicardial arteries. All baseline angiograms and gray-scale and VH-IVUS images were prospectively analyzed without knowledge of subsequent events using prespecified definitions and methodology. Plaque burden and luminal area as prospectively measured by gray-scale IVUS and plaque composition (thin-cap fibroatheroma) as assessed by VH-IVUS were determined to be independent predictors of future adverse cardiovascular events (Fig. 7-12).



## PREDICTION OF NO-REFLOW DURING INTERVENTIONAL PROCEDURES

IVUS guidance may also be useful to identify high-risk lesions before intervention, such as those that cause no-reflow or periprocedural myocardial infarction, particularly noncalcified attenuated plaque.[54-57] Noncalcified attenuated plaque may be a gray-scale indication of a larger necrotic core and/or fibroatheroma (96% of attenuated plaques contained a fibroatheroma vs. 52.3% on nonattenuated plaques, $p < 0.0001$).[9] In support of this, multiple VH-IVUS studies have shown that a larger necrotic core is related to distal embolization during percutaneous coronary intervention in both acute coronary syndromes and stable angina patients.[58-61]

## ASSESSMENT OF INTERVENTIONAL COMPLICATIONS

IVUS detects poststent dissections or other complications more often than angiography.

One type of dissection, intramural hematoma, appears as an angiographic dissection in 60%, as newly developed stenosis that does not disappear after nitroglycerin (i.e., not a spasm) in 11%, and as no angiographic abnormality in 29%.[62] Similarly, perivascular trauma appears as an angiographic perforation in 24%, as angiographic dissection in 33%, as new stenosis in 5%, and as no abnormality in 38%. Angiographic "haziness" at the stent edge may demonstrate an edge dissection or residual plaque, especially a calcified eccentric plaque, when studied by IVUS.

## RESTENOSIS, LATE MALAPPOSITION, STENT FRACTURE, AND STENT THROMBOSIS

In the bare metal stent (BMS) era, serial IVUS studies in humans showed (1) that tubular-slotted stent designs exhibit almost no chronic recoil, (2) that in-stent restenosis was almost entirely neointimal hyperplasia, (3) that there was no predilection for tissue accumulation within any one segment, and (4) that neointimal thickness was independent of stent size.[63,64] It is for these reasons that many studies have reported that the absolute minimum stent area (MSA) by IVUS was the strongest quantitative predictor of clinical and angiographic in-stent restenosis.[65-67]

Because drug-eluting stents (DES) have less neointimal hyperplasia, the MSA necessary to minimize restenosis can be smaller than with BMS. Using the data from SIRIUS, Sonoda and coworkers reported that the best cutoff to predict an MLA at follow-up of 4 $mm^2$ was an MSA of 5 $mm^2$ for sirolimus-eluting stents (SES) and 6.5 $mm^2$ for BMS.[68] A similar study by Hong and colleagues showed that the MSA that best separated angiographic restenosis from no restenosis was 5.5 $mm^2$ in SES.[69] We combined various TAXUS studies and reported that the best cutoff to predict angiographic binary restenosis for the paclitaxel-eluting stent (PES) was 5.7 $mm^2$.[70] However, "bigger is better" is still true; also, (1) a larger MSA is still associated with a lower restenosis rate, whereas (2) an MSA of 5.0 to 5.5 $mm^2$ may not be achievable in small vessels that are increasingly stented.

On the other hand, full lesion coverage may be more important in the DES era than in the BMS era. Costa and colleagues reported that longitudinal geographic miss (GM)—injured or diseased segment not covered by SES—was observed in 47.6%,; axial GM—balloon-artery size ratio less than 0.9 or greater than 1.3—was observed in 35.2%; and both GM in 16.5%.[71] One-year target vessel revascularization rates were 6.1% in the longitudinal GM group versus 2.6% in the no-longitudinal GM group ($p = 0.001$); the GM was the independent predictor for target vessel revascularization. In support of this, Liu and co-workers reported that the stent edge plaque burden that best separated restenosis from no restenosis was approximately 50%.[72]

Figure 7-13 summarizes the percentage of neointimal hyperplasia (%NIH = NIH volume divided by stent volume) and late acquired malapposition in various multi-center randomized trials.[73-83] In BMS, %NIH averaged (approximately) 30% of stent volume, and %NIH was consistently greater in diabetes than nondiabetes.[84] In the DES era, %NIH was reported as 2.7% to 3.1% in SES, 2.5% to 6.9% in everolimus-eluting stents, 7.4% to 12.2% in PES, and 16.1% to 17.6% in zotarolimus-eluting stents. Though NIH varied among DES, the clinical efficacy (target vessel revascularization) and safety (stent thrombosis) were similar in noncomplex lesions.

IVUS predictors of either drug-eluting acute/subacute stent thrombosis or restenosis are stent underexpansion and residual edge "problems," such as GM, adjacent secondary plaques, or significant edge dissections—but not acute malapposition.[85-87] Stent underexpansion was more diffuse in stent thrombosis than restenosis.[88]

IVUS studies have documented late-acquired stent malapposition in approximately 5% of BMS in non-STEMI (ST elevation myocardial infarction) patients, about 5% to 15% of BMS in STEMI patients and DES in non-STEMI patients, and about 25% to 30% of DES in STEMI patients.[73-83,89-92] Late-acquired stent malapposition is typically the result of positive vessel wall remodeling and/or thrombus dissolution behind the stent struts (especially in myocardial infarction patients). Cook and colleagues reported that 10 of 13 very late stent thrombosis patients (mean 1.8 years after stent implantation) had stent malapposition with a malapposition area twice as large as in control patients with malapposition, but without very late stent thrombosis (mean = 8.3 vs. 4.0 $mm^2$).[93] Alfonso and co-workers reported 15 (1.3%) patients with an angiographic aneurysm 9 months post-DES implantation; subsequently, 3 patients (with significantly larger aneurysms than others) suffered late stent thrombosis.[94] One metaanalysis suggested that there was an increased frequency of very late stent thrombosis in the setting of large areas of late malapposition.[95] In a second report, Cook and colleagues correlated the presence and size of the malapposition area with inflammatory cells from intracoronary aspirates, suggesting that it was not just the malapposition, but malapposition in the setting of vessel wall inflammation, that

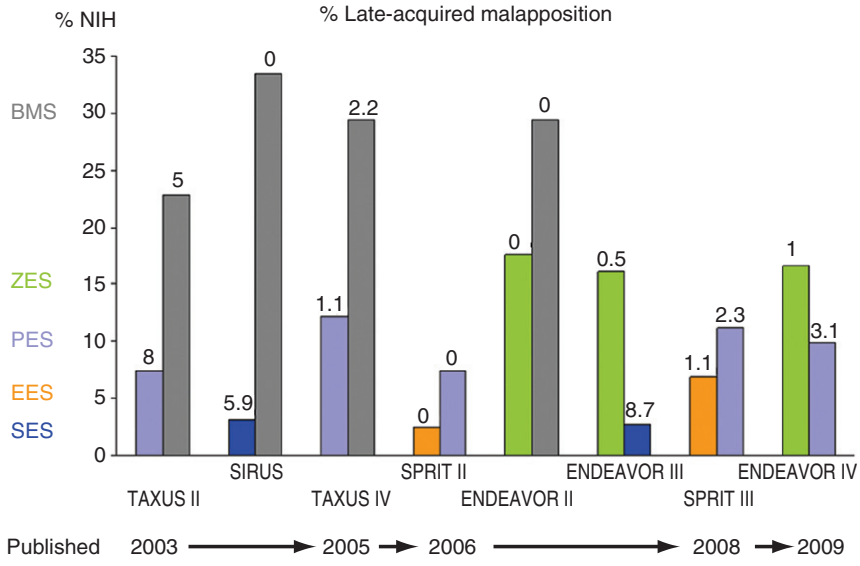

**Figure 7-13** Summary of %NIH (neointimal hyperplasia volume divided by stent volume) in various drug-eluting stent randomized trials. *BMS*, bare metal stent (*gray*); *ZES*, zotarolimus-eluting stent (*green*); *PES*, paclitaxel-eluting stent (*lavender*); *EES*, everolimus-eluting stent (*orange*); *SES*, sirolimus-eluting stent (*dark blue*). The numeric values above each bar indicate the incidence of late-acquired malapposition.

contributed to very late stent thrombosis.[96] In addition, in-stent neoatherosclerosis and subsequent rupture causing very late stent thrombosis has been reported by IVUS, VH-IVUS, optical coherent tomography, and coronary angioscopy.[97-100]

More recently, stent fracture is being implicated as a cause of DES failure, especially with SES. In a prior retrospective IVUS study of 17 non-STEMI patients with 20 stent strut fractures, 18 (90%) occurred in SES and 2 (10%) in BMS, but none in PES.[101] Of note, 5 of 20 stent fractures were accompanied by coronary aneurysm formation with two very late stent thromboses (Fig. 7-14). It has been proposed that biologic reactions to the eluted drug cause positive vessel remodeling with aneurysm formation and malapposition that allow motion and/or kinking of the stent within the aneurysm, leading to strut fracture. Angiographic data from three PES trials in nonacute coronary syndromes revealed a 1.1% rate of stent fracture associated with restenosis and/or stent thrombosis.[102] In the Nordic IVUS study, stent malapposition and stent fracture were found in 43% (37 of 87) and 16% (14 of 87) of DES thrombosis cases and 27% (10 of 37) and 27% (10 of 37) of BMS thrombosis cases.[103]

## TREATMENT OF IN-STENT RESTENOSIS

The uses of IVUS in evaluating patients with in-stent restenosis include (1) determining whether in-stent restenosis is severe enough to treat, (2) identifying occult mechanical problems with the stent that (presumably) occurred at the time of implantation, (3) assessing the patterns of in-stent restenosis, and (4) assessing the acute results. Using integrated TAXUS data (331 treated with PES and 304 treated with BMS who did not require revascularization in the first 9 months postintervention), we reported that the optimal thresholds of MLA that best predicted subsequent target vessel revascularization-free survival during the subsequent 3 years were 4.2 $mm^2$ for PES and 4.0 $mm^2$ for BMS.[104]

There are a number of technical and mechanical complications of stent implantation that can remain unrecognized until the patient presents with in-stent restenosis. These include (1) missing the lesion, (2) stent underexpansion, (3) stent "crush," and (4) having the stent stripped off the balloon during the implantation procedure. Because most stents are radiolucent, some lesions, especially aortoostial lesions, can be missed. Incomplete stent expansion during implantation can be missed angiographically because stents are porous and contrast can flow through and around them. Chronic stent recoil is rare.[63,105] If the guidewire is accidentally removed and, in recrossing the freshly placed (and presumably not fully implanted) stent, it courses adjacent to the stent and enters the stent through one of the diamonds, subsequent adjunct balloon dilation can crush part of the stent against the vessel wall. These mechanical problems constitute a minority of in-stent restenoses. However, the treatment of in-stent restenosis must begin by excluding these problems and, if they are present, by correcting them. Examples are shown in Figures 7-15 and 7-16. In an analysis of more than 1000 consecutive in-stent restenosis lesions, the frequency of these mechanical complications was found to be 4% to 5%.[106]

## BIOABSORBABLE STENTS

The first generation of bioabsorbable everolimus-eluting stents (BVS) implanted in 30 simple de novo lesions showed higher acute recoil than conventional metallic platform stents. At 6 months, the 11.8% reduction in scaffold area (chronic recoil) and a small neointimal response of 5.5% resulted in a total 24.3% decrease in MLA by IVUS.[107] However, at 2 years, the lumen area increased because of decrease in plaque size without change in vessel size.[108] The second-generation BVS had an improved scaffold that had only a 2% chronic recoil.[109]

## DOES IVUS GUIDANCE REDUCE STENT RESTENOSIS AND THROMBOSIS?

A number of randomized and nonrandomized studies compared IVUS versus angiographic guidance of BMS implantation.[110-112] A metaanalysis of the seven randomized IVUS versus angiography trials showed that IVUS improved final BMS dimensions to reduce BMS restenosis and repeat revascularization.[112] In the DES era, Roy and co-workers reported that IVUS guidance reduced stent thrombosis both within 1 month and from 1 to 12 months (0.7% vs. 2.0% at

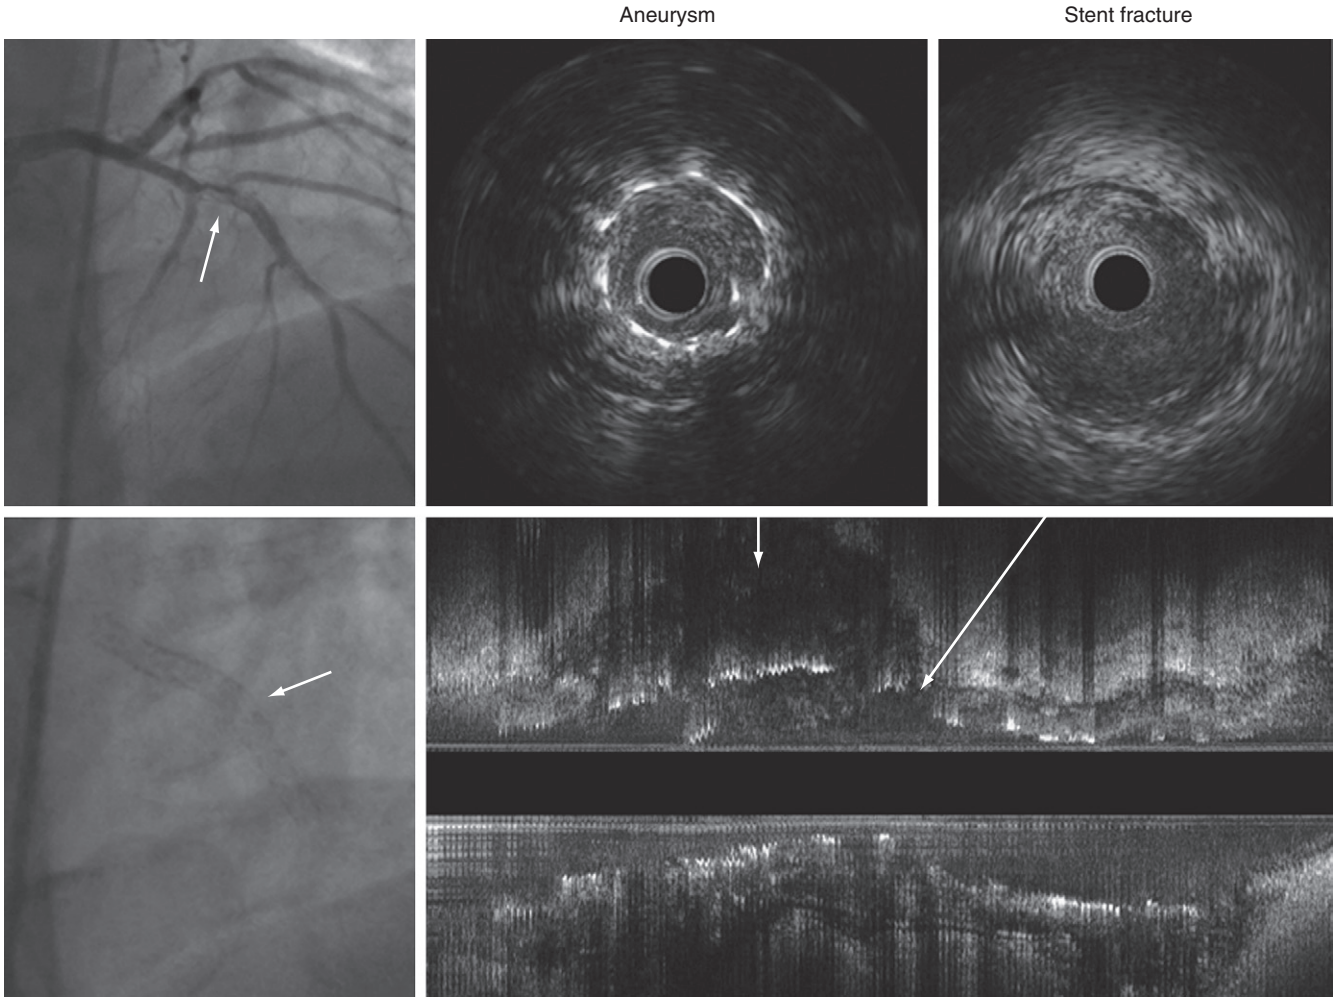

**Figure 7-14** An example of late-acquired aneurysm with stent fracture and very late stent thrombosis.

1 year, p = 0.014), supporting the use of IVUS during interventional procedures.[113] The improvement of major adverse cardiac events, particularly mortality, has been supported by Park and colleagues in unprotected LMCA-treated arteries.[114]

## PRACTICAL RECOMMENDATIONS

In practical day-to-day terms, how should IVUS be used during stenting procedures? The following is one suggested algorithm for routine use of IVUS. It begins with preintervention IVUS and concludes with iterative IVUS to optimize the final result. Perform preintervention IVUS to assess lesion characteristics and measure reference vessel size and lesion length. From the maximum reference lumen diameter, determine the maximum achievable stent dimension. Select stent length based on distance between proximal and distal references.

After the stent is implanted, repeat IVUS imaging to assess the MSA. If the MSA is adequate, stop. If the MSA is inadequate, perform additional high-pressure inflations, if necessary using a larger balloon. If additional balloon inflations are performed, recheck the IVUS results. If IVUS detects a complication such as a major dissection, an intramural hematoma, or perforation, treat appropriately and repeat IVUS to ensure that the complication is corrected. Conversely, if, despite the angiographic appearance, IVUS imaging shows a good acute result, stop.

If the interventional cardiologist wants to selectively used IVUS, it will be especially useful in the following three situations: (1) when you expect a good result, but flow is limited (IVUS can identify a correctable cause such as flow-limiting dissection or intramural hematoma); (2) any patient presenting with stent failure in which IVUS may identify a mechanical problem such as simple stent underexpansion or a crushed stent; and (3) with LMCA lesions or small-vessel stenting.

### KEY POINTS

- IVUS provides a unique, tomographic view of the artery from the inside out with high resolution.
- Standardization improves the clinical utilization of IVUS.
- IVUS images all components of the arterial wall, providing information beyond the luminal profile displayed by angiography to include plaque burden and distribution, remodeling, true vessel size, high-risk plaque morphology, and so forth.
- IVUS can guide stent implantation to optimize the acute results and reduce late complications.
- The added information from IVUS is particularly helpful for angiographically ambiguous lesions, unusual lesions, and complex clinical scenarios.

**Future Directions**

Although technology has transformed almost all aspects of our daily lives, the bedside cardiac physical examination uses technology that is almost 200 years old. In 1816, embarrassed to examine an obese young woman by putting his head to her chest, René Théophile-Hyacinthe Laennec rolled a sheet of paper, then placed one end over her precordium and the other to his ear. Thus, the stethoscope was born.[1] The sphygmomanometer for measurement of blood pressure dates back to 1881, when it was invented by Samuel Siegfried Karl Ritter von Basch. It is with these two ancient tools that most physicians approach a patient at the bedside to this day. In the interim, the explosive growth of medical technology has spawned relatively inexpensive, miniature ultrasound machines, which can be taken to the bedside and allow immediate imaging across several medical specialties.

Smaller ultrasound systems are now routinely used, and often required, for safe placement of central venous lines, as well as for applications such as bladder size determination, wound loculations, paracentesis, thoracentesis, and arthrocentesis. Some smaller ultrasound devices are also configured to allow cardiac examination. These hand-carried cardiac ultrasound (HCU) devices are being used for diagnostic cardiac imaging in many different locations, in and out of the hospital, by cardiologists and noncardiologists alike. Because of their relative ease of use, portability, and affordable cost, HCU systems have made point-of-care (bedside) echocardiography available to all medical personnel as an "ultrasound-stethoscope." Currently, the appropriate training, scope of practice, and credentialing for point-of-care echocardiography by various health care providers is an area of active investigation and ongoing discussion.

## Background

In 1978, J. R. Roelandt proposed the first miniaturized HCU system.[2] Since that time, bulky keyboards, large monitors, and video recorders have now been replaced by touch pads, flat screens, and digital storage devices. The American Society of Echocardiography defines an HCU device as a small ultrasound machine typically weighing less than 6 pounds that can obtain images and data.[3] Since that publication in 2002, advances in ultrasound technology have incorporated all the capabilities expected of a full sized system into these small machines (Fig. 8-1).[4-6]

### TYPES OF ECHOCARDIOGRAPHIC INSTRUMENTS

Currently, there are four basic types of echocardiographic systems (Table 8-1):

1. Large, very expensive systems carrying the most advanced instrumentation, capable of two-dimensional (2D), M-mode imaging, designated contrast settings, color flow Doppler, pulsed-wave (PW) and continuous-wave (CW) Doppler, tissue Doppler imaging, tissue harmonic imaging, speckle strain imaging, stress echocardiography formats, and broadband multifrequency imaging with image processing and digital storage, as well as volumetric (three-dimensional [3D], four-dimensional [4D]) imaging and transesophageal, intravascular, and intracardiac echocardiography. These systems typically are based in a hospital echocardiography laboratory or large office practice, with an instrument cost over $250,000.
2. Compact, smaller version of the full-sized systems that are more portable and less expensive, but have most of the features available on larger systems. Some are capable of transesophageal echocardiography (TEE) but lack volumetric (3D) imaging. With a compact system, resolution and penetration may be less robust with a lower cost between $100,000 and $150,000. These systems are usually located in an echocardiography laboratory or cardiology office but also are offered in smaller, battery-powered options that can be attached to a cart or separated and carried for portability.
3. Handheld or hand-carried ultrasound (HCU) devices are small, light, battery powered, less expensive systems with good 2D imaging quality and full Doppler capabilities, often with digital and wireless communication, some with stress and TEE options. These systems can be cart mounted or hand carried and may be in an office, emergency department, or hospital setting to provide "point-of-care" ultrasound with multiprobe capability. HCU systems cost between $50,000 and $100,000, depending on options.

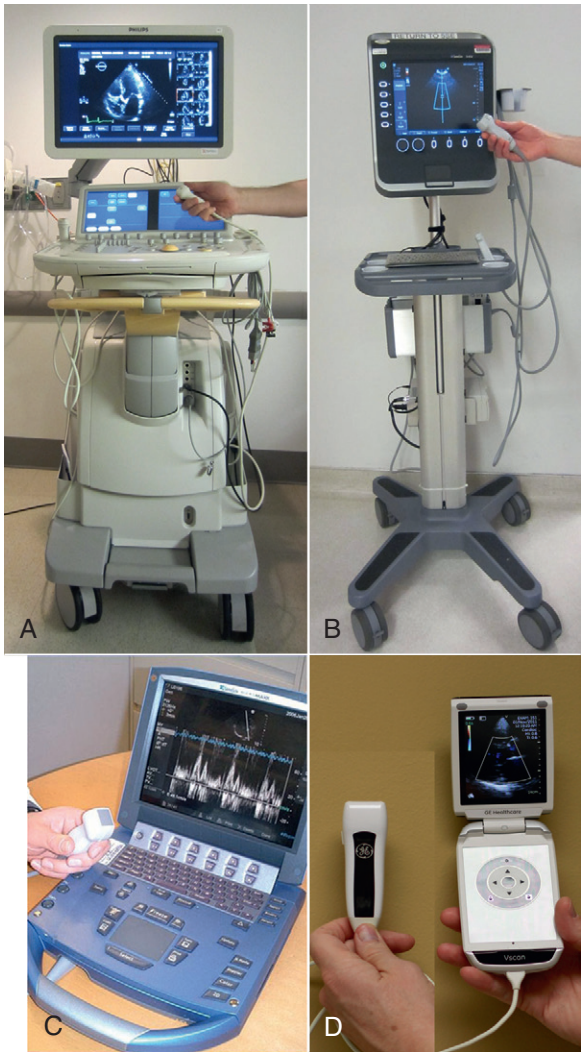

**Figure 8-1** **A,** A complete echocardiographic system (Philips iE33, Philips Healthcare, Andover, Mass.), which allows advanced imaging modalities such as 3D imaging but is relatively large and expensive. This type of system is used both in the echocardiography laboratory and for portable inpatient studies. **B,** A compact system (S-ICU system, Sonosite, Inc., Bothell, Wash.) that is more portable and lower in cost but lacks some features of a complete system. These systems may also include transducers for noncardiac imaging. **C,** A hand-carried system (MicroMaxx, Sonosite, Inc., Bothell, Wash.) that can be carried to the bedside. **D,** A palm-sized ultrasound device (Vscan, GE Healthcare, Waukesha, Wisc.) with limited functions but a relatively low cost and small size that fits in a pocket.

4. Palm-sized devices are very small. They can truly be held in one hand and viewed on a small screen and have potential as a smartphone application. These devices can image in 2D, with a caliper for measurement, usually with no or limited color flow Doppler and no electrocardiographic gating. They are relatively inexpensive for their size and capability, around $10,000, and can be used for point-of-care screening or as a true "echo-stethoscope."

These echocardiographic systems can be separated on the basis of performance capability, size, weight, and cost. Some of the smaller systems can perform a full examination, whereas the palm-sized units can be applied for screening of left ventricular (LV) function, wall thickness, chamber size, hypertrophy, pericardial effusions, and abdominal aortic aneurysms (Fig. 8-2). Ultimately, the choice of system to use will vary with the goal of the examination, the skill and experience of the persons performing the imaging, and its interpretation (Table 8-2). Typically, complete and compact echocardiography systems are used by cardiologists in the context of an echocardiography laboratory. The focus of this chapter is the use of hand-carried and palm-sized echocardiography systems outside the echocardiography laboratory by health care providers in other specialties. The two most important considerations in the clinical use of these smaller, readily accessible, heavily promoted systems are (1) the technical performance of the imaging device and (2) the appropriate level of skill and training to acquire and interpret the images.

**TABLE 8-1 Classification of Currently Available Echocardiography Machines According to Size and Function**

| *Echocardiography Machines* | *Capabilities* |
|---|---|
| Stationary high-end systems | Full range of standard echocardiographic modalities and measurements (MM, 2D, PW, CW, Color, TDI, TEE), and advanced modalities (3D, contrast) |
| Mobile (smaller machines on wheels, middle range technology) | Full range of standard echocardiographic modalities and measurements (MM, 2D, PW, CW, Color, TDI, TEE) |
| Portable (small machines that can be carried by a person) | Basic, standard echocardiographic modalities and measurements (MM, 2D, PW, CW, Color) |
| Handheld or pocket-size imaging devices | Limited functions (2D, Color) and measurement package |

From Sicari R, Galderisi M, Voigt JU, et al: The use of pocket-size imaging devices: a position statement of the European Association of Echocardiography. *Eur J Echocardiogr* 12:85-87, 2011.

*Color*, Color Doppler; *MM*, M-mode; *PW*, pulsed ware; *TDI*, tissue Doppler imaging.

## RELIABILITY AND ACCURACY

The reliability and accuracy of the hand-carried ultrasound devices have been validated in studies comparing their performance to full-size systems with images obtained by skilled technicians or physicians. Vourvouri and colleagues[7,8] demonstrated greater than a 90% concordance between results using an HCU and a standard full-size system in the echocardiographic evaluation of LV size and function with older-generation hand-carried devices including the OptiGo (Philips Healthcare, Andover, Mass.) and Sono-heart (Sonosite, Bothell, Wash.). Vourvouri and co-workers[9] also imaged 300 consecutive patients referred to a cardiologist with a hand-carried device. Agreement between the HCU device (OptiGo) and the standard system for the detection of major abnormalities was excellent (98%). However, even this level of agreement may be suboptimal in the clinical setting, because the HCU did miss 4% of the major findings.

Because of limitations in penetration and resolution, HCUs may underestimate severity of wall motion abnormalities in patients with poor ultrasound tissue penetration, which is often a problem in overweight or obese patients. In general, the quality of the images obtained with an HCU device correlates directly with the skill and experience of the personnel acquiring and interpreting the images. Cardiology fellows had 100% agreement between HCU and conventional echocardiography on qualitative assessment of LV systolic function and a 94% concordance for LV end-diastolic dimension and interventricular septal thickness, with an ultrasound imaging time of only 6 ± 2 minutes.[10] Therefore, with proper training, HCU devices

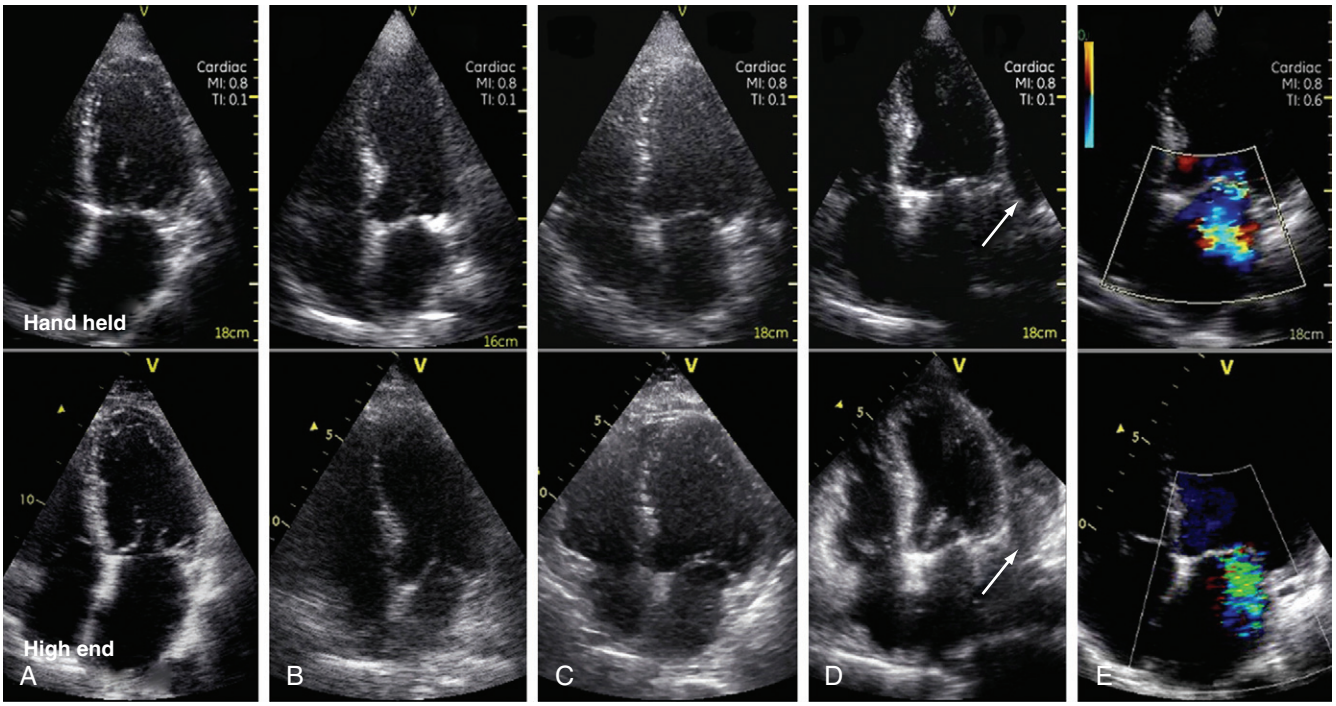

**Figure 8-2** Comparison of image quality of the handheld device (*top*) and a high-end device (*bottom*). **A,** Echogenic patient. **B,** Patient with suboptimal echogenicity. **C,** Patient with very poor echogenicity. **D,** Patient with pericardial effusion (*arrow*). **E,** Patient with mitral regurgitation. The pathology is somewhat more easily detected with the wider image sector of the high-end device. *(From Prinz C, Voigt JU: Diagnostic accuracy of a handheld ultrasound scanner in routine patients referred for echocardiography.* J Am Soc Echocardiogr *24:111-116, 2011.)*

represent a valuable alternative to standard echocardiographic systems for well-trained personnel in some specific clinical applications.

Even the smallest palm-sized devices, potentially true cardiac "stethoscopes," have been evaluated against more sophisticated echocardiographic systems. Dalla Pozza and colleagues[11] used three small ultrasound devices in a pediatric population. The two larger HCU systems (a laptop-sized Philips p50 and a compact Philips CX 50) had excellent image accuracy (93%) compared to full echocardiography instruments; however, the palm-sized device (ACUSON P10, Siemens Healthcare, Malvern, Pa.) had only a 64.5% accuracy. Prinz and Voigt[12] compared the diagnostic accuracy of a palm-sized device (Vscan, GE Healthcare), used for imaging by an experienced cardiologist in 349 routine patients with varying LV function, to that of two laptop-sized HCU systems (either a Vivid 7 or E9, GE Healthcare). The palm-sized HCU showed excellent correlation in the evaluation of regional wall motion, visual ejection fraction, LV wall thickness and dimensions, and valve regurgitation (Fig. 8-3). These studies corroborate that HCUs and even palm-sized devices can be used by experienced, qualified sonographers and physicians for routine clinical cardiac imaging and may represent a valuable alternative to standard echocardiographic systems, for certain applications.

## Ultrasound "Stethoscope"

The concept of a stethoscope is that the physician listens to the patient's heart sounds to deduce clinical and hemodynamic information from the noise created by blood flow and valve

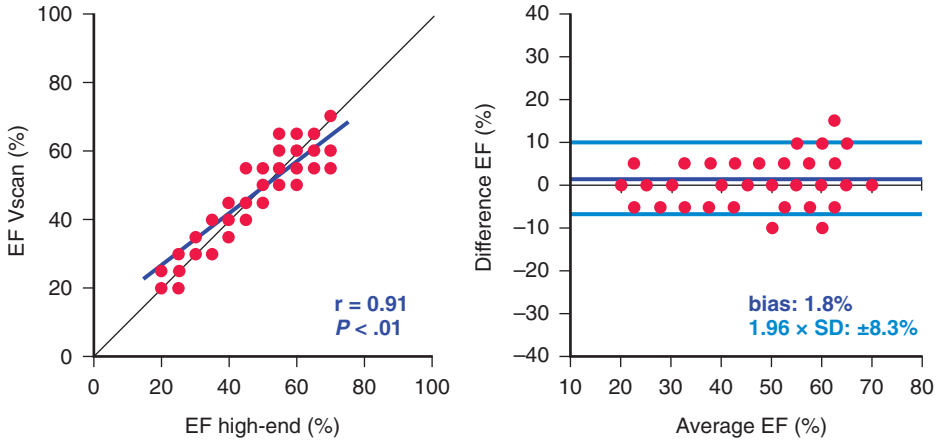

**Figure 8-3** *Left*: Good correlation (r = 0.91, *P* < .01) between ejection fraction calculations with a handheld device (Vscan) versus a high-end echocardiography system. *Right*: Bland-Altman plot shows no relevant bias and normal variation of assessments. Data points of several patients are clustered because of ejection fraction assessment in prespecified levels of 5%. *(From Prinz C, Voigt JU: Diagnostic accuracy of a handheld ultrasound scanner in routine patients referred for echocardiography.* J Am Soc Echocardiogr *24:111-116, 2011.)*

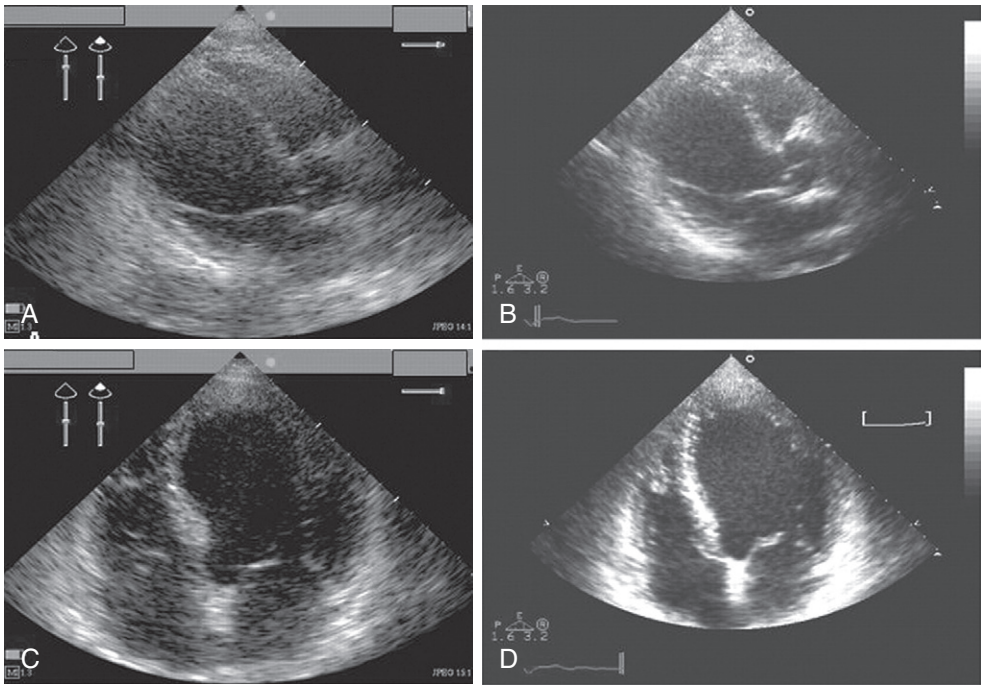

**Figure 8-4** Parasternal long-axis (*top*) and apical four-chamber views (*bottom*) acquired with hand-carried ultrasound (**A, C**) and standard echocardiography (**B, D**) showing dilated LV in a 67-year-old man with history of stroke. A neurologist had referred this patient to the outpatient cardiology clinic for electrocardiographic abnormalities and dyspnea on effort. *(From Trambaiolo P, Papetti F, Posteraro A, et al: A hand-carried cardiac ultrasound device in the outpatient cardiology clinic reduces the need for standard echocardiography.* Heart *93:470-475, 2007.)*

motion. Echocardiography has the potential to work like a stethoscope by using (ultra)sound waves to create images of the heart and visualization of blood flow that provide more accurate data than can be obtained from the acoustic sounds appreciated with a conventional stethoscope. Integrated into the physical examination, the HCU or palm device, as an ultrasound stethoscope, facilitates rapid identification of cardiac abnormalities (e.g., valve disease, chamber dilation, hypertrophy, pericardial effusion, or wall motion abnormalities). This can eliminate more sophisticated, costly studies and expedite appropriate therapeutic interventions (Figs. 8-3 to 8-5).[13-15] The Naples Ultrasound Stethoscope in Cardiology study[16] demonstrated that whereas the physical examination diagnosed cardiac abnormalities in 38.2% of patients, the addition of a palm-sized echocardiography examination increased the detection of cardiac abnormalities to 69.7%. The goal of promoting these very portable palm-sized or HCU systems is not to replace the comprehensive, carefully done Doppler echocardiographic examination, a detailed anatomic and hemodynamic evaluation, but to complement and improve the physical examination.[17]

The European Society of Echocardiography recommended indications for palm-size echocardiography devices reflect this approach (Box 8-1).[18] In addition to this limited list of indications, they further recommend:

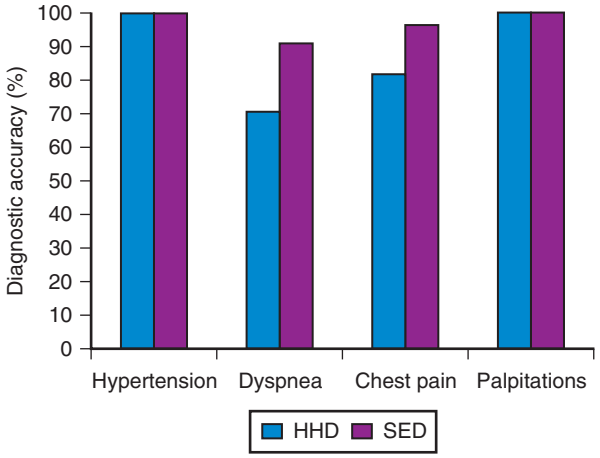

**Figure 8-5 Ability of echocardiographic examination to resolve the referral question.** Handheld device (HHD) showed good reliability in examination of patients referred for hypertension or palpitations, but was less accurate than standard echocardiographic device (SED) for those who presented with dyspnea or chest pain, as a result of biases in measurements of wall thicknesses and in assessment of valvular diseases and regional wall motion. *(From Giannotti G, Mondillo S, Galderisi M, et al: Handheld echocardiography: added value in clinical cardiological assessment.* Cardiovasc Ultrasound *3:7, 2005.)*

**Box 8-1**

**SUMMARY OF INDICATIONS FOR POCKET-SIZE DEVICES**

1. Complement to a physical examination in the coronary and intensive care unit
2. Tool for a fast initial screening in an emergency setting
3. Cardiologic counselling in outpatient health care facilities and hospitals
4. First cardiac evaluation in ambulances
5. Screening programs in schools, industry, and community activities
6. Triaging candidates for a complete echocardiographic examination
7. Teaching tool
8. Semi-quantification of extravascular lung water

From Sicari R, Galderisi M, Voigt JU, et al: The use of pocket-size imaging devices: a position statement of the European Association of Echocardiography. *Eur J Echocardiogr* 12:85-87, 2011.

- HCU imaging results should be included in the physical examination documentation and the images stored according to rules for other imaging data at each institution.
- Training and certification in HCU is recommended for all users, specific to the scope of practice for each user.
- Patients should be made aware that an HCU examination does not replace a complete echocardiogram.

## Education and Training Guidelines and Requirements

Both the American Society of Echocardiography (ASE) and the American College of Emergency Physicians (ACEP) have produced written guidelines and documents on the training of physicians using cardiac ultrasound and echocardiography. Comprehensive echocardiography training guidelines have been described by the ASE and are documented in a position paper, the American College of Cardiology/American Heart Association Clinical Competence Statement on Echocardiography.[19] These training guidelines are applicable for those physicians and practitioners who perform comprehensive echocardiography. However, the training requirements for comprehensive echocardiography exceed the training needed for point-of-care echocardiography in many clinical situations. For example, the requirements for emergency physicians who are performing focused ultrasound in the emergent setting are limited to the specific diagnoses being evaluated.[20] Similarly, intensivists have a limited scope of practice compared to a comprehensive echocardiographic examination with a correspondingly limited training scope and duration.[21]

For specific HCU training, the ASE recommends at least Level 1 training (performing 75 examinations and personally interpreting 150 examinations). However, this time commitment is usually practical only for cardiology training programs. There is no consensus on the appropriate training protocols required for HCU for noncardiologist and non–emergency department use. Various focused transthoracic echocardiography (TTE) training programs for intensivists, emergency-department physicians, anesthesiologists, hospitalists, and other medical specialties have been proposed, varying from a few hours to a few days.[22-24] As expected, a meta-analysis found that the accuracy of hand-carried echocardiography depended on the training time allocated and level of skill of the personnel performing the echocardiogram, ranging from medical students to cardiologists.[25] Ultimately, each professional specialty society will be responsible for maintaining the integrity of their training protocols and for ensuring the responsible practice and use of these imaging techniques.

### MEDICAL STUDENTS

The use of HCU by medical students completing abbreviated training programs has been evaluated in several studies and has been found to be additive to the history and physical examination. Diagnoses by medical students trained on an HCU system (OptiGo) for 18 hours were compared with those of a board-certified, experienced cardiologist using a standard physical examination.[26] Medical students performing echocardiography correctly identified 75% of abnormal findings compared with 49% by a cardiologist's physical examination as adjudicated by findings using a standard echocardiographic system. Another study showed that a medical student echocardiography curriculum, which included 60 hours of didactics and 40 hours of supervised imaging, resulted in a significant improvement in the accuracy of bedside diagnosis.[27]

### MEDICAL RESIDENTS

In a formal training program of noncardiologists using HCU by Alexander at Duke, 20 medical house officers participated in a standardized 3-hour HCU training program (30 minutes of introduction to ultrasound and the HCU device, 75 minutes of case reviews, and 75 minutes of hands-on practice).[28] The study demonstrated that the HCU substantially improved the assessment of LV function and pericardial effusion over history and physical examination, but was less effective for aortic valve disease. This study suggested that despite having only a 3-hour

training period, medical residents can use HCU echocardiography to substantially improve their assessment of LV function and pericardial effusion with an acceptable level of accuracy compared with standard echocardiography. Kimura and associates[10] devised an HCU curriculum consisting of a 1-hour lecture on cardiac physical examination and a 1-hour session of echocardiogram instruction for internal medicine residents and successfully improved their ability to accurately determine LV function.

### EMERGENCY PHYSICIANS

The ACEP Recommendations for Emergency Physicians who are performing Focused Ultrasound in the Emergent Setting (FOCUS)[20] are available online (http://www.acep.org/) and include both a training-based and a practice-based pathway. Residency training in ultrasound should include appropriate verification. The practice-based pathway includes didactic education plus performance of 25 ultrasound studies with confirmatory studies for each primary indication or a total of 150 studies for general emergency medicine ultrasound privileges. The ACEP also encourages point-of-care ultrasound for many other organ systems other than the heart. Their guidelines recommend 80 hours of general ultrasound instruction throughout residency and performance of 25 to 50 cardiac ultrasound examinations.[29] Wright and colleagues[30] suggest that because of the steep learning curve for echocardiography, emergency-department physicians with an interest in TTE at point of care should establish a quality assurance relationship with the cardiology echocardiography section of their institution.

### INTENSIVISTS

Intensivists who supervise care of a hospital's most complex and unstable patients have also integrated general and cardiac ultrasound into their armamentarium. Manasia and co-workers[31] found that after ten 1-hour tutorial sessions, intensivists who performed limited echocardiograms to assess LV function, volume status, and source of hypotension in 90 patients in the intensive care unit successfully performed a diagnostic limited TTE in 94% of patients and interpreted them correctly independently in 84% of patients. Importantly, new cardiac information provided a change of management in 37% of patients and additionally useful information was found in 41% of patients.

### RECOMMENDATIONS

All of these studies on the type and duration of training needed for HCU examination by physicians at various levels of training and in various specialties will be helpful in defining the standards for the use of HCU by health care providers. Clearly we need evidence-based recommendations for education and training of health care providers, tailored to the scope of practice in each specialty. We also need to work toward methods of competency testing and credentialing of practitioners as HCU becomes more widespread. In a recent editorial in *Chest*,[32] Schmidt calls for all intensivist training programs to incorporate a formal ultrasound curriculum for their fellows, including hands-on guidance. He cautions that "with the coming boom in ICU [intensive care unit] ultrasound, it is essential that skills spread as fast as the machines."

## Clinical Applications

The application of HCU is undergoing active investigation in several clinical settings. The goals of HCU in each setting depend on the specific clinical issues, and the long-term effect of point-of-care ultrasound is in evolution (Fig. 8-4). However, studies already support the use of HCU to improve the diagnosis, treatment, and risk stratification of heart failure in outpatient and inpatient settings and to improve the use of full echocardiographic examinations (Table 8-3).[12,21,22,33-37]

### EMERGENCY DEPARTMENT

The ASE and ACEP recently published a consensus statement that defines the important role of focused cardiac ultrasound (FOCUS).[20] FOCUS is a time-sensitive evaluation of the symptomatic patient that includes assessment for pericardial effusion and evaluation of chamber size, global cardiac function, and patient volume status. Intravascular volume may be assessed by chamber size, function, inferior vena cava size, and respiratory change. The examination may also guide emergency pericardiocentesis and transvenous pacemaker placement. The consensus statement emphasizes the complementary role of FOCUS to that of comprehensive echocardiography. HCU can supplement the physical examination, as well as facilitate the rapid triage of emergency department or intensive care patients (Box 8-2).

### INTENSIVE CARE UNIT

The general indications for performing an echocardiographic or ultrasound examination in the ICU include hemodynamic instability, suspected pulmonary embolism, infective endocarditis, aortic dissection or rupture, unexplained hypoxemia, source of embolus, central line placement, and assessment of pleural effusion and intraabdominal fluid collections.

The FREE (focused rapid echocardiography evaluation) examination, which incorporates a rapid assessment of LV and RV function and relative inferior vena cava size and its respiratory change to assess overall volume status and cardiac status, was feasible in 80% of 53 patients in a trauma unit, 85% of whom were mechanically ventilated.[38] Overall, 54% had a change in clinical management based on the FREE examination.

**Box 8-2**

**GOALS OF FOCUSED CARDIAC ULTRASOUND IN THE SYMPTOMATIC EMERGENCY-DEPARTMENT PATIENT**

- Assessment for the presence of pericardial effusion
- Assessment of global cardiac systolic function
- Identification of marked right ventricular and LV enlargement
- Intravascular volume assessment
- Guidance of pericardiocentesis
- Confirmation of transvenous pacing wire placement

From Labovitz AJ, Noble VE, Bierig M, et al: Focused cardiac ultrasound in the emergent setting: a consensus statement of the American Society of Echocardiography and American College of Emergency Physicians. *J Am Soc Echocardiogr* 23:1225-1230, 2010.

**TABLE 8-3 Selected Studies of Point-of-Care Echocardiography**

| Year of Publication | Clinical Setting | Study Group | Comparison | Outcomes | Reference |
|---|---|---|---|---|---|
| 2007 | Cardiology outpatient clinic | 222 consecutive patients with echocardiography in 108 | HCU by a cardiologist vs. complete TTE | Overall agreement between POC and TTE was 73%, and a definite diagnosis was established by HCU in 31% | 36 |
| 2008 | Heart failure inpatients | 75 adults with decompensated HF | Clinical evaluation, BNP levels, and echocardiography of IVC | Larger IVC diameter at discharge predicted 30-day readmission rates | 34 |
| 2009 | Medical ICU | 44 ICU patients | LV function HCU vs. formal TTE | Correct agreement for normal vs. abnormal LV systolic function in 86% with agreement on severity of LV dysfunction in 82% | 22 |
| 2009 | Medicine inpatients | 10 hospitalists evaluating 354 patients | Cardiac physical exam vs. HCU with full TTE as reference standard | Compared to physical exam, HCU improved hospitalists estimate of LV function but did not improve evaluation of valve dysfunction | 35 |
| 2011 | General medicine outpatient clinic | 175 adults with heart failure | Internist HCU vs. BNP levels | HCU was the only independent predictor of death or hospitalization for cardiac disease (hazard ratio 5.55, 95%CI 2.04-14.28) at 48 ± 7 month follow-up | 33 |
| 2011 | Echocardiography lab | 349 adults referred for a diagnostic study | HCU versus high-end echocardiography | No significant differences in assessment of LV size, ejection fraction or regional wall motion between HCU and high-end echocardiography. Agreement for pericardial effusion, valve stenosis, and regurgitation also was very good | 12 |
| 2011 | Cardiology outpatient clinic | 189 patients at initial consultation | Physical exam vs. HCU by cardiologist | HCU was diagnostic in 75% and indicated that no further cardiac evaluation was needed in an additional 20% | 37 |
| 2011 | ICU | 201 ICU patients | HCU by recently trained resident vs. experienced intensivist | After 12 hours of training, residents adequately assessed global LV function, LV dilation, dilated IVC, and pericardial effusion | 21 |

## INTERNAL MEDICINE

In a general community outpatient clinic, 175 patients with suspected heart failure were examined using an HCU device (OptiGo, Philips, Andover, Mass.) by an internist who had received 4 weeks of training in HCU. The examination included assessment of LV size and systolic function, left atrial size, and valve dysfunction. In the 90 patients (55%) with an abnormal baseline HCU study, 25% were hospitalized for cardiac indication over the next 48 months. On multivariate analysis, an abnormal HCU examination was a strong predictor of clinical outcome with a hazard ratio of 5.55 (95% confidence interval 2.04-14.28, $P = .0004$) and was more predictive than serum BNP levels (Fig. 8-5).[33]

## CARDIOLOGY

A limited examination on a relatively inexpensive HCU system can be time efficient and cost effective. In a cardiology clinic, a hand-carried ultrasound system (OptiGo, Philips) was compared to a standard echocardiographic system with a mean examination time of 6.7 ± 1.5 minutes using an HCU versus 13.6 ± 2.4 minutes using the standard echocardiographic system.[6] The HCU was considered satisfactory in 85% of patients, and the data were concordant with the standard echocardiographic system in 83.8% of patients. Certainly, a cardiologist could incorporate an HCU examination as part of the bedside evaluation with great utility and impact on clinical management (Fig. 8-6).

Because of its time saving and ability to eliminate unnecessary examinations, screening and triaging with HCU or palm-sized systems is cost effective to eliminate unnecessary full examinations. One analysis estimated a 29% reduction in departmental workload, at a significant cost savings if all patients with a complete echocardiogram requested for LV function assessment underwent HCU initially and only those with abnormal scans underwent complete standard echocardiography.[39] HCU's high accuracy for detection of normal

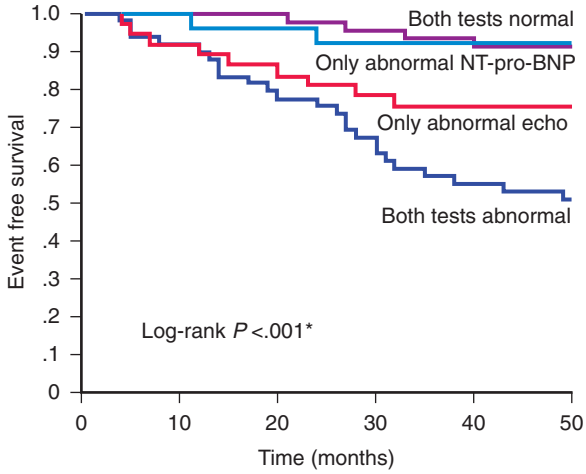

**Figure 8-6** Kaplan-Meier event-free survival curves for 175 outpatients with heart failure symptoms or risk factor, stratified according to hand-carried echocardiographic results and N-terminal pro–brain natriuretic peptide (*NT-pro-BNP*) in combination: both normal, only abnormal NT-pro-BNP, only abnormal hand-carried echocardiographic results, and both abnormal. *Difference statistically significant for both abnormal echocardiographic results and NT-pro-BNP versus others. *(From Lipczyńska M, Szymański P, Klisiewicz A, Hoffman P: Hand-carried echocardiography in heart failure and heart failure risk population: a community based prospective study.* J Am Soc Echocardiogr *24:125-131, 2011.)*

cardiac anatomy and function also is an efficient tool in eliminating unnecessary examinations.

## Future Directions

Point-of-care ultrasonography has become state-of-the-art care provided by several different medical specialties as well as primary care providers. In their *New England Journal of Medicine* article, Moore and Copel[40] note that ultrasonography is a user-dependent technology, and as usage spreads, there is a need to ensure competence, define the benefits of appropriate use, and limit unnecessary imaging and its consequences. They focus on procedural guidance, diagnostic assessment, the e-FAST examination (focused assessment with sonography for trauma, extended to include an examination of the chest for pneumothorax), and screening, especially for abdominal aortic aneurysms. There is minimal mention of cardiac imaging. Although they state that point-of-care ultrasound may be particularly cost effective by eliminating more expensive imaging tests, appropriate training and quality assurance as well as outcome and clinical effectiveness studies are needed.[41] True point-of-care ultrasound and echocardiographic examinations will be performed in the emergency department as well as by hospitalists and medical house staff. The same caution for adequate training and interpretation should be applied to the propagation of point-of-care cardiac echocardiographic imaging by noncardiologists.

William Zoghbi, in his capacity as president of the American Society of Echocardiography, editorialized that point-of-care echocardiography fulfills the mandate of the Patient Protection and Affordable Care Act of 2010 that rewards value, quality, and outcomes over quantity. HCU is poised to deliver cost-effective quality care.[39,42] With the graying and aging of Americans, there will be an increased incidence of valvular heart disease and murmurs on physical examination.[43] Inexpensive HCU cardiac examinations may provide effective triage for those patients requiring full echocardiographic examinations, thereby expediting care, ensuring appropriate use of expensive technologies, and reducing health care costs. Integration of hand-carried or palm-sized ultrasound devices into the medical school physical examination curriculum could empower future clinicians with the basic skills for image acquisition and interpretation and improve medical care, expediting critical decisions at significant savings to the health care system.

### KEY POINTS

- Hand-carried ultrasound (HCU) refers to small, lightweight systems with basic 2D imaging capability.
- Palm-sized devices are best suited as an adjunct to supplement the bedside physical examination.
- HCU is ideal for inexpensive screening of large populations with low prevalence of disease.
- Training guidelines for image acquisition and interpretation vary by specialty and need.
- Small but technologically complete laptop-sized systems are also available but require the same level of training and expertise as larger complete echocardiography systems.

# Quantitative Evaluation of Left Ventricular Structure, Wall Stress, and Systolic Function

GERARD P. AURIGEMMA, MD | WILLIAM H. GAASCH, MD

**Definitions and Theoretical Considerations**
**Assessment of Left Ventricular Mass, Volume, and Geometry**
M-Mode Echocardiography
Two-Dimensional Echocardiography
Alternative Methods for Quantitation of Left Ventricular Structure and Function
**Assessment of Left Ventricular Systolic Function**
Ejection Fraction
Fractional Shortening and Related Indices
Stress-Shortening Relations
Pressure-Volume Analysis
**Potential Limitations**

The quantitation of left ventricular (LV) systolic function, size, and geometry is critical to the proper evaluation and management of patients with all types of heart disease.[1] For example, the assessment of LV function in patients with coronary artery disease provides better prognostic information than does knowledge of the number of diseased vessels (Fig. 9-1). Even when only one or two vessels are diseased, a low ejection fraction (EF) is associated with a higher mortality than that seen in patients with three-vessel disease and a normal EF.[2] Large LV systolic and diastolic volumes are also associated with a poor prognosis; thus, a patient with a reduced EF after a myocardial infarction can be categorized according to subsequent risk based on the absolute end-systolic volume (ESV) (Fig. 9-2).[3] Furthermore, information concerning LV size and geometry has important therapeutic implications, in view of the salutary effects of therapy with angiotensin-converting enzyme inhibitors on postinfarction remodeling and prognosis in patients with a reduced EF.[4,5]

Similarly, in cardiomyopathy of any cause, mortality remains high in patients with an EF less than 35%,[1,6] even with medical therapy. A depressed EF is uniformly present in patients with idiopathic dilated cardiomyopathy and results from a combination of afterload excess and depressed contractility. In this setting, indices of LV geometry, such as the relative wall thickness (RWT) or the mass/volume ratio (Fig. 9-3), provide prognostic information that is independent of the EF. Conversely, it is important to identify the significant percentage of patients with heart failure symptoms who have a normal EF (Fig. 9-4).[7,8]

Measurement of LV volume, mass, and function can provide data that are necessary to define the optimal time for surgery in patients with volume overload hypertrophy owing to chronic, severe mitral regurgitation or aortic regurgitation. In this regard, the prognostic usefulness of ventricular end-diastolic volume (EDV) and ESV, the EF, the ratio of EDV to mass, systolic stress-shortening relations, and end-systolic pressure-volume (P-V) relations has been tested in a variety of clinical studies. The ESV and EF appear to provide the most useful clues to prognosis.[9-15] Certainly, a most important determinant of postoperative survival is the level of LV systolic function (Fig. 9-5).

In pressure overload hypertrophy due to aortic stenosis, an assessment of systolic function is perhaps less important than in the regurgitant lesions. Although severe depression of the EF may indicate an increased surgical risk, patients with an EF as low as 20% to 25% can show substantial clinical improvement after aortic valve replacement.[16-18] In such patients, excessive systolic loads are usually responsible for the low EF; this situation is termed *inadequate hypertrophy* or *afterload excess.* Alternatively, *excessive* or *inappropriate hypertrophy,* indicated by a high RWT, appears to identify a group of patients having a high perioperative risk[19,20]; in this situation, a normal or high EF does not seem to be beneficial. In aortic stenosis, therefore, indices of LV geometry[20] (RWT) appear to provide prognostic clues that are not reflected in the EF.

It is well established that increased LV mass is a strong predictor of cardiovascular morbidity and cardiovascular and all-cause mortality, even when age, blood pressure, and other risk factors are considered.[21-27] Some investigators have suggested that LV geometry provides prognostic information that is incremental to the extent of LV hypertrophy.[24-26] For example, an increased ratio of LV wall thickness to cavity dimension[27] identifies patients at higher risk for cardiovascular morbidity and mortality (Table 9-1).

Thus, a substantial body of clinical research has demonstrated the prognostic value of indices of LV volume, mass, geometry, and function. Most if not all of these indices are routinely available to the clinician from standard M-mode and two-dimensional (2D) and Doppler echocardiography. In this chapter the echocardiographic techniques for evaluating LV geometry, stress, and systolic function are reviewed. Principles and methods are discussed, and clinical applications to patients with pressure and volume overload hypertrophy are emphasized.

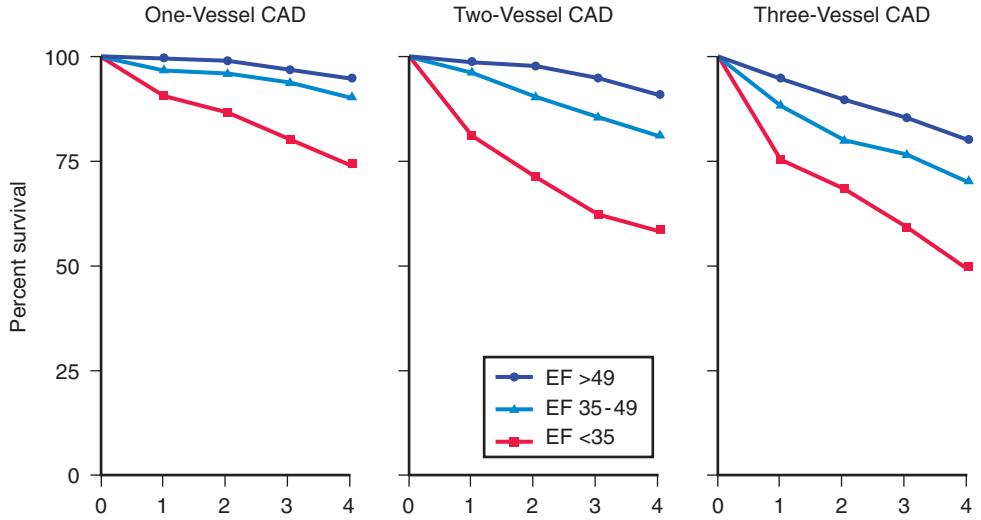

**Figure 9-1 The relation between LV ejection fraction (*EF*) and survival in patients with single-, double-, and triple-vessel coronary artery disease.** The negative impact of a low EF is seen in all three groups. Survival is better in patients with three-vessel coronary artery disease (*CAD*) and a normal EF than in those with one- or two-vessel disease and a low EF. *(Adapted from Mock MB, Rindqvist I, Fisher LD, et al: Survival of medically treated patients in the coronary artery surgery (CASS) registry.* Circulation *66:562-567, 1982. ## Definitions and Theoretical Considerations

The systolic pumping of the LV is a complex process that involves a coordinated contraction of subendocardial, midwall, and subepicardial muscle fibers. These fibers are arranged in a complex, helical fashion (See Fig. 10-16). At the equator of the ventricle, midwall fibers are oriented circumferentially; contraction of these fibers mainly contributes to a decrease in the minor axis (or dimension) of the ventricle and is responsible for generation of much of the stroke volume (SV) (Fig. 9-6). Longitudinally oriented fibers in the subendocardium and subepicardium contribute to shortening of the long axis of the ventricle, also contributing to SV. In addition to circumferential and long-axis shortening, the apex of the LV rotates counterclockwise during systolic contraction, and the base rotates clockwise (as viewed from the apex).[28,29] Such "twist," like fiber shortening, appears to be influenced by the contractile state of the myocardium (see Fig. 10-14). In concert with these shortening and twisting motions, wall thickening contributes to volume displacement and generation of the SV. Preload, afterload, contractility, and geometry influence shortening and thickening.[30]

The pumping activity of the LV provides oxygenated blood to the tissues of the body; therefore, the SV can be used as a parameter of the pump performance of the ventricle (Box 9-1). Because LV systolic pressure and SV are inversely related, using

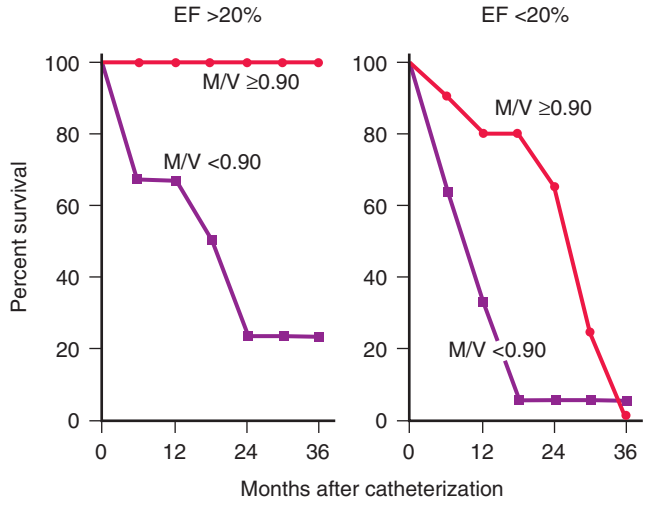

**Figure 9-3 The relation between LV mass/volume ratio (*M/V*) and survival in patients with an ejection fraction (*EF*) greater than and less than 20%.** Data were obtained from patients with dilated cardiomyopathy. Patients with a normal M/V ratio exhibit better survival than those with a low ratio; this trend is seen in EF categories. *(Adapted from Feild BJ, Baxley WA, Russell RO Jr, et al: Left ventricular function and hypertrophy in cardiomyopathy with depressed ejection fraction.* Circulation *47:1022-1031, 1973. *CV*, Cardiovascular; *LVH*, left ventricular hypertrophy; *RWT*, relative wall thickness.

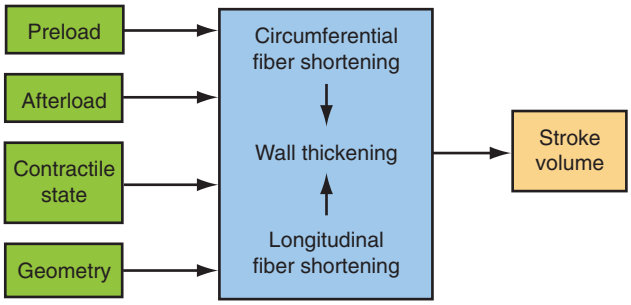

**Figure 9-6 Circumferential and longitudinal fibers contribute to wall thickening and volume displacement.** These functions are influenced by LV preload, afterload, contractile state, and geometry. *(From Aurigemma GP, Gaasch WH, Villegas B, Meyer TE:* Curr Probl Cardiol *20:374, 1995.)*

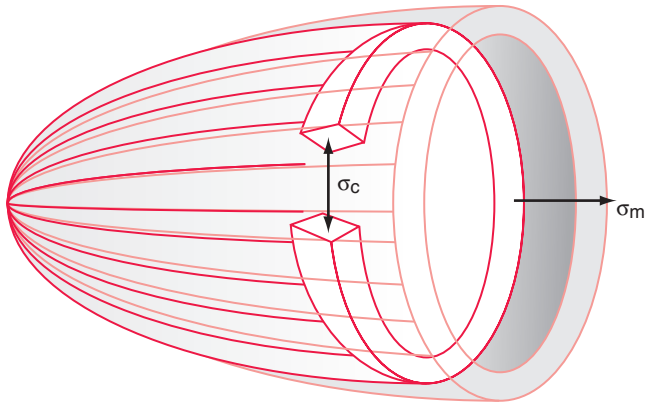

**Figure 9-7 Schematic of the LV (represented as a truncated ellipsoid) illustrating the major stress vectors.** Meridional stress ($\sigma_m$) is the force acting along the long axis of the LV; meridional stress opposes long-axis shortening. Circumferential stress ($\sigma_c$) is the force acting in the equatorial direction; circumferential stress opposes circumferential fiber shortening, and circumferentially oriented fibers are located in the midwall of the LV. The inner shell represents the LV in systole, and the outer, the ventricle in diastole. *(From Aurigemma GP, Gaasch WH, Villegas B, Meyer TE:* Curr Probl Cardiol *20:375, 1995.)*

**Box 9-1**

## ASPECTS OF VENTRICULAR FUNCTION

**Pump Performance**
The pumping activity of the LV that results in the delivery of oxygenated blood to the tissues. Stroke volume and stroke work are parameters of pump performance.

**Ventricular Function**
LV performance assessed relative to end-diastolic fiber length (or related parameter).

**Myocardial Contractility**
A basic property of the myocardium that reflects its active state, rather than loading conditions.

**Contractile Function**
A descriptor of ventricular performance or function that is affected by inotropic state, fiber length, or load.

stroke work as an index of ventricular performance can be more appropriate; a stroke work parameter credits the ventricle for the development of pressure and for shortening. When performance is assessed relative to end-diastolic fiber length or a related parameter, ventricular function can be described. Thus, a ventricular function curve can be generated by plotting stroke work against end-diastolic pressure, diameter, volume, or wall stress. Volume loading therefore produces an increment in stroke work (i.e., performance) through use of the Frank-Starling mechanism. By contrast, increased myocardial contractility also can produce an increment in stroke work, but in this case performance is augmented through a change in inotropic state rather than by a change in end-diastolic fiber length. In other words, contractility refers to a basic property of the myocardium that reflects the intensity of its active state. The use of the term *contractility* should be restricted to situations in which a change in performance or EF cannot be ascribed to a change in preload or afterload. *Contractile function* is a more general term used to describe changes in performance or function that could be affected by changes in inotropic state, fiber length, or loads. Thus, a change in the EF might best be classified as a change in contractile function; this term is often used interchangeably with *systolic function*. To fully describe the ventricle, it is necessary to define several additional terms that refer to its mechanical properties.[30]

*Stress* is defined as the force per unit cross-sectional area (CSA) of a material. It is an engineering term used to compare loads borne by different-sized elements of a material; the total load is less important than the load per unit of material. If the same load is borne by a smaller amount of material, the stress on that material is higher. In a spherical model of the LV, wall stress ($\sigma$) is directly proportional to the transmural pressure ($P$) and inversely proportional to the product of chamber radius ($R$) and wall thickness ($Th$):

$$\sigma = PR/2Th$$

In the LV, geometry is much more complex, and several components of stress exist within the wall (Fig. 9-7). Of these, meridional and circumferential stresses have most commonly been used in the analysis of LV mechanics. The meridional stress vector is oriented in the longitudinal or apex-to-base direction and represents the component of the load resisting long-axis shortening; circumferential stress is oriented along the equator, perpendicular to the long axis, and represents the component of the load resisting minor-axis shortening. Meridional stress ($\sigma_m$) can be calculated as

$$\sigma_m = P \times LVID/[4 \times Th(1 + LVID/Th)]$$

in which $P$ is pressure (mm Hg), $Th$ is wall thickness, and $LVID$ is cavity dimension.[31] This stress parameter does not require measurement of the long axis of the LV cavity. Circumferential stress ($\sigma_c$) can be calculated as

$$\sigma_c = P \times a^2[1 + (b^2/r^2)]/(b^2 - a^2)$$

in which $P$ is end-systolic pressure (mm Hg), $a$ is the internal (endocardial) radius, $b$ is the external (epicardial) radius, and $r$ is the midwall radius.[32] Other approaches to the calculation of circumferential stress, using minor- and major-axis dimensions, have been evaluated.[32] Formulas for calculation of meridional and circumferential stress using 2D echocardiographic data are as follows[33]:

$$\sigma_m = 1.33P\ A_m/A_c \times 10^3\ \text{kdyn/cm}^2$$

in which $A_t$ is the short-axis area subtended by the LV epicardium and right side of the septum, $A_c$ is the cavity (endocardial) area, $A_m = A_t - A_c$ or myocardial area, and $L$ is the LV cavity

length, obtained from the apical four-chamber view. 2D and M-mode methods yield somewhat different results, with M-mode–derived $\sigma_m$ being higher than 2D-derived values, even in normal subjects. In spherical ventricles, $\sigma_m$ by any method tends to overestimate afterload.[34]

The determination of wall stress requires assessment of LV pressure. Invasively determined values may be combined with echocardiographic dimensions, but they are often not available or simultaneously obtained. Three methods have been proposed for using noninvasive recordings to ascertain LV systolic pressures; LV diastolic pressures (and therefore diastolic stress) cannot be reliably determined noninvasively. Although these methods assume that there is no LV outflow gradient, the first and easiest method assumes that end-systolic LV pressure can be approximated by peak arterial pressure.[30] Thus, cuff systolic blood pressure is substituted for LV end-systolic pressure. The second method involves calibration of an externally recorded pulse recording using cuff systolic and diastolic pressures, with calculation of arterial pressures at the dicrotic notch.[35] The third involves the substitution of mean arterial pressure, derived from cuff recording, for end-systolic pressure, given the close correlation between these two values, as shown by Rozich.[36]

Because wall stress parameters incorporate appropriate size normalization, they allow comparison among the mechanical properties of different hearts. End-systolic wall stresses, calculated using end-systolic pressures (or the surrogates discussed earlier) and dimensions, are taken as indices of LV afterload, whereas end-diastolic wall stress, calculated using end-diastolic pressure and dimension, is a measure of LV preload.

*Preload* is the force (i.e., load) acting to stretch the resting myofibril. Preload is commonly estimated as the LV end-diastolic pressure, diameter, or volume, but to be more precise, this force should be normalized for each unit CSA of muscle and expressed as end-diastolic wall stress. In this manner, LV preload is analogous to the preload on a strip of isolated cardiac muscle in a myograph. This force, which acts to stretch the myocardium, is resisted by the stiffness of the muscle. Thus, the extent to which the myocardial fiber is stretched depends on an interaction between preload and muscle stiffness.[37] Because preload influences initial fiber length, it affects LV systolic performance. This phenomenon, which operates on a beat-to-beat basis, is generally referred to as *Starling's law of the heart* or the *Frank-Starling mechanism*.

The preload reserve of the ventricle depends on the baseline hemodynamic conditions and the stiffness of the myocardium. Thus, in the upright posture, normal human subjects exhibit a substantial preload reserve, whereas in the recumbent posture they may exhibit a minimal preload reserve. The difference in preload reserve is related to difference in the baseline EDV, which is lower in the upright posture than it is when the subject is recumbent, owing to the differences in venous return. This fact should be kept in mind when interpreting exercise studies; the EDV of the normal LV generally increases during upright exercise, but it may not during recumbent exercise. Moreover, the ability to recruit the Frank-Starling mechanism may also be limited in hypertrophied ventricles that have abnormal ventricular compliance characteristics (Fig. 9-8). Thus, in patients with aortic stenosis or hypertensive heart disease, there may be little or no increment in LV EDV during exercise, and consequently the EF may not increase normally.[38-40] Such limited preload reserve occurs as a result of a steep diastolic PV relation in which large changes in filling pressure cause only small changes in volume. This mechanism may even underlie marginal LV function in the basal state.

Despite a low EF, many dilated hearts (particularly those with compensated mitral or aortic regurgitation) generate a normal or high SV. In this instance, although the Frank-Starling mechanism may be a contributing factor, the large SV is primarily a function of the large EDV. In other words, the presence of a large LV chamber does not necessarily indicate use of preload reserve at the fiber level. Many such hearts retain the ability to use preload reserve to augment SV. By contrast, in end-stage heart failure, preload reserve may be exhausted.

*Afterload* can be thought of as the force (i.e., stress) developed by the myocardium after the onset of contraction. As described by the Laplace relation, afterload (systolic wall stress) is directly related to LV systolic pressure and radius and inversely related to wall thickness. Afterload varies with time, and thus it can be

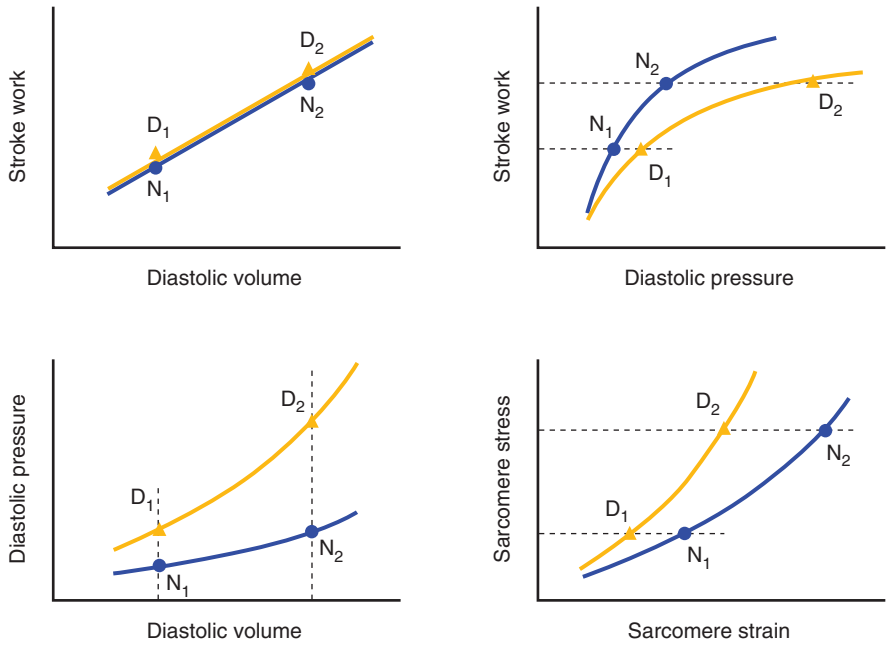

**Figure 9-8 The effect of diastolic dysfunction on the relation between LV systolic performance and preload.** Classic ventricular function curves relating stroke work to end-diastolic volume are shown in the *top left* panel; stroke work is related to end-diastolic pressure in the *top right* panel; diastolic pressure-volume curves are shown *below*. When the LV end-diastolic pressure is used as an index of preload, ventricular systolic function in diastolic heart failure ($D_1$, $D_2$) appears to be less than normal ($N_1$, $N_2$). These results are extrapolated to sarcomere stress-shortening relations. For a given level of sarcomere stress (point *1* to point *2*), there is much less sarcomere strain in patients with diastolic failure ($D_1$, $D_2$) than in normal ($N_1$, $N_2$). *(From Aurigemma GP, Zile MR, Gaasch WH: Contractile behavior of the left ventricle in diastolic heart failure: with emphasis on regional systolic function.* Circulation *113:296-304, 2006.)*

calculated at the instant of aortic valve opening, at the end of ejection, or at any instant throughout systole. Whereas LV systolic pressure and systemic vascular resistance can affect afterload, neither of these should be considered the equivalent of afterload.[41-43] Likewise, aortic input impedance influences systolic pressure and stress, but impedance is not the equivalent of afterload.[44]

In aortic stenosis, the LV systolic pressure may exceed 250 mm Hg, but if there is an appropriate increase in LV wall thickness, the force borne by each unit of heart muscle might remain near normal (i.e., afterload is normal).[30] On the other hand, an acute increase in systolic pressure or chamber size can result in an increased afterload.[45] By virtue of the inverse relation between load and shortening, an acute increase in afterload generally causes a decrease in shortening, and vice versa.

Contractility can be defined as the quality of cardiac muscle that determines performance independent of loading conditions. Contractility is easiest to study and define in isolated heart muscles when loading conditions are held constant. For example, if resting length is held constant, the addition of digitalis or norepinephrine to an isolated muscle preparation results in an increase in the extent and velocity of force development and shortening; such increased performance under constant loading conditions reflects an augmented inotropic state (i.e., increased contractility). In many cardiac diseases, abnormal LV pump function may be caused by disordered loading conditions, depression of contractility, or both. For this reason, it may be difficult to determine the exact cause of decreased fiber shortening. Accordingly, there has been considerable interest in the development of a sensitive index of contractility that is not affected by changes in loading conditions.[46,47] Unfortunately, there is no completely load-independent index of basal contractile state.[30] Thus, directional changes in contractility (during acute hemodynamic interventions) are relatively easy to demonstrate, but it is not possible to define a basal level of contractility in patients with chronic heart disease.

## Assessment of Left Ventricular Mass, Volume, and Geometry

Remodeling of the LV in valvular heart disease, heart failure, and hypertensive heart disease is characterized by changes in LV mass and geometry. Descriptors of LV geometry include the RWT, short-axis/long-axis ratio, and mass/volume ratio. These descriptors are easily obtained by M-mode and 2D echocardiography. As suggested earlier, alterations in LV geometry have been used to assist risk stratification in a variety of diseases and to describe more completely remodeling changes effected by valve replacement. In patients with idiopathic dilated cardiomyopathy, for example, a poorer survival is associated with larger short-axis dimension and a greater ratio of short/long axes (i.e., a more spherical LV geometry).[48,49]

### M-MODE ECHOCARDIOGRAPHY

#### *Mass*

Whereas newer and more costly tomographic methods, such as ultrafast computed tomography and magnetic resonance imaging (MRI), permit more precise quantitation, echocardiography remains the most commonly used technique for estimating LV mass and geometry. This subject has been reviewed by the Chamber Quantification Writing Group of the American Society of Echocardiography (ASE).[50] M-mode echocardiography is universally available and relatively low cost, and there is a considerable body of evidence supporting its accuracy in LV mass quantitation.[51,52] Quantitation of mass is based on the geometric assumption that the ventricle is a prolate ellipsoid with a 2:1 long-axis/short-axis ratio.[51,52] In practical terms, LV mass estimates are most accurate in ventricles with normal shape, specifically, a long-axis/short-axis ratio that approximates 2:1. It is assumed, of course, that minor-axis dimensions are measured in a region free of wall motion abnormalities. This assumption is invalidated in ischemic heart disease with focal wall motion abnormality or in right ventricular overload. Estimates of myocardial mass and volume are derived from LV minor-axis dimensions obtained with the transducer in the parasternal position (Fig. 9-9). Under 2D echocardiographic guidance, the ultrasound beam is aligned so that it is perpendicular to the interventricular septum and posterior wall at a

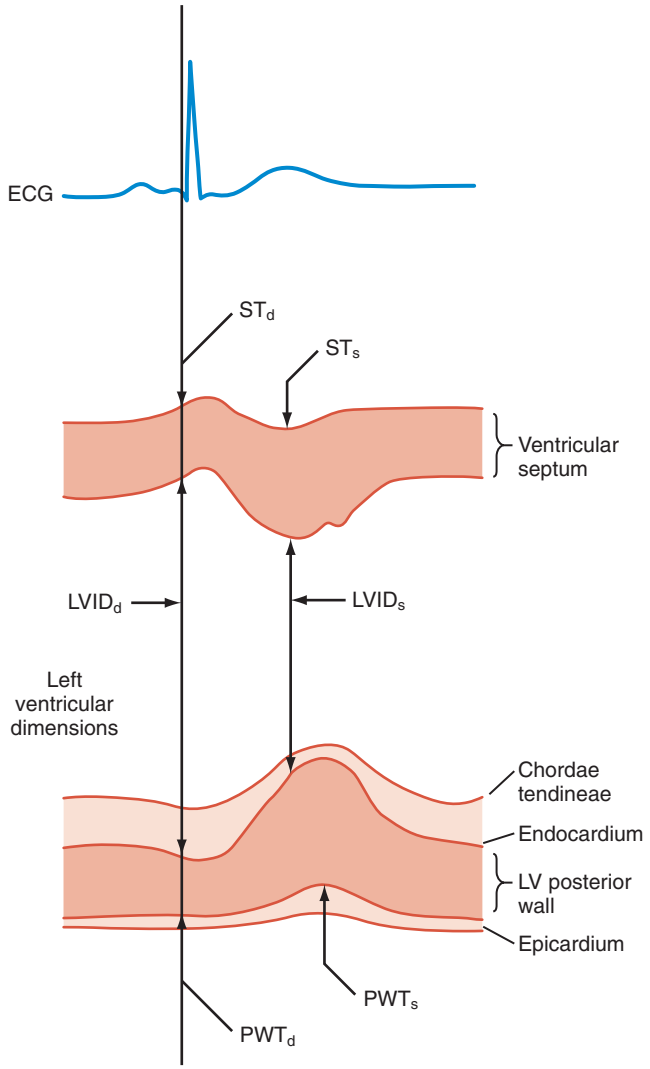

**Figure 9-9 Schematic of an M-mode echocardiogram obtained using 2D echocardiographic guidance.** Measurements are made coincident with the Q wave of the simultaneous electrocardiogram. *ECG*, Electrocardiogram; *$LVID_d$*, left ventricular internal dimensions in diastole; *$LVID_s$*, left ventricular internal dimensions in systole; *$PWT_d$*, posterior wall thickness in diastole; *$PWT_s$*, posterior wall thickness in systole; *$ST_d$*, ventricular septal thickness in diastole; *$ST_s$*, ventricular septal thickness in systole. *(From Aurigemma GP, Gaasch WH, Villegas B, Meyer TE:* Curr Probl Cardiol *20:381, 1995.)*

level slightly below the mitral leaflet tips; the chamber dimension is obtained from the parasternal long-axis view.[49-51] This approach maximizes the LV cavity dimension and ensures that proper beam orientation with respect to the papillary muscles is obtained. LV mass is estimated from measurements of septal and posterior wall thickness and LV cavity dimensions at end-diastole using the anatomically validated cube formula[51,52]:

$$\text{LV mass} = 0.8[1.04(\text{ST}_\text{d} + \text{LVID}_\text{d} + \text{PWT}_\text{d})^3 - \text{LVID}_\text{d}^3] + 0.6\ \text{g}$$

in which $ST_d$ is the diastolic septal thickness, $LVID_d$ is the diastolic LV cavity dimension, $PWT_d$ is the diastolic posterior wall thickness, and 1.04 is the specific gravity of myocardium. The measurements are made using the leading-edge ASE standard technique.[50] As shown by Devereux and colleagues,[1,52] LV mass estimates made with ASE measurements overestimate true anatomic LV weights by 20%, necessitating a correction factor of 0.8. The chamber quantification recommendations note that direct measurements by 2D echocardiography may be substituted for 2D-derived M-mode measurements.[50] It is important to note, however, that direct 2D measurements will yield lower values than 2D-directed M-mode measurements.[50] The accuracy of three-dimensional (3D) methods for calculating LV mass has been demonstrated (see Chapter 4).

### Volume

A simple estimate of LV volume may be obtained from the LV minor-axis internal dimension (LVID), derived by M-mode echocardiography as

$$\text{V} = \text{LVID}^3$$

The geometric assumptions are similar to those used for LV mass calculation. However, in the dilated, spherical LV encountered in long-standing valvular regurgitation or dilated cardiomyopathy, the ratio of length to minor-axis dimension decreases, leading to significant overestimation of LV volumes by this simple method. Teichholz and colleagues[53] derived a formula that attempts to correct for this problem:

$$\text{V}_\text{d} = [7/(2.4 + \text{LVID}_\text{d})] \times \text{LVID}_\text{d}^3$$

LV volumes derived with this formula correlate well with single-plane angiographic estimates.[53] Because M-mode echocardiography provides minor-axis dimensions of the LV in systole and diastole, the Teichholz method may be used to compute LV volumes at end-systole and end-diastole and thus to derive SV and cardiac output (Table 9-2). A compelling advantage of this method is that LV volume can be determined rapidly from easily obtained M-mode measurements. However, given the required geometric assumptions, 2D and 3D methods will always be preferable to M-mode estimates of ventricular volumes.[50]

**TABLE 9-2 Relationship between Chamber Size and Stroke Volume**

| | $LVID_d$ (cm) | EF (%) | SV (mL) |
|---|---|---|---|
| Normal | 5 | 65 | 81 |
| LVH | 4.4 | 75 | 63 |
| DCM | 7.5 | 20 | 84 |

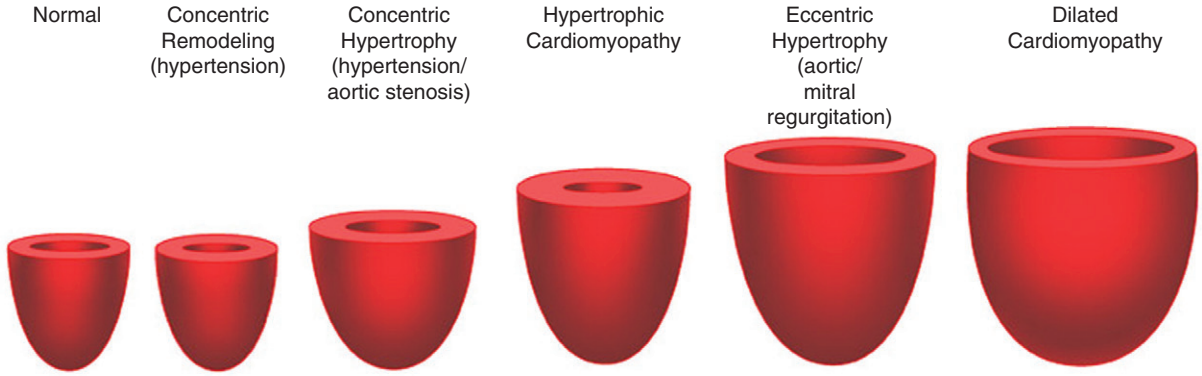
This table illustrates the relationship between chamber size and resting stroke volume (SV). End-diastolic volumes are estimated from the $LVID_d$ using the Teichholz method[53] and SV calculated as the product of end-diastolic volume and ejection fraction (EF). Note that resting SV may be normal in dilated cardiomyopathy (DCM) and less than normal in extreme hypertrophic remodeling. Depending on heart rate, resting cardiac output in patients with extreme LVH or hypertrophic cardiomyopathy may be lower than normal. This table suggests the teleologic reason for chamber dilation.

*LVH*, Left ventricular hypertrophy; $LVID_d$, left ventricular internal dimensions in diastole.

### Relative Wall Thickness

M-mode estimates of myocardial mass and volume are derived from LV minor-axis dimensions obtained with the transducer in the parasternal position (see Fig. 9-9). These same measurements are used to describe LV geometry. Although the amount of LV mass is an important predictor of subsequent cardiac events in hypertensive disease, the geometry and pattern of LV hypertrophy also provide insight into the pathophysiology of hypertensive hypertrophy[49] and may confer prognostic information (see Chapter 34).[24-26] The most commonly used index of the pattern of hypertrophy is the RWT,[27] which is calculated as

$$\text{RWT} = 2 \times \text{PWT/LVID}$$



in which *PWT* is the posterior wall thickness and *LVID* is the LV internal dimension, respectively; RWT may be measured in diastole or systole. RWT also has been expressed as $h/R$, in which $h$ is wall thickness and $R$ is cavity radius. In the normal or compensated ventricle, the RWT increases in direct proportion to elevations in systolic pressure.

In untreated hypertensive patients, LV mass and relative wall thickness determinations may be used to subdivide the population into four general categories (Fig. 9-10):

1. Concentric hypertrophy (elevations in both LV mass and RWT),
2. Eccentric hypertrophy (elevation in LV mass with normal RWT),
3. Concentric remodeling (normal mass but abnormally high RWT), and
4. Normal LV mass and RWT.

In a population of untreated hypertensive patients, the majority had normal LV mass and normal RWT; concentric hypertrophy was the least common abnormal pattern observed.[27] More recently, Khouri and associates[54] have used MRI to refine this original paradigm and added a subclassification of geometric subtypes (see Fig. 9-9; Figs. 9-10 and 9-11). These authors suggest that concentric or eccentric LVH can each be subclassified into two subgroups, yielding four distinct geometric patterns.[54,55] In this and another large, population-based study utilizing MRI, there was a strong association between obesity and concentric LVH, helping to dispel the notion that LVH in this condition is exclusively eccentric.[56]

What is the clinical relevance of the mass and geometry subcategories? Patients with concentric hypertrophy have a relatively high incidence of adverse cardiovascular and noncardiovascular events compared with patients with eccentric hypertrophy.[25-27] In addition, concentric geometry, even without hypertrophy, appears to be associated with adverse consequences during follow-up (see Table 9-1). Thus, in hypertensive disease, as noted earlier, incremental information regarding risk for both cardiovascular and noncardiovascular events is provided by assessing geometry and LV mass. The RWT may provide insight into the appropriateness of hypertrophy.[49] There is occasionally more muscle mass than would be required for the observed pressure; thus, a high RWT, such as is encountered in hypertrophic cardiomyopathies, "hypertensive hypertrophic cardiomyopathy of the elderly,"[57] uncommonly in hypertension, and not infrequently in aortic stenosis,[58] indicates excessive or inappropriate LV hypertrophy. In our experience, RWT values

| | Normal | Concentric Remodeling (hypertension) | Concentric Hypertrophy (hypertension/ aortic stenosis) | Hypertrophic Cardiomyopathy | Eccentric Hypertrophy (aortic/ mitral regurgitation) | Dilated Cardiomyopathy |
|---|---|---|---|---|---|---|
| Mass | N | N | ↑ | ↑ | ↑↑ | ↑↑ |
| Volume | N | N-↓ | N | N-↓ | ↑↑ | ↑↑↑ |
| RWT | N | ↑ | ↑ | ↑↑ | N-↓ | ↓ |
| M/V | N | ↑ | ↑ | ↑↑ | N-↓ | ↓ |

| Systolic shortening | | | | | | |
| Endocardial | N | N | N-↓ | ↑↑ | N | ↓ |
| Midwall | N | N-↓ | ↓ | – | N | ↓ |

**Figure 9-10 LV volume, mass, and geometry, stress, and systolic shortening in various cardiac disorders.** Different cardiac disorders are classified with respect to LV mass, volume, relative wall thickness (*RWT*), and mass/volume (*M/V*) ratio, and stress and shortening as normal (*N*), increased (*up arrows*), or decreased (*down arrows*). *(Redrawn from Aurigemma GP, Gaasch WH, Villegas B, Meyer TE:* Curr Probl Cardiol *20:385, 1995.)*

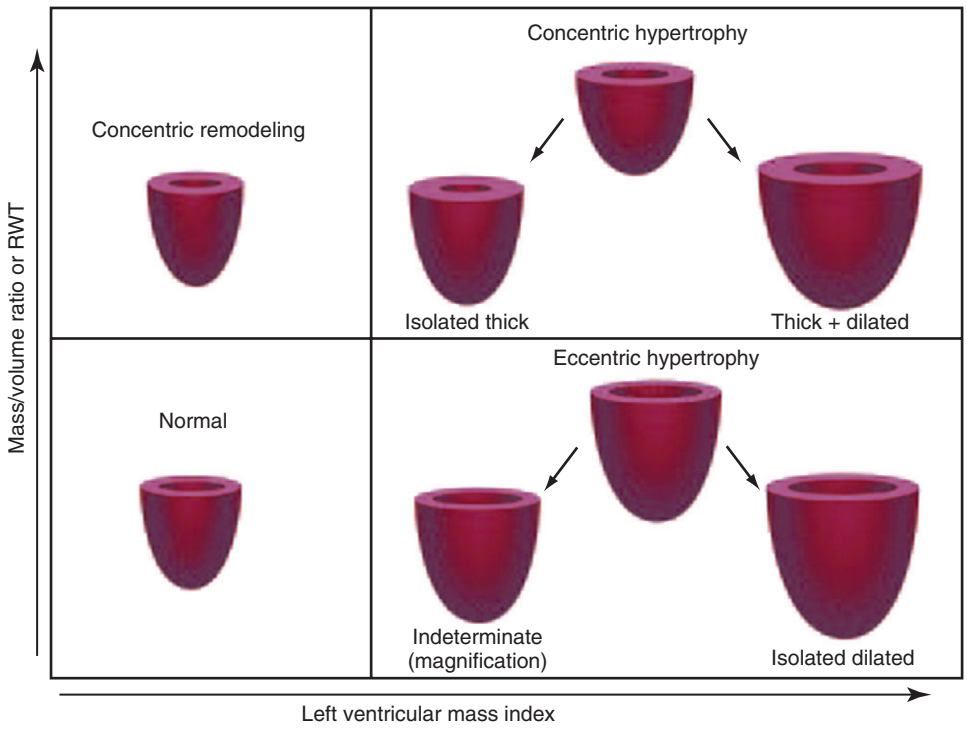

**Figure 9-11 Remodeling subtypes.** Individuals may be classified by presence or absence of LVH (horizontal axis) and by geometry (vertical axis), depending on mass-to-volume ratio. If mass-to-volume ratio is high, geometry is classified as concentric. The paradigm of Khouri and colleagues[54] subdivides the two LVH classes by whether chamber dilation is present. *RWT*, Relative wall thickness.

greater than 0.8 are uncommon in aortic stenosis, but when present, they appear to represent inappropriate hypertrophy.

The interaction among shape, load, and function is complex and important because each one may influence the others. A decompensated heart clearly demonstrates abnormalities of all three—low RWT, high afterload, and reduced function—yet it is not possible to state which abnormality is primary. Does the ventricle dilate, thereby raising afterload and reducing pump performance, or is shortening impaired first, leading to dilation, which then raises afterload? Human studies shed little light because of the lengthy time course of disease and other confounding factors; animal studies suggest that all three events may occur in concert.[58]

## TWO-DIMENSIONAL ECHOCARDIOGRAPHY

2D echocardiography permits acquisition of data with excellent spatial orientation because the LV can be sampled in real time at multiple levels. In many laboratories, therefore, 2D echocardiography is the principal noninvasive means for quantitation of LV volume and for the assessment of global and regional systolic function. LV mass and volume quantitation by 2D echocardiography requires high-quality images and true long- and short-axis images of the LV. A variety of geometric models are used to approximate the shape of the LV and to compute LV volumes, including the prolate ellipse model, the hemiellipse model, and others that represent a combination of geometric shapes. Detailed review of the geometric principles underlying these volumes for formulas may be found elsewhere.[49] This chapter emphasizes the applications most suited for clinical use.

### *Mass*

Theoretically, 2D echocardiographic assessment of LV mass can improve on the limitations of M-mode methods; mean wall thickness can be back-calculated from planimetered short-axis myocardial area, which helps avoid reliance on single-dimensional determinations. One of the most practical 2D methods for mass calculation, the area-length method, approximates the LV as a cylinder-hemiellipsoid; volume is calculated for both the inner and outer "shells" (the LV cavity and total myocardial area, respectively):

$$V = 5/6\ A \times L$$

in which *A* is planimetered short-axis area obtained at the high papillary muscle level, and *L* is the LV length obtained from the apical four-chamber view; area and length measurements are made at end-diastole. In this way, total LV and internal (LV cavity) volume are determined; myocardial volume is the difference between the inner and outer shells.[59] Myocardial volume is then multiplied by the specific gravity of myocardium (1.04 g/mL) to compute myocardial mass. The model has been validated by comparing echocardiographic and anatomic LV mass in 21 patients who underwent 2D echocardiographic studies shortly before death[60]; there was an excellent correlation between anatomic and echocardiographic mass (r = 0.93, standard error = 31 g). It is important to note that phantom-generated regression equations were used to correct clinical mass measurements for each 2D echocardiographic machine. Although more complicated 2D and 3D echocardiographic methods provide greater accuracy for LV mass determination, the 2D cylinder-hemiellipsoid area-length method represents a relatively simple and practical approach that yields acceptable results.[49]

### *Volume*

A variety of geometric approaches have been described for the quantitation of LV volume from 2D echocardiography. There are theoretical advantages for use of the Simpson's rule algorithm, and this approach is preferable when ventricular shape is distorted, such as with an apical aneurysm. The Simpson's rule approach, also known as the *method of disks,* is predicated on the fact that the volume of the whole LV (or of any object) may be computed as the sum of individual "slice" volumes. In general, the accuracy of the measurement varies directly with the number of slices:

$$V = \sum_{i=1}^{n} A_i T$$

*V* is total volume (cavity or myocardial), *A* is planimetered area, and *T* is slice thickness. Myocardial volume is then multiplied by the specific gravity of myocardium to estimate myocardial mass. It is best to compute LV volume from two orthogonal apical views with the LV length divided equally along that length[50,61]; apical four- and two-chamber views at end-diastole should be recorded to maximize ventricular length. The use of the cylinder-hemiellipsoid (area-length) method for calculating the volume component represents a reasonable alternative to the method of disks.

### *Geometry*

Compared with M-mode echocardiography, 2D echocardiography offers improved spatial orientation because the LV can be sampled in real time at multiple levels. Accordingly, 2D echocardiography may be used to quantify the LV mass and chamber volumes of abnormally shaped ventricles, and because measurements of LV length are possible, this technique provides more extensive description of LV geometry. Estimates of both the short-axis/long-axis ratio and the volume/mass ratio[62] are possible with 2D echocardiography. In patients with normal LV mass and function, the short-axis/long-axis ratio ranges from 0.45 to 0.62.[62-64] In untreated hypertensive patients with normal LV ejection fraction, the short-axis/long-axis ratios range from 0.52 ± 0.04 in patients with concentric remodeling to 0.63 ± 0.03 in patients with eccentric hypertrophy. The short-axis/long-axis ratio also provides information regarding ventricular compensation in valvular heart disease. As in patients with dilated cardiomyopathy, in whom the ventricle becomes more spherical, patients with poorly compensated aortic stenosis and aortic regurgitation (those with low EFs) tend to have higher short-axis/long-axis ratios.[64] A high ratio in turn alters the relationship of meridional to circumferential stresses, a change in the distribution of afterload that may affect overall pump performance.[64]

The end-diastolic volume/mass ratio in normal men and women, as defined by 2D echocardiography, is approximately 0.8.[63] It has been traditionally assumed that the ratio of LV volume to mass is relatively constant from the most basal to the most apical slices of the LV. A study using the technique of ultrafast computed tomography, which can provide approximately eight tomographic slices through the LV, showed that in normal subjects, the volume/mass ratio decreased from approximately 0.8 at the most basal slice, a finding consistent with results of 2D echocardiography, to approximately 0.25 at the most apical slice. LV mass exceeds LV volume at each slice location.[65]

It is important to emphasize that 2D echocardiographic methods have problems that limit their routine use for quantitation in the clinical setting[49] (Box 9-2). M-mode echocardiography samples at approximately 1000 frames per second, whereas the frame rate for 2D echocardiography is orders of magnitude less: 30 to 60 frames per second under optimal conditions. There is considerable image degradation when stop frames are used, making precise endocardial definition problematic. Near-field artifact and poor lateral resolution make it difficult to reliably identify endocardium around the entire ventricular perimeter. Apical views often do not yield images of sufficient quality for manual tracing, and computations tend to be tedious. The use of intravenous contrast has improved the accuracy of LV volume determinations. 3D echocardiography (see Chapter 4) has been shown to provide the most accurate ultrasound determination of LV volume, mass, and EF, largely because the need for geometric assumptions and on-axis views will be eliminated.[50,64-68]

**Box 9-2**

**LIMITATIONS OF ULTRASOUND METHODS FOR MASS AND VOLUME QUANTITATION**

**General**
- All methods require high-quality images with good endocardial definition.
- Most methods require geometric assumptions about LV shape and are applicable only to normally shaped hearts.

**M-Mode Echocardiography**
- Small errors in measurement may lead to large errors in mass/volume determinations.
- May be insensitive to small changes in mass (20 to 40 g) observed in response to antihypertensive treatment.

**Two-Dimensional Echocardiography**
- Limited frame rate, making timing of cardiac events difficult.
- Considerable degradation when images are stop-framed.
- Apical images may foreshorten true LV length.
- Tedious, labor-intensive computations.

## ALTERNATIVE METHODS FOR QUANTITATION OF LEFT VENTRICULAR STRUCTURE AND FUNCTION

In addition to cardiac ultrasound, the clinician may use other noninvasive and invasive techniques to measure LV size and function. A brief review of some of the more commonly used techniques is therefore appropriate.

### *Doppler Echocardiography*

Routine Doppler measurements of flow velocity may be combined with echocardiographic dimensional data to determine SV and cardiac output.[69,70] This technique is known as the velocity-time integral (VTI) method. The appeal of this method is that, unlike M-mode and 2D echocardiographic measurements, VTI measurements do not require geometric assumptions about cardiac shape.

To compute SV using the VTI method, an integral of the systolic pulsed-wave flow envelope in the aortic outflow tract is computed (Fig. 9-12). To obtain this velocity spectrum, the transducer is placed in the apical position with the sample volume positioned at the level of the aortic-valve annulus. Although the VTI may be obtained in other locations, such as the pulmonary artery or LV inflow across the mitral valve, accuracy seems to be best with measurements made in the proximal ascending aorta. The cross-sectional linear dimension of the proximal ascending aorta is obtained in the same approximate location where the pulsed- or continuous-wave Doppler velocity spectrum is recorded, using the parasternal long-axis window. SV is then the product of the VTI and CSA of the aortic annulus, which is assumed to be circular:

$$CSA = \pi(D/2^2)$$

$$SV = CSA \times VTI$$

in which *CSA* is the cross-sectional area of the aortic annulus, *D* is the linear dimension of the annulus, and *VTI* is the

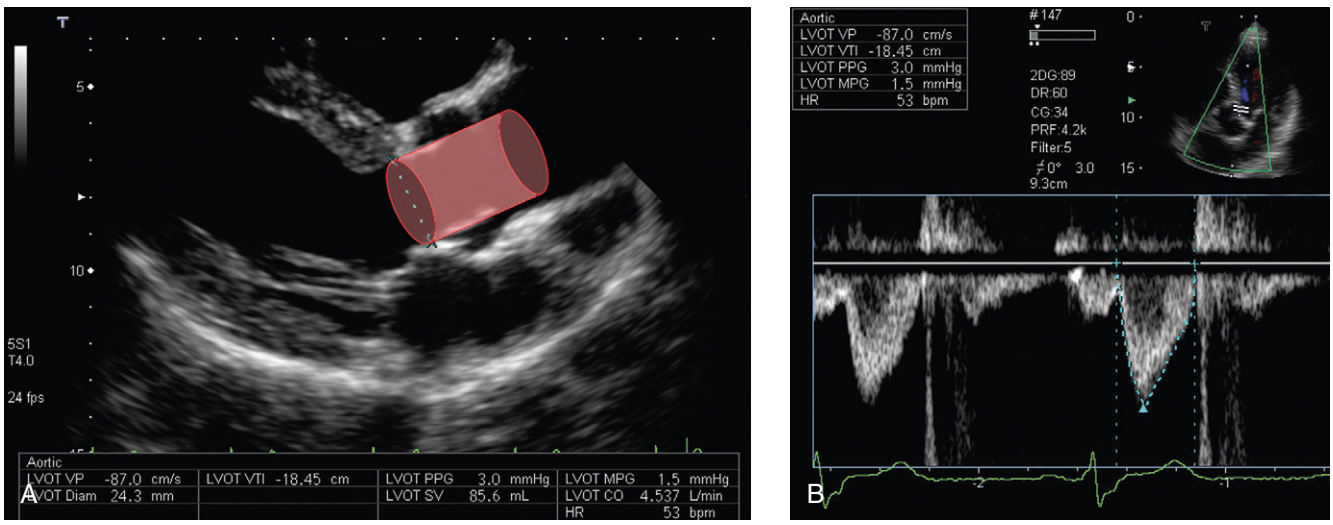

**Figure 9-12 Calculation of cardiac output using the velocity-time integral (VTI) method.** The pulsed-wave Doppler-derived VTI is displayed. The LV outflow tract (*LVOT*) dimension is approximately 24 mm, and radius 12 mm. π times the square of the annular radius yields the LVOT cross-sectional area, and the VTI is 18.5 cm by planimetry. The stroke volume is 84 mL per beat (LVOT cross-sectional area multiplied by the VTI) and yields a cardiac output of 4.5 L/min at the patient's heart rate of 53 bpm.

velocity-time integral. SV and cardiac output obtained by the VTI method correlate well with results of concurrent thermodilution cardiac output determinations in patients who were without left-sided valvular regurgitation.[69,70] The Doppler VTI method is highly dependent on accurate measurements of aortic annular diameter because the CSA formula involves squaring the annular dimension; it is also assumed that the Doppler beam is oriented parallel to flow. This method also requires that there be no significant aortic or mitral valve disease. This method can be particularly useful for following changes in a single patient—beat to beat, or over weeks to months.

Doppler echocardiographic assessments of LV function do not depend on measurements of ventricular size (and thus avoid the attendant geometric assumptions and sources of error); they rely on information derived from flow velocities.[71] This information includes measurement of LV SV, cardiac output, and peak flow velocity of aortic ejection, all of which, being ejection phase indices, are dependent on afterload. Another Doppler approach to evaluation of systolic function is to measure the rate of rise of ventricular pressure ($dP/dt$) from the continuous-wave profile of the mitral regurgitant flow.[72]

### *Magnetic Resonance Imaging*

In many respects, MRI is the ideal method to quantitate LV mass and volume and is considered the reference standard for LV quantitation.[66,73] It combines the attributes of ultrafast computed tomography (noninvasive and permitting true tomographic imaging throughout the entire cardiac volume) with several unique advantages. MRI does not require contrast administration or ionizing radiation, and there is no limitation to image plane selection; thus, the heart may be imaged not only in the familiar contrast ventriculography views but also in the long- and short-axis planes used in standard transthoracic echocardiography. MRI usually provides images with excellent contrast between myocardium and the blood pool so that manual or even semiautomated computerized mass and volume quantitation is possible.[74,75] For these reasons, MRI has provided the most accurate noninvasive estimates of LV mass and volume to date, even in ventricles distorted by myocardial infarction.[76] Gradient echocardiographic techniques display the heart in cineloop fashion at up to 64 frames per cardiac cycle. This technique can be used to quantitate EF and regional function and to estimate the severity of valvular regurgitation.[77]

## Assessment of Left Ventricular Systolic Function

The major factors affecting LV systolic performance and function are preload, afterload, myocardial contractile (or inotropic) state, and heart rate. Nonuniform contraction can also be important; thus, regional variations in mechanical function, as occur in coronary heart disease or even with electronic ventricular pacing, can affect SV. Only if synchronous contraction is present, heart rate is stable, and loading conditions are constant does a change in performance indicate a change in contractility. These traditional concepts relating preload, afterload, and contractility are generally considered in the assessment of an acute response to altered hemodynamic conditions. Thus, an isolated increase in preload is said to produce an increment in performance through the Frank-Starling mechanism, whereas an isolated increase in afterload is said to produce a decrease in the SV (or EF) by virtue of the inverse force-shortening relation. Unfortunately, in the intact heart, especially in patients with chronic heart disease, it is virtually impossible to produce an *isolated* change in preload or afterload. For example, nitrates are classified as vasodilators and agents that primarily affect preload, but the associated decrease in LV volume and arterial pressure leads to a reduction in afterload. Likewise, a pure arterial vasodilator also reduces heart size (and preload) by augmenting the SV. It is apparent, therefore, that preload and afterload are intimately related, and that it is an oversimplification to assume that isolated changes in preload or afterload occur in patients with chronic heart disease.

Most interventions that produce an acute change in preload or afterload also result in a length-dependent change in intrinsic myocardial contractility,[78] which further complicates the assessment of global systolic function. Therefore, acute changes in preload produce changes in performance through the Frank-Starling mechanism *and* through this length-dependent activation. The importance of this phenomenon in the chronically enlarged or diseased heart is unknown.

It is usually not difficult to detect an acute change in LV performance or contractile function, but it is harder to determine the major mechanism or mechanisms responsible for the change. Chronic changes in LV volume, mass, and geometry are even more difficult to interpret because such changes tend to limit our use of the traditional interrelationships of preload, afterload, and contractility. Indeed, there is no acceptable index of basal contractility that can be used in patients with chronic heart disease, nor can LV end-diastolic pressure or even absolute EDV be used as a surrogate for fiber stretch in chronically diseased hearts. For these and other reasons, the evaluation of contractile function and the distinction between a compensated and a decompensated ventricle often rest on empiric observations coupled with analyses based on physiologic principles. In the following section, the use and limitations of several clinically useful approaches to the evaluation of contractile function are discussed (Box 9-3).

### EJECTION FRACTION

The EF is the most widely used measure of LV systolic function. This parameter is defined as the change in LV volume (i.e., SV) divided by the initial volume (i.e., EDV):

$$EF = (EDV - ESV)/EDV$$

in which *EDV* is end-diastolic volume and *ESV* is end-systolic volume; these may be obtained by either M-mode or 2D echocardiography.[50] The EF, representing volume strain, is appropriately normalized; it can be used as an index of systolic function that is independent of the size of the patient or the ventricle.

The normal ventricle ejects more than half of its EDV; the average EF, as determined by 2D echocardiography, varies from 63% to 69%.[50] In patients with coronary disease or idiopathic

**Box 9-3**

**CLINICAL METHODS USED TO EVALUATE SYSTOLIC FUNCTION**

Ejection fraction

Stress-shortening relations
Pressure-volume analysis

cardiomyopathy, it is generally conceded that values in the range of 40% to 50% are abnormal but of little clinical significance.[6] However, in patients with mitral regurgitation, an EF in this range may denote significant depression in contractile function.[79]

### *Hemodynamic Determinants of the Ejection Fraction*

Acute changes in LV loading conditions are known to exert a major influence on the EF. Thus, an acute increase in preload and/or a decrease in afterload results in a higher EF. By contrast, an acute decrease in preload and/or an increase in afterload reduces the EF. Under such circumstances, it can be difficult to decide whether a change in contractility has occurred. If, however, alterations in load are associated with a change in the EF that is opposite to the expected result, it is possible to conclude that a simultaneous change in contractility (i.e., inotropic state) also occurred. For example, an increased EF in the presence of increased afterload likely represents increased contractility because an increase in afterload would normally be expected to cause a lower EF. Despite its load sensitivity, the EF can therefore provide useful information, even during acute hemodynamic interventions. In this regard, the concept of preload reserve is important.

In patients with chronic heart disease, the EF can be an important index of contractile function, in part because of its sensitivity to increased afterload. As LV dysfunction develops and dilation occurs, afterload tends to increase, as dictated by the Laplace relationship, and the EF falls. Such a decline in the EF can be useful in identifying LV dysfunction early in the course of a disease; it does not, however, identify the underlying mechanism or mechanisms. Therefore, in patients with chronic heart disease, the EF must be interpreted with consideration of the magnitude and time course of changes in loading conditions that evolve during progression of the disease. For example, early in the course of aortic regurgitation, LV preload and afterload tend to be increased; these changes affect the EF in opposite directions, and it remains within the normal range. As the ventricle remodels and eccentric hypertrophy develops, the loads normalize despite LV enlargement; if myocardial contractility is preserved, the EF remains normal. As the hemodynamic burden increases (or contractile dysfunction develops), the afterload increases and the EF decreases. Thus, even a modest decline in the EF can be an important early marker of LV dysfunction.

In decompensated aortic stenosis, LV systolic pressures increase in parallel with an increase in wall stress, as predicted by the Laplace relationship. As wall stress progressively rises, EF decreases. Carabello and colleagues[16] have shown that patients with critical aortic stenosis, congestive heart failure, and decreased EF owing to high levels of wall stress ("afterload mismatch") may anticipate improvement in systolic function following afterload reduction associated with valve replacement[16,79,80]. By contrast, those patients whose reduction in EF is out of proportion to the high levels of wall stress are thought to have developed cardiomyopathic changes in addition to excess afterload; such patients generally do not experience functional improvement after valve replacement.[16,80] This subgroup of patients may be identifiable by a low transvalvular gradient (usually less than 30 mm Hg) in association with severe stenosis of the aortic valve.[16] In the clinical setting, making the proper diagnosis can be challenging. Because the Gorlin equation is flow dependent, patients with primary LV dysfunction and coexistent (mild) calcific aortic stenosis can be difficult to distinguish from those with LV dysfunction caused by unrelieved severe aortic stenosis (See Chapter 23.) Dobutamine echocardiography is used to help make this distinction and to assess prognosis.[81]

## FRACTIONAL SHORTENING AND RELATED INDICES

The fractional change (percentage) in minor-axis dimension is a widely used index of systolic performance; fractional shortening is usually derived from M-mode echocardiographic tracings (Fig. 9-13). This measurement is particularly useful because LV circumferential fiber shortening is responsible for most of the SV. In this regard, fractional shortening is similar to the EF; in the absence of focal wall motion abnormalities, the two indices correlate closely, although the absolute values for fractional

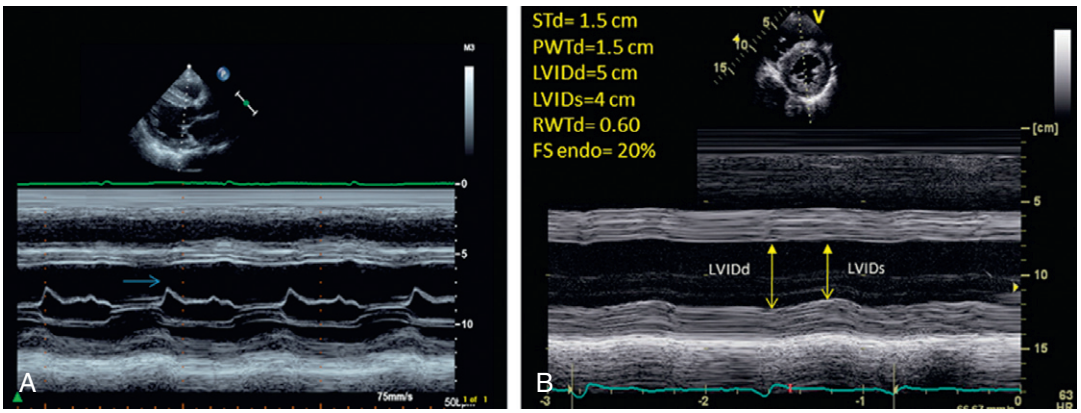

**Figure 9-13 M-mode echocardiographic findings in systolic dysfunction.** Although M-mode is not currently used as the principal means to assess LV systolic function, it can furnish important data. **A,** M-mode obtained in a patient with dilated cardiomyopathy. Poor stroke volume shown by exaggerated separation between the most anterior excursion of the anterior leaflet of the mitral valve and the interventricular septum (E-point septal separation—*arrow*). **B,** From a patient with systemic amyloidosis. Image shows thick walls, high ratio of wall thickness to cavity dimension (relative wall thickness, RWT), and reduced endocardial fractional shortening. The constellation of thick walls, high RWT, nondilated LV cavity, and poor fractional shortening should always prompt consideration of amyloid cardiomyopathy.

shortening are obviously less than those for EF. Fractional shortening, measured at the endocardium ($FS_{endo}$ [%]), is calculated as

$$FS_{endo} = 100 \times (LVID_d - LVID_s)/(LVID_d)$$

Normal values for $FS_{endo}$ exceed 25%.[49] As is the case with EF, $FS_{endo}$ is influenced by factors in addition to contractile state and should be interpreted in the light of loading conditions; increases in preload and decreases in afterload increase fractional shortening.

A refinement of fractional shortening, the velocity of circumferential shortening ($V_{cf}$) reflects the mean velocity of ventricular shortening at the level of the LV minor axis, and it is also calculated from M-mode echocardiographic dimensions:

$$V_{cf} = FS_{endo}/ET$$

in which *ET* is the ejection time derived from the duration of aortic valve opening, from the period of aortic forward flow (pulsed-wave or continuous-wave Doppler), or from a carotid pulse tracing. The $V_{cf}$ is expressed in circumferences per second (the lower limit of normal is 1.1 c/s). Because $V_{cf}$ measures the velocity rather than the extent of shortening, it is theoretically a more sensitive index of contractility than $FS_{endo}$ and may be an earlier marker of abnormality in chronic disease states. As with the EF and fractional shortening, this parameter is normalized for LV chamber size and may be used to make comparisons between patients. $V_{cf}$ has been shown to be relatively insensitive to acute changes in preload.[82,83] However, it is also possible that this preload insensitivity may be a result of acute elevations in preload increasing heart size (and pressure) and thus increasing afterload. Thus, augmentation in afterload may offset the increased shortening caused by the increased preload. A further refinement in $V_{cf}$, the rate-corrected $V_{cf}$,[84] may be obtained by dividing $V_{cf}$ by the square root of the preceding RR interval. This index is designed to allow comparison between patients with differing heart rates. The incremental value of velocity of shortening methods (e.g., $V_{cf}$, rate-corrected $V_{cf}$) compared with extent of shortening (e.g., fractional shortening) may be marginal.[85]

Standard M-mode measurements also may be used to estimate circumferential fractional shortening at the midwall ($FS_{mw}$ [%]), using the same standard M-mode echocardiographic measurements. $FS_{mw}$ is calculated using a modified two-shell cylindrical model.[86] This method assumes constant LV mass throughout the cardiac cycle and does not require the assumption that inner and outer wall thickening fractions are equal.[74,87] Most important, in contrast to $FS_{endo}$, $FS_{mw}$ is not influenced by LV geometry (RWT) and therefore has particular use in the evaluation of the hypertrophied heart with increased RWT.

Normal systolic function includes the excursion of the mitral annulus toward the relatively immobile apex; thus, the long axis of the LV shortens during systole. An assessment of the longitudinal (or long-axis) shortening of the LV can be made using M-mode measurements under 2D echocardiographic guidance.[88] Using the apical window, the transducer is oriented to maximize apical endocardial to mitral annular distance. M-mode tracings are made with the cursor directed through the lateral aspects of the mitral annulus; recordings of multiple cardiac cycles are made on strip chart paper,[88] and mitral annular excursion is normalized for initial diastolic length.

Several investigators have used mitral annular excursion and long-axis shortening as a descriptor of ventricular systolic function. Keren and LeJemtel[71] showed that the principal systolic mitral annular excursion toward the apex coincides with the systolic component of pulmonary venous flow; this systolic phase of mitral annular motion is markedly attenuated in patients with dilated cardiomyopathy. Jones and Gibson[88] showed that in the normal LV mitral annular excursion toward the apex precedes circumferential shortening, which leads to a more spherical LV shape early in systole.[88] These investigators also showed that mitral annular descent was reduced in patients with mitral disease who had undergone valve replacement.[71] In patients with "compensated" hypertensive heart disease, that is, LV hypertrophy and normal EF, long-axis shortening is depressed compared with normal controls.[71] Similar findings have been reported using the technique of strain imaging and MRI tagging, as will be described later.[89,90]

Other ultrasound techniques have been employed in recent years to investigate LV systolic and diastolic function. The timing of ventricular ejection and relaxation can be used to derive a combined index of ventricular function (Fig. 9-14).[89] Doppler tissue imaging applies a modification of pulsed Doppler methods to the assessment of myocardial systolic motion.[91,92] In this way, the velocity of myocardial tissue or of the mitral annulus, and not just the total excursion, may be measured. The velocity of the diastolic mitral annular motion has been applied to the study of LV diastolic function (see Chapter 11). This technique is now being employed to evaluate the extent of systolic dyssynchrony and to evaluate the appropriateness of biventricular pacemaker implantation, as described in Chapters 10 and 26.

## STRESS-SHORTENING RELATIONS

On the basis of extensive experimental and clinical experience, the myocardial force-velocity relation provides a framework for evaluating the contractile state and function of the LV. A most important advantage of assessing function with a stress-shortening analysis is that it avoids afterload dependency, the major limitation of the EF alone. Unfortunately, end-diastolic

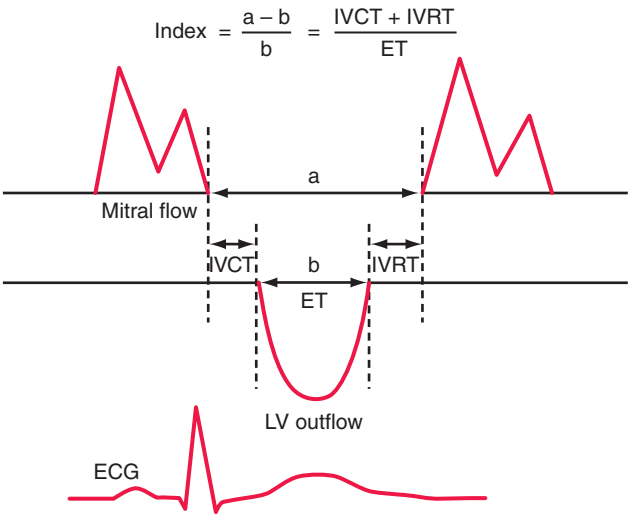

**Figure 9-14 Principle of the Tei (myocardial performance) index.** The index is calculated as the sum of isovolumic contraction time (*IVCT*) and isovolumic relaxation time (*IVRT*) divided by ejection time (*ET*). In the extreme, a heart that has very long isovolumic times compared to the ET has very poor performance. *ECG*, Electrocardiogram. *(From Tei C. New non-invasive index for combined systolic and diastolic ventricular function. J Cardiol 26:135-136, 1995.)*

fiber length (or the degree to which the resting fiber is stretched) is difficult if not impossible to measure; LV end-diastolic pressure, EDV, or even wall stress fails to provide an absolute measure of fiber length. For this reason, length is generally omitted and the simpler force-velocity or stress-shortening relation is used as a substitute for the force-length-velocity relation.

Both systolic stress (the force per unit CSA of myocardium) and shortening (fractional change in length or volume) are appropriately normalized and allow accurate comparisons among hearts of different sizes.[75] Therefore, contractile function in pressure overload hypertrophy, volume overload hypertrophy, and dilated and hypertrophic cardiomyopathies may be assessed within the framework of the stress-shortening relation (Fig. 9-15).

A major limitation of the simple stress-shortening analysis is the assumption that differences in resting length do not substantially influence the stress-shortening relation. In this regard, a distinction must be made between acute interventions and chronic steady-state conditions. Changes in fiber length and appropriate use of preload reserve certainly occur during acute or short-term hemodynamic interventions. However, under chronic conditions (e.g., chronic compensated volume overload), this may not be the case.[93] After the acute or subacute phase, when the compensatory remodeling process is complete and chronic changes in LV volume and mass are established, end-diastolic fiber length may not be substantially different from normal.[94] In pressure overload or concentric hypertrophy, end-diastolic sarcomere lengths may even be less than normal.[95,96] In such hearts, high chamber stiffness apparently limits use of the preload reserve. It appears, therefore, that assumptions about chronic changes in fiber length are unwarranted.

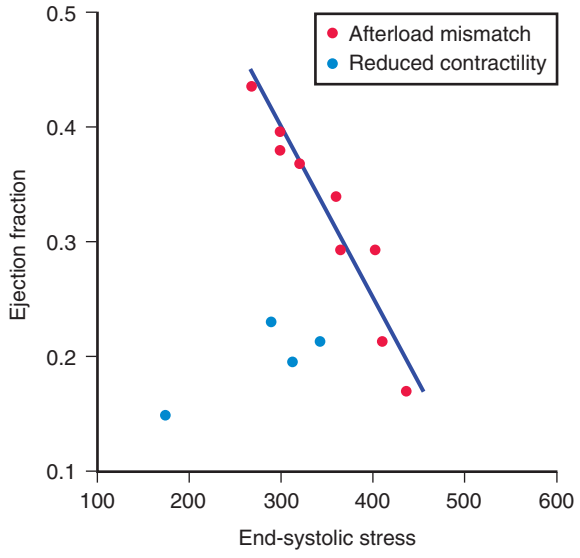

**Figure 9-15 Relationship between ejection fraction (EF) and end-systolic stress in patients undergoing cardiac catheterization for critical aortic stenosis and severe congestive heart failure.** All patients were free of significant coronary artery disease. Patients falling close to the regression line relating EF to stress (*red circles*) are thought to have LV dysfunction owing to excessive wall stress (afterload). These patients experienced a gratifying functional recovery after aortic valve replacement. In contrast, the four subjects who fell below the regression line (*blue circles*) have depressed EF beyond that predicted by the level of afterload and are considered to have depressed contractility as well. These patients did not experience functional recovery after valve replacement. *(Adapted from Carabello BA, Green LH, Grossman W, et al: Hemodynamic determination of prognosis of aortic valve replacement in critical aortic stenosis and advanced congestive heart failure.* Circulation *62:42, 1980. In Aurigemma GP, Gaasch WH, Villegas B, Meyer TE:* Curr Probl Cardiol *20:416, 1995.)*

## *Midwall Stress-Shortening Analysis*

The analysis of midwall stress-shortening relations may be superior to that of endocardial stress-shortening relations, especially for comparison of contractile state between hearts differing in LV geometry (Figs. 9-16 and 9-17). The first advantage

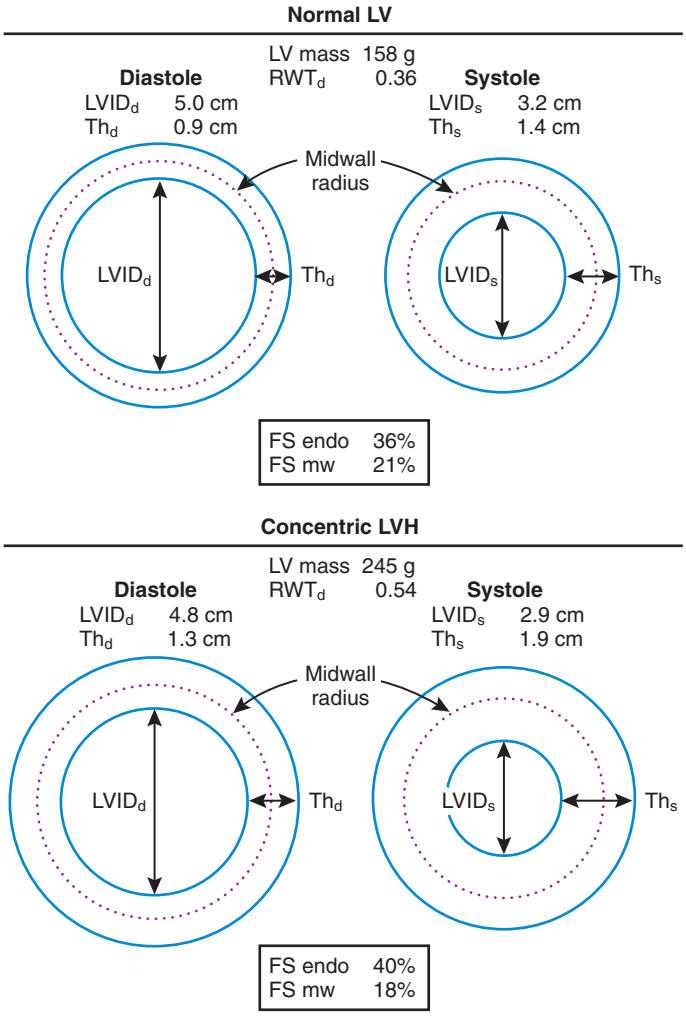

**Figure 9-16 Relationship between LV shortening and LV hypertrophy.** LV shortening in a normal LV (*top*) and with concentric LV hypertrophy (*LVH*) (*bottom*), illustrating the added insight into systolic function provided by midwall shortening. LV endocardial dimension (*LVID*), wall thickness (*Th*), relative wall thickness (*RWT*), and LV mass are measured in diastole (*d*). Systolic dimensions (*s*) are shown at *right*. Midwall circumference indicated by *dotted line*. Systolic shortening refers to percent reduction in circumference that occurs from diastole to systole. *FS endo*, percent reduction of endocardial circumference (*dark inner circle*), and *FS mw*, percent reduction of midwall circumference (*dotted line*), are in normal range. However, concentric LVH (elevated relative wall thickness dimension *RWTd* and LV mass) is associated with an increased value for FS endo, but a diminution in FS mw, compared with normal LV, owing to the nonuniformity of systolic thickening. Myocardial fibers in the inner (subendocardial) layers contribute more to systolic thickening than those in the outer (epicardial) layers; this effect is exaggerated when concentric geometry is present.

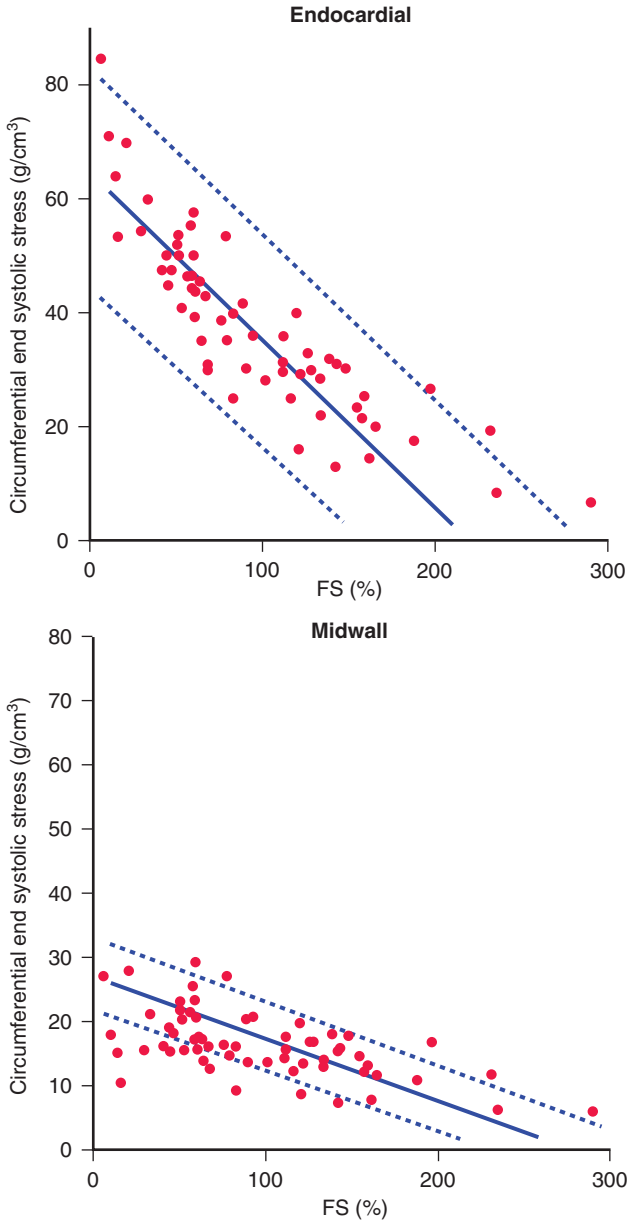

**Figure 9-17 Endocardial and midwall stress-shortening relations in pressure overload hypertrophy.** *Top* panel: Fractional shortening (FS) at the endocardium versus circumferential stress in a consecutive series of patients with severe, symptomatic aortic stenosis who were free of segmental wall motion abnormalities. All patients fall within the 95% confidence intervals of the stress-shortening relationship, suggesting normal contractile function. In contrast, the *bottom* panel shows midwall shortening versus circumferential stress in the same population. A substantial portion (approximately one third) of these patients demonstrates a diminution in contractility by midwall analysis.

of midwall measurements is that the (circumferential) stress vector and the shortening transient are oriented in the same direction because circumferential fibers predominate in the midwall of the LV.[30]

Second, the values for midwall (but not endocardial) shortening are consonant with experimental data indicating that myocardial fibers shorten by approximately 15% to 20%. Circumferential midwall strain ranges from 9% ± 2% in the anesthetized, open-chest dog (implanted markers)[97] to 30% ± 7% in conscious humans (MRI tagging).[97a] We believe that the experimental results represent an underestimate of strain, but MRI techniques likely overestimate true myocardial shortening. All methods indicate that circumferential shortening at the endocardium exceeds that seen at the midwall. We believe that studies designed to assess myocardial contractile function should ideally be based on midwall stress-shortening data and not on endocardial shortening parameters, which may be contaminated by altered ventricular geometry.

An example of the usefulness of a midwall stress-shortening analysis is shown in Figure 9-18. The endocardial stress-shortening relation is normal in patients with pressure overload hypertrophy owing to aortic stenosis; thus, LV function is normal. By contrast, the midwall stress-shortening relation is abnormal in approximately one third of the patients, indicating a subtle depression of myocardial function in these individuals.[74]

In the past decade, there have been many studies of strain imaging techniques[91,92,98-101] (see Fig. 9-18). A variety of techniques are now in use for the assessment of regional and global systolic and diastolic function and are covered in detail in Chapter 10. Strain imaging has as a principal virtue the ability to assess regional systolic function and may be one day be used to lessen the subjectivity involved in gauging wall motion in the clinical arena. Normal strain values have been derived—and there have also been applications to systemic disease, such as hypertensive disease. It is important to realize that, like all systolic function parameters, systolic strain is inversely proportional to the level of afterload (Figs. 9-19 and 9-20).

## PRESSURE-VOLUME ANALYSIS

By plotting LV pressure against volume throughout the entire cardiac cycle, a P-V loop can be generated (Fig. 9-21). The height of the loop is determined by systolic pressure, and its width is determined by SV; thus, the area within the loop is a measure of stroke work. By definition, such loops incorporate EDV and ESV; thus, the SV and the EF are displayed. The bottom limb of the loop (i.e., the diastolic P-V curve) describes ventricular diastolic compliance. Therefore, the P-V loop can provide a simple yet comprehensive description of ventricular pump function.[102] Such loops can be generated from a variety of techniques that provide ventricular volume data in conjunction with LV pressure.[84,103,104] Online, beat-to-beat determinations of LV volumes with automated edge detection can be combined with LV pressure measurements to yield real-time pressure-volume loops, useful in both clinical and research settings[104,105] (Fig. 9-22).

By manipulating LV volume and/or arterial pressure, multiple coordinates of the maximal ratio of pressure to volume or dimension (which occurs near end-ejection) can be obtained; these coordinates exhibit a nearly linear direct relation. The slope of this relation ($E_{max}$) is relatively insensitive to acute changes in loading conditions. The relation shifts upward and to the left during positive inotropic interventions, and it shifts downward to the right when the ventricle is depressed; the slope of the relation generally increases with the former and decreases with the latter (Figs. 9-23 and 9-24).

This end-systolic index of contractility is sensitive to acute changes in contractility, but its reliability is diminished in chronically diseased hearts, especially dilated hearts. In large ventricles, the end-systolic P-V curve can be displaced down and to the right (depressed $E_{max}$), in the absence of a depressed

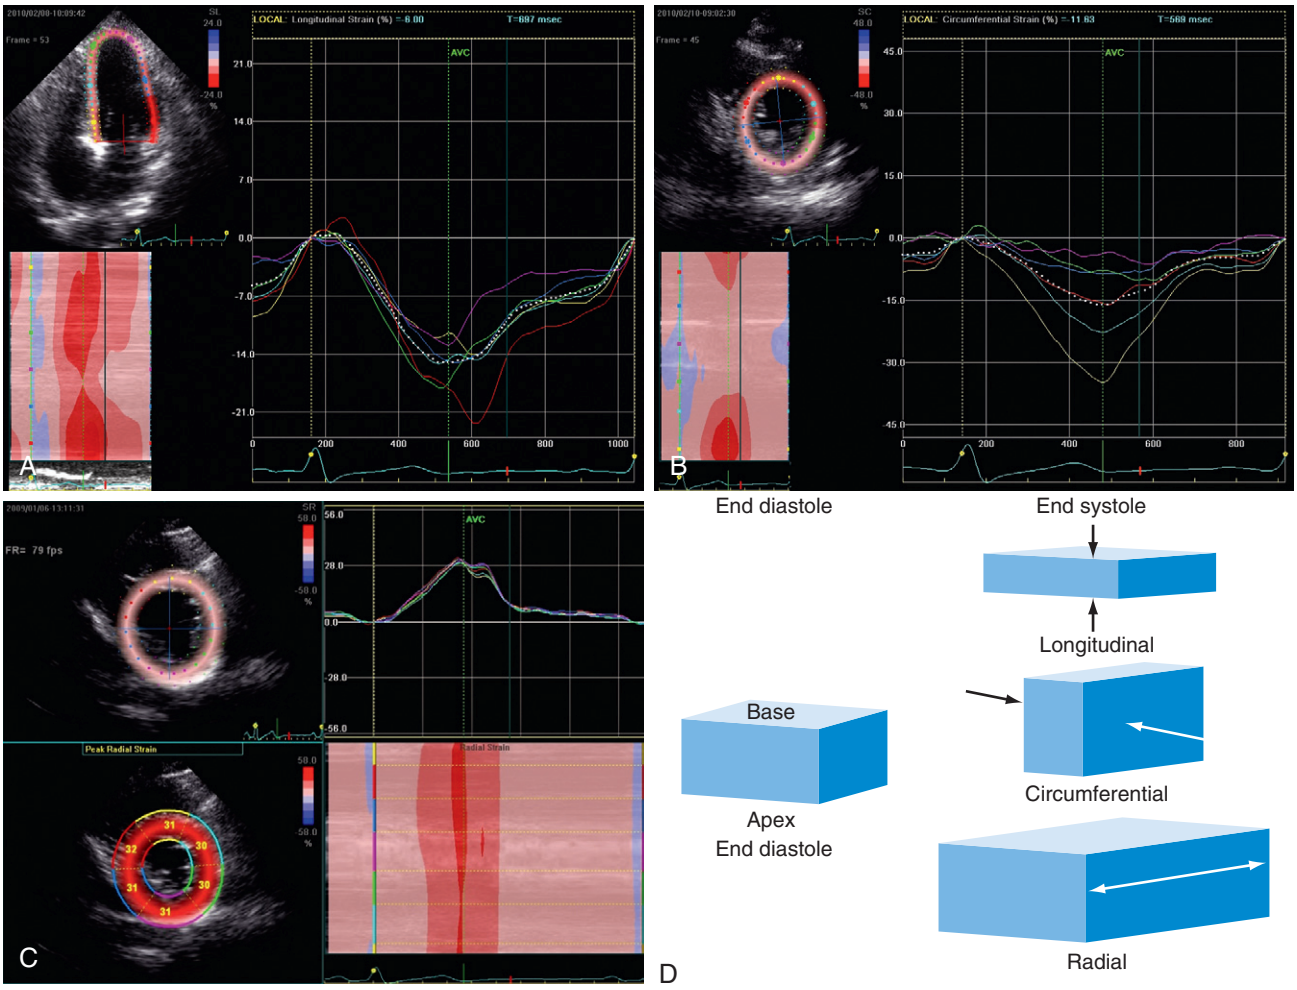

**Figure 9-18** **Principal strains.** Three principal systolic strains from a normal subject. **A,** Typical longitudinal strains related to long-axis shortening. Average systolic longitudinal strain in this example is 15%, though there is regional heterogeneity. Each colored curve represents average longitudinal strain in that segment. Parametric display shows that this strain is negative, indicating compression of myocardium in systole. **B,** Circumferential strain, which, like longitudinal strain, is negative, indicating compression of myocardium in circumferential plane. Average circumferential strain is likewise 15% in this normal individual. **C,** Radial strain, which represents wall thickening and is therefore positive in this parametric display. **D,** Schematic showing the three principal strains. During systole, a cube of myocardium deforms along its long axis (longitudinal shortening), along its circumference (circumferential shortening) and therefore the cube thickens along its endocardial to epicardial axis (radial strain, or thickening).

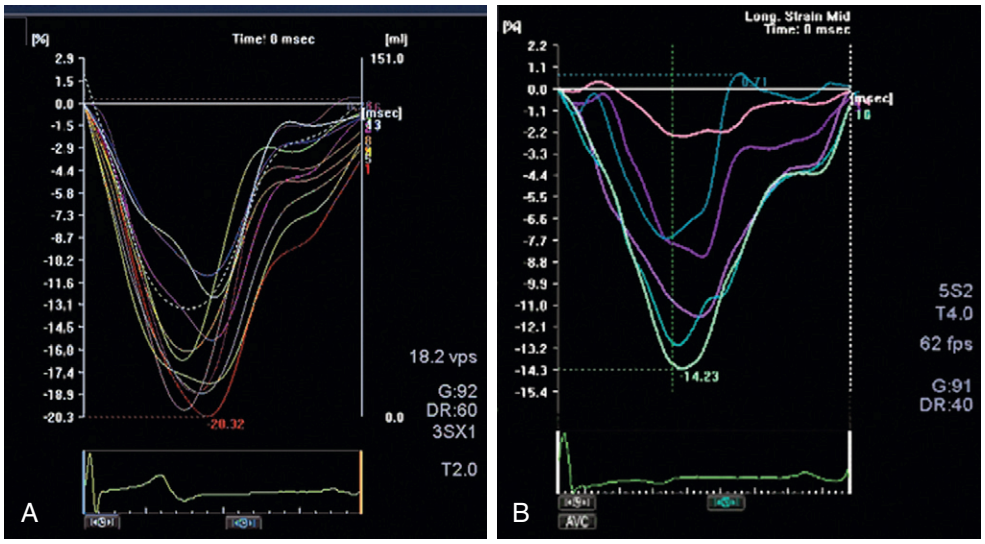

**Figure 9-19** **Strain imaging in hypertensive heart disease. A,** Normal longitudinal strain contrasted with (**B**) strain display from a 43-year-old hypertensive man. LV mass index was elevated as was relative wall thickness; ejection fraction was estimated at 45% by modified Simpson's rule. Strain curves display mild global depression in longitudinal shortening with some regional heterogeneity. Patient underwent subsequent magnetic resonance imaging, which showed scattered areas of delayed hyperenhancement. Catheterization demonstrated no obstructive coronary artery disease and myocardial biopsy was consistent with hypertensive heart disease. *(Adapted from Bogaert J, Rademahers F: Regional non-uniformity of normal adult left ventricle.* Am J Physiol Circ Physiol *280:H610-H620, 2001.)*

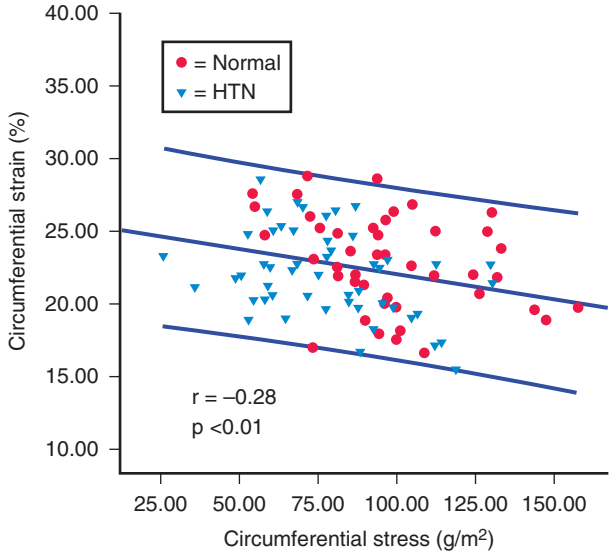

**Figure 9-20** **Load dependency of strain.** Relationship between circumferential strain and circumferential end-systolic stress. As expected, there is a negative correlation, indicating that strain is not load independent. *HTN*, Hypertension. *(From Narayanan A, Aurigemma GP, Chinali M, et al: Cardiac mechanics in mild hypertensive heart disease: a speckle-strain imaging study.* Circ Cardiovasc Imaging *2:382-390, 2009.)*

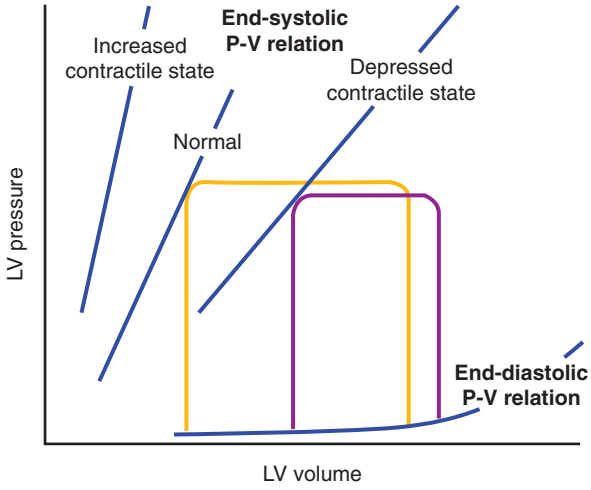

**Figure 9-21** **LV pressure-volume (P-V) loops.** *Yellow* loop indicates normal ventricle. Acute decrease in contractile state shown in *purple*; the loop is displaced to the right, and the end-systolic P-V line shifts downward and to the right. Effect of an acute increase in contractile state is illustrated by the line at *left*; slope of the end-systolic P-V line is increased (corresponding loop is not shown). *(From Aurigemma GP, Gaasch WH, Villegas B, Meyer TE:* Curr Probl Cardiol *20:418, 1995.)*

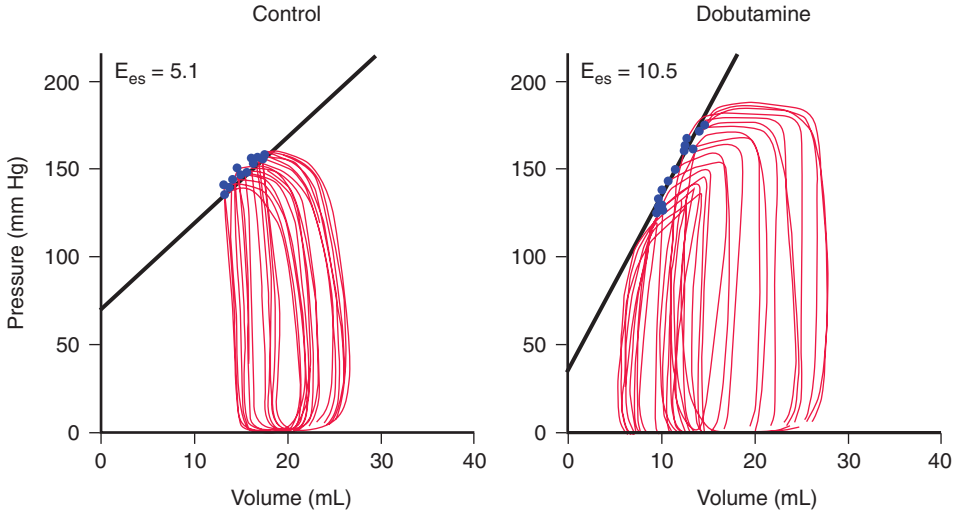

**Figure 9-22** **Pressure-volume loops with inferior vena caval occlusion at baseline and with 3 µg/kg/min of dobutamine infusion in an intact canine model.** Volume assessed online with transesophageal echocardiographic border detection using a Simpson's rule algorithm. End-systolic elastance ($E_{es}$) or the slope of the end-systolic pressure-volume (P-V) relation, increased with positive inotropic modulation, which is consistent with increased contractility. *(Courtesy Dr. John Gorcsan III.)*

contractility. For this reason, $E_{max}$ should be normalized for heart size,[106,107] as illustrated in Figure 9-23. In this example of chronic aortic regurgitation, there is modest LV enlargement, the ESV is less than 60 mL/m$^2$, the EF is normal, and the total SV is high. Such data indicate that the ventricle is compensated, albeit larger than normal. However, the depressed slope of the end-systolic P-V relation inappropriately suggests depressed contractility. These disparate conclusions can be reconciled if the effect of chamber dilation on $E_{max}$ is considered.[107] Thus, if the slope is normalized for chamber size, it approximates that seen in the normal heart.

Recognizing this limitation, end-systolic stress-volume or stress-dimension relations should not be a major criterion for the diagnosis of chronic contractile dysfunction. Certainly, they are not useful as a measure of basal contractility, and they have limited applicability in comparisons among normal and diseased hearts. The raw P-V or stress-dimension data provide important diagnostic information, and, with few exceptions, the simple measurement of the ESV or dimension identifies a depressed ventricle.

An example of the usefulness of echocardiography pressure-dimension loops is shown in Figure 9-24. This example

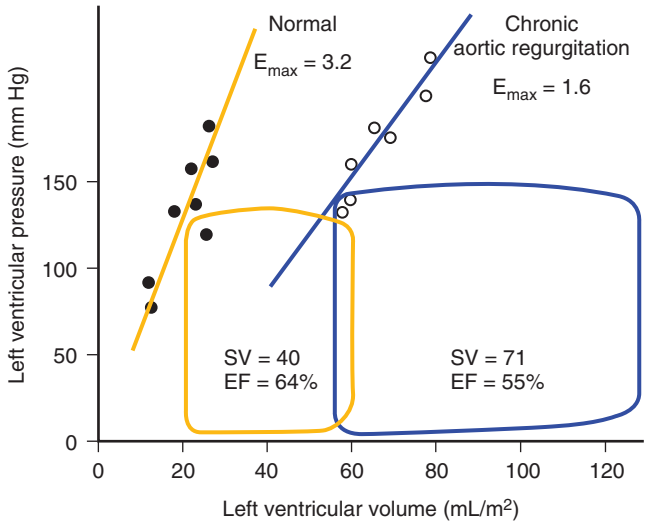

**Figure 9-23 LV pressure-volume loops and end-systolic pressure-volume lines illustrate effects of chronic aortic regurgitation on ventricular size and function.** Moderate ventricular enlargement is present, ejection fraction (*EF*) is normal, and stroke volume (*SV*) is high. Data are consistent with compensated aortic regurgitation. However, slope of the end-systolic pressure-volume relation ($E_{max}$) is reduced. This apparent inconsistency may be resolved by considering the effect of chamber size on $E_{max}$. If slope is normalized for chamber size (end-diastolic volume), result indicates that $E_{max}$ is similar in the two ventricles. *(Adapted from Shen WF, Roubin G, Choong CYP, et al: Evaluation of relationship between myocardial contractile state and left ventricular function in patients with aortic regurgitation.* Circulation *71:31-38, 1985. In Aurigemma GP, Gaasch WH, Villegas B, Meyer TE:* Curr Probl Cardiol *20:420, 1995.)*

illustrates the effect of mitral valve replacement on LV size and function in compensated and decompensated chronic mitral regurgitation. In compensated mitral regurgitation, the chamber is enlarged but the end-systolic dimension is only 42 mm, systolic stress is minimally increased, and the fractional shortening is normal (35%). After valve replacement, the stress-dimension loop returns to near normal. In decompensated mitral regurgitation, the EDV and ESV are markedly increased and fractional shortening is low (26%). After mitral valve replacement, there is persistent LV enlargement and a further decline in shortening. A similar analysis has been used in patients with aortic regurgitation.[108] (See Chapter 20.)

## Potential Limitations

It is worthwhile to briefly reiterate some of the practical limitations of echocardiographic evaluation of LV structure and function. It is axiomatic that quantitation of mass and volumes requires high-quality echocardiographic images, with good endocardial definition. For a variety of reasons, such high-quality images may not be available in many patients encountered in clinical practice. As noted previously, M-mode (and most 2D) quantitative methods require that the ventricle not have major shape distortion. Meticulous attention to beam orientation is also imperative for M-mode quantitation of the LV. Every millimeter of inaccuracy in LV chamber dimension results in an 8-g difference in LV mass[109]; a 1-mm inaccuracy in LV wall thickness measurement results in a 15-g difference in LV mass. Moreover, experience with the technique of 3D echocardiography[109] raises significant questions about whether ultrasound beam orientation is truly orthogonal to the long axis of the LV in routine clinical practice. These findings may help to explain why, for the individual patient, serial M-mode echocardiographic studies may be insensitive to the 20- to 40-g changes in

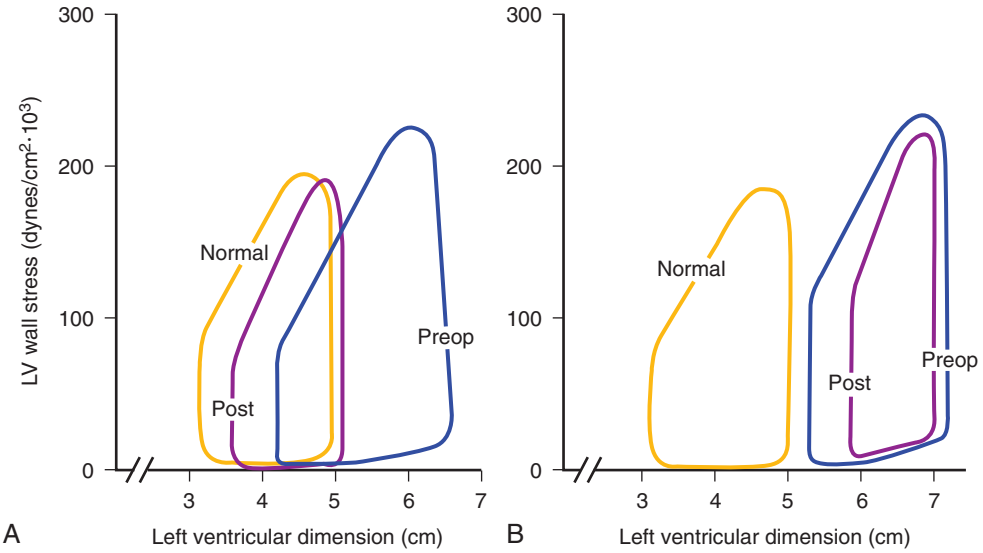

**Figure 9-24 LV response to mitral valve replacement in compensated and decompensated mitral regurgitation.** LV stress-dimension loops in two cases of mitral regurgitation, before (*Preop*) and after (*Post*) mitral valve replacement. **A,** Preoperative loop indicates compensated ventricular function; end-diastolic dimension is 6.5 cm, end-systolic dimension is 4.2 cm, systolic stress is minimally elevated, and fractional shortening is normal (35%). After valve replacement the end-diastolic dimension and end-systolic wall stress return to normal but fractional shortening decreases (29%). **B,** Preoperative loop indicates a decompensated ventricle; end-diastolic and end-systolic dimensions are markedly increased (7.3 cm and 5.4 cm, respectively) and fractional shortening is low (26%). After valve replacement there is persistent LV enlargement and a further decline in fractional shortening. *(From Aurigemma GP, Gaasch WH, Villegas B, Meyer TE:* Curr Probl Cardiol *20:421, 1995.)*

LV mass that are observed, on average, in response to antihypertensive treatment.[110,111]

As noted previously, 2D echocardiographic methods also have limitations, including limited frame rate (which renders precise timing of cardiac events difficult), near-field artifacts, and poor lateral resolution. Apical views often do not yield images of sufficient quality for manual tracing, and foreshortening of the long axis of the LV leads, in part, to volume estimates lower than those obtained by contrast ventriculography. Despite these important limitations, however, quantitative ultrasound techniques find widespread clinical and research applications because of their portability and low cost, and because results are immediately obtainable.

## KEY POINTS

- Assessment of LV mass, volume, and geometry is critical for the management of patients and the assessment of prognosis.
- Current noninvasive methods, M-mode echocardiography, 2D echocardiography, and 3D echocardiography are utilized for assessment of mass, volume, and shape. Each has strengths and limitations.
- Assessment of LV systolic function generally involves computation of the EF, but other aspects of systolic function, such as SV and cardiac output, can be calculated as well.
- A major limitation of EF is its dependence on load; this limitation is particularly important in the assessment of systolic function in valvular heart disease.
- There are compelling advantages to use of midwall shortening as an index of systolic function when the LV has undergone hypertrophic remodeling in response to hypertension.

In daily clinical practice, left ventricular (LV) function is commonly evaluated by two-dimensional (2D) and M-mode echocardiography. Despite all obvious advantages, visual evaluation of LV function by 2D echo suffers from being subjective and provides only semiquantitative data. Furthermore, visual assessment has limited ability to detect subtle changes in function and changes in timing of myocardial motion throughout systole and diastole. M-mode echocardiography provides quantitative data, but does not allow comprehensive evaluation of regional LV function. Tissue-Doppler imaging (TDI) and speckle tracking echocardiography (STE) have been introduced as quantitative and more objective methods to quantify regional and global LV systolic and diastolic function.[1]

This chapter explains the technical principles behind TDI and STE and the physiologic meaning of the different parameters. The clinical application of the methodologies is reviewed. Finally, synchronization of ventricular contraction is addressed.

## Physical Principles of Tissue Doppler Echocardiography

### VELOCITY AND DISPLACEMENT IMAGING

#### *Velocities by Color Doppler*

The Doppler principle has traditionally been used to measure blood flow velocities, but may also be used to measure myocardial and other tissue velocities. Separation between velocities in myocardium and blood is possible because of different signal amplitudes and Doppler frequencies. The myocardium is moving at a much lower speed than blood, and therefore Doppler frequencies are lower. Furthermore, the amplitude of myocardial signals is much higher than for blood. These differences allow myocardial velocities to be separated from blood flow velocities by using filters that reject echoes originating from the blood pool (Fig. 10-1). Velocities can be recorded using color Doppler or pulsed Doppler mode.

Myocardial velocity imaging was first introduced in the early 1990s[2,3] and is now an established clinical method for quantifying LV systolic and diastolic function. Similar to color flow imaging, TDI utilizes an autocorrelator technique to calculate and display multigated points of color-coded velocities along a series of ultrasound scan lines within a 2D sector. As illustrated in Figure 10-2, myocardial motion can be imaged as color-coded velocities superimposed on a 2D gray-scale image in real time. The frame rate for 2D color Doppler is typically from 80 to 200 frames per second, depending on the width of the ultrasound sector, and is usually set higher than for the simultaneous gray-scale images. Myocardial velocities are automatically decoded into numeric values that can be stored digitally for later offline analyses.[4] By convention, velocities toward the transducer are color-coded red and velocities away from the transducer are coded blue. Figure 10-3 shows 2D images from a normal person and from a patient with acute myocardial infarction.

During normal LV systole the base of the ventricle descends toward the apex, and moves back during diastole, while the apex is relatively stationary. Therefore, from apical views, long-axis motion is dominated by red-encoded velocities in systole and blue-encoded velocities during early filling and atrial-induced filling. Dysfunctional myocardium, however, may show grossly abnormal motion with reversed longitudinal velocities during systole. Assessment of myocardial function by the 2D color display, however, is not very useful in practical diagnostics, and velocity analysis should be done as postprocessing. In some cases it may be helpful to use the curved M-mode format, which provides a quick view of direction and timing of

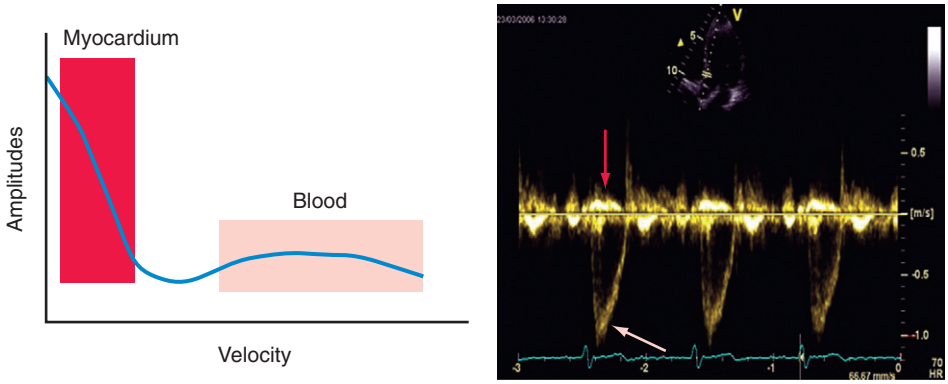

**Figure 10-1 Principle for separation of myocardial velocities from blood flow velocities.** (*Left* panel) The difference in velocity and amplitude between myocardial and blood velocities. (*Right* panel) A recording in the LV outflow tract that samples both myocardial and blood flow velocities. High-intensity signals from the myocardium (*red arrow*); low-intensity but high-velocity signals from the blood (*white arrow*).

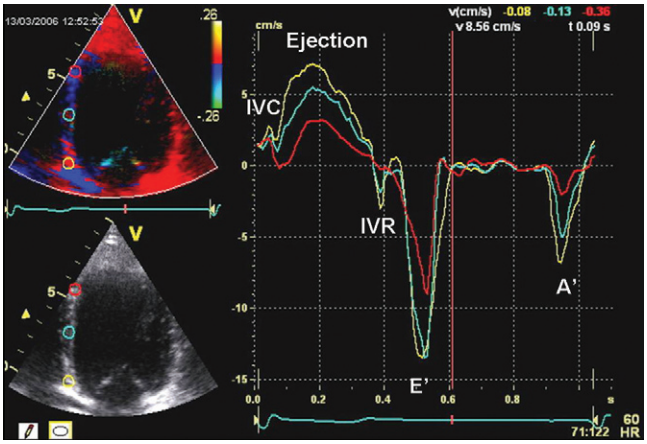

**Figure 10-2 Normal myocardial velocities.** Tissue Doppler velocities from the anterior wall of the LV in a healthy individual. *A'*, Velocity during atrial-induced filling; *E'*, velocity during early diastolic filling; *IVC*, isovolumic contraction; *IVR*, isovolumic relaxation.

velocities in different segments (Fig. 10-4). The standard approach, however, is analysis of velocity traces from multiple regions within a 2D image, as illustrated in Figure 10-2. This analysis allows direct comparison of velocities in different segments on the same image. The most important measures from the velocity traces are peak systolic ejection velocity (S) and peak early-diastolic lengthening velocity (E′). One should be aware that a velocity obtained with the autocorrelation method used in TDI in 2D color mode represents the mean value of an instantaneous velocity spectrum recorded from the same location.[4,5] A schematic presentation of all tissue Doppler modalities (tissue velocities, displacement, strain rate, and strain) from the apical four-chamber view is demonstrated in Figure 10-5.

Assessment of LV function from the parasternal short axis is possible, but only a very limited number of segments can be imaged (Fig. 10-6). Therefore most often apical views are preferred when assessing LV function by TDI.

### *Velocities by Pulsed Doppler*

Another approach is to use spectral tissue Doppler with pulsed Doppler activated, which is applied mainly to measure mitral and tricuspid annular velocities. It is important to be aware that the pulsed Doppler mode presents the peaks of the instantaneous velocity spectrum, whereas the color mode provides mean velocities. This implies that velocities measured by the 2D color method described earlier are lower than velocities by pulsed Doppler—typically about 25% lower.[6,7] The difference, however, depends on the band width of the velocity spectrum, which is determined by sample volume and by acoustical noise. Figure 10-7 illustrates the difference between velocities by color Doppler and pulsed Doppler modes. Disadvantages of the pulsed Doppler method are (1) limited spatial resolution and (2) the fact that velocities are obtained from only one region at a time.

### *Limitations of Velocity Imaging*

#### Angle Dependency

Like all other Doppler modalities, velocity imaging is angle dependent, because only velocity components in the beam direction are recorded. Therefore it is essential that the ultrasound beam be aligned parallel to the LV wall in long-axis imaging and perpendicular to the wall for radial measurements in the short axis. In longitudinal views, velocities should not be measured near the apex because the apical curvature gives large angle problems.

#### Movement of Sample Volume Relative to Myocardium

Tissue Doppler measures velocity within a fixed area in space, but not within a defined piece of myocardium. Because of cardiac motion, the difference between the two may be significant. This limitation, which applies to all TDI modalities, can in part be compensated for by using tracking algorithms that move the sample volume continuously or in steps during the heart cycle.

#### Reverberations

Reverberations are echoes due to multiple reflections within the body, and in transthoracic imaging they are often caused by relatively motionless tissue layers close to the body surface. In gray-scale imaging, they are seen as false echoes or reduced contrast. For color TDI, the reverberations may cause a bias in the mean velocity estimate, and often the bias is toward zero velocity. The amount of bias depends on the intensity of the reverberation signal relative to the tissue velocity signal. Still, the sign of the velocity is seldom affected, so it might be difficult to detect reverberations when using the color display.

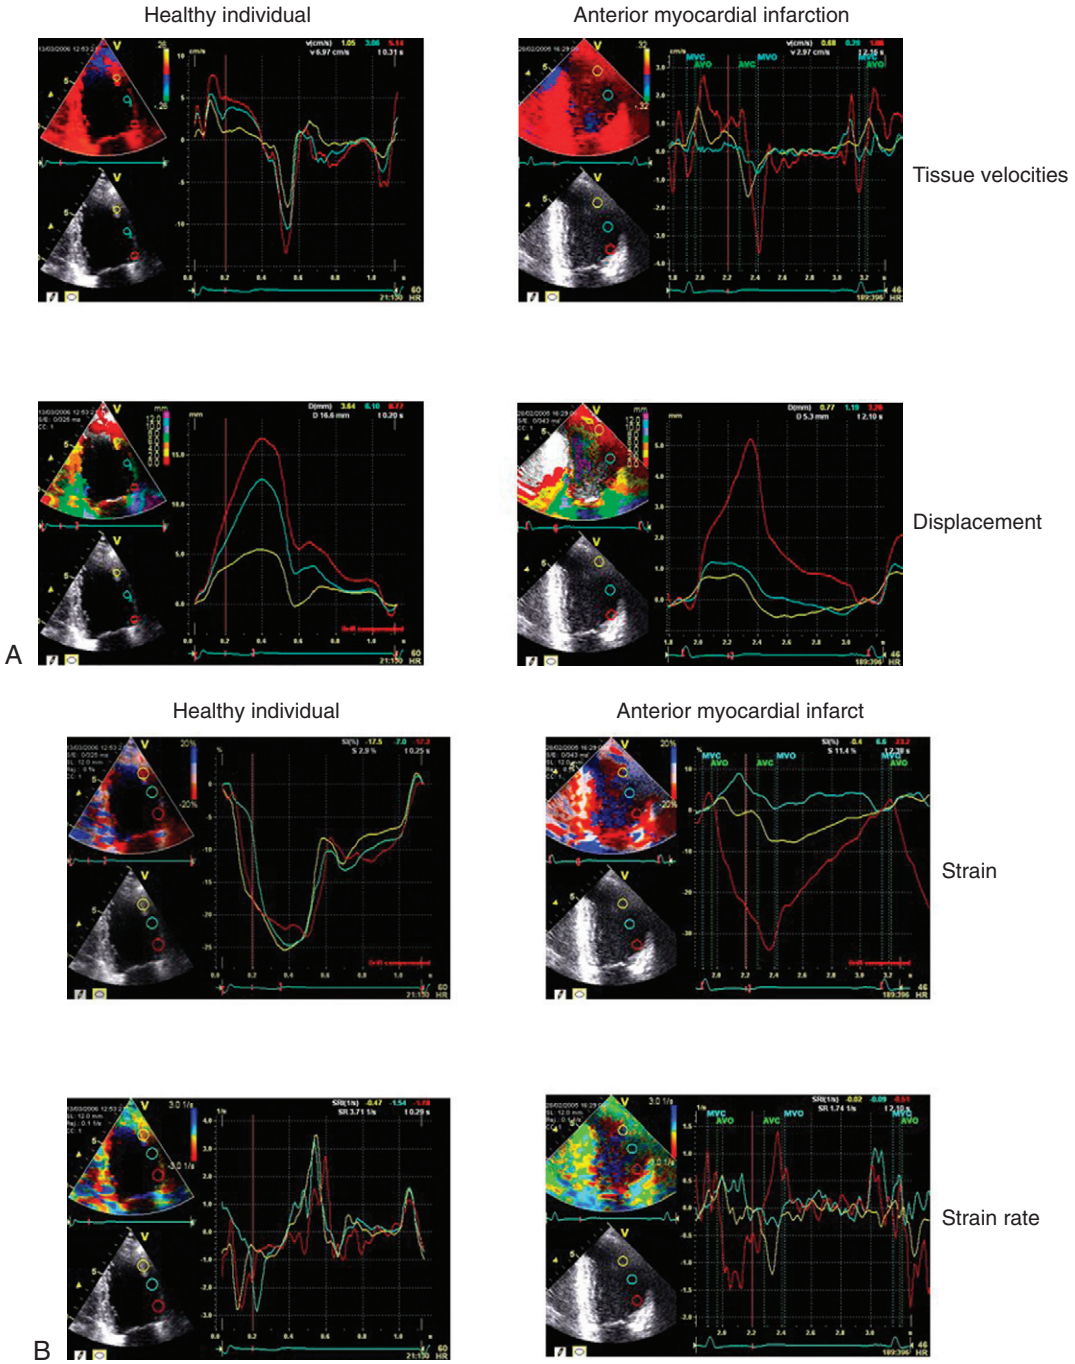

**Figure 10-3** **Acute myocardial infarction.** Recordings from a healthy individual (*left*) and from a patient with anterior myocardial infarction (*right*; be aware of different scales). All tissue Doppler modalities are sampled from three identical levels along the anterior left ventricular wall. In ischemic myocardium, systolic velocities and displacement are typically reduced (**A**), and there are reductions in systolic strain and strain rate (**B**).

## Tethering Effects and Cardiac Translation

Because myocardium in one region of the ventricle is tethered to neighboring myocardium, velocities in one region are affected by motion in adjacent tissue. In addition, regional velocities may be due to motion of the entire heart (translation).[8-10] Therefore myocardial velocities demonstrate marked regional nonuniformity in the normal ventricle.[11,12] These factors are not limitations of the TDI methodology, but reflect a limitation of velocity to serve as a parameter of regional contractility.

## Load Dependency

Similar to global ejection fraction, all regional ejection phase indices are load dependent.[9,11] This problem, however, is less important than for ejection fraction, because the TDI parameters are used primarily to diagnose regional myocardial dysfunction, and regional differences are likely to persist even when there are changes in global ventricular loading. This is not a limitation of the technology, but reflects a fundamental relationship between myocardial fiber shortening and load.

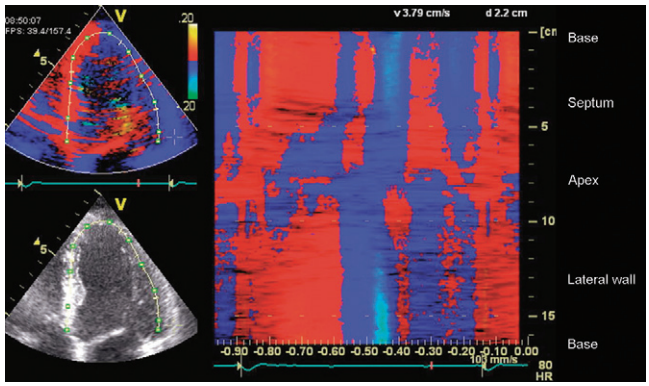

**Figure 10-4 Curved M-mode display of myocardial velocities.** Tissue Doppler imaging velocities in 2D display in systole from a normal heart (*left*) and as curved M-mode (*right*).

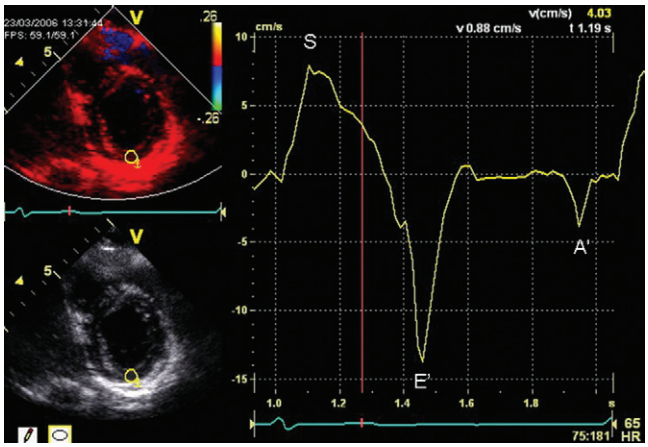

**Figure 10-6** Myocardial velocities from the posterior LV segment in a parasternal short-axis view. *A'*, Velocity during atrial-induced filling; *E'*, velocity during early diastolic filling; *S*, systolic ejection velocity.

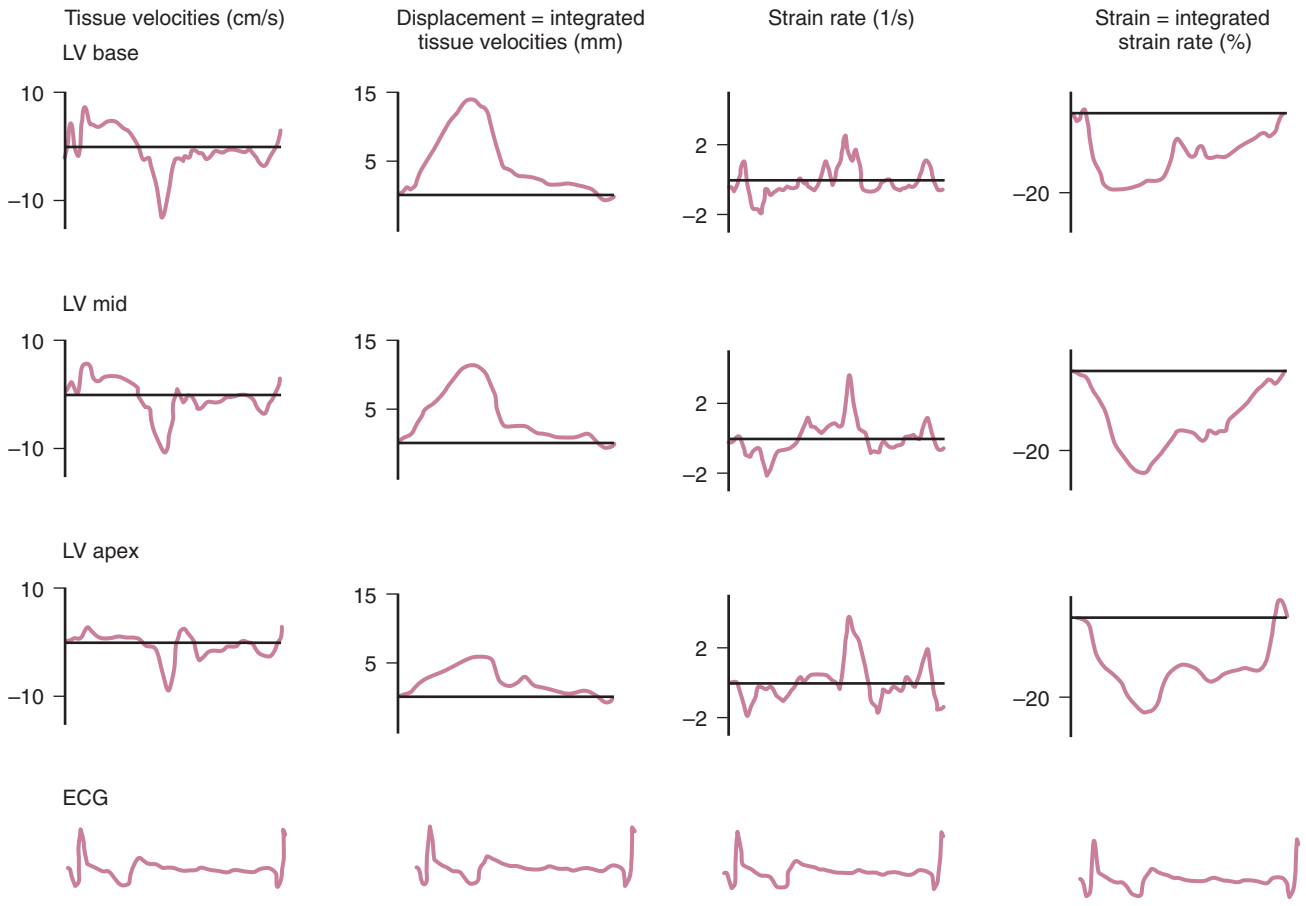

**Figure 10-5 Tissue Doppler recordings from the septum of a normal subject in a long-axis view.** The *first* column shows velocity tracings, with positive velocities (toward the apex) in systole, and negative velocities (away from the apex) in diastole. The *second* column shows displacement curves obtained by temporal integration of the velocities. The *third* column shows strain rate, obtained by a spatial derivation of velocity data. Strain rate is negative in systole (shortening) and positive in diastole (lengthening). The *fourth* column shows strain, obtained by temporal integration of strain rate. The time axis is the same for all modalities. Velocity and displacement decrease from base to apex, whereas strain and strain rate are relatively similar in magnitude at all levels. *(From Smiseth OA, Stoylen A, Ihlen H: Tissue Doppler imaging for the diagnosis of coronary artery disease.* Curr Opin Cardiol *19[5]:421-429, 2004.)*

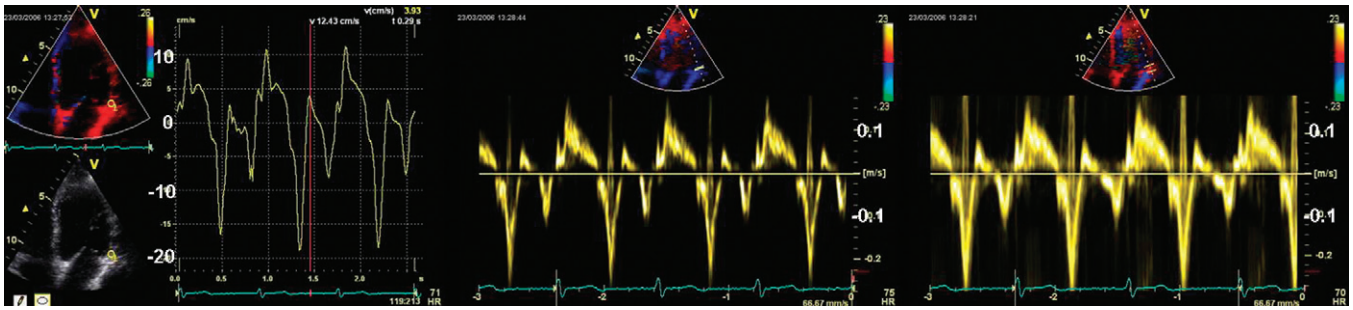

**Figure 10-7 Comparison between myocardial velocities by color Doppler and pulsed Doppler modes.** All images are recorded from identical position in the same LV. Myocardial color Doppler (*left panel*); pulsed Doppler (*middle* and *right panels*). Because the color mode gives mean velocities, amplitudes are smaller than with pulsed Doppler mode. The recording in the *right* panel is performed with a larger sample volume (12 mm) and higher gain than for the *middle* panel (5 mm). Please note the effect of sample volume and gain on signal amplitudes in systolic and diastolic velocities.

### *Displacement Imaging*

By performing temporal integration of velocities from a particular region, one obtains *displacement* curves (see Figs. 10-3 and 10-5). In long-axis views, velocity and displacement increase progressively from apex toward base. Displacement can be displayed in real time as color-coded bands or measured offline from displacement curves. At the present time, this modality has not proven to provide added diagnostic value to velocity imaging.[11] The limitations that are listed for velocity imaging also apply to displacement imaging.

## DEFORMATION IMAGING

*Strain* means deformation and is an excellent parameter for quantification of myocardial function. Analogous to LV ejection fraction, which quantifies global contractility, myocardial strain quantifies regional contractility. In principle, strain may also be used to quantify diastolic function, but this application has not been well developed.

Quantification of myocardial function in terms of strain and strain rate has been available for a long time in cardiac physiology using implanted myocardial markers.[13] The first clinical method that could measure myocardial strain was magnetic resonance imaging with tissue tagging, but complexity and cost have limited this methodology to research protocols.[14] More recently, strain-rate imaging by TDI and that by STE have been introduced as bedside, clinical methods.[9,15-18]

### *Definitions of Strain and Strain Rate*

Strain is a measure of how much an object has been deformed, and several formulas can be used to calculate different types of strain. In cardiac mechanics, we use the simple approach proposed by Mirsky and Parmley[19,20] and calculate strain as percent or fractional change in dimension. This implies that systolic strain is a measure of percentage shortening when measurements are done in the long axis, and percent thickening for radial measurements in the short axis. This strain measure is named Lagrangian strain and is given by Equation A. The Greek letter epsilon (ε) is used as the symbol of Lagrangian strain. In the formula, L is the current length and $L_0$ is the original length.

$$\text{Strain} = \frac{L - L_0}{L} = \frac{\Delta L}{L_0} \qquad \text{(A)}$$

Figure 10-8 illustrates schematically the principles for calculation of Lagrangian strain, and Figure 10-9 shows a typical myocardial strain trace recorded from implanted myocardial markers in an anesthetized dog. By convention, lengthening and

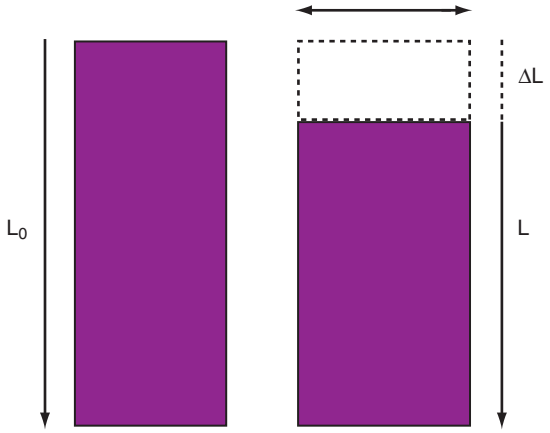

**Figure 10-8 Schematic illustration of myocardial strain.** Lagrangian strain equals $\Delta L/L_0$. *L*, Current length; $L_0$, original length.

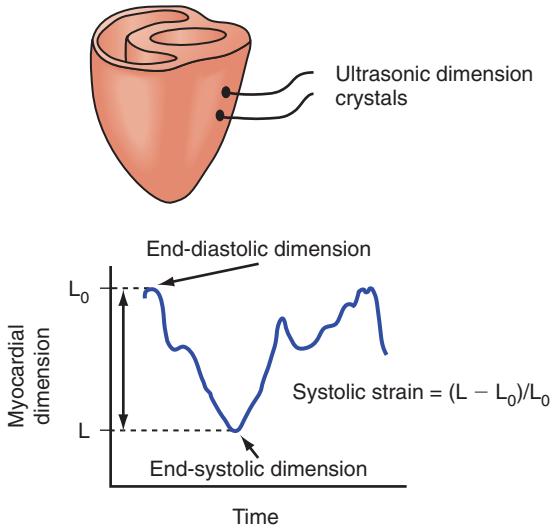

**Figure 10-9 Typical longitudinal myocardial strain trace.** The recording shows strain by sonomicrometry in an anesthetized dog. Strain was recorded between two ultrasonic crystals implanted into the myocardium. The figure illustrates calculation of systolic strain. Please note that peak systolic strain equals systolic shortening fraction. *L*, Current length; $L_0$, original length.

thickening strains are assigned positive values and shortening and thinning strains negative values. This implies that systolic shortening results in negative strains, and systolic thickening in positive strains.

When strain is measured in one dimension, there will only be shortening and lengthening strains or thickening and thinning strains, respectively. During the heart cycle, however, the LV myocardium goes through a complex three-dimensional (3D) deformation that leads to shear strains, when one border is displaced relative to another. In a clinical context, however, we only assess the one-dimensional myocardial strains.

## STRAIN RATE AND STRAIN BY TISSUE DOPPLER IMAGING

### *Basic Principles*

It was proposed by Fleming and associates[21] that myocardial Doppler velocity gradients may be used to assess myocardial contractility. The theoretical basis for measuring strain by TDI is that myocardial velocity gradient is an estimate of strain rate, and therefore strain can be calculated as the temporal integral of strain rate. Using these concepts, Heimdal and co-workers[16] introduced real-time strain-rate imaging based on myocardial Doppler velocities. Strain rate, commonly abbreviated SR, can be estimated by TDI as a velocity gradient between two spatial points ($x$ and $x + \Delta x$) as shown in Equation B.

$$SR \approx \frac{v(x) - v(x + \Delta x)}{\Delta x} \quad (B)$$

Temporal integration of the velocity gradient gives the logarithmic strain estimate denoted *natural strain* ($\varepsilon_N$) shown in Equation C. The name refers to the use of the natural logarithm function, ln. Lagrangian strain ($\varepsilon$) can be derived from natural strain using the mathematical conversion in Equation D. To accurately determine strain, it is necessary to track and follow the motion of the material points (fixed particles) within the myocardium through time. This is not feasible with TDI, and therefore only estimates, not direct measures, of strain can be obtained by this imaging modality.

$$\varepsilon_N = \ln(L / L_0) \quad (C)$$

$$\varepsilon = \exp(\varepsilon_N) - 1 \quad (D)$$

The rationale for using spatial velocity gradient as a marker of myocardial function is that a velocity difference between two adjacent regions implies either compression or lengthening of the tissue in between, and the spatial velocity gradient equals strain rate. When LV systolic function is studied in the LV long axis, strain rate measures regional shortening rate, and strain measures regional shortening fraction. In the LV short axis, strain rate measures systolic thickening rate. During diastole, strain rate measures myocardial lengthening and thinning rates, respectively. Because strain is dimensionless, strain rate has units of 1/s.

In principle, strain rate is not influenced by overall motion of the heart (translation) or by motion caused by contraction in adjacent segments. This is in contrast to *velocity* within a myocardial segment, which is the net result of motion caused by contractions in that segment, motion due to tethering to other segments, and cardiac translation.[9,22] The effect of tethering explains why LV longitudinal velocities measured from an apical window increase progressively from the apex toward the base. Strains and strain rates, however, are essentially similar between apex and base. Therefore strain and strain rate in principle are superior to velocity as markers of regional contractility. However, there are technical issues that make strain-rate imaging more challenging than velocity imaging.

### *Limitations of Strain and Strain-Rate Imaging by Tissue Doppler Imaging*

#### Signal Noise

Strain rate by TDI has significant problems with random noise. This reflects an effect of measuring a difference between velocities, because the error is the sum of the errors of the two velocities. The signal-to-noise ratio for strain rate can be improved by increasing the spatial offset (strain length) for the velocity points, which increases the velocity difference but will reduce the spatial resolution. The problem with random noise can also be reduced by temporal averaging within a heart cycle and by averaging multiple heart cycles. However, these methods for noise reduction represent compromises between optimal signal-to-noise ratio and requirements for high spatial and temporal resolution. The spatial offset for measurement of longitudinal strain and strain rate is typically between 5 and 12 mm but can be defined by the operator. For transmural strain, wall thickness and translational motion restrict the range for adjustment of strain length. As a rule of thumb, the strain length should be set to approximately half the systolic thickness of the wall.[23] Strain-rate imaging has limited lateral resolution, which limits the ability to measure separately from subendocardial and subepicardial wall layers in long-axis views. Furthermore, when the sample volume is at the inner or outer LV wall layers, the signal may in part represent velocities in the blood pool and pericardium, respectively. Fortunately, measurement of strain is associated with fewer noise problems than measurement of strain rate, because integration tends to eliminate random noise. In the strain signal, however, there may be significant drift within a given heart cycle.

#### Angle Dependency

Another problem with strain-rate imaging is strong sensitivity to misalignment between the cardiac axis and the ultrasound beam. Similar to measurement of blood flow velocity, myocardial velocity is reduced in proportion to the cosine of the angle between the velocity vector and the ultrasound beam. Furthermore, because myocardium is virtually uncompressible, shortening in one axis is always accompanied by thickening in the other axis, and this increases measurement problems due to misalignement.[9] Therefore care should be taken to align the ultrasound beam parallel to all myocardial segments of interest. It is of special importance to avoid misinterpretation in myocardial areas close to the LV apex because of the apical curvature. Angle problems can be reduced by using the smallest possible sector and recording from one wall at a time. Some reports indicate that the problem with misalignment might be less than anticipated.[11,24]

#### Reverberations

Reverberations are a major source of error in strain-rate imaging. A small local bias in the velocity will cause large changes in the spatial velocity gradient and therefore in the strain rate. The only way to avoid reverberation noise is to get a better scanning window. When analyzing the strain-rate data, it is important to recognize the reverberation artifacts and to

avoid the regions affected. Curved anatomic M-mode can be an effective tool to identify larger reverberation artifacts and, for the experienced user, can be seen as "unphysiologic" color patterns.

### Movement

Movement of the myocardium relative to the sampling volume and load dependency are limitations as discussed in the section on limitations of velocity imaging.

#### *Preferred Tissue Doppler Imaging Modalities in Clinical Routine*

In spite of theoretical advantages of strain rate and strain relative to velocity,[25] there are unresolved technical limitations of these modalities. Therefore, with the present state of the technologies, velocity imaging is preferred as the primary TDI methodology for assessing regional function. Strain and strain-rate imaging may be used as a supplementary method for exploring changes in regional function. Strain by STE appears more robust and is preferable to TDI-based strain. Displacement imaging needs more validation before it can be recommended for routine clinical use. Normal values for mitral annular velocities by TDI are presented in Table 10-1.[26] Velocities measured in 2D color mode are lower than by pulsed wave Doppler, and this needs to be taken into account when interpreting E′ in a clinical context. In adults, E′ velocity decreases with age; therefore age-based normal values should be utilized when applying these measures of LV diastolic function in clinical practice.

## Physical Principles of Speckle Tracking Echocardiography

### BASIC PRINCIPLES

Speckle tracking echocardiography (STE) measures local myocardial displacement in echocardiographic images and may be used to quantify myocardial function in terms of velocity and strain. Furthermore, STE may be used to assess LV rotation and twist. The speckles are created by interference of ultrasound beams in the myocardium and are seen in gray-scale B-mode images as a characteristic speckle pattern (Fig. 10-10). The speckles are the result of constructive and destructive interference of ultrasound that is back-scattered from structures smaller than the wavelength of ultrasound. Random noise is filtered out by the computer algorithm, yielding small segments of myocardium with temporarily stable and unique speckle patterns.[27] These segments, or "kernels," serve as acoustic markers that can be tracked from frame to frame within an image plane using block matching. Figure 10-11 shows recordings from a normal heart. It is also possible to calculate myocardial velocity vectors that are displayed superimposed on the dynamic gray-scale images (Fig. 10-12).[28] Because of the relatively low frame rate of STE, this imaging modality is not optimal for measuring strain rate.

#### *Strain by Speckle Tracking Echocardiography*

In contrast to tissue Doppler–based strain, which measures velocities from a fixed point in space with reference to an external probe, STE measures instantaneous distance between two kernels. This implies that STE is relatively angle independent and can measure strain in different directions in the same image, including circumferential and radial strains in multiple segments from LV short-axis images and longitudinal strain from myocardial areas close to the LV apex. However,

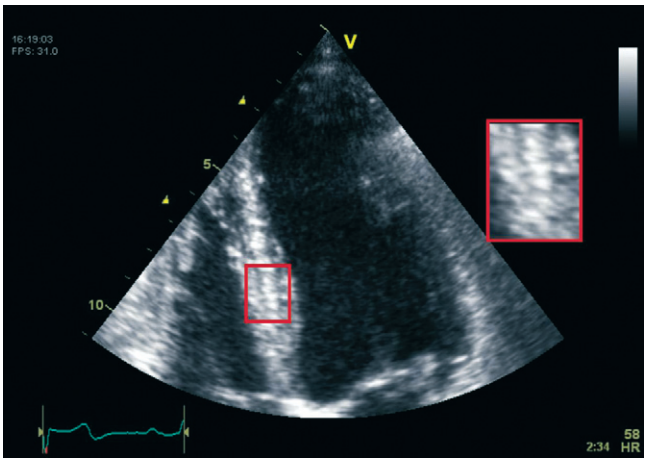

**Figure 10-10 Myocardial speckles.** Speckle tracking echocardiography measures strain by tracking speckles in gray-scale echocardiographic images. A part of the septum (*red box*) from a four-chamber view is enlarged.

Modified from Dalen H, Thorstensen A, Vatten LJ, et al: Reference values and distribution of conventional echocardiographic Doppler measures and longitudinal tissue Doppler velocities in a population free from cardiovascular disease. *Circ Cardiovasc Imaging* 3(5):614-622, 2010.
*cTDI*, Color tissue-Doppler imaging; *pwTDI*, pulsed-wave tissue-Doppler imaging.

STE is not totally angle independent, because ultrasound images have better resolution along the ultrasound beam than perpendicular to the beam direction. Therefore, in principle, speckle tracking works better for measurements of motion and deformation in the direction along the ultrasound beams than for other directions. The ability of STE to measure strain had been documented in studies that have used both sonomicrometry and magnetic resonance imaging as reference methods.[17,29]

When applying STE, it is important to optimize image quality of the gray-scale image. This includes keeping the focus position at intermediate depth and adjusting the sector depth and width to include little but the region of interest. Assessment of 2D strain by STE is a semiautomatic method that requires a brief manual definition of a few points along the endocardial border. Furthermore, the sampling region of interest needs to be adjusted to ensure that most of the wall thickness is incorporated in the analysis and to avoid the pericardium. When automated tracking does not fit with the visual impression of wall motion, regions of interest need to be adjusted manually. End-systole is defined by aortic valve closure in the apical long-axis view, and this view should therefore always be analyzed first.

In most patients, 2D strain can be successfully assessed by STE in multiple LV segments. Strain values are calculated for each segment (segmental strain), for each of the theoretical vascular distribution areas (territorial strain), and as the average value of all segmental strains (global strain).[18] Feasibility is best for longitudinal and circumferential strain and is more challenging for radial strain.[30] One explanation for the lower feasibility for radial assessment of strain is that fewer speckles are present in this direction. Figure 10-13 shows segmental and

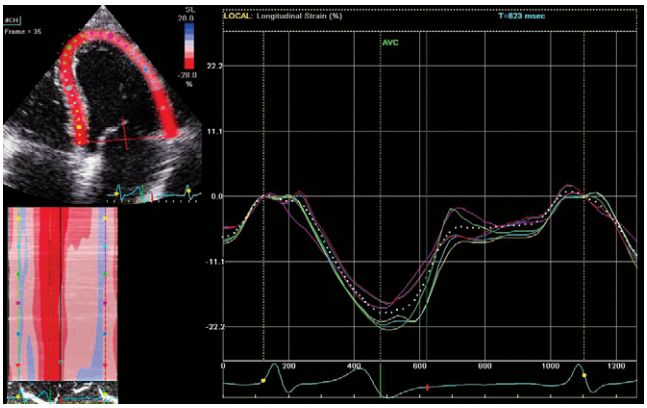

**Figure 10-11 Speckle tracking echocardiography showing long-axis strains.** The figure demonstrates a typical strain pattern from a normal LV. The colors in each strain trace correspond to the colorized LV segments in the 2D display at *upper left*. *AVC*, Aortic valve closure; *T*, time.

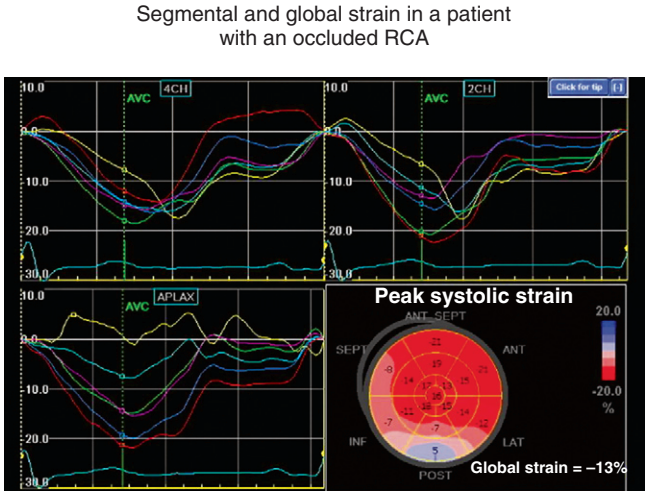

**Figure 10-13 Segmental longitudinal strain curves from all 16 LV segments in a patient with a myocardial infarction caused by an occlusion in the right coronary artery.** The bull's-eye plot at *lower right* demonstrates peak systolic strain value in each segment. *Red* color indicates shortening strains and *blue* indicates lengthening strains (see scale in *lower right panel*). The longitudinal global strain is the average value of peak systolic strain in all 16 LV segments and is –13% in this example.

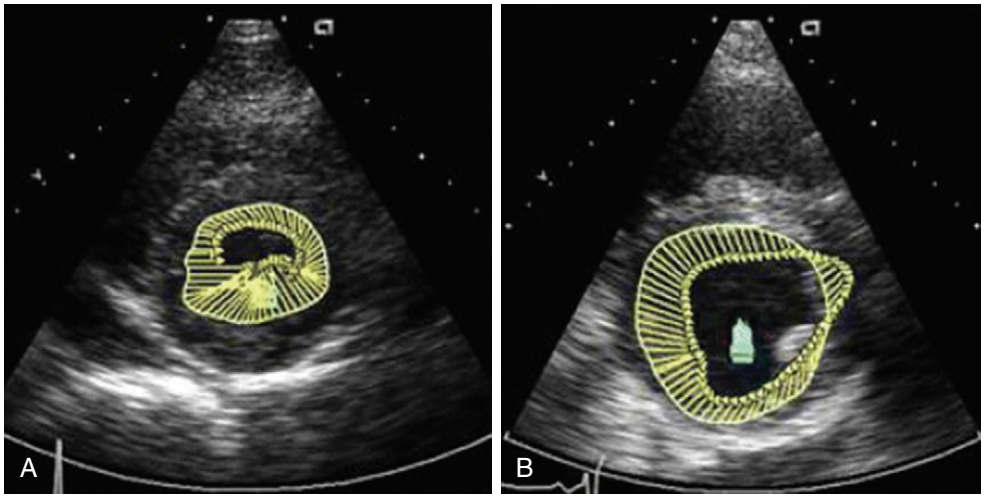

**Figure 10-12 Instantaneous myocardial velocity vectors can be calculated and displayed on dynamic gray-scale images.** This figure shows radial velocity vectors in the apical short-axis view from a normal patient (**A**) and a patient with left bundle branch block (LBBB) (**B**). In the normal patient, in late systole, the radial vectors show a synchronous pattern. In LBBB, in late systole, the septal vectors have peaked, whereas the lateral wall vectors are directed in the opposite direction (dyssynchronous). *(Modified from Vannan MA, Pedrizzetti G, Li P, et al: Effect of cardiac resynchronization therapy on longitudinal and circumferential left ventricular mechanics by velocity vector imaging: description and initial clinical application of a novel method using high-frame rate B-mode echocardiographic images.* Echocardiography *22[10]:826-830, 2005.)*

| Parameter | Peak Systolic Strain (%) | Peak Systolic Strain Rate (1/s) | Early Diastolic (E′) (1/s) |
|---|---|---|---|
| Mean ± SEM | −18.6 ± 0.1 | −1.10 ± 0.01 | 1.55 ± 0.01 |
| Lower 95% limit | 18.5 | −1.09 | 1.54 |
| Upper 95% limit | −18.7 | −1.11 | 1.56 |

Modified from Marwick TH, Leano RL, Brown J, et al: Myocardial strain measurement with 2-dimensional speckle-tracking echocardiography: definition of normal range. *JACC Cardiovasc Imaging* 2(1):80-84, 2009.

global strain in a patient with myocardial infarction. Normal global longitudinal strain values are reported between 18% and 25% in healthy individuals.[18,31] Measurements of longitudinal and circumferential LV deformation appear to be superior to LV ejection fraction as measures of LV function in patients with myocardial infarction.[30,32]

When evaluating LV systolic function, strain can be measured as peak systolic strain (positive or negative), as peak strain at end-systole (at time of aortic valve closure), or as peak strain regardless of timing (in systole or early diastole). There is no consensus regarding which time point should be used to measure peak strain in the assessment of systolic function.[33] Table 10-2 shows normal ranges for longitudinal strain and strain rates.[31]

It is also feasible to measure right ventricular (RV) and atrial strain by STE. However, because of the thin walls of these structures, signal quality may be suboptimal.

More recently, real-time 3D STE has been introduced as a method to measure LV volume, and preliminary results are promising.[34] In contrast to 2D STE, which cannot track motion occurring out of plane, 3D STE can track motion of speckles within the scan volume, irrespective of its direction. One limitation of the 3D STE technique is its dependency on image quality and in particular its ability to define the endocardial border. Furthermore, 3D STE is limited by random noise and relatively low temporal and spatial resolution.

### *Limitations of Strain Imaging by Speckle Tracking Echocardiography*

#### Inadequate Tracking

Like other 2D imaging techniques, STE relies on the assumption that morphologic details can be tracked from one frame to the next—that is, that they can be identified in consecutive frames. Because of the complex motion of the LV, this assumption may not always be valid.

Suboptimal tracking of the endocardial border may be a problem, in particular when image quality is poor. Because of the spatial smoothing, an erroneous segmental tracking might influence neighboring segmental strain values. When strain traces appear unphysiologic, one should evaluate signal quality and suboptimal tracking as potential causes. The global strain might be misjudged if too many segmental strain values are discarded because of suboptimal tracking. This is particularly true in localized myocardial diseases where strain values are unevenly distributed.

#### Spatial and Temporal Resolution

Raw tracking data are often quite noisy, so temporal and spatial averaging is needed to extract useful information. The smoothing is often performed using a spline method, which gives a good fit to the raw data while preventing too-rapid fluctuations. Frame rates of 40 to 80 frames per second are recommended. Too low a frame rate may cause the speckles to move out of plane or beyond the search area in successive frames. Too high a frame rate is not recommended because this is normally achieved by reducing the number of ultrasound beams in each frame, and thereby reducing the image quality. However, higher frame rates than 80/s may be needed to avoid undersampling in tachycardia. The relatively low temporal resolution of STE is a limitation in particular in regard to assessment of peak velocities and strain rates, because accurate measurement of these variables may require higher frame rates.

#### Reverberations

Reverberation with resulting underestimation of the true deformation represents an important and very common source of error. Furthermore, any artifacts that resemble speckles will influence the speckle tracking quality, and care should be taken to avoid these.

#### Off-Axis Image Plane

Because the polarity of radial strain is opposite to that of longitudinal and circumferential strains, it is essential that measurements be taken with optimal orientation of image planes. If the image plane intersects the ventricular wall at an angle intermediate between the long and the short axes, the measurement will underestimate true strain in the main axis. This implies that foreshortening might affect the 2D STE results and should be reduced to a minimum. Similarly, the short-axis views should be circular to assess the deformation in the true circumferential or radial planes.

## LV ROTATION AND TWIST BY SPECKLE TRACKING ECHOCARDIOGRAPHY

Left ventricular twist is the relative rotation of the apex around the LV long axis with respect to the base during the cardiac cycle. When viewed from apex to base, the apex rotates counterclockwise during systole and the base rotates in the opposite direction (Fig. 10-14). This is visualized in the simulation in Cines 1 and 2 (at ExpertConsult.com). The *rotation* and the apex-to-base difference in rotation, referred to as LV *twist* angle, are both expressed in degrees. The term *torsion* is a normalized value and refers to the base-to-apex gradient in rotation angle, expressed in degrees per centimeter (°/cm). It has been demonstrated that STE can measure LV rotation and twist (Fig. 10-15).[35,36] Because echocardiography does not provide accurate measures of the distance between the two image planes, it is difficult to measure torsion. Therefore the echocardiographic measures are limited to rotation and twist.

### *Limitations of LV Rotation and Twist by Speckle Tracking Echocardiography*

When using STE to measure LV twist, image quality of basal LV short-axis recordings represents a limitation. This is in part due to acoustic problems related to the depth of the basal part of the ventricle and to the wide sector angle that is needed to visualize the entire LV base. Furthermore, measurements are complicated by out-of-plane motion when the base descends toward the apex in systole. Because the twist increases toward the apex, it is important to standardize the apical short-axis view. It is often easiest to find the correct circular apical short-axis view by tilting the probe from the apical four-chamber view

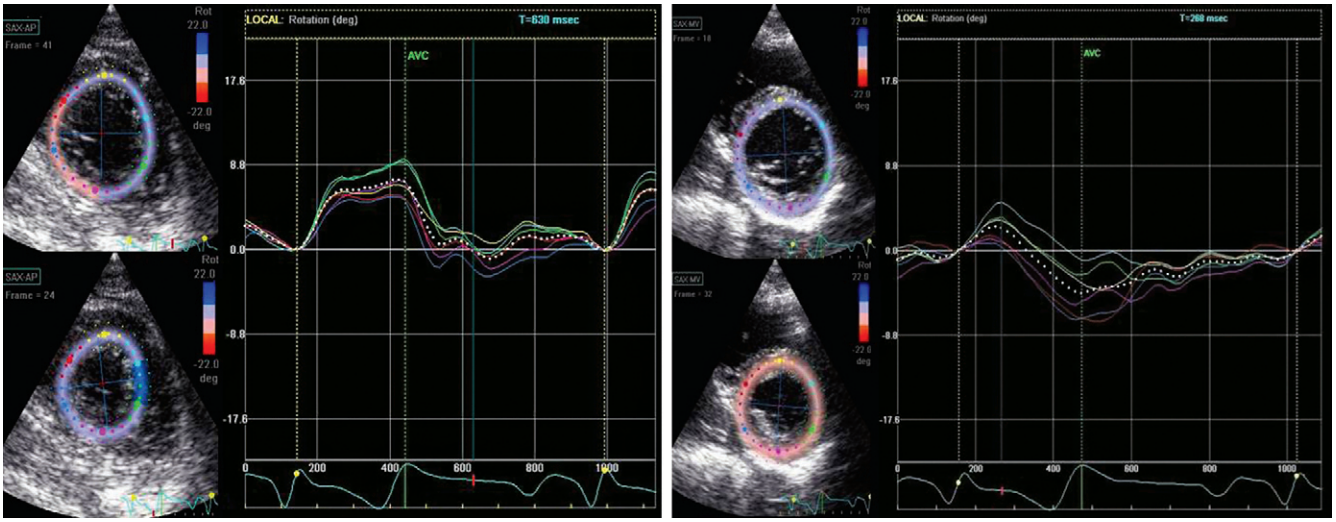

**Figure 10-14 LV rotation by speckle tracking echocardiography.** Apical rotation (*left panel*); basal rotation (*right panel*). The LV short axis in the *upper* windows of both panels represents end-diastole; *lower windows* represent the beginning of diastole and end of rotation. Note that when viewed from the apex, apical rotation is counterclockwise and basal rotation, clockwise, as shown by the *crosses* in the short-axis views. Clockwise rotation is represented by negative numbers in the scales, and counterclockwise rotation is represented by positive numbers.

rather than moving the probe in the apical direction from the parasternal short-axis view. This also increases the chance of capturing a circular apical short-axis view where the endocardium nearly closes at end-systole.[35]

The lack of standardization of imaging planes and different speckle tracking algorithms among vendors make it difficult at the present time to implement LV twist as a clinical measure. More documentation is needed before clinical recommendations can be given regarding assessment of LV twist as a diagnostic modality.

## Normal Physiology of the Left Ventricle

In order to interpret echocardiographic recordings by myocardial velocity and deformation imaging, it is important to understand the physiology of LV function. During normal systole, longitudinal myocardial shortening causes the LV base to descend toward the apex,[31,32,37] and there is circumferential shortening. Systolic thickening is a result of both longitudinal and circumferential shortening. The systolic descent of the base is approximately 12 to 15 mm in healthy people,[37] whereas the apex is relatively stationary, moving only a few millimeters. During diastole, there is myocardial lengthening during early diastole and during atrial-induced filling.

In addition, there is a twisting motion (torsion) of the left ventricle about its long axis, reflecting the fact that apex and base rotate in opposite directions (see Fig. 10-15). Left ventricular twist and untwist appear to play an important role for normal LV function.[38-42] Left ventricular untwist is associated with release of restoring forces, which contributes to diastolic suction and thereby facilitates early diastolic filling.[42] The twisting during systole and untwisting during early diastole have been referred to as a wringing motion of the left ventricle. The structural basis for LV twist is the spiral architecture of myocardial fiber orientation (Fig. 10-16). The subendocardial fibers are arranged in a right-handed helix and the subepicardial fibers in a left-handed helix.[36,43,44]

The magnitude and characteristics of LV twist have been described in various clinical and experimental studies, and it is well established that LV rotation is sensitive to changes in both regional and global LV function.[45-57] Therefore assessment of LV rotation represents an interesting approach for quantifying LV function. However, until recently magnetic resonance tagging has been the only clinical method available.[47,53-56,58-61] It has recently been shown that LV rotation and twist can be measured with STE.[35,36]

In LV short-axis images, TDI shows that the subendocardium moves faster than the subepicardium, which results in a transmural velocity gradient. Figure 10-17 illustrates that this velocity gradient reflects a progressive increase in strain (thickening fraction) when moving the sample volume from the epicardium toward the endocardium. More thickening in subendocardium than subepicardium does not represent a difference in contractility between wall layers, but is just a consequence of geometry and tissue incompressibility. As illustrated in Figure 10-18, the transmural gradient in thickening is consistent with the behavior of wall layers in simple spherical and ellipsoidal models.[62,63] Therefore a similar transmural strain gradient would occur with a noncontracting structure when compressed from the outside. In the LV long axis, there are also higher velocities and strains in the inner than in the outer wall layers, but the differences are smaller than for radial measurements and are difficult to measure by current technology.[64]

During the cardiac cycle, the LV velocity trace has three major velocity spikes (see Fig. 10-2).[4] In the long axis, the dominant systolic velocity component is directed toward the LV apex and represents the ejection phase. There are two major velocity components during diastole: an early diastolic velocity and an atrial-induced velocity, both directed toward the LV base. In addition, there are well-defined velocity spikes during isovolumic contraction and isovolumic relaxation.[65] All these velocity spikes are distinct features of the velocity trace and can be seen in virtually any imaging projection, but magnitude and direction of the velocities depends on projection.

### ISOVOLUMIC CONTRACTION

As illustrated in Figure 10-3, there is a sharp but brief velocity spike during isovolumic contraction. This velocity spike is caused by shortening that starts before mitral valve closure

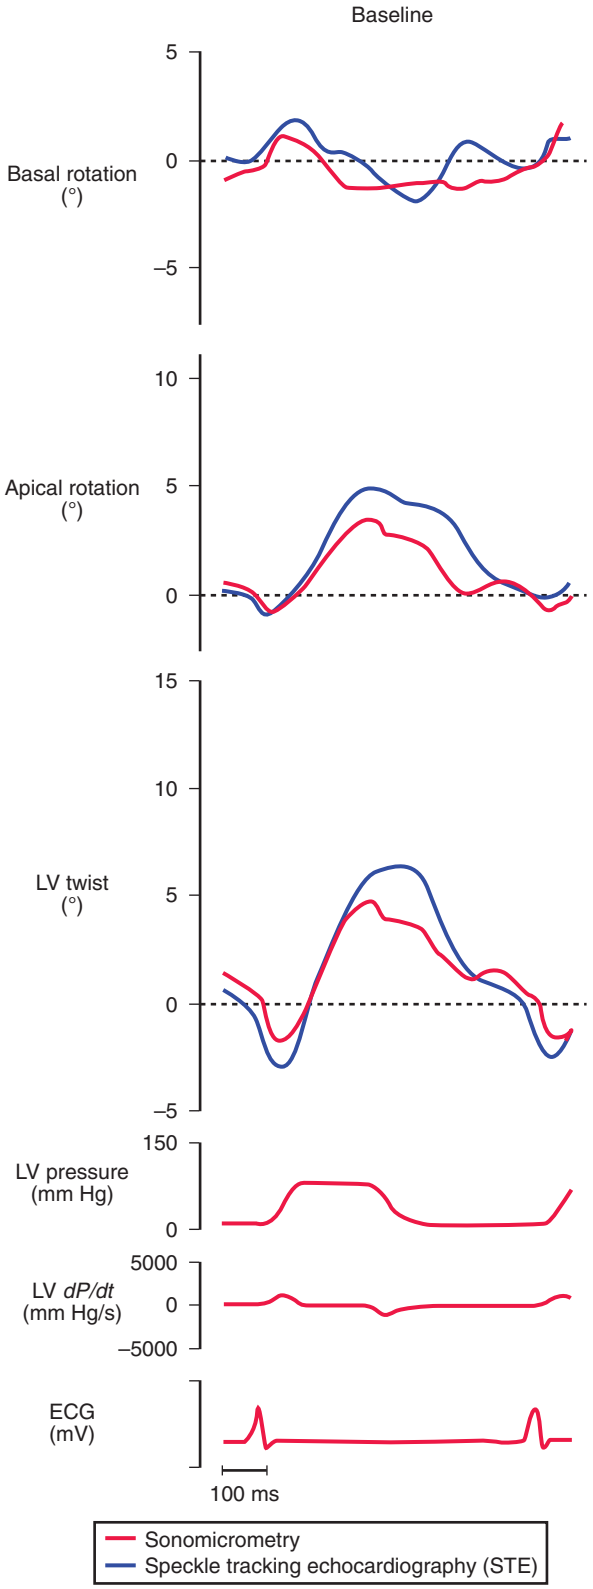

**Figure 10-15** Representative traces from an experimental study showing LV rotation and twist by sonomicrometry (*red lines*) and STE (*blue lines*). Twist is calculated as the difference between apical and basal rotation. Counterclockwise rotation is represented by positive numbers. *ECG*, Electrocardiogram. *(Modified from Opdahl A, Helle-Valle T, Remme EW, et al: Apical rotation by speckle tracking echocardiography: a simplified bedside index of left ventricular twist.* J Am Soc Echocardiogr *21[10]:1121-1128, 2008.)*

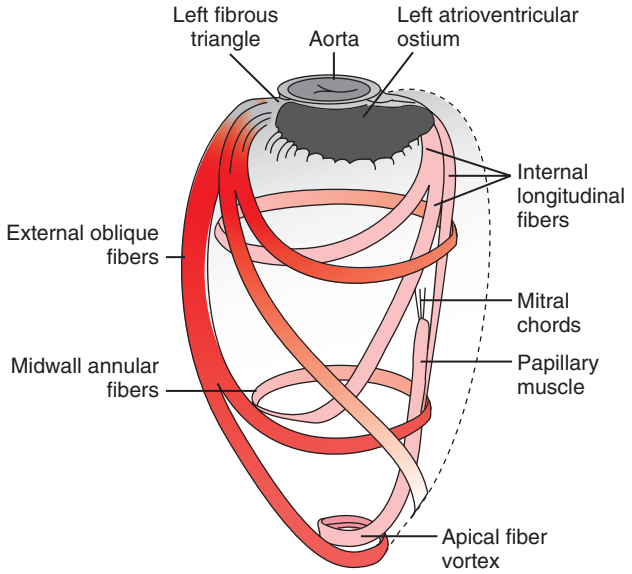

**Figure 10-16 Schematic drawing of fiber orientation in the left ventricle.** The subendocardial fibers have an approximately longitudinal orientation and the midwall fibers approximately circumferential orientation. The subepicardial fibers are oriented about 60° relative to the circumferential direction. *(From http://biomed.brown.edu/Courses/BI108/2006-108websites/group05ventrestoration/Website/cardiac_geometry.htm.)*

and is temporarily arrested when the mitral valve reaches its final closing position.[66] Myocardial shortening during isovolumic contraction can occur because blood is displaced toward the LV base and into the bulging mitral leaflets, which causes reduction in LV long and short axis, but no real change in LV volume. In some cases there is a small negative velocity component at the end of isovolumic contraction (see Fig. 10-2), which may reflect slight normal asynchrony in electromechanical activation.

The high frame rate of TDI enables measurement of myocardial acceleration, and studies of mitral and tricuspid ring motion suggest that isovolumic contraction acceleration can serve as an index of contractility.[67,68] This is an interesting concept and may be valid for studies of global LV function. However, regional myocardial acceleration does not reflect regional contractility during ischemia.[69] More studies are needed before isovolumic contraction acceleration can be recommended as a clinical tool to measure contractility.

## EJECTION

Peak systolic ejection velocity (S) has proven to be a marker of regional systolic function.[5,10,70-72] Myocardial velocity reaches a peak during the early phase of ejection and then decreases gradually. In some cases a second, smaller peak occurs later during ejection. Longitudinal velocities are more reproducible than radial velocities and can be measured in virtually all vascular territories of the LV. Therefore longitudinal velocities are recommended in the assessment of LV function. Table 10-1 presents normal ejection velocities from the LV long axis as assessed by TDI.

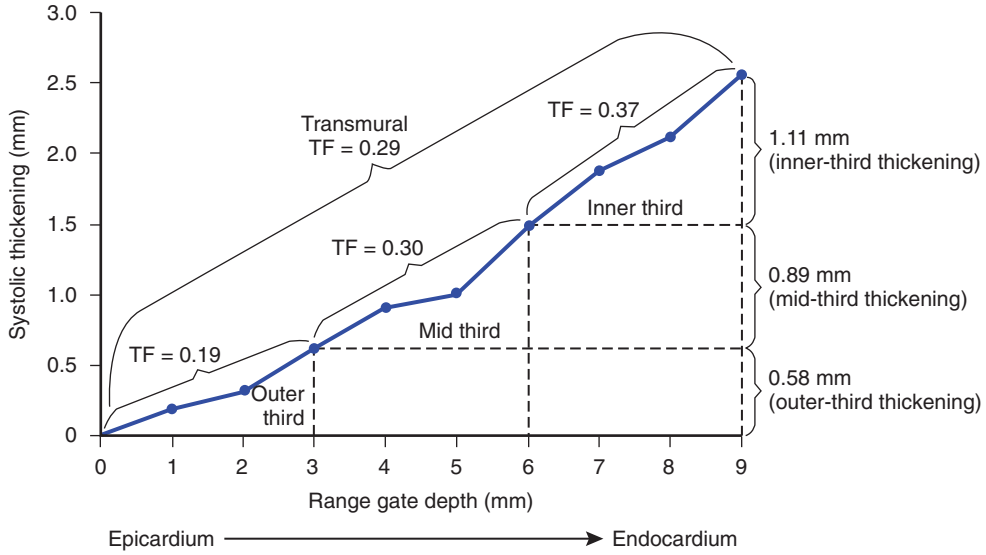

**Figure 10-17 Demonstration of transmural gradient in myocardial strain (thickening fraction) between inner and outer LV wall layers in a canine study.** The LV wall was divided into three layers, each 3 mm thick. Systolic thickening was measured by a 10-MHz miniaturized Doppler probe that was sutured to the epicardium. The figure displays systolic thickening fraction layer by layer and demonstrates that the inner layer thickens more than the outer layer. *TF,* Thickening fraction. *(Reproduced from Zhu WX, Myers ML, Hartley CJ, et al: Validation of a single crystal for measurement of transmural and epicardial thickening.* Am J Physiol *251[5 Pt 2]:H1045-H1055, 1986.)*

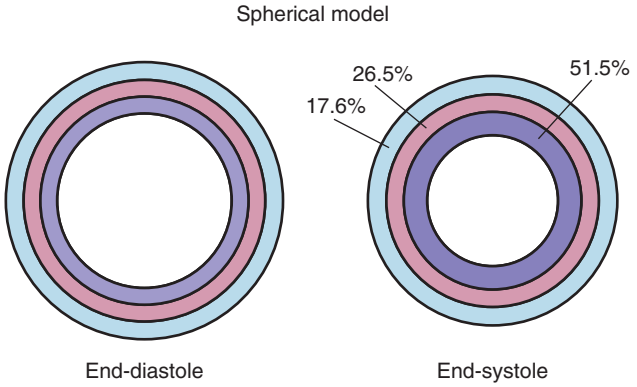

**Figure 10-18 Explanation of transmural strain gradient in LV short-axis strain.** A spherical model in which the wall is divided into equally spaced layers. The model assumes homogeneity of regional function and conservation of mass. In this model, there are no contractile elements, and therefore the difference in thickening between layers is only a geometric effect. The starting position (*left*) simulates end-diastole. At *right*, systole is simulated by reducing inner radius by 25%. Note the marked differences in the thickening of the inner (51.5%), middle (26.5%), and outer layers (17.6%). The same principle applies to cylindrical models, but the magnitude of the gradient is smaller. *(Reproduced from Hexeberg E, Homans DC, Bache RJ: Interpretation of systolic wall thickening. Can thickening of a discrete layer reflect fibre performance?* Cardiovasc Res *29[1]:16-21, 1995.)*

## ISOVOLUMIC RELAXATION

In the LV long axis, there is a negative velocity spike during isovolumic relaxation, which starts near end-systole and is temporarily interrupted by aortic valve closure[66] reflecting myocardial lengthening (see Fig. 10-2). This is analogous to the mechanism for the isovolumic contraction velocity and is attributed to a slight increase in LV volume associated with aortic valve closure and bulging of the valve leaflets into the LV. The volume increase at the end of systole is smaller than the volume decrease at the beginning of systole, consistent with the smaller cusps of the aortic valve compared with the mitral valve leaflets. At the end of isovolumic relaxation, there is normally a small positive velocity component that represents slight postsystolic shortening.[73] The etiology of this velocity component is not known, but it may reflect normal intraventricular asynchrony of relaxation.[74] In the diseased ventricle, and in particular during myocardial ischemia, there may be marked postsystolic shortening, and the postsystolic velocity may extend into the diastolic filling phase. Postsystolic velocities and strains in healthy subjects, however, are of low amplitude and occur before mitral valve opening.[73]

## DIASTOLE

Assessment of mitral annulus velocities by TDI plays an important role in the evaluation of patients with suspected diastolic dysfunction. Measurements are done from apical views, and velocities may be measured at septal, lateral, anterior, and inferior mitral annular areas. However, most often mitral annulus velocities are measured from an apical four-chamber view, and the septal, the lateral, or an average value of septal and lateral mitral annulus velocities is used. There are two main velocity waves, which reflect early-diastolic (E′) and atrial-induced (A′) myocardial lengthening (see Fig. 10-2). The E′ wave is often followed by an oppositely directed wave of low amplitude (E″) during early diastasis, which reflects changes in geometry associated with redistribution of blood within the LV cavity. In patients with markedly elevated LV filling pressure and delayed apical filling, E″ may be reduced or eradicated. Similar to systolic velocities, diastolic velocities decrease progressively from base toward apex.

Normal values for mitral annular velocities by TDI are presented in Table 10-1. Velocities measured in 2D color mode are lower than those measured by pulsed wave Doppler, and this needs to be taken into account when interpreting E′ in a clinical

context. In adults, E′ velocity decreases with age; therefore age-based normal values should be used when applying these measures of LV diastolic function in clinical practice.[75]

The magnitude of E′ is closely related to myocardial relaxation as indicated by its correlation with the time constant of LV isovolumic relaxation.[76-79] In addition to relaxation, which reflects the decay rate of active fiber force, E′ is determined by LV restoring forces, which represent release of energy that is stored in the myocardium when the ventricle has contracted below its resting length.[80] During early diastole, the restoring forces recoil the fibers back to their resting length, analogous to the recoil of a spring that has been compressed below its unstressed length. Restoring forces increase progressively when end-systolic volume is reduced and are therefore dependent on LV contractility. This illustrates the tight coupling between systolic shortening and diastolic lengthening and implies that E′ is determined by systolic as well as diastolic function. In the failing heart, however, when LV end-systolic volume is increased, restoring forces are essentially abolished, and systolic function has less influence on E′.

In addition to LV relaxation and restoring forces, E′ is also determined by early-diastolic load, which is LV pressure at onset of filling.[80] Strictly speaking, it is not LV intracavitary pressure, but LV transmural pressure (LV pressure minus pericardial pressure) that represents the distending force during filling.[81] Therefore the early-diastolic transmural LV pressure represents the load that causes LV lengthening and is named *LV lengthening load*.[80] In general, LV lengthening load will track changes in LV preload because changes in early-diastolic pressure are accompanied by changes in end-diastolic pressure. Thus the three main determinants of E′ are rate of relaxation, restoring forces, and lengthening load. In addition, LV diastolic stiffness may modulate E′.

In the failing ventricle, E′ is much less load dependent than are transmitral flow velocities.[79,82-84] Thus, when LV filling pressure becomes elevated in a failing ventricle, E increases more than E′, and the E/E′ ratio becomes elevated. This relative load independency of E′ forms the basis for using the E/E′ ratio as a marker of elevated LV filling pressure.[77,78,83,85]

It is also possible to measure diastolic strain rates and strains by TDI or STE. As shown in Figure 10-19, there are diastolic strain rates that correspond to the E′ and A′ velocity spikes, and strains that reflects early-diastolic and atrial-induced lengthening. In contrast to velocities, strain rates and strains are relatively similar at all measurement levels between base and apex. Strain rate and strain by TDI, however, have not proven to give added diagnostic value in routine assessment of diastolic function.

Therefore, at the present time, TDI-derived mitral annulus velocities by pulsed wave Doppler are recommended for the routine clinical evaluation of LV diastolic function.[79,86] Measurement of diastolic function by strain and strain rate needs more validation before recommendations can be made with regard to routine clinical use. Given the current state of the technologies, strain imaging by STE appear more robust than strain imaging by tissue Doppler.

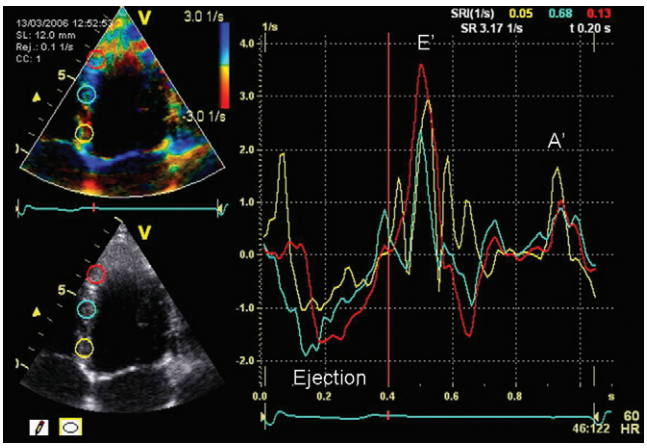

**Figure 10-19 Strain rates from the septum in a healthy individual.** The dominant negative trace during systole corresponds to ejection. The two dominant positive spikes are during early diastolic filling (*E′*) and during atrial-induced filling (*A′*).

## Myocardial Ischemia

Myocardial ischemia may be caused by either a reduction in coronary blood flow, as in acute coronary syndrome, or by an increase in myocardial oxygen demand during stress in patients with coronary artery stenosis. In either case, ischemia leads to reduction in regional myocardial function, which ranges from reduced systolic shortening (hypokinesia) to systolic lengthening (dyskinesia). Furthermore, myocardial ischemia leads to postsystolic shortening, that is, segmental shortening after end of LV ejection. Reduced systolic shortening and postsystolic shortening, which are the two hallmarks of ischemic dysfunction, can be quantified both by velocity and by deformation imaging.[9,16,72,87-91] Typical velocity and strain traces in acute myocardial ischemia are shown in Figure 10-3.

The main advantage of strain relative to velocity imaging is that measurements are less influenced by translational motion and tethering, and this makes strain more specific with regard to segmental localization of ischemia.[9,92] Therefore, in patients with acute infarctions, strain better defines the transitional zone between intact and dysfunctional myocardium and is superior to velocity imaging for defining anatomical extension of dysfunctional myocardium.[11]

In principle, strain is better than ejection velocity to quantify myocardial function, and in particular to differentiate between degrees of ischemic dysfunction. Whereas ejection velocity differentiates well between normal and ischemic myocardium, it has limited ability to differentiate between hypokinetic and dyskinetic myocardium. As demonstrated in Figure 10-20, systolic ejection velocity approaches zero in hypokinetic segments and becomes slightly negative in dyskinetic segments, but the difference between hypokinesis and dyskinesis is only minor. The strain trace in dyskinetic myocardium, however, is strikingly different from that in hypokinetic myocardium.

By extending velocity analysis to the isovolumic phases, however, velocity imaging may also identify dyskinetic myocardium. In ventricles with preserved systolic function, there is a dominantly positive longitudinal velocity during isovolumic contraction, with only a minor negative velocity component. With severe ischemia, the positive velocity component diminishes, and the negative component increases.[65,93] In dyskinetic myocardium, the positive velocity component is replaced by a large negative isovolumic contraction velocity (see Fig. 10-20). Furthermore, dyskinesia is associated with enhanced postsystolic velocity due to postsystolic shortening. Therefore a typical velocity trace from dyskinetic myocardium has a large negative velocity spike during isovolumic contraction and a large positive velocity during isovolumic relaxation, with velocities near

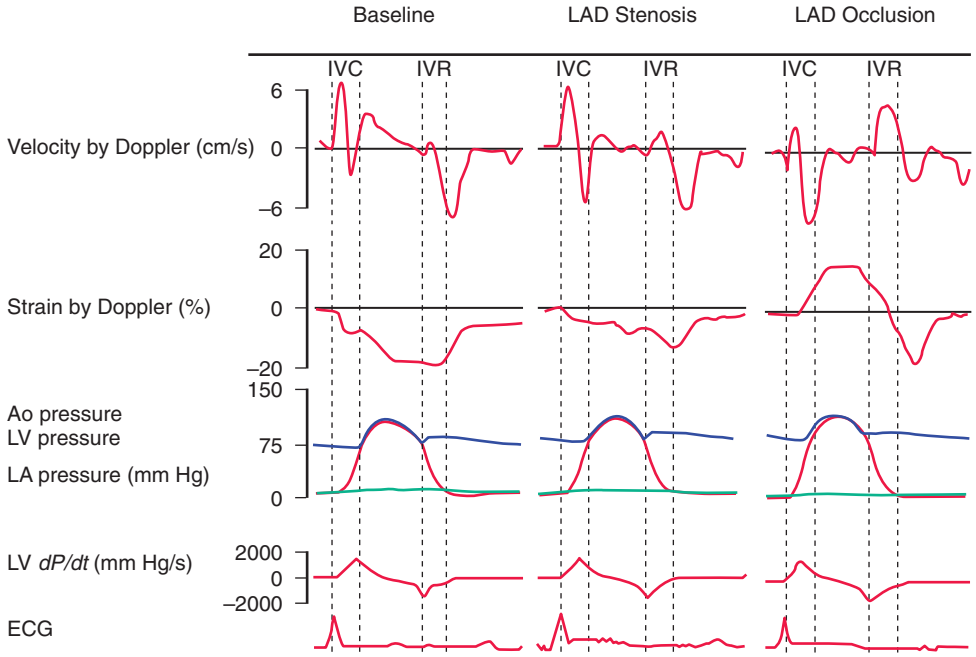

**Figure 10-20** Representative traces at baseline, during left anterior descending (*LAD*) stenosis and occlusion in an anesthetized dog showing myocardial Doppler velocities, strain, and pressure traces. Note that the ejection velocities are relatively similar during LAD stenosis and LAD occlusion, whereas the isovolumic contraction (*IVC*) and isovolumic relaxation (*IVR*) velocities are markedly different. During LAD occlusion, the large negative velocity spike during isovolumic contraction corresponds to systolic lengthening, as demonstrated in the strain trace. Furthermore, the marked postsystolic velocity during isovolumic relaxation corresponds to late systolic and postsystolic shortening in the strain trace. *(Modified from Skulstad, Urheim S, Edvardsen T, et al: Grading of myocardial dysfunction by tissue Doppler echocardiography: a comparison between velocity, displacement, and strain imaging in acute ischemia.* J Am Coll Cardiol *47:1672-1682, 2006.)*

zero during ejection. One should be aware that myocardial lengthening may not occur in nontransmural infarcts, because of shortening of intact subepicardial fibers.

Postsystolic shortening by TDI (Fig. 10-21) can be used as a marker of acute as well as stress-induced myocardial ischemia.[4,65,89,94] The mechanism of postsystolic shortening can be delayed active contraction, passive recoil of dyskinetic myocardium, or a combination of active contraction and passive recoil.[95] When postsystolic shortening occurs in entirely passive or necrotic myocardium, it is analogous to the behavior of a stretched elastic spring that recoils passively when the stretching force is removed. In moderately ischemic myocardium, postsystolic shortening is due to delayed active contraction.[95] Postsystolic shortening is not a specific sign for tissue viability because it occurs in actively contracting as well as in necrotic myocardium. Experimental work suggests that postsystolic shortening that far exceeds systolic lengthening may be a marker of tissue viability,[96] but the validity of this concept needs to be tested clinically. Clinically, postsystolic shortening, measured either as a postsystolic velocity or postsystolic strain, serves as a marker of ischemia, although low-magnitude postsystolic shortening can be present in some patients with a normal LV velocity pattern.[73,97]

Ischemia is also associated with changes in diastolic myocardial velocities, which could improve the ability of TDI to identify ischemic regions.[72,95,98] The clinical value of assessing diastolic velocities other than isovolumic relaxation velocities during ischemia, however, remains to be determined.

Displacement imaging and strain-rate imaging can also be used for assessing ischemic dysfunction. In clinical practice, however, they have no proven added value. The most robust TDI methodology is velocity imaging, which is recommended as the primary method; strain imaging may be used as a supplementary method.

In this section we have mainly discussed longitudinal TDI measures, because apical views give the most extensive imaging of the LV. Similar findings during ischemia can be observed with radial measurements in short-axis images, but are restricted to anteroseptal and posterior segments. Some authors present radial measurements as *velocity gradient* instead of strain rate.[26,99] This is a valid approach but is not used very much clinically.

In summary, myocardial ischemia is characterized by reduction in systolic ejection velocity and a postsystolic shortening velocity. Furthermore, in dyskinetic myocardium there is a marked negative velocity during isovolumic contraction representing systolic lengthening. Strain measurement can be used to verify changes in tissue velocities and is very useful to confirm dyskinesia. Furthermore, strain imaging provides a more site-specific measure.

## Cardiac Synchrony

Normal ventricular activation spreads rapidly through the conduction system, and the result is a synchronized ventricular contraction. In patients with severe heart failure, however, there is often prolonged inter- or intraventricular conduction, which leads to inter- or intraventricular mechanical dyssynchrony, resulting in ineffective ventricular function. Approximately one third of patients with low LV ejection fraction and class III to IV heart failure have a QRS duration longer than 120 ms. In addition, heart failure patients may have prolonged

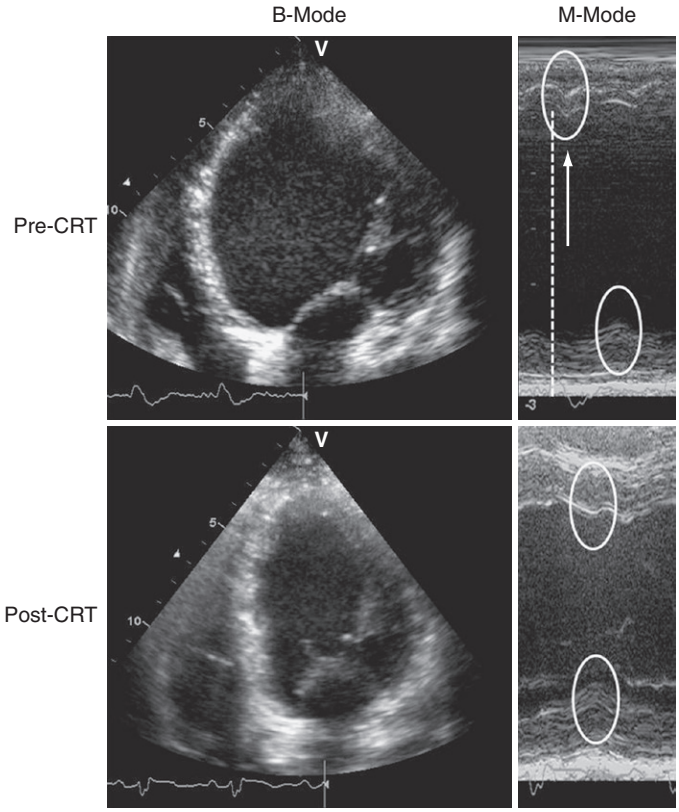

**Figure 10-21** B-mode and M-mode images from a patient responding to cardiac resynchronization therapy (*CRT*). *Upper panels* show LV before CRT and *lower panels* after 6 months of treatment. The M-mode recording demonstrates a typical septal beaking (*arrow*). This is seen as abnormal rapid leftward motion of the septum during preejection followed by rightward (paradoxical) motion. After CRT, a postsystolic septal displacement is observed. Peak systolic displacements (*ovals*) are dyssynchronous during left bundle branch block, but become more synchronous after CRT. *Dotted vertical line* indicates onset R in electrocardiogram. *(Courtesy Ola Gjesdal.)*

atrioventricular interval and therefore atrioventricular dyssynchrony. Of the three types of cardiac dyssynchrony, it is LV intraventricular dyssynchrony that appears to be the principal factor associated with development of heart failure.

## MECHANISMS OF LV MECHANICAL DYSSYNCHRONY

In principle, LV mechanical dyssynchrony has three possible etiologies: (1) delay in electrical conduction, (2) regional prolongation of electromechanical coupling time, and (3) different timing of myocardial shortening due to ischemia or nonuniform loading conditions. However, there is little evidence that disturbances in electromechanical coupling cause LV dyssynchrony. Therefore the clinical challenge is to differentiate between dyssynchrony that is caused by electrical conduction delay (electrical dyssynchrony) and dyssynchrony that is due to load or ischemia (primary mechanical dyssynchrony). This differentiation is important, because presumably only electrical dyssynchrony can be treated with biventricular pacing. Therefore, when patients are evaluated as candidates for biventricular pacing, it is essential to determine whether there is LV electrical dyssynchrony. A method that combines invasive LV pressure and myocardial strain by echocardiography has been proposed to differentiate between the two etiologies of dyssynchrony, but the method has not been clinically tested.[100] At present, QRS width in the electrocardiogram (ECG) is the only routine method that is used to identify electrical dyssynchrony, and the left bundle branch block pattern is the QRS morphology that best predicts success of cardiac resynchronization therapy. Chapter 26 discusses how to apply echocardiography in selection of candidates for cardiac resynchronization therapy.

## EFFECT OF LEFT BUNDLE BRANCH BLOCK ON LV FUNCTION

The most prominent echocardiographic feature of left bundle branch block (LBBB) is abnormal systolic motion of the interventricular septum.[101] (See Cine 3 at ExpertConsult.com.) The abnormal motion starts with rapid leftward motion of the septum during preejection, followed by rightward (paradoxical) motion, and is referred to as *septal beaking* when imaged by M-mode echocardiography[102] (see Fig. 10-21) and as *septal flash* (Fig. 10-22) when using myocardial velocity imaging.[103]

When using strain imaging, the abnormal systolic shortening pattern during LBBB can be assessed in more detail. In the normal heart the septum, similar to the LV free wall, shortens continuously during the LV ejection phase. In patients with LBBB, the septum has two phases with systolic shortening, one during preejection and one during midejection, and is followed by two phases of systolic lengthening.[104] This is illustrated in Figure 10-23.[104] The two phases of shortening are followed by early- and late-systolic lengthening. The preejection shortening and relengthening correspond to septal beaking and flash. The result of the abnormal motion is that net septal shortening, measured at the time of aortic valve closure, is markedly reduced compared to a normal heart. Therefore intraventricular dyssynchrony results in reduced contribution from the septum to LV stroke volume, and there is significant waste of myocardial work.[104-106] Reduced septal contribution is partly compensated for by increased shortening of the late-activated LV free wall, which is prestretched by the early septal contraction[107] (see Fig. 10-23). Strain analysis suggests that early-systolic septal shortening in LBBB causes a pressure rise that stretches the lateral wall and increases regional shortening via the Frank-Starling mechanism.[108] This in turn leads to increased work in the LV lateral wall and is a stimulus to regional hypertrophy and remodeling.[109] The pattern of septal strains, however, may be different in patients with septal dysfunction due to ischemia or other causes.

The mechanism of abnormal preejection motion of the septum in LBBB has been debated, but a recent study concludes that septal beaking during LBBB is caused by active septal contraction that is unopposed by the late-activated lateral LV wall.[110] It was previously proposed that preejection leftward septal motion occurs because the RV is activated first, causing RV pressure to transiently exceed LV pressure, thereby pushing the septum leftward like a passive membrane.[111,112] As shown recently, this mechanism may contribute to septal beaking but plays a minor role.[110] Therefore onset of preejection septal shortening represents timing of septal activation.

The early systolic lengthening of the septum can be attributed to forceful contraction of the hyperextended, late-activated LV lateral wall, which increases the transseptal pressure gradient and thereby pushes the septum rightward. The late-systolic

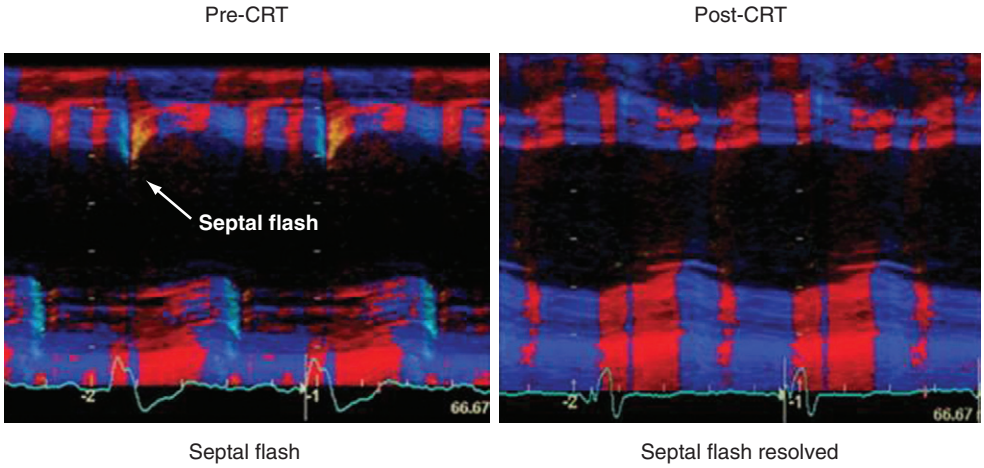

**Figure 10-22 Septal flash during left bundle branch block.** In dyssynchrony (*left*), the septum shows an early and fast thickening (*blue* color) and thinning (*red* color) during preejection. *CRT*, Cardiac resynchronization therapy. *(Modified from Parsai C, Bijnens B, Sutherland GR, et al: Toward understanding response to cardiac resynchronization therapy: left ventricular dyssynchrony is only one of multiple mechanisms.* Eur Heart J *30[8]:940-949, 2009.)*

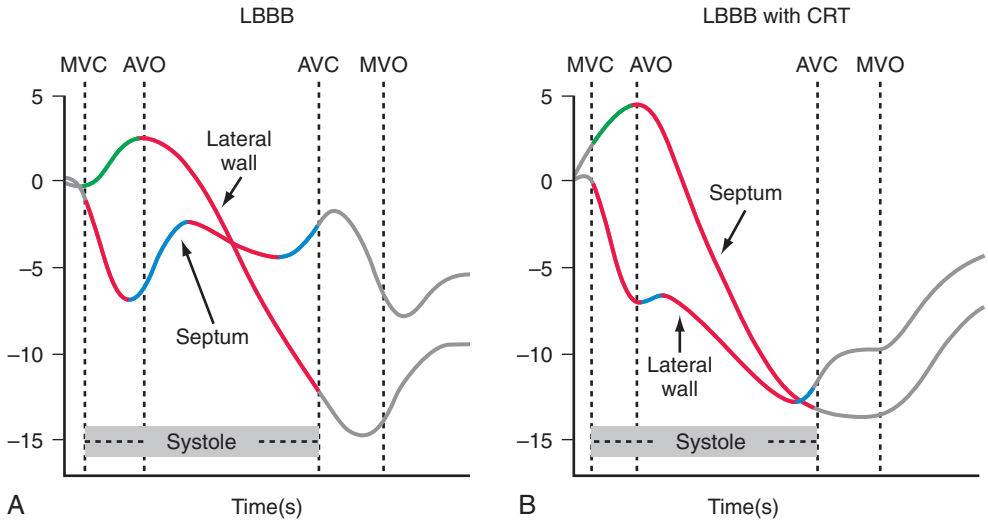

**Figure 10-23** The figure demonstrates systolic strain traces from septum and lateral wall in a patient with left bundle branch block (*LBBB*) before (*left*) and after (*right*) treatment with cardiac resynchronization therapy (*CRT*). During LBBB without CRT, there is a marked septal shortening (*red lines*) during preejection, and there is shortening during midejection. Each shortening is followed by lengthening (*blue lines*), resulting in both early- and late-systolic lengthening. The lateral wall shows preejection stretch (*green lines*) before treatment. These changes are reverted after treatment. A preejection stretch has appeared in the septum after treatment with CRT, indicating that there is also slight dyssynchrony during CRT. *AVC*, Aortic valve closure; *AVO*, aortic valve opening; *MVC*, mitral valve closure; *MVO*, mitral valve opening. *(Modified from De Boeck BW, Teske AJ, Meine M, et al: Septal rebound stretch reflects the functional substrate to cardiac resynchronization therapy and predicts volumetric and neurohormonal response.* Eur J Heart Fail *11(9):863-871, 2009.)*

lengthening of the septum probably reflects that the early activated septal segments start relaxing earlier than the late-activated lateral wall segments.[112]

## Mechanical Dispersion

In this section we describe a recently introduced application of velocity and deformation imaging that quantifies temporal nonuniformity of myocardial contraction: *mechanical dispersion*. This variable has turned out to be a promising marker of risk for ventricular arrhythmias and sudden death.[113,114] Mechanical dispersion can be assessed by either velocity or strain imaging and is calculated as the standard deviation of the time from onset of the Q-wave on the ECG to maximum myocardial shortening in 16 LV segments. Figure 10-24 shows typical recordings by strain imaging in a healthy individual and in a patient who has experienced ventricular arrhythmias. In the healthy heart, there is essentially similar timing of end of shortening in all myocardial segments. In the patient with arrhythmia, however, there is marked variability between segments in timing of end of shortening, and this variability is termed *mechanical dispersion*.

In patients with ischemic heart disease, increased mechanical dispersion has been associated with risk of arrhythmic events, independently of LV ejection fraction.[113] Because the majority of patients who suffer from malignant arrhythmias have ejection fractions above 35%, there is a need for new methods to identify risk.

Mechanical dispersion can also be demonstrated in patients with long QT syndrome (LQTS).[114,115] Until recently, LV function

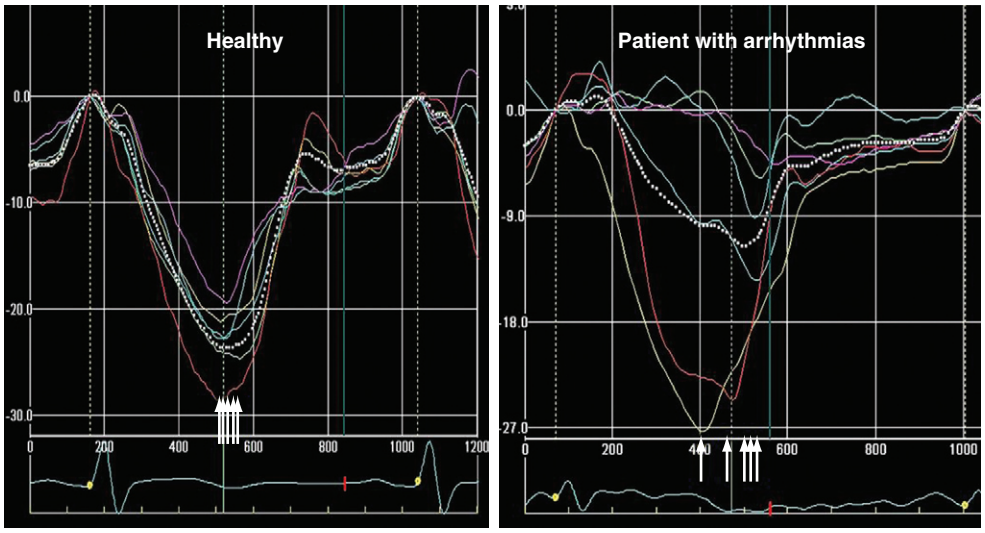

**Figure 10-24** Mechanical dispersion by strain echocardiography in a healthy individual (*left*) and a patient with previous ventricular arrhythmias (*right*). *Arrows* indicate the timing of peak strain in each of the myocardial LV segments as seen from the apical four-chamber view. The patient who has experienced previous ventricular arrhythmia has markedly dispersed timing of peak strain compared to the healthy individual. *(Modified from Haugaa KH, Smedsrud MK, Steen T, et al: Mechanical dispersion assessed by myocardial strain in patients after myocardial infarction for risk prediction of ventricular arrhythmia.* JACC Cardiovasc Imaging *3[3]:247-256, 2010.)*

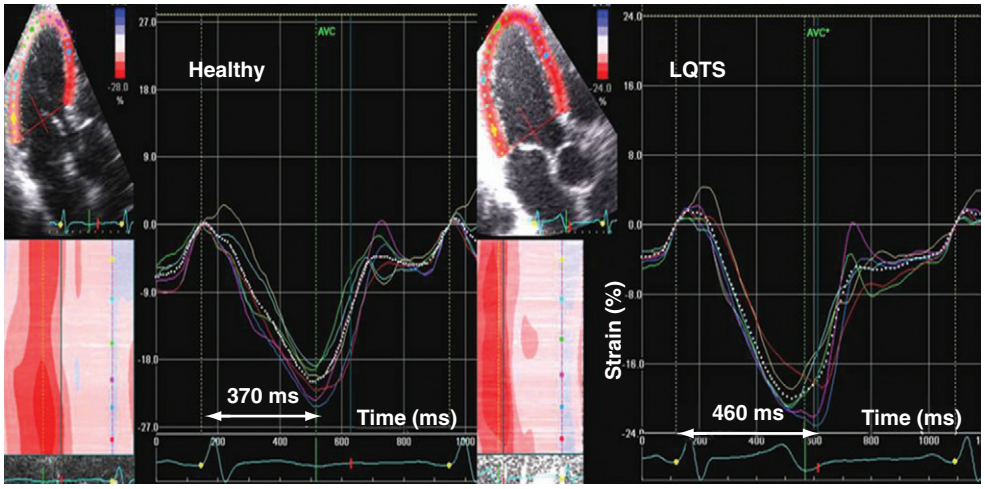

**Figure 10-25** Mechanical dispersion in a healthy individual (*left*) and a symptomatic long QT syndrome (*LQTS*) patient (*right*). Septal segments (*red, violet,* and *blue* curves) from apical long-axis view in the LQTS patient show prolonged myocardial shortening. The timing of peak strain in the LQTS patient is markedly dispersed compared to the healthy individual. *(Modified from Haugaa KH, Amlie JP, Berge KE, et al: Transmural differences in myocardial contraction in long-QT syndrome: mechanical consequences of ion channel dysfunction.* Circulation *122[14]:1355-1363, 2010.)*

was regarded as normal in these patients. Assessment of myocardial function by myocardial velocity and strain imaging, however, has revealed that LQTS patients have mechanical dispersion, that is, regional differences in duration of myocardial contraction (Fig. 10-25). The presence of mechanical dispersion was associated with a higher risk of cardiac arrhythmias in LQTS patients.[115] Potentially, mechanical dispersion in LQTS patients is related to the prolonged action potential duration and dispersion of action potential repolarization that are part of the syndrome. Both prolonged action potential duration with development of early after depolarizations and dispersion of electrical repolarization are considered to be important mechanisms of ventricular arrhythmias in these patients.

Mechanical dispersion as a clinical measure of risk of ventricular arrhythmias and sudden death is currently undergoing further testing. At the present time, assessment of mechanical dispersion is not established as a clinical routine method and should be considered a research tool.

## Right Ventricular Function

The RV has a complex anatomical structure. The RV is functionally divided into two parts, the inflow tract and the outflow tract, separated by the crista supraventricularis. Echocardiographic imaging of RV function and measurement of ejection fraction have been difficult because of the complex form and motion pattern of the RV and problems with defining the endocardial surface of the thin RV free wall. Another important factor that complicates the interpretation of RV function is the varying loading conditions. In daily cardiology practice, RV function is usually evaluated qualitatively by 2D echocardiography (see Chapter 32).

During systolic contraction there is longitudinal shortening of the RV, with the base descending toward the apex, while the apical part is relatively stationary. In addition, there is circumferential shortening that squeezes the ventricle. The interventricular septum contributes to RV as well as to LV function, and the relative contribution can be different in the normal and the diseased heart. The precise role of the septum remains to be determined.

RV (fractional area change) is also widely used as a measure of RV function.[116] It can be regarded as an area-based measure of RV function and is calculated from a four-chamber view.

Tricuspid annular plane systolic excursion (TAPSE) can be measured by M-mode echocardiography. TAPSE is a relatively fast and accurate measure of RV function. TAPSE correlates well with RV ejection fraction measured by radionuclide angiography.[117-119] A similar measure is obtained by TDI measurements of displacement.

The RV long-axis function can be expressed as velocity, strain, and strain rate along the lateral RV wall. All these measurements are helpful for quantifying RV longitudinal motion and will provide useful information in terms of quantification.

## KEY POINTS

- TDI provides measures of myocardial velocity, displacement, strain rate, and strain but is angle dependent.
- STE provides angle-independent measures of myocardial strain in multiple directions and can also be used to measure LV rotation and twist.
- TDI and STE provide unique diagnostic information in a number of cardiac diseases, but also have significant technical limitations.
- Assessment of mitral annulus velocities by TDI plays an important role in the evaluation of patients with suspected diastolic dysfunction.
- Myocardial velocity and strain imaging can be applied clinically to diagnose myocardial ischemia.
- Myocardial velocity and strain imaging can be used to quantify methods for quantification of LV dyssynchrony.
- Assessment of LV mechanical dispersion by velocity and strain imaging is a promising approach for prediction of risk of ventricular arrhythmias.

Restrictive versus Constrictive Physiology

Heart failure (HF) is a major public health problem in the Western world. Over the years, our understanding of the natural history of HF has evolved to recognize that cardiovascular disease can result in systolic and or diastolic dysfunction of the heart.[1,2] To date, echocardiography remains the most robust and widely used technique in the evaluation of diastolic function.[3] This chapter discusses the state-of-the-art echocardiographic techniques used in the optimal assessment of diastolic function. The role of echocardiography in specific cardiac diseases, that cause diastolic dysfunction, is then highlighted.

## Basic Principles

### PHYSIOLOGY OF DIASTOLE

The cardiac cycle is broadly divided into two phases: systole and diastole. Diastole is the time period that extends from the closure of the aortic valve to the termination of the mitral inflow (closure of the mitral valve). It is divided into four phases: isovolumic relaxation, early rapid filling, diastasis, and atrial systole. These phases are shown relating the aorta, left ventricle (LV), left atrium (LA), and LV volumes[4] (Fig. 11-1).

#### *Isovolumic Relaxation*

By definition, this period extends from the time of aortic valve closure to mitral valve opening and occurs without a change in LV volume.[5] It is an energy-dependent process, which occurs until middiastole. Ventricular pressure ($P_v$) decay during the isovolumic period follows an approximately exponential curve that can be characterized by its starting pressure ($P_o$) and its time constant ($\tau$).[6] This curve can be fitted with the assumption of either a zero asymptote $P_v = (P_o e^{-t/\tau})$, or a nonzero asymptote $P_v = (P_o e^{-t/\tau} + P_b)$ (to account for subatmospheric pressure and the effects of pericardial pressure), where $P_b$ is the LV pressure at the time of aortic closure or peak negative $dp/dt$, t is the time after the onset of relaxation, and $\tau$ is the time constant of relaxation.

A low $\tau$ value is suggestive of fast relaxation, whereas a high value represents slow relaxation. Isovolumic relaxation ends when the LV pressure falls below the LA pressure, resulting in mitral valve opening and the beginning of the rapid filling phase.[7]

#### *Rapid Filling*

The rapid filling phase starts with the opening of the mitral valve.[7] Left ventricular suction, continued LV relaxation, and elastic recoil leads to a continuous fall in LV pressure, resulting in the development of an LA-to-LV pressure gradient, with subsequent blood acceleration.[7] This gradient is influenced by the level of LA pressure at mitral valve opening, and the rate of decline of LV pressure.[8] Blood rapidly enters the LV from the LA during the early filling period with approximately 70% of the stroke volume received by the LV during the first third of diastole.[9] Active ventricular suction plays an important role in the rapid filling phase.[10] It occurs as a result of the recoil of the compressed elastic myocardial fibers during contraction.[11] Rapid filling ends in the moment that atrial and ventricular pressures equilibrate.[7]

#### *Diastasis*

Diastasis occurs between the rapid filling and the atrial contraction phases. After rapid filling, LA and LV pressures equilibrate, yielding no forward driving gradient.[7]

#### *Atrial Systole*

The atrial filling phase of diastole occurs when the LA pressure rises above the LV pressure. This late diastolic transmitral flow increases ventricular end-diastolic volume by 25% in normal individuals, with only a small rise in mean pulmonary venous pressure. Diastole ends with the onset of ventricular systole, when the rapid increase in ventricular pressure closes the mitral valve.[7]

### DETERMINANTS OF DIASTOLIC FUNCTION

The following are the major determinants of diastolic function: (1) active myocardial relaxation; (2) LV compliance; (3) LA function; (4) heart rate; and (5) the pericardium.[7,11]

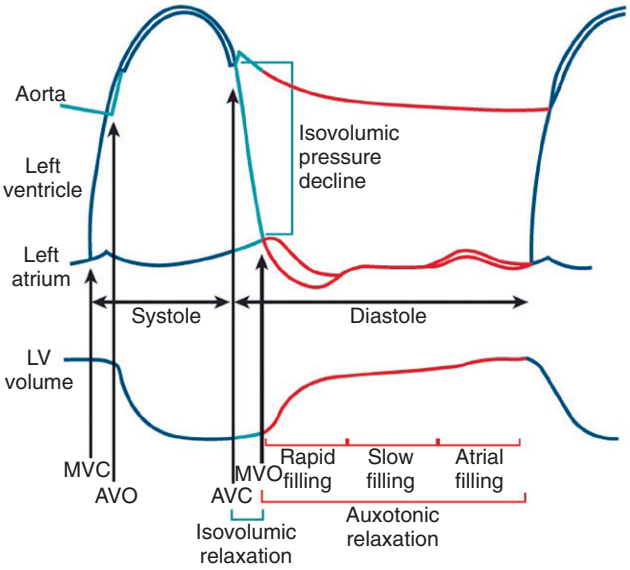

**Figure 11-1** Changes in left ventricular pressure and volume throughout the cardiac cycle. The cardiac cycle is divided into systole, the time period from mitral valve closure (*MVC*) to aortic valve closure (*AVC*), and diastole. Diastole is further divided into isovolumic relaxation (the time period from AVC to mitral valve opening (*MVO*) during which the LV pressure declines with no change in volume) and autoxonic relaxation (the time period from MVO to MVC during which the LV volume increases at variable pressure. *AVO,* Aortic valve opening. *(Adapted from Bonnema DD, Baicu C, Zile MR. Pathophysiology of diastolic heart failure: relaxation and stiffness. In: Klein AL, Garcia MJ, editors:* Diastology: clinical approach to diastolic heart failure. *Philadelphia, 2008, Saunders, pp 11-25.)*

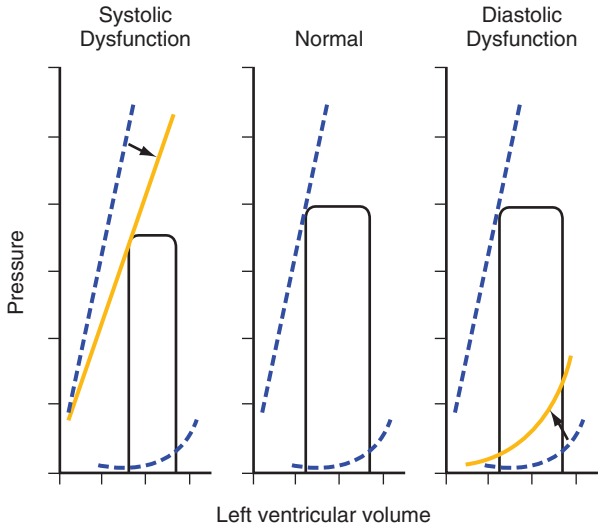

**Figure 11-2** Schematic representation of ventricular pressure-volume loops. The *center* panel demonstrates the normal situation. Note the exponential nature of the curve through late diastole. In systolic dysfunction (*left*), the end-systolic pressure line is displayed downward and is manifested by a decreased ability of the LV to generate high pressures for a given volume. Diastolic dysfunction (*right*) involves an upward and leftward shift of the exponential curve, a result of elevated filling pressures for a given volume. *(From Katz AM: Influence of altered inotropy and lusitropy on ventricular pressure-volume loops.* Am Coll Cardiol *11:438-445, 1988.)*

Myocardial relaxation, which occurs during isovolumic relaxation and early diastolic filling, is an active process involving the use of intracellular adenosine triphosphate and calcium by the myocardium.[12] Several factors affect isovolumic relaxation, including internal loading forces (cardiac fiber), external loading factors (wall stress, arterial impedance), and reduced or inhibited myocardial contractility (metabolic, neurohormonal, or pharmacologic).

Ventricular compliance is the ratio of change in volume to change in pressure ($dV/dP$), and stiffness is the mathematical inverse of compliance ($dP/dV$). From a conceptual standpoint, we can divide it into two components: intrinsic myocardial and chamber compliance. Compliance is the net result of a variety of factors: viscoelastic nature of the myocardium; chamber size, shape, and wall thickness; right ventricular (RV) and LV pressure-volume interactions; pleural pressure; and pericardial characteristics.[13] Intrinsic myocardial stiffness relates to the amount of collagen within the myocardium. Collagen plays an essential role in converting the contractile force of the myocytes into intraventricular pressure and determining the overall ventricular size and shape.[14,15] Pressure-induced hypertrophy is associated with increased collagen content deposition, with secondary increase in overall chamber stiffness. Evaluation of LV ventricular compliance has been studied and quantified extensively using pressure-volume loops, which demonstrate the degree to which pressure and volume change vis-à-vis each other over a wide range of physiologic pressures and volumes[16-18] (Fig. 11-2). The volume of blood that enters the LV is largely determined by the characteristics of the pulmonary veins, the LA, and the mitral valve .[7] The pressure gradient between the pulmonary veins or LA and the LV, the rate of myocardial relaxation, and ventricular suction are responsible for early rapid filling.[10,19] Hence, diseases of the mitral valve, such as mitral stenosis, delay LV filling and prevent early rapid filling.[7]

The LA predominantly acts as a passive reservoir of blood during early LV filling, and as an active pump at end-diastole.[20] Atrial systolic function (active phase) may be essential to maintain the cardiac output in disease states.[21,22] In young and healthy normal individuals, the atrial contribution is less than 20% of the total volume, whereas in older normal subjects, the atrial "kick" accounts for a greater proportion of the total LV filling.[23] Atrial contractile function has delayed recoery (stunning) following electrical cardioversion.[24] Decreased atrial systolic function as a result of infiltration plays a role in the reduction in forward transmitral atrial contraction wave by Doppler echocardiography as seen in advanced cardiac amyloidosis.[25]

*Heart rate* has a direct impact on cardiac output in cases of diastolic dysfunction.[26,27] As heart rate increases, the diastolic filling period preferentially decreases with respect to the systolic ejection period. As ventricular filling is functionally delayed, adequacy of inflow deteriorates and cardiac output paradoxically falls. Catecholamines may enhance relaxation and increase heart rate, thus decreasing the diastolic period.[28]

Other factors that affect diastolic function include neurohormonal activation, conduction abnormalities, and the stiffness of the pericardium. LV relaxation may be impaired by conduction abnormalities that cause segmental asynchrony.[29] This may contribute to decreased exercise tolerance in patients with left bundle branch block or RV paced rhythms. The pericardium considerably affects diastolic function as commonly seen in constrictive pericarditis.[30]

## DEFINITION OF DIASTOLIC DYSFUNCTION

Heart failure can be divided in two groups: heart failure with a reduced ejection fraction (HFrEF), and heart failure with a preserved ejection fraction (HFpEF), or diastolic HF. A study from

the Mayo Clinic evaluated a total of 4596 consecutive patients admitted with decompensated HF. Of these, 53% had a reduced ejection fraction. The proportion of patients with HFpEF increased over the period from 1987 to 2001. There are several differences between HFrEF and HFpEF from the structural and functional standpoint. In HFrEF, there is LV cavity enlargement, eccentric LV remodeling with low LV mass/volume ratio, and abnormal systolic and diastolic function; whereas in HFpEF, there is normal cavity size, concentric hypertrophy with high LV mass/volume ratio, and abnormal diastolic function. Myocardial structure follows a similar trend with cardiomyocyte hypertrophy in HFpEF and loss of myofilaments in HFrEF.[31-34]

Bhatia et al evaluated the epidemiology and outcomes of patients with HFpEF in a population-based study. Patients with HFpEF were more likely to be older and female and to have a history of hypertension and atrial fibrillation. The presenting symptoms and clinical presentation were similar to patients with reduced ejection fraction. The survival of patients with HFpEF was similar to those of patients with reduced ejection fraction (Fig. 11-3).[35] As a result of modern evidence-based HF therapy, the prognosis of patients with HFrEF has improved progressively over the past three decades. Conversely, despite frequent use of similar pharmacologic agents, the prognosis of patients with HFpEF remained unaltered over the same time period.[36]

Because diastolic dysfunction is common as an isolated disease in the elderly and also increases the burden of HF among patients with systolic dysfunction, these results have major public health implications for the future, particularly given the increasing age of our population.

Differentiation between HFrEF and HFpEF cannot be made on the basis of history, physical examination, electrocardiogram, or chest radiograph alone, because these clinical markers have the same frequency of occurrence in these two forms of HF.[37] The following criteria (Table 11-1) for HFpEF were proposed by the Working Group for the European Society of Cardiology: (1) presence of signs or symptoms of HF; (2) LV ejection fraction greater than 50%; and (3) evidence of LV diastolic dysfunction.[38] These diagnostic criteria have three major problems. The first is the requirement that there be signs *or* symptoms of HF. It is well recognized that the mere presence of breathlessness and fatigue is not specific for the presence of HF. It would be more prudent to use specific diagnostic criteria, such as the Framingham criteria. Second is the requirement that a measurable abnormality in diastolic function be present. Similar to measurements of systolic function, measurements of ventricular relaxation, filling, and compliance are load dependent. Therefore, their poor specificity, sensitivity, and predictive accuracy limit the application of this requirement in the clinical setting. Vasan and Levy have refined these criteria and divided

All four sets of guidelines require the simultaneous presence of HF signs and/or symptoms and normal LV systolic function and diastolic LV dysfunction. Criteria for normal LV systolic function are comparable, but criteria for diastolic LV dysfunction are variable.

*A*, Atrial wave mitral flow velocity; $A_{dur}$, duration of atrial wave mitral flow velocity; *Ar*, pulmonary vein atrial reversal velocity; $Ar_{dur}$, duration of reverse pulmonary vein systole flow velocity; *DT*, deceleration time; *E*, early mitral flow velocity; *E′*, early tissue Doppler lengthening velocity; *HF*, heart failure; *HFpEF*, heart failure with preserved LV ejection fraction; *IVRT*, isovolumic relaxation time; *LVEF*, left ventricular ejection fraction; *LVH*, left ventricular hypertrophy; *NT-proBNP*, N-terminal pro-B-type natriuretic peptide; *PCWP*, pulmonary capillary wedge pressure.

them into definite, probable, and possible diastolic HF.[39] Definite diastolic HF requires definitive evidence of HF; objective evidence of normal systolic function, with an ejection fraction greater than 50% within 72 hours of the HF event; and objective evidence of diastolic dysfunction on cardiac catheterization. If objective evidence of diastolic dysfunction is lacking, but the first two criteria are present, this fulfills the criteria for probable diastolic HF. If the first criterion is present and ejection fraction is greater than 50% but not assessed within 72 hours of the HF event, this fulfills the criteria for possible diastolic HF. Possible diastolic HF can be upgraded to probable diastolic HF if one of a number of additional criteria is present. The clinical application of these guidelines is limited, because they are both complex and empiric. Controversy exists whether measurements of LV relaxation or compliance by cardiac catheterization or Doppler echocardiography are actually needed when LV hypertrophy or concentric remodeling is present.[33] Recently, further definitions of diastolic HF or HF with preserved ejection fraction (HFpEF) have been proposed.[40]

## Echocardiographic Evaluation of Diastolic Function

Echocardiography has been the mainstay for understanding the physiology of diastolic function, and identifying the pathophysiology of diastolic dysfunction. In current practice, the clinician has a number of techniques in the evaluation of diastolic function, including the traditional Doppler techniques, which include mitral inflow and pulmonary vein flow and the newer modalities, such as tissue Doppler imaging and color M-mode Doppler. Table 11-2 provides the common diastolic filling variables that can be measured in clinical practice. Table 11-3 provides the clinical utility and technical limitations of various

**TABLE 11-2 Criteria Used to Define the Grade of Diastolic Dysfunction**

*A*, Filling wave due to atrial contraction; *Ar,* pulmonary vein atrial reversal; *D*, diastolic PV flow; *DT*, deceleration time; *E*, early diastolic filling velocity; *IVRT*, isovolumic relaxation time; *PV*, pulmonary vein; *S*, systolic PV flow; *Vp*, velocity of propagation.

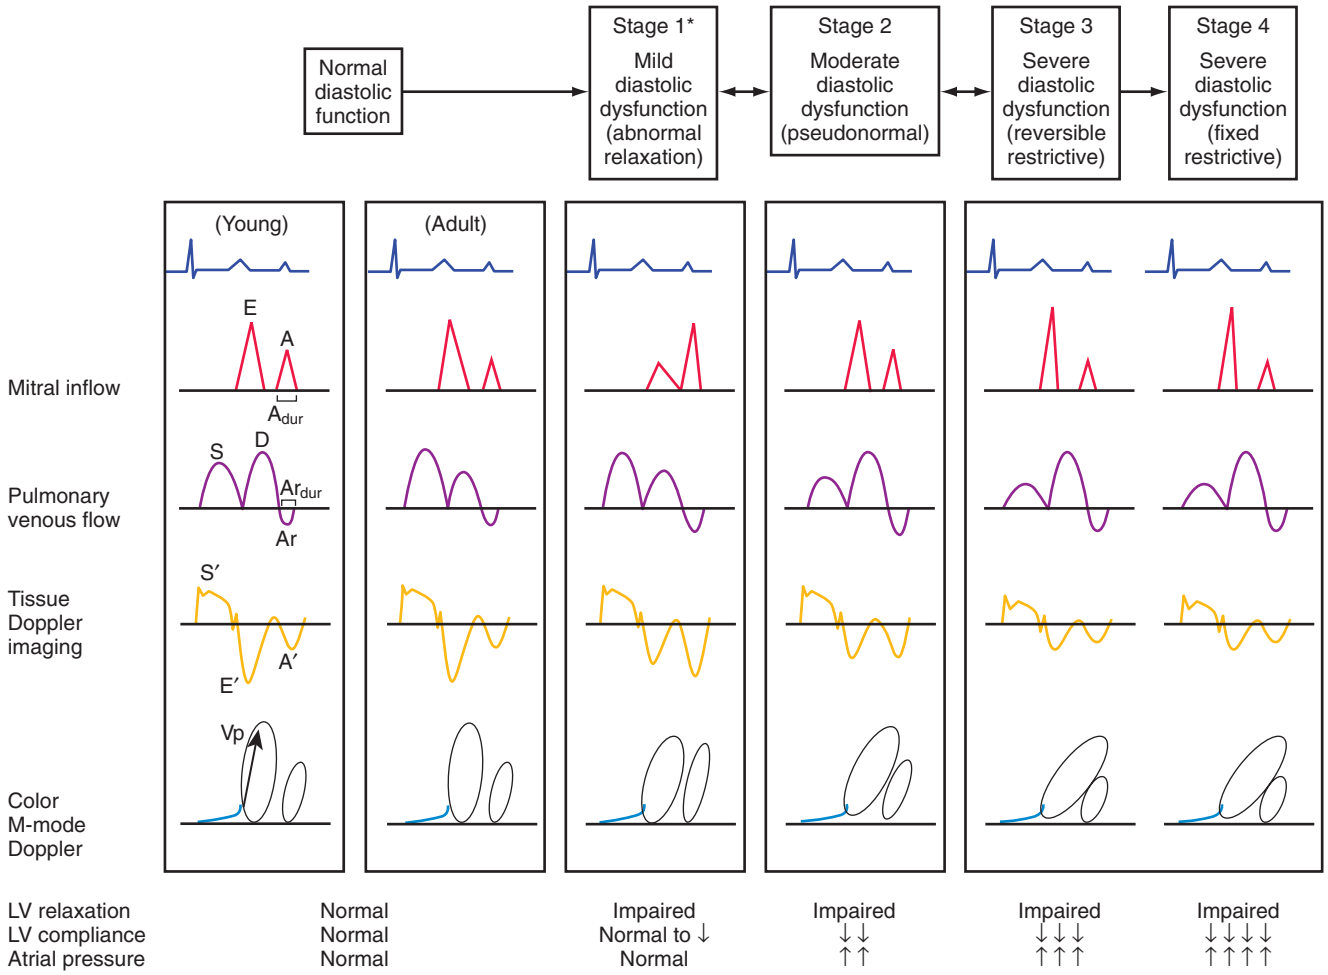

**Figure 11-4** Stages of diastolic function. Schematic representation of the typical patterns seen with mitral inflow, pulmonary venous flow, tissue Doppler echocardiography, and color M-mode propagation velocity (*Vp*) for normal (young and adult), impaired relaxation, pseudonormal, and restrictive diastolic function. The stages of diastolic dysfunction can be determined using an integrated approach with these four different modalities for assessment of diastolic flow pattern. *A*, Late mitral filling; *A′*, tissue Doppler atrial velocity; *Ar*, pulmonary vein atrial reversal velocity; $Ar_{dur}$, duration of pulmonary vein Ar; *D*, pulmonary vein diastolic filling; *E*, early mitral filling; *E′*, tissue Doppler early diastolic velocity; *S*, pulmonary vein systolic filling; *S′*, tissue Doppler systolic velocity; *Vp*, propagation velocity.
*Stage 1 can be divided into stage 1A and stage 1B depending on an elevated LV end-diastolic pressure. *(Adapted from Garcia MJ, Thomas JD, Klein AL: New Doppler echocardiographic applications for the study of diastolic function.* J Am Coll Cardiol *32:865-875, 1998.)*

echocardiographic techniques in assessment of diastolic function. A framework of the different imaging modalities is shown in Figure 11-4 in normal subjects and in patients with different stages of diastolic dysfunction.

## DOPPLER TECHNIQUES IN ASSESSMENT OF DIASTOLIC FILLING PATTERNS

There is a large body of scientific evidence validating the typical patterns of diastolic filling in normal subjects, and those with diastolic dysfunction. These filling patterns are generally not characteristic of a particular disease process, but represent the end product of a complex set of pathophysiologic events. Furthermore, these patterns can also be affected by operator-related issues (e.g., precise placement of the sample volume) and physiologic factors (e.g., heart rate and volume status) and are not a reflection of true diastolic function.[33]

### *Transmitral Flow Assessment*

The most traditional technique of assessment of LV filling patterns involves using pulsed-wave Doppler mitral flow velocity recordings.[41] The following are the variables derived from mitral inflow interrogation: peak early diastolic transmitral flow velocity (E), peak late diastolic transmitral flow velocity (A), early filling deceleration time (DT), and A-wave duration ($A_{dur}$). Normal mitral flow velocity curves vary with loading conditions, age, and heart rate.

Normal individuals demonstrate a rapidly accelerating E wave, relatively rapid deceleration, and an A wave significantly smaller than the E wave. The E/A ratio is greater than 1, the mitral DT (reflecting LV compliance) is typically between 160 and 240 ms, and the isovolumic relaxation time (IVRT) is between 70 and 90 ms. With normal aging, there is slowing of LV relaxation and, hence, a gradual decrease of the peak E wave velocity, and an increase of A wave peak velocity. In most individuals, E and A waves become approximately equal in the sixth decade of life.[42]

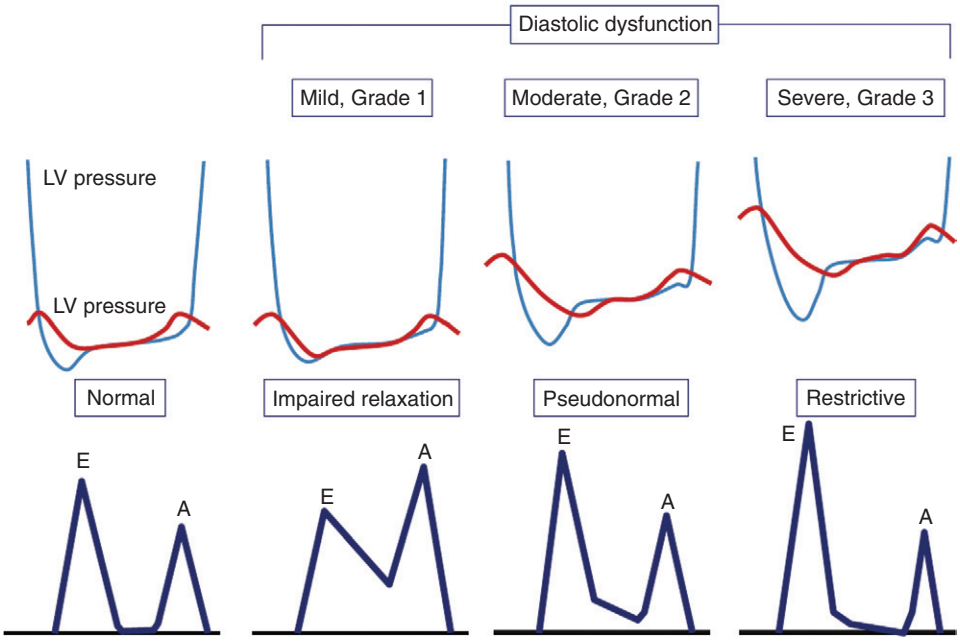

**Figure 11-5** Schematic representation of LV and LA pressures (*upper*) and transmitral flow velocity patterns (*lower*) in normal patients and in different types of diastolic dysfunction. This schema divides patients into four filling patterns: normal pattern of relaxation and filling; impaired relaxation, or grade 1 mild diastolic dysfunction; pseudonormal relaxation, or grade 2 moderate diastolic dysfunction; and restrictive filling pattern, or grade 3 severe diastolic dysfunction. *(Adapted from Yamada H, Klein AL: Diastology 2010: clinical approach to diastolic heart failure.* J Echocardiogr *8:65-79, 2010.)*

The evolution of traditional diastolic parameters with progressively worsening diastolic function, occurs in the following manner: For patients with diastolic dysfunction, three abnormal filling patterns are initially recognized[26,43] (Fig. 11-5). In stage 1 diastolic dysfunction (abnormal relaxation), there is a low E wave and a high A wave, resulting in an E/A ratio less than 1. DT is prolonged and is usually greater than 240 ms and IVRT is greater than 90 ms. Stage 2 diastolic dysfunction, or pseudonormal pattern, is associated with a normal appearance of the transmitral inflow with an E/A ratio between 1 and 1.5, a DT between 160 and 240 ms, and an IVRT between 60 and 100 ms. With disease progression (stage 3 diastolic dysfunction or restrictive filling), there is a very high E wave, a low A wave, and a significantly decreased DT. The E/A ratio is usually greater than 2 with a DT less than 160 ms, and IVRT less than 70 ms.

Further observations have subcategorized this last pattern to either reversible or fixed restrictive pattern (stage 4) depending on the response to the Valsalva maneuver or other preload reducing maneuvers.[44] The major challenge in the interpretation of Doppler mitral inflow patterns is in distinguishing the normal from the pseudonormal pattern. To accurately assess and stratify the degree of diastolic abnormality, further measurements are generally necessary. There are several traditional methods that are useful in distinguishing normal from pseudonormal patterns, including the Valsalva maneuver, pulmonary venous (PV) flow measurements, and the tissue Doppler annular velocities (E′).

### *Mitral Inflow at Peak Valsalva Maneuver*

Because preload affects interpretation of diastolic dysfunction, the Valsalva maneuver is another supplement to the measurement of mitral inflow parameters (Fig. 11-6). The strain phase of the Valsalva maneuver is a simple approach used to decrease LA pressure. During this phase, E wave velocity normally decreases by 20% with a smaller decrease in A velocity.[41] In patients with pseudonormal mitral inflow patterns, Valsalva strain lowers LA pressure and unmasks the underlying impaired LV relaxation, resulting in a measured E/A less than 1.[45] Patients with restrictive filling patterns or individuals who are preload sensitive will revert to a pseudonormal or even impaired relaxation pattern. Patients with restrictive filling patterns without any change with Valsalva have severe irreversible or fixed diastolic dysfunction. The primary limitation in the use of Valsalva to assess diastology is obtaining adequate signals for measurement. Ommen and colleagues[45] were able to obtain satisfactory Doppler data in only 61% of patients during a Valsalva maneuver. In addition, the inherent limitations in performance of an adequate Valsalva maneuver limit its utility in routine practice.

### *Pulmonary Venous Flow*

PV flow velocity variables provide an integrated approach with mitral inflow in the evaluation of diastolic dysfunction. The four useful variables from the PV flow interrogation are peak systolic PV flow velocity (S), peak diastolic PV flow velocity (D), peak PV atrial reversal flow velocity ($PV_a$), and $PV_a$ duration ($a_{dur}$). Figure 11-5 shows a schematic representation of the PV variables in normal diastolic function and in various stages of diastolic dysfunction.[43]

The flow from the PV to the LA occurs in three phases: systolic phase (peak early and late systolic PV flow velocity); early diastolic phase (peak diastolic PV flow velocity); and retrograde flow during the late diastole with atrial contraction. With a normal LA pressure, the majority of the flow into LA occurs in systole. However, when the mean LA pressure increases, the majority of the antegrade flow occurs in diastole with a concomitant reduction in systolic flow. A decreased systolic fraction of less than 40% is associated with an elevated mean LA pressure greater than 15 mm Hg.[46] Similar to mitral inflow, the pulmonary vein flow demonstrates a U-shaped curve,

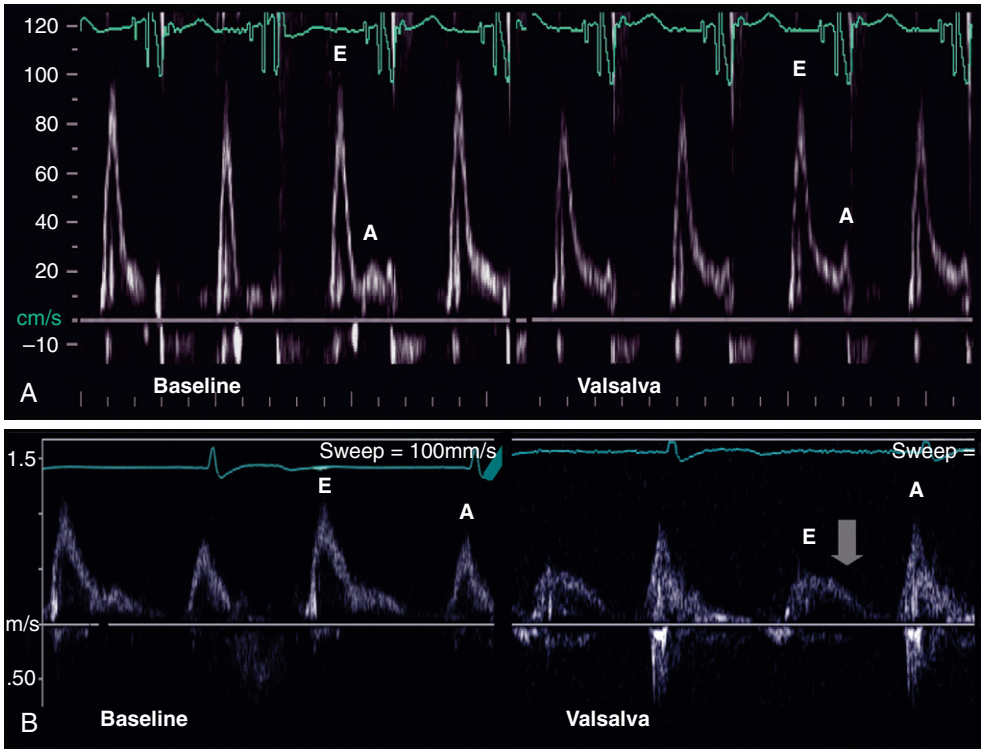

**Figure 11-6** Effect of Valsalva maneuver on mitral inflow in a patient with different stages of diastolic dysfunction. **A,** Patient with stage 3 diastolic dysfunction. Notice that after Valsalva maneuver, the E wave remains the same, consistent with irreversible diastolic dysfunction (stage 4). **B,** Patient with stage 2 diastolic dysfunction. With Valsalva, there is blunting of the E wave and appearance of stage 1 diastolic dysfunction. *A*, Atrial component of diastolic filling; *E*, early diastolic filling.

suggesting preload dependence. Pulmonary vein atrial reversal velocity and duration provides incremental value in assessing diastolic function. An atrial reversal velocity greater than 35 cm/s and an duration of 30 ms longer than the mitral inflow A-wave duration is predictive of an LV end-diastolic pressure greater than 15 mm Hg.[47] For multiple reasons, however, it may be difficult to optimally assess PV flow. A frequent reason is inadequate PV flow profiles, commonly seen as a result of body habitus and operator dependence. Blunting of PV systolic waves may be present in young healthy individuals as a result of rapid diastolic "suction," and atrial reversal may be absent in advanced diastolic dysfunction as a result of the loss of atrial function.[25,48] Therefore, newer modalities, including color M-mode Doppler and tissue-Doppler imaging (TDI), have evolved to provide additional information for the assessment of diastolic function and evaluation of LV filling pressures[45] (Fig. 11-7).

### *Evaluation of the Right Heart by Doppler*

Diastolic function of the right-sided heart can be evaluated by the interrogation of the tricuspid inflow, hepatic veins, and superior vena cava flows.[49] The Doppler flow patterns in the hepatic veins and superior vena cava are somewhat similar to the PV flow patterns.[50,51] In addition to the systole (S), diastole (D), and atrial waves, a second reversed flow is often seen between the S and the D wave at the end of ventricular contraction.[23] Right-sided flow velocities normally increase during inspiration and decrease with Valsalva.[23,52] As with the PV flow, the S wave is related to right atrial (RA) relaxation and tricuspid annular descent, and the D is related to early RV filling velocity (E). The magnitude of atrial reversal and ventricular contraction varies according to RV stiffness, RA contractility, and central venous pressure.[53] The effect of respiration of the right-sided flows is useful in differentiating constriction from restriction and estimating right-sided filling pressures.[50,51]

### *Tissue-Doppler Imaging for Evaluation of Diastolic Function*

The Doppler principle states that the velocity of a moving object will alter the frequency of a reflected sound wave. Ultrasonic Doppler technique is a direct application of this effect and is based on the analysis of the amount of frequency shift of ultrasound waves reflected by a moving object. This ultrasound principle has been applied in cardiovascular medicine for many years, predominantly for blood flow velocity measurements within the heart and great vessels.[54] In conventional Doppler color imaging, wall filters are employed to eliminate high-amplitude, low-frequency signals reflected from myocardium in favor of the low-amplitude, high-frequency signals reflected from moving red blood cells. These low Doppler frequency shifts are produced by the contracting myocardium and provide information for the assessment of myocardial function during systole and diastole. TDI is an echocardiographic technique that directly measures myocardial velocities. In TDI, wall filters are bypassed to specifically measure the velocities of the myocardium, which typically range from 0 to 20 cm/s. Doppler gain settings also must be increased to adequately visualize the TDI waveforms (see Chapter 10).

TDI was first described in 1989 by Isaaz and colleagues,[55] who demonstrated that low myocardial velocities at the posterior mitral annulus correlated with abnormal posterior wall motion on LV angiography.

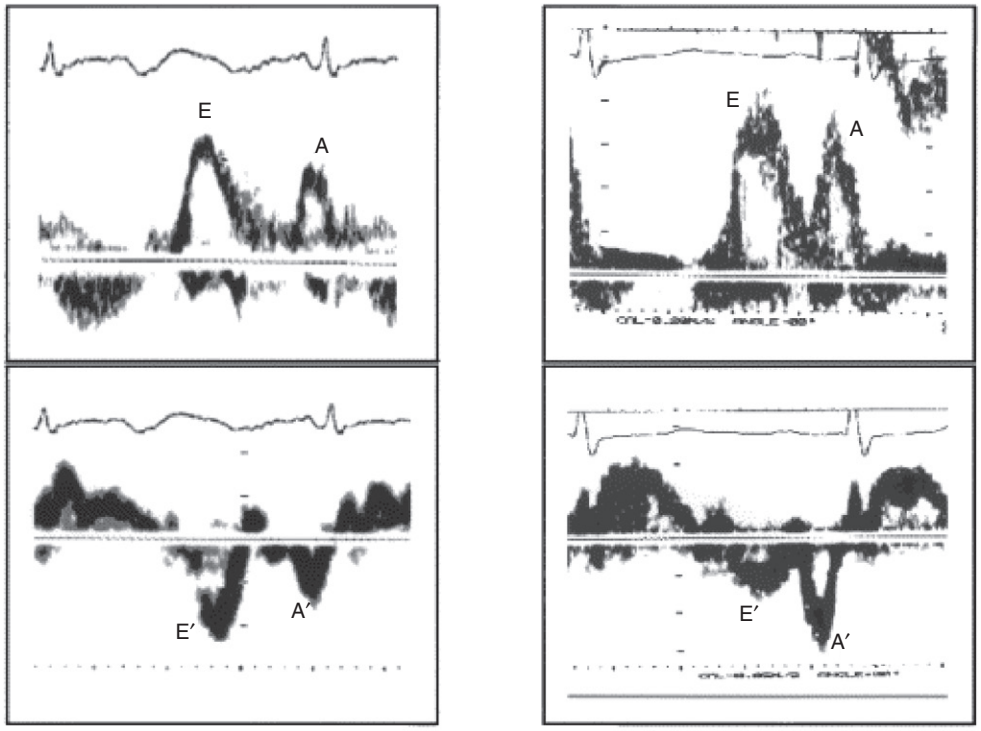

**Figure 11-7** Standard pulsed Doppler transmitral inflow (*upper panels*) showing the early (*E′*) and atrial (*A*) filling velocities, and myocardial axial velocities (*lower panels*) recorded at the basal lateral wall in a healthy volunteer and in a patient with severe aortic stenosis, LV hypertrophy, and elevated filling pressures (pseudonormal). Early diastolic myocardial velocity (*E′*) is significantly reduced, as well as the early-to-atrial velocity ratio (*E′/A′*) in the pseudonormal patient. *(From Garcia MJ, Thomas JD, Klein AL: New Doppler echocardiographic applications for the study of diastolic function.* J Am Coll Cardiol *32[4]:865-875, 1998.)*

## Techniques of Tissue-Doppler Imaging

Pulsed and color TDI have been used for the assessment of myocardial function; however, both techniques show advantages and disadvantages. Using pulsed Doppler techniques we can (1) obtain high-quality Doppler signals, (2) measure mean and instantaneous local acceleration, and (3) obtain quantitative wall motion information (i.e., velocity, acceleration, and displacement). However, the pulsed Doppler technique has many shortcomings, including (1) the need for manual mapping, (2) a limited spatial resolution making it difficult to distinguish subendocardial from subepicardial myocardial velocities, (3) difficulty in simultaneous recording of different ventricular wall segments, and (4) recognition that important qualitative differences exist between the various echocardiographic machines in terms of obtained signals. On the other hand, using color TDI of the myocardium, we can superimpose wall motion velocity on the two-dimensional (2D) echocardiographic imaging by velocity color coding. 2D color Doppler imaging of the myocardium (1) enables rapid visual qualitative assessment of wall dynamics, (2) provides a good spatial resolution to differentiate between velocity profiles of subendocardial and subepicardial layers, and (3) allows simultaneous analysis of various myocardial regions. However, it is limited by poor temporal resolution. In contrast, M-mode color-coded tissue imaging is characterized by a high spatial and temporal resolution, but sampling is performed only along a single line.

In the assessment of diastolic function, velocities typically are measured at the annuli or myocardium in the longitudinal axis to minimize the effect of cardiac translation.[56] From either the apical four-chamber or two-chamber acoustic windows, the region of interest is placed at the level of the mitral annulus on the septal, lateral, anterior, or posterior aspects of the annulus. Recordings are obtained during apnea to minimize translation-induced motion artifacts. In clinical TDI applications, three waveforms are visualized per cardiac cycle: the peak systolic wave (S′), early diastolic wave (E′), and end-diastolic wave produced by atrial contraction (A′).

In evaluation of velocities in healthy subjects, the annular early diastolic wave velocities recorded in the short-axis view were higher at the posterior wall than at the anteroseptal wall.[57] Garcia and colleagues[57] found an average value of 6.3 ± 1.7 cm/s for E′ at the anteroseptal wall versus 9.3 ± 3 cm/s at the posterior wall. In the apical view, myocardial diastolic velocities recorded by TDI are higher at the base than at the mid-LV or at the apex.[58,59] Although TDI velocities decrease with age, a healthy 50-year-old adult has spectral TDI values of 10 cm/s or greater and color TDI values of generally 6 cm/s or greater for S′, E′, and A′.

## Relationship of E′ to Active Relaxation

E′ is a relatively preload-independent measure of myocardial relaxation in patients with cardiac disease, whereas it appears load dependent in patients with normal systolic function.[56,60] It has been shown that in patients with abnormal relaxation, saline loading led to a pseudonormal transmitral pattern, whereas TDI E′ and E′/A′ remained unchanged. Also, the authors showed that the time constant of relaxation (τ) was better linearly related to E′ and E′/A′ than to transmitral velocity variables.[56] A value of E′ less than 8.5 cm/s with a ratio E′/A′

less than 1 identified a pseudonormalized transmitral velocity pattern with a 88% sensitivity and 67% specificity (Fig. 11-8). Another study[60] included three groups of patients: 34 normal subjects, 40 asymptomatic patients with normal ejection fraction and transmitral E/A less than 1 (abnormal relaxation), and 51 patients with HF and E/A ratio greater than 1 (pseudonormal). It was shown that E′ was lower with a decreased E′/A′ in both impaired relaxation and pseudonormal compared with normals; the ratio E/E′ was similar between normals and patients with impaired relaxation but was significantly higher in the patients with pseudonormal transmitral pattern.

## Estimation of LV Filling Pressures

Sohn and colleagues demonstrated that E′, correlated with invasive indices of myocardial relaxation (τ).[56] Nagueh and colleagues[60] showed that the pulsed Doppler peak early mitral inflow velocity (E) divided by TDI early diastolic mitral annular velocity (E′) resulted in a ratio (E/E′) that correlated with pulmonary capillary wedge pressure (PCWP). In their study, they evaluated 60 patients in whom the mean PCWP was measured (Fig. 11-8), finding a good correlation between the E/E′ ratio and the mean PCWP (correlation coefficient $r = 0.87$).[60]An E/E′ ratio greater than 10 indicated a PCWP greater than 12 mm Hg with a 91% sensitivity and a 81% specificity of 62%. Ommen and colleagues[45] corroborated their work, demonstrating that the E/E′ is useful in estimating mean LV filling pressures. The E/E′ ratio has since been demonstrated to be useful in estimating LV filling pressures in patients with hypertrophic cardiomyopathy (HCM),[61] sinus tachycardia,[61] atrial fibrillation,[62] and postcardiac transplantation.[63]

However, there are certain situations where E/E′ may not provide an accurate assessment of pulmonary capillary wedge pressure. First, in the normal heart, E′ behaves as a load-dependent variable. As a result, E/E′ actually decreases in response to massive fluid loading, as seen in experimental animal models.[64] Nevertheless, this finding is of very little clinical importance, because the LA pressure is rarely elevated in patients with normal hearts.[65] Second, E/E′ does not increase in patients with constrictive pericarditis, despite elevated PCWP. E′ increases as constriction gets worse. As a result, the E/E′ ratio decreases as diastolic filling pressures increase (annulus paradoxus).[65] Third, E/E′ may not provide an accurate calculation of filling pressures in patients with mitral valve disease (mitral annular calcification, mitral stenosis, mitral regurgitation) or after mitral valve surgery (mitral valve annuloplasty or mitral valve replacement).

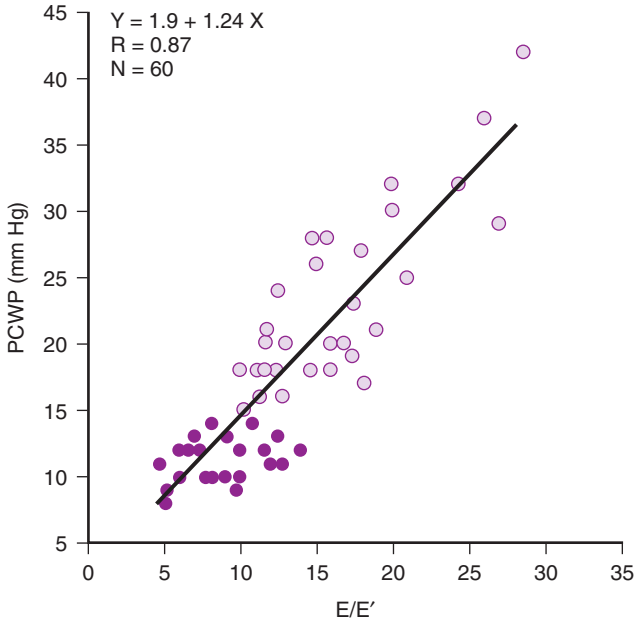

**Figure 11-8** Relation of early transmitral velocity to tissue Doppler mitral annular early diastolic velocity (E/E′) to pulmonary capillary wedge pressure (PCWP) in 60 patients. The *solid dots* indicate patients with impaired LV relaxation. The *open dots* indicate patients with a pseudonormalized pattern of diastolic filling. *(From Nagueh S, Middleton JK, Kopelen HA, et al: Doppler tissue imaging: a noninvasive technique for evaluation of left ventricular relaxation and estimation of filling pressures.* J Am Coll Cardiol *30[6]:1527-1533,1997.)*

More recently, concerns have been raised in terms of the ability of E/E′ to estimate LV filling pressures in the patients with decompensated HF. Mullens and co-workers[66] prospectively evaluated a cohort of patients with advanced decompensated HF (ejection fraction less than 30%, NYHA class III or IV symptoms) who underwent simultaneous echocardiographic and hemodynamic evaluation on admission, and after 48 hours of intensive medical therapy. They concluded that in decompensated patients with advanced systolic HF, TDI-derived mitral E/E′ ratio may not be as reliable in predicting intracardiac LV filling pressures, particularly in those with larger LV volumes and more impaired cardiac indices, and in the presence of cardiac resynchronization therapy.[66] In a follow-up article addressing the controversy, Little and Oh[67] stated that the failure of E/E′ to perform adequately may result at least partially from the characteristics of the patients studied. Significant mitral regurgitation was present in nearly a quarter of the patient population, where, as mentioned previously, E/E′ may not correlate well with PCWP. Additionally, half of the patients had undergone cardiac resynchronization therapy, and most had a prolonged QRS with variable degrees of mechanical dyssynchrony.[68] In contrast, a recent paper by Nagueh and associates[68] found that Doppler echocardiography provided good accuracy in the assessment of hemodynamics in 79 patients with decompensated heart failure.

Given that in patients with elevated LV filling pressures the cardiac myocytes are under strain, B-type natriuretic peptide (BNP) levels can be useful in determining the presence of elevated filling pressures. A recent study demonstrated that BNP had a significant correlation ($r = 0.51$) with mitral E/E′. Other investigators have shown that BNP and mitral E/E′ are similarly accurate in diagnosing clinical HF in patients hospitalized for dyspnea; however, a comprehensive Doppler assessment using 2D, conventional Doppler, and TDI variables appeared more specific than BNP.[69] In patients with indwelling pulmonary artery catheters, E/E′ and BNP were highly and equally sensitive for PCWP greater than 15 mm Hg, but E/E′ was more specific.

## Tissue Doppler Assessment of Diastolic Function and Prognosis

Recently, there has been tremendous interest in the prognostic implications of TDI diastolic variables. One study demonstrated that after first acute myocardial infarction, E′ and E/E′ were univariate predictors of death or hospital readmission. Another population-based study[70] showed that patients with increasing degrees of diastolic dysfunction (using a comprehensive Doppler-echocardiography assessment including TDI variables) have increasingly worse outcome. E/E′ has been demonstrated to be a strong multivariate predictor of patient outcome when assessed a mean of 1.6 days after acute myocardial infarction.[71] In a study of 225 patients who had symptomatic

HF, E/E′ predicted mortality, transplantation, and hospitalization for HF and was incremental to deceleration time and ejection fraction.[72]

### *Color M-Mode Doppler*

During isovolumic relaxation, the LV pressure drops without LV filling. The time constant of LV pressure decline (τ) is an index of LV relaxation that is relatively independent of heart rate and preload. After mitral valve opening, LV filling occurs with variable LV pressures (auxotonic relaxation). Measurements made during auxotonic relaxation are determined both by active relaxation and passive chamber stiffness, with the latter becoming increasingly important toward the end of ventricular filling.[73] The active processes during early diastole lead to a rapid LV pressure drop during isovolumic relaxation and fast active filling at low pressures during early auxotonic relaxation. As early as the 1930s, normal ventricular relaxation was thought to result in "active suction" of the blood into the LV. However, only in the early 1980s, the presence of diastolic intraventricular pressure gradients were confirmed.[74-76] The gradients between the ventricular base (mitral valve) and apex were suggested to exert a suction effect ("recoil"). It was later demonstrated that these gradients were diminished by ischemia and related to systolic function.[76] With the demonstration of intraventricular pressure gradients during early diastole in filling and in nonfilling heartbeats, their potential role as an index for isovolumic and early auxotonic ventricular relaxation was established.[77] Because pressure gradients in fluids imply fluid acceleration and fluid currents, a noninvasive index of fluid acceleration would, in theory, reflect these intraventricular pressure gradients. The color M-mode velocity propagation index (Vp) can potentially fulfill this promise.

#### Acquisition of Color M-Mode Images

Color M-mode Doppler is a pulsed Doppler technique in which mean velocities are color encoded and displayed in time (on the horizontal axis) and depth along the entire scan line (on the vertical axis). Acquisition is made in the four-chamber view. To visualize the direction of the inflowing blood, a large color box is placed from the mitral valve to the apex. The scan line should ideally go through the center of the mitral valve and along the central part of the blood column.[78,79] Switching to M-mode and with the chart recorder set at a sweep rate of 100 mm/s, an M-mode spatial-temporal velocity map with the shape of a flame is displayed (see Fig. 11-5). By digital processing, for each pixel of the displayed color M-mode map, time, depth, and numerical velocity can be determined. The Euler equation enables the calculation of instantaneous pressure gradients along the inflow tract in a noninvasive way; however, it is too cumbersome for routine practice.[79] Therefore, for clinical practice, the spatial-temporal velocity information is expressed as distance-to-time ratios (cm/s) and is known as the flow propagation velocity because it has the dimensions of velocity and it has been interpreted as the distance the flow-wave (E-wave) propagates into the LV as a function of time. The following techniques have been proposed for determining flow propagation velocity: (1) Stugaard and colleagues[80] measured the time delay between onset of maximal flow velocity at the mitral valve tips and at 3.7 cm toward the apex. This technique requires offline postprocessing using dedicated software to decode the color of each pixel into numerical values. It depends on two individual pixels, and the reliance on accurate measurement of apical flow constitutes its primary limitation.[81] (2) Brun and colleagues[82] measured slopes of the isovelocity lines formed by transition of no color to color (black to red). The technique was later modified by Garcia and colleagues,[83] who traced the slope of the first "aliasing" velocity (red to blue) from the mitral valve plane to 4 cm distal in the LV (Vp in cm/s) (see Fig. 11-10, later). The latter technique only requires online adaptation of the Nyquist range limit or baseline to obtain aliasing. Both techniques rely on a large number of pixels, and the measurements can be performed online. (3) The Takatsuji method of flow propagation velocity calculation depends on offline, progressive scaling down of the Nyquist range by specific software. The slope between the site of the highest velocity at the mitral valve connected with the point in which aliasing becomes apparent when the Nyquist range is further scaled down by 30% (regardless of the depth of this point) is defined as Vp (Fig. 11-9).[84]

#### Flow Propagation Velocity and Hemodynamics

It has been demonstrated that despite worsening relaxation, E wave increases as a result of increasing filling pressures (pseudonormalization), but Vp does not rise.[84] This indirectly suggests preload independence. In invasive canine studies, significant preload alteration[80,85] did not induce significant change in propagation velocity. Recently, preload independence has also been demonstrated in human patients with and without LV systolic dysfunction.[85,86] There is an inverse relationship between Vp and the isovolumetric time constant of relaxation (τ). In dogs, Stugaard and colleagues showed a significant reduction of Vp in parallel with an increase in τ during induction of diastolic failure with regional[80] or global ischemia and with high-dose propranolol.[87] Similar highly significant correlations between Vp and changes in τ during esmolol and dobutamine infusion were obtained in dogs by Garcia and colleagues.[85] Invasive studies in humans also show a consistent high inverse correlation between tau and the propagation rate Vp. Takatsuji and colleagues[84] found a strong inverse relation in 40 patients undergoing cardiac catheterization ($r = -0.82$; $P$ less than

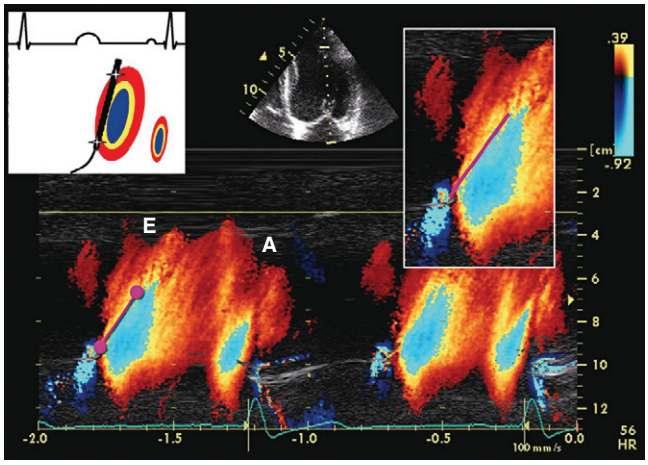

**Figure 11-9** Example of color M-mode of LV inflow propagation velocity (Vp). Measure Vp from the intersection of the anterior mitral valve leaflet M-mode extending along the first edge of uniform color or aliasing velocity approximately 4 cm into the left ventricle. Schematic diagram (*upper left* corner) represents color M-mode measurement of inflow propagation. *A*, Late filling or atrial contribution; *E*, early filling. *(Adapted from Morehead AJ: Sonographer's perspective of evaluating diastolic function. In Klein AL, Garcia MJ, editors:* Diastology: clinical approach to diastolic heart failure. *Philadelphia, 2008, Saunders, pp 215-229).*

0.001), similar to values reported by Garcia and colleagues ($r = -0.86$; $P$ less than 0.001),[83] and Brun and colleagues ($r = -0.73$; $P$ less than 0.0001).[82]

### Clinical Use of Color M-Mode Doppler

In normal adults, little loss in blood velocity occurs between the basal ventricle and the apical region. The color M-mode flame appears at the apical region before early flow at the mitral valve level has stopped. The slope of the displayed filling wave is relatively steep. With impaired relaxation, the slope of the first filling wave is less steep; velocity loss makes the maximal velocities reside at the level of the mitral tips, and they mostly do not reach the apical region. With further reduction in diastolic relaxation and elevation of filling pressures as a result of reduced compliance, the slope of the early filling wave will stay reduced; the wave usually gets blurry as a result of low flow velocities in the apical region, which can continue after early mitral inflow has stopped or even after mitral valve closure. Brun and colleagues[82] have been the first to show that velocity propagation is related to wall relaxation. The progressive decrease of Vp runs in parallel with the increase of the isovolumic relaxation constant $\tau$, irrespective of rising filling pressures.[84] Nishihara and colleagues[88] have confirmed that the strong correlation between $\tau$ and Vp is also valid in HCM. Using his acquisition method, Garcia and colleagues[89] have proposed a cutoff value of 55 cm/s and 45 cm/s to define impaired relaxation in young and middle-aged adults, respectively.

### Estimation of Filling Pressures and Prognosis

Combined indices of 1/Vp, as a preload-independent surrogate for $\tau$, with preload and relaxation-dependent mitral inflow parameters, provide close prediction of mean PCWP.[83,86,90,91] PCWP can be predicted accurately using a combination of IVRT and Vp with an r-value of 0.89 ($P$ less than 0.0001), and the regression equation: $PCWP = 4.5 \times (10^3/[\{2 \times IVRT\} + Vp]) - 9$ (in mm Hg, 1 SEE = 3.3).[90] Reported positive and negative predictive values for $(10^3/[\{2 \times IVRT\} + Vp])$ greater than 5.5 to predict PCWP greater than 15 are 100% and 94%, respectively.[90] However, E/Vp is the most widely used index. In a heterogeneous group comprising normal, ischemic, hypertrophic, and dilated hearts, PCWP was calculated as follows: $PCWP = [5.27 \times E/Vp] + 4.6$ (in mm Hg, SEE = 3.1) ($r = 0.80$, $P$ less than 0.001).[83] Reported positive and negative predictive values for E/Vp greater than 1.5 to predict PCWP greater than 12 mm Hg are 93% and 70%, respectively.[86] Correlation between E/Vp and PCWP outperforms correlations with maximal E ($r = 0.62$) and E/A ($r = 0.52$), independent of ejection fraction. Nagueh and colleagues[61,92] have confirmed that the same formula is valid in HCM. The E/Vp ratio has also been applied to assess filling pressures in atrial fibrillation with reasonable accuracy: averaged over three heartbeats, E/Vp yields a 100% specificity and 72% sensitivity in predicting a PCWP greater than 15 mm Hg.[93] It favorably corresponds to NYHA-class and elevated values of brain natriuretic peptide in this group.[94]

### Limitations of Vp as a Preload Independent Index for Relaxation

Reliability and reproducibility of the three different acquisition and reading methods constitute a major limitation for the application of Vp. In a direct comparison of the three methods, large differences in obtained numerical values and in interobserver and intraobserver reproducibility of Vp were generated.[81] The method described by Garcia and colleagues[83] is advocated because of the acceptable and superior reproducibility compared to the other methods.[81] Reported intraobserver and interobserver variability varies from less than 10%; in the lower (pathologic) ranges of Vp and up to 20% in the "higher" (normal) range of Vp and for TEE acquisitions.[83,85,90,93] Moreover, it does not require dedicated software and therefore is the most feasible technique for rapid, online measurements.

All conditions associated with altered intraventricular flow patterns giving rise to significant turbulence or significant local pressure gradient formation constitute a limitation to the application of the technique: significant aortic regurgitation, mitral stenosis, artificial mitral valves, and intracavity obstructions. Merging of early and late inflow as a result of tachycardia or atrioventricular conduction delay could lead to erroneous measurements. Marked variations on both transmitral inflow and Vp recordings can be seen during atrial fibrillation and in some patients during respiration. In these patients, it should be recommended to average more than three cardiac cycles.

## LA VOLUME INDEX

The measurement of LA volume is highly feasible and reliable in most echocardiograms, with the most accurate measurements obtained from the apical four-chamber and two-chamber views.[95] This measurement is very relevant clinically, as there is a significant relationship between LA volume and echocardiographic indexes of diastolic function.[96] The E/E′ ratio is a reflection of the filling pressures at the time of the examination. In contrast, the LA volume is a reflection of the cumulative effects of filling pressures over time. Some echocardiographers have compared the LA volume in diastology with the hemoglobin A1c of diabetology. Observational studies including 6657 patients without history of atrial fibrillation or valvular heart disease have shown that an LA volume index of 34 $nL/m^2$ or greater is an independent predictor of death, HF, atrial fibrillation, and ischemic stroke.[97] However, it is important to recognize that a dilated LA may be seen in athletes and in patients with bradycardia and four-chamber enlargement, anemia, and other high-output states; atrial flutter or fibrillation; and significant mitral valve disease, in the absence of cardiovascular disease.[67] Normal values of the left atrial volume index (LA volume/BSA) are shown in Table 11-4.

## STRAIN IMAGING IN EVALUATION OF DIASTOLIC FUNCTION

### *Assessment of Diastolic Function by Strain Echocardiography*

One advantage of the new ultrasound deformation strain indices for the study of diastolic events is that they offer high real-time temporal resolution of deformation (sampling rates greater than 200 frames/s) compared with other noninvasive imaging modalities (Fig. 11-10). This is important when studying diastole, because high-amplitude, short-lived deformations occur during this time period.[98,99] SR imaging has shown the normal sequence of regional changes in deformation during diastole to be complex.[98] Regional lengthening begins in the midinferior septal segment, might happen before aortic valve closure, and may have propagated to the apex by the time of mitral valve opening. The basal segments are the last to start to lengthen in early diastole. Their lengthening is associated with the onset of flow into the LV. On the other hand, in the free walls, changes in deformation are more

Both amplitude and timing of mechanical events can be used to assess regional function by SR imaging. SR tracing (*upper*): *1*, Peak systolic SR; *2*, peak early diastolic SR; *3*, peak late diastolic SR; *6*, time to peak systolic SR. Strain tracing (*middle*) is obtained by integrating the SR signal. This procedure is automatic in most custom or commercially available analysis packages. *4*, Peak systolic strain; *5*, time to peak. *7*, SR signal showing low systolic SR but presence of postsystolic SR (*lower*). Schematic illustrating concept of strain and SR (*right*). Strain (ε) is change in length normalized to initial length of muscle (*upper right*). Thus, decrease in length (such as occurring in muscle contraction) would result in negative strain, increase in length (muscle relaxation) would result in positive strain, and rate at which length changes occur would be SR. *(From Yip G, Abraham T, Belohlavek M, Khandheria BK:* J Am Soc Echocardiogr *16[12]:1334-1342, 2003.)*

variable. After the cessation of early lengthening as a result of early filling, there is a reverse lengthening wave caused by passive recoil, which starts at the apex and spreads toward the base. During diastasis there are usually no measurable changes in deformation. Diastasis is followed by a base-apex wave of lengthening that is caused by atrial filling of the ventricle. This normal pattern may be markedly altered in disease. However, in describing regional deformation changes during filling, not only must regional radial and longitudinal deformation be examined, but also an attempt should be made to resolve regional twisting/untwisting occurring during IVRT. To do this, circumferential shear strain must be measured. Circumferential radial shear strain can be shown to be abnormal in diseased segments. Diastolic strain rate measurements that comprise all LV segments are advantageous over myocardial velocities for the assessment of diastolic function. The ratio of mitral early diastolic velocity (E) to strain rate during the isovolumic relaxation (SRivr) can be used to estimate LV filling pressures. Wang and collaborators used these parameters in the evaluation of 50 patients with simultaneous right heart catheterization and echocardiographic imaging. Mitral E/SRivr ratio had the best correlation with mean wedge pressure. E/SRivr was most useful in patients with an E/E′ ratio of 8 to 15 and was more accurate than E/E′ in patients with normal ejection fraction and evidence of regional LV dysfunction.[100]

### Left Atrial Strain

Analogous to assessing LV mechanics by strain (ε) and strain rate (SR) imaging, measures of myocardial deformation have been increasingly adapted to study LA mechanics. Both echocardiographic methods of measuring strain and SR, color TDI,[101-104] and 2D speckle tracking imaging[105-108] have been adapted to the measurement of LA deformation. In both methods, different measures of myocardial deformation, tissue velocity (V), strain ε, and strain rate SR can be derived at the three respective phases of the LA phasic cycle (conduit, reservoir, and contractile phases). The advantage of analyzing LA myocardial mechanics with strain and SR imaging is the insight that can be obtained about each component of LA phasic function. One could use this method to resolve the exact change in LA phasic function with different disease states and investigate the effect after treatment. Research in this field remains sparse but shows promise. The reasons for the transition from asymptomatic diastolic dysfunction to symptomatic diastolic HF are not fully understood. A recent study has drawn attention to the presence of a lower atrial contractile reserve in patients with diastolic HF.[109] Kurt and colleagues[110] concluded in their study that LA strain La(ε) is significantly reduced and that LA stiffness is the most accurate index in identifying patients with diastolic HF.

## TORSION ECHOCARDIOGRAPHY

LV torsion (or twist) plays an important role with respect to LV ejection and filling.[111] During the cardiac cycle, there is a systolic twist, followed by an early diastolic untwist of the LV over its long axis due to oppositely directed apical and basal rotations. As viewed from the LV apex, the base of the heart rotates clockwise, while the apex rotates in a counterclockwise direction. LV rotation is sensitive to changes in both regional and global LV function.[112-114] Therefore, assessment of LV rotation represents an interesting approach for quantifying global LV function during systole and diastole. Historically, magnetic resonance imaging (MRI) tagging was the first clinically available method,[114,115] and as a result, implementation of the evaluation of LV torsion was limited by the complexity and cost of the technique.

Speckle tracking imaging (STI) has provided the possibility of evaluating the deformation mechanics of the myocardial fibers during the different parts of the cardiac cycle[116] (see Chapter 10). This non-Doppler assessment of cardiac mechanics could rival MRI or TDI in measuring LV torsion and may prove more versatile in assessing patients in clinical and research settings. Motion analysis by speckle tracking has been attempted using block matching and autocorrelation search algorithms.[117] Speckle motion has been closely linked to underlying tissue motion when small displacements are involved. On the basis of this displacement estimation technique, LV rotation (angle displacement about the central axis of LV in the short-axis view) for assessment of LV torsion can be measured.[72]

### Validation of Torsion Calculated by Speckle Tracking

The accuracy and consistency of speckle tracking imaging method for LV torsion measurement was assessed in comparison with tagged MRI and TDI in 15 patients.[117,118] LV torsion was defined as the net difference of LV rotation at the basal and apical planes. Data on 13 of 15 patients could be used to perform speckle tracking analysis. The LV torsion profiles estimated by STI strongly correlated with those obtained by tagged MRI. The STI torsional velocity profiles also correlated well with those obtained by the TDI method.

In another study, apical and basal rotation by speckle tracking was measured from short-axis images by automatic frame-to-frame tracking of gray-scale speckle patterns in mongrel dogs and healthy humans and compared to sonomicrometry (dogs) and MRI (humans).[119,120] In dogs, the mean peak apical rotation was $-3.7 \pm 1.2°$ and $-4.1 \pm 1.2°$, and basal rotation was $1.9 \pm 1.5°$ and $2.0 \pm 1.2°$ by sonomicrometry and speckle tracking, respectively. Apical rotation by both methods decreased during left anterior descending coronary artery occlusion ($P$ less than 0.007), whereas basal rotation was unchanged. In healthy humans, apical rotation was $-11.6 \pm 3.8°$ and $-10.9 \pm 3.3°$, and basal rotation was $4.8 \pm 1.7°$ and $4.6 \pm 1.3°$ by MRI tagging and speckle tracking echocardiography, respectively. Torsion measurement by speckle tracking echocardiography showed good correlation and agreement with sonomicrometry ($r = 0.94$; $P$ less than 0.001) and MRI ($r = 0.85$; $P$ less than 0.001).

### Left Ventricular Untwisting Rate by Speckle Tracking Echocardiography

As mentioned previously, LV filling results from the positive early diastolic transmitral pressure gradient and depends on both the LV pressure drop during isovolumic relaxation and the LA driving pressure.[65,100] The rapid decline in LV pressure during this phase is caused by active myocardial relaxation and LV elastic recoil. LV elastic recoil/untwisting generates the suction force for LV filling. Accordingly, LV untwisting rate may provide an additional noninvasive insight into LV diastolic dysfunction. Previous work with MRI in an animal model, has shown that LV untwisting rate correlates closely with the time constant of LV relaxation.[121]

In a recent study, Wang and collaborators[122] conducted a study evaluated 67 patients with simultaneous right heart catheterization and echocardiographic imaging. Patients with LV systolic dysfunction had a significantly lower untwisting rate, in comparison with the control group, and the patients with normal ejection fraction. The determinants for untwisting rate were twist, end-systolic volume (ESV), and τ. In patients with diastolic dysfunction and normal ejection fraction, twist and ESV were the independent predictors. A recent study by the same group[123] showed that the untwisting rate calculation method that best reflects LV relaxation is the peak negative time derivative of twist during early diastole.

### Comprehensive Integration of Systolic and Diastolic Mechanics

Wang and colleagues[124] examined myocardial deformation and rotation in patients with HF aiming at elucidating the mechanisms that account for normal ejection fraction in patients with diastolic HF. LV longitudinal and radial strains are reduced, but circumferential deformation and twist are normal in diastolic HF patients. On the other hand, in patients with systolic HF, longitudinal, radial, circumferential, and twist are all reduced. Multivariate regression analysis suggests that preserved LV twist and circumferential strain may contribute to normal ejection fraction, in patients with diastolic HF.[124]

### NEW ASE/EAE GUIDELINES

In 2009, Nagueh and colleagues[3] published recommendations for the evaluation of LV diastolic function by echocardiography, which represents a big leap forward in the field. The guidelines present an organized approach for grading the degree of diastolic dysfunction, and for calculation of filling pressures in the patient with normal or depressed systolic function. Using the guidelines, the first step is to grade the diastolic dysfunction. The grading scheme is mild or grade 1 (impaired relaxation pattern), moderate or grade 2 (pseudonormal), and severe or grade 3 (restrictive pattern) (Fig. 11-11). The next step is the estimation of LA pressures, which can be accomplished by following the algorithms provided depending on the systolic function of the patient (normal or depressed) (Figs. 11-12 and 11-13, respectively). When grading the degree of diastolic dysfunction, it is important to realize that patients would not necessarily fulfill all the criteria mentioned in a given grade. In these situations, judgment must be exercised as to what is the grade that best characterizes the patient, after carefully evaluating and balancing the parameters obtained and the predominance of the criteria during the comprehensive evaluation of the patient.

## Clinical Utility of Diastolic Function Assessment

The clinical utility of echocardiographic assessment of diastolic function in specific diseases is discussed in this section.

### MYOCARDIAL DISEASES

#### *Dilated Cardiomyopathy*

Dilated cardiomyopathy manifests with a multitude of diastolic filling patterns. Differences in diastolic function may explain differences in clinical symptoms between patients with similar degrees of systolic dysfunction. When systolic dysfunction is

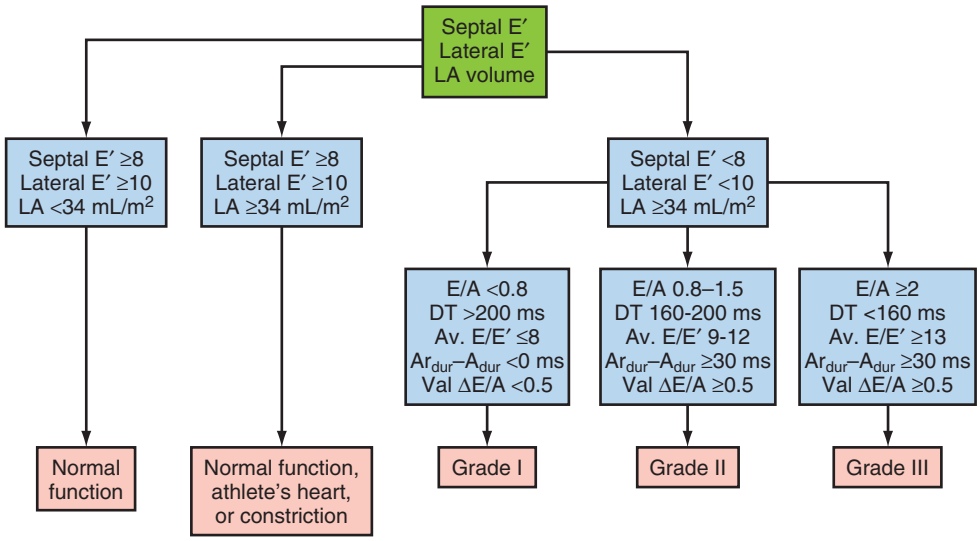

**Figure 11-11** Scheme for grading diastolic dysfunction. *Av.*, Average; *Val*, Valsalva. *(Adapted from: Nagueh SF, Appleton CP, Gillebert TC, et al: Recommendations for the evaluation of left ventricular diastolic function by echocardiography.* J Am Soc Echocardiogr *22:107-133, 2009.)*

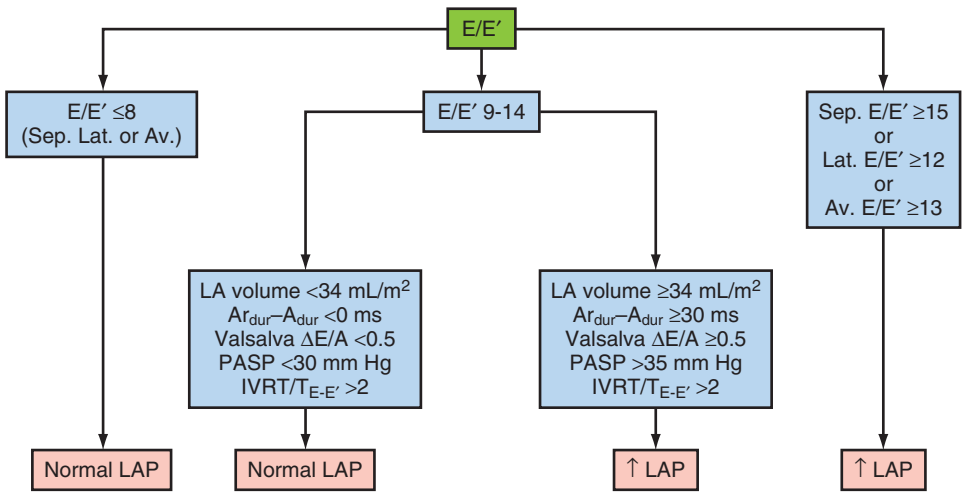

**Figure 11-12** Diagnostic algorithm for the estimation of LV filling pressures in patients with normal ejection fraction. *Av*, Average; *LAP*, left atrial pressure; *Lat*, lateral; *PASP*, pulmonary artery systolic pressure; *Sep*, septal. *(Adapted from Nagueh SF, Appleton CP, Gillebert TC, et al: Recommendations for the evaluation of left ventricular diastolic function by echocardiography.* J Am Soc Echocardiogr *22:107-133, 2009.)*

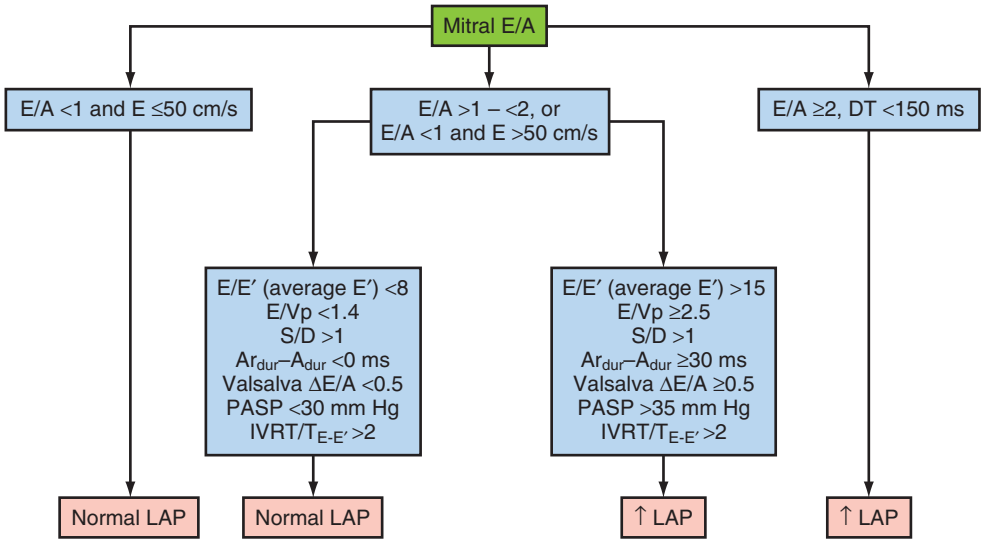

**Figure 11-13** Diagnostic algorithm for the estimation of pressures in patients with depressed ejection fraction. *(Adapted from Nagueh SF, Appleton CP, Gillebert TC, et al: Recommendations for the evaluation of left ventricular diastolic function by echocardiography. J Am Soc Echocardiogr 22:107-133, 2009.)*

present, the elevated ESV results in a shift along the pressure-volume curve to a steeper segment. This means that for a given diastolic pressure-volume relationship, compliance is reduced at higher LV volumes. Thus, the expected pattern of diastolic filling in advanced dilated cardiomyopathy is that of reduced compliance: a high E velocity, rapid deceleration slope, low A velocity, and E/A ratio greater than 1 (stage 3).

### *Amyloidosis*

Cardiac amyloidosis is associated with abnormal LV and RV diastolic function (see Chapter 28). As the disease process worsens following impaired relaxation, there is worsening of compliance, resulting in pseudonormal and restrictive patterns associated with a progressive decrease in compliance with progressive deposition of amyloid fibrils in the myocardium.[125] The prognosis of cardiac amyloidosis is generally poor, but it depends on the type of disease, with AL (primary) amyloidosis having the worst prognosis.[126] In a serial study of more than 800 patients with primary amyloidosis over a 10-year period, the median survival was 2.1 years, and less than 6 months once congestive HF had occurred.[127] Mean LV wall thickness and LV impairment have been suggested as useful variables in the assessment of cardiac involvement and prognosis. In a study of 132 patients with biopsy-proven amyloidosis, those with a wall thickness of 15 mm or greater had a median survival of 0.4 years compared with 2.4 years for those with a mean wall thickness of greater than12 mm but less than 15 mm.[128] There are associated abnormalities of RV diastolic function.[49] In patients with RV free wall thickness of less than 7 mm, there is abnormal relaxation, and when the RV wall is greater than 7 mm in thickness, restrictive physiology is present. Doppler echocardiography has also been shown to be useful in the prognostic stratification of patients with amyloidosis. Patients with a DT of the mitral early filling wave at baseline study of 150 ms or less had a significantly reduced survival compared to those whose DT was greater than 150 ms.[129] (Fig. 11-14) A Doppler index combining systolic and diastolic performance (Tei index) has shown significant prognostic importance in cardiac amyloidosis.[130] RV enlargement has also been identified as an independent predictor of poor outcomes among patients with primary amyloidosis.[131] Newer diagnostic tools, including strain and SR imaging, have been used to characterize patients with cardiac amyloidosis before the onset of congestive symptoms and with preserved LV function and tissue Doppler velocities.[132] Among patients with AL amyloidosis, the mean basal strain, a measure of longitudinal LV function, was a powerful predictor of outcome and was superior to standard 2D echocardiography, Doppler flow measurements, and simple tissue Doppler velocity indexes.[133]

### *Hypertrophic Cardiomyopathy*

Patients with HCM often have a pattern of LV diastolic filling consistent with impaired relaxation. (See Chapter 27.) Some studies have suggested that Doppler evaluation of LV diastolic filling can be used to assess the effects of medical therapy (e.g., beta-blockers or calcium channel blockers) on diastolic function in this disease.

SR imaging indices have been shown to be better than regional velocity profile data in detecting regional abnormalities in patients with asymmetric septal hypertrophy and in discriminating HCM from physiologic hypertrophy. SR imaging has also been shown to be better than either gray-scale M-mode or velocity data either in detecting changes in regional function after septal ablation[134] or in detecting the regression of hypertrophy after antioxidant treatment for HCM.

## HYPERTENSION AND HYPERTENSIVE HEART DISEASE

In left ventricular hypertrophy, the predominant abnormality is impaired relaxation, resulting in a pattern of reduced early diastolic filling and an enhanced atrial contribution to filling. The Doppler velocity curve typically shows a prolonged IVRT, reduced acceleration to a reduced E velocity, prolonged early diastolic deceleration slope, an increased A velocity, and an E/A ratio less than 1. When LV systolic dysfunction supervenes, the elevated LV end-diastolic pressure and elevated LA pressure may result in pseudonormalization of this pattern with an enhanced E velocity (related to a higher mitral valve opening gradient) and reduced A velocity (resulting from the elevated LV end-diastolic pressure).

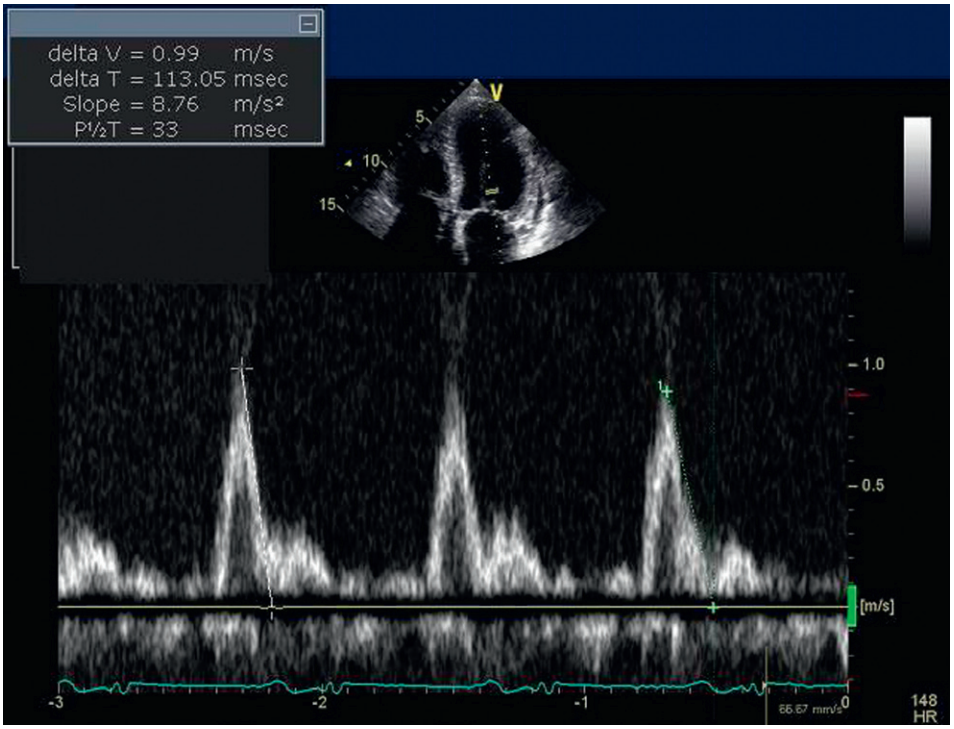

**Figure 11-14 Survival Curves in Cardiac etc.** Survival in 63 patients with cardiac amyloidosis subdivided on the basis of the deceleration time (DT) of 150 msec. Patients with a shortened deceleration time of less than 150 msec (*blue line*) had significantly reduced survival compared with patients with a deceleration time of greater than 150 msec. (*From Klein AL, Hatle LK, Taliercio CP, et al:* Circulation *83:808-816, 1991.*)

TDI has been demonstrated as a better discriminator between normal controls and patients with primary or secondary LV hypertrophy with a decrease in E′ and in ratio E′/A′ and with a prolonged time from the electrocardiogram Q wave to the onset of E′ in pathologic groups.[58] Differences in the onset of diastolic myocardial velocity waves between the different myocardial components of the cardiac base have been reported in both primary and secondary LV hypertrophy.[135] The etiology of LV volume overload leading to LV hypertrophy may result in different TDI velocity patterns.[135] Abe and colleagues[135a] have reported lower E′ and prolonged time to E′ onset in patients with chronic aortic regurgitation when compared with those with mitral regurgitation. Myocardial early diastolic velocities have been demonstrated to decrease with age.[135,136] However, it has been shown that the difference between normal controls and patients with LV hypertrophy remained significant even after accounting for age.[136]

Recently, strain imaging has been shown to differentiate between control subjects and patients with hypertension and among patients with hypertension, to differentiate between those with and without diastolic dysfunction.[137]

## ISCHEMIC CARDIAC DISEASE

In patients with coronary artery disease and no prior myocardial infarction, induction of ischemia results in diastolic dysfunction before systolic dysfunction. Diastolic filling curves with ischemia induced by balloon inflation during percutaneous transluminal angioplasty show rapid onset of a reduced E velocity, with resolution of these changes as ischemia is relieved. In acute myocardial infarction, a pattern of delayed relaxation is seen acutely. At follow-up, one of several patterns of LV filling may be observed. With successful reperfusion and little myocardial damage, LV diastolic filling returns to normal. With an infarction but preserved LV systolic function, the pattern of impaired relaxation often persists. (See Chapter 14.) With a large infarction and significant LV systolic dysfunction, the pseudonormalized pattern of high E velocity and low A velocity as a result of a combination of reduced compliance, a high LV end-diastolic pressure, and a shift along the diastolic pressure volume curve (increased ESV) can be seen.

Many patients with ischemic heart disease demonstrate abnormal diastolic function recorded by pulsed Doppler TDI despite having normal systolic function.[55] Recent studies have also shown a reduced E′ and E′/A′ ratio in ischemic or infarcted segments.[138,138a] One study also showed that the number of segments with abnormal E′/A′ ratio was higher in ischemic patients with a decreased transmitral Doppler E/A ratio compared with those with a normal transmitral E/A ratio. Recording diastolic TDI has also been shown to be a sensitive method for detecting transient myocardial ischemia—for example, during inflation of an angioplasty balloon.[139,140]

## PERICARDIAL DISEASE

With both pericardial tamponade and pericardial constriction, cardiac filling is impaired by pericardial extrinsic constraint, and there is marked reciprocal respiratory variation of LV and RV filling. In the case of tamponade physiology, filling is impaired in both early and late diastole. With constrictive pericarditis, early diastolic filling tends to be normal, with marked impairment of filling late in diastole when the heart has expanded to the maximum allowed by the fibrotic pericardial encasement. TDI is useful in separating restrictive from constrictive physiology (see Chapters 28 and 29).

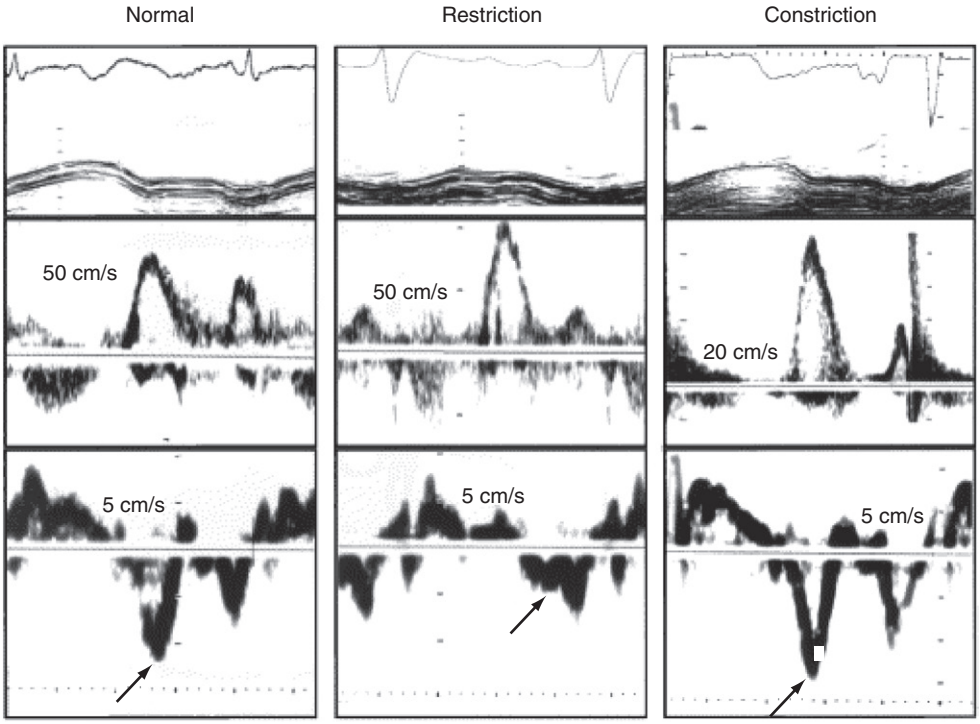

**Figure 11-15** Representative samples of the mitral annular M-mode tracings, tissue Doppler imaging velocities in the longitudinal axis, and transmitral Doppler flow velocities in a normal volunteer, a patient with restrictive cardiomyopathy, and a patient with constrictive pericarditis. A marked difference in early diastolic longitudinal axis velocities, despite similar early transmitral flow velocities, is appreciated. *(Adapted from Garcia MJ, Thomas JD, Klein AL: New Doppler echocardiographic applications for the study of diastolic function.* J Am Coll Cardiol *32[4]:865-875, 1998.)*

## RESTRICTIVE VERSUS CONSTRICTIVE PHYSIOLOGY

Hearts encased with the constrictive process have normal or enhanced relaxation (thus increased E′ velocity and color M-mode slope) and could fill mainly in a longitudinal fashion. In contrast, hearts with restrictive diseases showed marked impairment of relaxation due to the myopathic process and had decreased E′ velocities and decreased annular E′ velocities.[141] As a result E′ can also be used to distinguish between restrictive and constrictive physiology[142] (Fig. 11-15). It has been demonstrated that E′ measured by pulsed Doppler at the level of the lateral part of the mitral annulus was significantly lower in 7 patients with restrictive cardiomyopathy than in 15 normal subjects and 8 patients with constrictive pericarditis. In another study, abnormal pulsed TDI velocity pattern was reported in 12 patients with constrictive pericarditis versus a group of 20 normal subjects.[143] A cutoff of E′ of 8 cm/s or greater was useful in separating constrictive pericarditis from restriction in another study.[144]

Reuss and coworkers found that in control patients mitral lateral E′ velocity is 25% higher than the septal one. Whereas in constrictive pericarditis, averaged lateral E′ velocity was 2% lower than septal E′ velocity. This reversal of the relationship between the velocities is called annulus reversus.[145]

Recently, Choi and colleagues performed a study comparing E′ of the septal annulus (sE′), lateral mitral annulus (lE′), and right lateral tricuspid annulus (rlE′) in patients with constrictive pericarditis and restrictive cardiomyopathy. They concluded that the ratio between lateral and septal E′ is significantly reduced in constrictive pericarditis compared to normal controls and restrictive cardiomyopathy. The reduced lE′/sE′ , and rE′/sE′ appear to be useful diagnostic parameters for the diagnosis of constrictive pericarditis. Moreover, reduced lE′ is correlated with pericardial thickness on the respective side.[146]

However, E/E′ fails to characterize the filling pressure in this group of patients, a phenomenon called annulus paradoxus. There is an inverse relationship between E/E' and LV filling pressure.[147]

## KEY POINTS

- Diastolic HF is as common as systolic HF and is associated with significant morbidity and mortality.
- The major parameters of diastolic function include active myocardial relaxation, LV compliance, LA function, pulmonary vein flow, mitral valve characteristics, and heart rate.
- Echocardiographic techniques for evaluation of diastolic function include mitral inflow, pulmonary venous flow, tissue Doppler imaging, and color M-mode Doppler and LA volume index.
- For patients with diastolic dysfunction, four abnormal filling patterns are recognized: stage 1 (mild) or abnormal relaxation, stage 2 (moderate) or pseudonormal, stage 3 (severe) or restrictive, and stage 4 (severe) or irreversible restrictive.

## KEY POINTS—cont'd

- TDI and color M-mode Doppler evaluation of LV diastolic filling are less preload dependent than mitral inflow or PV flow.
- The ratio of peak early mitral inflow velocity divided by TDI early diastolic mitral annular velocity (E/E′) correlates with PCWP. Similarly, the ratio of peak early mitral inflow velocity divided by color M-mode flow propagation (E/Vp) correlates with PCWP.
- An E/E′ ratio greater than 15 or E/Vp greater than 1.5 suggests elevated LV filling pressures.
- Mitral inflow and PV flow can adequately assess LV filling pressures in patients with systolic HF. TDI and color M-mode are needed when there is primary diastolic HF (with a normal ejection fraction).
- A short mitral inflow DT is associated with a poor prognosis in most diseases, except for hypertrophic cardiomyopathy.
- Strain and strain rate (SR) are measures of myocardial mechanical properties. Myocardial strain is a dimensionless index of change in myocardial length in response to an applied force and is expressed as fractional or percentage of change. SR is the time derivative of strain with unit of per second ($s^{-1}$).

Intelligent Ultrasound Systems

Digital image processing techniques nowadays can be found in any ultrasound machine or offline analysis system. Moreover, ultrasound systems have evolved into fully digital, computerized systems. Digital image storage and digital processing of echocardiographic images, both for image enhancement and for analysis, have become standard techniques. Several automated image analysis tools are commercially available for two-dimensional (2D) and three-dimensional (3D) echocardiographic data, and more advanced automated analysis techniques are appearing rapidly.

Such automated approaches include automated structure localization, automated border detection (ABD) techniques, tissue tracking, and tissue/function classification or computer-aided diagnosis. Automated analyses can potentially supply the echocardiologist with quantitative and more objective tools for research and clinical practice. However, ultrasound is a difficult imaging modality for interpretation, for both humans and machines. In this chapter, we want to provide the clinician with an overview of available tools, some insight into the background of different techniques with their possibilities and limitations, and some practical guidelines for the choice and use of techniques. We concentrate on ABD.

## Digital Image Processing and Automated Analysis: Definition and Motivation

*Digital image processing* concerns manipulation of images by a computer. More specifically, it refers to enhancement or analysis of images. *Image enhancement* aims at improvement of images, for visual interpretation or for further automated analysis. This can range from a simple contrast adjustment to sophisticated filtering. *Image analysis* generally involves the derivation of some quantitative measures or parameters from images. In a narrower sense, this often refers to automatic localization and outlining (border detection) of certain structures, or to the tracking of the motion of such structures. In echocardiography, the left ventricular (LV) myocardium is of prime interest. Outlining of the LV endocardial border allows quantitative measurements of LV cavity area, shape, volume, and so on. Combination with the epicardial border allows calculation of wall thickening and LV mass. Tracking the motion of tissue or borders over the cardiac cycle allows the calculation of local wall displacement, velocity, relative shortening (strain), etc. Similar analyses may be applied to other structures such as the right ventricle (RV), atria, and valves.

In clinical practice, quantitative measurements are still underemployed: Visual estimation of parameters such as ejection fraction or semiquantitative classification (e.g., wall motion scoring for stress echocardiography) still plays a dominant role. Such *eyeballing* can be done fast, without much ado, and some experts reach an admirable accuracy. In general, however, it is inaccurate, irreproducible, subjective, and hard to learn.[1] Visual estimation of quantifiable measures should be discouraged for any purpose beyond a rough classification, whenever a quantitative alternative is present. Quantitative analysis is advisable when repetitive interpretations are done, when more subtle differences are sought, when interpretation experience is limited, and whenever scientific research is the goal.

The classic method of outlining the borders is *manual drawing*. Any ultrasound machine or offline analysis system has facilities for this, using a mouse or trackball. Manual drawing, however, is known to have high inter- and intraobserver variability; it is strenuous and time consuming for the operator and requires expertise and dexterity. Concerning consistency and workload, manual drawing is especially hard to perform practically when large sets of images are involved: for example,

analyzing one or more complete cardiac cycles, for several cross sections, and over multiple stages (as in stress echocardiography); or analyzing the hundreds of 2D frames in a full-cycle 3D data set. ABD can provide solutions to these problems. Moreover, if ABD can be performed fully automatically and fast, it allows real-time monitoring of clinical parameters.

Procedures such as stress echocardiography that currently rely on visual scoring of wall motion could benefit enormously from automated analysis; the lack of quantification and the large inter- and intraobserver and interinstitution variabilities[2] are perceived as important limitations. The potential of real-time 3D echocardiography for volume estimation and regional wall motion quantification also depends largely on automated analysis.

## Digital Image Storage, Communication, and Compression

### DIGITAL IMAGES

Inside any modern ultrasound system, images are created as *digital* images. The generation of the ultrasound images (ultrasound physics, signal processing, and instrumentation) is beyond the scope of this chapter. Excellent descriptions can be found in many handbooks.[3-5] Digital images consist of *pixels* whose brightness or color is represented by a numeric (digital) value. *Brightness level* is also referred to as *intensity* or *gray value*. A *cineloop* or movie is a sequence of such images, typically at a *frame rate* of 20 to 200 images per second. The digital representation makes it possible to store and process images in a computer—hence, digital image processing. Modern ultrasound systems are totally digitized and support the storage and communication of digital images and cineloops. For display on a monitor and recording on VCR, these digital images are converted into an analog video signal. The use of analog video output or VCR tape should be strongly discouraged for analysis purposes. Although it is possible to redigitize the analog video with devices such as frame grabbers, this results in severe, irreversible loss of information and image quality: spatial resolution, frame rate, and intensity accuracy will be degraded; separation among image, graphics, and color overlays is lost; and calibration and patient information disappears.

### STORAGE FORMATS AND IMAGE COMMUNICATION

#### *DICOM*

The method of choice for digital image storage and exchange is *DICOM* (Digital Imaging and Communications in Medicine[6]). DICOM is a generally accepted international standard for medical images of all modalities, including all types of ultrasound imaging. The DICOM standard (current version: 2009) is still being extended and improved to better support new developments in medical imaging. As its name implies, DICOM is a communication standard rather than a file format—it defines how medical imaging devices such as ultrasound systems, Picture Archiving and Communications Systems (PACS) servers, and printers communicate to transport, store, retrieve, find, or print images and associated patient information. All major manufacturers have committed themselves to support DICOM. Ultimately, this should lead to the integrated electronic patient record, which contains the full patient file, including patient history, laboratory reports, images of all modalities, and other information. Therefore, DICOM is a very complicated standard: the full description covers several thousand pages.[6] A very readable explanation of DICOM for echocardiographers is given by Thomas.[7]

Note that if a device is labeled "DICOM compliant," this does *not* mean that it will automatically work with every other DICOM device: DICOM defines a multitude of services and imaging modalities. For every device, a *DICOM Conformance Statement* defines precisely which services are supplied and supported for what modalities and to what extent. To verify interoperability between devices, their conformance statements should be compared—not a simple job for a novice in DICOM. In particular, interoperability between vendors is rather limited for ultrasound, because many essential parameters are stored in vendor-specific "private tags" that are not accessible to others. Also, there is as yet no standardized format for 3D data storage.

#### *General-Purpose Formats*

Other widely used *general-purpose image formats* such as BMP, TIF, GIF, and JPEG are often used for export of screen shots or single images for use in reports, presentations, and publications. For movies, AVI, MPEG, and QuickTime are popular formats. These general-purpose formats usually cannot store additional patient information and can lead to significant image quality degradation because of lossy compression (see later discussion). Therefore, they should not be used for primary image storage or archiving.

### IMAGE COMPRESSION

To reduce data storage requirements, *image compression* can be employed. *Lossless* compression techniques (such as run-length encoding [RLE], lossless JPEG) can reduce file sizes by a factor of 2 to 5, and uncompressing will produce a perfect copy of the original image. *Lossy* compression reaches much higher compression ratios (up to 20 to 100) by eliminating information for which the eye is least sensitive, at the cost of some irreversible image degradation. This degradation is acceptable visually (JPEG factor 20 has been found to produce no diagnostically significant degradation[8]) and is marginal compared to the degradation associated with VCR storage. However, the compression artifacts may certainly influence digital image processing and analysis. Severely lossy compression is not advisable for archiving or when digital image postprocessing is foreseen. Lossy compression techniques include lossy JPEG, fractal and wavelet compression, and MPEG. DICOM currently[6] supports RLE, JPEG (lossless and lossy), JPEG2000, and MPEG2 compression schemes.

## Medical Image Processing

Medical image processing is a thriving subdiscipline of digital image processing.[9,10] Several good handbooks on medical image processing, with special attention to ultrasound, are available.[11,12]

### IMAGE ENHANCEMENT: LEVEL MANIPULATIONS, FILTERING

Image enhancement deals with the improvement of images, either for visual interpretation or as a preprocessing for analysis. Image-enhancement techniques used by ultrasound machines and analysis programs are similar to those used by most

general-purpose image manipulating programs (such as photo editors). The simplest class of such operations includes *level manipulations* or *lookup-table operations*: these change the brightness level (or color or transparency) of each pixel without considering any neighboring pixels. The original brightness of the pixel is simply used to look up the new value in a conversion table. Lookup-table operations include *brightness level manipulations* and *pseudocoloring*. In 3D visualization, such operations are the main tools to control the appearance of the volume rendering, in terms of brightness, transparency, and surface extraction.

*Brightness level manipulations* include all one-to-one conversions of image brightness levels (input) to display brightness levels (output), either linear or nonlinear. Examples are digital contrast/brightness adjustments, image inversion, and gamma correction. Some examples are given in Figure 12-1. Note that many level manipulations may result in *clipping* (see Fig. 12-1, *C*, *D*, and *E*) and in reduction of the effectively used number of brightness levels. The extreme example is *thresholding* (see Fig. 12-1, *E*), in which all brightness levels above a threshold are set to white, and all below to black.

*Pseudocoloring* involves a direct conversion of brightness levels to a color scale, generally labeled with names such as Rainbow, Ocean, or Harvest. Because the eye is more sensitive to color differences than to intensities, this may reveal subtle intensity differences. It can be visually pleasing but may also be highly suggestive, as it clusters similar gray values into color groups. Because brightness levels in ultrasound are highly dependent on signal attenuation and local gain settings, the borders that are suggested visually by these colors have little practical significance.[13] Pseudocoloring is also sometimes applied to highlight brightness differences with respect to some baseline value (e.g., increase above the local brightness level in a baseline image) with a color (e.g., to visualize the arrival of contrast agents in perfusion imaging). This is an effective tool, but one should be aware that tissue motion may also induce a brightness change and show up as color.

*Filtering* entails image operations that consider pixels within their neighborhood and deal with the spatial or temporal aspects of the image. Filtering operations include smoothing (noise reduction), and sharpening (edge enhancement). Smoothing or low-pass filtering (e.g., uniform, Gaussian) is used in many ABD methods (see later discussion) to reduce the speckle noise and get more or less homogeneous regions; high-pass edge enhancing or detection filters (e.g., Sobel, Laplacian) are often used to find (candidate) border points. Note that most smoothing methods slightly change the positions of edges and differentiate poorly between noise and weak signals. High-pass filters tend to be very sensitive to noise. In general, filtering does not improve the appearance of ultrasonographic images without simultaneously removing valuable information. Smoothing and sharpening filters may be available on your 3D ultrasound machine for real-time use: keep the caveats just mentioned in mind when using this option.

**TABLE 12-1 Abstraction Level Hierarchy**

| *Level* | *General* | *Speech* | *Image* | *Cardiac* | *Associated Operations* |
|---|---|---|---|---|---|
| 0 | Raw data | Samples | Pixels | Pixels | Image generation |
| 1 | Features | Amplitude, frequency | Intensity, textures, gradients | Intensity, textures, gradients | Preprocessing, filtering, feature extraction |
| 2 | Structures | Phonemes | Edges, regions | Edges, regions | Linking, merging, matching, clustering |
| 3 | Objects | Words | World entities, borders, objects | Cardiac structures (lumen, endocardium valve) | Model relaxation, border finding, classification |
| 4 | Object sets | Sentences | Scene | Cardiac scene | Scene modeling, interobject relationships |
| 5 | Interpretation | Significance | Scene interpretation | Interpretation and diagnosis | High-level interpretation, expert systems, rules |

## IMAGE INTERPRETATION: THE INTERPRETATION PYRAMID

The interpretation of medical images is an extremely complicated task that is very hard to transfer into a computer. For us humans, vision is a natural task that we perform instantly and automatically. From the study of human perception however, we know that vision is anything but a simple, straightforward process. Think of the many well-known optical illusions: there is a lot of hidden interpretation going on. In the interpretation of images, several information abstraction levels can be distinguished. This is generally known as the *image interpretation pyramid* (Fig. 12-2). The levels of this pyramid give us more insight into the mechanisms of different automated techniques and their limitations. A good analogy is found in the interpretation of handwriting or spoken language. This analogy is described in Table 12-1. For interpretation of a written text, one has to know about the alphabet, spelling, vocabulary, syntax, and semantics, and ultimately about the subject of the text, the intentions of the source, and adornments such as humor, sarcasm, and metaphors. These last aspects are not about language—they refer to the real-world domain that the text is discussing. Interpretation is not a simple bottom-up process of combining letters into words into sentences into significance. Text can be fragmented; there are imperfections, such as misspellings and ambiguities, and missing domain knowledge that necessitate feedback between all levels, and even guessing, to come to a consistent interpretation.

### *Cardiac Image Interpretation*

In image interpretation, we have a similar hierarchy. At the base, we find the raw image information (pixels). Going up, we encounter image *features* such as local texture and gradients; *structures* such as regions (groups of adjacent pixels with similar properties) and edges (lines of sudden change, between regions); *objects* such as a square or a person; and a *scene*, such as a football match. At the top we have *significance*, such as finding out who's winning; this requires very specific knowledge of the behavior of players and audience, rules of play, and so on.

Interpretation of cardiac images is still more difficult, because it requires expert knowledge about the 3D anatomic structures in the heart, their dynamic behavior, pathology and anatomic variability between patients, and the intricacies of the imaging modality involved. This last point specifically is not to be underestimated for ultrasound. Furthermore, missing or ambiguous information, noise and artifacts, and higher-level knowledge of anatomy, physiology, and pathology are involved and necessitate feedback and interactions between levels.

Clearly, very different sorts of knowledge are applied at each level to come to a valid interpretation, and only the lower levels have to do with image properties: higher levels concern anatomical models of the heart, physiology, congenital or pathologic conditions, and so on. ABD systems generally have very limited knowledge at the higher interpretation levels and resolve this in one of three ways:

1. They use simplifying assumptions regarding the objects. For example, the LV is considered to be a dark, round object in the middle of the image; the endocardial contour is convex, the endocardium is the strongest edge in the image, and the cardiac wall will not move more than *x* pixels per frame. Most of such assumptions will hold only to some extent or are overly general.
2. They limit themselves to a subset of the problem domain, such as certain standard views (e.g., only short-axis at mid-papillary level), image quality (no dropouts, low noise), anatomy (e.g., no congenital defects), or imaging equipment type or settings (scale, gain, frequency).
3. They require the user to handle the high-level aspects by initializing, guiding, or correcting the system.

### *Rules for a Well-Behaved Automated Border Detection Method*

No practical system can do without the intervention of the user. Ideally, there is only one desired and necessary interaction: when multiple interpretations could be correct, the user should have the final decision. In practice, a computer system can never have all the high-level knowledge that the physician has, and it requires the physician's intervention to handle such blind spots. Systems with little high-level knowledge and models, however, rely heavily on the user to handle their shortcomings and mistakes—which most users find deeply irritating.

With these limitations in mind, we can formulate a few criteria for a good and well-behaved ABD method.

1. The method should generate "correct" contours. Because this judgment may be subjective (in the light of multiple possible interpretations), a system should preferably be able to adapt to the expert user's general ideas about correct contours.
2. The contours should be reproducible. This seems obvious for an automatic system, but almost all systems require some type of user interaction (parameter choices, indicating a start point or region, corrections), which will lead to some variability in results. This inter- and intraobserver difference should possibly be smaller than the inter- and intraobserver variabilities associated with similar manual work.
3. The method should be user friendly. It should only address the user for high-level expert decisions, not for handling "stupid" mistakes or do repetitive corrections. This implies:
   - It should not generate physically or anatomically impossible solutions; unlikely solutions should be marked as such. It should supply alternative solutions when relevant.
   - It should not override user-drawn contours (apart from cleanup of minor imperfections).
   - It should allow for easy, intelligent, minimized control and correction (e.g., by applying the intent of the correction throughout the whole image set).

## Automated Border Detection in Echocardiography

### PROBLEMS AND PITFALLS OF BORDER DETECTION IN ECHOGRAPHY

Ultrasound is a particularly difficult imaging modality for interpretation. Inexperienced users mostly find it harder to interpret than other tomographic modalities such as computed tomography and magnetic resonance imaging. Ultrasound exhibits several specific properties that impede automated analysis.

1. Pixel intensity does not directly reflect any physical property of the tissue visualized, in contrast to the Lambert-Beer law for radiography or the Hounsfield units for computed tomography. In ultrasound, images are formed by sound reflection and scattering, resulting in a combination of interference patterns (ultrasound speckle patterns) and reflections at tissue transitions or inhomogeneities. Different tissues are often distinguishable only by subtle differences in texture (speckle patterns) or by the coherent behavior of this texture over time, rather than by different intensity values.
2. Ultrasonographic image information is very *anisotropic* and position-dependent. Reflection intensity, lateral and radial point-spread functions, and signal-to-noise ratio are strongly dependent on both the depth and the angle of incidence of the ultrasound beam, as well as on the user-controlled time gain compensation settings.
3. Image disturbances (*artifacts*) are caused by factors such as side lobes, reverberations, clutter, and aberration. Many of these problems are especially prominent with high gain settings, which are often necessary in obese or older patients.
4. Parts of the anatomy are not imaged, because of *dropouts* (for structures parallel to the ultrasound beam), *shadowing* (behind acoustically impermeable structures such as bone or lung), scan sector limitations, and limited echocardiographic windows. Still-frame images generally miss some information; the human eye compensates for this when viewing a sequence of images. It resolves ambiguities and interpolates the missing parts by exploiting the temporal coherence of structures and speckle, which allows discrimination among noise, artifacts, and anatomy.
5. In specific cases (especially in 3D imaging) the limited temporal resolution and the scanning process may introduce artifacts. The sequential scanning of lines combines information from different moments into one image. For quickly moving structures, this may lead to spatial distortion. Sharp transitions between "older" and "newer" image parts may appear. This is particularly prominent in real-time 3D ultrasound, where information from different heartbeats is stitched together to include a complete object (such as the LV).
6. In 2D ultrasound, the exact spatial localization of the cross-sectional plane is generally not known. This in contrast to 3D techniques (3D ultrasound, magnetic resonance imaging, or computed tomography), where the 3D context is known, and this information is often employed in model positioning for detection. In 2D cardiac ultrasound, the choice of the imaged cross section depends both on the skill and precision of the sonographer and on the available echocardiographic window, which is limited by ribs, lungs, and so on. Apart from volume measurement errors, this may also result in detection problems if the ABD method relies on assumptions of shape and the presence or absence of other structures such as valves or papillary muscles.

### PRACTICAL CONSIDERATIONS FOR AUTOMATED BORDER DETECTION

Practical considerations for appropriate border detection (either automatic or manual) are listed in Box 12-1, subdivided into three categories. A few explanations follow.

#### *Acquisition and Image Quality*

The primary requirement for automated analysis is *optimal image quality.* For ABD this is even more crucial than for manual tracing or visual analysis. If the border cannot be seen, an intelligent guess or interpolation is the only option (for computer

BOX 12-1

**PRACTICAL CONSIDERATIONS FOR AUTOMATED BORDER DETECTION**

**Acquisition and Image Quality**
Optimize border visualization
Limit variation in system settings (gain, power, time gain control, lateral gain control)
Limit variation in cross sections (use landmarks)
Proper region of interest/depth
High frame-rate
Digital storage (preferably lossless); no filtering
No spatial/temporal subsampling or small regions of interest for storage

**Contour Definitions and Consistency**
Inventory of desired calculations
Standardize border drawing definitions:
  Inclusion or exclusion of papillary muscles, trabecular structures, valves, etc.
  Position of edges: leading, peak, trailing
Exclusion criteria and special cases:
  Image quality: foreshortening, dropouts, artifacts, noise
  Pathologies: hypertrophy, dilation, cardiac masses, etc.
  Congenital deformations, etc.
Assess inter- and intraobserver variabilities:
  To test standardization
  To check errors against study goal, estimate patient population size for significance
Include acquisition protocol?

**Choice of Detection Technique**
Check specifics of technique against problem:
  Views/cross sections
  Cardiac objects (LV, RV, endocardium, epicardium)
  Border definitions
  Single frame, end-diastolic/end-systolic, full-cycle, multicycle
  Real-time online or offline with corrections
  Dependence on image quality, artifacts, settings
  Amount and types of user interaction
Is manual analysis a practical alternative?

*and* human). Therefore, one should take every precaution to optimize image quality, standardize system settings, and reduce variability in settings and cross sections.

Select a view and depth such that the object of interest is in focus, fits well inside the scan sector, and fills most of it. Try to adjust acoustic power, overall gain, and time gain control such that the endocardium is best and most homogeneously visualized. Remember that stop-frame images are much harder to interpret than moving sequences; individual frames may be much less pleasing than the cineloop suggests.

A high frame rate (at least 25 frames per second) is advisable, both for full-cycle analysis and for proper selection of end-diastolic (ED) and end-systolic (ES) frames in case of ED/ES analysis. For most tissue tracking or speckle tracking techniques, a higher frame rate (above 50) is advised, because such techniques rely on local correlation between consecutive frames, which quickly degrades for lower frame rates.

### *Contour Definitions and Consistency*

Before attempting manual or automated detection, make sure that proper criteria are defined for the desired contours. This may depend on the desired calculations to be performed from the contour. Trabecular structures, papillary muscles, or valves can either be included or excluded for certain calculations (LV volume, regional wall motion, LV mass). Many topics need to be standardized: whether leading, mid, or trailing edges are drawn; and what to trace in case of foreshortening, dropout, and so on.[13] When possible, perform inter- and intraobserver comparisons and try to reach consensus between observers *before* starting a large study. In some cases, this should include the image acquisition protocol, to assess inter- and intraoperator variability in the choice of cross section, ultrasonographic system settings, and other factors.

### *Choice of Detection Technique*

When considering an automated technique for border detection, it is wise to thoroughly check the specifications of the automated method with respect to the purpose of your study, and familiarize yourself with its peculiarities on the broadest possible range of images. Most methods are tailored to an application or have distinct restrictions in their applicability: the imaging modes involved (M-mode, B-mode, 3D, contrast, etc.); the views or cross sections involved; the object to be detected (e.g., LV, RV, atrium); the type of contour to be found (blood-tissue border or other, such as epicardium); single-frame, ED/ES, full-cycle or multicycle analysis; the brand and type of echocardiographic machine used, and online or offline availability of the detection; possibilities for user correction of the boundaries; dependency on system gain, image quality, and common artifacts such as dropouts or noise; and amount of user interaction needed. If no suitable automated technique is found for a certain analysis, manual measurements might provide the only practical alternative.

## Overview of Automated Border Detection Methods

Ever since the invention of echocardiography, methods have been devised for the automated analysis of these images. Literally hundreds of methods have been reported,[14,15] most of which have only academic value. An excellent overview was recently published by Noble and Boukerroui.[14] We limit ourselves to the main directions of research, based on the levels of the interpretation described above. We refrain from any comparisons of reported success scores, as there are no standard test data sets (yet) for this purpose, nor standard test criteria. Detected contours are generally compared with contours manually drawn by one or more experts, or derived values such as area or volume are compared with an alternative measurement. Most of these results are hard to compare between studies. Note that good results on one or two cases do not prove a method's merit: no matter how naive the method, one can always find some images on which it will work. Robustness can only be assessed by applying the method on large sets of clinical-quality images.

A listing of representative techniques is given in Table 12-2. We pay special attention to modern 3D approaches.

### FEATURE-DRIVEN METHODS

This class of ABD methods relies principally on image intensity values and basic features (levels 0 and 1 of the image pyramid) without making strict assumptions on shapes of borders and so forth. Such techniques are typically useful for finding irregular or topologically undetermined shapes (tumors, lesions) and less useful when detecting objects of

**TABLE 12-2 Overview of Automated Border Detection Methods at Different Abstraction Levels**

| *Level Name* | *Basic Technique(s)* | *Advanced Techniques* |
|---|---|---|
| 1. Preprocessing | Heavy smoothing for noise/speckle reduction<br>Contrast stretching, histogram equalization | Integrated backscatter thresholding (AQ)[16]<br>Speckle suppression: anisotropic diffusion,[76] adaptive filtering,[37] morphologic filters,[77] wavelet transforms[78]; Fourier-based filters[20] |

Interpretation, high-level knowledge | None<br>User intervention: correction of contours, etc. | Adaptation of models to image and user[38,67]<br>Use of patient group–derived models: appearance eigenvariations (AAM)[59-68]<br>Learning behavior over all cases analyzed: marginal space learning, probabilistic boosting networks[70-73]<br>Rule-based analysis,[75] multiple hypothesis generation<br>Pathology awareness, automated classification[74]<br>Analysis-based acquisition, automated scan assistants[56-58] |

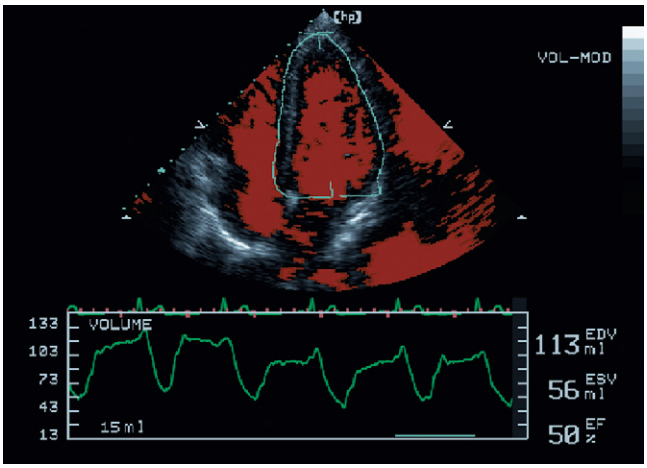

**Figure 12-3** Acoustic quantification on Philips (Hewlett-Packard) equipment. *(Courtesy Philips Medical Systems Ultrasound, Andover, Mass.)*

well-defined shape in an imperfect image (such as LV segmentation in echocardiograms). Thresholding, clustering, region growing, and level set techniques can be placed in this class. Thresholding uses a fixed level of intensity to separate different tissues, such as blood and myocardium. One of the earliest commercial automated analysis techniques, Acoustic Quantification[16] (Fig. 12-3), was based on thresholding of the integrated backscatter level of the radiofrequency signal to separate blood from tissue. In clustering techniques, pixels of similar properties are categorized into groups (e.g., blood or myocardium) based on some statistical distribution, such as Gaussian[17] or Rayleigh[18] distributions. Most clustering approaches use pixel intensity, but they may also be edge or phase based.[19] In classical region growing,[20] an object is segmented by iteratively adding similar neighboring pixels to a region and/or removing dissimilar pixels. Level set approaches[21,22] are related to region growing but mathematically similar to deformable models (described later). The contour is implicitly described by an evolution equation, and the detected objects can take any shape and topology. As mentioned earlier, all of these methods pose no or few restrictions on shapes of the found regions; this makes them vulnerable to typical ultrasound artifacts such as dropouts or clutter. Therefore, these methods are often integrated into methods with explicit models to handle such artifacts.[23]

## STRUCTURE-BASED METHOD: TISSUE TRACKING

A good example of a structure-based method can be found in the various 2D tissue tracking methods. Such approaches track the motion of certain structures by finding correspondence between regions in consecutive images. Most approaches rely on straightforward block similarity measures such as normalized cross correlation or sum of absolute differences. An alternative approach, optical flow, was already proposed in an early stage for 2D tissue tracking[24,25] and recently has gained new interest.[26,27] Also, tissue tracking can be formulated as a deformation problem, and image registration can be applied.[28] In general, such tissue tracking techniques can provide motion information in the form of displacement of a set of points (generally along a user-drawn line) or calculate a complete 2D displacement vector field. Recently, several 3D tissue tracking approaches have been realized as well.[29-33] By calculating time integrals, total relative deformation (strain) can be calculated in all directions. As a 2D or 3D approach, tissue tracking can overcome the principal limitation of tissue Doppler imaging (TDI[34]). TDI supplies a direct physical (Doppler) velocity measurement that can be performed with high temporal resolution, but it can only give a one-dimensional motion estimate (in the direction of the ultrasound beam).

As an example of a structure-based tracking method, we describe the approach of Lysyansky, Friedman, and colleagues[35,36] for 2D tissue tracking. This method forms the basis of the 2D speckle tracking software in the EchoPAC analysis system (GE-Vingmed Medical Systems, Horten, Norway) (Fig. 12-4).

The user loosely traces an approximate endocardial contour in one frame of a cycle. A band outside this contour is used as the region of interest. Within this region (Fig. 12-4, *A*), the

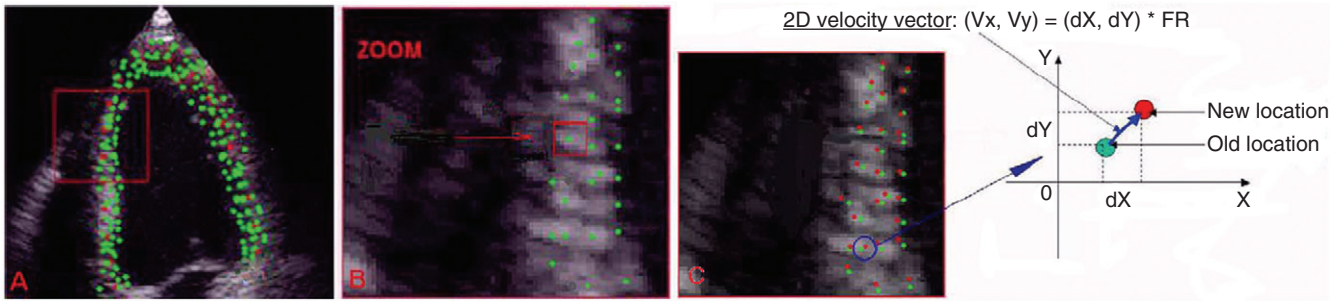

**Figure 12-4** **2D strain imaging. A,** In a region defined by a loosely drawn endocardial contour (*red dots*), natural acoustic markers are identified in the myocardium (*green dots*). **B,** Zoomed display of found acoustic markers (*green dots*: center of each marker). **C,** These markers are tracked from frame to frame, and their displacements define 2D velocity vectors. *(Modified from Leitman M, Lysyansky P, Sidenko S, et al: Two-dimensional strain—a novel software for real-time quantitative echocardiographic assessment of myocardial function.* J Am Soc Echocardiogr *17:1021-1029, 2004.)*

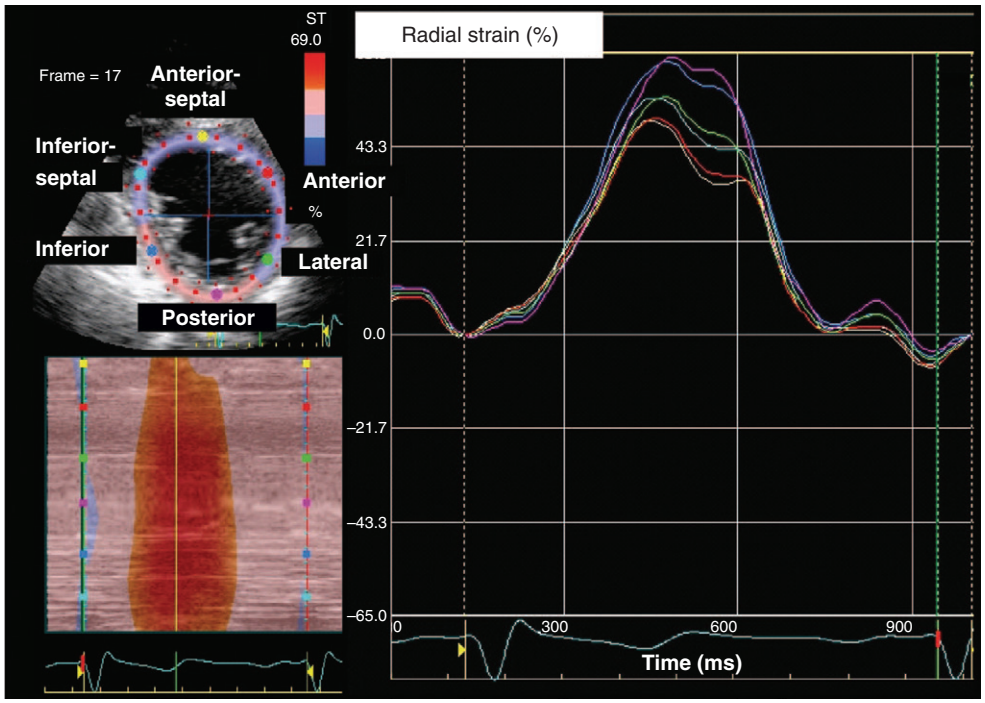

**Figure 12-5** **An example of radial time-strain curves in a normal control subject from the midventricular short-axis view.** Radial strain was calculated by speckle tracking from multiple circumferential points over a cardiac cycle. These data were averaged to six time-strain plots to represent standard segments. Note that time to peak strain in a normal subject occurs synchronously over a very narrow time range. *(From Suffoletto MS, Dohi K, Cannesson M, et al: Novel speckle-tracking radial strain from routine black-and-white echocardiographic images to quantify dyssynchrony and predict response to cardiac resynchronization therapy.* Circulation *113:960-968, 2006.)*

speckle structure is analyzed and speckles of high intensities are identified as natural targets (see Fig. 12-4, *A* and *B*). These targets are tracked over consecutive frames (see Fig. 12-4, *C*) by block matching with a sum of absolute differences similarity criterion.[34,36] From the resulting velocity field, local displacement and strain are calculated (Fig. 12-5).

Similar speckle tracking approaches from other vendors are available. A prerequisite for successful application is a sufficiently high frame rate and good image quality.

## OBJECT-BASED METHODS: GEOMETRIC MODELING

Several popular border detection techniques are based on deformable geometric models. In these methods (known under names such as active contours, snakes, and balloons), the border is represented as a geometric object: a curved line or surface that should separate blood from tissue. This object obeys geometric constraints: it should resemble a certain shape, it should be smooth, and so on. For detection, the model is initialized somewhere in the image and deformed iteratively to best fit the image data. Mostly this involves minimizing some energy terms, related to the amount of deformation applied to the model (internal energy) and the quality of fit to the image data (external energy). The latter can be represented by, for example, edge strength on the border, or contrast between inner and outer regions. Methods of this class can vary widely in the type of image features, the shape or motion model, their shape constraints, and their initialization and optimization strategies.

These methods operate mainly on levels 1 and 2 of the image pyramid, employing a geometric model (level 2), driven by image features (level 1). They are especially useful if much variation in borders is expected for different patients, such as if congenital defects are present.[37] However, it can be difficult to

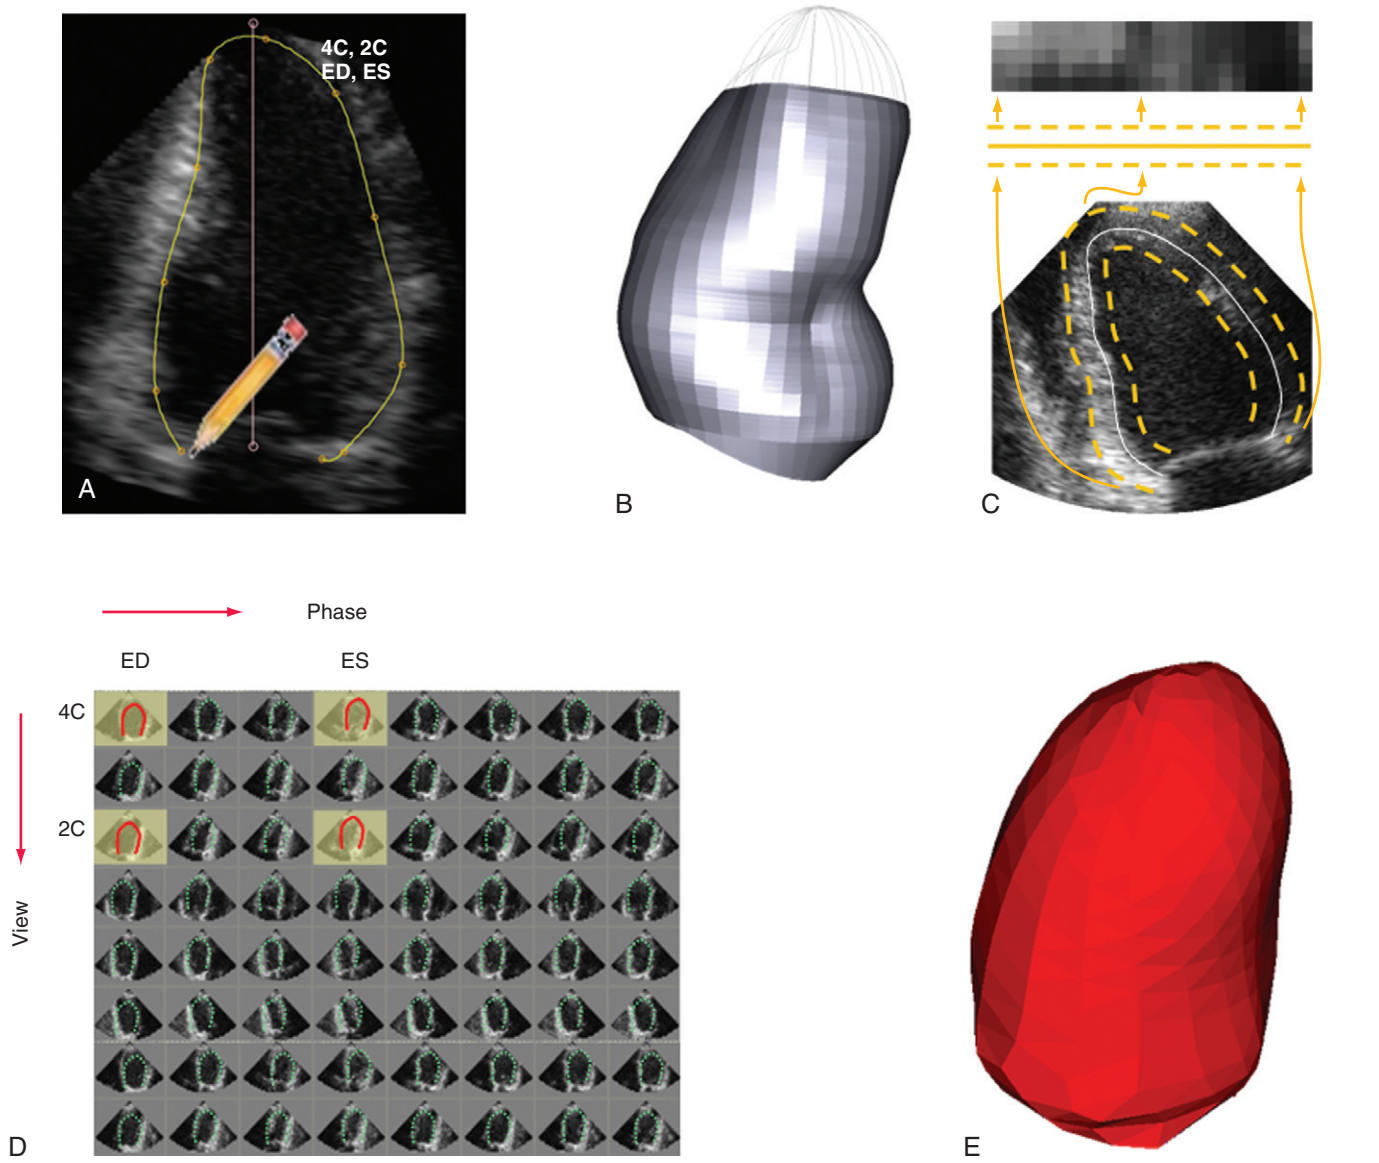

**Figure 12-6** **Semiautomatic four-dimensional (4D) border detection based on geometric models and pattern matching. A,** The method is initialized by manual delineation in four- (*4C*) and two-chamber (*2C*), in end-diastole (*ED*) and end-systole (*ES*). From these borders, a geometric model (**B**) and edge patterns (**C**) are obtained. **D,** These are matched to the remaining cross sections and cardiac phases by dynamic programming. **E,** One of the 3D endocardial borders automatically detected over the full cycle. *(Modified from Van Stralen M, Bosch JG, Voormolen MM, et al: Left ventricular volume estimation in cardiac 3D ultrasound: a semi-automatic border detection approach.* Acad Radiol *12:1241-1249, 2005.)*

achieve a balance here: preventing entirely implausible solutions while allowing for a range of normal and pathological shapes.

## PATTERN MATCHING

A four-dimensional (4D) semiautomatic model-based approach[38] was developed in our lab based on pattern matching and dynamic programming, which can derive a 4D segmentation with very limited user interaction. It was based on the earlier Echo-CMS system[39] for 2D image analysis that has been applied in studies on wall motion patterns for cardiac resynchronization therapy by biventricular pacing[40] and regional wall motion quantification for myocardial viability,[41] stress echocardiography,[42] and LV remodeling.[43]

Each 3D image of the 4D sequence is represented as a (cylindrical) set of long-axis 2D image slices. To initialize, one ED and ES contour are manually drawn in the four-chamber and two-chamber slices (Fig. 12-6). These shapes are interpolated spatiotemporally to form a 4D geometric model. In addition, a 4D pattern of the intensities is created by spatiotemporal interpolation of the image intensity patterns close to the manually delineated borders. This 4D "edge pattern" is thus a user-defined description of the borders. The intensities close to the interpolated 4D geometric model are then matched with the edge pattern. Optimal connective borders are determined using dynamic programming.[44] After detection of all contours (see Fig. 12-6, *D*), the user may apply any corrections by overdrawing part of a contour. Consecutively, all models are updated with the extra user-defined information, which is interpolated and extrapolated over the sequence, followed by a redetection of all nonmanual contours. The detected borders will resemble the user's definition of the border, and the method is thus suitable for different delineation protocols, not limited to intensity

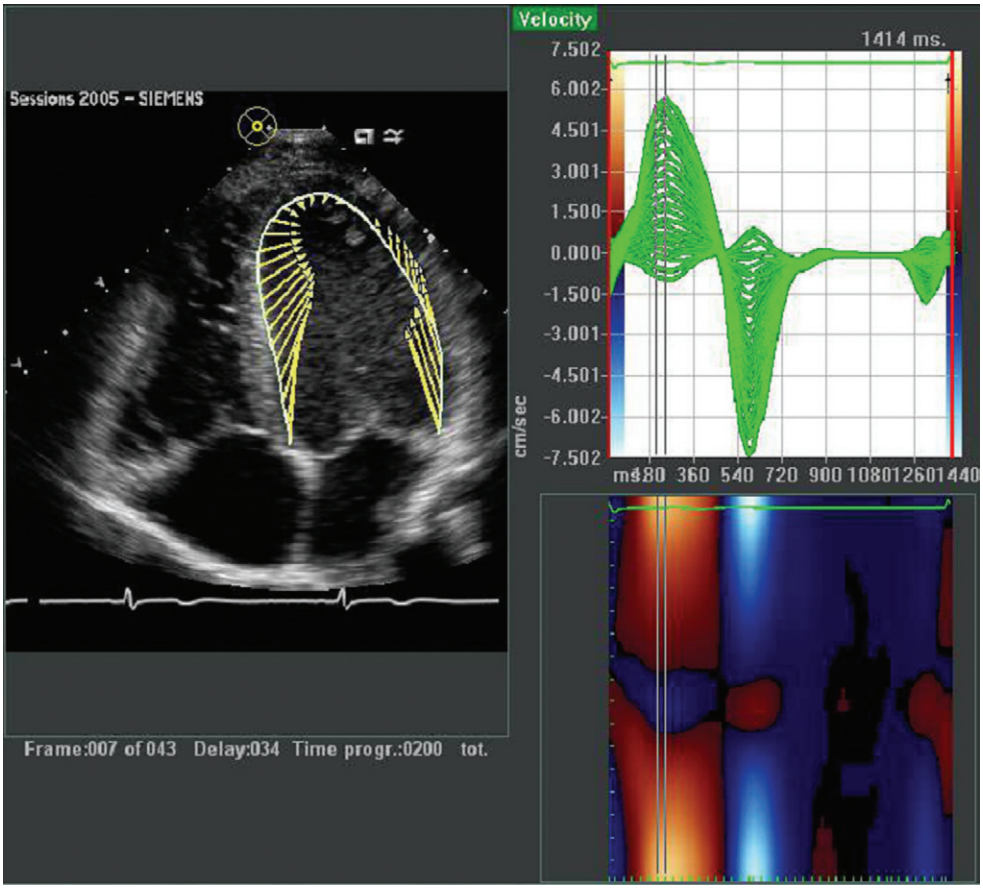

**Figure 12-7** Siemens Axius Velocity Vector Imaging. Border with *arrows* showing the local direction of border motion (*left*). Velocity for all points on border as function of time and displayed as a tissue Doppler imaging–style color map (*right*). *(Courtesy Siemens Medical Solutions, Malvern, Pa.)*

transitions, and including contrast-enhanced images. For research purposes, it has been shown to be a valuable tool, especially since it allows effective, smooth 4D corrections with little interaction.

Similar techniques are available for 2D analysis, such as the Axius Velocity Vector Imaging[45,46] approach commercialized by Siemens Medical Solutions (Malvern, Pa.). This technique, based on the work of Pedrizzetti and Tonti,[47] requires a user-drawn initial border and tracks the points of this border over one or more heart cycles. It applies template matching by cross correlation along lines perpendicular to the initial border and finds a one-dimensional path in the temporal direction for each point, by searching a maximum likelihood over its neighborhood in the subsequent frames. Consecutively, it tracks the motion of all points along the direction of the border (tangential) as well. Combining these perpendicular and tangential displacements supplies a 2D velocity vector in each point (Fig. 12-7, *left*). From the resulting borders, volumes are calculated, but TDI-like velocity, strain and strain rate plots are also generated (Fig. 12-7, *right*). The technique does not rely on speckle tracking or radiofrequency information and can be applied online or offline on B-mode images of most transducers and systems. Initial clinical validation shows promising results especially for cardiac resynchronization therapy.[45,46]

## 3D ACTIVE SURFACE DETECTION

Several practical methods for segmentation of 4D (3D + time) ultrasound images are now available. Semiautomatic analysis tools such as 4D-LV-Analysis (TomTec Imaging Systems GmbH, Unterschleissheim, Germany) are widely used and have shown good results in comparison to MRI.[48-50] This method uses manually traced borders in three views (the four-chamber view, and views at 60° and 120° rotation) in end-diastole and end-systole as initialization. A 3D spline-based spatiotemporal deformable model is then applied,[51,52] which ensures that the surface is smooth in time and space. The TomTec 4D RV-Function software (Fig. 12-8) uses essentially the same approach for detecting borders in the RV, initialized by manual delineation of the borders in two perpendicular long-axis views.[53]

Another example is the semiautomatic 4D detection as implemented in the Philips QLAB analysis package. This method is based on the active surface detection technique described by Gérard and co-workers.[54] A deformable surface is described as a two-simplex mesh; for each mesh vertex, the internal energy is determined by the local surface smoothness, and external energy by nearby image gradients combined with image intensity. The 3D mesh is initialized in the ED and ES 3D images by manually indicating five markers for mitral valve and apex in the two-chamber and four-chamber cross sections. A standard LV 3D shape is fitted affinely to the manual points to define an initial mesh, and the active surface optimization is started from there in a coarse-to-fine manner. First, rigid-body and affine transforms are applied, then local mesh deformations and mesh refinement.

After ED and ES surfaces have been found, the detection can be extended over the full cycle. For all remaining phases, an initial mesh is generated by propagating the ED and ES shapes using a 4D statistical heart motion model. The active surface optimization is then applied in each 3D image separately (Fig. 12-9). The found shapes can be manually edited conveniently by 3D mesh dragging. A wide range of analytical parameters is

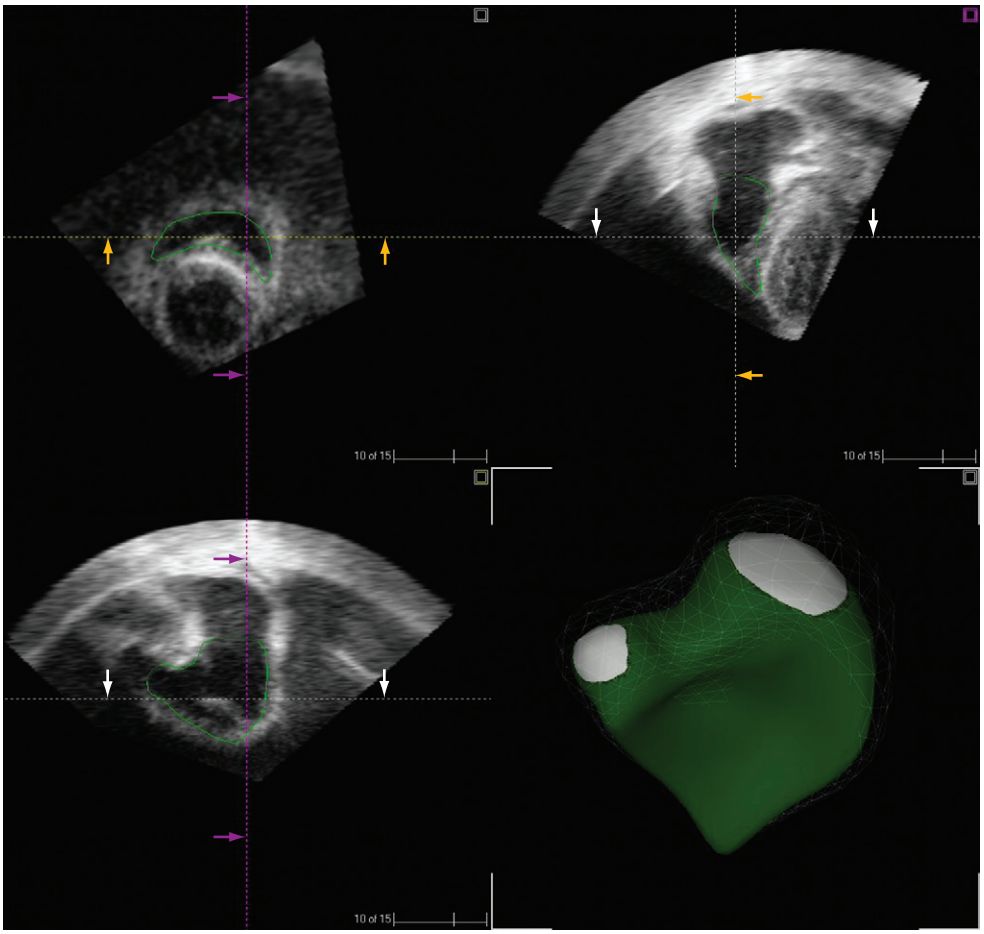

**Figure 12-8 Tomtec 4D RV-function, semiautomated segmentation of RV from 4D echocardiograms.** *Bottom right*: 3D representation of segmented RV lumen. *Other views*: Three orthogonal cross sections showing the RV endocardial contour in *green*. *(Courtesy Tomtec Imaging Systems, Unterschleissheim, Germany.)*

derived from the 3D shapes, concerning global and regional volumes and wall motion indexes. This method has been validated successfully against several other modalities.[50,54]

The method is fast and reasonably robust and supplies a practical tool for analysis of the 3D endocardial volume. One should note that because of the nature of the detection approach and its spatiotemporal smoothness constraints, the found surfaces and graphs are always relatively rounded and smooth. Furthermore, it may be hard to apply manual corrections, because this disturbs the nice temporal continuity of shapes and graphs: such corrections are not propagated over the temporal sequence.

Recently, GE introduced the 4D LVQ tool in the EchoPAC software[55] (Fig. 12-10), an active surface technique that uses 18 manually placed points as initialization (mitral valve annulus and apex on three apical views, in end-diastole and end-systole).

Orderud and colleagues[33] have combined 3D deformable models with a very efficient Kalman filter update scheme, which allows fast convergence of the model to the data and subsequent fully automated real-time segmentation of 3D echocardiographic data. Not only does this supply real-time quantification possibilities, it may also allow real-time optimal view extraction[56,57] or feedback on imaging system settings.[58]

## POPULATION-MODEL BASED METHOD: ACTIVE APPEARANCE MODELS

A relatively new class of techniques called *active appearance models* (AAMs) holds great promise. These techniques were originally developed by Cootes and co-workers[59] for facial recognition and medical image analysis, as an extension of the active shape model[60,61] approach. AAMs have been applied to magnetic resonance imaging[62,63] and 2D and 3D echocardiography[63-65] with very promising results. These techniques derive the typical shape and appearance of an echocardiogram from a large set of example images with expert-drawn contours. Principal component analysis (PCA) on a point distribution model extracts the average organ shape and the principal variations (*eigenvariations*) of shape. By warping all examples to the average shape, an average image and principal image variations can be found. By applying another PCA, simultaneous shape and intensity, eigenvariations are modeled in an *appearance model* (Fig. 12-11, *A*). Such an appearance model can synthetically generate "probable" echocardiographic images (see Fig. 12-11, *C*) similar to the variations shown in Figure 12-11, *A*. By deforming the model along the characteristic model eigenvariations, using a gradient descent minimization of the difference between the synthetic and the real image, the desired structure can be found (see Fig. 12-11, *B*). This can be done fast and fully automatically with good results.[66]

This technique has some significant advantages: it models both average organ shape and all variations over a population of examples; it models the complete organ appearance, including typical artifacts; it captures the expert's definition of proper border definition; it can model complex shapes (e.g., LV endocardium plus LV epicardium, RV, valves); it is not limited to blood-tissue borders; and it is easily customizable for different types of images. Limitations of this technique are its dependence on the training data, the selected population of examples, and the quality of the expert contours.

Leung, Rotterdam, The Netherlands.)*

A recent commercial application that employs a similar approach is the Axius Auto Ejection Fraction software (Auto EF) by Siemens Medical Solutions (Malvern, Pa.). Auto EF is based on the work of Comaniciu and colleagues[67,68] It comprises a fully automated endocardial contour detection approach for the apical four-chamber and two-chamber cross sections, which employs a population-based statistical model of endocardial shape and appearance in end-diastole and end-systole. After a rough determination of the position of the ventricle, the appearance model matches to the image and finds the endocardial contour for the estimated end-diastolic and end-systolic frame. Using a robust information fusion approach, the contour is tracked over the complete sequence from both frames, merging the motion estimated from the images (by an optical flow approach) with a dynamics model. The PCA-based shape model is strongly adapted to the current patient, and the motion estimates and their varying confidence (Fig. 12-12) are combined with expected shape dynamics using a Kalman filter–based tracking. From the found contours, ED and ES volumes and EF are calculated, along with a full-cycle volume curve. Initial clinical evaluations show promising results.[69]

## CLASSIFICATION AND AUTOMATED LOCALIZATION

A novel approach for image analysis is the use of large databases of expert-analyzed example data to train classifiers.[70-73] The intent is to use automated classification to find positions of certain structures in the image, or generate a view classification or even a diagnosis by image similarity. The principle is very much like the automated face localization in digital cameras and uses large numbers of simple structural image features generated from a selected region. By feeding a classifier many positive and negative examples, it can be trained to select a signature of such features that robustly identifies the sought structure. Such signatures can be calculated very effectively for many candidate positions and allow fast localization of typical structures (Fig. 12-13).

## Future Promise

In recent years, several instrumental developments have had important beneficial effects on the feasibility of ABD, and the ABD methods themselves have improved considerably. Recently,

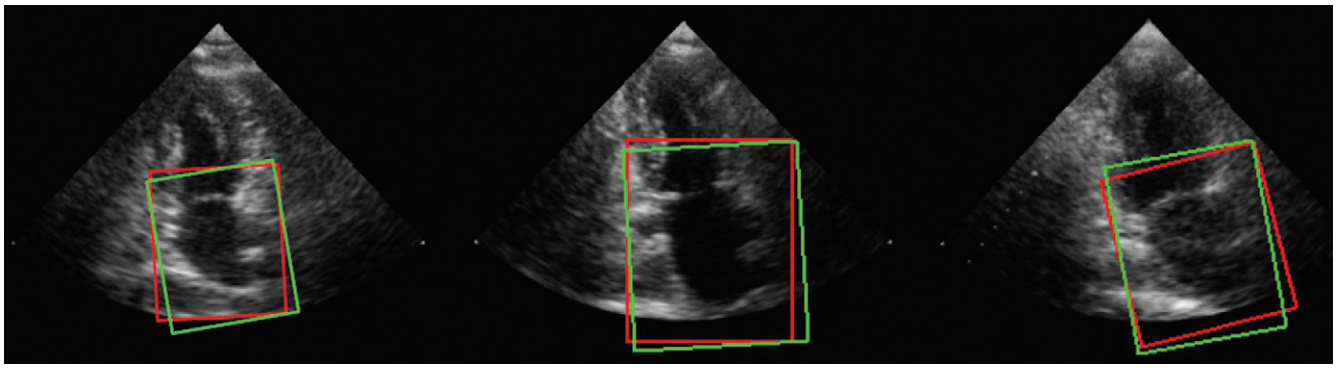

**Figure 12-13 Three examples of automatic localization and pose estimation of left atrium (LA) in apical two-chamber images by a Probabilistic Boosting Network (PBN) classifier.** Ground truth pose of LA (*red box*); automatically detected by PBN (*green box*). *(Modified from Zhang J, Zhou SK, McMillan L, Comaniciu D: Joint real-time object detection and pose estimation using probabilistic boosting network. In* Proceedings of the IEEE Conference on Computer Vision and Pattern Recognition, *Minneapolis, Minn., June 2007, pp 1-8.)*

several useful tools for ABD have become available commercially,[30,36,45,48,53-55,68] and in the near future, further improvements in the applicability of ABD can be expected.

The complete digitization of image formation and storage has improved image quality considerably. Front-end improvements resulting in clutter reduction, higher frame rates, and other benefits have also contributed considerably. The advent of real-time 3D imaging turned ultrasound into a truly 3D modality and also has greatly boosted development toward automated analysis. The continuous increase in computing power and the advent of novel algorithms have enabled such developments. In general, any further improvement in image quality is likely to enhance ABD as well.

## INTELLIGENT ULTRASOUND SYSTEMS

As discussed earlier, there are several important developments that together may bring automated echocardiographic image analyses to a new level of intelligence. Robust classification approaches[70-73] seem to offer solutions for the automated localization of structures and may replace manual initialization of segmentation. More realistic models (such as statistical models of object shape or appearance[59-67]) can capture patient variability and typical artifacts and thus provide more natural and realistic segmentations and even classification.[74] Modeling of the complete 3D anatomy will allow handling of view variability. Integration of tissue tracking and segmentation offers mutual improvements.[31] The advent of real-time tracking, segmentation, and classification allows great opportunities for direct quantification and image-guided feedback on probe position and image optimization. Significant research is already taking place in this field, especially aimed toward handheld and pocket-sized ultrasound devices, which are targeted at users who are less experienced in echocardiographic acquisition. Automated scan assistants that can derive information such as cardiac phase[58] or judge the correctness or quality of an acquired view in real time[57] can significantly improve the applicability and user friendliness of such small devices.

Especially for diagnosis, contributions from the realm of artificial intelligence[75] and computer-aided diagnosis are desirable: formal reasoning from rule-based expert knowledge; generating multiple hypotheses with measures of confidence; reasoning with pathologic or congenital conditions during detection; checking overall consistency of an interpretation and taking action to resolve conflicts; opportunistically choosing an optimal detection strategy for the image data presented; and learning from operator corrections and actions. Ultimately, such developments should lead to an intelligent "automated image interpretation assistant" for echocardiographers.

## KEY POINTS

- ABD plays an increasingly important role in 2D and 3D clinical echocardiography and allows a more quantitative use of echocardiography.
- Optimal image quality and rigorous standardization of image acquisition and analysis are essential for reliable ABD.
- Digital image storage with lossless or no compression is highly recommended.
- Application of ABD in clinical research should be applied with care. The user should be aware of the possibilities and limitations of the technique, should be able to distinguish imaging and detection artifacts from pathology, and should remain critical about the outcome.
- Modeling of anatomical and pathological variability over patient groups plays an increasingly important role in ABD techniques.
- 2D tissue tracking approaches complement tissue-Doppler imaging applications as well as wall motion analysis by border detection. 3D tracking is gaining importance and will soon allow assessment of the true 3D contraction patterns of the myocardium.
- Instrumental hardware improvements, more elaborate 3D and 4D modeling/analysis techniques and artificial intelligence approaches have boosted, and will further improve, clinical feasibility of ABD.

# The Role of Echocardiographic Evaluation in Patients Presenting with Acute Chest Pain to the Emergency Department

KIRSTEN E. FLEISHMANN, MD | SARAH G. WEEKS, MD

**Background and Principles**
**Echocardiography and the Physiology of Acute Ischemia**
**Technical Aspects of Echocardiography in the Emergency Department**
Image Acquisition
Stress Echocardiography
Image Interpretation
Myocardial Contrast Echocardiography
**Clinical Applications**
Triage of Patients with Chest Pain
Clinical Use of Myocardial Contrast Echocardiography
Use of Echocardiography in Chest Pain Units and Clinical Algorithms
Cost Effectiveness
Assessment of the Need for Urgent Coronary Angiography
Risk Stratification and Analysis of Long-Term Clinical Outcome
Evaluation of Other Causes of Chest Pain
**Limitations**
Ischemia Evaluation
Image Quality
Personnel Availability
**Future Developments**
Tele-echocardiography
Strain Analysis for Regional Function
**Summary**

## Background and Principles

Coronary artery disease (CAD) accounted for 4.0 million hospital discharges in 2007 with more than 8 million patients presenting each year to emergency departments in the United States with a chief complaint of chest pain.[1] The challenge for the clinician is to identify those patients with a serious cause of chest pain requiring intervention. Acute coronary syndrome (ACS) often presents with atypical symptoms and a lack of diagnostic changes in the electrocardiogram (ECG) or cardiac markers. Time is critical when it comes to a patient with chest pain. Early treatment of myocardial injury, as well as other serious diagnoses, improves morbidity and mortality rates. Patients without a clear diagnosis are often admitted for observation as well as further cardiac testing, resulting in significant expense. Of patients presenting with chest pain, fewer than 30% are eventually diagnosed with ACS.[2,3] Efficient diagnosis not only aids the patient, but reduces hospitalization time and costs.

The diagnosis of myocardial infarction is based on evidence of myocardial necrosis in a clinical setting consistent with myocardial ischemia.[4] Most commonly this involves a change in cardiac biomarkers in conjunction with symptoms, ECG changes, or abnormal cardiac imaging. Use of serum cardiac markers (troponin, CK-MB) is central to the evaluation of chest pain and/or dyspnea in the emergency department. Unfortunately, these markers often take hours from symptom onset to exceed the normal range and are not elevated in acute coronary syndromes that are not associated with frank myocardial necrosis. Depending on the particular cardiac marker, levels can also be elevated in the absence of acute coronary syndrome, such as in the setting of renal insufficiency.[5] Electrocardiographic changes are frequently nonspecific.

Given these limitations, echocardiography can be a useful adjunct in assessing the emergency-department patient with chest pain. The evaluation of left ventricular (LV) systolic function, specifically wall thickening, with myocardial perfusion can aid in the diagnosis and triage of patients with chest pain. Echocardiography may also be useful in the diagnosis of other etiologies of chest pain, including aortic dissection, aortic stenosis, hypertrophic cardiomyopathy, and pericardial effusion (Box 13-1). This chapter focuses on the current application of echocardiography for early diagnosis of ACS.

## Echocardiography and the Physiology of Acute Ischemia

Acute ischemia is associated with a number of biochemical and physiologic changes in myocardial tissue.[6] The ischemic cascade begins with biochemical changes causing subsequent abnormalities in diastolic and systolic function. These abnormalities typically precede the development of symptoms, electrocardiographic changes, or the increase in cardiac biomarker levels.[7] The ability to detect myocardial ischemia earlier in the cascade of events by assessment of global and regional function has led to an interest in the use of echocardiography in patients presenting with chest pain without a clear diagnosis of ACS.

**Box 13-1**

**GOALS OF ECHOCARDIOGRAPHY IN EVALUATION OF PATIENTS WITH ACUTE CHEST PAIN**

Diagnosis of acute coronary syndrome
- Determination of coronary vascular territory involved
- Assessment of the area of myocardium at risk
- Evaluation of global ventricular function

Exclusion of other causes of chest pain
- Aortic dissection
- Pericarditis (with effusion)
- Aortic stenosis
- Hypertrophic cardiomyopathy

In addition, while coronary blood flow is maintained at a constant rate over a wide range of coronary pressure through autoregulation, myocardial contrast echocardiography (MCE) may also be helpful in assessing suspected CAD. Only once a coronary vessel is more than 85% obstructed does the flow fall below a normal threshold.[8] However, MCE evaluates myocardial perfusion and thereby may detect severely stenotic lesions noninvasively as well.

## Technical Aspects of Echocardiography in the Emergency Department

### IMAGE ACQUISITION

The emergency department environment often makes the echocardiogram more challenging than in the controlled environment of the echocardiography lab. Transthoracic echocardiographic (TTE) examination of patients with chest pain should focus on the evaluation of biventricular function and the presence of regional wall motion abnormalities (lack of normal wall thickening, particularly if in a vascular territory). It may also include assessment of myocardial blood flow using echocardiographic contrast (if available). The study should also serve to screen for nonischemic causes of cardiac chest pain such as aortic stenosis, hypertrophic cardiomyopathy, pericardial effusion, and aortic dissection (although sensitivity for the last diagnosis is limited, and a negative TTE is not sufficient to rule it out).

The standard two-dimensional (2D)-TTE views necessary for assessment of wall thickening are the parasternal long- and short-axis views and the apical four-chamber, two-chamber and three-chamber views (Fig. 13-1 demonstrates the apical two-chamber and short-axis views). If adequate image quality cannot be achieved from the parasternal or apical views, subcostal views can be extremely helpful. Off-axis or foreshortened views make the interpretation of regional wall motion abnormalities difficult and increase the likelihood of error. Images should be analyzed in accordance with the American Society of Echocardiography guidelines.[9]

The use of echocardiographic contrast agents can be invaluable in defining endocardial borders for wall motion analysis (see Chapter 3). Commercially available intravascular echocardiographic contrast agents contain gas-filled microbubbles, which are small enough to pass through the pulmonary circulation, resulting in opacification of the LV. This results in enhancement of endocardial borders (Fig. 13-2).

A well-trained, experienced sonographer or echocardiographer is essential in the emergency setting. The sonographer should acquire necessary images in an efficient manner with attention to proper patient positioning, transducer selection, and technical settings. The technical settings may vary depending on the patient characteristics, such as the use of lower-frequency imaging in obese patients. Second harmonic imaging increases the signal-to-noise ratio, resulting in clearer imaging. The use of echocardiographic contrast requires changes in technical settings for endocardial definition versus myocardial perfusion, particularly in mechanical index.

The advancement of echocardiographic technology has substantially reduced the number of patients with inadequate echocardiographic images. In an early study by Horowitz and colleagues on the use of echocardiography in patients with acute chest pain, adequate images were obtained in 81% of patients.[10] A recent study evaluated patients with technically difficult imaging and found that the addition of contrast agent improved the percentage of myocardial segments visualized from 68% to 99%. This improvement had a direct impact on patient care.[11]

### STRESS ECHOCARDIOGRAPHY

Echocardiographic imaging in conjunction with exercise or pharmacologic stress to assess for ischemia is safe and effective in detecting inducible wall-motion abnormalities. Exercise stress can be performed using a standard treadmill protocol (i.e., Bruce) or a supine bicycle protocol. The advantage of bicycle protocols is the ability to image wall motion throughout exercise, as the patient exercises on an echocardiographic table that can be tilted into a left lateral position. The supine bicycle protocol increases the energy expenditure, typically in 30-watt increments every 3 minutes. This allows for image comparison at low, medium, and high workload. Additional Doppler information including pulmonary artery systolic pressure estimate, transaortic stroke volume, and valvular gradients can be obtained.

Treadmill studies image patients at baseline and just after peak exercise only. For maximum sensitivity, it is essential that the echocardiographic imaging begin immediately after exercise terminates, before significant heart rate decrease. This stress modality is primarily for assessment of global and regional systolic function (see Chapter 15).

For patients unable to exercise adequately, pharmacologic stress testing can be performed (see Chapter 16). Dobutamine is the agent most studied and, therefore, most commonly used in North America. Dobutamine stress echocardiography (DSE) has demonstrated excellent negative predictive value for the presence of obstructive CAD (96% at 6 months).[12] Baseline images are obtained, followed by the infusion of dobutamine at incremental levels (usually 5, 10, 20, 30, 40 mcg/kg/min) of 3 minutes' duration. The test is terminated when the patient's heart rate reaches 85% of maximum predicted heart rate, or there is evidence of myocardial ischemia, hypotension, significant arrhythmia, significant LV outflow tract obstruction, or drug-related side effects. Patients who do not reach target heart rate despite 40 mcg/kg/min of dobutamine can perform handgrip maneuvers or be given intravenous atropine in doses of 0.1 to 0.25 mg up to a total of 1 mg.

Endocardial definition is essential for reliable wall motion assessment. Images during stress decrease in quality because of the cardiac movement and hyperventilation. The use of second harmonic imaging has increased the sensitivity for the diagnosis of CAD from 64% to 92% in patients with poor image quality.

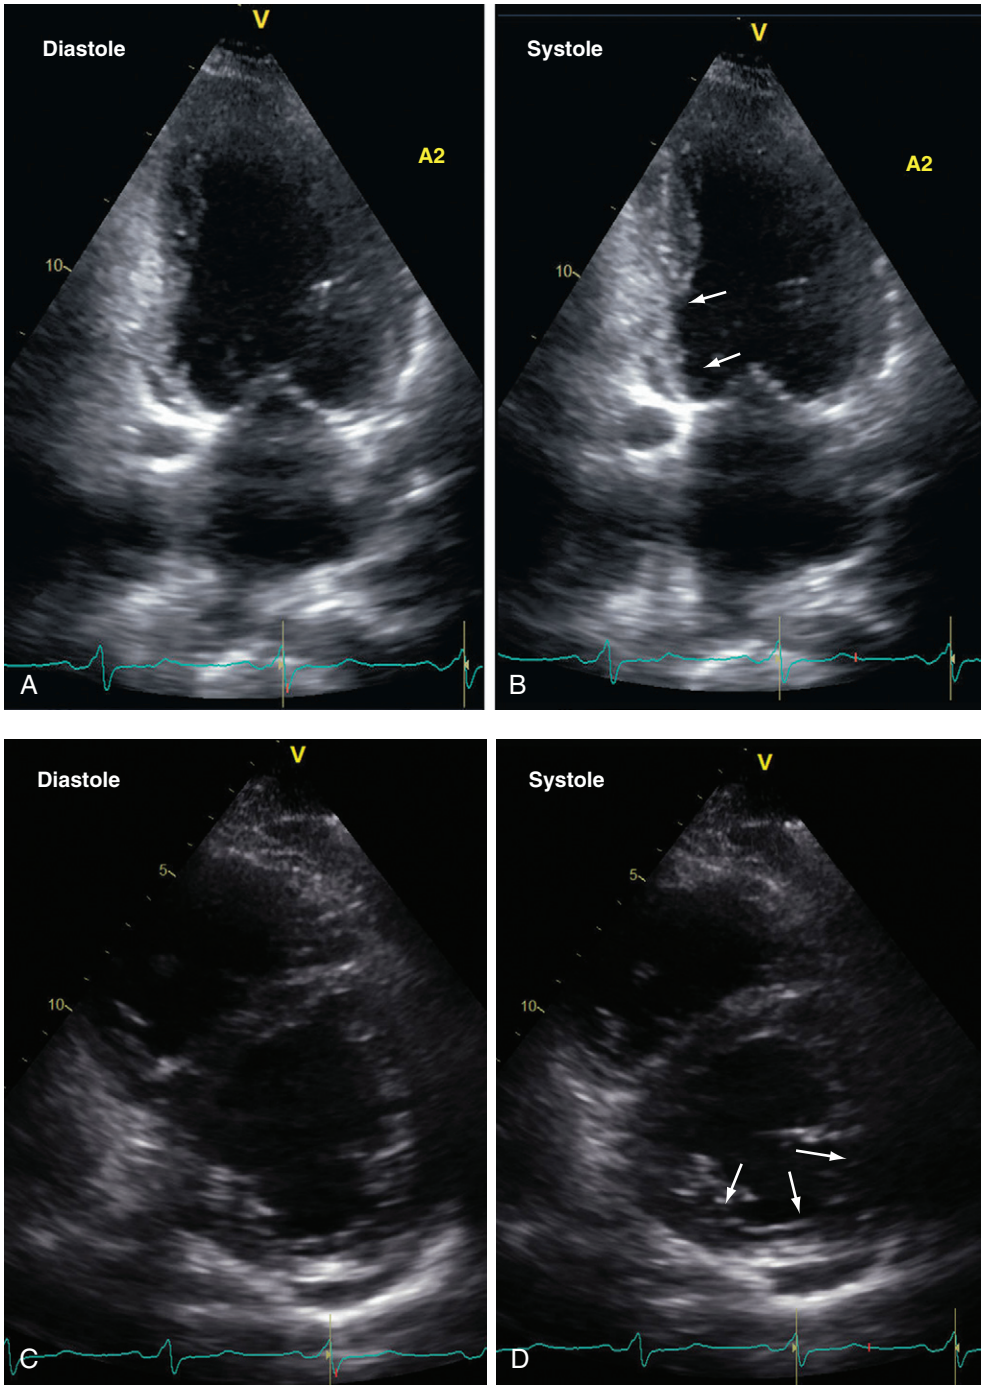

**Figure 13-1** Still frames from the echocardiogram of a patient with acute chest pain, showing akinesis (*arrows*) of the basal inferior and inferolateral segments, in the apical two-chamber view (**A,** diastole; **B,** systole) and the basal parasternal short axis (**C,** diastole; **D,** systole).

Specificity is unchanged with second harmonic imaging.[13] The use of echocardiographic contrast agents has also increased the sensitivity of stress echocardiography for the diagnosis of CAD. Rainbird and colleagues[14] analyzed 300 consecutive patients undergoing DSE. The percentage of wall segments visualized increased from 94.4% to 99.8% with the use of LV opacification during peak exercise (*P* less than 0.01). There was no decrease in segment visualization at peak exercise, as was the case if an echocardiographic contrast agent was not used.

This technique has been safely used when performed by specially trained nurses and sonographers, with images electronically transferred to the cardiologist for interpretation.[15,16]

## IMAGE INTERPRETATION

Accurate interpretation of regional wall motion also requires an experienced echocardiographer. Wall thickening and systolic endocardial motion are evaluated for each LV segment, leading to its classification as hyperkinetic, normal, hypokinetic, akinetic, or dyskinetic.

The American Society of Echocardiography recommends a 16-segment model of regional wall motion evaluation (Fig. 13-3).[9] This model is consistent with the models used in nuclear and magnetic resonance imaging. Each segment is assigned a score based on visual assessment of contractility: normal = 1, hypokinesis = 2, akinesis = 3, dyskinesis = 4, and

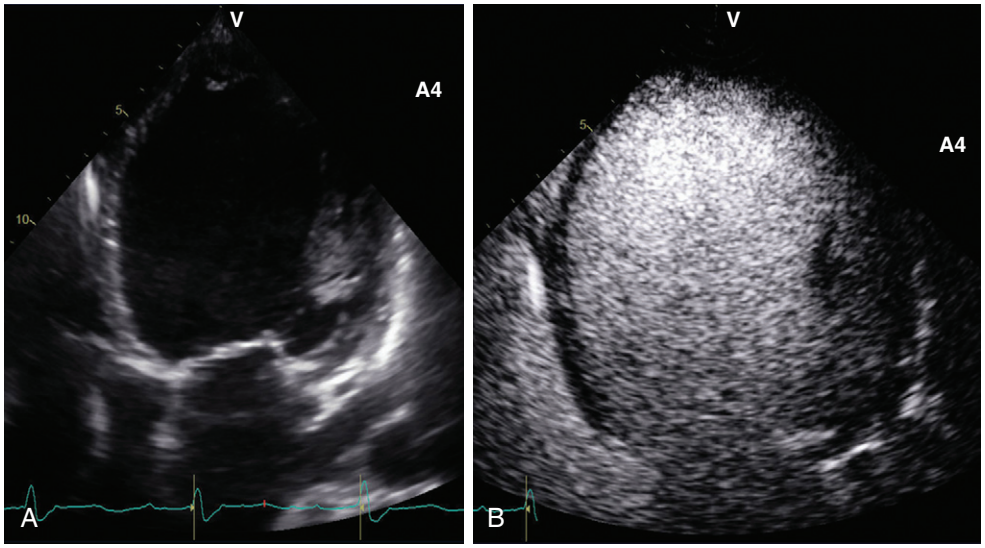

**Figure 13-2** Improvement in LV endocardial border delineation, particularly at the apex, with the use of intravenous echocardiographic contrast and second harmonic imaging (**A,** without contrast; **B,** with contrast).

aneurysmal = 5. The wall motion score index, a semiquantitative measure of regional wall motion abnormality, is calculated by averaging wall motion scores for visualized segments. An LV with normal systolic function has a wall motion score index of 1, whereas a dysfunctional ventricle will have an increasing wall motion score index proportional to the severity. This score correlates with myocardial infarct size on pathologic studies[17] and to perfusion defect size on single photon emission computed tomographic (SPECT) imaging.[18] A similar 14-segment wall motion index predicts long-term survival in patients with chest pain.[19]

Evaluation of stress-induced regional wall motion abnormalities is based on detailed comparison of rest and stress images, which is facilitated by simultaneous, synchronized display of images.

Recent refinements in tissue Doppler/speckle tracking imaging and the measurement of myocardial velocity allow for quantitative analysis of regional function.[20,21] Although not routine at present, these quantitative measures have been shown to distinguish between patients with non–ST-elevation myocardial infarction and unstable angina or noncoronary chest pain.[22]

### MYOCARDIAL CONTRAST ECHOCARDIOGRAPHY

MCE allows for the assessment of myocardial perfusion with the use of intravenous echocardiographic contrast agents, as well as assessment of wall thickening. Myocardial perfusion is assessed by the injection of microbubbles at the bedside, in real time, with rapid image acquisition. These inert, intravascular microbubbles are delivered to the capillary bed in territories with normal perfusion. Areas that are hypoperfused lack the echocardiographic enhancement generated by the contrast agent (perfusion defect). The difference in areas with and without adequate perfusion is highlighted by destruction of the bubbles at timely intervals, allowing for image acquisition as the areas of normal perfusion increase in signal intensity faster compared to areas with hypoperfusion. The destruction of bubbles occurs with the use of high-intensity pulses (mechanical index 1.0) synchronized to end-systole, whereas imaging occurs at a mechanical index of approximately 0.5 (Fig. 13-4).

**TABLE 13-1 Chest Pain in the Emergency Department**

| *Suspected Cause of Chest Pain* | *Alternate Imaging Techniques* |
|---|---|
| Dissection | Transesophageal echocardiography, CT angiography, MR angiography, aortogram |
| Coronary artery disease | CT angiography, nuclear perfusion imaging, left heart catheterization |
| Pericarditis/myocarditis | Cardiac MRI |
| Pulmonary embolus | Ventilation/perfusion scan, CT angiography, pulmonary angiography |

*CT*, Computed tomography; *MR*, magnetic resonance; *MRI*, magnetic resonance imaging.

## Clinical Applications

### TRIAGE OF PATIENTS WITH CHEST PAIN

Ischemia-induced regional wall motion abnormalities develop quickly once myocardial blood flow falls below a critical level. Rest echocardiography has therefore been used in the assessment of patients with symptoms suggestive of ACS. The diagnostic accuracy has, however, varied vastly between studies, likely because of the following factors: timing in relation to symptoms, infarct size, and technical variation. A recent study of emergency department patients with symptoms suggestive of ACS reported TTE to have a negative predictive value of 97%; however, the positive predictive valve was only 24%.[23] Although normal systolic function at rest is reassuring, it is insufficient to exclude the diagnosis of ACS (Table 13-1). The evaluation of wall thickening by TTE is deemed appropriate in patients with suspected ACS but nondiagnostic initial testing.[24]

### CLINICAL USE OF MYOCARDIAL CONTRAST ECHOCARDIOGRAPHY

The ability to analyze perfusion has added a potential new dimension to the echocardiographic assessment. A multicenter study by Kang and colleagues[25] enrolled 114 consecutive patients presenting to the emergency department with chest pain on exertion or at rest. Patients with ST elevation or Q waves on ECG were excluded. Echocardiography and MCE were performed to evaluate regional wall motion as well as myocardial perfusion. The sensitivity and specificity of a myocardial perfusion defect for the diagnosis of acute myocardial infarction were

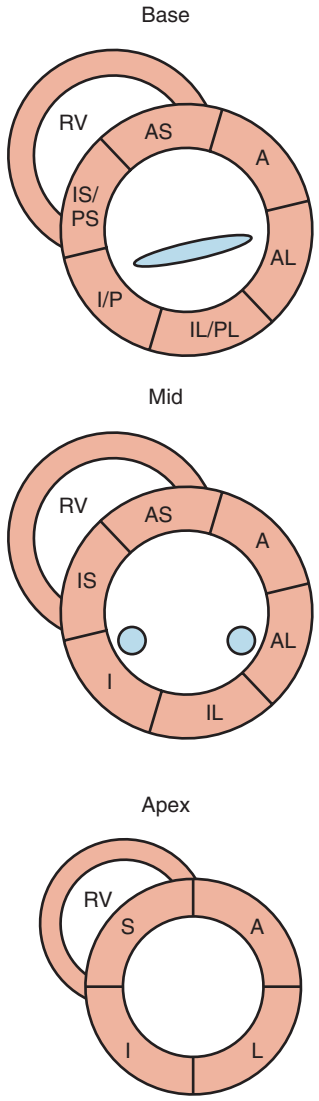

**Figure 13-3** A 16-segment model for evaluation of regional wall motion as recommended by the American Society of Echocardiography. *A*, Anterior; *AL*, anterolateral; *AS*, anteroseptal; *I*, inferior; *IL*, inferolateral; *IS*, inferoseptal; *PL*, posterolateral; *PS*, posteroseptal. *(Adapted from Schiller NB, Shah PM, Crawford M, et al: Recommendations for quantification of the left ventricle by two-dimensional echocardiography.* J Am Soc Echocardiogr *2:358-367, 1989.)*

93% and 63%, respectively. For the diagnosis of unstable angina, the sensitivity was 59% with a specificity of 96%. The authors concluded that the use of MCE to predict clinically confirmed acute coronary syndrome was more sensitive than the use of ECG, cardiac troponins, or echocardiographic assessment of regional wall motion abnormalities alone.

MCE has been compared to the use of the TIMI (Thrombolysis In Myocardial Infarction) risk score for risk stratification of patients presenting with chest pain.[26] More than 900 patients with suspected cardiac chest pain and a nondiagnostic ECG underwent MCE for perfusion and regional wall motion. Only 2 of 523 patients with normal regional function had a primary event. In patients with abnormal regional function, myocardial perfusion was better able to differentiate patients between intermediate- and high-risk groups.

MCE and SPECT were found to be equivalent in their ability to diagnose acute myocardial infarction in the emergency department in a multicenter study. MCE provided a 17%

**Box 13-2**

**ESSENTIAL FEATURES OF A SUCCESSFUL CHEST PAIN UNIT**

1. Telemetry capabilities
2. Timely serial cardiac marker measurements and electrocardiographic testing
3. Access to timely investigations such as: treadmill testing, echocardiography, computed tomography, nuclear imaging, and angiography
4. Bed availability to hold majority of patients 6 to 12 hours

increase in ability to predict future events.[27] In a large, single-center study, wall thickening and myocardial perfusion were significant predictors of cardiac events in patients presenting with chest pain and no ST-segment elevation[28] (Fig. 13-5).

A predictive model for chest pain patients with nondiagnostic initial testing has been developed. Abnormal regional function with or without abnormal myocardial perfusion was found to be an independent predictor of nonfatal myocardial infarction and cardiac death.[29]

## USE OF ECHOCARDIOGRAPHY IN CHEST PAIN UNITS AND CLINICAL ALGORITHMS

Chest pain units specializing in evaluation of patients presenting with acute chest pain have become widely used (Box 13-2). Use of clinical algorithms has been evaluated by clinical outcomes. For example, Gibler and colleagues[30] developed a "Heart ER Program," a diagnostic and treatment program for patients with chest pain in an urban tertiary-care emergency department. More than 1000 patients with symptoms suggestive of ACS were enrolled. Patients with known CAD, acute ST segment shift, hemodynamic instability, or clinical presentation consistent with unstable angina were admitted directly. Two-dimensional echocardiography and graded exercise testing were performed on all patients at the end of a 9-hour observation period. The results determined the disposition of the patient. The vast majority of patients were discharged from the emergency department (82.1%); only 15% were admitted for further evaluation. Of patients admitted, 34% were found to have a cardiac etiology for their symptoms. Stress echocardiography can be safely used in those patients at low risk, after an initial 6-hour observation period.[31]

DSE has also been studied in a clinical algorithm for chest pain assessment in the emergency department.[32,33] Patients with normal ECG and cardiac markers underwent rest 2D echocardiograms. If the rest images were normal, a DSE protocol was used with a trained nurse and sonographer. The test was completed in an average time of 5.4 hours from presentation. Using clinical follow-up and cardiac catheterization data for comparison, the protocol was found to have a sensitivity of 89.5%, a specificity of 88.9%, and a negative predictive value of 98.5%.[32]

The prognostic valve of predischarge DSE in chest pain patients with negative cardiac markers was evaluated in 377 patients by Bholasingh and co-workers.[12] Cardiac events occurred in 30% of patients with a positive DSE versus 4% of those with a negative DSE (odds ratio [OR] 10.7, *P* less than 0.0001).

A group in Italy evaluated 6723 intermediate-risk patients in the emergency department presenting with chest pain and a

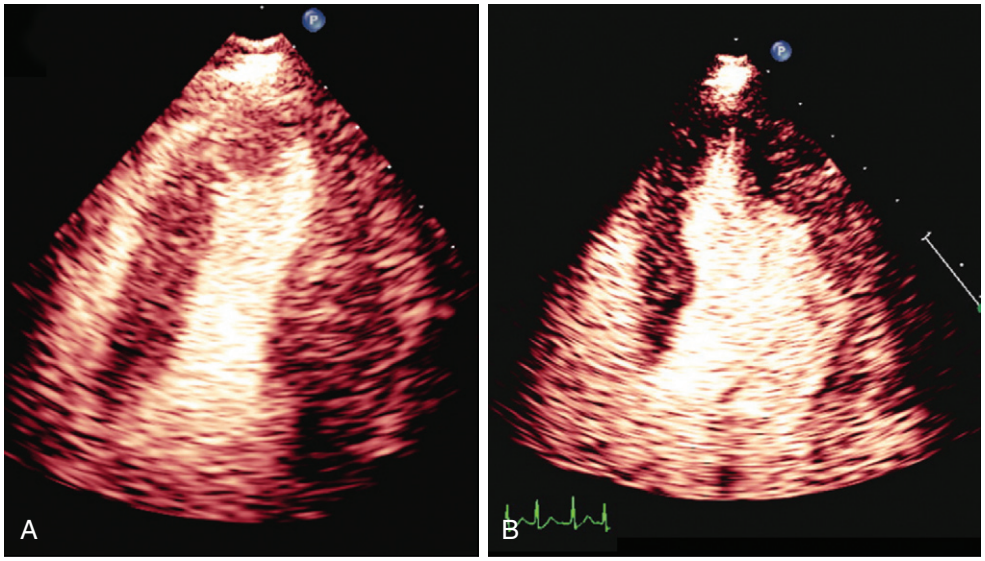

**Figure 13-4** **An example of a normal and a positive stress echocardiogram using intravenous echocardiographic contrast material for assessment of myocardial perfusion. A,** Apical four-chamber view with normal myocardial perfusion septum and basal lateral wall (myocardium appearing dark); **B,** apical four-chamber view with an inducible perfusion defect of the septum and apex at stress (myocardium appears dark when compared to the lateral wall).

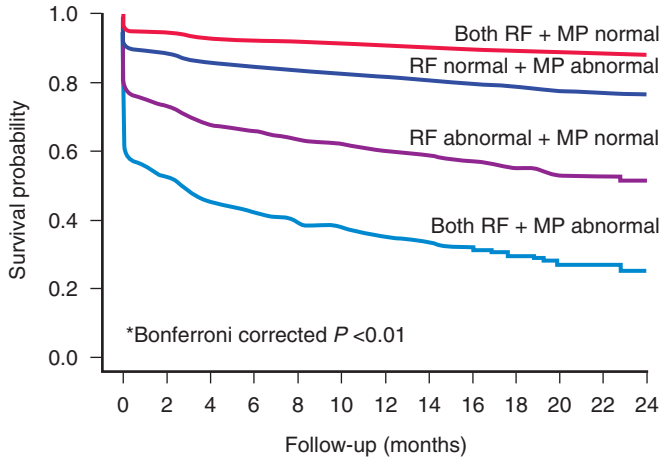

**Figure 13-5** Survival probabilities for patients presenting to the emergency department with chest pain and no ST segment elevation on electrocardiogram (ECG) with different combinations of regional function (*RF*) and myocardial perfusion (*MP*) after adjustment for age, hypertension, diabetes, hypercholesterolemia, smoking status, and ECG. *(From Rinkevich D, Kaul S, Wang XQ, et al., Regional LV perfusion and function in patients presenting to the emergency department with chest pain and no ST-segment elevation.* Eur Heart J *26:1606-1611, 2005.)*

nondiagnostic ECG.[34] In general, older patients or those with multiple risk factors or nondiagnostic ECGs had SPECT imaging, younger patients and those with fewer than two risk factors and normal ECGs underwent treadmill exercise testing, and those unable to exercise or with uncertain or nondiagnostic ETT or SPECT results had DSEs. Although the multiple types of testing performed make interpretation of this group's results more difficult, this protocol enabled them to make the early diagnosis of CAD in 22% of their chest pain unit patients, with early discharge in 78%.

A subsequent manuscript reported on approximately 500 patients with recent chest pain, but without ischemic ECG changes or definite evidence of CAD after a 6-hour workup including troponin levels. Patients unable to exercise and those with left bundle-branch block or poor echocardiographic windows were excluded. Patients had exercise echocardiography and exercise sestamibi nuclear stress imaging within 24 hours and patients with abnormal troponin levels at any time or positive stress tests were recommended for angiography. Endpoints for the study were greater than 50% stenosis on catheterization or cardiovascular events at 6 months. The exercise echocardiogram was positive in 20% of the cohort, the exercise sestamibi study in 24%. Fourteen patients with negative exercise echocardiograms were ultimately diagnosed with CAD versus 13 patients with negative exercise sestamibi studies. The sensitivity of exercise echocardiography and exercise sestamibi imaging for the ultimate diagnosis of CAD in this study was similar (85% vs. 86%), whereas the specificity of exercise echocardiography was slightly higher (95% vs. 90%), leading to a higher likelihood ratio for a positive exercise echocardiography test.[35]

## COST EFFECTIVENESS

Cost-effectiveness analyses of diagnostic strategies for patients with chest pain have found the preferred initial strategy to be noninvasive testing for patients with low to intermediate pretest probability of CAD, and coronary angiography for those with high pretest probability.

For example, in one study,[36] the incremental cost of exercise echocardiography compared with exercise electrocardiography in 55-year old men with atypical angina was $41,900 per quality-adjusted life-year (QALY), a range generally considered cost-effective in comparison to other accepted interventions. In comparison, exercise SPECT cost $54,800 per QALY as compared with exercise electrocardiography for these patients. However, in higher risk patients, such as 55-year-old men with typical angina, the incremental cost-effectiveness ratio of routine coronary angiography compared with exercise echocardiography was only $36,400 per QALY saved, making angiography an attractive strategy from a cost-effectiveness standpoint. The incremental cost-effectiveness ratio of exercise electrocardiography compared with no testing was $57,700 per QALY saved for 55-year-old men with nonspecific chest pain. The authors concluded that exercise electrocardiography or exercise

echocardiography resulted in reasonable cost-effectiveness ratios for patients at mild to moderate risk for CAD.

The cost effectiveness of MCE in the emergency department was evaluated by Wyrick and colleagues.[37] Patients with a nondiagnostic ECG, cardiac sounding chest discomfort and a normal MCE had a very low 24-hour event rate (0.6%). Using MCE would have negated the admission of 45% of those patients admitted, with an average cost savings of $900 per patient.

## ASSESSMENT OF THE NEED FOR URGENT CORONARY ANGIOGRAPHY

Coronary angiography is still generally regarded as the gold standard test for diagnosing obstructive epicardial CAD. Patients with a nondiagnostic ECG and a high pretest probability of CAD often proceed directly to angiography and possible percutaneous coronary intervention. This technique leads to prompt diagnosis; in most cases, however, it does not yield information about the functional significance of stenosis found. Functionality of lesions can be assessed in the catheterization suite with the use of pressure wires, but this is often time consuming and costly. Echocardiographic findings may assist in the decision regarding the need for urgent coronary angiography. Normal global and regional function could lead to a more conservative approach, with later stress imaging to rule out significant coronary stenosis. Conversely, the finding of a new wall motion abnormality may prompt more urgent coronary angiography.

MCE for perfusion assessment may also be beneficial in determining the need for and timing of coronary angiography. Angiographic flow does not necessitate the presence of tissue perfusion. Several studies have evaluated the use of contrast echocardiography to assess microvascular reperfusion after acute myocardial infarction. Greaves and co-workers[38] performed contrast echocardiography in 15 patients post primary percutaneous coronary intervention for acute myocardial infarction. Analysis showed that a perfused hypokinetic or akinetic segment was 50 times more likely to recover function than a nonperfused segment. MCE predicted segmental myocardial recovery with a sensitivity of 88%, a specificity of 74%, and positive and negative predictive values of 83% and 81%, respectively. MCE outperformed other known modalities such as TIMI frame rate, myocardial blush grade, and percentage of ST segment resolution.

Myocardial viability post acute myocardial infarction determined by MCE and SPECT imaging were compared in 99 patients. Only MCE-determined viability was found to be an independent multivariate predictor of morbidity and mortality.[39]

## RISK STRATIFICATION AND ANALYSIS OF LONG-TERM CLINICAL OUTCOME

A number of studies have demonstrated incremental utility of echocardiography, beyond clinical assessment and electrocardiography in predicting clinical outcome of patients with acute chest pain.[40,41] In a prospective study of patients visiting a large urban emergency department, Fleischmann and colleagues[40] identified echocardiographic predictors of serious predischarge complications (significant recurrent myocardial ischemia, heart failure, and arrhythmia) in patients with chest pain. Doppler echocardiograms performed an average of 21 hours after presentation assessed biventricular, regional, and valvular function. In univariate analysis, LV function (OR 2.9), right ventricular (RV) function (OR 2.7), LV end-diastolic dimension (OR 1.6), LV end-systolic dimension (OR 1.4), and wall motion index (OR 3.0) predicted complications. Wall motion index was an independent predictor of complications beyond clinical and electrocardiographic variables.

The long-term survival of 448 patients in this study was examined.[13] Over a follow-up period of 35 ± 12 months, independent predictors of survival were moderate or severe LV dysfunction and more than mild valvular regurgitation. These echocardiographic findings offered incremental prognostic value over clinical and ECG findings in patients presenting with acute chest pain. Kaplan-Meier survival curves stratified by LV function and the grade of mitral regurgitation in this study are shown in Figures 13-6 and 13-7, respectively.

DSE has been shown to predict subsequent cardiac events in patients with known or suspected CAD.[42] A cohort of 860 patients was assessed using the 16-segment model for wall motion and followed for 52 months. The independent

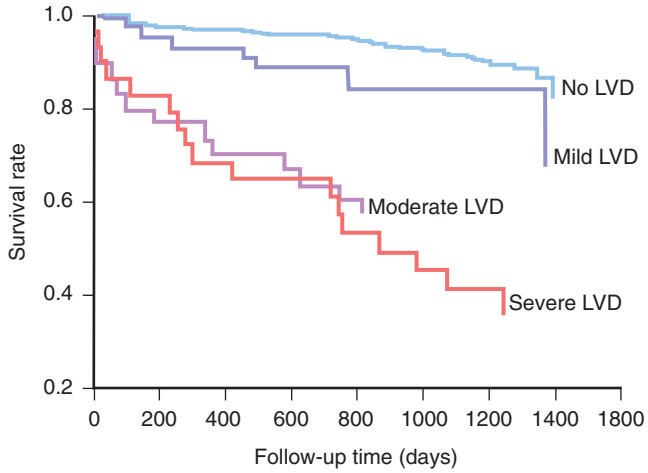

**Figure 13-6** Kaplan-Meier survival curves for patients presenting with chest pain stratified by LV dysfunction (*LVD*). *(From Fleischmann KE, Lee RT, Come PC, et al: Impact of valvular regurgitation and ventricular dysfunction on long term survival in patients with chest pain.* Am J Cardiol *80:1266-1272, 1997. **Figure 13-7** Kaplan-Meier survival curves for patients presenting with chest pain stratified by grade of mitral regurgitation (*MR*) (on a 4+ scale). *(From Fleischmann KE, Lee RT, Come PC, et al: Impact of valvular regurgitation and ventricular dysfunction on long term survival in patients with chest pain.* Am J Cardiol *80:1266-1272, 1997. From Excerpta Medica Inc.)*

predictors of cardiac events were history of congestive heart failure (hazard ratio 2.51), percentage of abnormal segments at peak stress (hazard ratio 1.23), and abnormal LV end-systolic volume response to stress (hazard ratio 1.98). The noninvasive diagnosis of CAD in women has been historically more difficult than in men. DSE may be the diagnostic test of choice in this patient population given its higher specificity.[43]

The use of exercise over pharmacologic stress has the advantage of accurately assessing functional capacity, an important prognostic indicator. Exercise echocardiography has been compared to DSE for the detection of CAD. A study by Dagianti and co-workers[44] compared dipyridamole echocardiography and dobutamine echocardiography with exercise echocardiography for the detection of CAD in 100 patients. Diagnostic accuracy was equal for exercise and dobutamine echocardiography at 87%, which was higher than that for dipyridamole (78%).

### EVALUATION OF OTHER CAUSES OF CHEST PAIN

Although the assessment of global and regional ventricular function is the core of the echocardiogram for the patient presenting with chest pain, it is essential to also provide a rapid screen for other nonischemic causes of chest pain.

Aortic dissection is a life-threatening diagnosis that may be detected on TTE, although sensitivity is limited (see Chapter 36). An intimal flap may be identified in the aortic root, proximal ascending aorta, arch, or descending abdominal aorta. It is important to note that the sensitivity of TTE imaging for aortic dissection is only 79%, compared to 99% for transesophageal echocardiograms.[45] Therefore, a negative TTE is not sufficient to exclude the diagnosis if clinical suspicion exists. Other potential clues to aortic dissection would include aortic regurgitation, a dilated proximal aorta, and the presence of a pericardial effusion.

Pericardial effusion can be diagnosed on TTE. The subcostal window is especially useful in patients with limited apical and parasternal image quality (Fig. 13-8). The potential hemodynamic consequences of a pericardial effusion may be evaluated by scanning for signs of right atrial collapse, RV collapse, exaggerated respiratory variation in tricuspid and/or mitral valve inflow velocities, and inferior vena cava size and respiratory variation. (See Chapter 29.) The use of echocardiographic guidance for pericardiocentesis has been shown to enhance the safety of the procedure.[46]

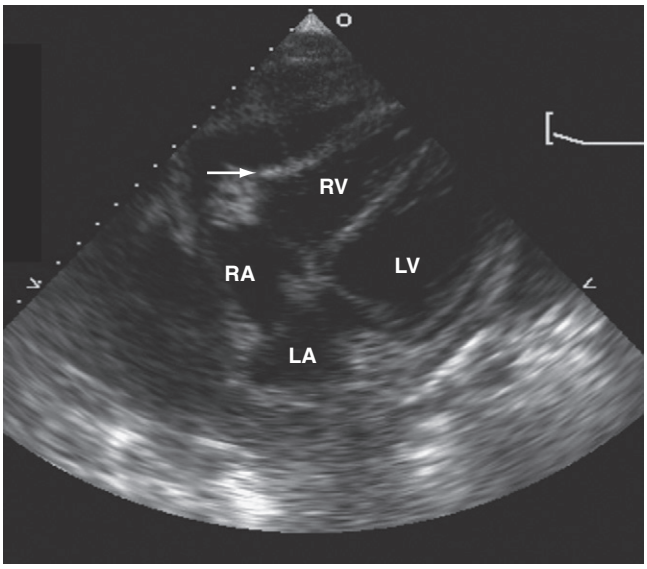

**Figure 13-8 Transthoracic images of a patient presenting to the emergency department with atypical chest pain.** This subcostal view shows a small pericardial effusion (*arrow*). The patient was diagnosed with pericarditis.

Screening for aortic stenosis involves 2D imaging for calcification and restricted movement of the valve, as well as Doppler measurement of transvalvular gradients (see Chapter 23). Similarly, signs of hypertrophic obstructive cardiomyopathy include hypertrophy (asymmetric), the presence of systolic anterior motion of the anterior mitral valve leaflet, and Doppler evidence of a dynamic gradient in the LV outflow tract (see Chapter 27).

## Limitations

### ISCHEMIA EVALUATION

Echocardiographic evaluation of patients with suspected acute coronary syndrome has several limitations. Between episodes of cardiac ischemia, the wall thickening may be completely normal, so normal LV systolic function in a pain-free patient cannot rule out cardiac ischemia as the cause of the patient's symptoms. In addition, small areas of ischemic myocardium, particularly in the subendocardium, may not result in a discernible wall motion abnormality, leading to false negatives. Using MCE to evaluate perfusion provides better risk stratification in these patients. Additional testing as appropriate to the patient's risk should be considered after infarction is ruled out.

The presence of preexisting LV dysfunction makes the evaluation of new regional wall motion abnormalities more difficult and may decrease the specificity of this technique.

### IMAGE QUALITY

Detection of regional wall motion abnormalities requires adequate visualization of endocardial borders, which may be difficult in patients with morbid obesity, chest wall deformity, chest trauma, or recent thoracic surgery. The use of second harmonic imaging with echocardiographic contrast administration may improve endocardial border delineation in such patients and make echocardiographic evaluation in the emergency department more feasible.

### PERSONNEL AVAILABILITY

Ready availability of skilled sonographers and echocardiographers is essential to expanding the use of echocardiography in the evaluation of patients with chest pain in the emergency department. Both sonographers and echocardiographers are generally available during usual working hours in most hospitals. However, it may not be economically practical to have personnel on site 24 hours a day for many medical centers. Contacting "on-call" sonographers and echocardiographers outside the hospital is inevitably associated with delays in the management of such patients. The national shortage of sonographers complicates the situation further.[45]

Digital tele-echocardiography systems, which allow transmission of digital images over a high-speed network to an experienced echocardiographer outside the hospital for immediate evaluation, may aid in ensuring adequate image interpretation.

**TABLE 13-2 A Sampling of Clinical Studies for Use of Echocardiography in the Assessment of Chest Pain**

| *Year* | *Study* | *Sample Size* | *Population* | *Result* |
|---|---|---|---|---|
| 1984 | Nishimura[a] | 61 | Patients within 12 hours of an acute MI | Increased wall motion score index was predictive of in-hospital complications |
| 1990 | Peels[b] | 43 | Acute chest pain with non diagnostic ECG and no history of CAD | 88% sensitive<br>78% specific for diagnosis of ischemia when compared to angiography |
| 1991 | Sabia[c] | 171 | Patients presenting with cardiac symptoms | LV systolic dysfunction predicts both short- and long-term cardiac events |
| 1994 | Fleischmann[d] | 513 | Patients presenting with chest pain | Moderate LV systolic dysfunction and significant valvular regurgitation independently predict survival |
| 1997 | Trippi[e] | 163 | Patients presenting with chest pain, normal markers and nondiagnostic ECG | DSE has a negative predictive value of 98.5% for coronary artery ischemia |
| 2003 | Bholasingh[f] | 377 | Patient with chest pain and nondiagnostic ECG, negative markers | DSE was an independent predictor of cardiac events |
| 2005 | Kang[g] | 114 | Patients presenting with chest pain at rest | Myocardial perfusion defect on contrast echocardiography was associated with an odds ratio of 21 for the diagnosis of acute MI |
| 2005 | Tong[h] | 957 | Patients with chest pain and nondiagnostic ECG | Contrast echocardiography provides short- and long-term prognostic information before results of cardiac markers |
| 2005 | Rinkevich[i] | 1017 | Patients with chest pain, no ST elevation | Wall thickening and myocardial perfusion predicted cardiac events |
| 2010 | Wei[j] | 720 | Patients with chest pain and no ST elevation | Regional wall motion abnormality ± abnormal perfusion was an independent predictor of nonfatal MI and cardiac death |

## Future Developments

### TELE-ECHOCARDIOGRAPHY

Electronic transmission of images has been used successfully in a variety of telemedicine projects (Table 13-2). Successful use in nonemergent settings has been reported in the difficult diagnostic cases, such as patients with congenital heart disease requiring special expertise.[47-49] Trippi and colleagues[15] (described previously) used DSE in the emergency department to determine which patients presenting with chest pain could be safely discharged. In this study, echocardiograms were digitized into a quad-screen systolic eight-frame cineloop format (resolution 320 by 240 pixels), then transmitted to the interpreting physician over the standard telephone line using a proprietary "lossless" format predating current DICOM standards.[50,51]

Technologic developments since that time, including higher memory capacity, faster microprocessors, and network connections via the Internet or dedicated lines, may result in more widespread use. Of course, transmission of patient-specific data also requires proper encryption and adequate safeguards to ensure patient privacy.

### STRAIN ANALYSIS FOR REGIONAL FUNCTION

Tissue-Doppler imaging[52-54] and speckle tracking have been shown to increase the sensitivity of regional function assessment (Fig. 13-9). Currently used for research purposes, these techniques have potential to aid in evaluation of regional wall motion once techniques are simplified for use on a routine clinical basis. (See Chapter 10.)

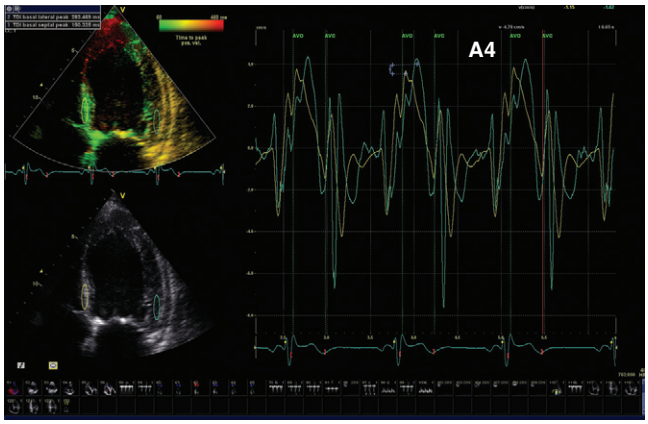

**Figure 13-9 Tissue-Doppler imaging of the LV in the apical four-chamber view in a patient with ischemia-induced LV dysfunction.** Areas of interest are highlighted at the basal septum and basal lateral wall. Results on the right represent the tissue velocities in the two areas of interest throughout the cardiac cycle.

## Summary

TTE can provide useful information in the diagnosis and triage of patients presenting with acute chest pain. Depending on the situation, stress echocardiography or transesophageal

echocardiography may provide additional information. The echocardiogram elicits information about global function, regional function, valvular function, and pericardial effusion. This not only helps in triage of patients with suspected acute coronary syndrome, but also can provide information on both short- and long-term outcomes. Newer techniques using echocardiographic contrast agents for LV opacification and myocardial perfusion have further enhanced the bedside echocardiographic assessment of patients with chest pain.

## KEY POINTS

- Acute chest pain results in millions of emergency department visits annually. Early diagnosis improves patient outcomes as well as reduces hospital costs.
- Echocardiography can help screen for the presence of myocardial ischemia with the assessment of wall motion. Wall motion abnormalities occur before the onset of symptoms or ECG changes in the ischemic cascade.
- The presence of aortic valve disease, LV or RV dysfunction, elevated pulmonary systolic pressure, or pericardial effusion could all be helpful in diagnosis of the patient with chest pain.
- Myocardial contrast agents are now commonly used not only for LV opacification and better endocardial definition, but also for perfusion assessment. MCE has a sensitivity of greater than 90% for the presence of acute myocardial infarction.
- Stress echocardiography is a safe and cost-effective way to assess for the presence of significant CAD.
- Treadmill stress echocardiograms require rapid acquisition of images after peak exercise to maintain sensitivity.
- Bicycle echocardiography can assess for evidence of inducible ischemia, as well as the effect of exercise on valvular disease, shunt or pulmonary artery pressure.
- Dobutamine echocardiograms have been used for the assessment of chest pain in patients with normal cardiac markers and normal ECG. The negative predictive valve has been shown to be greater than 98%.
- For patients at intermediate risk of CAD, stress echocardiography has been shown to be cost effective over routine treadmill testing or SPECT imaging.
- Echocardiograms performed early in the evaluation of patients with chest pain are prognostic for in-hospital complications as well as long-term prognosis.

## Applicable Modes of Echocardiography in the Coronary Care Unit

Echocardiography is ideally suited for cardiac imaging in the coronary care unit, with major advantages compared to other imaging modalities including its portability, ease of use, relative low cost, and the wealth of anatomic, hemodynamic, and functional information able to be obtained rapidly at the bedside. Soon after its earliest introduction, the use of transthoracic echocardiography (TTE) was extended to routine use in the coronary care unit, where it provides rapid bedside assessment of all stages of ischemic heart disease, ranging from presentations with undifferentiated acute chest pain, confirmation of acute myocardial infarction (MI), acute MI mechanical complications and heart failure, and the management of chronic ischemic heart disease.[1]

In the patient presenting with chest pain who has a nondiagnostic electrocardiogram (ECG), identification of a segmental wall motion abnormality assists in the determination of definitive therapy. High-quality two-dimensional (2D) imaging obtained either during chest pain or shortly thereafter has a negative predictive value of approximately 95% for the identification of acute MI. In the patient with an established MI, early evaluation of left ventricular (LV) ejection fraction, regional wall motion, diastolic function, and mitral regurgitation greatly assists with management. When recurrent chest pain complicates reperfusion therapy, electrocardiographic changes may be nonspecific. In this situation, echocardiography helps differentiate between recurrent ischemia and pericarditis. The cause of hemodynamic instability in patients with MI, including pump failure and mechanical complications, often can be established by bedside TTE without invasive monitoring.

Despite advances in echocardiographic imaging, assessment of regional wall motion remains a challenge with interobserver variability. The use of left-sided contrast agents for LV opacification improves interobserver agreement and has been shown to be superior to routine evaluation for the detection of acute coronary syndromes.[2] Because perfusion abnormalities precede wall motion abnormalities in the ischemic cascade, myocardial contrast echocardiography has a higher sensitivity for the detection of coronary artery disease.[3] Myocardial contrast echocardiography also has a significant role in the evaluation of myocardial viability.[4] Quantitation with myocardial strain techniques is a further significant step forward to reduce interobserver variability in the assessment of regional wall motion abnormalities. Myocardial strain was initially based on tissue Doppler, with the main limitation of angle dependence, and has been largely replaced by the development of speckle-tracking techniques.[5-7]

Progressive improvements and miniaturization of handheld echocardiographic instruments have resulted in their increasing use as an adjunct to the physical examination. They are particularly useful for targeted evaluation of global and regional LV and right ventricular (RV) systolic function and for the detection of pericardial effusion. Several studies have shown the utility of these systems,[8-10] but they are not yet comparable to

full-service systems, and care should be exercised to ensure that clinicians using and reporting studies with these instruments are appropriately trained. (See Chapter 8.)

In patients with severe hemodynamic compromise, TTE may be limited by mechanical ventilation, recent cardiac surgery, and an inability to adequately position the patient. Whereas the use of contrast agents has reduced the need for alternative imaging modalities in this situation, transesophageal echocardiography (TEE) has proven to be efficacious, especially in ruling out complications related to cardiac rupture and for the assessment of global and regional ventricular function. With careful sedation and close monitoring, TEE can be performed safely early after acute MI.

Stress echocardiography has an important role in the postinfarction period for the assessment of myocardial viability and inducible myocardial ischemia. (See Chapters 15 and 16.) Dobutamine stress echocardiography (DSE), using low doses that do not significantly alter hemodynamics, improves function in viable but not in nonviable myocardial segments. Higher doses of dobutamine and exercise echocardiography can be used to detect residual ischemia. DSE should be used with caution early after MI as a result of reports of free wall rupture in association with high-dose dobutamine stress testing within the first week following MI.[11] Cardiac magnetic resonance imaging (MRI) is increasingly used for the assessment of myocardial viability as well as ischemia and may provide improved image quality. However, MRI is not as readily available as TTE in most cardiac centers, is not portable, and is not suitable in certain patients, including patients with a pacemaker or implanted cardiac defibrillator, and those with certain arrhythmias.

Three-dimensional (3D) echocardiography has evolved from a research tool with limited clinical applicability to widespread clinical use. (See Chapter 4.) Recent reports have demonstrated the clinical feasibility of volumetric analysis of real-time 3D echocardiographic data that allows fast, semiautomated, dynamic measurement of LV volume and ejection fraction; automated detection of regional wall motion abnormalities[12]; and real-time 3D echocardiographic perfusion imaging.[13] It is likely that real-time 3D echocardiography will continue to play a prominent role in the comprehensive assessment of patients with coronary artery disease.

## Echocardiography in the Diagnosis and Localization of Acute Myocardial Infarction

### DIAGNOSTIC ROLE OF ECHOCARDIOGRAPHY

The accuracy of an echocardiographic diagnosis of an MI is dependent on its ability to detect wall motion abnormalities in the involved segment. The severity of the wall motion abnormality depends on the transmural extent of the infarction, and the circumferential limits depend on the arterial distribution and collateral blood supply. Images of the left ventricle (LV) adequate for segmental analysis of wall motion can be obtained in more than 90% of patients by skilled sonographers, and the use of left-sided contrast agents has increased the percentage of patients in whom technically adequate images can be obtained.[14,15] The most widely used scoring system for grading the severity of a wall motion abnormality is that recommended by the American Society of Echocardiography,[16] as shown in Table 14-1. Several studies have examined the specificity of echocardiographic wall motion abnormalities for diagnosis of acute coronary syndromes, showing a higher specificity for infarction than for ischemia. Other causes of segmental dysfunction must be recognized, and a false-positive diagnosis can often be avoided if wall thickening is examined in addition to endocardial motion. The inward motion of the endocardial surface may be delayed or paradoxical owing to abnormal conduction in the presence of Wolff-Parkinson-White syndrome,[17] a left bundle branch block,[18] or RV pacing.[19] Paradoxical septal motion also is present in RV volume overload and following open-heart surgery.[20] In these conditions, the systolic thickening of the septum or other involved segment (e.g., posterolateral wall in Wolff-Parkinson-White syndrome) should be preserved. Nonischemic causes of segmental dysfunction that result in reduced systolic thickening and endocardial motion include focal myocarditis, idiopathic cardiomyopathy, and the apical ballooning syndrome (takotsubo cardiomyopathy).[21] TTE is valuable in the diagnosis of takotsubo cardiomyopathy, with characteristic acute features of LV impairment in a noncoronary distribution and early improvement of LV function on serial echo consistent with myocardial stunning rather than MI.[22] Tong and colleagues[23] reported on the diagnostic and prognostic value of myocardial contrast echocardiography in 957 patients presenting to the emergency department with suspected cardiac chest pain and a nondiagnostic ECG. Only 2 of 523 patients with normal regional function had an early primary event, and regional function provided incremental prognostic value for predicting intermediate and late events. In patients with abnormal regional function, myocardial perfusion further classified patients into intermediate- and high-risk groups. The authors suggested that patients with both abnormal regional function and abnormal myocardial perfusion are at high risk for early cardiac events and could be triaged even before cardiac serum markers become available. Although this is a promising technology, expertise in the acquisition and interpretation of the images may not be widely available, and the cost effectiveness requires further study. Newer techniques for the evaluation of regional wall motion, including myocardial strain rate imaging and tissue characterization, are discussed in more detail in Chapter 10.

**TABLE 14-1 Scoring System for Grading Wall Motion[16]**

| *Score* | *Wall Motion* | *Endocardial Motion** | *Wall Thickening** |
|---|---|---|---|
| 1 | Normal | Normal | Normal (>30%) |
| 2 | Hypokinesis | Reduced | Reduced (<30%) |
| 3 | Akinesis | Absent | Absent |
| 4 | Dyskinesis | Outward | Thinning |
| 5 | Aneurysmal | Diastolic deformity | Absent or thinning |

*In systole.

### LOCALIZATION OF INFARCTION

The classification of acute MI according to electrocardiographic patterns has been based largely on comparing autopsy findings with the distribution of pathologic Q waves during the chronic phase of infarction. Echocardiographic localization has significant advantages over electrocardiographic localization, particularly for apical and lateral wall infarction.

In 1989, the American Society of Echocardiography recommended a 16-segment model for LV segmentation.[16] More recently, in an attempt to establish segmentation standards applicable to all types of imaging, including echocardiography,

nuclear perfusion imaging, cardiovascular MRI, and cardiac computed tomography (CT), a 17-segment model has been proposed.[24] This new model includes the apical cap, which is the segment beyond the end of the LV cavity, and is generally only seen with some contrast and myocardial perfusion studies. With routine echocardiographic studies, the 16-segment model can be used, without the apical cap. The LV segments and the approximate and most common coronary arterial distribution in relation to these segments are depicted in Figures 14-1 and 14-2, respectively. The anterior, anterolateral, anteroseptal, and

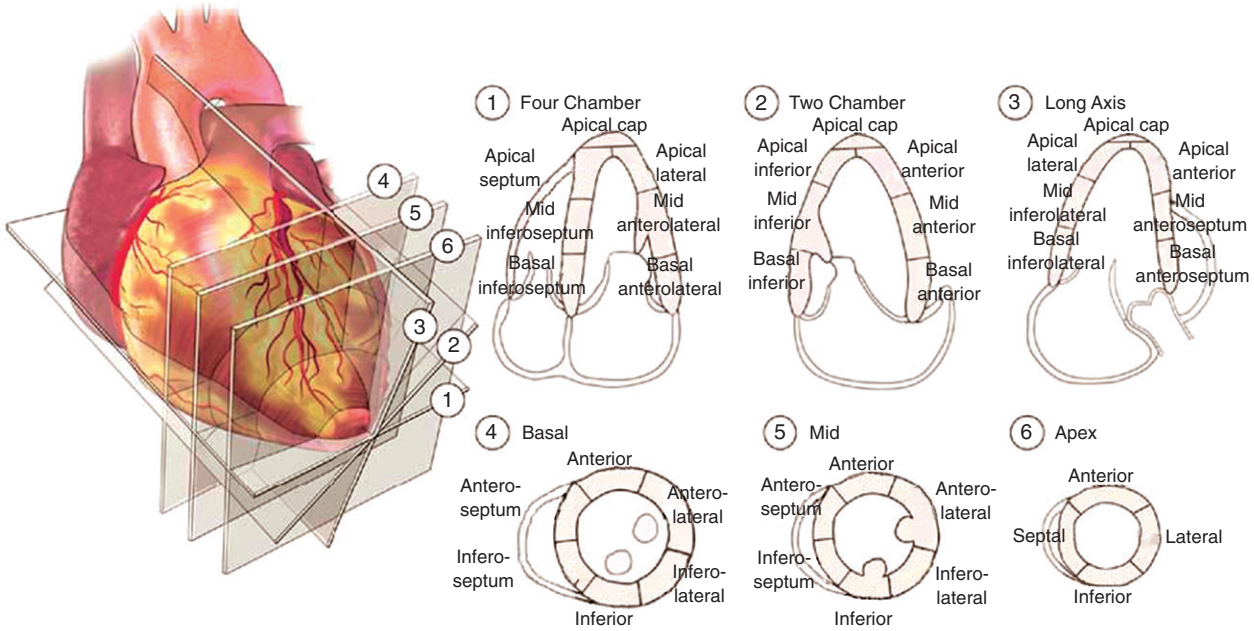

**Figure 14-1** Segmental analysis of LV walls, based on schematic views, in parasternal and apical views. *(From Lang RM, Bierig M, Devereux RB, et al: Chamber Quantification Writing Group; American Society of Echocardiography's Guidelines and Standards Committee; European Association of Echocardiography. apical (anterior and septal) segments correspond to the left anterior descending (LAD) artery distribution. Isolated disease in a diagonal branch of the LAD artery results in a discrete wall motion abnormality in the portion of the anterolateral wall supplied by that vessel. The lateral wall and lateral apex are in the distribution of the left circumflex artery. The inferolateral wall is supplied by the posterior descending artery. In 80% of the population, the posterior descending artery arises from the right coronary artery and supplies the inferolateral wall and the inferior free wall and inferior septum (right dominant). In the other 20% of patients, the posterior descending artery arises from the circumflex artery (left dominant system). The right ventricle (RV) is supplied by the right coronary artery via its acute marginal branches. In general, infarctions in the LAD distribution tend to be more apically situated, whereas those in the right coronary artery and the circumflex distribution are more basal in their location. The extent of apical involvement and its distribution depends, to a degree, on the relative supply from the left anterior and posterior descending arteries. It should be noted that the extent of the segmental wall motion is related to the exact coronary anatomy in an individual patient, which may be variable. In addition, the presence of collaterals and previous bypass surgery alters the distribution of ischemia and infarction relative to the involved arterial supply.

Direct visualization of the ostia of the left main coronary artery and right coronary artery and the proximal LAD artery in adults may be achieved using TTE and TEE, and this may be useful to exclude anomalous coronary artery origins. (See Chapter 17.) Transthoracic Doppler echocardiography may also be useful to determine coronary artery flow. Otsuka and colleagues[25] recently showed that the detection of reverse flow in the distal right coronary artery and the inferior septal branches using transthoracic Doppler echocardiography detected an occluded right coronary artery with a sensitivity and specificity of 100% and 98%, respectively. Lee and colleagues[26] showed in a study of 46 consecutive patients with first acute anterior MI that diastolic peak distal LAD artery flow velocity equal to 25 cm/s by transthoracic Doppler echocardiography could distinguish TIMI 3 flow in the LAD coronary artery from TIMI 2 flow with a sensitivity, specificity, and accuracy of 77%, 94%, and 89%, respectively. The use of contrast agents may expand the feasibility of this technology to localize a coronary artery stenosis and quantify coronary flow.

## RIGHT VENTRICULAR INFARCTION

Although RV infarction was first described in the 1930s, it was only after the hemodynamic consequences were recognized in the 1970s that RV infarction was considered a clinical entity.

RV infarction occurs in up to 50% of inferior MI, but hemodynamic compromise develops in fewer than half of such cases.[27] The RV is predominantly supplied by acute marginal branches of the right coronary artery, and occlusion of the right coronary artery proximal to the origin of these branches results in ischemic dysfunction of the RV. When the occlusion is distal to the right atrial (RA) branches, augmented RA contractility enhances RV function and cardiac output. Conversely, more proximal occlusions result in ischemic depression of RA contractility, which impairs RV filling and function, resulting in more severe hemodynamic compromise. Much less commonly, RV infarction occurs in association with acute anteroseptal MI as a result of a variation of coronary artery anatomy in which RV branches arise from the LAD artery.[28] In addition, the anterior apex of the RV may be supplied by the LAD "wrapping" around the apex of the heart. Isolated RV infarction has been reported to occur in fewer than 3% of autopsy studies of acute MI.[28]

**Box 14-1**

### ECHOCARDIOGRAPHIC SIGNS OF RIGHT VENTRICULAR INFARCTION

**Primary**
RV dilation
Segmental wall motion abnormality of the RV free wall
Decreased descent of the RV base
Tricuspid valve annulus peak systolic velocity <12 cm/s

**Secondary**
Paradoxic septal motion
Tricuspid regurgitation
Tricuspid papillary muscle rupture
Pulmonary regurgitant jet pressure half-time <150 ms
Dilated inferior vena cava
Right-to-left interatrial septal bowing
Right-to-left shunting across patent foramen ovale

The diagnosis of RV infarction should be suspected in a patient with jugular venous distention and clear lung fields in the setting of an inferior MI. The clinical importance of RV infarction is emphasized by the much higher incidence of hemodynamic compromise, arrhythmias, and in-hospital mortality than MI involving only the LV.[29] The electrocardiographic sign of 1-mm ST segment elevation in $V_{4R}$ is sensitive and specific for the diagnosis, but these changes may resolve within 12 hours and do not provide information as to the extent of involvement or its hemodynamic impact.[30]

Echocardiography plays a vital role in the evaluation of patients with suspected RV infarction[31] (Box 14-1). In an early report, Sharpe and colleagues[32] described the M-mode echocardiographic findings of RV infarction including RV enlargement and paradoxical septal motion. The 2D echocardiographic signs of RV infarction include RV dilation, decreased RV function, segmental wall motion abnormalities, and paradoxical septal motion.[33] In many cases, the inferior wall motion abnormality may be relatively small with preserved overall LV function. Tissue Doppler echocardiography may provide complementary evidence for RV infarction. In a study of 60 patients with a first acute inferior MI, a tricuspid valve annulus peak systolic velocity less than 12 cm/s had a sensitivity, specificity, and negative predictive value of 81%, 82%, and 92%, respectively, for RV infarction.[34] Tricuspid annular plane systolic excursion of 14 mm or less is a useful objective measure of RV dysfunction and should be measured in patients with suspected RV infarction. Reduced RV compliance may be detected by an increased A wave velocity on the hepatic vein flow signal and by a short pressure half-time of the pulmonary regurgitant jet (less than 150 ms). The latter has been shown to be a predictor of in-hospital events in patients with RV infarction.[35] Characteristic echocardiographic features of RV failure with high RA pressures include bowing of the interatrial septum into the left atrium (LA) and dilation of the inferior vena cava with lack of inspiratory collapse. These echocardiographic indicators of RV function correlate with clinical status and prognosis.[36]

Echocardiography also plays a crucial role in detecting complications of RV infarction, including ventricular septal rupture,

severe tricuspid regurgitation (as a result of papillary muscle ischemic dysfunction or rupture) and functional regurgitation resulting from tricuspid valve annular dilatation. In addition, severe hypoxemia resulting from right-to-left shunting across a patent foramen ovale may occur with large RV infarction associated with elevated RA pressures.

In most cases of RV infarction, RV function improves and returns to near normal within 3 to 12 months regardless of the patency of the infarct-related artery, although the improvement may not be complete when compared to a control group.[37] Experimental evidence suggests that this unique feature of RV functional recovery is a result of the beneficial effects of collaterals and the more favorable oxygen supply-demand characteristics compared to the LV.[37] Because the acutely ischemic dysfunctional RV represents predominantly viable myocardium, which may spontaneously recover or respond favorably to successful reperfusion even late after the onset of occlusion, it has been suggested that the term *RV infarction* is largely a misnomer and that the term *RV ischemic dysfunction* should be used.[38] However, it is important to recognize that RV infarction is associated with high in-hospital mortality, and early pharmacologic[39] or mechanical[33] reperfusion enhances recovery of RV function with an improved clinical course and survival. Although relatively uncommon, cardiogenic shock due to RV infarction has similar poor outcomes to patients with cardiogenic shock due to LV infarction.[40]

## Detecting Complications of Acute Myocardial Infarction

The prognosis of MI markedly improved with the advent of thrombolysis and primary percutaneous coronary intervention (PCI), and survival is excellent for most patients who receive timely restoration of flow of the culprit vessel. A large MI, typically due to prolonged occlusion of the LAD resulting in a large territory of severely hypokinetic myocardium, may be complicated early and late by pump failure. In the acutely hemodynamically unstable patient, it is critical to exclude cardiac rupture, a situation that is potentially amenable to surgery, before concluding that cardiogenic shock is on the basis of pump failure (Box 14-2). In most cases, TTE (supplemented when necessary by TEE) is sufficient to exclude papillary muscle, free wall, and ventricular septal rupture. Most of the earlier published studies on the incidence of mechanical complications of acute MI were performed in the prethrombolytic era, when TTE was in its relative infancy with respect to image quality and expertise in reporting. Table 14-2 compares the incidence of mechanical complications after acute MI before and in the reperfusion era.

### HEMODYNAMIC CLASSIFICATION OF MYOCARDIAL INFARCTION USING DOPPLER ECHOCARDIOGRAPHY

In 1967, Killip and coworkers[41] classified patients with acute MI into four groups depending on the clinical manifestations of cardiac failure on admission. In 1977, Forrester et al[42] classified patients with acute MI using right heart catheterization into four groups based on cardiac index and pulmonary capillary wedge pressure (PCWP). Both classifications predicted in-hospital mortality independently of the patient's age, gender, precipitating factors, and location of the MI. Although invasive measurement of PCWP and cardiac output may be performed in patients with acute MI complicated by cardiac failure or cardiogenic shock, recent data suggest that the use of invasive catheters in critically ill patients may be associated with increased mortality.[43]

A carefully performed Doppler echocardiographic study can provide sufficient information to determine a patient's hemodynamic category after infarction. The noninvasive measurement of cardiac output and PCWP in patients with acute MI and cardiac failure is useful to guide therapy and for prognosis.

A simple echocardiographic method of estimating cardiac output is to measure the velocity-time integral of aortic flow by pulsed-wave or continuous-wave Doppler. In patients with acute MI, various measures of LV diastolic function have been shown to accurately estimate PCWP when compared to invasive measurements. Earlier studies demonstrated the value of transmitral Doppler to estimate PCWP. In a study of postinfarction patients with LV ejection fraction less than 35%, a mitral deceleration time of less than 120 ms was highly predictive of a PCWP greater than 20 mm Hg.[44]

Subsequent studies showed the value of pulmonary venous flow Doppler to estimate PCWP. In subjects older than 40 years of age with normal filling pressures, pulmonary venous peak velocities and velocity-time integrals are higher during systole

**Box 14-2**

### ECHOCARDIOGRAPHY IN COMPLICATIONS OF MYOCARDIAL INFARCTION

**Hemodynamic States**
Hypovolemia
RV infarction
Globally reduced LV contractility

**Mechanical Complications**
Papillary muscle rupture and severe mitral regurgitation
Ventricular septal rupture
Free wall rupture and tamponade

**Other**
LV aneurysm
Mural thrombus
Pericardial effusion

**TABLE 14-2 Comparison of the Incidence of Mechanical Complications after Acute Myocardial Infarction before and in the Reperfusion Era**

| *MI Complication* | *Before Reperfusion Era (Average)* | *In Reperfusion Era* |
|---|---|---|
| Pericardial effusion | 25% | 6.6% |
| LV thrombus (anterior MI) | 35-40% | 5.5% |
| Mitral regurgitation | 53% | 28% |
| Infarct expansion | 30% | 4% |
| Septal rupture | 1-3% | 0.6% |
| Free wall rupture | 2% | 0.8% |

*MI*, Myocardial infarction.

than during diastole, and the duration of the pulmonary venous A wave is less than that of the mitral A wave. With high filling pressures, diastolic filling predominates and the A wave duration exceeds that of the mitral A wave. In patients with acute MI, a systolic fraction of pulmonary venous flow less than 45% was highly associated with a PCWP greater than 18 mm Hg.[45] In a study comparing pulmonary venous flow Doppler to transmitral Doppler to estimate PCWP in patients with acute MI, the deceleration time of the diastolic component of pulmonary venous flow had a better correlation with PCWP than the mitral deceleration time. The sensitivity and specificity of a diastolic component pulmonary venous deceleration time less than 160 ms in predicting a PCWP greater than or equal to 18 mm Hg were 97% and 96%, respectively, compared with 86% and 59%, respectively, for a mitral deceleration time of less than 130 ms.[45]

Several newer parameters of LV diastolic function have been studied in postinfarction patients. Tissue Doppler imaging measuring mitral annular velocities is a well-validated method for estimating PCWP.[46] The Tei index, defined as the sum of isovolumic contraction and relaxation times divided by ejection time, expresses global LV function. In patients with acute MI, the Tei index has been shown to correlate significantly with the PCWP and the cardiac index. A Tei index of 0.60 or greater diagnosed impaired hemodynamics (PCWP of at least 18 mm Hg and/or cardiac index of 2.2 L/min/$m^2$ or less) with a sensitivity, specificity, and accuracy of 86%, 82%, and 83%, respectively.[47] In addition, a Tei index of 0.55 or greater can distinguish pseudonormal/restrictive mitral flow from normal mitral flow with a sensitivity, specificity, and accuracy of 84%, 100%, and 88%, respectively.[48]

Elevated pulmonary artery systolic pressure is associated with increased mortality in acute MI.[49] Doppler echocardiographic measurement of pulmonary artery systolic pressure using tricuspid regurgitant jets has been well validated, and the size and respiratory dynamics of the inferior vena cava can be used to estimate RA pressure.

Combining these parameters with measurements (quantitative or qualitative) of LV and RV function, color flow Doppler interrogation for mitral regurgitation, and assessment of mechanical complications results in a comprehensive evaluation of the hemodynamic state after infarction. When the data from a transthoracic examination are incomplete, one should not hesitate to employ TEE given its established safety even in the critically ill patient. Of course, the hemodynamic information available from an echocardiographic examination is available only at a single point in time, and continued invasive monitoring may be necessary in patients with ongoing instability.

## POSTINFARCTION PERICARDITIS AND PERICARDIAL EFFUSION

Postinfarction pericarditis occurs within the first 4 days following an ST segment elevation MI treated with early thrombolysis or primary PCI.[50,51] The reported frequency of postinfarction pericarditis is variable depending on the definition used, with most studies basing the diagnosis on the presence of one or more of the following: pericardial chest pain, pericardial friction rub, and/or typical ECG changes. Regardless of the definition used, the incidence of postinfarction pericarditis has markedly decreased from up to 25% in the prethrombolytic era to approximately 5% in large studies of patients treated with thrombolytics and/or primary PCI, with a prevalence related to the timing of restoring patency of the culprit vessel.[52] Colchicine may be used for the treatment of pericarditis in this setting, and early postinfarction pericarditis is usually self-limiting after a few days. Late cardiac tamponade and constrictive pericarditis are not recognized complications. Onset after 10 days is usually considered Dressler syndrome, which also has a much lower incidence in the modern era of early reperfusion, of 0.5% with thrombolysis and 0.1% with primary PCI.

A pericardial effusion that occurs after an MI is not pathognomonic of pericarditis, and there is only a weak association between pericarditis and pericardial effusion in this setting. Several investigators have reported on the incidence of pericardial effusion following infarction, with an average incidence of approximately 25%.[53] In these studies, pericardial effusion was associated with larger infarctions as measured by wall motion scores or degree of creatine kinase elevation. The incidence of congestive heart failure and mortality is higher in those patients with effusions apparent on echocardiography. These earlier reports of a high incidence of pericardial effusion after an MI were mostly in the prethrombolytic era in the 1980s. In a contemporary large study of 908 patients from 25 French hospitals,[54] a pericardial effusion was noted in 6.6% of patients when assessed by ECG at admission and at discharge. In most cases the effusion was small and hemodynamically insignificant. Infarct-associated pericardial effusion usually occurs within the first 5 days but may occur at anytime during the first 3 weeks. The effusion is usually small, and circumferential effusions are rare. Spontaneous resolution of the effusion is usually slow, ranging up to 6 to 18 months. Moderate to large pericardial effusion (10 mm or more) after an MI is uncommon. Although most often associated with LV free wall rupture, it can also occur with heart failure or pericarditis. In the largest published study on moderate to large pericardial effusion after an MI, the overall 30-day mortality rate was 43% and was higher in those with cardiac tamponade and electromechanical dissociation (89%) than in those with cardiac tamponade and hypotension (22%) and those without initial tamponade (17%). Even in the absence of electromechanical dissociation or tamponade, mortality was twice that of patients with a moderate to large pericardial effusion.[55]

Although cardiac rupture is the most common cause of a moderate to large pericardial effusion early after acute MI, the differential diagnosis in the acute setting must include aortic dissection and perimyocarditis. In addition, iatrogenic pericardial effusion may occur after coronary stenting with vessel rupture, after implantation of a temporary pacemaker with perforation of the RV, after cardiac biopsy, and after a transseptal puncture for interventional procedures.

## ACUTE MITRAL REGURGITATION

Acute mitral valve incompetence in the setting of MI is usually a result of necrosis and rupture of papillary muscle tissue (Fig. 14-3). Incomplete coaptation of the mitral valve leaflets secondary to LV remodeling and distortion of ventricular architecture may also cause mitral regurgitation, and this is discussed in more detail later.

The clinical recognition of mitral regurgitation in the setting of MI may be confounded by several variables. Up to 50% of patients with hemodynamically significant mitral regurgitation do not have an audible murmur owing to rapid equalization of LV and LA pressures (especially in a low output state) or because

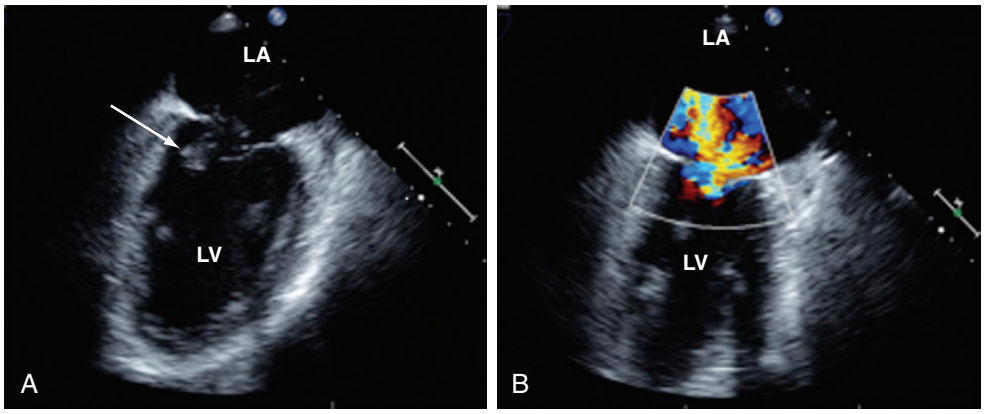

**Figure 14-3** TEE (65° view) showing (**A**) papillary muscle rupture (*arrow*) and (**B**) severe mitral regurgitation due to papillary muscle rupture.

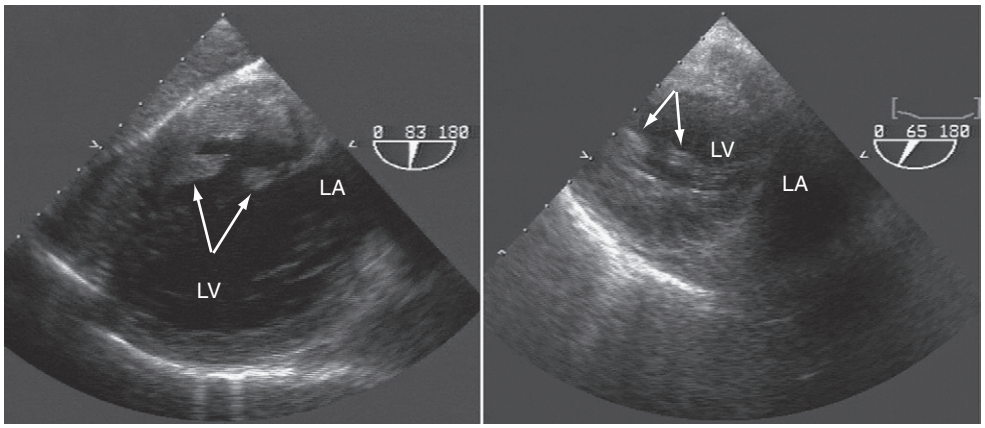

**Figure 14-4** TEE (transgastric views) of posteromedial papillary muscle rupture (*left*), which is more common as a result of its single blood supply, and anterolateral papillary muscle rupture (*right*), which is less common as a result of a dual blood supply.

the murmur is obscured by lung sounds in a patient with pulmonary edema or mechanical ventilation. In those patients with a new systolic murmur and evidence of cardiac failure, the main differential diagnosis is papillary muscle rupture and acute ventricular septal rupture. In this situation, TTE is highly accurate in establishing the cause, but TEE may be necessary to determine the precise anatomic defect.

Detection and grading of mitral regurgitation is accomplished with 2D, M-mode, color, and spectral Doppler techniques. 2D imaging may detect abnormalities in the mitral valve apparatus, including flail leaflets and/or ruptured papillary muscle. Even if not clearly visualized, papillary muscle rupture should be suspected when there is an eccentric jet of mitral regurgitation with a relatively normal-sized LA. Although color flow parameters are those most often used, accurate grading of mitral regurgitation severity should encompass other Doppler-echocardiographic signs as well.[56] In the patient with pulmonary edema, the unexpected findings of a small infarction, a hyperdynamic LV, or increased early mitral inflow velocity[57] should prompt a careful search for mitral regurgitation even when color flow Doppler mapping is unrevealing.

Papillary muscle necrosis with rupture and acute severe mitral regurgitation is a life-threatening complication of MI that almost always requires urgent surgical intervention. In a review of papillary muscle rupture, 15 of 17 cases occurred in patients with inferior infarction and rupture of the posteromedial papillary muscle.[58] The more frequent involvement of the posteromedial papillary muscle is due to its blood supply from a single coronary artery (posterior descending artery) compared to the dual coronary artery supply of the anterolateral papillary muscle (LAD and circumflex arteries) (Fig. 14-4). Chordae to both leaflets arise from each of the papillary muscles, so that in cases of "complete" rupture of the entire trunk of a papillary muscle, both leaflets are affected. In less severe cases, the rupture is "incomplete" and only a single head is torn. The 2D echocardiographic findings include prolapse of one or both leaflets, a flail leaflet, and liberation of a portion of the papillary muscle. In some patients, the ruptured muscle may remain tethered to the chordae, and chaotic motion is present. Spectral and color flow Doppler imaging of the jet is usually easily accomplished with surface imaging, but an eccentric path of flow may complicate its identification. TEE is superior in this regard.

When only a single head of the papillary muscle is affected (incomplete rupture), medical stabilization often is possible. When rupture is complete, involving the main trunk of the papillary muscle, the complication is uniformly fatal without immediate recognition and prompt surgical repair.

## VENTRICULAR SEPTAL RUPTURE

Ventricular septal defect owing to myocardial rupture had a reported incidence during the prethrombolytic era of 1% to 2% of all acute MIs and up to 5% of all fatal infarctions.[59] In the GUSTO-1 trial, the incidence of ventricular septal rupture was only 0.2% (84 of 41,021 enrolled patients), suggesting that

thrombolytic therapy reduced the incidence of rupture.[60] Primary PCI has also reduced the incidence of ventricular septal rupture to 0.2% to 0.5%. In the largest published series, of 408 patients with ventricular septal rupture complicating acute MI between 1990 and 2007, the rate of rupture remained unchanged at 0.25% to 0.31%, and the mortality rate remained high and relatively constant. The survival benefit associated with surgical repair was seen only in hospital but not at 30 days or 1 year. Overall in-hospital, 30-day, and 1-year mortality rates were 50%, 54%, and 65%, respectively, similar to previous reports.[59]

Ruptures occur only in the presence of transmural infarction and result from hemorrhage within the necrotic zone. Independent risk factors for the development of a ventricular septal defect include first infarction, advanced age (older than 65 years), hypertension, female gender, and chronic renal disease.[61] In addition, there is a higher incidence in patients without a history of prior angina and with infarcts in the distribution of a single vessel. Thus, septal rupture is more likely following abrupt occlusion of a single artery that vascularizes a territory for which there is little collateral flow. Unlike papillary muscle rupture, ventricular septal rupture occurs with equal frequency among patients with anterior (LAD) and inferior (right coronary artery) infarctions but less frequently in those with lateral (left circumflex artery) infarctions.[62]

In the prethrombolytic era, ventricular septal rupture usually presented 3 to 6 days after acute MI, whereas most ventricular septal ruptures associated with early thrombolytic therapy or primary PCI occur at a peak incidence time within 24 hours after treatment.[60] Thus, although timely restoration of culprit vessel patency reduces the rate of rupture, it tends to occur earlier. Thrombolytic therapy that is delayed more than 12 hours following the onset of chest pain may increase the incidence of ventricular septal rupture.[63]

Patients with ventricular septal rupture usually present with recurrent chest pain, dyspnea, and sudden hypotension or shock. A new harsh pansystolic murmur is present in approximately 50% of patients but may be difficult to distinguish clinically from acute severe mitral regurgitation and may be relatively soft with LV failure or pulmonary hypertension. Particular ECG changes may be associated with an increased likelihood of septal rupture. It has recently been shown that in patients with anterior MI with ST-segment elevation in all inferior ECG leads in addition to anterior leads, ventricular septal rupture occurred in 9 of 21 patients (43%), but those ECG changes were present in only 10 of 275 patients (3.6%) of those who did not have septal rupture.[64]

Bedside echocardiography is highly sensitive and specific in the diagnosis of ventricular septal rupture. Simple ventricular septal rupture is a discrete defect with a direct through-and-through communication between the LV and RV, with ventricular entry and exit sites located at a similar horizontal level. Complex ventricular septal rupture has entry and exit sites at different levels along the ventricular septum through a dissecting hemorrhage. A dissecting hematoma is seen as intramyocardial echocardiographic lucent defects. Ventricular septal ruptures may be multiple, and there may be associated LV free wall or papillary muscle rupture. Infarct expansion is readily diagnosed by echocardiography and typically occurs before rupture. Ventricular septal rupture due to occlusion of the right coronary artery usually occurs in the basal inferior septum (Fig. 14-5), and ventricular septal rupture after acute anterior MI most often occurs in the distal one third of the septum (Fig. 14-6). When ventricular septal rupture is clinically suspected, it is often necessary to use nonconventional imaging planes, first with color Doppler to locate the defect, and then with 2D imaging. The width of the jet by color flow Doppler correlates with the size of the defect as measured at surgery. Although the peak gradient across the ventricular septal defect measured with continuous wave Doppler allows an estimate of RV systolic pressure, the measurement should be used with caution in patients with complex defects involving indirect tracts through the myocardium. Associated echocardiographic findings of elevated RV pressure include RV dilation, decreased RV systolic function, and paradoxical septal motion. Signs of increased RA pressure include RA dilation, bowing of the interatrial septum toward the left throughout the cardiac cycle, and plethora of the inferior vena cava. When TTE is suboptimal, TEE is highly accurate with improved delineation of the site of defect, morphology, presence of multiple defects, and extent of RV involvement.

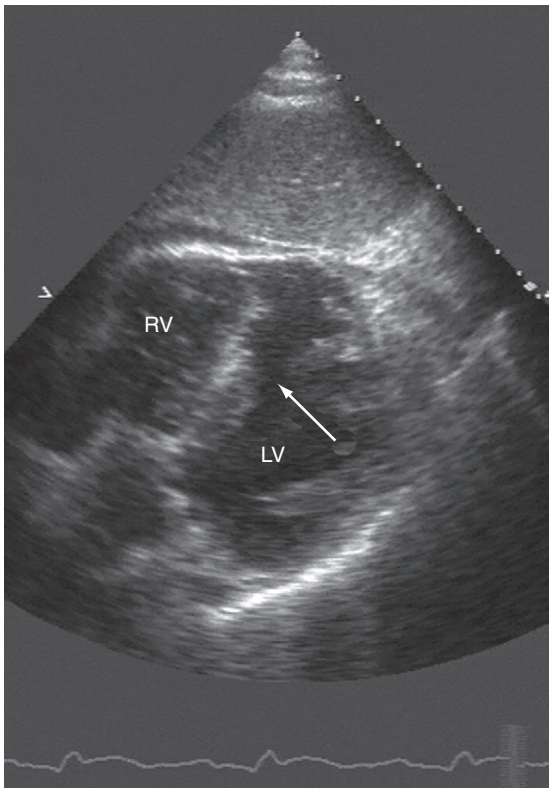

**Figure 14-5** TTE (subcostal view) showing a large ventricular septal defect resulting from a rupture in a patient with a large inferior myocardial infarction. The area of discontinuity can be visualized as a large, irregularly shaped area of myocardial dropout (*arrow*). Note the dilated RV consistent with RV infarction or RV volume/pressure overload.

Although ventricular septal rupture carries a very high mortality rate, with and without urgent surgery, echocardiography may risk stratify patients. Complex septal ruptures and RV involvement are significant determinants of adverse clinical outcome.[65] Rupture of the posterior septum after inferior MI is associated with a higher mortality rate, related to the degree of associated RV dysfunction. Moreover, posterior septal ruptures tend to be more complex and associated with remote myocardial involvement. In contrast, anterior septal defects more often have a direct course and involve a discrete myocardial region. The strongest indicator of poor prognosis is the development of cardiogenic shock associated with as much as a 90%

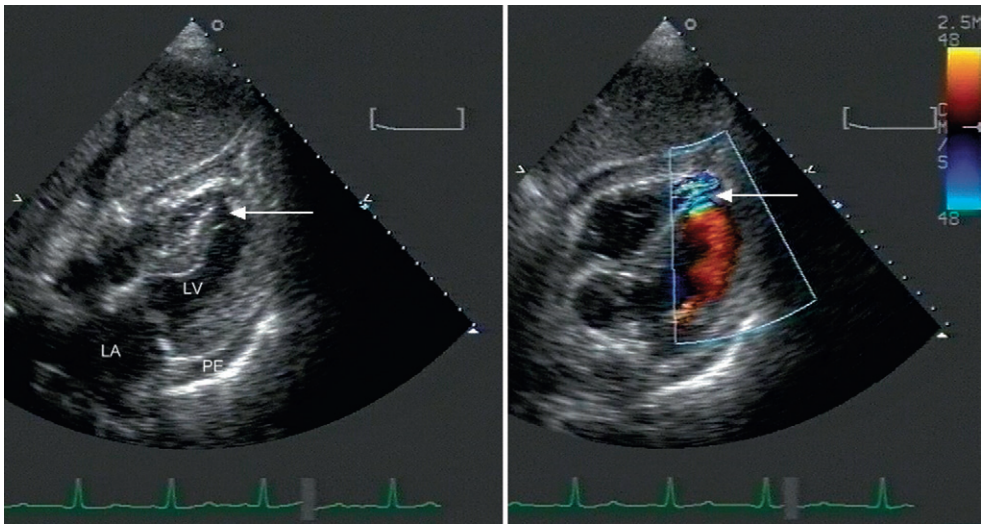

**Figure 14-6** TTE (subcostal view) showing a ventricular septal defect resulting from rupture involving the apical septum (*left*). Color flow Doppler demonstrates left-to-right shunting across the septal defect (*right*). Also note the small circumferential pericardial effusion (*PE*).

mortality rate. Early surgery appears to improve survival when cardiogenic shock is present, with the SHOCK trial investigators reporting a survival rate of 19% in the surgically treated group compared to 5% in the medically treated group.[66] When the patient can be stabilized medically, operative mortality may be improved when surgical repair is delayed until 6 weeks following the event. In select patients, a conservative approach may be appropriate and associated with a good midterm outcome. A recent report described 7 patients of 27 with post-MI ventricular septal rupture who did not undergo surgery and were followed up for a mean of approximately 3 years. All 7 patients had single-vessel disease, small defect size (on average 9.8 mm), minimal left-to-right shunt, and preserved RV function.[65] Although early definitive surgical correction remains the gold standard for treatment, percutaneous device closure should be considered in certain cases (Fig. 14-7). Potentially suitable candidates for a transcatheter approach include simple defects that are smaller than 15 mm, either in the acute setting when the surgical risk is considered prohibitively high, or in the subacute and chronic setting with comparable mortality to surgery.[67]

## RUPTURE OF THE VENTRICULAR FREE WALL

Rupture of the free wall of the LV is the second most common mechanical cause of death in acute ST segment elevation MI after cardiogenic shock due to pump failure and is usually, although not invariably, a fatal event.[68] Risk factors for free wall rupture are similar to those for papillary muscle and ventricular septal rupture; however, this complication is more likely to occur in patients with a transmural MI involving the inferolateral wall associated with a left circumflex occlusion or with a LAD occlusion.[69] Early successful reperfusion appears to decrease the risk of rupture. In a study of 1300 patients, the overall incidence of cardiac rupture was lower in those receiving thrombolytic therapy (1.7%) than in those in the conventional therapy group (2.7%). Among patients who received thrombolytic therapy, patients older than 70 years and women had higher rates of rupture.[70] Moreover, patients in whom reperfusion was unsuccessful have a significantly higher rate of rupture than those who were successfully reperfused (5.9% versus 0.5%).[71] Conversely, late reperfusion appears to increase the risk of myocardial rupture though decreasing overall mortality.[72] Nonrandomized, retrospective studies comparing primary PCI with thrombolysis have shown a significantly lower risk of free wall rupture in patients treated with primary PCI.

Ventricular free wall rupture usually presents clinically as an acute catastrophic event rapidly leading to death. However, recent pathologic and clinical studies have suggested that some cases may take a subacute or chronic course when a small rupture is temporarily sealed by fibrinous pericardial adhesions or thrombus. Intramural hematoma or hemorrhage at the junction of the necrotic and the normal myocardium results in a small endocardial rent. The tear usually takes a circuitous pathway through the myocardium, ending in a small epicardial opening. A prodrome of persistent or recurrent chest pain (in the absence of an elevation in creatinine kinase), repetitive large-volume emesis, unexplained agitation, hypotension, or syncope may be associated with the initial small tear. A small amount of hemorrhage into the pericardial space may precede the final catastrophic event. Patients diagnosed during this subacute phase and taken promptly to surgery have a greater chance of survival. In a prospective study of 608 consecutive patients with acute MI, subacute free wall rupture (death occurring 30 minutes to a few days after the first clinical indication of the event) was identified in 2.5%, whereas acute free wall rupture (death within 30 minutes) occurred in 4.1% cases. The long-term outcome of survivors who underwent urgent surgery was good.[73]

Echocardiography has a high sensitivity for diagnosing rupture. An echocardiographic feature of risk for rupture is infarct expansion with significant wall thinning at the infarct site. A small pericardial effusion is a common finding after an uncomplicated transmural MI, but increasing size of a pericardial effusion and the presence of thrombus in the pericardial space significantly increases the specificity for rupture (greater than 98%), as shown in Figure 14-8. The absence of pericardial effusion virtually excludes rupture. An intrapericardial thrombus appears as an echo-dense mass; it may be mobile, undulating within the pericardial space, or immobile, impinging on the cardiac chambers.[73] Direct visualization of the myocardial tear

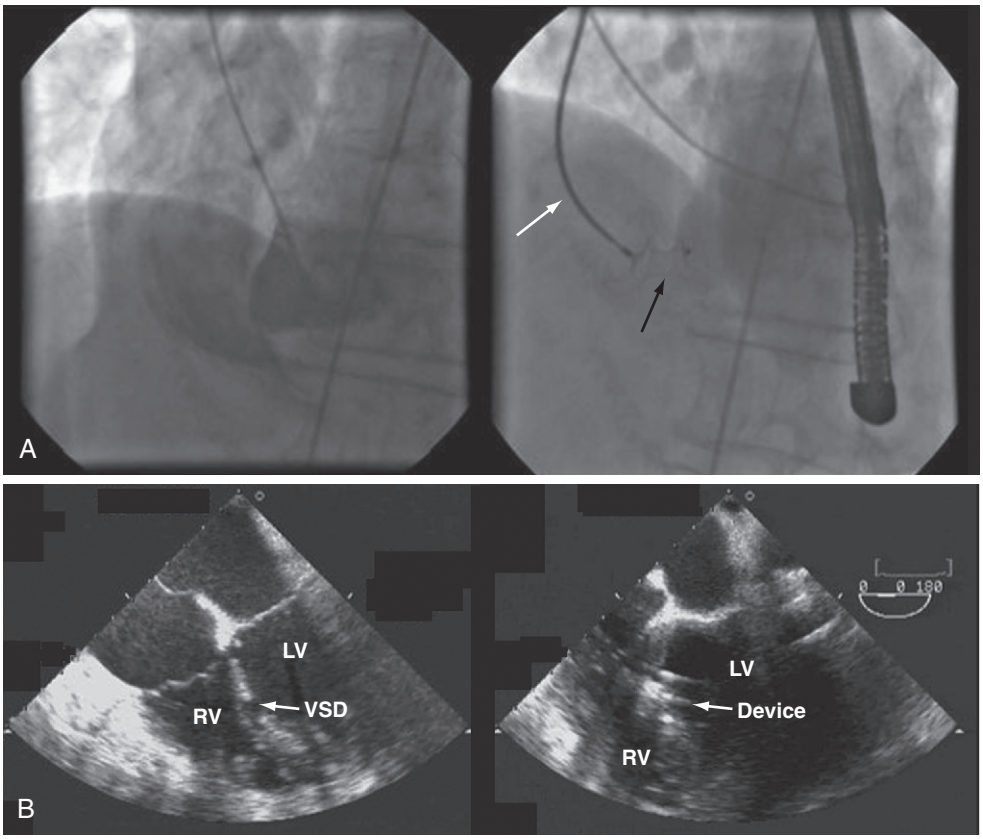

**Figure 14-7** **A,** Left ventriculography before closure of postinfarction ventricular septal defect showing left-to-right shunt (*left panel*) and angiographic image (*right panel*) showing the Amplatzer device in position (*black arrow*), before release from delivery cable (*white arrow*). **B,** TEE images at 0° showing a postinfarction ventricular septal defect (*VSD*) located in the mid inferior septum (*left panel*) and postprocedure showing device placement in the mid inferior septum (*right panel*). *(From Ahmed A, Ruygrok P, Wilson N, et al. Percutaneous closure of post-myocardial infarction ventricular septal defects: a single centre Experience.* Heart Lung Circ *17:119-123, 2008.)*

with TTE is relatively uncommon, reported in up to 40% of patients. When the diagnosis is uncertain, the use of left heart contrast may clearly delineate the tear.[74]

The mortality rate of free wall rupture in the absence of surgical intervention has been reported to be very high, although recent series report as much as a 50% survival rate in patients who underwent pericardiocentesis and conservative medical management.[75] The in-hospital mortality rate for those who undergo surgical repair is in the range of 40%. Those who survive until hospital discharge appear to have a good long-term prognosis.[68] Thus, early echocardiographic diagnosis with prompt surgical or percutaneous drainage is mandatory in patients who develop postinfarction myocardial rupture.

## PSEUDOANEURYSM

A pseudoaneurysm is a contained rupture of the LV free wall. It usually represents a complication of an acute MI, but it may also occur after cardiac surgery, chest trauma, and endocarditis. An LV pseudoaneurysm is not uncommonly diagnosed

incidentally, with 48% (25 of 52 patients with LV pseudoaneurysm) diagnosed incidentally in a series from the Mayo Clinic. The majority of pseudoaneurysms are located in the inferoposterior or inferolateral regions (associated with right coronary or left circumflex coronary occlusions) and rarely occur within the ventricular septum.[76]

It is important to distinguish a pseudoaneurysm, which has a high likelihood of spontaneous rupture, from a true aneurysm, which seldom ruptures. The walls of the pseudoaneurysm are composed of organizing thrombus from hemorrhage into the pericardial space after cardiac rupture, and varying amounts of the epicardium and parietal pericardium. In contrast, the wall of a true aneurysm consists of dense fibrous tissue with excellent tensile strength (Fig. 14-9). An often-described distinguishing echocardiographic feature of a pseudoaneurysm is the narrow neck, with a ratio of neck diameter to maximum aneurysm diameter less than 0.5, compared with the broader "entrance" to the body of a true aneurysm. However, this sign may not always be reliable and has been reported to be only 60% sensitive in distinguishing a pseudoaneurysm from a true aneurysm.[76] This is particularly the case with aneurysms at the base of the heart, most commonly after inferior MI. Spectral and color Doppler imaging demonstrate characteristic flow in and out of the pericardial cavity at the site of the tear (Fig. 14-10), as well as abnormal flow within the pseudoaneurysm.

Surgical repair is the preferred treatment, although conservative medical treatment in certain high-risk patients may not be associated with an increased risk of cardiac rupture.[77] Percutaneous closure of a pseudoaneurysm is a potential approach in carefully selected patients and is performed with TEE guidance (Fig. 14-11).

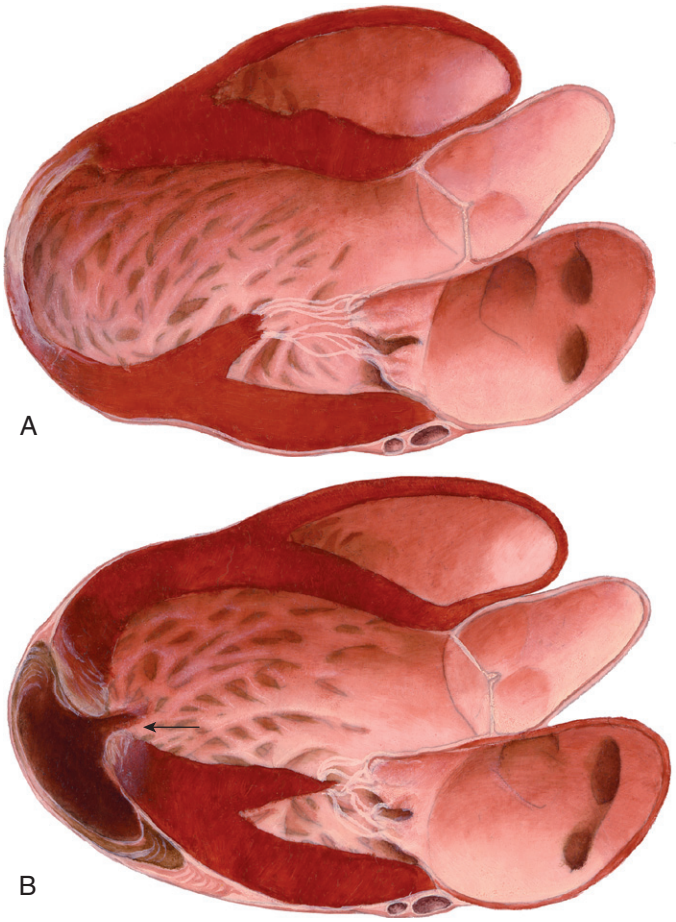

**Figure 14-9** Difference between true aneurysm (**A**) and false aneurysm (**B**). Note that in true aneurysm there is continuity of myocardium in the region of dilation (*arrows*), in contrast to loss of this continuity in pseudoaneurysm with abrupt area of rupture (*arrow*). *(Modified from MacKenzie JW, Lemole GM: Pseudoaneurysm of the left ventricle.* Tex Heart Inst J *21:296-301, 1994.)*

## INFARCT EXPANSION AND TRUE ANEURYSM FORMATION

Infarct expansion represents acute remodeling with an increase in the circumferential extent of the area of infarction that results from stretching and thinning of the infarcted zone. This process typically occurs 24 to 72 hours after acute transmural MI. Early

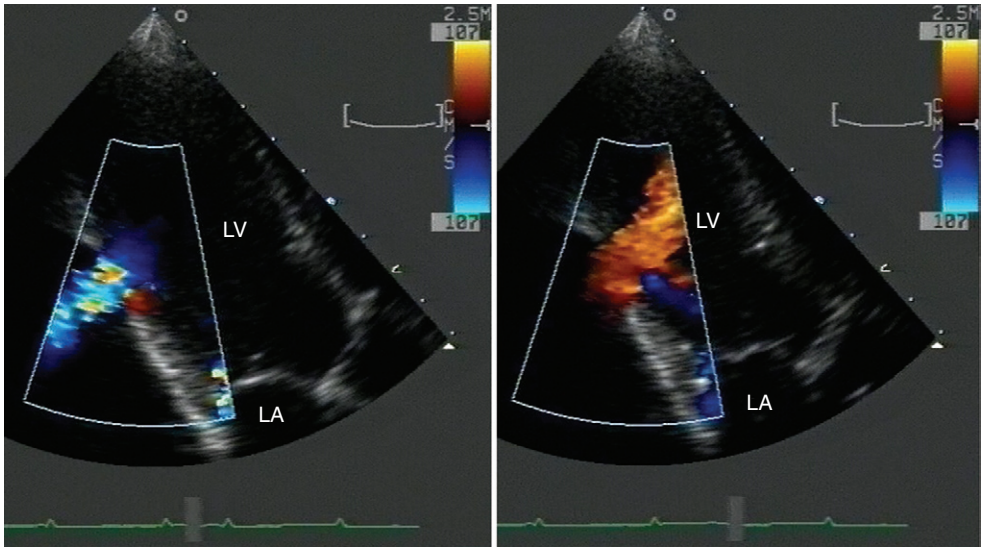

**Figure 14-10** TTE in apical three-chamber view demonstrating rupture of midinferolateral wall with flow from LV cavity into pseudoaneurysm in systole (*left*) and from pseudoaneurysm into LV cavity in diastole (*right*). Wall of pseudoaneurysm is not shown.

Appearance after transcatheter closure is shown at *right*. *Solid arrow*, Amplatzer device; *dashed arrow*, catheter.

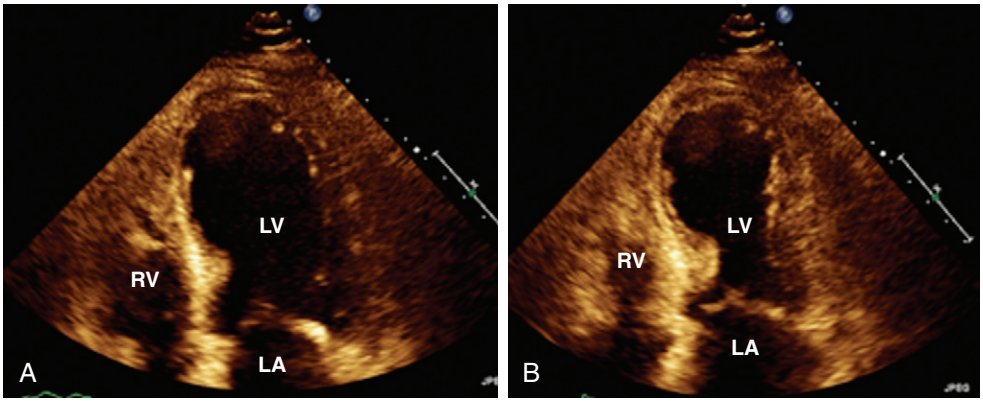

**Figure 14-12** **A,** Apical four-chamber view at end-diastole. Note thin-walled and expanded apex compared to basal and mid-LV segments. There is no diastolic deformity of apex; thus this is not a true apical aneurysm. **B,** Apical four-chamber view at end-systole. Note augmented contractility of basal and mid-LV segments, and akinetic and expanded apex.

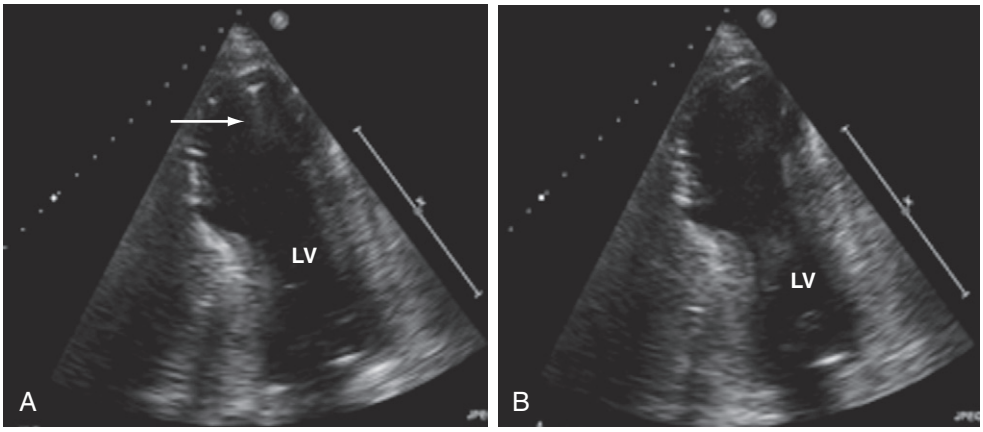

**Figure 14-13** **A,** Apical four-chamber view of LV at end-diastole. Note aneurysmal apex (*arrow*) with characteristic deformity of true apical aneurysm. **B,** Apical four-chamber view of LV at end-systole. Note augmented contractility of basal and mid-LV segments, but not of aneurysmal apex.

clinical studies demonstrated that infarct expansion with a consequent increase in LV volume and wall stress was associated with an in-hospital mortality rate up to 40%. Although any region of the LV may be affected, it is more common after anteroapical MI. Echocardiographic features of infarct expansion include an aneurysmal bulge of the myocardium with reduced local wall thickness (Fig. 14-12). This thin necrotic wall has low tensile strength and typically precedes mechanical complications including ventricular septal rupture, free wall rupture, and papillary muscle rupture.

In the absence of rupture, the final expression of infarct expansion is aneurysm formation, which occurs only with transmural infarction and a full-thickness scar. A true aneurysm is defined as a deformity of the thinned infarct segment that is apparent during diastole as well as during systole and demonstrates a diastolic contour abnormality (Fig. 14-13). In contrast,

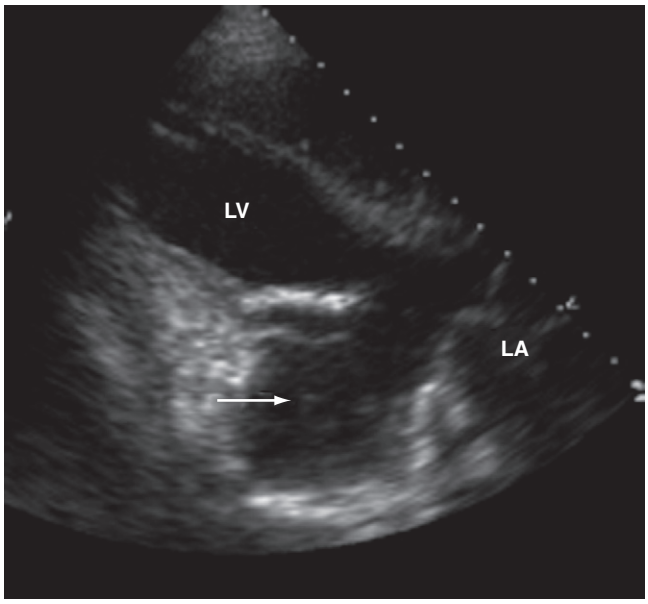

**Figure 14-14** Parasternal long-axis view showing massive basal inferior wall aneurysm (*arrow*). Note wide neck of aneurysm consistent with true aneurysm, rather than pseudoaneurysm.

a dyskinetic myocardial segment deforms during systole, extending beyond the normal contour of the myocardium. The involved myocardial segment is scarred with thin walls (less than 7 mm) and increased echogenicity owing to the increased collagen content. The wall of the aneurysm may eventually calcify. Most aneurysms occur in the LV apex and anterior wall, and less commonly in the inferior wall (Fig. 14-14). Aneurysms of the lateral wall are very uncommon. The reported incidence of aneurysm formation after acute MI before the reperfusion era is quite variable, with an average of 30%[78,79] Although the use of thrombolytic therapy per se has not been convincingly shown to reduce the frequency of aneurysm formation, a study of 205 patients presenting with acute MI reported a significantly reduced incidence of aneurysm formation in those patients receiving thrombolytic therapy and exhibiting a patent infarct-related artery compared to those who received thrombolytic therapy but without a patent infarct-related artery.[78] A similar reduced incidence of LV aneurysm formation of primary PCI has been reported.

Serial 2D echocardiographic studies show that aneurysmal dilation is present as early as 5 days after MI. New aneurysms after 3 months are unlikely. Spontaneous rupture of an acute aneurysm is rare, and late rupture virtually never occurs. Aneurysms may vary in size; very small aneurysms may be difficult to visualize by echocardiography. Technically, the detection of an apical aneurysm is highly dependent on the skill of the operator. Routine employment of high-frequency transducers with a shallow focal point enhances near-field resolution and aids examination of the LV apex. Left-sided contrast agents also may enable detection of small apical aneurysms. Using these methods, the sensitivity of TTE for detection of apical aneurysms should approach 100%. It should be noted that TEE may not provide adequate visualization of the LV apex and therefore, in our experience, is less sensitive than surface imaging.

Echocardiographic recognition of a LV aneurysm is clinically relevant for the following reasons: First, the early formation of an aneurysm adversely affects early (in-hospital) and late (1 year) mortality and is associated with an increased incidence of cardiac failure. Second, thrombi are frequently found within aneurysms and are associated with systemic embolization. Third, aneurysms may cause life-threatening ventricular arrhythmias. In patients with heart failure or ventricular arrhythmias, aneurysmectomy may be recommended, and echocardiography plays an important role in patient selection. When considering aneurysmectomy, it is important to ensure that the basal portions of the LV have normal function. A basal (residual) shortening fraction or ejection fraction greater than 18% or 40%, respectively, is more likely to be associated with a satisfactory result. Newer surgical approaches to managing ventricular aneurysms include reduction myoplasty and Dor myoplasty.[80] Echocardiography also plays an important role in assessing the feasibility of these techniques.

## LEFT VENTRICULAR THROMBUS

Studies in the prethrombolytic era reported incidence rates of thrombus formation after anterior MI, especially those involving the apex, of up to 60%, and rarely in inferior infarction.[81] LV thrombus tends to develop on the endocardium of akinetic, nonviable segments. The peak timing of thrombus formation after acute MI is 3 days, but thrombus may occur as early as within a few hours in large areas of apical akinesis and may occur a few weeks after an MI. In general, thrombolytic therapy has decreased the rate of mural thrombus development, but thrombus formation may still occur after lytic therapy and concurrent antithrombin and antiplatelet agents. In the GISSI-2 trial there was no significant difference between the four treatment groups (recombinant tissue plasminogen activator with or without heparin, streptokinase with or without heparin), with respect to thrombus formation with an overall incidence of 28%.[82] The overall tendency for reperfusion therapy to decrease the size of the infarction is likely to lower the risk of thrombus formation. The incidence of LV thrombus is also reduced by primary PCI for acute MI. In a recent study of 100 consecutive patients with acute anterior ST-elevation MI (excluding patients who presented with cardiogenic shock) treated with stenting of the LAD within 2 to 12 hours of symptom onset, LV thrombus was diagnosed by echocardiography in 13 patients and by cardiac MRI in 2 patients. All patients underwent echocardiography within the first 1 to 3 days, 4.5 ± 1.1 days post-MI, and after 3 months.[83] All patients were treated with aspirin 75 mg/day and clopidogrel 75 mg/day, 50% were treated with a glycoprotein IIb/IIIa inhibitor, and 20% received thrombolysis before stenting. Of the 15 patients (15%) diagnosed with LV thrombus, 10 were diagnosed within the first week, 4 were diagnosed between 1 and 4 weeks, and 1 was diagnosed between 4 and 12 weeks. Other studies have reported a lower prevalence of LV thrombus in patients with acute MI treated with primary stenting,[84,85] but these studies included patients with lower-risk nonanterior MIs, were retrospective, and did not utilize serial echocardiograms or MRI. Thus, LV thrombus remains a common complication of anterior MI treated with contemporary intervention. The major focus of the currently used pharmacologic agents after acute MI is the antiplatelet effects, and antiplatelet treatment has little or no influence on thrombin generation, which plays a key role in the development of LV thrombus. The major mechanism of the reduced prevalence of LV thrombus in the reperfusion era is rapid restoration of culprit vessel patency and limited myocardial damage.

The echocardiographic appearance of a mural thrombus is that of a mass distinct from the endocardium and protruding to a variable extent into the LV cavity (Fig. 14-15). Under ideal conditions, the surface of the thrombus can be distinguished clearly from the underlying endocardium and the mass can be visualized in two different imaging planes. The tissue characteristics of an acute thrombus are usually similar to those of the myocardium. A chronic thrombus may have increased reflectivity, demonstrate a layered appearance corresponding to the lines of Zahn, and contain areas of calcification. The base of attachment to the wall may be broad in the case of a sessile thrombus and narrow in a pedunculated thrombus. Occasionally, thrombus may have a cystic appearance with a relative echolucency to the center of the thrombus. False-positive echocardiographic diagnoses are usually a result of pseudotendons (i.e., false chordae) spanning the LV apex, coarse trabeculations associated with LV hypertrophy, or near-field artifacts (commonly present with low-frequency transducers). High-frequency transducers with a short focus point can sometimes differentiate true thrombus from these other phenomena. Left-sided contrast agents may outline the contours of the thrombus, creating a filling defect with improved detection of thrombus (Fig. 14-16).

The greatest clinical concern of a mural thrombus is the potential for systemic embolization, especially stroke. The likelihood of an embolic event is highest in the first 2 weeks after an acute MI and decreases over the following 6 weeks. After this time, there is endothelialization of the thrombus associated with reduced embolic potential. When multiple characteristics of the thrombus are analyzed, mobility of the thrombus is most closely associated (positive predictive value 85%) with embolic events, and when both mobility and protrusion of the thrombus into the LV cavity occur, embolic rates of up to 40% have been reported. Anticoagulant therapy appears to decrease the risk of embolic events and enhances the resolution of thrombus, but there are no prospective randomized studies confirming this. Spontaneous resolution of LV thrombus may occur. In any given patient on anticoagulation, the morphology may spontaneously change from sessile to pedunculated and vice versa; mobility may resolve spontaneously.[86] This emphasizes the need to follow patients with LV thrombus with serial echocardiography. Thrombectomy should be considered in selected patients in whom a very high-risk thrombus morphology is detected.

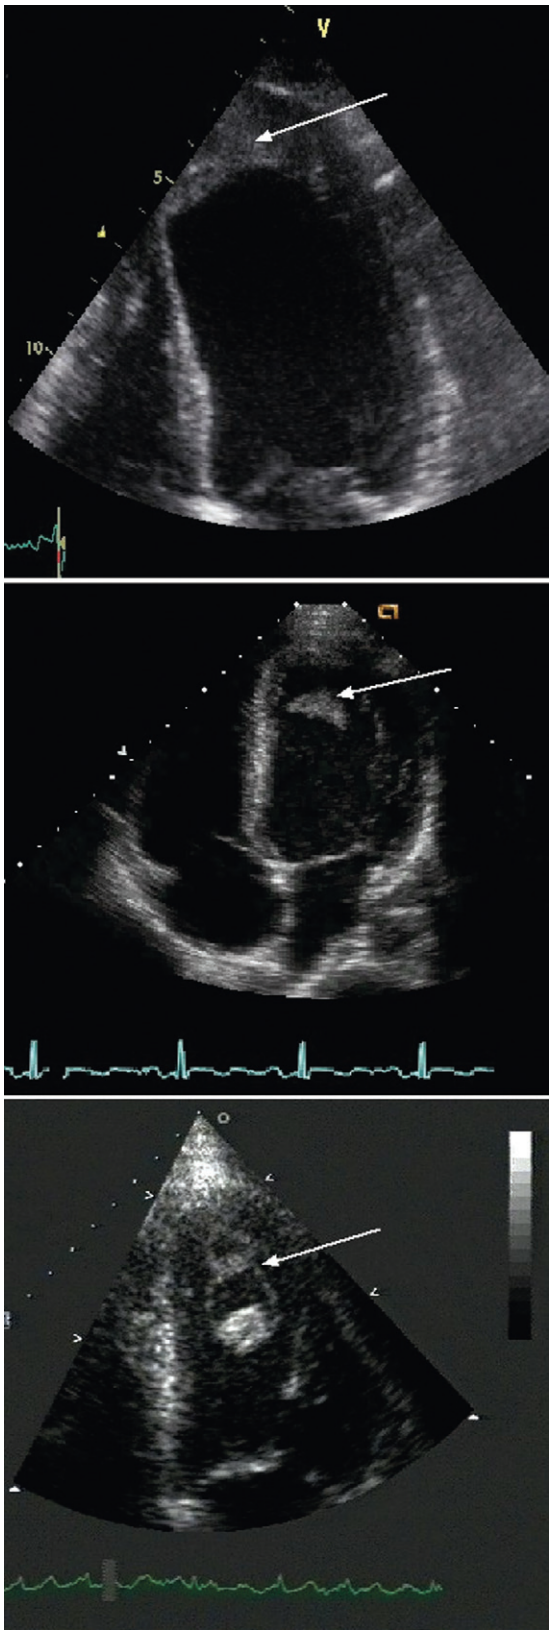

**Figure 14-15** *Top*, Acute thrombus (*arrow*) in LV apex. Note that thrombus is homogeneous in texture, without evidence of calcification. *Middle*, Protruding thrombus (*arrow*), a feature associated with increased embolic risk. *Bottom*, Uncommonly, thrombus may be cystic in appearance (*arrow*).

## Risk Stratification after Myocardial Infarction

Despite advances in the management of acute MI, patients who survive are at increased risk of cardiac morbidity and mortality. Routine echocardiographic measures after acute MI include assessment of LV volume, systolic and diastolic function, regional wall motion abnormalities, and the presence and degree of mitral regurgitation. In addition, evaluation of myocardial viability and residual ischemia guides revascularization strategies.

### LEFT VENTRICULAR SYSTOLIC FUNCTION

Echocardiographic measures of global LV systolic function including LV ejection fraction and LV end-systolic volume are well established predictors of prognosis after acute MI and can be accurately measured by echocardiography in the vast

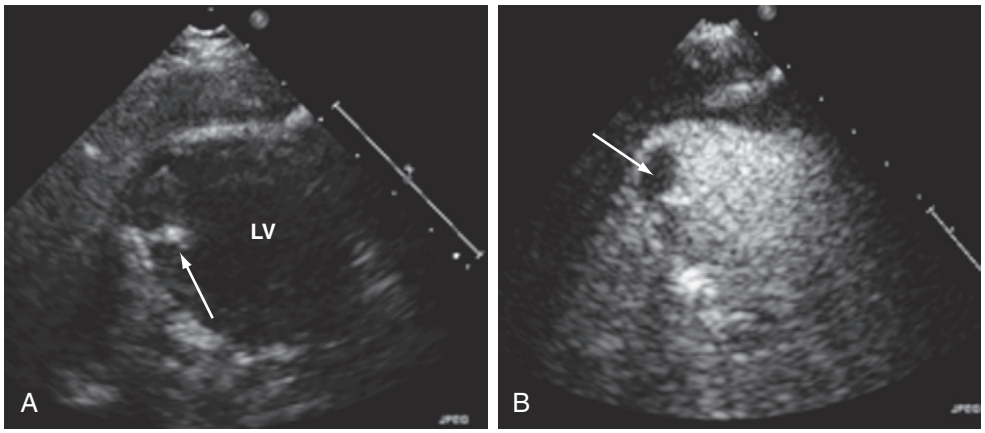

**Figure 14-16** **A,** Apical four-chamber view of LV showing nonspecific echodensity at apical septum (*arrow*). **B,** With use of myocardial contrast, apical thrombus (*arrow*) is now more obviously visible as a filling defect.

majority of patients. Although LV ejection fraction is a powerful predictor of outcome, the ejection fraction may be normal as a result of compensatory regional hyperkinesis in the noninfarcted segments despite extensive myocardial damage, such as in inferior MI.[87] In a study of 605 patients with acute MI, White and colleagues[88] showed that LV end-systolic volume was the single best prognostic indicator for survival, and superior to LV ejection fraction in patients with LV ejection fraction less than 50%.

## REGIONAL WALL MOTION SCORE

Semiquantitative assessment of regional systolic function using wall motion score index is an alternative to ejection fraction for the assessment of LV systolic function.[89] An echocardiographic wall motion score has been the most widely used measure of functional infarct size in clinical practice. The total score is derived by assigning a grade of 1 through 5 (see Table 14-1) to each myocardial segment that is adequately visualized. For a segment to be scored, the majority of the endocardium within that segment must be apparent, and wall thickening and endocardial motion should be examined. The scores for each segment are added and then divided by the number of segments graded for a total wall motion score. Several studies have demonstrated that a higher wall motion score index (12 to 24 hours after admission) is associated with a higher rate of in-hospital complications, including malignant arrhythmias, pump failure, and death.[89,90] A higher wall motion score index also predicts a higher rate of complications, including free wall rupture, ventricular septal rupture, papillary muscle rupture, and death from cardiogenic shock. A higher wall motion score, signifying a more extensive infarction, also is predictive of late mortality. In a study of 767 patients with acute MI, echocardiography was performed at a median of 1 day after admission, and patients were followed for a median of 19 months. Whereas both LV ejection fraction and wall motion score index were powerful predictors of all-cause mortality by univariate analysis, wall motion score index was an independent predictor of death, primarily in patients with non–ST segment elevation MI. In addition, mortality was high in patients with extensive regional wall motion abnormalities but relatively preserved ejection fraction, most likely as a result of compensatory regional hyperkinesis.[91]

Wall motion abnormalities remote from the infarction site may be present early in the course of the infarction or may develop in the presence of postinfarction angina, suggesting de novo ischemia. The echocardiographic finding of remote asynergy at or soon after clinical presentation is strong evidence of multivessel disease. Abnormal wall motion in a second (or even third) coronary distribution is possibly a result of (1) previous infarction, (2) increased myocardial oxygen demands placed on the noninfarcted segment as a result of increased wall stress outstripping its oxygen supply, or (3) a cessation in its collateral blood supply that originated from the newly occluded vessel.

**TABLE 14-3 The Role of Diastolic Functional Parameters in Prognosis after Myocardial Infarction**

| *Study* | *n* | *Comment* |
|---|---|---|
| MeRGE AMI (2008)[93] | 3396 | Restrictive filling is independent predictor of mortality after acute MI regardless of LV ejection fraction, LV end-systolic volume index, and Killip class. |
| Kruszewski (2010)[92] | 400 | Ratio of mitral E wave to early mitral annulus diastolic velocity (E/E′) >15 measured day 1 after acute MI associated with increased risk of adverse events within first year and medium-term mortality. |
| Whalley (2006)[95] | 3855 | Mortality is four times higher in patients with restrictive filling pattern than in those with nonrestrictive filling patterns after acute MI. |
| Moller (2003)[94] | 110 | Patients with a persistently abnormal or a deterioration of LV filling pattern as opposed to improved or normal filling are at increased risk of cardiac death and readmission as a result of heart failure. |
| Moller (2000)[96] | 125 | Restrictive filling and pseudonormal filling independently predicted death. |
| Hillis (2004)[97] | 250 | Ratio of mitral E wave to early mitral annulus diastolic velocity (E/E′) >15 was the most powerful independent predictor of survival. |
| Moller (2001)[98] | 67 | Ratio of mitral E wave velocity to color M-mode flow propagation velocity ≥1.5 was a significant predictor of the composite of cardiac death and readmission for heart failure. |

*MeRGE*, Meta-analysis Research Group in Echocardiography.

## LEFT VENTRICULAR DIASTOLIC FUNCTION

Doppler echocardiography for the assessment of LV diastolic function provides accurate prognostic information in the early phase after acute MI[92-98] (Table 14-3). The ratio of early (E

wave) to late (A wave) transmitral peak velocities and a shortened deceleration time of early transmitral flow were one of the earliest measures of LV diastolic function shown to be powerful predictors of outcome. In a study of 125 consecutive patients with acute MI, Moller and colleagues[96] demonstrated that pseudonormal and restrictive filling patterns were related to progressive LV dilatation and predicted cardiac mortality. Specifically, 1-year survival was 100% in patients with normal filling, 89% in those with impaired relaxation, 50% in those with a pseudonormal pattern, and 35% in those with a restrictive pattern. The Meta-Analysis Research Group in Echocardiography (MeRGE)[93] is the largest study published to date on the Doppler echocardiography in acute MI. This study showed that a restrictive filling pattern occurs in approximately 20% of patients with acute MI and when present is associated with a nearly threefold increase in mortality. This relationship is independent of age, LV size, LV ejection fraction, and Killip class. In a tissue Doppler study of 250 patients with acute MI, an E/E′ ratio greater than 15 predicted all-cause mortality incremental to LV ejection fraction, age, and a restrictive filling transmitral filling pattern.[97] In addition, this study showed that measurement of E/E′ allowed risk stratification among patients with normal and reduced LV systolic function. The value of serial echocardiography after MI is emphasized by the finding that patients with a persistently abnormal or deteriorating LV filling pattern as opposed to improved or normal filling are at increased risk of cardiac death and readmission as a result of heart failure after acute MI.[98]

## LEFT ATRIAL VOLUME

In contrast to Doppler indices of LV diastolic function, LA volume is a more stable parameter integrating the effects of elevated left filling pressures from preexisting cardiovascular conditions and acute disease. Beinart and colleagues[99] demonstrated that LA volume index (corrected for body surface area) measured within 48 hours of an acute MI is an independent predictor of 5-year mortality and was a more powerful predictor than LV volumes and the presence of mitral regurgitation. Similarly, Moller and colleagues[100] showed that LA volume index was a powerful predictor of mortality and remained an independent predictor after adjustment for clinical factors, LV systolic function, and Doppler-derived parameters of diastolic function.

## LEFT VENTRICULAR REMODELING

After transmural MI, alterations in LV structure and function occur, commonly referred to as LV remodeling.[101] The early phase of LV remodeling is confined to the infarct zone and consists primarily of infarct expansion, whereas the late phase involves changes in the entire myocardium and may continue for months. The major factors that determine the magnitude and duration of the remodeling process include the size and location of the initial infarct (usually a complication of a larger anterior infarction), the patency and time to restoration of flow in the infarct-related artery, neurohormonal activation, and the ability of the extracellular matrix to form a stable, mature collagen scar.[102] The major clinical significance of remodeling is the resultant ventricular dilatation with reduced contractility, associated with an increased incidence of cardiac failure, arrhythmias, and death. In addition, remodeling may also cause mitral regurgitation as a result of apical and lateral displacement of the papillary muscles, a process that is associated with increased mortality and risk of cardiac failure. The use of beta-blockers and angiotensin-converting enzyme inhibitors after acute MI has been shown to prevent or retard remodeling.

Echocardiography, including 3D echocardiography, plays a major role in predicting ventricular remodeling and functional recovery. Although thrombolysis and percutaneous coronary artery interventions frequently restore patency of the infarct-related artery, myocardial perfusion may be absent, which is associated with adverse outcomes. Myocardial contrast echocardiography is an accurate measure of reperfusion at a microvascular level, has been shown in multiple studies to predict LV function after MI,[103,104] and may predict functional recovery after acute MI.[105-108] Echocardiography during low-dose dobutamine infusion is used to detect myocardial viability in segments that have persistent dysfunction following reperfusion. Low-dose DSE can detect contractile reserve of dysfunctional myocardium and predict LV dilatation[109,110] and functional recovery.[111] LV strain and strain rate quantified using tissue-Doppler or speckle-tracking imaging after acute MI can differentiate between transmural and nontransmural MI and thus reflect the extent of nonviable myocardium.[112] In addition to this useful diagnostic information, the LV strain parameters have been shown to independently predict death or the development of heart failure during follow-up after acute MI and may provide incremental prognostic information beyond LV ejection fraction.[113,114] Studies utilizing color-coded tissue Doppler imaging and speckle-tracking radial strain analysis for the assessment of LV dyssynchrony after acute MI have shown that the presence of LV dyssynchrony at baseline was significantly related to the extent of LV dilatation at 6 months follow-up.[115] Additional larger studies are needed to determine the prognostic valve of measures of LV dyssynchrony after acute MI.

## STRESS ECHOCARDIOGRAPHY

Echocardiography during higher-dose dobutamine infusion or with dynamic stress can be used to detect residual ischemia and provides prognostic value superior to that of exercise electrocardiography in the postinfarction period. A normal stress echo provides favorable prognostic information in patients with preserved ejection fraction after MI, with a reported 5-year survival of 94%. In addition, a 95% 1-year survival after acute MI was reported in patients with a negative stress echocardiogram compared with 85% and 75% in those with high- and low-dose ischemia, respectively.[116] Caution should be exercised in the first week after a transmural infarction because cases of myocardial rupture during high-dose dobutamine infusion have been reported.[11] Improvement of wall motion during low-dose dobutamine infusion (contractile reserve) indicates the presence of viable (stunned) myocardium that improves spontaneously in function after acute MI and is associated with an improved outcome. Stress echocardiography is discussed in further detail in Chapters 15 and 16.

## CORONARY FLOW RESERVE

Coronary flow reserve is defined as the ratio between the hyperemic diastolic flow velocity (after intravenous adenosine infusion) and the resting diastolic flow velocity. Noninvasive assessment of coronary flow reserve, especially of the LAD

artery, has been shown to provide prognostic information in patients with stable coronary artery disease and in patients early after acute MI.[117] In a study of 329 patients with known or suspected coronary artery disease and a negative stress echocardiogram, a coronary flow reserve of 1.92 or less was the best predictor of future cardiac events, with a sensitivity of 77% and specificity of 85%. The optimal cutoff ratio for predicting myocardial viability was 1.5 for coronary flow velocity reserve 24 hours after acute PCI for acute anterior MI, with a sensitivity and specificity of 94% and 91%, respectively.[118] In a further study of 15 patients with first acute anterior MI who underwent PCI, a diastolic deceleration time of the LAD artery flow velocity less than 190 ms was always related to nonviable myocardium.[119]

## MITRAL REGURGITATION

Mitral regurgitation is common among patients presenting with acute MI, and the prevalence increases twofold in patients with heart failure.[120] Earlier studies reported a prevalence of mitral regurgitation in acute MI by angiography of 2% to 19%,[121] whereas echocardiographic studies report a widely varying prevalence of 8% to 74%.[122] The different reported prevalences of mitral regurgitation may be a result of different sensitivities of the two imaging modalities and the timing of imaging. In addition, some recent studies included patients with troponin-positive acute coronary syndromes, which previously may not have been considered an acute MI.

Mitral regurgitation diagnosed in acute MI may be a result of preexisting mitral regurgitation, for example as a result of structural leaflet disease (such as mitral valve prolapse), which needs to be differentiated from ischemic causes directly related to the MI, such as papillary muscle rupture (discussed in detail previously). Ischemic mitral regurgitation can be defined as valvular incompetence associated with myocardial ischemia or infarction in the absence of primary leaflet or chordal pathology and may vary from trivial to severe[123] (Fig. 14-17). Papillary muscle dysfunction represents malfunction of the scarred papillary muscle and of the underlying ventricular wall. This results in retraction of the anterior or posterior leaflet and malcoaptation. The LV remodeling process that occurs after a transmural MI may also result in apical and posterior displacement of the LV wall supporting the papillary muscle and the papillary muscle itself, with abnormal mitral leaflet coaptation and mitral regurgitation. In addition, dilatation of the mitral annulus to varying degrees usually also contributes to the regurgitation. It is important to realize that, depending on the site of the infarction and the degree of remodeling, one mitral leaflet may be more involved than the other (the posterior leaflet is more commonly involved) and the regurgitation jet may therefore be eccentric, which is a common cause for underestimating the severity of mitral regurgitation.

The presence of ischemic mitral regurgitation in acute MI is associated with an adverse prognosis and increases mortality even when mild, with a graded relationship between severity and reduced survival.[124] In a study of 417 patients with acute MI, mild mitral regurgitation (present in 29%) and moderate or severe mitral regurgitation (present in 6%) diagnosed by echocardiography were independently associated with increased 1-year mortality.[125]

In patients requiring surgical myocardial revascularization, it is generally accepted that mitral valve surgery is necessary for severe ischemic regurgitation and not for mild regurgitation, but it is controversial how to treat moderate ischemic mitral regurgitation.[126] A recent study demonstrated that coronary artery bypass graft surgery alone may be sufficient to correct moderate mitral regurgitation when regurgitant severity decreases during DSE.[127]

## Summary

Early experimental models employing echocardiography for the detection and quantitation of ischemia and infarction helped investigators elucidate the pathophysiology. This work was directly transferable into the coronary care unit and provided the basis for the clinical, diagnostic, and prognostic role of echocardiography. Advances in echocardiography, especially color flow Doppler imaging, increased the capabilities of echocardiography in detecting the occurrence of complications, such as ventricular septal defect and papillary muscle rupture. Newer modalities, including myocardial contrast echocardiography, speckle-tracking radial strain analysis, and 3D

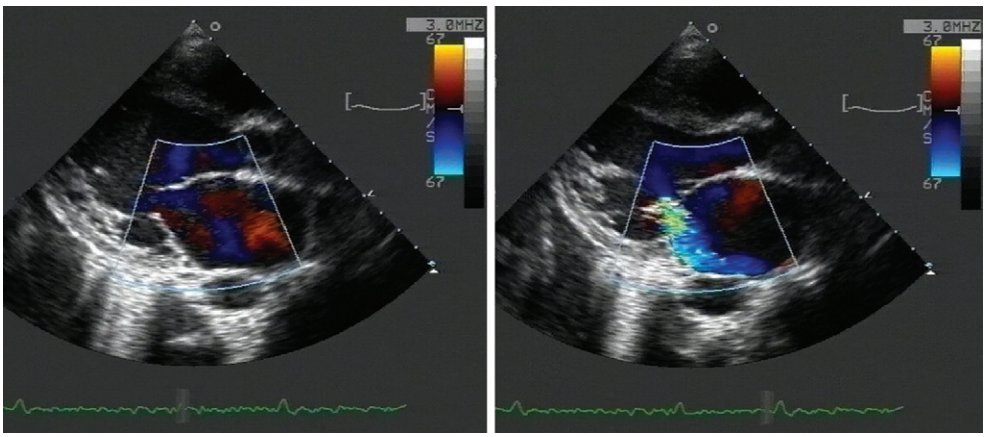

**Figure 14-17 Ischemic mitral regurgitation in patient with inferolateral myocardial infarction.** Note normal thickening in systole of anterior interventricular septum compared to lack of thickening of akinetic inferolateral wall (systolic frame at *right* compared with end-diastolic frame at *left*), with resultant posteriorly directed jet of mitral regurgitation.

echocardiography, continue to show promise in the comprehensive evaluation of patients admitted to the coronary care unit, including accurate assessment of LV systolic and diastolic function, regional wall motion abnormalities, and myocardial perfusion and viability. Based on a wealth of accumulated data on the diagnostic and prognostic value of echocardiography in the coronary care unit, its portability and noninvasive nature, and continuing advances in technology, will ensure that echocardiography remains the noninvasive imaging modality of choice in the coronary care unit.

## KEY POINTS

- The principal advantages of TTE in the coronary care unit include its portability, noninvasive nature, and the wealth of anatomic and hemodynamic information provided.
- The use of left-sided contrast agents has increased the percentage of patients in whom technically adequate images can be obtained.
- TTE provides key prognostic information after MI.
- All mechanical complications of MI can be detected by echocardiography.
- Echocardiography is the gold-standard imaging modality for the evaluation of ischemic mitral regurgitation.
- Provided proper precautions are taken, TEE is safe in the early postinfarction period and provides complementary information to TTE when needed.
- Pharmacologic stress echocardiography with dobutamine allows the identification of viable myocardium and residual ischemia after MI, which helps determine optimal revascularization strategies.
- Handheld echocardiographic instruments provide a rapid bedside assessment of wall motion, global ventricular function, and pericardial effusion.
- Myocardial contrast echocardiography allows a comprehensive assessment of global and regional LV function, myocardial perfusion, and myocardial viability and can predict functional recovery after MI.
- Myocardial strain with speckle-tracking techniques allows accurate quantification of regional wall motion.
- Ongoing advances in echocardiographic imaging, including 3D echocardiography, will see real-time 3D echocardiography play an increasing role in the assessment of patients with coronary artery disease.

Coronary Artery Disease: Initial Diagnosis
Coronary Artery Disease: Known Coronary Artery Disease
Coronary Artery Disease: Prognosis
Coronary Disease Diagnosis in Women
Risk Stratification Prior to Noncardiac Surgery
Hypertrophic Cardiomyopathy
Dilated Cardiomyopathy and Cardiac Transplantation
Valvular Heart Disease
Other Applications
**Future Directions**

Stress echocardiography integrates echocardiographic imaging with exercise electrocardiographic (ECG) testing to aid in real-time evaluation of ischemic, valvular, and cardiopulmonary heart disease. Accuracy for stress echocardiography to detect extent and location of myocardial ischemia is excellent, particularly when baseline ECG abnormalities render standard exercise ECG testing nondiagnostic.[1,2] In addition to initial coronary disease diagnosis, stress echocardiography is used to monitor disease progression in patients with known disease and assess clinical response to medical therapy. Stress echocardiography provides valuable information on myocardial viability, risk stratification, and prognostication. Nonischemia applications of stress echocardiography include evaluation and clinical management of cardiopulmonary, congenital, and valvular heart disease. Future advances include three-dimensional (3D) imaging, spectral Doppler interrogation with stress, myocardial strain and strain rate analysis, and integration of coronary flow reserve data using myocardial perfusion images.

The premise of stress echocardiography is provocation of transient myocardial ischemia by one of various cardiac stressors.[3-6] Nonexercise cardiac stressors include pharmacologic and pacing protocols (see Chapter 16). Pharmacologic stressors include agents that increase myocardial contractility and oxygen demand (dobutamine) and agents that induce transient regional hypoperfusion via coronary vasodilation (dipyridamole). Exercise stress is generally preferred over pharmacologic stress, as it allow for evaluation of exercise tolerance, symptom provocation, and prognostication.[7] Exercise stressors include treadmill and bicycle ergometry protocols. Images are acquired during peak exercise or, because of imaging difficulty due to patient motion, immediately after exercise cessation. Imaging data are then integrated with ECG data, exercise tolerance, and patient symptoms for final interpretation.

Capability for echocardiography to detect myocardial ischemia was shown more than three decades ago in animal models demonstrating concordance between severity and duration of coronary perfusion impairment and visualized regional wall motion abnormalities.[8,9] Early corroborating human studies using M-mode imaging demonstrated left anterior descending artery territory ischemia via reduced interventricular septal motion.[10] In one of the earliest descriptions of inducible ischemia during bicycle exercise, septal wall motion abnormalities, visualized by M-mode imaging, correlated with occlusion of the left anterior descending artery.[11] However, inability to image more than a discrete portion of the heart with M-mode imaging limited its overall utility as a diagnostic tool. Subsequent development of two-dimensional (2D) imaging allowed tomographic cardiac imaging, increasing utility for ischemia assessment.[12] Advances in transducer performance and development of harmonic imaging and digital loop grabbers have dramatically improved image quality and simplified interpretation. Stress echocardiography is now widely available.[13] Clinical guidelines provide recommendations regarding application of stress echocardiography as a first-line diagnostic tool.[5,6]

## Physiologic Principles of Exercise Echocardiography

During exercise, increases in myocardial oxygen demand results in augmented systolic function with increased myocardial thickening. With a hemodynamically significant coronary stenosis, the relative disparity in oxygen delivery to the distal coronary bed cannot meet increases in myocardial oxygen demand. Transient hypoperfusion results in mechanical dysfunction of affected myocardium. Stress echocardiography is well suited to assess this ischemic response by visualizing global and regional myocardial motion, allowing for localization of coronary lesions, given that coronary artery anatomy and myocardial distribution are relatively similar among patients (see Chapter 13).[14]

Myocardial ischemia generally progresses in a defined sequence of events, termed the *ischemic cascade*.[15] Ischemia is initiated by regional hypoperfusion of a distal coronary bed. After resultant metabolic changes within affected myocardium, alterations in function occur; initially with abnormalities in myocardial relaxation (diastolic dysfunction), and subsequently with systolic dysfunction of affected segments. Only in the later stages of ischemia are characteristic ECG changes, such as ST segment depression, and frank angina manifest (Fig. 15-1).[16,17] Propagation of ischemia generally proceeds from the subendocardium outward to the subepicardial layer in cases of more severe or prolonged ischemia.[18] However, because endocardial myocardial oxygen demand is higher, only moderate ischemia is needed to produce visually identifiable contractile dysfunction. With exercise ECG testing, ischemia diagnosis occurs with onset of angina or ECG changes, occurring in the later stages of the ischemic cascade (Fig. 15-2), contributing to acknowledged limitations in diagnostic accuracy for exercise ECG testing. In contrast, stress testing with integrated cardiac imaging identifies ischemia earlier, at onset of regional hypoperfusion (nuclear perfusion stress) or with systolic dysfunction (echocardiography). With stressor cessation and restoration of adequate coronary flow, induced abnormalities typically recover rapidly, but may persist if ischemia is severe. Early studies using echocardiographic imaging during angioplasty balloon inflation demonstrate onset of regional systolic dysfunction as early as 19 seconds after balloon inflation, with subsequent ischemic ECG changes and angina occurring 30 to 40 seconds after inflation. These abnormalities typically resolved within 10 to 20 seconds after balloon deflation.[17,19,20] Angioplasty balloon inflation models represent ischemia from a dynamic obstruction; imaging during provoked ischemia with a fixed coronary obstruction has shown a similar temporal progression with mechanical dysfunction preceding ECG changes and angina.[21,22]

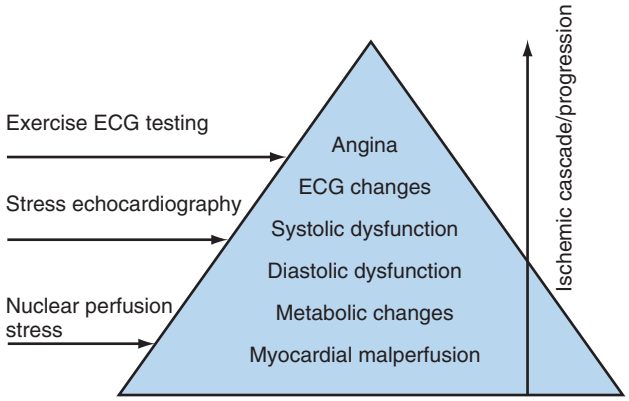

**Figure 15-1 Ischemic cascade.** Ischemia is initiated by myocardial hypoperfusion. Following metabolic changes within affected myocardium, alterations in function occur; initially with diastolic dysfunction, then progressing to systolic dysfunction. In the later stages of ischemia, characteristic electrocardiographic (*ECG*) changes and frank angina manifest.

In the absence of a physiologically significant coronary narrowing, the myocardial response to stress is augmented systolic function with increased inward *hyperdynamic* motion. In the presence of ischemia, myocardial responses include the following:

1. *Hypokinesis*, myocardial thickening with inward motion less than 5 mm or relatively less than the rest of the myocardium
2. *Akinesis*, absence of thickening or inward motion
3. *Dyskinesis*, thinned myocardium with paradoxical outward systolic motion, a passive myocardial response to increased intraventricular pressure[23]

In absence of disease, baseline systolic function is generally normal and myocardial response to exercise is hyperdynamic (Fig. 15-3). In ischemic but noninfarcted myocardium, the stress response is concordant with ischemia severity: hypokinesis in mild cases progressing to akinesis in more severe cases. Chronically infarcted regions with permanent transmural injury appear thinned and akinetic or dyskinetic. Acutely infarcted myocardium appears hypokinetic or akinetic with normal wall thickness as postinfarction remodeling has not yet occurred. If blood flow is rapidly restored to acutely infarcted

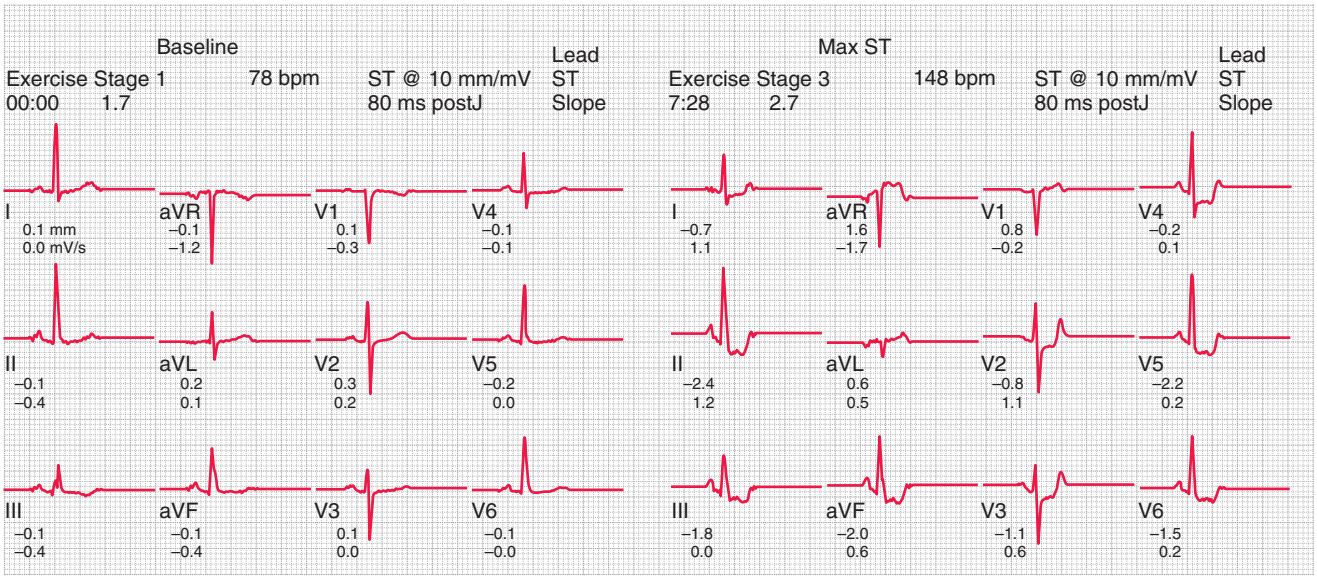

**Figure 15-2 Treadmill exercise ECG stress study.** This patient exercised 7 minutes and 28 seconds on a standard Bruce protocol (9 METs) and experienced chest discomfort and presyncope at peak stress. Baseline electrocardiogram (ECG) showed normal sinus rhythm with T wave inversion in lead III (*left*). Peak stress ECG showed horizontal ST depression in leads II, III, aVF, and V4-V6. Subsequent angiography revealed a proximal 80% left anterior descending artery lesion and moderate disease in the left circumflex artery.

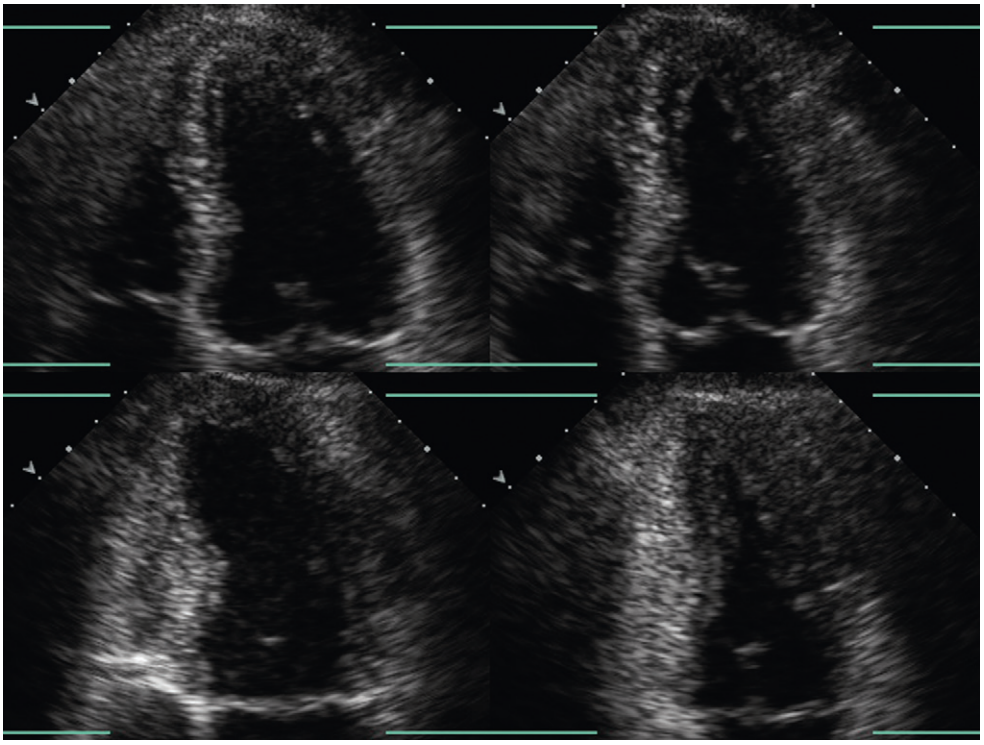

**Figure 15-3 Images from a normal exercise echocardiogram study taken at rest and immediately after cessation of treadmill exercise.** *Upper left*: Apical four-chamber view during rest. *Upper right*: Apical four-chamber view after exercise stress, *Lower left*: Apical four-chamber view during rest. *Lower right*: Apical four-chamber view after exercise stress. At rest, LV chamber size is normal. After exercise, there is hyperdynamic function of all segments with a decrease in chamber size.

myocardium, return of function is variable temporally and spatially. Regions of transmural infarct resulting from prolonged ischemia typically remain hypocontractile, but tissue subjected to only a short duration of coronary flow limitation typically regains contractility. Time duration of myocardial recovery after an infarction varies from days to months and is termed *stunned myocardium*. Prediction of functional recovery stunned segments may be accomplished with low dose dobutamine stress echocardiography or other modalities of viability testing (see Chapter 16).

The effect of ischemic on myocardial wall motion and thickening is proportional to the severity of impaired coronary blood flow.[22,24] For intermediate-range lesions (50% to 60% stenosis of the epicardial vessel) or single-vessel disease where only a few myocardial segments are affected, abnormalities during ischemia are typically subtle and transient or may be absent altogether. Assuming use of an adequate stressor, the severity of coronary narrowing where systolic dysfunction is perceptible is approximately 60% stenosis, with progression to akinesis when greater than 80% stenosis is present (Fig. 15-4). Note that visual estimates of stenosis severity based on planar angiographic images may not necessarily correlate with physiologically significant occlusions.[24-26] In the absence of significant coronary stenoses, exercise-induced reductions in relative coronary flow reserve may occur in patients with microvascular disease or increased myocardial mass, as occurs in left ventricular hypertrophy. In these cases, although a stressor may produce characteristic ECG changes or anginal symptoms, frank regional wall motion abnormalities may not be evident.[27,28]

## Exercise Stressors Used for Stress Echocardiography

In individuals able to exercise maximally, exercise stress is preferred over nonexercise stressors, as it allows for a contextual understanding of results relative to patient symptoms and functional capacity.[29] Metabolic equivalents (METs) are a measure of oxygen ($O_2$) consumption where 1 MET (resting metabolic state) equals 3.5 mL $O_2$ per kg/min. Exercise stressors should be used unless the patient is unable to achieve at least 5 METs or use the exercise equipment. Exercise protocols most widely used are treadmill and bicycle ergometry (upright or supine). In the United States, treadmill protocols are more common, unless the patient has neurologic, vascular, or orthopedic constraints that limit treadmill exercise performance.

Regardless of exercise stress type, an adequate workload is necessary to provide a diagnostic study. The most common hemodynamic target used is achievement of a heart rate goal based on patient age and gender, calculated as 85% of the maximal predicted heart rate: (estimated 220 − patient's age − For men and 210 − patient age for women). If necessary, workload can be augmented with other measures such as hyperventilation or handgrip exercise.[30] During the stress study, patients should subjectively report exertion level, using standardized scales, such as the Borg rating of perceived exertion (Box 15-1).[31] It is institution and physician dependent whether exercise is discontinued once hemodynamic targets are achieved, or whether the patient continues to maximum exercise capacity.

With treadmill exercise protocols, baseline echocardiographic images are obtained in a left lateral decubitus position to facilitate acoustic windows (Table 15-1). Exercise then commences according to standardized protocols.[31] Most patients who are reasonably active perform the Bruce protocol. However, in patients with mobility restrictions or limited exercise tolerance, the Cornell or Naughton protocols are other options to allow for at least 6 to 12 minutes of continuous exercise. Systolic blood pressure is monitored throughout the study and should increase by at least 20 mm Hg with exercise. The treadmill portion is halted for:

(1) concerning symptoms (severe angina, ataxia, dizziness, pallor,

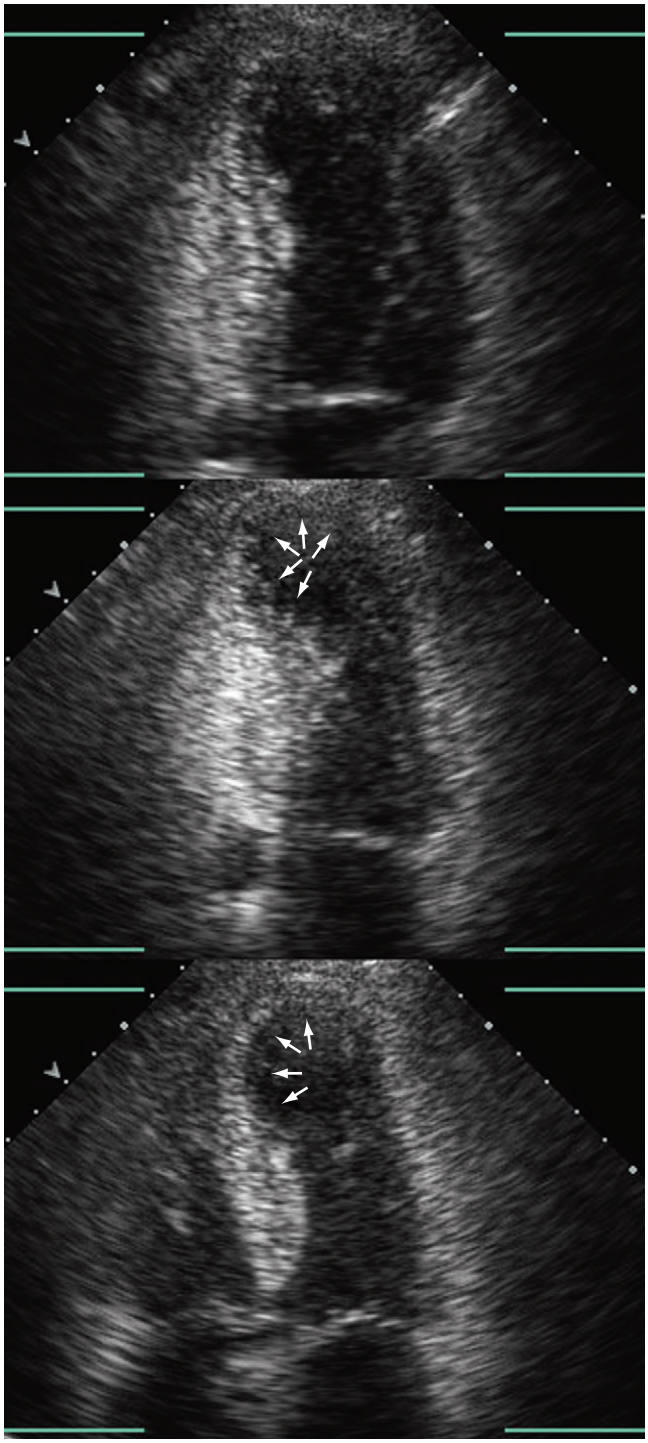

**Figure 15-4 Abnormal treadmill stress echocardiogram.** The patient exercised 7 minutes and 30 seconds on a standard Bruce protocol and developed angina at peak stress. *Top*: Apical two-chamber view atrest during systole. *Middle*: After exercise, there is thinning and hypokinesis of the entire apex and distal inferior wall in the apical two-chamber view (*arrows*). *Bottom*: On the apical four-chamber stress view, there is thinning and dyskinesis of the entire apex and distal inferoseptum (*arrows*). All other segments became hyperdynamic.

(2) severe hypertension (systolic blood pressure greater than 220 mm Hg),
(3) hypotensive response (more than 10 mm Hg drop in systolic blood pressure),
(4) concerning ECG changes or arrhythmias, or

(5) hemodynamic targets are achieved.[31] Based on total exercise duration, a nomogram based on age, gender, and degree of physical conditioning provides an estimate of functional aerobic impairment.[32]

Because patient motion limits imaging during active treadmill use, "stress" imaging is performed immediately after exercise cessation without a cool-down period. The duration of ischemia induced abnormalities is variable, dependent on coronary occlusion severity, number of vessels affected, presence of collateral blood flow, and achieved workload.[33] Although ischemic abnormalities can persist for some time after exercise cessation, most reverse within minutes. Therefore, expeditious imaging is critical; image acquisition within 60 to 90 seconds after exercise completion is generally adequate. Reasonable patient agility is required to transition to the imaging table, reassume a left lateral decubitus position, and allow imaging within this time window (see Table 15-1). If prolonged delays in patient transfer occur or acoustic windows are suboptimal, transient ischemia may be missed. This is particularly true with intermediate-range occlusions or single-vessel disease where induced abnormalities are often fleeting. Although feasibility of peak stress imaging on the treadmill has been demonstrated, the minimal incremental benefit attributable to time savings while scanning upright coupled with difficulties in obtaining reproducible results limits widespread use.[34]

For bicycle ergometry, baseline images are obtained in a left lateral decubitus position (see Table 15-1). Patients perform either upright or supine bicycle exercise with a goal of achieving increases in wattage, 2 to 3 minutes per stage. At each stage, pedal resistance increases in a stepwise manner and the patient must maintain a constant cadence (about 60 rpm). Because workload is effort driven, achievement of maximal workload is more patient dependent than in treadmill protocols. After completion of exercise, the patient reassumes a left lateral decubitus position for further imaging. If apical windows are not easily accessible, subcostal views provide an alternative. During upright or supine ergometry, most myocardial segments can be well visualized.[35] However, care must be taken to avoid apical foreshortening as can occur with even mild head elevation. For supine bicycle ergometry, integrated imaging stretchers allow patient rotation and positioning such that transition to a separate imaging bed is obviated, resulting in time savings (see Table 15-1). Bicycle protocols allow for a relatively stationary position for simultaneous image acquisition during active exercise.[36,37]

Imaging concurrent with peak stress, as opposed to immediate posttreadmill imaging, increases sensitivity for detecting transient ischemia.[36,38,39]

In the United States, treadmill stress is favored over bicycle ergometry because of widespread availability of treadmills in hospital settings and familiarity of walking as a form of exercise. Treadmill ECG testing, as an established diagnostic modality, is well validated, providing a wealth of prognostic information referenced to exercise duration and ECG response to exercise. With treadmill exercise, patients generally achieve higher workloads than with bicycle exercise, increasing likelihood of attaining hemodynamic targets. Supine ergometry stress typically produces a lower heart rate increase and a systolic blood pressure response about 20 mm Hg higher than that of upright exercise because of physiologic differences in preload. Additionally, maximum oxygen uptake tends to be lower with bicycle ergometry (10% to 20%) and should be considered during study interpretation.[31] Last, with supine ergometry, where the lower extremities must be supported against gravity, if quadriceps fatigue precedes maximal workload, patients may prematurely discontinue exercise.

In Europe, where bicycling is a more common form of exercise, bicycle protocols are favored. Guided by real-time wall motion evaluation, bicycle protocols allow for ischemia detection at onset, allowing identification of the ischemic threshold, in contrast to treadmill protocols that use ECG changes or symptom onset as a time point to discontinue exercise. Real-time ischemia identification allows for increased detection of subtle or transient ischemia with single-vessel disease or intermediate-severity lesions. Bicycle protocols allows imaging without the "all-or nothing" constraints of a narrow immediate poststress imaging window, as seen in treadmill protocols. The choice of which stressor to employ should be individualized to the ability of the patient to perform exercise, experience level of the personnel administering the study, and availability of equipment. Published reports demonstrate comparable accuracy between different exercise protocols.[39-41] As long as an adequate workload is achieved, overall accuracy is likely equivalent regardless of the stressor employed.[42]

# Methodology

## EQUIPMENT

The standard for laboratories performing exercise echocardiography includes high-quality instruments with a digital frame grabber, harmonic imaging capability, and an offline analysis system. Appropriate equipment (treadmill or bicycle ergometer) should be available, as should imaging beds with lateral cutouts to facilitate apical imaging. A cardiac arrest cart and defibrillator should be easily accessible.[5,6]

Digital frame grabbers and split-screen displays allow side-by-side comparison of rest and stress images to facilitate identification of regional wall motion abnormalities. Digital frame capture rates ranging from 20- to 100-ms intervals are looped and replayed continuously for analysis.[43,44] These intervals allow for variable capture within the cardiac cycle ranging from systole alone to the entire cardiac cycle. Most systems acquire eight frame digital loops per view with about 50 ms for each frame. However, if heart rate exceeds 150 bpm, image quality may be improved by reducing the capture interval to 30 to 40 ms. Digital clips of about 10 to 20 seconds per view are needed for adequate wall motion analysis. Gating of baseline and stress images to the ECG allows comparative analysis of endocardial motion at the same point in the cardiac cycle, optimizing identification of interval changes in regional function. A videotaped backup recording of the study is helpful to ensure that digital loops accurately reflect myocardial motion.[45]

## PROCEDURE

A brief history is taken to document symptoms, atherosclerosis risk factors, and current medications and to review basic laboratory findings. Written informed consent should be obtained before the procedure. An activity-specific questionnaire may aid in predicting peak exercise capacity.[46] Patients should refrain from oral intake 3 to 4 hours before the procedure.[31] Medications that may affect maximal workload (i.e., atrioventricular nodal blocking agents) should be held for one or two doses, unless the study purpose is to diagnose ischemia while on active therapy or risk of an adverse event off medication is deemed too high. Telemetry leads are placed at standard limb and precordial sites, slightly displacing leads that interfere with acoustic windows. One ECG lead is concurrently displayed on the echocardiography monitor to allow image gating and correlate changes in wall motion with ECG abnormalities. Information on heart rate, rhythm, exercise capacity, and blood pressure is recorded (Box 15-2).[29] Common ECG criteria for ischemia are greater than 1 mm horizontal or down-sloping ST depression at least 60 ms after the end of the QRS complex in anatomically contiguous leads.[29] Patients should be intermittently asked for presence or severity of symptoms. If severe symptoms occur or ischemia develops, the study should be discontinued. Monitoring should continue until blood pressure, heart rate, and ECG have returned to near-baseline levels and any induced symptoms have resolved. Study results should be conveyed to the

referring provider promptly, with immediate discussion when the stress test is strongly positive.

Optimal acoustic windows are located and baseline echocardiographic images obtained. If baseline abnormalities are seen, a brief transthoracic study should be performed to evaluate ventricular dysfunction, significant valvular abnormalities, or pericardial effusion. If baseline image quality is suboptimal (up to 20% of cases), transpulmonary contrast aids endocardial border definition (Fig. 15-5). Transpulmonary contrast is particularly helpful for assessing anterior and lateral wall motion, regions that may be more difficult to see in larger patients or those with underlying pulmonary disease. However, because contrast lasts only 1 to 2 minutes after injection, separate injections are needed for baseline and stress images. For treadmill studies, contrast is injected during peak exercise so it is in place during poststress imaging.

## IMAGING

Myocardial segments are evaluated in multiple views to avoid misdiagnosis due to an oblique image plane. Prestress optimization of image planes and views is critical to maximize diagnostic accuracy. The four basic views used are concordant with standard transthoracic tomographic planes: the parasternal short- and long-axis views and the apical four- and two-chamber views. Subcostal views are not commonly used but may be substituted in the rare instance when they provide better images, such with intervening lung tissue due to chronic pulmonary disease.[35] Once baseline images are obtained, acoustic windows are identified and marked to minimize transducer repositioning on poststress imaging. Because induced ischemia may normalize quickly, sequencing for poststress imaging typically starts with apical windows, moving to parasternal windows. Several digital loops are acquired in each view in rapid sequence to optimize loop selection for comparison. Vigorous cardiac contraction, tachycardia, and exaggerated respiration increases translational and rotational movement of the heart. Patients with excessive cardiac motion should briefly halt respiration at

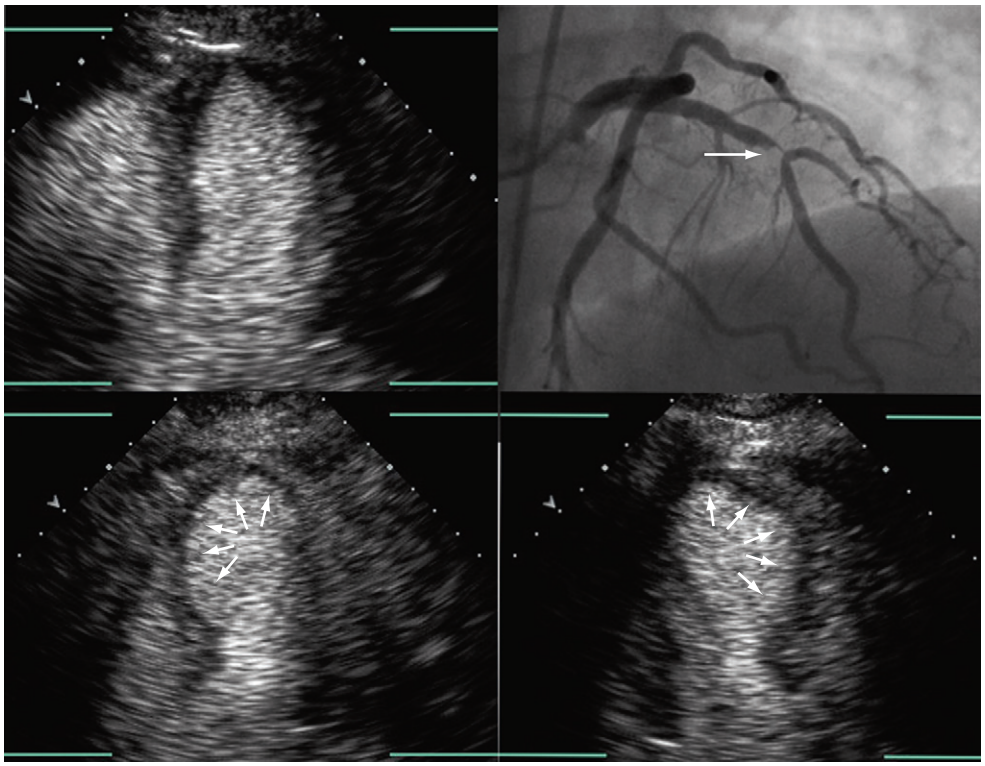

**Figure 15-5** Abnormal treadmill stress echocardiogram with transpulmonary contrast to enhance the endocardial border. *Upper left*: Resting four-chamber view shows normal LV cavity size with symmetric systolic wall motion. *Bottom left* and *right*: After exercise, aneurysmal dilation and hypokinesis are seen in the entire apex, distal inferoseptum, and distal anterior wall (*arrows*). end- or midexpiration to aid in maintaining a relatively constant imaging plane. With normalization of heart rate near to baseline, an additional set of images should be obtained to evaluate for late-onset ischemia.

## DOPPLER

Doppler echocardiography is not routinely performed during stress echocardiography for ischemia evaluation. Rapid heart rate and additional time requirements for imaging do not allow for reliable data acquisition. Doppler-derived indicators of myocardial response to stress include left ventricular (LV) ejection velocity, aortic systolic ejection rates, transmitral filling velocities, and tissue Doppler interrogation of myocardial velocities. Although research-based applications using Doppler interrogation during peak stress suggest some additive value, the additional time demands of Doppler interrogation in its current state, coupled with relatively small incremental gain in information, limit routine use. In patients with valve lesions who have equivocal symptoms or are asymptomatic, tailored Doppler interrogation during exercise echocardiography provides objective data on exercise tolerance, symptom provocation, hemodynamic effects of exercise, and pulmonary pressure response to exercise (see later discussion).[47]

## ROOM LAYOUT

Room layout is critical to success of the procedure. The narrow time window between exercise cessation and recording of post-stress images necessitates spatial optimization to maximize time savings and facilitate image acquisition. A typical floor plan minimizes the number of steps and impediments for patient transfers (Fig. 15-6).[48] Adequate space around the imaging bed for the ECG and echocardiography instruments, sonographer, and medical professionals is necessary. Patients should receive clear instructions on maneuvers required after exercise termination to avoid introducing unnecessary delay. Often, it helps to have a "practice" transition from the treadmill to the imaging bed so the patient knows what is expected. Emergency medical equipment, drugs, and supplies should be readily available.

## PERSONNEL

Staffing for exercise echocardiography requires at least two people: a sonographer and a medical professional to monitor the patient and evaluate for symptom onset.[6] A physician trained in advanced cardiac life support should be in the immediate vicinity of the stress laboratory and available for emergencies.[29,49] In many laboratories, physician supervision is a requirement, either physically or more remotely, observing from a monitor. However, several studies document the safety of exercise supervision by properly trained allied health professionals such as physician assistants, exercise physiologists, or registered nurses.[50,51] Regardless of the personnel used, considerable skill on the part of the medical supervisor, sonographer, and/or technician is needed to facilitate an adequate study and recognize signs and symptoms of ischemic heart disease.

There is a significant learning curve associated with the technical challenges of image acquisition, study implementation, and interpretation. To optimize imaging, sonographers should have completed training in standard transthoracic imaging with an additional 3 months of training in exercise echocardiography and should possess basic knowledge of coronary anatomy and myocardial distribution. It is recommended that sonographers complete more than 50 stress studies to claim proficiency and perform more than 10 studies per month to maintain appropriate skill level. Physicians responsible for supervision and interpretation should be at least level II trained in echocardiography (Box 15-3). Supervised overreading of at least 100 studies by a level III–trained echocardiographer with independent interpretation of 200 studies is recommended to attain a minimum competence level for independent interpretation, and additional interpretation of more than 15 studies per month is recommended to maintain skills.[6,52] Although these volumes are reasonable for routine study interpretation, more specialized applications, such as evaluation of valvular heart

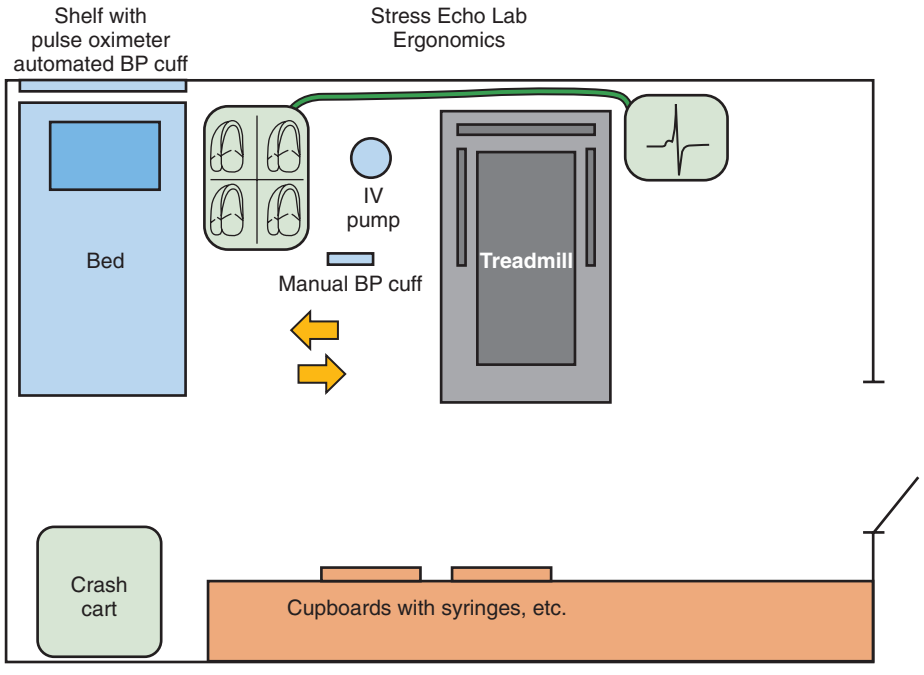

**Figure 15-6 Room layout.** Stress echocardiography laboratory equipment set-up. Beginning at the bottom of the figure and moving clockwise: storage cupboards with intravenous (*IV*) equipment, crash cart, imaging bed with shelf above for pulse oximeter and automated blood pressure (*BP*) cuff, echocardiography machine with frame grabber, IV pump for pharmacologic stress echocardiography, manual BP cuff, treadmill, electrocardiography (ECG) machine. The patient moves between the imaging bed and the treadmill, requiring no more than two steps in each direction (*yellow arrows*).

**Box 15-3**

**RECOMMENDED PHYSICIAN KNOWLEDGE FOR PERFORMANCE AND INTERPRETATION OF STRESS ECHOCARDIOGRAPHY[6]**

- Understand indications and limitations of exercise echocardiography with knowledge of alternative diagnostic procedures
- Knowledge of cardiovascular drugs and effects on stress response
- Understand study endpoints and indications for study termination
- Understand diagnostic accuracy and prognostic value of stress echocardiography in different patient populations
- Identify LV wall segments, recognize wall motion abnormalities, and interpret digitally acquired images
- Understand conditions and circumstances for indeterminate or false test results
- Competence in cardiopulmonary resuscitation
- Apply Doppler data to physiologic changes occurring during stress (hemodynamic studies)

**TABLE 15-2 Interpretation of Myocardial Response to Stress**

| *Resting Myocardial Appearance* | *Myocardial Response to Exercise* | *Interpretation* |
|---|---|---|
| Normal | Hyperdynamic | Nonischemic |
| Normal | Hypokinetic or akinetic | Ischemic |
| Normal | Unchanged (lack of hyperdynamic response) | Microvascular ischemia or balanced ischemia |
| Hypokinetic | Akinetic | Infarcted myocardium |
| Akinetic | Dyskinetic | Transmural infarct |

disease, warrant more clinical expertise and volume.[53] Continuous quality-improvement practices should be employed to ensure consistency and accuracy of interpretations.[54]

## INTERPRETATION

A normal study is one where there is normal resting wall motion with a hyperdynamic response to exercise (see Fig. 15-3). With abnormal studies, location, extent, and severity of interval changes are noted and recorded (Table 15-2). During interpretation, provoked abnormalities concordant with a coronary artery distribution should be noted. More detailed segmental analysis using the 16-segment LV model (see Figure 13-3) and standard wall motion analysis scale (normal, hypokinetic, akinetic, dyskinetic) may be used for reporting.[14] Several factors affect myocardial appearance and response to stress:

1. Compensatory hyperdynamic function of nonischemic regions
2. Tethering of nonischemic regions
3. Balanced ischemia
4. Lack of hyperdynamic response to stress

With prolonged ischemia, compensatory hyperdynamic function in regions remote to ischemic zones occurs because of a physiologic response of the ventricle to maintain overall cardiac output.[55] If pronounced, this may mask stress induced abnormalities in ischemic segments. Nonischemic segments adjacent to ischemic myocardium may show decreased motion despite the presence of adequate blood flow because of *tethering* from akinetic regions, leading to overestimation of ischemic burden.[56] Stress-induced global hypokinesis, or a lack of hyperdynamic response to exercise, may be seen in patients with disease in all major epicardial coronary arteries, or "balanced" ischemia. However, other markers of coronary artery disease are usually identifiable, such as decreased exercise tolerance, ischemic ECG changes, or angina. Rarely, a lack of hyperdynamic response occurs in absence of major coronary artery obstruction, such as in left ventricular hypertrophy, diabetes, severe arterial hypertension, and hypertrophic cardiomyopathy. Angiographic studies in these subsets suggest a reduction in coronary flow reserve due to microvascular disease, with smaller regions of ischemia failing to manifest in frank mechanical dysfunction. Because heterogeneity in wall motion is absent, diagnostic accuracy to identify ischemia is lowered.[57,58] Although current diagnostic testing does not allow for definitive diagnosis of microvascular ischemia, advances in myocardial contrast perfusion imaging may increase understanding of this disease process in the future.

Interpretation of stress echocardiography remains largely qualitative, with visualized wall motion abnormalities the core marker of ischemia. This approach is generally adequate for patient management. Reliability and reproducibility of study interpretation are largely dependent on interpreter experience.[59] Adequate physician and sonographer training and conservative interpretation criteria improve diagnostic sensitivity, consistency, reliability and validity.[60,61] A logical approach to interpretation is essential. Echocardiographers should be cognizant of the patient's clinical history. For example, in patients with prior coronary bypass surgery, wall motion analysis may suggest collateralized vessels, not a typical pattern for patients without coronary disease. Similarly, in individuals with prior infarcts, tethering effects on adjacent nonischemic regions should be considered.

Interpreters should be vigilant for induced wall motion changes that do not actually signify ischemia. Such "false-positive" findings include abnormal septal motion with ventricular pacing, an intrinsic conduction abnormality, or postoperative changes. Another false-positive septal abnormality is early relaxation of the anteroseptal region relative to other segments. "Early relaxation" can usually be timed in the cardiac cycle to just before mitral valve opening and is not indicative of ischemia.[62] Other commonly misdiagnosed regions include the basal inferior wall. Without prior bypass revascularization, an isolated basal wall motion abnormality should be scrutinized closely, given the unlikelihood of an isolated proximal wall abnormality with hyperdynamic mid and distal segments.[59] Falsely negative studies are most commonly due to procedural difficulties, such as inadequate workload, performance below the ischemic threshold, inexperienced interpreters, poor endocardial border definition, and inferior image quality. Myocardial regions more subject to "false negatives" or missed ischemia include the lateral wall, particularly in obese patients, and those where interposed lung tissue hinders imaging.

With residual coronary occlusion and chronic ischemia, stress echocardiography can be used to evaluate for viable myocardium. Viable myocardium is hypokinetic, as minimally adequate blood flow meets basal metabolic needs but is insufficient to support normal function. Distinguishing between viable or infarcted myocardium has been applied to coronary revascularization, based on the premise that revascularization of viable tissue improves systolic function and reduces ischemic burden.[4] For stress echocardiography, a "biphasic" response is

the hallmark of viable myocardium where mild augmentation in wall motion occurs following a low-level stressor, but with higher stressor doses, segments become frankly ischemic and decrease contractility, again becoming hypokinetic or akinetic. Because of the subtlety in wall motion assessment during viability testing, exercise stressors have not proven reliable, and conventional protocols use pharmacologic stressors (see Chapter 16). The future role of viability testing is not clear. A recent substudy of the Surgical Treatment for Ischemic Heart Failure Trial found that identification of substantial viable myocardium did significantly affect 5-year mortality comparing medical therapy with and without bypass surgery, implying that viability assessment alone should not be the deciding factor in determining treatment strategy.[63]

More quantitative approaches to exercise echocardiography provide standardized interpretation but are labor intensive to implement. The most commonly used semiquantitative application is the *wall motion score index*, in which the LV is divided into segments and regional wall motion of each segment is assessed (see Chapter 13, page 239).[14] Wall motion is graded between 1 and 4 depending on abnormality severity (0 hyperkinetic, 1 normal motion, 2 hypokinetic, 3 akinetic, and 4 dyskinetic). The summed total is divided by the number of segments evaluated to calculate a global wall motion score index. Alternatively, individual coronary artery distributions can be assigned to obtain a regional wall motion score index. Similar to qualitative interpretation, overscoring of nonischemic segments "tethered" to ischemic myocardium overestimates ischemic burden.

Computer-driven algorithms offer the potential for decreasing time demands for quantitative analysis. The *centroid* and *centerline* algorithms gauge wall motion referenced to a "baseline" within the LV. With the centroid method, multiple radii extending from a geometric center of mass to the endocardial and epicardial surfaces of the LV are generated and relative differences in wall motion between rest and stress images are compared. With the centerline method, distance measurements of the endocardium and epicardium perpendicular to the midpoint of the myocardium are compared. However, subjective decision making by the interpreter is still needed in marking endocardial and epicardial borders. (See Chapter 12.) Availability of automated endocardial border recognition algorithms is increasing. However, the need for superior image quality for accurate border delineation is paradoxic, because excellent qualitative interpretation is usually possible without the time demands of quantitative measurement. Moreover, most available analysis packages rely on radial motion analysis and do not reliably account for torsional or translational movement. Although a quantitative tool is an attractive concept to increase ease and reliability of interpretation, with the added labor requirements no currently available tools supplant standard qualitative analysis.[64]

## Diagnostic Accuracy of Exercise Echocardiography

Diagnostic accuracy of cardiac stress testing is generally reported as sensitivity and specificity to detect angiographically identified lesions. However, consideration of stenosis severity that denotes disease presence should be made. Stenosis thresholds create artificial distinctions (disease present versus not present) in a process that actually represents a spectrum. If the "set point" is higher (use of greater than 70% versus greater than 50% coronary artery stenosis used as the definition of disease presence), patients with true ischemia but less severe occlusion would be erroneously labeled "false positive." Higher set points increase sensitivity by increasing true positive likelihood and reducing false negatives.[24,65-70] Additionally, there are acknowledged limitations of 2D angiography in measuring hemodynamic significance of lesions.[71,72] However, limited data using quantitative angiography demonstrate excellent correlation with stress echocardiography results.[22,25]

Diagnostic accuracy is affected by factors that introduce bias.[73,74] Early exercise echocardiography studies suffered from reporting bias, where newer modalities are favored over old. For example, if echocardiographic stress test accuracy is compared with standard ECG testing, the exercise ECG portion is the same. Echocardiographic imaging is only additive with impossibility for a "worse" performance. Validation studies for exercise echocardiography tended to be performed at higher-volume centers with increased clinical expertise, drawing from patient groups with prior myocardial infarction or known disease, where higher pretest probability increased test sensitivity. With acceptance of test validity of a modality, posttest referral bias is introduced (Fig. 15-7), where only positive tests are referred for confirmatory testing (in this case, angiography), and negative tests are accepted as correct without verification.[75] Last, with accepted use of a modality and more widespread application, pretest disease probability drops with drifts in sensitivity and specificity. This has been documented with nuclear perfusion stress, for which larger-cohort data are available.[76]

Diagnostic accuracy depends on disease prevalence in the tested population, definition of disease "presence," and criteria used to define a positive test. Inclusion of borderline or equivocal findings (i.e., identifying a lack of a hyperdynamic response as ischemia) increases likelihood of identifying disease, raising sensitivity at the expense of specificity by increasing false positives. If image quality is suboptimal or with delay in poststress imaging, diagnostic accuracy suffers (Table 15-3).[36,38,39,42,70] With single-vessel disease, the ischemic zone is relatively smaller and

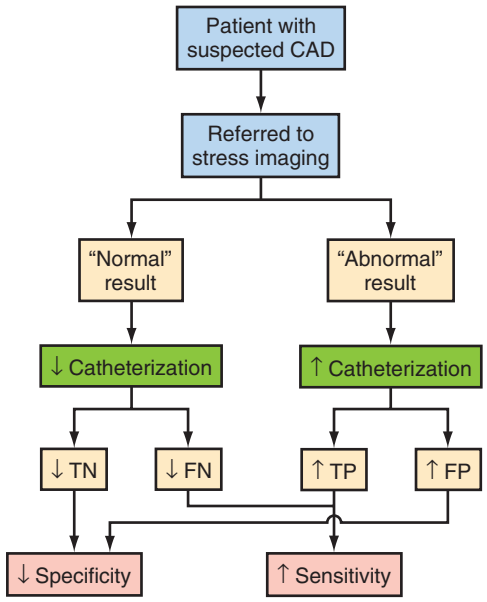

**Figure 15-7 Posttest referral bias.** Because abnormal test results lead to increased referral for confirmatory coronary catheterization, studies evaluating diagnostic accuracy have relatively higher true positive and false positive rates, which result in higher sensitivity and lower specificity.[74]

**TABLE 15-3 Factors Affecting Exercise Echocardiography Interpretation and Accuracy**

| *Lowered Specificity (False-Positive Errors)* | *Lowered Sensitivity (False-Negative Errors)* |
|---|---|
| Hypertensive response to stress as abnormal | Poor image quality |
| Basal inferior wall abnormalities as abnormal | Excessive postexercise delay to imaging |
| Tethered segments as abnormal | Single-vessel disease |
| Lack of hyperdynamic response as abnormal | Testing patients with lower pretest disease probability |
| Early septal relaxation as abnormal | Lateral wall abnormalities |
| Interventricular conduction delay or paced rhythms | Inadequate workload (suboptimal effort or medications) |
| Valvular heart disease with loss of contractile reserve | Multivessel disease with balanced ischemia |
| Cardiomyopathies | Mild or intermediate-severity stenoses |
| Inexperienced personnel | Inexperienced personnel |

ischemia is more difficult to detect, lowering sensitivity by increasing false-negative studies, approximately 75% compared to overall sensitivity of 84% in all patients with coronary disease.[70,77] Patients unable to achieve a high workload are less likely to reach an ischemic threshold, as can occur in patients on medications that lower heart rate response to exercise (i.e., atrioventricular nodal blocking agents). Last, interpreter experience is critical, with increased diagnostic accuracy seen for higher-volume, more experienced readers. Overall, exercise echocardiography is both sensitive and specific for ischemia identification (accuracy 85% to 90%) (Table 15-4). A meta-analysis of more than 2600 patients drawing from 24 studies reported overall sensitivity of 85% and specificity of 77%.[78]

## Comparison with Other Stress Modalities

Exercise ECG testing is the most established stress modality, widely available and well validated for initial coronary artery disease diagnosis, cardiac risk assessment, and prognostication. In a review of 58 exercise ECG studies involving nearly 12,000 patients undergoing both coronary angiography and exercise testing, mean sensitivity was 67% with mean specificity of 72%.[29] The greatest diagnostic value for exercise ECG testing is its negative predictive value. However, if baseline ECG abnormalities are present, sensitivity and specificity decline.[57] Additionally, ECG ST segment changes during exercise can be effected by factors other than ischemia, such as endogenous estrogen, which can have a digoxin-like effect on the ECG, and hyperventilation, which can cause diffuse ST segment abnormalities.[79] For patients with baseline ST-T segment abnormalities, left bundle branch block, left ventricular hypertrophy, and paced rhythms, imaging cardiac stress testing (echocardiography or nuclear perfusion stress) is preferred over exercise ECG testing. Although overall diagnostic accuracy for ischemia is improved with the addition of imaging, additional equipment, space, and personnel with specialized expertise are needed. With the added time demands and costs, it is logistically impossible and cost ineffective to replace all exercise ECG tests with imaging studies. Exercise imaging studies should therefore be targeted in those with nondiagnostic ECGs, either at baseline or anticipated during stress (Table 15-5).

**TABLE 15-4 Selected Studies: Diagnostic Accuracy for Exercise Echocardiography**

| *Study* | *Mode* | *Number of Patients* | *Criteria for Significant Occlusion* | *Sensitivity* | *Specificity* | *Accuracy* |
|---|---|---|---|---|---|---|
| Armstrong (1986)[1] | TME | 95 | >50% | 88% | 87% | 87% |

Stress echocardiography and nuclear perfusion stress provide reasonably comparable information with regard to ischemia diagnosis, diagnosis of myocardial viability, and prognostication.[78,80] Accuracy for both modalities is improved with multivessel disease, increased disease severity, a higher ischemic workload achieved, and more experienced readers. However, because echocardiographic imaging is performed in real time, stress echocardiography can provide concurrent data on valvular function and pulmonary pressures during testing and offers

additional information and safety by identifying preexisting conditions that may affect testing, such as valvular heart disease. For exercise echocardiography, radiation exposure is absent and, unless transpulmonary contrast is needed, intravenous access is not needed. Stress echocardiography can be performed within 1 to 2 hours, whereas nuclear perfusion stress requires, at a minimum, several hours to complete.

Comparative studies between echocardiography and nuclear perfusion stress modalities tend to occur in centers where expertise in a particular modality is favored. Earlier comparative studies with nuclear modalities used thallium scintigraphy. Contemporary practice currently uses sestamibi or thallium single photon emission computed tomography (SPECT), which reduces imaging artifacts. Studies document comparable performance between echocardiography and nuclear modalities.[69,81-83] Summary receiver operating characteristic curves show superiority of exercise echocardiography to exercise ECG testing, with comparable sensitivity to exercise SPECT. When specificity is reduced (higher sensitivity valued), nuclear perfusion stress modalities tend to perform better (Fig. 15-8).[84] A meta-analysis drawing from 44 studies confirmed comparable sensitivity between echocardiography (85%) and nuclear testing (87%).[78] For both modalities, sensitivity for single-vessel disease is lower than for multivessel disease (in one study, sensitivity for single-vessel disease was 61% for nuclear versus 58% for echocardiography).[81]

Stress echocardiography differs from nuclear perfusion stress by assessing functional consequences of ischemia rather than alterations in regional myocardial perfusion. Therefore, if resting wall motion abnormalities are present, subtle ischemia may be more difficult to interpret, resulting in slight advantages in sensitivity seen with nuclear perfusion stress. Overall, nuclear perfusion stress tends to offer higher sensitivity, higher technical success rate, less interobserver variability, and better accuracy for detecting ischemia when resting wall motion abnormalities are present. Advantages for stress echocardiography include shorter test time, greater patient convenience, higher specificity, versatility, the absence of radiation exposure, and lower cost. In most centers, the choice is driven by local personnel expertise and facility accommodation.

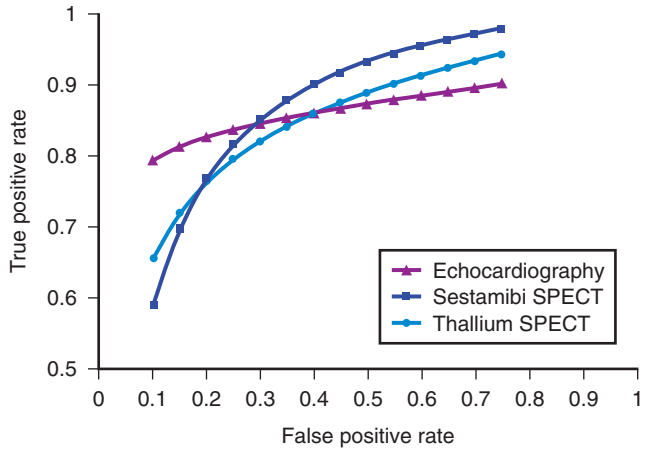

**Figure 15-8 Receiver operator characteristic curves for exercise echocardiography compared to nuclear perfusion stress testing.** True positive rate (sensitivity) is plotted on the y-axis and false positive rate (1-specificity) is plotted on the *x*-axis. When specificity is valued, echocardiography tends to perform better.[84] *SPECT*, Single photon emission computed tomography.

## COST EFFECTIVENESS

Care providers should be aware of, and incorporate into their clinical practice, relative costs of procedures. Cost considerations for various cardiac stress modalities include the patient's incurred costs, Medicare and insurer reimbursement charges, and additional costs of downstream diagnostic testing prompted by the study. Prior comparative cost analyses highlight the importance of pretest disease probability assessment in selecting diagnostic modality type. For example, with high pretest probability, the most cost-effective course may be to proceed directly to angiography.

Several papers comment on cost effectiveness for cardiac stress testing.[85-87] Medicare fees provide comparative and relative costs for professional and technical fees.[29] The "test-only" relative value units for exercise ECG testing are least, with imaging additive, approximately 2.3× higher for echocardiography and 5.3× higher for nuclear perfusion stress.[29] However, test-only costs do not account for increased accuracy and reduced confirmatory downstream testing that imaging confers. When this is accounted for, cost-based analyses favor stress imaging studies, particularly when the likelihood of a nondiagnostic stress ECG study is high.[85-89]

The diagnostic value of any testing modality is greatest when it significantly increases (based on a positive result) or lowers (based on a negative result) coronary artery disease suspicion. Thus, the greatest value is in patients with intermediate range pretest probability (range 20% to 80%). In patients with a low pretest probability, such as those with few cardiovascular risk factors, a positive result is more likely "false positive." Similarly, in individuals with high pretest probability, a negative result may be looked on with skepticism, and direct coronary angiography should be considered. Providers should be aware of direct and downstream costs of different diagnostic options and relative expertise in the various modalities at their institutions. Current diagnostic schemes and pathways have not yet incorporated routine use of newer diagnostic technologies such as cardiac magnetic resonance imaging or multislice computed tomographic angiography.

## SAFETY

There are no adverse effects with exercise echocardiography other than those associated with physical exercise and risk incurred from provoked ischemia. Unlike other forms of diagnostic testing, such as angiography or nuclear perfusion stress, radiation exposure is absent. Major complications are rare, with myocardial infarction reported in approximately 1 in 2500 tests and death in approximately 1 in 10,000.[29,31,90] Contraindications include those normally associated with exercise ECG testing (Box 15-4).

## APPROPRIATE USE AND QUALITY ASSURANCE

Cardiac imaging studies comprise about 50% of medical diagnostic testing. However, recent studies suggest that about 10% to 15% of these studies are either inappropriate or noncontributory.[91] With impending concerns around Medicare solvency, there is now increased scrutiny on appropriate use of cardiac imaging modalities.[92,93] Implications of appropriate use are critical, because such testing often dictates downstream use of other tests, such as coronary angiography. The American College of Cardiology has published appropriateness criteria to

Box 15-4

**CONTRAINDICATIONS FOR EXERCISE ECHOCARDIOGRAPHY**

| Absolute Contraindications | Relative Contraindications |
|---|---|
| Acute myocardial infarction (within 48 hr) | Left main coronary stenosis |
| High-risk unstable angina | Severe arterial hypertension (SBP >200 mm Hg, DBP >110 mm Hg) |
| Uncontrolled cardiac arrhythmias | Poor acoustic windows/image quality (not aided by transpulmonary contrast) |
| Symptomatic severe aortic stenosis | Mental or physical impairment with inability to exercise |
| Symptomatic heart failure | Tachyarrhythmias or bradyarrhythmias |
| Acute pulmonary embolus | Atrioventricular nodal blocking agents |
| Acute aortic dissection | Hypertrophic cardiomyopathy |
| Acute myocarditis or pericarditis | |

*DBP*, Diastolic blood pressure; *SBP*, systolic blood pressure.

provide expert consensus–guided recommendations for cardiac imaging, drawing from clinical scenarios; a score is assigned to clinical scenarios ranging from 1 (inappropriate) to 9 (appropriate).[94] For example, an "appropriate" stress echocardiography indication would be in a patient with an intermediate pretest probability of coronary artery disease and an uninterpretable ECG, versus an "inappropriate" indication such as routine transpulmonary contrast use despite adequate visualization of all segments on noncontrast images. Recent studies evaluating these developed criteria suggest that approximately 10% to 15% of studies may be classified as "inappropriate."[95] Future refinement should aid in altering clinical practice to guide individual patient care and maximize cardiac imaging utility by educating care providers and influencing policy making regarding payer coverage. Additional recent publications have also addressed quality assurance for stress echocardiography.[54]

## Applications

### CORONARY ARTERY DISEASE: INITIAL DIAGNOSIS

The primary application of exercise echocardiography is in diagnosing and managing coronary disease.[5,6] In patients with angina symptoms and moderate pretest probability, stress testing should be performed within 3 to 7 days of symptom onset as long as the patient is asymptomatic at the time of the study. Symptomatic patients with higher pretest disease probability (ischemic ECG change or positive cardiac biomarkers) should proceed directly to coronary angiography. Exercise echocardiography is also valuable for distinguishing between ischemic and nonischemic cardiopulmonary disease such as pulmonary hypertension or valvular heart disease.[96]

Historically, initial evaluation for chest discomfort was in the emergency department, with hospital admission to rule out acute infarction prior to risk stratification. Now, intermediate- and lower-risk patients are increasingly managed with emergency department "chest pain units" that perform triage and risk stratify patients and provide expedited stress testing once an acute coronary syndrome has been excluded.[97,98] (See Chapter 13.) This approach has been effective in identifying higher-risk individuals while concurrently reducing inpatient stays.[99] Although test modality is institution dependent, reports demonstrate improved accuracy with exercise echocardiography over exercise ECG testing, with comparable performance compared to nuclear perfusion stress.[100,101] Given this, exercise echocardiography is an attractive option for an initial diagnostic study, especially considering shorter test duration, absence of radiation exposure, cost savings, and patient convenience.

Exercise testing in asymptomatic individuals for coronary disease diagnosis is not recommended.[102] Although functional capacity and hemodynamic response to exercise are gauged, there is no evidence that results from such testing affect clinical outcome, especially given that prognosis in low-risk patients is excellent and false-positive findings may instigate unnecessary additional testing. However, judicious testing in certain asymptomatic high-risk subsets, such as those with diabetes or vascular disease, is often considered, particularly for those contemplating higher-risk activities such as a new vigorous exercise regimen.[102]

### CORONARY ARTERY DISEASE: KNOWN CORONARY ARTERY DISEASE

Cardiac stress testing after a recent myocardial infarction allows assessment of injury extent and residual ischemia, potentially aiding in decision making for future therapies. Although now rare in contemporary practice, if a patient with a recent infarction did not undergo angiography, a *submaximal* predischarge stress test 3 to 7 days after the event is recommended for risk assessment.[103] Submaximal protocols have lower hemodynamic endpoints (goal only 5 METs or 70% predicted maximum heart rate).[104] As early as 2 to 3 weeks after an infarction, a *symptom-limited* stress test can be performed reasonably safely, with incidence of infarction less than 1%.[29,105] Given ECG abnormalities frequently present, the sensitivity of exercise ECG testing in this population is poor, in the range of 50% to 70%.[81] As with other applications, overall diagnostic accuracy for cardiac imaging stress studies is significantly improved over exercise ECG testing, with visual localization of ischemic territory.

In individuals under consideration for revascularization (percutaneously or surgically), echocardiography viability protocols are well established for pharmacologic stressors (i.e., dobutamine) (see Chapter 16).[106] Viability testing with exercise stressors is not routinely performed. Although limited data using low-level bicycle ergometry demonstrates feasibility, accuracy is not as high as with pharmacologic applications, and tethering from resting wall motion abnormalities increases difficulty of interpretation.[107,108] In 52 postinfarction patients who underwent low-level supine bicycle exercise and low-dose dobutamine echocardiography, sensitivity for predicting functional recovery with exercise was only 81%, compared to 91% for dobutamine.[109]

Following percutaneous revascularization, stress echocardiography can document improvement in exercise tolerance and regional function.[110,111] Echocardiographic imaging provides improved diagnostic accuracy for restenosis over exercise ECG, with one study showing sensitivity for exercise echocardiography 83% compared to only 42% for exercise ECG.[110-113] As with other comparative studies, exercise echocardiography performs similarly to nuclear perfusion stress for restenosis diagnosis, with 89% concordance.[114] Exercise echocardiography after surgical coronary revascularization allows assessment of graft patency and evaluation for residual ischemia.[115-117] However, in clinical practice, cardiac stress testing surveillance in any asymptomatic individual is controversial, considering the lack of impact on clinical outcomes.

## CORONARY ARTERY DISEASE: PROGNOSIS

Presence of resting wall motion abnormalities, ejection fraction, and location and severity of regional wall motion abnormalities identified by echocardiography are well-validated predictors of cardiovascular events in patients with coronary disease, chest discomfort, or congestive heart failure.[118-121] Prognostic factors derived from exercise ECG testing include exercise duration, achieved workload, induced ST segment abnormalities, and hemodynamic response to exercise, including heart rate recovery.[122-124] With visual assessment of ventricular function, ischemic response, and additional information gained from the exercise ECG portion of the study, exercise echocardiography is well suited to allow prognostication.[125-128] Poorer outcome is seen in patients with resting wall motion abnormalities, larger ischemic regions, and shorter exercise duration and time onset to ischemia.[129-135] In an observational study of 4004 patients undergoing exercise echocardiography, 16.7% of patients developed echocardiographic evidence of ischemia despite symptom absence or ischemic ECG changes and were more likely to suffer a major adverse cardiac event or death in the following 5 years.[136] Exercise echocardiography has also demonstrated prognostic value in patients with baseline systolic dysfunction. In 1107 patients with ejection fraction less than 50%, 5-year mortality was significantly higher in those with who developed ischemia during stress echocardiography (Fig. 15-9).[137] The positive predictive value for myocardial infarction and death for stress echocardiography ranges from 63% to 80%, with negative predictive value 78% to 95%, and is uniformly improved over exercise ECG testing, particularly in patients with resting ECG abnormalities.[136,138,139]

In patients without known coronary disease, the negative predictive value of exercise echocardiography is excellent, with likelihood of a major cardiac event over the next several years less than 1%.[140-142] A meta-analysis evaluating the prognostic value of stress imaging showed comparable results between exercise echocardiography and exercise nuclear perfusion stress. For exercise echocardiography, negative predictive value for primary outcomes (infarction or cardiac death) was 98.4% with an estimated annualized rate for a primary outcome of only 0.54% per year.[141]

## CORONARY DISEASE DIAGNOSIS IN WOMEN

Women with coronary disease tend to have fewer obstructive coronary lesions and less single-vessel disease, are older at the time of presentation, and have more comorbidities and functional debilitation, leading to acknowledged limitations in cardiac stress testing. Moreover, there is a relative paucity of female representation in cardiovascular studies that evaluate different diagnostic modalities. Poor study representation and inadequate test validation adversely affect diagnostic accuracy. In a metaanalysis of studies published between 1966 and 1995, only 27 studies included at least 50 women who underwent exercise testing and angiography, and only 3 used exercise echocardiography.[143]

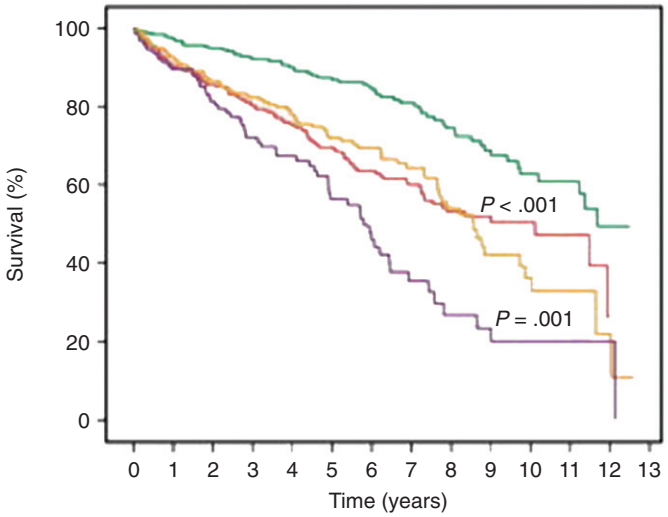

**Figure 15-9** All-cause mortality according to severity of baseline systolic dysfunction and ischemia presence during exercise echocardiography.[137] Survival curves are shown for patients with mild LV dysfunction and no ischemia (*green line*), mild LV dysfunction and ischemia (*red line*), moderate to severe LV dysfunction and no ischemia (*yellow line*), and moderate to severe LV disjunction with ischemia (*purple line*).

Exercise ECG testing in women is associated with increased false-positive findings, often due to resting ST-T wave abnormalities or hypertension-induced abnormalities.[29,144] Studies document false-positive ST segment depressions in as many as 40% of women compared to less than 10% of men.[145,146] Because of isotope scatter and attenuation, nuclear imaging also has limitations; accuracy of thallium-201 perfusion imaging is reduced with obscuration of the inferior wall in obese patients and of the anterior wall in large-breasted women. This has been ameliorated, in part, with use of technecium-99m, a higher-energy radioisotope that provides better tissue penetration.[147]

In a meta-analysis of 19 exercise ECG studies which included at least 50 women, weighted mean sensitivity was only 61% with specificity of 70%.[143] Imaging increases diagnostic accuracy with a weighted mean sensitivity of 86% and specificity of 79% for stress echocardiography and 78% and 64%, respectively, for nuclear perfusion stress.[143] Published diagnostic accuracy of exercise echocardiography in women is presented in Table 15-6. Because likelihood of a nondiagnostic exercise ECG study is higher in women, some studies support imaging stress studies as an initial diagnostic modality.[148] A cost analysis balancing cost with the lowest number of false negatives and fewest inappropriate angiography referrals found that exercise echocardiography provided the best accuracy at the lowest cost.[149] However, uniform referral for imaging stress studies would be logistically difficult and impractical, particularly given that the negative predictive value of a normal exercise ECG study remains high.

Concordant with the general population, stress echocardiography provides prognostic information in women.[150-153] In a

**TABLE 15-6 Diagnostic Accuracy of Exercise Echocardiography in Women**

community-based study of 1188 women, resting wall motion abnormalities or exercise-induced ischemia predicted higher rates of myocardial infarction and death.[151] Prospective, female-specific investigations for coronary disease diagnosis remain sparse. The NHLBI's Women Ischemia Syndrome Evaluation study is the largest prospective female-specific study to date, studying different modalities of cardiac diagnostic testing and evaluating influence of menopausal status and hormones on diagnostic test results in nearly 1000 women.[144] Future results will shed light on the gender-specific issues that effect variances on diagnostic accuracy or all cardiac stress testing modalities.

## RISK STRATIFICATION PRIOR TO NONCARDIAC SURGERY

Given the hemodynamic burden associated with surgery, preoperative risk stratification in intermediate- to high-risk asymptomatic individuals such as those with vascular disease, diabetes, prior ischemic heart disease, or congestive heart failure, may aid in decision making, particularly where surgery is elective.[154] Patients with vascular disease typically carry significant cardiovascular risk factors. Therefore, diagnosis of vascular disease provides the opportunity to identify coronary disease in asymptomatic patients and initiate earlier medical therapy to limit long-term atherosclerotic disease sequelae. The greatest published experience in preoperative risk stratification is in patients with vascular disease, given that cardiac events are the main source of perioperative morbidity and mortality (death or myocardial infarction in approximately 10%). Pharmacologic stress is more commonly used, because exercise is usually obviated due to lower extremity claudication. A positive stress test is associated with 10% to 20% risk of a cardiac event perioperatively or in subsequent years. The benefit of routine preoperative stress testing in asymptomatic patients is questionable. Rather, empiric risk factor modification, as in any patient, should be prescribed. Studies suggest that preemptive revascularization for asymptomatic coronary disease is not beneficial, irrespective of a positive stress study result, given procedural risks and risk associated with perioperative discontinuance of antiplatelet therapy. The exception to this is in patients with proximal left anterior descending or left main artery equivalent disease, most of whom would be symptomatic regardless.[155,156]

## HYPERTROPHIC CARDIOMYOPATHY

Echocardiography is a critical diagnostic tool in patients with hypertrophic cardiomyopathy (see Chapter 27). Resting transthoracic imaging allows evaluation of septal wall thickness, gauging of left ventricular outflow tract (LVOT) obstruction severity via continuous-wave Doppler–derived pressure gradients taken, and assessment of associated mitral regurgitation due to systolic anterior motion of the mitral valve and/or subvalvular apparatus. Studies drawing from hypertrophic cardiomyopathy cohorts demonstrate association of resting LVOT gradients with adverse cardiovascular events and heart failure.[157] During stress, changes in ventricular loading may provoke dynamic outflow obstruction; LVOT obstruction is present in about 30% of hypertrophic cardiomyopathy patients at rest, but approximately an additional 33% develop LVOT obstruction with exercise. Exercise-induced LVOT gradients are a predictor of developing heart failure symptoms. Current expert consensus recommendations support septal reduction (surgical myomectomy or alcohol septal ablation) in patients with severe heart failure symptoms or with an LVOT gradient greater than 50 mm Hg at rest or provoked during exercise.[158] Exercise echocardiography for hypertrophic cardiomyopathy patients primarily involves LVOT gradient assessment, but also includes assessment of mitral regurgitation severity.[159] Exercise stress testing should not be performed in symptomatic patients or patients with peak LVOT gradient greater than 90 mm Hg.

During exercise testing, standard exercise protocols are used, with cessation of exercise if symptoms develop or a gradient greater than 50 mm Hg is provoked (Fig. 15-10). Because of the ability to image at peak stress, supine bicycle stress is preferred over treadmill protocols where provoked gradients may have returned to baseline by the time imaging is completed. LVOT velocity should be recorded at baseline and at each stage of stress. After recording LVOT velocity, mitral regurgitation severity (vena contracta) is recorded. It is often difficult to identify separate peak velocities for LVOT and mitral regurgitant jets, and care must be taken to differentiate Doppler signals. Because mitral regurgitation velocity reflects the transmitral pressure difference and LVOT velocity reflects the LV-to-aortic pressure difference, mitral regurgitation peak velocity is always higher than LVOT velocity, and the LVOT signal is typically later peaking than the mitral regurgitation signal because of dynamic LVOT obstruction (Fig. 15-10). Exercise-induced regional wall motion abnormalities that develop in absence of coronary disease are thought to be due to microvascular ischemia. After septal reduction intervention, stress echocardiography is used to document reduction in LVOT gradient and monitor treatment efficacy.

## DILATED CARDIOMYOPATHY AND CARDIAC TRANSPLANTATION

Both pharmacologic and exercise stress echocardiography have been safely used in patients with dilated cardiomyopathy, but pharmacologic testing is predominantly used, such as in identification of viable myocardium after an infarction. Exercise echocardiography for earlier identification of patients at risk for systolic dysfunction, such as those with myocarditis or cancer survivors exposed to cardiotoxic agents, has also been examined.[159,160] Exercise echocardiography had been proposed as an approach to identify candidates for resynchronization therapy, with exercise dyssynchrony correlating with declines in cardiac

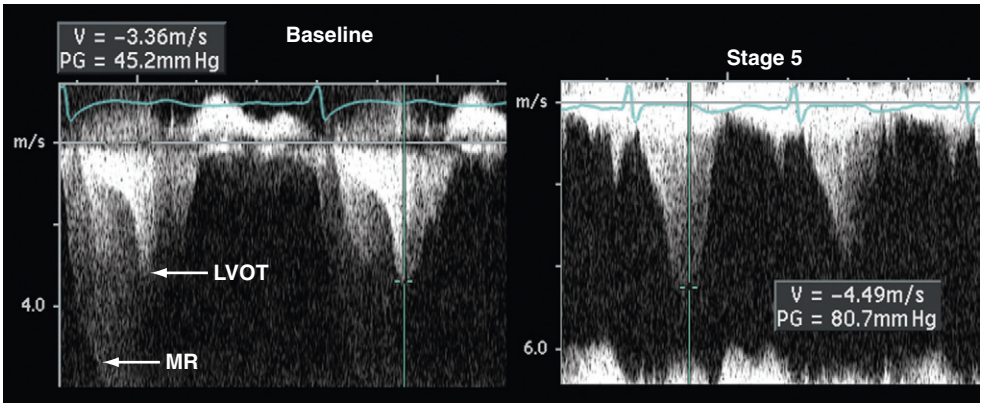

**Figure 15-10 Spectral Doppler tracings taken during supine bicycle exercise stress in a patient with hypertrophic cardiomyopathy.** *Left*: At baseline, superimposed Doppler tracings for mitral regurgitation (*MR*) and the left ventricular outflow tract (*LVOT*) are shown. Peak LVOT velocity is measured at 3.4 m/s (*arrows*). Care must be taken to ensure that correct Doppler signal is interrogated to accurately reflect severity of LVOT obstruction. With increasing workload, peak LVOT velocity increased to 3.9 m/s in stage 3 and 4.1 m/s in stage 4. With exaggerated respiratory effort and patient motion during ergometry, peak measured velocities may underestimate severity of LVOT obstruction because of transiently less optimal Doppler interrogation angle. In this example, peak velocity was measured at 4.5 m/s in stage 5; in the same clip, second heartbeat was discarded because of its underestimation of peak LVOT velocity.

output and worsening mitral regurgitation.[161] However, recent studies, such as PROSPECT, have not shown echocardiographic markers of dyssynchrony, such as M-mode, Doppler tissue velocities, strain, and wall motion timing, to be predictive of clinical response to resynchronization therapy.[162,163]

Allograft vasculopathy after cardiac transplantation is typically asymptomatic. Surveillance testing for allograft vasculopathy primarily uses pharmacologic (dobutamine) stress testing and coronary angiography with intravascular ultrasound. Diagnostic accuracy of dobutamine echocardiography for allograft vasculopathy is reasonable and provides prognostic information for subsequent cardiac events.[164] Limited data with exercise echocardiography demonstrate reasonable specificity (range 86% to 95%), but poor sensitivity (approximately 25%), likely due in part to poor autonomic heart rate response of the denervated heart.[165,166]

## VALVULAR HEART DISEASE

Stress echocardiography is an adjunct in management of patients with valvular heart disease by gauging disease severity and aiding in understanding dynamic response of valve function to physiologic demand.[167,168] Stress echocardiography allows evaluation of:

1. Exercise tolerance and contextual evaluation of a patient's clinical status
2. Hemodynamic response to exercise (blood pressure, heart rate)
3. Pulmonary hypertension
4. Ventricular function
5. Direct evaluation of stenosis or regurgitant severity
6. Exercise-induced arrhythmias

Patients with significant valve lesions (stenotic or regurgitant) should have a complete standard transthoracic echocardiogram documenting severity of cardiac and valve function, evaluating coexisting valve lesions, and providing pulmonary pressure estimates. Exercise testing for valvular heart disease should not be performed in symptomatic patients because of increased risk of hemodynamic compromise and arrhythmia. Clinical guidelines recommend valve intervention for symptomatic valve disease, such as surgery, without need for exercise testing.[47,169] In asymptomatic patients or those with equivocal symptoms, stress testing is useful for clinical decision making, such as optimizing timing of intervention, given that physiologic effects of valve lesions may not be present at rest, but may be provoked during exercise.

Indicators of increased hemodynamic significance of valve lesions include failure to augment flow across a stenotic valve during stress or abnormal stress-induced increases in pulmonary pressure. For regurgitant lesions, changes in ventricular loading resulting from exercise may alter ventricular geometry, resulting in increased regurgitation severity. Exercise stress is preferred over pharmacologic stress because it provides data regarding symptom provocation, exercise tolerance, and hemodynamic response to exercise. Intervention should be considered with provocation of cardiopulmonary symptoms (exertional dyspnea, heart failure, arrhythmias, angina, or syncope).[47] Concurrent ischemia evaluation is often suboptimal because of underlying ventricular structural abnormalities, such as left ventricular hypertrophy, arrhythmia, or patient inability to achieve target workload.

In patients with aortic stenosis, if symptom status is not clear or there has been an unexplained decline in activity level, exercise stress testing allows gauging of exercise tolerance and exertional symptoms.[170,171] (See Chapter 23.) Transaortic valve velocities and gradients may be taken during exercise echocardiography, but are difficult to reliably record because of exaggerated respiratory cardiac motion and time limitations of data acquisition for poststress treadmill protocols. Exercise testing can be safely performed if supervised by an experienced physician, but should be ended promptly if there is a hypotensive response or only a minimal increase in blood pressure, or greater than 4 mm of horizontal ST depression in contiguous leads, or if the patient experiences cardiopulmonary symptoms such as dyspnea, dizziness, or angina.[172-174] Exercise-induced ST segment changes do not correlate well with coronary artery disease presence or severity. Reduced exercise tolerance, symptom provocation, an abnormal exercise response (rise in transvalvular gradient greater than 20 mm Hg), or a relative limitation in contractile reserve suggests a worse prognosis; these patients should be considered for valve replacement.[174-176] In a study of 69 patients with severe aortic stenosis, exercise

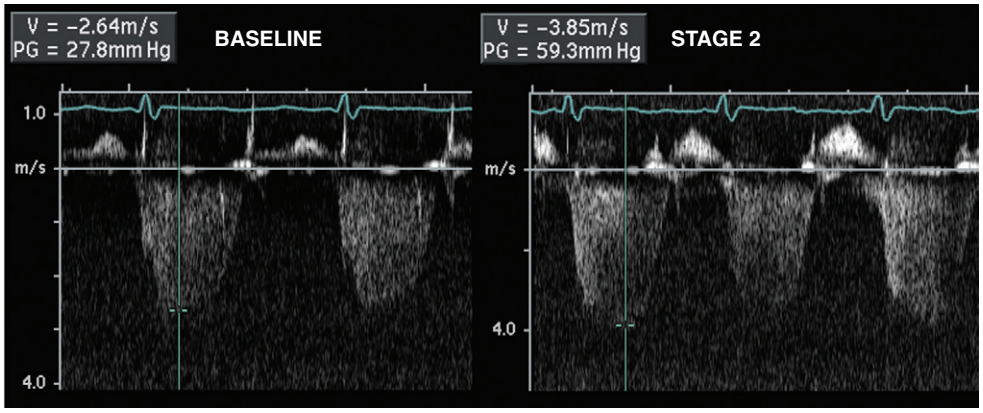

**Figure 15-11 Spectral Doppler tricuspid regurgitant tracings during supine bicycle exercise stress in a patient with prior posterolateral myocardial infarction, normal volume status, and exertional dyspnea.** Nuclear perfusion stress did not show new ischemia. *Left*: At rest, LV chamber size is normal with thinning of the inferolateral segments. There is moderate, functional mitral regurgitation. Resting pulmonary systolic pressure is normal at 28 to 33 mm Hg (TR jet velocity 2.6 m/s). *Right*: During exercise, patient developed dyspnea. Mitral regurgitation severity was comparable by color mapping, but pulmonary systolic pressure increased to 59 to 64 mm Hg (TR jet velocity of 3.9 m/s). *TR*, Tricuspid regurgitation.

increases in transaortic pressure gradient over 18 mm Hg were an independent predictor of symptom onset in the ensuing 15 months.[174] The role of exercise stress for low-flow, low-gradient aortic stenosis evaluation is limited. In these patients, low-dose dobutamine stress is typically used to augment cardiac output for evaluation of LV contractile reserve and aortic valve hemodynamics.

For patients with mitral stenosis and equivocal symptoms, echocardiographic evaluation with exercise focuses on pulmonary arterial systolic pressure estimate, but should also include assessment of central venous pressure (inferior vena cava diameter), valve anatomy, mitral valve area, and concurrent mitral regurgitation. (See Chapter 21.) Intervention, such as mitral valvuloplasty, should be considered when pulmonary systolic pressure exceeds 50 mm Hg (rest) or 60 mm Hg (with exercise), or if transmitral mean gradient increases to over 15 mm Hg.[47] During stress, mitral valve area measurements from Doppler transmitral tracings are technically difficult to acquire because of increased heart rate and alterations in the atrial-ventricular filling with rapid deceleration of LV filling velocity and decreases in pressure half-time. The continuity equation provides an alternative method for mitral valve area calculation.[167,177,178] For patients with rheumatic valve disease and only mild regurgitation at rest, exercise echocardiography may unmask significant mitral regurgitation during exercise, suggesting a mechanism for symptoms in patients not normally be expected to be symptomatic.[179]

Disease progression in chronic regurgitation can be insidious. Timing of surgical intervention in asymptomatic patients is predicated on evidence of adverse hemodynamic effect on the LV, such as impaired systolic function or ventricular enlargement.[47,169] (See Chapter 18.) In asymptomatic patients with normal indices at rest, significance of valve lesions may manifest with decreased exercise tolerance, increase in pulmonary pressure, or worsening of regurgitation with changes in ventricular loading (Fig. 15-11).[47,167] Symptom provocation, worsening pulmonary hypertension (greater than 60 mm Hg with exercise), decreased exercise capacity, or loss of contractile reserve should prompt earlier consideration of surgical intervention.[180-182] Echocardiographic evaluation during stress focuses on pulmonary systolic pressures, but also includes assessment of ventricular size and function, as well as simpler measures of regurgitation severity, such as vena contracta. Early stress applications evaluating mitral regurgitation severity via quantitative Doppler echocardiography show feasibility, but this is technically difficult to implement and is not yet widely used.[168] A prospective, multicenter registry to evaluate the potential role of exercise echocardiography in assessing ischemic mitral regurgitation in patients referred for coronary bypass surgery is currently underway.[183]

Patients with a prosthetic valve area that is small relative to body habitus may experience symptoms consistent with valve stenosis, such as decreased exercise tolerance or heart failure symptoms. (See Chapter 25.) There is an emerging role for exercise stress testing for evaluation of prosthetic valve-patient mismatch. During exercise, a significant increase in transvalvular gradient greater than 20 mm Hg for an aortic prosthesis or greater than 12 mm Hg for a mitral prosthesis in an otherwise normally functioning valve or provocation of cardiopulmonary symptoms is consistent with severe patient-prosthesis mismatch and should prompt consideration of redo valve replacement.[168]

### OTHER APPLICATIONS

Exercise protocols in the pediatric population are adjusted to account for decreased stature with similar indices of exercise tolerance, ECG monitoring, and identification of regional wall motion abnormalities.[184] However, ischemic heart disease is less prevalent in children, and therefore exercise echocardiography is primarily targeted at arrhythmia evaluation and assessment of hemodynamic significance of valvular and congenital abnormalities.

In patients with chronic pulmonary or systemic inflammatory disease, pulmonary arterial hypertension is associated with significant morbidity and mortality. (See Chapters 33 and 37.) However, early diagnosis may be hindered if resting pulmonary pressures are normal. Assessment of patients during exercise may enable earlier identification of patients to target earlier instigation of potentially beneficial therapies.[185-187]

## Future Directions

Quantitative approaches to interpretation should increase reproducibility and accuracy for stress echocardiography, particularly for less experienced readers. Historically, significant

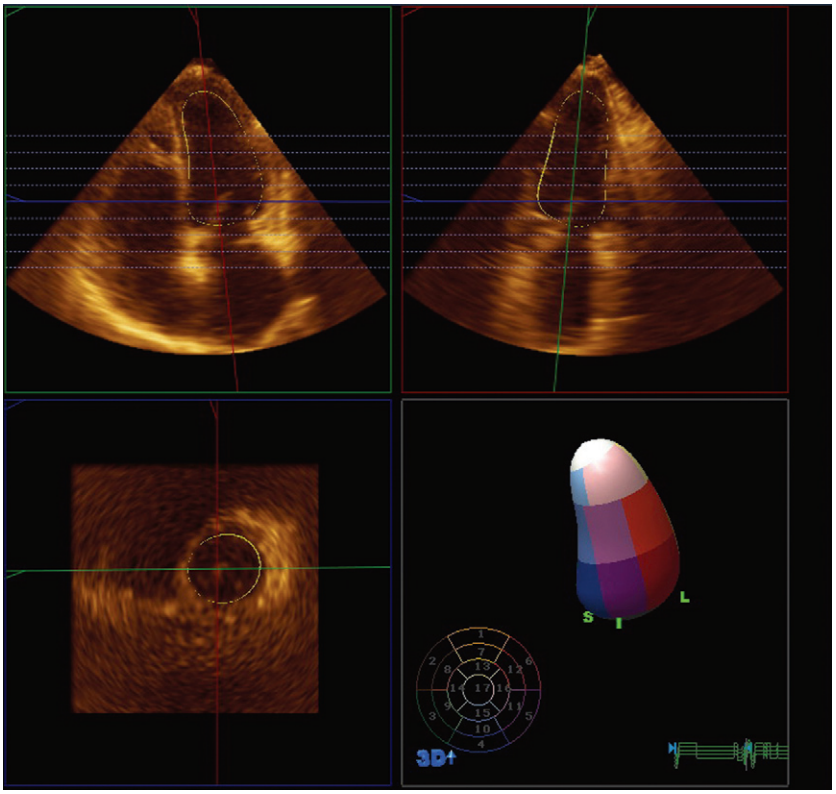

**Figure 15-12 Semiautomated border recognition to assess LV volume.** Marks are placed at the mitral annulus and apex, and LV volumes are estimated. Several image planes can be concurrently displayed. Regional wall motion can be assessed by segmenting the volume into the standard 16 segments, which can be viewed from multiple angles (*bottom right*). In this case, end-diastolic volume (*EDV*) is 65 mL, end-systolic volume (*ESV*) is 30 mL, and ejection fraction is 54%. Horizontal lines on apical views represent multislice short-axis image planes that can be simultaneously shown (see Fig. 15-14).

subjective input was needed to define cardiac borders for quantitative methods, which was time consuming. Advances in semiautomated border recognition algorithms and acoustic quantification now allow for more streamlined analysis of systolic and diastolic LV volumes, decreasing interpretation time with improved diagnostic accuracy, particularly for more inexperienced readers (Fig. 15-12).[188] Addition of echocardiographic diagnostic aids, such as transpulmonary contrast, to quantitative approaches may likely further improve diagnostic accuracy, allowing assessment of coronary flow reserve integrated with wall motion analysis.[189-193] In a study using parametric still images taken from contrast-enhanced echocardiograms, feasibility of automated quantitative regional wall motion analysis was demonstrated, with improved diagnostic accuracy for inexperienced readers over standard qualitative visual evaluation (specificity increased from 58% to 79% and accuracy increased from 74% to 84%).[194]

Assessment of diastolic function during stress may be beneficial in identifying ischemia earlier in the ischemic cascade. (See Chapter 11.) Strategies include evaluation of increased LV filling pressure (Doppler mitral inflow and mitral annular tissue velocity, E/E′ ratio) and identifying delayed relaxation via myocardial strain imaging.[195-197] As with any Doppler application, limitations include underestimation of velocities with nonparallel intercept angles, individual heterogeneity in velocities, and inaccurate velocity measurement due to increased translational cardiac motion. Although evaluation of diastolic function during stress echocardiography is feasible, individual variability in diastolic indices and time constraints of image acquisition during stress limit utility of diastolic function assessment to only supplemental to conventional systolic evaluation.

Tissue Doppler interrogation evaluates myocardial tissue velocity referenced to the transducer, identifying temporal abnormalities in regional contraction. (See Chapter 10.) This allows for differentiation of normal and hypokinetic motion, offering an adjunct to qualitative assessment of regional wall motion.[198-201] *Speckle tracking* allows simultaneous tracking of two or more adjacent points, or "speckles," evaluating relative velocity between points, rather than referenced to the transducer, and does not require a parallel interrogation angle. Strain and strain rate imaging are quantitative measures derived from tissue Doppler velocities or speckle tracking.[202] Strain rate refers to speed of myocardial deformation (m/s or cm/s), and strain represents relative deformation of a given myocardial segment (dimensionless), measured in three directions: radial, circumferential, and longitudinal. Alterations in these measures during stress suggest interval changes in function.[203] In the regional evaluation of systolic function, for segments with an appearance of systolic motion adjacent to hypokinetic or akinetic segments, abnormal strain indices may identify tethered motion rather than normal motion. Strain analysis can also be applied to ischemia assessment during diastole, where normal decreases in myocardial strain are delayed (Fig. 15-13).[204] With background imaging noise and respiratory artifact, strain and strain rate imaging have been difficult to implement during exercise stress, with one study documenting noninterpretable data in as many as 36% of subjects.[205] Available systems allow offline analysis of prerecorded samples, but analysis remains technically

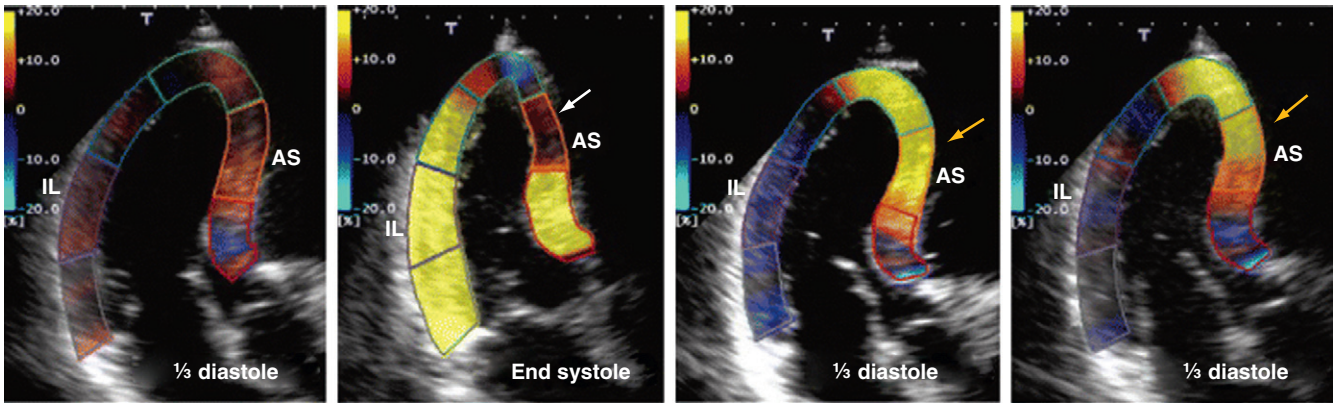

**Figure 15-13 Apical long-axis images in a patient with 70% left anterior descending coronary artery stenosis.** 2D speckle-tracking is superimposed on images taken at baseline, immediately poststress, and during recovery after treadmill exercise; *yellow* represents increasing strain. On immediate poststress images, decrease in peak systolic strain is seen in mid-anteroseptum (*white arrow*). Five minutes after exercise, high strain level due to delayed relaxation (*yellow arrow*) is seen in the midanteroseptal segment one third into diastole. Ten minutes after cessation of exercise, this was less pronounced (*yellow arrow*), but did persist.[204]

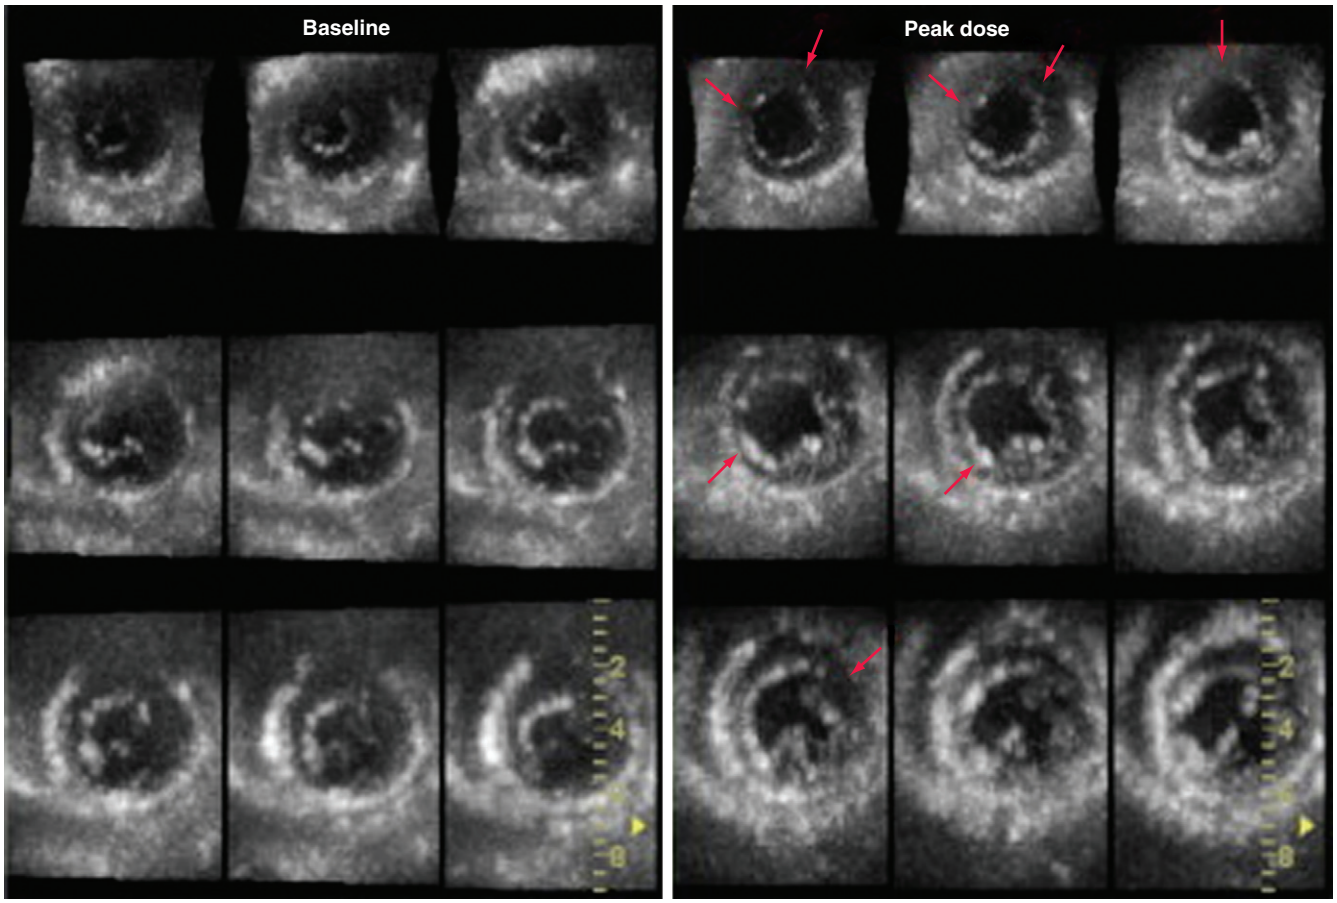

**Figure 15-14 Multislice short-axis views of heart at baseline and at peak dobutamine infusion.** For each stage (baseline and peak dobutamine dose infusion), short-axis cuts are shown from apex (*upper left*) progressing toward base of heart (*lower right*). In this example, new stress-induced regional wall motion abnormalities were seen in the apex, inferoseptum, and lateral wall (*red arrows*).[209]

challenging with a lengthy time requirement, prohibiting routine clinical use. There has been recent progress in automating strain data and abbreviating time for image analysis.[201]

Advantages of 3D echocardiography for LV function assessment include the ability to use and optimize infinite image planes within an acquired 3D volume, leading to improved accuracy by decreasing assumptions on ventricular shape and avoiding LV foreshortening (see Chapter 4).[206] Initially, single-beat 3D volume acquisitions were restricted by pyramidal volume size, limiting imaging of larger ventricles. Relative to 2D imaging, image resolution for 3D was significantly inferior. Spatial imaging was poor because of inadequate line density, and temporal resolution was poor because of decreased frame rate. Time requirements for offline analysis made 3D imaging

prohibitive for mainstream use. Newer real-time 3D matrix-array transducers have an increased number of imaging elements within a smaller transducer footprint, providing considerably improved image resolution. Temporal resolution and spatial resolution have significantly improved. Full volumes are now generated via sequential image synchronization over several cardiac cycles (about four to seven), combining subvolumes into one image volume.[207] However, alignment of subvolumes may be limited in patients underlying arrhythmia ("stitch" artifact).

Rather than drawing from an entire 3D volume set, matrix-array transducers display concurrent images from biplanar (orthogonal planes) or triplanar modes, providing the ability to match image planes for resting and stress images within a volume, typically to planes concordant with standard apical two-chamber, four-chamber, and long-axis views (triplanar mode).[208] Because exercise echocardiography sensitivity decreases with longer time intervals from exercise cessation, a shorter image acquisition time point allows evaluation of LV function at higher workload. Display of multislice cuts through a single volume allows evaluation of concurrent multiple segments (Fig. 15-14).[209] Pretest optimization of image planes to reduce LV foreshortening is also beneficial given that even the most experienced sonographers require about 30 seconds for image acquisition with standard 2D protocols, and optimal image planes may be difficult to obtain.

Early studies demonstrate feasibility of real-time 3D stress imaging.[210-213] Most studies use pharmacologic stress (dobutamine), given that exercise-induced translational cardiac motion and exaggerated respiratory motion limit image quality during volume acquisition because of stitch artifact.[214] Feasibility of 3D stress echocardiography in patients with enlarged ventricles or poor image quality (where transpulmonary contrast would typically be used) has not been adequately assessed. Advantages of real-time 3D stress testing include reduction of scanning time and reduced operator dependence. However, manipulation of images and planes offline significantly increases analysis time.[207,215,216] Further applications of 3D stress echocardiography using quantitative measures for endocardial excursion and fractional area change have shown feasibility.[217]

In its current state, real-time 3D stress echocardiography provides relatively limited spatial resolution with lower frame rates compared to standard 2D imaging. Additionally, standardized 3D stress protocols are not yet available, making it difficult to justify use of 3D echocardiography independent from standard 2D imaging. However, with potential to provide real-time quantitative measures of LV volume, systolic function, and regional wall motion, advances will likely allow for future application.[206]

## KEY POINTS

- Exercise echocardiography integrates real-time echocardiography with exercise (ECG) testing to aid in evaluation of ischemic, valvular, and cardiopulmonary heart disease.
- For bicycle ergometry protocols, images are acquired during peak exercise, or, because of difficulties due to patient motion, images are acquired immediately after exercise for treadmill protocols. Imaging data is integrated with ECG data, exercise tolerance, and patient symptoms for final interpretation.
- When image quality is poor, transpulmonary contrast aids endocardial border definition.
- Stress echocardiography and stress nuclear studies provide comparable information on ischemia diagnosis, myocardial viability, and prognostication. Advantages of stress echocardiography include widespread availability, shorter test times, greater patient convenience, versatility, absence of radiation exposure, and lower cost.
- Future advances in stress echocardiography include real-time 3D imaging, spectral Doppler interrogation with stress, myocardial strain and strain rate analysis, and integration of coronary flow reserve data using myocardial perfusion images.

## Background

### INDICATIONS

The performance of a maximal level of stress is a critical determinant of the sensitivity of all stress modalities for the detection of coronary artery disease. Unfortunately, many patients—fully 30% to 40% at some tertiary centers—either cannot exercise at all or cannot exercise maximally, but may still need to undergo stress testing for diagnostic, decision-making, or prognostic purposes. The most common causes of limited exercise capacity are vascular disease and orthopedic problems. Other situations warranting nonexercise stress testing include severe cardiopulmonary disease and general debility, especially among the elderly, in whom pharmacologic testing has been shown to be well tolerated and reliable.

Although the inability of a patient to exercise maximally constitutes the main indication for the use of nonexercise stressors, such stressors are also indicated in other situations (Box 16-1). The most important of these situations include circumstances in which pharmacologic stress may offer diagnostic dimensions that are not available from exercise stress, for example, the diagnosis of coronary spasm using ergonovine testing. Although newer and simpler methods such as contrast-enhanced magnetic resonance imaging (MRI) have assumed a major role in viability assessment (see later discussion), stress echocardiography may be helpful in selected patients early or late after myocardial infarction, after which left ventricular (LV) dysfunction may not be permanent. The diagnostic challenge in this situation is that although stunned myocardium improves spontaneously, the revascularization of hibernating myocardium has implications for functional capacity and prognosis. Echocardiography can be used with dobutamine or dipyridamole stress, or both, for the identification of viable myocardium. A more historical role relates to the use of pharmacologic stress echocardiography in the cardiac catheterization laboratory—the functional evaluation of coronary stenoses having evolved to the evaluation of fractional flow reserve. Likewise, although use in the operating room was a legitimate reason to select pharmacologic stress, this is rarely performed in practice.

Finally, because of their relative technical ease, nonexercise methods have been used in preference to exercise echocardiography even in patients who are able to exercise. The incremental nature of these stressors means that the time course of ischemia can be identified; these data are difficult to gather using treadmill stress[1] or bicycle exercise testing, although it is possible.

**Box 16-1**

**INDICATIONS FOR NONEXERCISE STRESSORS**

| Unable to Exercise | Able to Exercise |
|---|---|
| Inability to exercise maximally | Specific indications |
| *Diagnosis of coronary artery disease, decision making* | *Coronary spasm* |
| *Risk stratification* | *Myocardial viability* |
| Situations preventing exercise | Developing indications |
| *Angiography laboratory, operating room* | *Onset of ischemia* |
| | *New technologies (TDI, CK, contrast)* |

*CK*, Color kinesis; *TDI*, tissue-Doppler imaging.

The decision to use a nonexercise stress still may not be justifiable with routine echocardiographic imaging at present. However, the facilitation of adjunctive techniques (which may be less feasible during exercise than nonexercise stress)—such as strain and contrast perfusion echocardiography—could in the future justify the use of nonexercise techniques in patients who are able to exercise.

## CHOICE AND MECHANISM OF ACTION OF NONEXERCISE STRESSORS

The two general groups of nonexercise stress agents induce ischemia by increasing myocardial work and oxygen consumption (exercise-simulating agents) or by influencing coronary perfusion and therefore myocardial oxygen supply (vasoactive agents). The latter include the coronary vasodilators dipyridamole and adenosine, which cause ischemia by altering regional flow, and ergonovine, which can be used to provoke coronary spasm. In addition, nonpharmacologic approaches including hand-grip and the cold pressor test have been used. Hand-grip testing is often combined with dobutamine-atropine testing, but the cold pressor test has not been widely adopted clinically because of limited efficacy and patient discomfort.

### *Exercise-Simulating Agents*

The exercise simulators include dobutamine and other sympathomimetic agents, pacing, and atropine (usually used as an adjunct to the other approaches), all of which increase cardiac work and myocardial oxygen requirement. The induction of ischemia and regional dysfunction reflects the inability of the diseased coronary circulation to respond to this increased oxygen demand, a process that parallels the response to exercise. Because increased cardiac workload and oxygen demand is the usual mechanism underlying ischemia in most ambulatory situations, the exercise-simulating agents are often considered to be a more physiologic means of stressing the heart. However, additional mechanisms include effects on cardiac metabolism producing an "oxygen-wasting" effect[2] and concurrent "supply" ischemia due to reduction of subendocardial perfusion and maldistribution of coronary flow.

### *Vasoactive Agents*

The use of dipyridamole in combination with myocardial perfusion imaging is based on the induction of maximal coronary vasodilation in all territories. Flow heterogeneities (and therefore apparent perfusion defects) develop if a coronary stenosis limits the regional hyperemic response.[3] Of note, this process may not involve the provocation of ischemia in a functional or metabolic sense. In contrast, the development of regional wall motion abnormalities at stress echocardiography necessitates the induction of ischemia.

The mechanism of vasodilator-induced wall motion abnormalities has been attributed to coronary steal.[3] Traditionally, horizontal steal involves blood flowing to nonstenosed from stenosed territory, owing to reduced collateral flow into the stenosed territory because of depressurization of vessels supplying the collaterals due to increased runoff. Vertical steal occurs because vasodilator-induced depressurization of the microcirculation causes subendocardial vessels to collapse under the greater extravascular pressure in this region and "steal" flow to the subepicardium from the subendocardium. However, in experimental studies, steal appears less important than previously proposed, and vasodilator-induced ischemia has been attributed to the combination of reduced endocardial myocardial blood flow reserve with increased myocardial oxygen demand caused by hypotension and reflex tachycardia.[4] The administration of atropine or increased sympathetic activity secondary to angina may augment this process. Systemic hypotension may certainly accentuate hypoperfusion, as driving pressure is the main determinant of myocardial perfusion when vasodilator reserve is exhausted. Stenosis "collapse" may be provoked if profound microcirculatory vasodilation causes a reduction of lateral pressure induced by increased flow.

### *Agents Used to Identify Myocardial Viability*

In the presence of dysfunctional but viable myocardium, regional function is enhanced by the inotropic effect of low-dose dobutamine. This appears to require both recruitable perfusion and an increment in metabolism. Viable myocardium supplied by a patent infarct-related vessel (generally corresponding to stunned myocardium) demonstrates a sustained improvement during the infusion, which then reverses after the test. Viable tissue supplied by a stenosed infarct-related artery (which may involve stunned or chronically malperfused tissue) is characterized by an initial improvement, occurring at low doses (less than 20 mcg/kg/min), or low heart rates, or both, followed by deterioration of regional function as the chronotropic effect becomes more prominent and myocardial work increases. If the region is supplied by a critically stenosed artery, however, it may be possible for the territory to become ischemic before there is a noticeable enhancement of contractility. Moreover, the ability of the myocardium to thicken is determined by the amount of infarcted tissue within the segment.

Myocardial viability may also be inferred from the contractile response to dipyridamole. The mechanism of this is also putative but probably relates to myocardial congestion with interstitial fluid due to vasodilation. A so-called mini-Starling effect may be caused by this congestive process, producing additional tension on the myofibrils.

# Basic Principles

## PHARMACOLOGY AND PHYSIOPATHOLOGY

### *Exercise-Simulating Agents*

The exercise-simulating agents include dobutamine, dopamine, epinephrine, and isoproterenol. Of these, dobutamine has become the most commonly administered exercise-simulating

agent, and the majority of published data on pharmacologic stress echocardiography have involved this agent. Although other sympathomimetic agents have been used for stress testing, dopamine may cause localized limb ischemia due to vasoconstriction, and epinephrine and isoproterenol are probably the more arrhythmogenic.

Dobutamine is predominantly a beta-1 agonist; normal areas of myocardium become hyperkinetic in response to its inotropic effect. Segments supplied by a stenosed coronary artery may become akinetic or dyskinetic, but more subtly, and are unable to augment their thickening and excursion. Vasodilation and chronotropy appear at higher doses, usually at the 20 mcg/kg/min level of the routine dobutamine stress protocols, reflecting the stimulation of other receptors to a lesser degree. This chronotropic response appears to be the most important factor in terms of precipitating ischemia. Most dobutamine stress protocols cause a mean heart rate increment of 40 to 50 beats per minute and mean peak heart rates of 110 to 120 beats per minute.[5] However, reflex bradycardia may occur in response to hypertension. Blood pressure normally rises in response to the inotropic effect of the drug, but high doses cause vasodilation and therefore cause blood pressure to fall at peak doses. Increases in myocardial oxygen demand due to increased cardiac work, as well as a weak vasodilator effect, lead to the development of coronary hyperemia in territories supplied by normal coronary arteries. Although this response is probably less than that induced by coronary vasodilators, the coronary hyperemic response to dobutamine stress permits its use with perfusion imaging, both scintigraphic and with microbubbles.[6] The detection of myocardial perfusion defects in the presence of coronary disease may be augmented by partial volume effects due to thinning of the ischemic wall.

### *Vasoactive Agents*

The principal coronary vasodilators are dipyridamole, adenosine, and regadenoson, which differ with respect to the onset and duration of their effects. Dipyridamole increases endogenous adenosine levels by reducing cellular reuptake and metabolism, and thereby acts indirectly.[3] This indirect mechanism causes some delay between the administration of this agent and the timing of peak vasodilation, and this indirect action may account for interindividual variations in the magnitude of its effects. Adenosine acts directly on the vasculature, its vasodilator efficacy being equivalent to that of papaverine. The potency and speed of onset of adenosine cause its side effects to be more intense but also more short-lived than those of dipyridamole. By comparison to adenosine, the new A(2A)-specific receptor agonists have fewer complications but a similar mechanism of action.[7] As with adenosine, however, their primary vasodilator role makes them more attractive for perfusion imaging than for wall motion assessment.

Ergonovine stress echocardiography is not widely practiced, although its use as a test for coronary spasm is well validated. This agent has a direct effect on the vessel; responsiveness to acetylcholine may be related to loss of nitric oxide production at the site of disease.

### *Exercise Simulation Using Pacing Stress*

Several nonpharmacologic stressors have been used, including "physiologic" stresses such as the cold pressor test, which are poorly tolerated. Pacing is an alternative means of increasing cardiac work; pacing-induced tachycardia increases myocardial oxygen consumption and causes myocardial ischemia in the setting of significant coronary stenoses. The reduction of subendocardial perfusion with pacing may also contribute to the development of ischemia.

Ventricular pacing is not favored, as it causes both abnormal regional contractility and abnormal perfusion, so that pacing stress techniques generally involve atrial stimulation, either transvenously or via the esophagus. Of the transesophageal pacing approaches, the "pill" electrode is effective but may cause significant discomfort. Attachment of pacing electrodes to transesophageal echocardiography (TEE) probes has been reported in trials but has not moved into commercial production. A small esophageal pacing catheter offers enhanced contact between the electrodes and the esophagus. The technique causes less discomfort than other pacing techniques because of the presence of smaller pacing thresholds but is not widely used.

Pacing stress may be useful in patients in whom the pharmacologic approaches are contraindicated or associated with side effects. Additional attractions that might justify its use in preference to pharmacologic testing include the capacity to achieve a target heart rate in virtually all patients, the potential to immediately terminate the tachycardia if the patient develops complications (in contrast to pharmacologic methods, which require a period of time for the effects to dissipate), and the ability to perform measurements in the ischemic ventricle at a low heart rate (after cessation of pacing). Using atrial pacing stress, ischemic myocardium has been shown to have reduced ventricular compliance. Sudden termination of stress during ischemia may also be of value in the combination of stress testing with color flow Doppler, as the use of low frame rates may pose a problem at high heart rates. However, despite the benefits of transesophageal atrial pacing, its availability for many years, and recent data showing correlation with dobutamine stress echocardiography (DSE) despite a shorter test duration and better patient tolerance, this technique has not become widely used because it remains somewhat invasive.

### *Combined Approaches*

Atropine reduces the depressant effect of vagal stimulation on heart rate and may be particularly useful when reflex reduction of the heart rate occurs in response to blood pressure elevation. Atropine is combined with dobutamine in patients who fail to develop an adequate degree of tachycardia in response to dobutamine, the most common situation involving patients taking beta receptor antagonists. Tachycardia (and therefore ischemia due to increased oxygen demand) may be obtained by combining atropine with dipyridamole.[8,9] In both circumstances, the addition of atropine to other stressors has been associated with an increment in sensitivity. Indeed, there is a trend toward earlier use of atropine during the dobutamine protocol, especially in beta-blocked patients. Early administration of atropine should not be allowed to interfere with the assessment of the low-dose response, so we do not administer this agent before the end of the 20 mcg/kg/min dose. A simple guide is that patients who fail to attain a heart rate of 70 beats per minute, or fail to increase heart rate by 5 beats per minute at this dose, rarely achieve target heart rate and might as well have the atropine early so as to avoid a prolonged test.

Combinations of dobutamine and dipyridamole have been described but are not used, because although the combination has afforded higher levels of sensitivity than the individual tests can provide, this is obtained at the cost of an unacceptably long stress protocol.

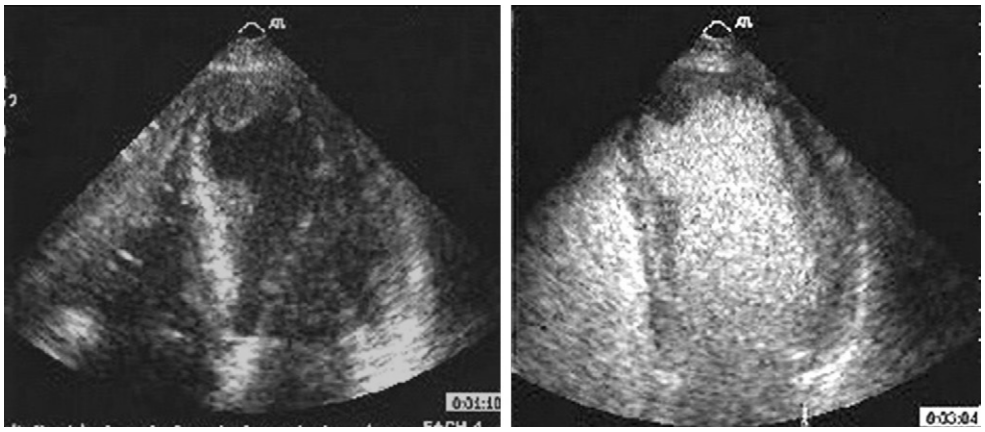

**Figure 16-1 Use of myocardial contrast for LV opacification during stress echocardiography.** Compared with harmonic imaging (**A**), the postcontrast end-diastolic apical four-chamber image (**B**) shows significant improvement of lateral wall resolution.

## ECHOCARDIOGRAPHIC APPROACH

### *Image Acquisition*

The technical challenges of pharmacologic and pacing stress, although less extreme than those posed by exercise echocardiography, mandate the use of the best available equipment. The development of harmonic imaging has had a major impact on endocardial visualization[10] and therefore on the feasibility of stress echocardiography.[11] Although very few patients (less than 2%) have completely uninterpretable images, failure to detect the endocardium in every myocardial segment is very common, and contrast is indicated if two segments are obscured (Fig. 16-1).

Typically, transthoracic images are obtained in the standard views (parasternal long- and short-axis and apical four- and two-chamber). Two additional views are helpful—an apical long-axis view, which may overcome technical problems with parasternal imaging, and an apical short-axis view. Of the complementary imaging techniques, including contrast, strain, and three-dimensional (3D) imaging (see later section), the evaluation of coronary flow reserve in the left anterior descending artery is the simplest addition, although this seems to be most feasible in combination with adenosine.[12]

TEE has been employed in combination with both pharmacologic and pacing stress, usually for patients with inadequate transthoracic images. During transesophageal imaging with pharmacologic stress, we approximate the standard imaging planes as closely as possible by recording transverse and longitudinal esophageal and transgastric short- and long-axis views. During pacing with electrodes attached to the TEE probe, the need to stimulate the esophagus inhibits the ability to move the transducer, so that imaging is performed in the transgastric planes only.

Although the constraints of a busy stress echocardiography schedule may preclude the performance of a detailed examination in every patient, a "screening" M-mode, pulsed wave (especially for LV inflow), and color Doppler echocardiographic examination should be performed at the beginning of every study. According to the setting, tissue Doppler images maybe helpful at baseline for the assessment of filling pressure[13] and dyssynchrony.[14] Time should also be taken to optimize two-dimensional (2D) echocardiographic images and gain settings (for endocardial detection) and to zoom on the ventricles (to obtain the best spatial resolution and frame rate). During the stress, the patient is imaged continuously, and the images are stored in digital clips. When the study is performed for the diagnosis of coronary disease, we favor a multiscreen display to show as many stages as possible, as changes may be transient. Many types of viewing software do not permit this. If so, the minimum default quad-screen display should include a resting image, a low-dose image (10 mcg/kg/min dobutamine, 0.56 mg/kg dipyridamole, or a small heart rate increment with pacing), a high-dose image (40 mcg/kg/min dobutamine or 0.84 mg/kg dipyridamole with or without atropine), and an early poststress image. The ability to save images at multiple stages enables easy alteration of this display. For example, when the clinical question pertains to the possibility of viable myocardium, the display could include two low-dose images (5 and 10 mcg/kg/min dobutamine) and one high-dose image.

### *Image Processing*

Digital techniques are critical for successful interpretation and archiving of stress echocardiograms. Digital image processing facilitates image display and interpretation by allowing a side-by-side display of resting, low-dose, and high-dose images, as well as the ability to review individual frames (which is useful to evaluate the temporal sequence of contraction). However, all studies should also be recorded in continuous format. Traditionally, this involved use of videotape, to provide a backup in case technical problems with the digital capture (especially triggering) or corruption of the archived data threaten loss of the study. Indeed, routine review of tape has a significant impact on diagnosis, probably by permitting review of off-axis images and regions that are not adequately represented by saving a single cardiac cycle. Although videotape is now rarely available in the echocardiography lab, continuous digital capture is an alternative.

### *Qualitative Interpretation*

The interpretation of stress echocardiograms for clinical purposes is based on a qualitative evaluation of regional function at rest and stress.[15] Some standardization is obtained by scoring regional wall motion and thickening in a number of segments. The American Heart Association has proposed a unified 17-segment model that includes the apical cap, to facilitate comparison between imaging modalities.[16] Although this template ignores the small but important detail that the true apex

is often not identified at echocardiography, its role as the standard should make its use preferred to the older 16-segment model (anterior, septal, lateral, and inferior at the apex, with these segments as well as anteroseptal and posterior segments at the base and midpapillary muscle level). Despite this standardization, however, the expertise of the physician interpreting the test is critical, and even accomplished echocardiographers require a significant learning period. In a study of echocardiographers learning dipyridamole stress echocardiography, Picano and colleagues reported that 100 supervised studies were required to bring the accuracy of "novices" to the level of "experts." Despite many technical advances in stress echocardiography in the past two decades, this learning curve remains important.

The standard qualitative algorithm for interpretation of pharmacologic stress echocardiography is summarized in Table 16-1. With the exception of the low-dose responses, which denote myocardial viability, it may also be applied to pacing or other stressors.

Regional wall motion at rest may be classified as normal, hypokinetic, akinetic, or dyskinetic. Severe hypokinesia may be difficult to distinguish from akinesia; a useful guide is based on endocardial excursion, with less than 2 mm identifying akinesia and less than 5 mm indicating hypokinesia. Regions that fail to thicken or that move only in late systole (after movement of the adjacent myocardium) may be moving passively and should be considered akinetic, irrespective of endocardial excursion. Segments with resting akinesis or dyskinesis are most likely composed of infarcted myocardium if the wall is thinned and dense, but in the absence of thinning are likely to consist of viable tissue. Indeed, hypokinetic segments are not identified as being infarcted, on the basis that residual contraction implies the presence of residual viability. Because the process of thinning and fibrosis takes some time after infarction, myocardium of normal thickness is commonly seen after recent or nontransmural infarction. Improvement of abnormal function in response to low doses of dobutamine (5 or 10 mcg/kg/min) or dipyridamole (0.28 or 0.56 mg/kg) suggests the presence of viable myocardium (Fig. 16-2). This finding is more reliable if the segment subsequently deteriorates, which indicates ischemia.

**TABLE 16-1 Interpretation of Myocardial Viability and Ischemia Using Dobutamine Echocardiography**

| *Diagnosis* | *Resting Function* | *Low-Dose* | *Peak/Poststress Function* |
|---|---|---|---|
| Normal | Normal | Normal | Hyperkinetic |
| Ischemic | Normal | Normal (unless severe CAD) | Reduction vs. rest<br>Reduction vs. other segments<br>Delayed contraction |
| Viable, patent IRA | Hypo/akinetic | Improvement | Sustained improvement |
| Viable, stenosed IRA | Hypo/akinetic | Improvement | Reduction (c/w low-dose) |
| Infarction | A/dyskinetic | No change | No change |

*CAD*, Coronary artery disease; *c/w*, compared with; *IRA*, infarct-related artery.

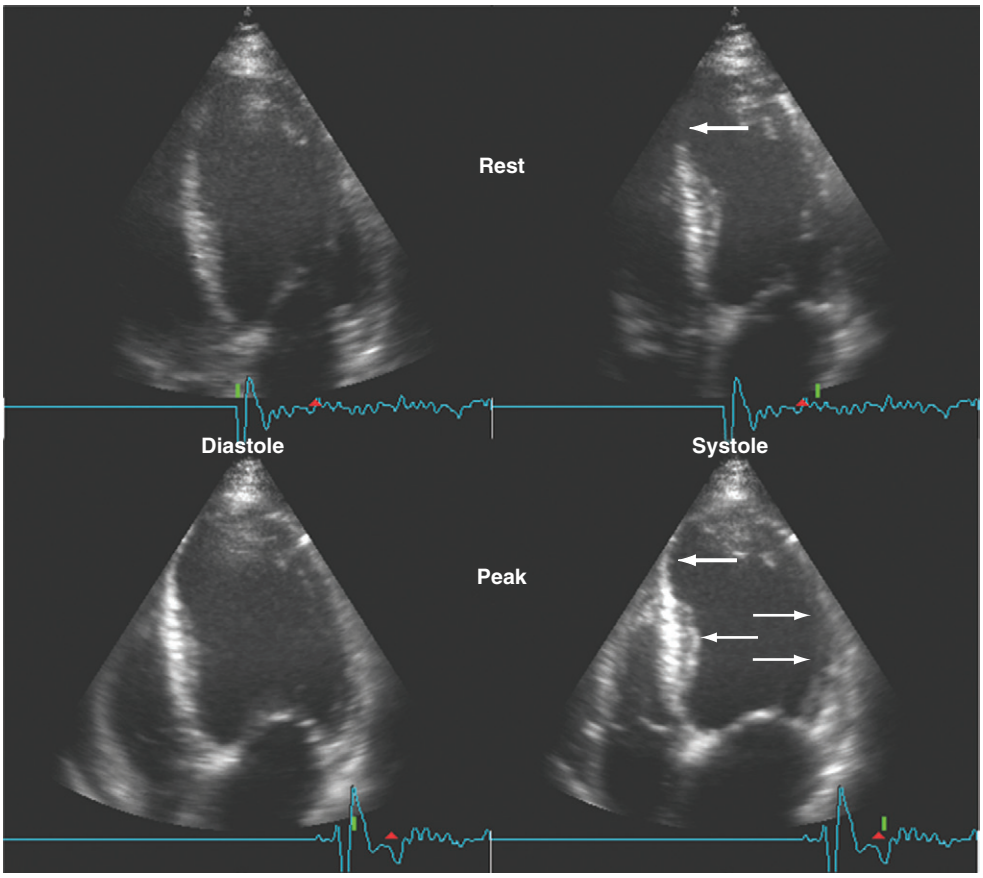

**Figure 16-2 End-diastolic and end-systolic freeze-frame images illustrating LV enlargement on DSE in a patient with LV dysfunction and multivessel coronary artery disease.** There is a resting wall motion abnormality in the apex (*large arrow*), which is unchanged with stress. At peak stress, there is LV enlargement with reduction of systolic motion and thickening of the lateral (and to a lesser degree the septal) wall.

The global LV responses to dobutamine stress include a reduction of cavity size and an increase in cardiac output—mainly due to increased heart rate rather than stroke volume after intermediate dose (e.g., 20 mcg/kg/min), a point that is pertinent to the LV strain response (see later discussion). LV dilation implies multivessel or left main coronary artery disease (see Fig. 16-2), but this is less commonly seen with pharmacologic than with exercise stress, probably because of reduction of loading. Together with an extreme inotropic response, this afterload reduction may produce cavity obliteration (Fig. 16-3) and even outflow obstruction—which is not meaningful. Although the LV cavity obliteration response is favorable prognostically (presumably reflecting a low probability of multivessel disease),[17] it may impair sensitivity both because of reduced transmural wall stress and because endocardial excursion is reduced and small areas of wall motion are unrecognized.[18] Use of intravenous beta-blockade allows the heart rate to slow rapidly after stress, filling the LV cavity and revealing wall motion abnormalities that were unidentified at peak stress.[19] A similar outcome can be obtained by poststress imaging.

The normal response to inotropic stress is to increase endocardial excursion, speed of contraction, and degree of myocardial thickening. A deterioration of function from rest, or after an initial enhancement of function, indicates ischemia (Fig. 16-4). Variants of overt deterioration include delayed contraction ("tardokinesis") and reduced myocardial thickening. Caution should be applied in the assessment of periinfarct zones, which may fail to improve function with stress, or even appear dyskinetic if the infarct bulges due to tethering by the infarcted zone. Examination of wall thickening may assist in distinguishing periinfarct ischemia and tethering.

The evaluation of segments with abnormal resting function is more difficult. Akinetic or even dyskinesic segments may still be viable if they augment in response to either low-dose dipyridamole or dobutamine. Care must be taken to avoid misinterpretation based on differences in image planes, especially if the wall motion abnormality is localized. Deterioration of augmenting myocardium identifies ischemia, but in the absence of augmentation, a deterioration of function probably reflects increased loading rather than ischemia. Segments with resting hypokinesia often reflect nontransmural infarction, although some normal segments may be mildly hypokinetic, and it is important to be wary of overinterpretation, especially in the posterior wall. Analysis of myocardial deformation using 2D strain techniques has suggested that the pattern of impaired longitudinal function with preserved radial or rotational motion may be used to identify nontransmural infarction, as measured by gadolinium-enhanced MRI. Hypokinetic segments are also the most challenging for the identification of ischemia; those demonstrating a stress-induced improvement are classified as normal, and those showing a deterioration (compared with either rest or low-dose) are identified as ischemic. However, differentiation between degrees of hypokinesia may be difficult, even with side-by-side cineloop analysis. Some caution needs to be applied in the interpretation of regional variations in the degree of hyperkinesis, as these may occur in normal patients. There is a risk of overinterpretation of hypokinetic regions that fail to improve function in response to stress, even if adjacent segments mount a hyperkinetic response. A decision to characterize these as ischemic should be made in the context of the rest of the study.

The greatest limitations of the current application of stress echocardiography are concerns related to subjectivity and reproducibility. Although single-center studies have suggested that the interobserver variation in interpretation is small, interinstitution variability (although similar to that of other imaging techniques) is significant.[20] Interinstitution variability is particularly a problem in studies of poor image quality and in patients with mild ischemia. This discordance has been progressively reduced by definition of standard reading criteria[21] and

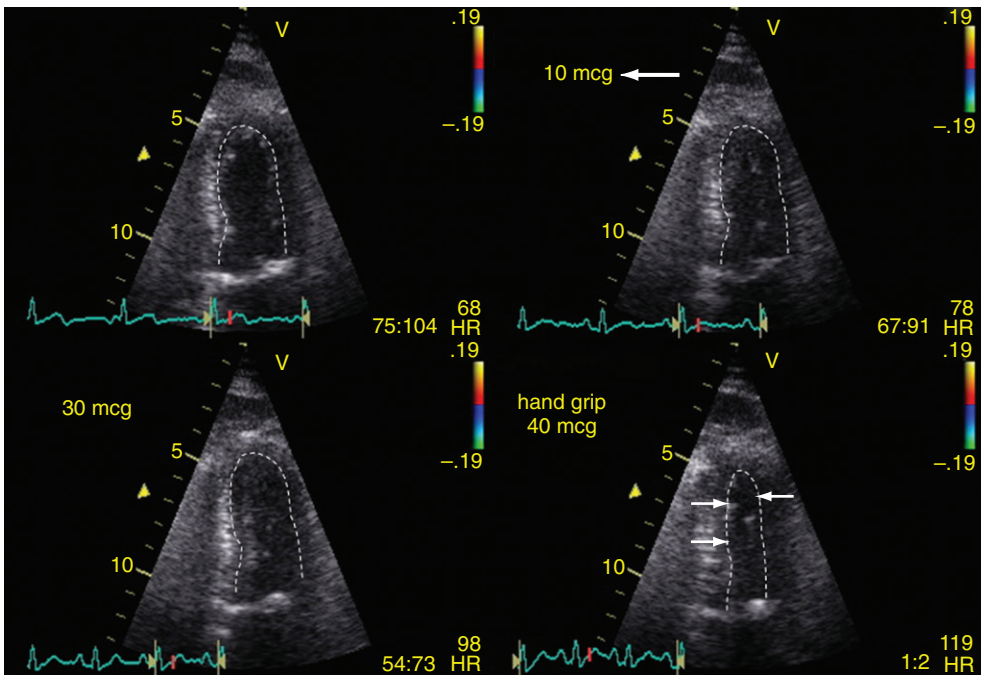

**Figure 16-3 End-systolic freeze-frame images of apical four-chamber views illustrating marked reduction in LV volume at peak stress, with close to cavity obliteration.** The resulting low transmural wall stress may prevent the induction of ischemia despite the presence of coronary artery disease.

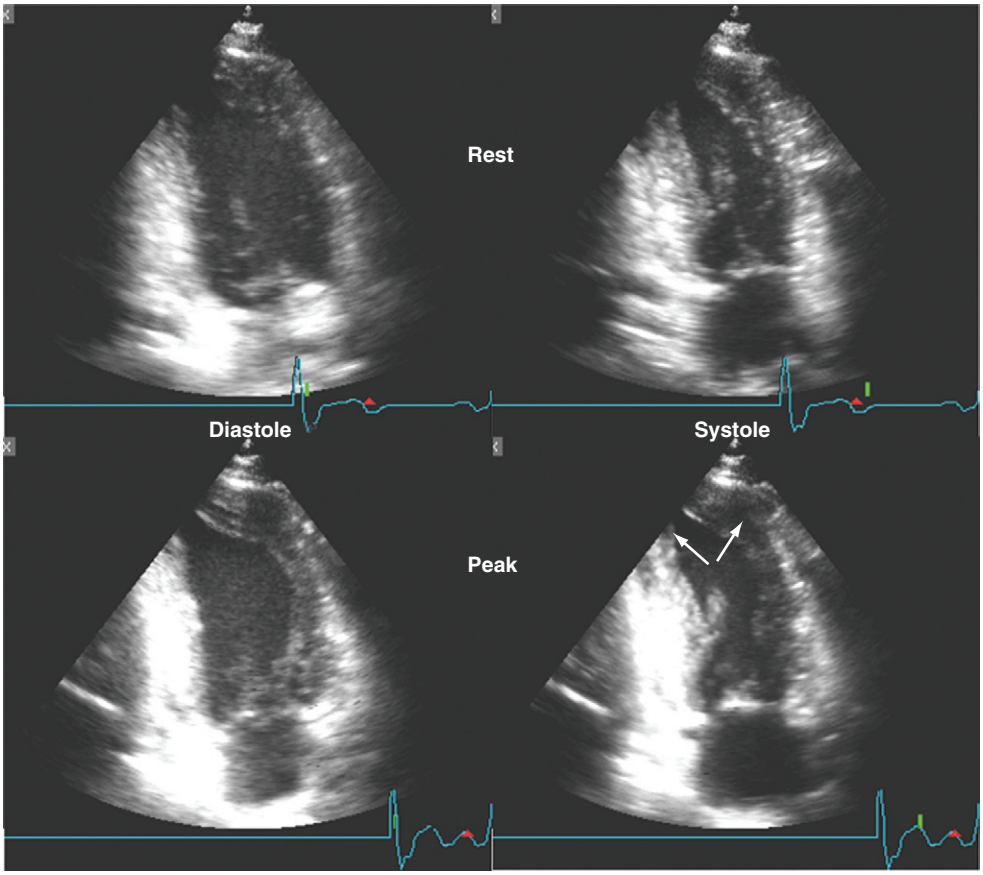

**Figure 16-4 Apical two-chamber views illustrating the development of myocardial ischemia (reduced wall thickening, *arrows*) of the apex during DSE.** End-diastolic images are given on the *left* and systolic images on the *right*, with resting images *above* and peak dose *below*.

the adoption of harmonic imaging.[22] The following reading guidelines are useful for controlling variation: Minor degrees of hypokinesia are not identified as ischemia (especially if only apparent at peak and not at poststress readings); focal abnormalities that do not follow angiographic territories are ignored; abnormalities are corroborated whenever possible with another view; basal inferior and septal segments are not identified as abnormal in the absence of a neighboring abnormal segment; studies are read by multiple observers whenever possible; and reading is blinded to all other data.

Finally, a standard sequence is of value in the interpretation of stress echocardiograms. We first review the resting data or previous transthoracic echocardiography (TTE) for non–wall-motion data that may color our interpretation, including M-mode and Doppler components. On the digital images, we first check that images are triggered correctly and that the prestress, peak stress, and poststress views are comparable. We then briefly review all of the side-by-side displays to see if there are new wall motion abnormalities or obvious changes in cavity size (suggesting multivessel disease) or cavity shape. Segmental analysis is carried out by careful comparison of regional function in each of the 16 segments, comparing the same site at rest and at stress. Both wall motion and thickening are compared, using both cineloop and frame-by-frame review of the digital images. Freezing the images and stepping through one frame at a time is invaluable—delayed contraction is a hallmark of ischemic tissue that is not apparent to the unaided eye, but is often recognizable when images are reviewed frame by frame. The reader should think twice about identifying resting- or stress-induced wall motion abnormalities in segments that move rapidly and smoothly in early systole. Focusing on the first part of systole may minimize the contribution of rotational or translational movement, and assessing the timing of contraction may also avoid false positive interpretations provoked by early relaxation (Fig. 16-5). The ability to save multiple cycles in each view has reduced the need to review continuous capture stress images, but these remain of value for nonstandard views and to check on uncertainties arising from the digitized images. The site, extent (number of abnormal segments), severity (segmental wall motion score), and time of onset and offset of ischemia, as well as the effect of ischemia on global LV function, should be recorded.

## Technical Aspects

### GENERAL CONSIDERATIONS

Patients are instructed to fast, partly because nausea is a side effect with some agents (especially dipyridamole and adenosine), and in case complications ensue, with attending aspiration risks. For dipyridamole stress testing, coffee, tea, and cola drinks should be avoided for 12 hours before the examination, as xanthines antagonize the effects of dipyridamole on adenosine metabolism, as well as by direct competitive inhibition of adenosine.

For diagnostic testing, patients should be instructed to stop antiischemic drugs on the day of the procedure, but medications may be continued if testing is being performed to assess

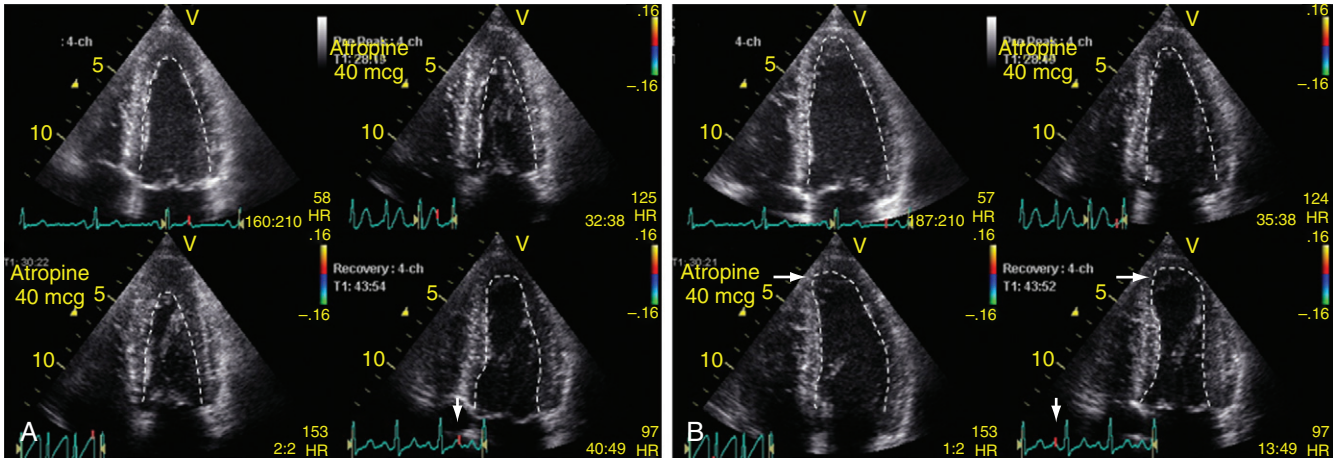

**Figure 16-5** **Apical four-chamber views illustrating the phenomenon of early relaxation. A,** Homogeneous contraction with reduction of apical cavity volume. **B,** Apical shape change after end of systole (*broad arrow* on electrocardiogram).

the adequacy of therapy. Intravenous access is secured, and monitoring electrodes may be moved away from the echocardiographic windows. Two personnel are mandatory for performance of these protocols, usually a sonographer and nurse, with a physician in close proximity. Clinical and electrocardiographic monitoring during the tests parallels the monitoring undertaken during exercise stress testing. In addition to the usual resuscitation equipment, intravenous beta-blocking agents and nitrates should be available to treat severe ischemia. For dipyridamole stress, aminophylline should be available for the treatment of severe ischemia.

## EXERCISE-SIMULATING AGENTS

### *Protocols for Administration of Sympathomimetic Agents*

Dobutamine has been administered using various empiric regimens, but none is clearly superior to the others. The most widely used is an incremental administration from 5 to 40 mcg/kg/min in 2- or 3-minute stages.[5] Variants include maximal doses of up to 50 mcg/kg/min; lower dose-rates administered over longer periods are able to attain hemodynamic effects similar to those achieved by the high-dose protocols. New accelerated dobutamine protocols that have been used to reduce the duration of the test appear to be safe[23] but may sacrifice the ability to identify a biphasic response. Whichever regimen is applied, a reasonable (i.e., 2- to 3-minute) period at peak heart rate is desirable, as ischemic wall motion abnormalities may take a short time to become apparent. If atropine is added to induce an increase in heart rate, the usual dose is 1 to 2 mg total in 0.25-mg increments.

### *Hemodynamic Responses to Sympathomimetics*

Low doses of dobutamine enhance LV contractility, usually without the development of tachycardia. At doses greater than 20 mcg/kg/min, systolic blood pressure increases and heart rate augments to more than 100 beats per minute. Heart rate can be expected to increase to about 120 beats per minute in most patients, reflecting a increment of 40 to 50 beats per minute. In normotensive patients, systolic blood pressure usually increases to about 170 mm Hg (i.e., by 30 to 40 mm Hg)—less during dobutamine than during exercise. The systolic pressure response may be marked in hypertensive patients and blunted in patients with LV dysfunction or multivessel coronary disease. The peak rate-pressure product is usually about 20,000—less than with exercise,[24-29] which has important implications for the relative sensitivity of dobutamine and exercise echocardiography. Although the development of ischemia at lower dobutamine doses and cardiac workloads indicates the presence of more extensive coronary disease, there is too much overlap for the hemodynamic response to be a reliable predictor of one-, two-, or three-vessel disease. The hemodynamic response to dobutamine shows significant variability between patients. Beta blockade may attenuate the physiologic response, with a significantly lower heart rate response (usually about 100 beats per minute), and a lower double-product (to levels of around 14,000), although this may be avoided by use of atropine.

### *Side Effects of Stress Testing with Sympathomimetic Agents*

Other than the development of myocardial ischemia, dose-limiting side effects generally reflect intense adrenergic stimulation. Consequently, dobutamine stress is contraindicated in patients with severe hypertension and serious arrhythmias. Serious side effects are rare during DSE, with death, myocardial infarction, or sustained tachyarrhythmias in about 3 per 1000.[8,30] Nonetheless, case reports of fatalities have been reported from ventricular fibrillation and cardiac rupture,[31] and safety in patients at highest risk—those with severe LV dysfunction—has been described only in small populations.[32] Nonetheless, considering that the sickest patients (those unable to exercise and with questions of myocardial viability) undergo the test, this safety profile is reasonable. This may reflect the detection of ischemia by online imaging, permitting termination before serious problems arise.

Less serious complications include palpitations (atrial and ventricular extra systoles), hypertension, anxiety (sometimes manifested as dyspnea or vagal reactions), tremor, and urinary urgency. Hypotension may arise from the vasodilator effect of high-dose dobutamine, the development of outflow tract obstruction, or the development of severe ischemia.[33] Unlike hypotension during exercise testing, it does not denote the presence of serious coronary disease or LV dysfunction. In particular, the finding of an LV outflow tract gradient does not appear

to be prognostically meaningful. The frequency of these side effects has varied from 5%, if only serious, dose-limiting side effects are considered, to 82%, if all side effects are included. Variability also relates to the type of stress protocol, the incidence being lower if the test is terminated for attainment of a target heart rate or at detection of ischemia or if submaximal test responses are excluded.

## VASODILATOR STRESS PROTOCOLS

### *Stress Protocols*

Dipyridamole is administered into a large proximal arm vein to minimize local discomfort from this strongly alkaline compound. Various dipyridamole administration regimens have been used. For myocardial perfusion imaging, the most commonly administered dose is 0.56 mg/kg IV, but the sensitivity of dipyridamole echocardiography is optimal if 2 minutes of infusion are added if the initial response is negative and no major side effects have appeared. Because the time of onset of ischemia correlates with the severity of coronary disease and prognosis, images are recorded every 2 minutes from the conclusion of the first dose until 18 minutes from the start. Digital images are saved at rest, before the start of the second dose (8 minutes), after the second dose (12 minutes, which is the most common time for the onset of ischemia), and at 16 minutes. Aminophylline (in aliquots of 50 to 75 mg intravenously) is used to reverse the effects of dipyridamole if severe ischemia or side effects arise; the threshold for using this agent is influenced by the overall LV function and the clinical state of the patient.

Because exogenous adenosine is able to act directly, it rapidly achieves steady state, and its biologic effects are of rapid onset. A fixed dose schedule of 0.14 or 0.17 mg/kg/min or incremental protocols (3-minute stages starting at 0.10 mg/kg/min, increasing to 0.14 and 0.18 mg/kg/ minute) been used for echocardiographic studies.[34,35] The use of aminophylline is rarely required for side effects, as these resolve within 1 minute of stopping the infusion.

### *Hemodynamic Responses to Vasodilators*

The mechanism of ischemia with of vasodilator agents is chiefly through coronary steal. There is a small contribution of increasing oxygen demand from tachycardia, which may be a response to angina and side effects rather than arising from the agents themselves. Similarly, blood pressure is usually little changed by these stressors, which may cause hypotension. The addition of atropine leads to an augmentation of heart rate and cardiac work,[9] effectively combining reduced coronary supply with increased oxygen demand.

### *Side Effects of Vasodilators*

Side effects during dipyridamole stress usually follow completion of the infusion, rarely preclude completion of the study, and usually resolve spontaneously. Minor side effects, including flushing and headache, occur in about two thirds of patients studied with high-dose dipyridamole. Severe or prolonged myocardial ischemia is infrequent but can be treated with nitrates or aminophylline. Serious side effects are very rare—probably less frequent than with dobutamine[8,36]—but severe myocardial ischemia and infarction, bronchospasm, complete heart block, and even death have been reported. Dipyridamole stress is contraindicated with atrioventricular block and bronchospasm, although patients with chronic obstructive airway disease with no or minimal airway reactivity may undergo the test.

The side-effect profile of adenosine is similar to that of dipyridamole, and although the intensity and frequency of side effects with adenosine is greater, they are of shorter duration. Some form of side effect occurs in most patients undergoing adenosine stress.[37] In a high-dose protocol,[35] side effects prevented about one third of patients from achieving peak dose, a comparable frequency to that found with dobutamine. Because the effect of adenosine is very transient, cessation of the infusion is usually the only treatment required for side effects. The use of regadenoson minimizes the risk of bronchospasm and heart block, is convenient because of a single dose, and has the same coronary vasodilator effect as dipyridamole,[38] but regadenoson is suited to study of perfusion rather than wall motion responses.

## VASOCONSTRICTOR PROTOCOLS

Ergonovine stress may be useful for the diagnosis of coronary spasm, the frequency of which is greater in smokers and patients with some coronary disease. Ergonovine testing has been most widely used in the angiography laboratory, because spasm can be visualized directly and intracoronary nitrates infused to treat severe spasm. However, ergonovine stress appears to be safe when applied noninvasively in patients without significant stenoses, and the test has been applied to some patient groups without previous angiography. The standard protocol involves repeated bolus doses of ergonovine maleate at 5-minute intervals up to a total cumulative dose of 0.35 mg, unless ischemia is detected.

## PACING STRESS

### *Stress Protocols*

The use of an implanted pacemaker to alter the heart rate during testing is often necessary to achieve target heart rate in the presence of atrioventricular block, even if pharmacologic stress is being used. Ventricular stimulation produces dyssynchronous contraction, but interpretable images are obtainable if image quality is sufficient to evaluate thickening, and atrial pacing poses no problems for interpretation.[39] The test endpoints are the same as those for other nonexercise stressors; in the absence of these endpoints, pacing at peak heart rate is continued for 3 minutes. No protocol has been uniformly accepted. We use pacing in combination with dobutamine in order to obtain the inotropic response to stress, and therefore maintain a 3-minute incremental protocol when pacing is added, usually starting at 100 beats per minute.

Transesophageal pacing requires topical pharyngeal anesthesia and mild sedation and is rarely used. Use of a short protocol minimizes the risk of electrode movement and loss of capture. Atropine is often required to overcome atrioventricular block.

### *Hemodynamic Responses*

The hemodynamic response to pacing is more controllable than with pharmacologic agents. Heart rates of 160 beats per minute are attainable, but systolic blood pressure is stable, giving a rate-pressure product of less than 20,000. Use of transesophageal pacing in an awake patient may itself provoke hemodynamic changes and hence ischemia, so that "resting" transesophageal echocardiographic images may not be truly acquired at rest.

### *Side Effects*

Fewer side effects occur during transesophageal pacing than with pharmacologic stress. Esophageal discomfort, gagging, or nausea are uncommon with modern pacing electrodes. Angina may be provoked by stress but is usually self-limiting after cessation of pacing. Atrial flutter or fibrillation may also be precipitated. Esophageal injury is theoretically possible in response to high levels of stimulation over a prolonged period, but this has not been reported.

## Accuracy for Diagnosis of Coronary Artery Disease

### DOBUTAMINE STRESS ECHOCARDIOGRAPHY

The comparative sensitivity and specificity of DSE for the detection of coronary artery disease has been well summarized in two meta-analyses. Kim and colleagues[40] reported an 80% (95% confidence interval [CI], 77% to 83%) sensitivity and 84% (95% CI, 80% to 86%) specificity in 82 pharmacologic stress studies between 1974 and 1999. In nearly 7000 patients from 62 DSE studies between 1991 to 2006, reported by Geleijnse and co-workers,[41] the sensitivity was 81% and specificity was 82%. No single feature accounts for false-positive results, although the most frequent site of false-positive results is the basal inferior wall. The correlates of false negative results are a matter of discussion. The meta-analysis just mentioned did not show an effect from a variety of features conventionally associated with enhanced sensitivity—use of a coronary stenosis cutoff of 70% (rather than 50%), higher achieved heart rate, cessation of beta-blockers at the time of testing, the use of atropine, and the incorporation of a biphasic response. Armstrong[42] has argued that these observations likely reflect the heterogeneity of testing in the meta-analysis, ranging from diagnostic testing for coronary artery disease, through evaluation of ischemia on therapy, to functional evaluation of coronary stenoses.

The use of a 50% or 70% stenosis cutoff is arbitrary and does not take into account stenosis location or vessel size, both of which clearly influence the likelihood of an abnormal response. This concern has been addressed in several studies that have compared the results of DSE with stenosis diameter at quantitative coronary angiography.[43] The angiographic cutoff value with the best predictive value for a positive dobutamine test was a luminal diameter of 1.07 mm, percent diameter stenosis of 52%, and percent area stenosis of 75%, of which minimal lumen diameter was found to have the best predictive value for a positive dobutamine stress test (odds ratio, 51; sensitivity, 94%; specificity, 75%). Stenoses less than 1 mm in diameter can be identified with a sensitivity of 86%.[43]

The use of myocardial fractional flow reserve (the ratio of mean hyperemic distal coronary to aortic pressure) as a functional index of coronary stenosis severity takes into account collateral flow and overcomes the limitations of comparing stress echocardiography with the anatomic severity of stenosis. The degree of dobutamine-induced dyssynergy correlates significantly better with myocardial fractional flow reserve than percent stenosis or minimal lumen diameter, and the sensitivity of DSE is significantly lower for lesions in vessels smaller than 2.6 mm than for larger vessels.

The existence of a regional wall motion abnormality identifies the presence of coronary disease, so DSE demonstrates higher sensitivities in patients with myocardial infarction. In patients with single-vessel disease, the sensitivity of DSE (40% to 70%) is lower than in multivessel disease. Because dobutamine produces a less potent stress on the heart than exercise (see earlier discussion), DSE is probably more susceptible to external influences than exercise echocardiography or myocardial perfusion scintigraphy. This may be pertinent to the extrapolation of results from clinical trials (in which patients were carefully supervised and tested under optimal conditions, off therapy), to routine clinical practice, in which patients are often tested on therapy and are more likely to have a "suboptimal" test result because of inability to complete the protocol or interference by beta-blocker therapy.[5]

### DIPYRIDAMOLE STRESS ECHOCARDIOGRAPHY

The sensitivity and specificity of vasodilator stress echocardiography have been reported as 80% (95% CI, 77% to 83%) and 84% (95% CI, 80% to 86%) in a recent meta-analysis.[40] The low-dose (0.56 mg/kg) protocol is associated with lower sensitivity than the high-dose regimen. Atropine appears to enhance sensitivity, although this is only about 50% in patients with single-vessel disease. TEE imaging enhances the accuracy of this test. The greater variation in the sensitivity of stress echocardiography with vasodilators than dobutamine and exercise stress seems to relate to patient selection and the definition of "significant" disease; many of the more favorable results pertain to populations with a high percentage of patients with more severe coronary disease. The specificity is excellent.

Investigators have sought to address the accuracy of dipyridamole stress with physiologic rather than anatomic criteria of significant stenosis. In 30 patients with isolated stenoses of the left anterior descending coronary artery, predictors of an abnormal dipyridamole echocardiogram were a stenotic flow reserve of less than 2.8, stenosis diameter greater than 59%, lumen diameter less than 1.35 mm, and coronary flow reserve less than 2.0, of which stenotic flow reserve was the only independent predictor of ischemia. This study was interesting on two grounds: First, it implies that dipyridamole identifies fewer mild stenoses than DSE, and second, it identified angiographic variables of stenosis severity to relate to dipyridamole echocardiographic results better than intracoronary Doppler variables. Other studies have confirmed that the optimal angiographic cutoff point for dipyridamole stress echocardiography is 60%, as compared with 58% for dobutamine and 54% for exercise echocardiography.[44]

### VASODILATOR STRESS WITH ADENOSINE ECHOCARDIOGRAPHY

The reported accuracy of adenosine stress echocardiography is variable. A recent meta-analysis[45] gave it a sensitivity of 68% and specificity of 81%, after weighting for study size. Favorable results are more likely with multivessel disease or prior infarction; the sensitivity is 60% or less in patients with a normal electrocardiogram or without prior infarction.[35] The intense coronary vasodilation induced by adenosine or dipyridamole[46] permits the comparison of rest and hyperemic images using contrast echocardiography. Similarly, coronary flow reserve may be measured at adenosine stress TTE or TEE.[47] The longer time course and less predictable peak flow with dipyridamole make this a less attractive agent; if dipyridamole is selected, a high dose is certainly required.[12]

## PACING STRESS ECHOCARDIOGRAPHY

Studies that have combined atrial pacing with echocardiography show very favorable results. A meta-analysis from the limited number of studies (and patients within studies) proposed a sensitivity and specificity of 91% and 86% for TTE and 86% and 91% for TEE.[45] The accuracy of both transesophageal imaging and pacing probably reflects the benefits of high-quality images as much as the role of pacing stress, as similar favorable findings have been obtained using TEE with dobutamine and dipyridamole. The discrepancy between the reported accuracy, feasibility, and patient acceptance of pacing stress contrasts with the limited application of the test. The following are important issues that influence our continued use of pharmacologic stress. First, the evidence base for diagnostic, management, and prognostic information using pharmacologic agents is greater than with pacing stress. Second, the pacing test is unlikely to be useful for the detection of viable myocardium, and even when this is not needed from a clinical standpoint, the biphasic response has been shown to facilitate the distinction of ischemia in the setting of resting wall motion abnormalities. Third, most patients and some clinicians look on the test as being excessively invasive. This test has several "niche" applications: patients with hypertension or rhythm contraindications to dobutamine, potentially unstable patients (because the stress can be stopped suddenly), or patients with chronotropic incompetence of various causes.

## COMPARISON BETWEEN NONEXERCISE STRESSORS FOR THE DIAGNOSIS OF CORONARY ARTERY DISEASE

### *Selection of the Optimal Pharmacologic Stress*

The comparative sensitivity and specificity of DSE and vasodilator stress echocardiography for the detection of coronary artery disease have been well summarized in the meta-analysis of Picano and associates.[48] Both tests are effective for the diagnosis of coronary artery disease. However, variations in the study groups make it difficult to compare the relative efficacy of the stressors by merely comparing the results of individual studies, and the limitations of meta-analyses for assessment of therapies likely applies to their application to diagnostic testing.

Figure 16-6[45] summarizes the accuracy of stress echocardiography with a variety of stressors and Table 16-2 summarizes large head-to-head comparisons of the tests in the same patients, under the same conditions.[27,49-52] The feasibility of dobutamine and vasodilator stress are similar. The sensitivity of DSE exceeds that of vasodilator stress; the main source of discrepancy appears to be patients with single-vessel coronary disease, among whom dobutamine appears to be superior. This difference parallels a significantly greater cardiac workload with dobutamine compared with vasodilator stress.

The contraindications to inotropes and vasodilators vary, so their selection may be individualized; patients with hypertension or arrhythmias should undergo a vasodilator stress, and

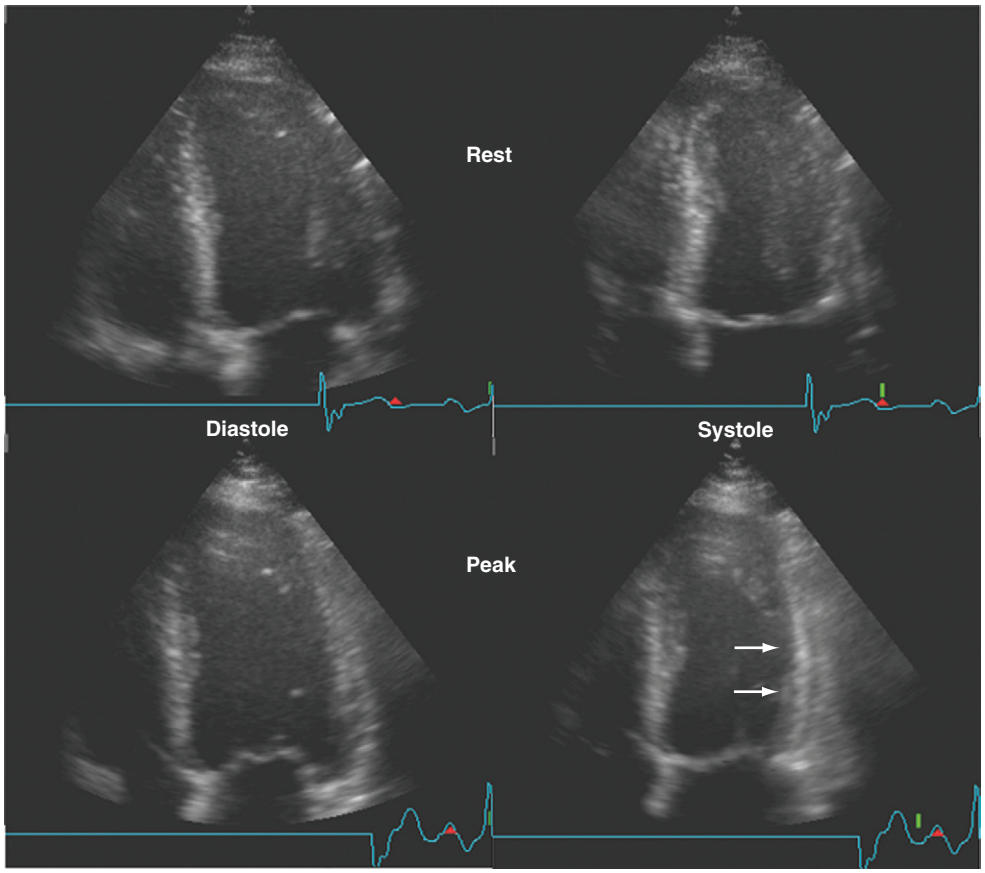

**Figure 16-7 Lateral wall ischemia.** Freeze-frame images in the apical four-chamber view demonstrate normal thickening at rest (*above*), with reduced thickening at peak stress (*below, arrows*).

patients with bronchospasm or conduction disorders should be submitted to inotropic stress. However, in the majority of patients who do not have these contraindications, dobutamine appears to be the most sensitive agent for pharmacologic stress echocardiography.

### *Selection of Pacing Rather Than Other Nonexercise Stress*

There are few comparative data between pacing and pharmacologic stress. Pacing is reportedly less feasible (77% versus 96%, $p$ less than .0001), but more sensitive (83% versus 43%, $p = .0005$) than dipyridamole echocardiography. Atrial pacing showed more favorable safety, duration, and patient acceptance than DSE.

## Assessment of Disease Significance

The use of stress echocardiography for identification of the "culprit" coronary lesion is often constrained by the assumptions inherent in allocating territories of the heart to individual coronary vessels. The most ambiguous areas in this respect are the apex (usually supplied by the left anterior descending coronary artery) and the posterior wall (usually supplied by the left circumflex artery). Because of the equivocal involvement of the right coronary or left circumflex vessels in the posterior territory, investigators have examined the ability to discern the presence of coronary disease in the anterior and posterior circulations. Although in the preharmonic imaging era the lateral wall was a source of false-negative results, the accuracy of DSE in this area has improved (Fig. 16-7).

The recognition of multivessel disease at stress echocardiography may be important in planning revascularization rather than medical therapy. The ability of stress echocardiography to predict multivessel disease is greatest in patients with a history of previous myocardial infarction. In these circumstances, its sensitivity for the correct identification of disease is 80% to 85% and its specificity is 88%. In contrast, the sensitivity for multivessel disease in patients without previous infarction is approximately 70%, exceeding the levels reported in this situation using exercise echocardiography. A close correlation has been demonstrated between the extent of ischemia defined by DSE and that defined by perfusion scintigraphy. Both, however, underestimate the angiographic extent of disease,[5] a reflection of the difficulties of assessing the functional implications of disease extent on anatomic grounds.

In addition to the "space coordinate" (extent of abnormal segments),[3] another indication of the extent of coronary disease is the "time coordinate" (ischemic threshold). Multivessel disease may be predicted if ischemia has an early onset (similar to the "ischemia-free" time at exercise testing), corresponding to its occurrence at a low dose or provocation at a low heart rate and rate-pressure product.[53] This corresponds to a lower ischemic threshold at exercise testing[54] as well as a worse prognosis.

## PROGNOSTIC EVALUATION AND PREDICTION OF CARDIAC EVENTS IN PATIENTS UNDERGOING MAJOR NONCARDIAC SURGERY

Coronary artery disease is highly prevalent in elderly patients undergoing major surgery, especially those with vascular disease. In addition to unstable coronary syndromes, particularly high-risk settings include severe valvular disease, decompensated heart failure, and significant cardiac arrhythmias. Indeed, cardiac events are the leading cause of perioperative complications at vascular surgery, as well as accounting for many late deaths after vascular surgery. However, although postoperative unstable angina and heart failure are frequent in these patients, perioperative "hard" endpoints (death, myocardial infarction) occur in less than 10%, and fewer among patients undergoing nonvascular procedures. In addition, apart from in patients with left main disease (where revascularization is linked to improved survival in unselected groups), the weight of evidence suggests that coronary revascularization before noncardiac surgery does not reduce morbidity and mortality. Because of these observations, and the realization that perioperative testing is among the most frequent inappropriate indications for testing, the current guidelines emphasize how important it is for the ordering physician to consider the likelihood that that an ordered test would influence patient management.

The selection of patients for evaluation before noncardiac surgery should be based on patient-specific factors and the risk of the surgery. The first step in preoperative risk stratification is clinical evaluation.[55] Patients with unstable coronary syndromes within the previous 6 months constitute a high-risk group and warrant careful functional testing or possibly angiography and preoperative intervention. The nature of the planned surgery is important; extensive risk evaluation is best directed toward vascular, major orthopedic, and major abdominal operations that engender significant cardiac risk. Those with previous bypass surgery (within 5 years) or negative coronary investigations within 2 years are at low risk and do not require reinvestigation in the absence of recurrent symptoms. Finally, the patient history has an important influence on risk; in more than 4300 patients[56] undergoing high-risk surgery, history of ischemic heart disease, congestive heart failure or cerebrovascular disease, insulin treatment, and preoperative serum creatinine level greater than 2.0 mg/dL were markers of risk; patients with none, one, two, or three or more of these factors had approximate major cardiac complication rates of 0.5%, 1%, 5%, and 10%, respectively. Inactive patients are usually asymptomatic even in the presence of significant coronary disease, so nonexercise stress imaging techniques are required if screening is to be undertaken.

Reports of functional testing with pharmacologic stress echocardiography and other noninvasive tests published between 1975 and 2001 has been subjected to meta-analysis.[57] In that study, the prediction of perioperative cardiac death and nonfatal myocardial infarction was accomplished with the greatest weighted sensitivity (85%; 95% CI: 74% to 97%) with DSE, although this test had modest specificity (70%; 95% CI: 62% to 79%). This result follows the general behavior of predictive testing in this setting—a negative test is a very reassuring feature (event rate with a negative test should be less than 5%), but the predictive value of a positive test is intermediate (from 20% to 70%)—reflecting the role of not only coronary stenoses but also medical treatment and anesthetic intervention in the genesis of events at surgery. Positive tests may be further stratified by paying attention to the ischemic threshold and the clinical risk factor status (Fig. 16-8). In the preceding meta-analysis,[57] receiver operating characteristic curve analysis showed DSE to be superior to other tests, especially myocardial perfusion scintigraphy (relative odds ratio 5.5, 95% CI: 2.0 to 14.9).

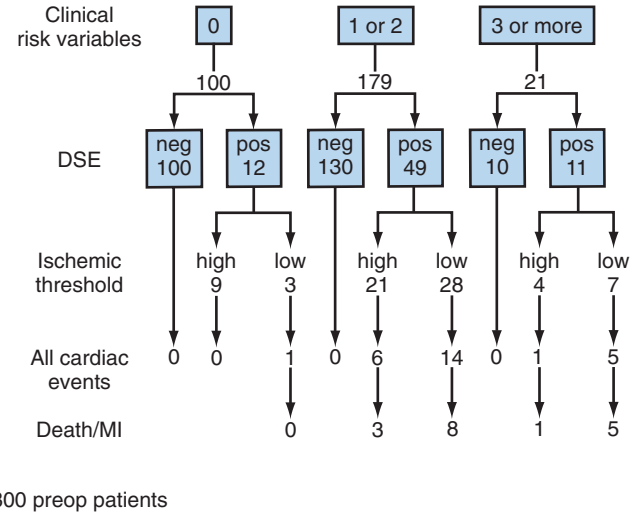

**Figure 16-8 Evaluation of risk in patients undergoing vascular surgery.** Patients without clinical predictors of risk rarely have a positive DSE study, are unlikely to suffer events, and usually do not require testing. The presence of ischemia is predictive of events, especially if the patient has multiple clinical risk factors or a low ischemic threshold. *MI*, Myocardial infarction; *neg*, negative; *pos*, positive; *preop*, preoperative. *(From Poldermans D, Arnese M, Fioretti PM, et al: Improved cardiac risk stratification in major vascular surgery with dobutamine-atropine stress echocardiography.* J Am Coll Cardiol *26:648-653, 1995.)*

Although beta adrenoceptor blockers protect against cardiac events at the time of major surgery, the universal use of beta blockade is also not without risk.[58] On the other hand, noninvasive evaluation before surgery is a frequent scenario of inappropriate testing[59] and should not be used in patients with low cardiac risk or those undergoing low-risk surgery. Exactly how to respond to a positive test is controversial—it does not appear that coronary revascularization is effective for the control of risk.[60]

## PROGNOSTIC EVALUATION OF PATIENTS WITH STABLE CORONARY DISEASE

Major cardiac events are infrequent in stable chronic coronary disease (less than 1% per year), but some patients have a more favorable prognosis with intervention. The detection of left main or multivessel disease at coronary angiography is often used to identify subgroups likely to benefit from revascularization, but this procedure is too costly and invasive to be used in all patients. As in the case of preoperative risk stratification, clinical data (including the severity of angina, prior infarction, heart failure, and diabetes) may identify high- and low-risk subgroups, and additional investigations are of most value in those at intermediate or greater risk. Exercise capacity and ST segment depression at exercise testing offer important prognostic information in patients who are able to exercise,[61] and exercise single photon emission computed tomography (SPECT)[62] or exercise echocardiography has been shown to provide incremental data in many patients.[63]

**TABLE 16-3 Use of Stress Echocardiography to Predict Events in Patients with Chronic Stable Coronary Disease**

| Study | Stress | Patients, N | Mean Follow-up, Mo | Predictive Value, % | | Comments |
|---|---|---|---|---|---|---|

| Picano[71] | Dipyridamole (high dose)<br>Dipyridamole (low dose) | 539<br>539 | 36<br>36 | 26<br>41 | 94<br>94 | |
| Schroder[64] | Dipyridamole | 134 | 19 | 27 | 92 | |

The prognostic implications[64] of pharmacologic stress echocardiography are summarized in Table 16-3.[64-72] Ischemia is an independent predictor of adverse outcomes, incremental to clinical and resting echocardiographic data. Ischemic threshold adds significantly to simple assessment of test positivity. For example, cardiac events occurred in 41% of patients with wall motion abnormalities occurring at low-dose dipyridamole, and 26% of those with high-dose responses. Ischemia is a better predictor of cardiac events than is coronary anatomy.[71] The prognostic value of pharmacologic stress appears to be preserved within various subgroups, including hypertensive patients.[73]

Dobutamine and dipyridamole offer comparable risk stratification in patients at low to moderate risk of cardiac events[74] and similar to that of SPECT.[74] The prognostic components of both tests include the presence, severity, and extent of induced ischemia. Perhaps the most important aspect of the prognostic literature is that a negative test portends extremely low risk, evidenced by an event rate of 1% or less per year. However, there are some exceptions—patients with diabetes are a high-risk group, among whom even patients with a negative test retain some risk, especially in the subset who are unable to exercise.[75] Likewise, the protection from ischemia provided by antianginal drug therapy does not necessarily translate to protection against subsequent cardiac events, so the predictive value of a negative test on treatment is less than in patients off treatment.[76]

### PROGNOSTIC EVALUATION OF PATIENTS AFTER MYOCARDIAL INFARCTION

Although the current era of early intervention has led to a reduction in the use of stress echocardiography following myocardial infarction, there is little to choose between the efficacy of invasive and noninvasive strategies. If the latter is chosen, clinical features such as age and the presence of heart failure should be used in the initial risk assessment. The extent of infarcted and ischemic myocardium are major determinants of outcome. Stress echocardiography permits the assessment of ischemia as homozonal dyssynergy (periinfarct ischemia) or heterozonal dyssynergy (multivessel disease), and infarction may also be estimated.

Table 16-4 summarizes the prognostic implications of positive and negative nonexercise stress echocardiography after infarction.[77-82] The presence of ischemia and its time of onset are important predictors of cardiac events[79]; in elderly patients, ischemia was an independent predictor of mortality.[83] All tests have proven to be effective for the detection of multivessel disease[77] and predictive for the subsequent development of cardiac events.

## Evaluation of Therapy

### MEDICAL THERAPY

The dependence of stress echocardiography on the development of ischemia is a disadvantage to the extent that antianginal therapy reduces its sensitivity, particularly with dipyridamole stress. Patients on beta-blockers account for most patients who fail to attain a heart rate greater than 85% of age-predicted maximum. With DSE, the interaction between dobutamine and beta-blockers involves competitive inhibition, and if enough dobutamine is administered, this effect may be overcome.[84] A similar role is relevant to atropine. The interaction between medical therapy and the development of ischemia may be of use in evaluating the adequacy of therapy.[85-87] Sequential testing is limited by the subjectivity of wall motion scoring, and this application requires a reliable quantitative approach.

### FOLLOW-UP AFTER CORONARY INTERVENTIONS

Stress echocardiography performed before and after angioplasty has been shown to confirm resolution of ischemia.[88] However, there is little justification for the routine use of a stress imaging test in *asymptomatic* patients within 2 years of percutaneous and 5 years of surgical revascularization.[89,90] Chest wall pains may be difficult to distinguish from recurrent symptoms due to restenosis or graft closure after angioplasty and bypass surgery. Stress echocardiography can be used effectively *in symptomatic patients* for the diagnosis of restenosis, progressive disease, and graft closure.[91-94]

## Assessment of Myocardial Viability

### CLINICAL SIGNIFICANCE

LV dysfunction after myocardial infarction is due not only to scarring but also to stunned and hibernating myocardium. Stunning shows spontaneous resolution of dysfunction,[95] but

**TABLE 16-4 Application of Nonexercise Stressors to Postinfarction Risk Evaluation (>100 Patients)**

hibernating tissue requires myocardial revascularization to resume normal function. The benefit of assessing myocardial viability has become more controversial in the light of the STICH trial, which showed no survival benefit from the interaction of viability testing and revascularization in an observational substudy of the use of these tests.[96] Previous studies showed that patients with viable myocardium may improve cardiac function or overall functional capacity, as well as avoid subsequent cardiac events from this inherently unstable tissue. Clinical decisions about whether to revascularize, which vessel to revascularize, and how to do it may be influenced by the detection of viable myocardium.

The recovery of function is an imperfect gold standard for defining viability (and thereby the performance of noninvasive testing), as it is influenced by the adequacy of revascularization, bypass graft closure, and restenosis. However, it has the attraction of having direct clinical relevance. Positron emission tomography and thallium scintigraphy using rest-redistribution or stress-redistribution-reinjection protocols are alternative markers of viability, as they have a high negative predictive value. On the other hand, they may be "too sensitive" a reference standard, because their high sensitivity for small regions of viable myocardium means that revascularization of some fails to improve regional function.

## USE OF DOBUTAMINE ECHOCARDIOGRAPHY FOR THE DIAGNOSIS OF VIABLE MYOCARDIUM

The typical response of viable myocardium is to increase thickening in response to low doses of dobutamine; in the presence of a stenosed infarct-related artery, function subsequently deteriorates as the tissue becomes ischemic. Indeed, there is a balance between the recovery of function and the development of ischemia—the latter may compromise the functional recovery of areas that are marginally perfused at rest. The high-dose response (greater than 20 mcg/kg/min) has been shown to be a less reliable predictor of recovery. Although some investigators start at lower doses, or use only a low-dose protocol for the assessment of viability, and others use 5-minute rather than 3-minute increments,[97] there does not appear to be a clear benefit in favor of any of these alternatives.

Dipyridamole enhances both segmental shortening and load-independent indices of ventricular function in stunned myocardium. The mechanism of this phenomenon is unclear, but a "local Frank-Starling response" (whereby augmentation of myocardial blood volume leads to increased sarcomere separation) appears to be the most likely explanation. In addition, an indirect sympathomimetic response to dipyridamole-induced ischemia may contribute to improvement of regional function, as may resolution of ischemia secondary to improvement of coronary perfusion. Dipyridamole is used for this purpose in low-dose and "infralow-dose" protocols; the choice of agent is dependent on local expertise and preference.

Viable segments are characterized by reduced resting function, which augments in response to low-dose dobutamine (usually 7.5 to 10 mcg/kg/min, although we extend this to 20 mcg/kg/min if long-acting beta-blockers such as carvedilol are being used). There is continued augmentation if there is a patent infarct-related artery or the tissue is well collateralized. In the presence of a stenosed infarct-related artery, an increasing proportion of segments become ischemic as the heart rate increases.[98] This initial improvement followed by deterioration in function constitutes the "biphasic response," which is strongly predictive of eventual functional recovery of the tissue.[98] A uniphasic response or a classic ischemic response is less predictive of the recovery of resting function. Because the biphasic response is the most reliable finding (Fig. 16-9), our preference is to induce ischemia whenever possible by proceeding to maximal stress (i.e., 40 mcg/kg/min dobutamine with or without atropine), rather than using a separate "viability" or low-dose protocol. In patients with severe LV dysfunction, this approach warrants caution, and early termination may be needed if ischemia is progressive or if other responses might induce instability. Finally, viability studies are the most difficult to interpret; we usually compare multiple low doses, using continuous videotape recording if there is uncertainty.

The response of regional function to dobutamine is influenced by the extent of viable tissue, the degree of residual stenosis, the extent and magnitude of collaterals, the size of the risk area (which influences tethering), and the presence of drug therapy.[99] The uniphasic response is ambiguous—it may be caused by part of the wall augmenting (i.e., admixture of scar

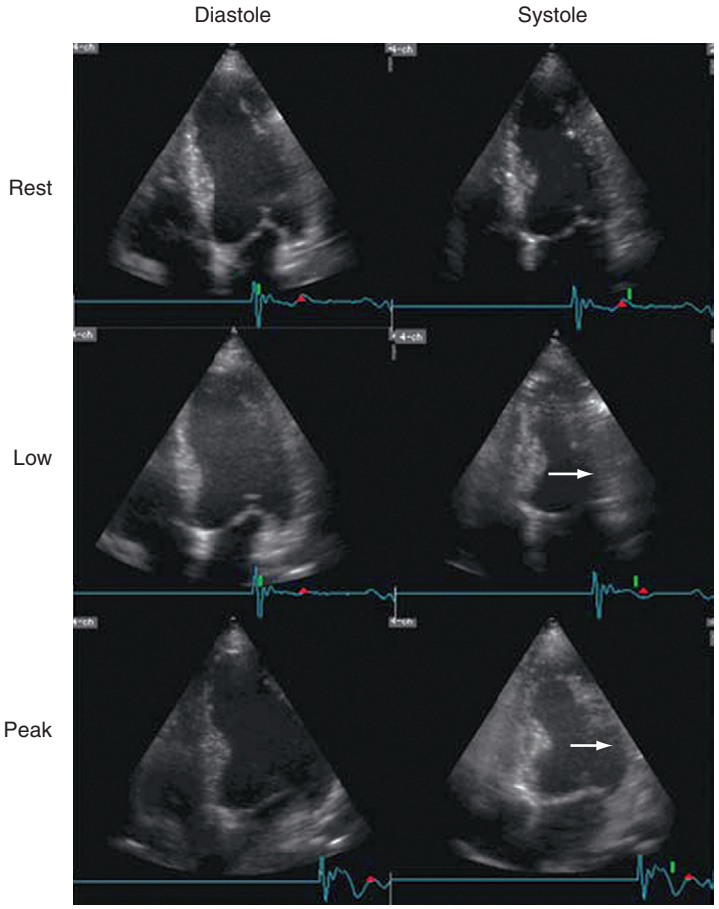

**Figure 16-9 Biphasic response to dobutamine stress.** Apical four-chamber diastolic (*left*) and systolic (*right*) views at rest (*top*), with low-dose dobutamine (*middle*), and with peak-dose dobutamine (*bottom*), illustrating reduced systolic thickening at rest, increment with low dose, and deterioration at peak dose in the lateral wall.

and normal tissue) or all of the wall mounting a partial response (i.e., viable myocardium). The ability to discriminate the extent of subendocardial damage, with its implications for the likelihood of subsequent functional recovery, is poor. The augmentation of function is dependent on delivery of more substrate; thus, tissue supplied by more severe stenosis may become ischemic before it augments function, which may compromise the recognition of viability.

The accuracy of dobutamine for prediction of regional functional recovery has been studied in a number of small trials, which Schinkel and colleagues[100] have combined in a meta-analysis of 1421 patients from 41 studies, showing a sensitivity of 80% and a specificity of 78%. The overall sensitivity of dobutamine appears greater than that of dipyridamole stress (approximately 60%), although the specificity of the former is less (78% versus 87%). Nuclear approaches are more sensitive but less specific than these techniques (Fig. 16-10).

## PREDICTION OF RECOVERY OF GLOBAL FUNCTION AND OUTCOME

Improvements in ejection fraction, exercise capacity, and outcome are goals of revascularization, whereas most studies have focused on improvement of LV function within individual

segments. Stress echocardiography can be used to predict improved global LV function after revascularization. Earlier work on this topic proposed that the identification of 4 of 16 viable (biphasic) segments at DSE gave 89% sensitivity and 81% specificity for prediction of a significant (5%) improvement in ejection fraction.[101] However, the meta-analysis just mentioned[100] showed that a variety of thresholds (13% to 25% of the LV showing a viable response) produced a sensitivity of 57% and specificity of 73%. The global ventricular response to low-dose dobutamine may be a better predictor of global functional recovery.[102] A large number of thinned and akinetic segments or large ventricular volumes imply a low likelihood of recovery.[103] The revascularization of patients with adequate amounts of viable myocardium (usually greater than 25% of LV mass) is associated with improved functional class. A recent meta-analysis of 4167 patients in 29 studies showed that the threshold extent of viability for association with improved outcome was 36% (95% CI: 32% to 40%) by stress echocardiography, 39% (95% CI: 28% to 50%) by SPECT, and 26% (95% CI: 17% to 35%) by positron emission tomography.[104] Viable myocardium may influence survival in two ways. First, revascularized viable tissue may lead to improved function and thereby improved outcome.[105] Second, nonrevascularized viable tissue may be unstable and act as a substrate for recurrent events,[106] including mortality.[105]

The clinical value of viability assessment has recently been questioned in the light of the STICH trial, funded by the National Institutes of Health.[96] This nonrandomized substudy of patients with coronary artery disease and LV dysfunction, participating in a randomized trial of medical therapy with or without coronary artery bypass graft, showed nearly 50% of patients to have evidence of extensive viability by either SPECT or DSE. Mortality was less common among patients with extensive viable myocardium (37 versus 51%; hazard ratio for death among patients with viable myocardium, 0.64; 95% CI: 0.48 to 0.86; $p = 0.003$), but there was no significant interaction between viability and treatment ($p = 0.53$). It is unclear to what extent these findings will alter the use of viability testing, which is often used to better understand the balance of risk and benefit of intervention, in the context of a variety of other variables. The results of these nonrandomized findings from STICH are balanced by a multicenter study showing that in patients with coronary artery disease and severe LV dysfunction who demonstrated myocardial viability, revascularization improved survival compared with medical therapy.[105]

## New Technologies

### IMAGE QUALITY

#### *Contrast Echocardiography for LV Opacification*

Although perfect image quality is certainly not essential for a stress echocardiographic study to be interpretable, it certainly favors concordance between observers[20] and facilitates an accurate diagnosis of disease extent and distinction of ischemia and scar. The use of contrast echocardiography may facilitate not only delineation of the endocardial border,[11] but provision of accurate results.[107] The implications of this finding are addressed in another chapter.

#### *Contrast Echocardiography for Assessment of Myocardial Perfusion*

The comparison of myocardial perfusion at rest and during hyperemia is now possible with either high or low mechanical index imaging.[108] The low mechanical index approach allows real-time imaging, which is probably easier during stress than intermittent imaging, and bubble destruction with a high-energy flash allows appreciation of refill, which depends on perfusion (Fig. 16-11). All stressors produce coronary

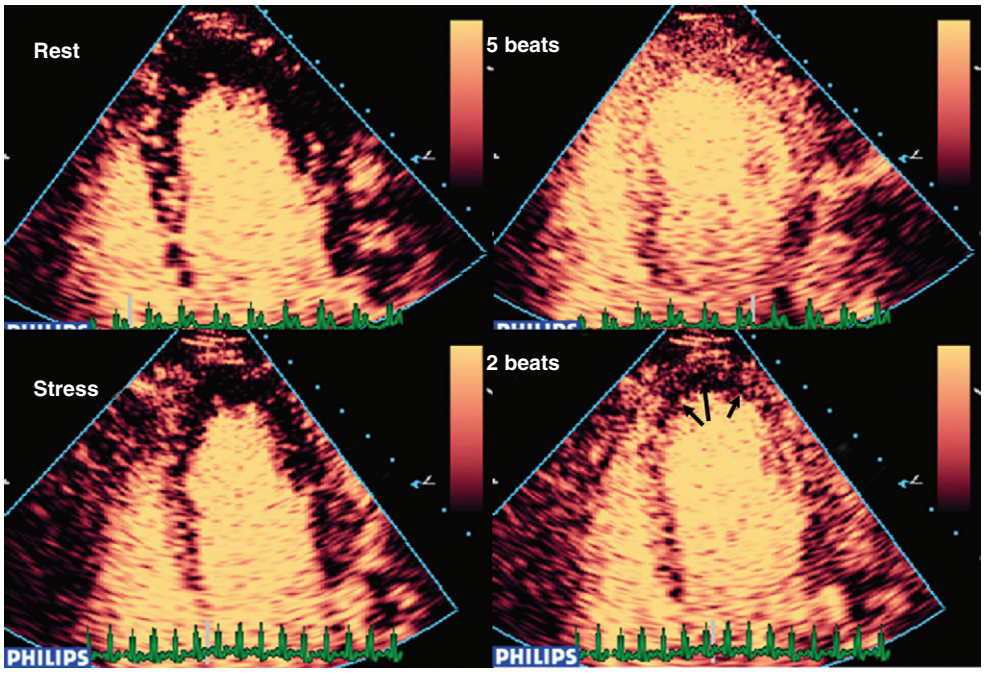

**Figure 16-11 Use of destruction-replenishment imaging to identify evidence of ischemia from perfusion as well as wall motion.** *Left*, Immediate postdestruction image (note lack of myocardial contrast) at rest (*above*) and at peak stress (*below*). *Right*, Return of contrast after sufficient time to allow for refill of myocardium. Note apical subendocardial perfusion defect (LV apex, *arrows*) in this patient who did not demonstrate abnormal wall motion.

hyperemia to some degree, although the vasodilator stressors have the most marked effect, and the lack of tachycardia with these agents facilitates imaging. The use of myocardial contrast for LV chamber opacification increase the sensitivity of wall motion assessment (Table 16-5)[109-117] and provide accuracy that is comparable to that of SPECT.[118] In addition, there are limited data to show an improvement of prognostic assessment.[119]

### *Three-Dimensional Echocardiography*

3D echocardiography resolves technical problems introduced by off-axis images and foreshortening of the apex as well as permitting interrogation of subsegmental areas (Fig. 16-12). The feasibility of this technique may be enhanced by the use of contrast for LV opacification.[120,121] The accuracy of stress 3D echocardiography is supported by a limited evidence base,[122,123] and despite major advances, the current version of this technology has limitations in temporal and spatial resolution.[124] Thus, the most prudent strategy is to use 3D echocardiography as an adjunct to standard stress echocardiography.

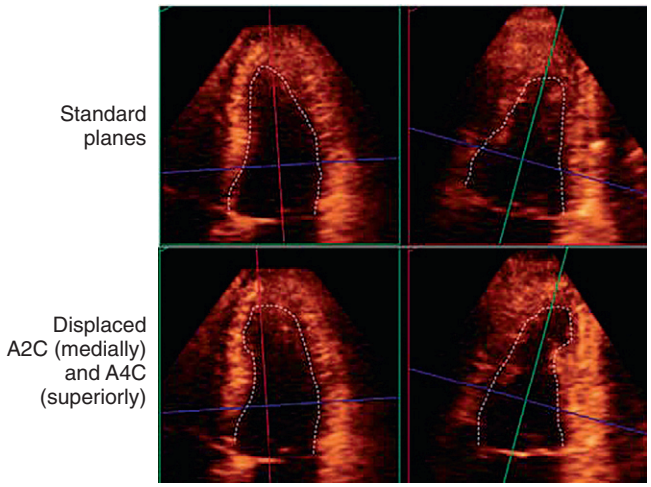

**Figure 16-12 Potential benefit of 3D echocardiography to stress echocardiography by identifying subsegmental wall motion abnormalities.** *Upper* panels, Peak-stress end-systolic freeze-frame images in conventional apical four-chamber and two-chamber views demonstrate homogeneous contraction. *Lower* panels, Off-axis images, with septal displacement of apical two-chamber (*red axis marker* on four-chamber view) and slight superior displacement of apical four-chamber (*green axis marker* on two-chamber view), demonstrate apical shape change consistent with left anterior descending territory ischemia.

## QUANTITATIVE APPROACHES TO INTERPRETATION

The current qualitative algorithm for interpretation of stress echocardiograms requires a significant level of expertise on the part of the observer. A less subjective means of interpretation could improve feasibility and reproducibility. Either semiquantitative or fully quantitative strategies of examining wall motion can be used to evaluate global and regional LV function. Global indices (ejection fraction or end-systolic volume) are insensitive to mild degrees of ischemia and are not an answer to the shortcomings of qualitative interpretation. Wall motion scoring offers a semiquantitative regional approach, which may improve the reproducibility of observers, but this does not constitute a major deviation from the regional approach used by most experienced readers and does not measure function independent of the observer.

The simplest approach to quantitation of regional function involves tracing of endocardial (and/or epicardial) interfaces and their superimposition using a fixed or floating reference system with measurement of endocardial excursion or myocardial thickening. The feasibility and accuracy of this approach has now been documented in several studies,[125] and the tedious and time-consuming process of tracing multiple systolic and diastolic frames has been automated by developments in contrast echocardiography and edge tracking.[126] However, failure to compensate for rotational or translational cardiac movement remains associated with false-positive results, and the method has not found broad clinical use.

Myocardial tissue Doppler may provide another means of quantifying regional function. It has the attraction of quantifying motion in the longitudinal (base-apex) direction, which corresponds to the contribution of longitudinal subendocardial muscle fibers. Peak velocity correlates with wall motion interpretation,[127] ischemia at dual isotope SPECT,[128] and angiographically defined coronary disease.[129] However, problems pertaining to angle dependency and susceptibility to tethering and translational movement make it unsuitable for clinical use.

Strain-rate and strain imaging overcomes the problems of tethering and translation. The measurement of myocardial shortening by this site-specific technique has been extensively validated,[130,131] and it appears that strain is an analog of regional ejection fraction, whereas strain rate corresponds to $dP/dt$.[132] The most successful application of strain rate has been to the assessment of augmentation at low-dose DSE (Fig. 16-13)[133-135]—a low-dose strain rate greater than 1.2/s or an increment of

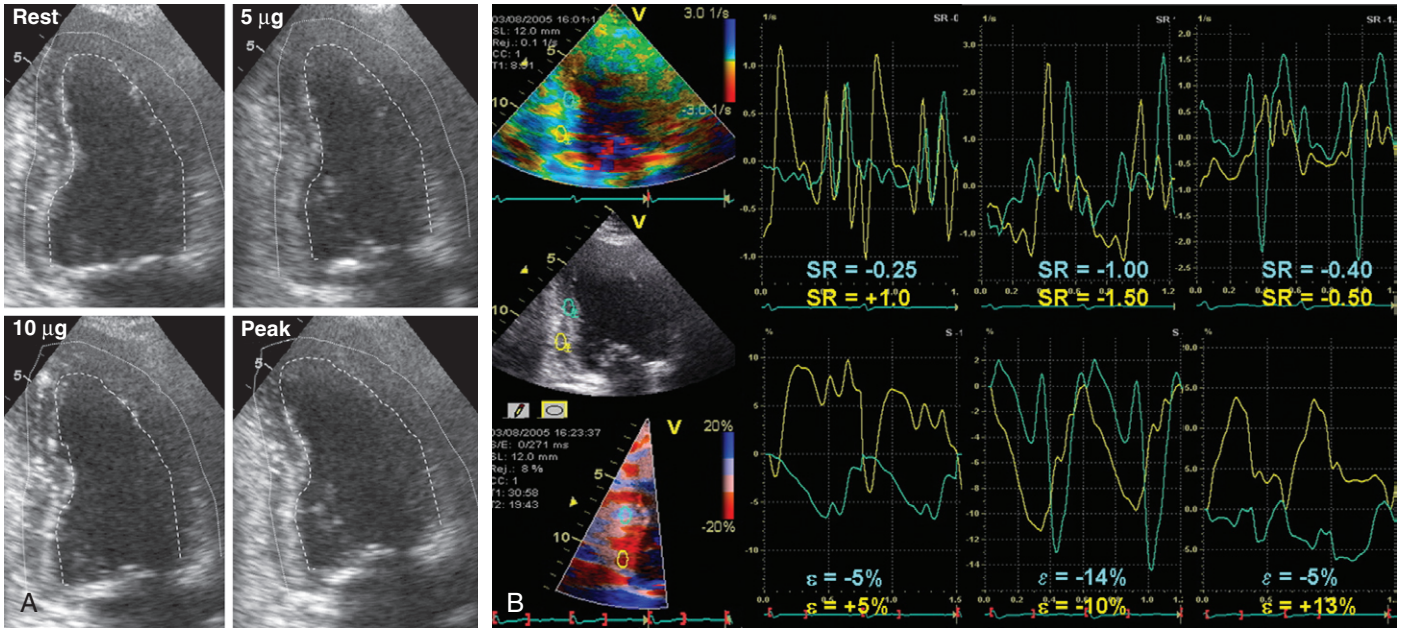

**Figure 16-13 Application of myocardial deformation imaging to stress echocardiography.** End-systolic freeze-frame images in apical two-chamber view (**A**) show less thickening in inferior wall at rest, which improves with low-dose and deteriorates again at peak. However, these changes are subtle; response is more readily identified from deformation imaging (**B**). Basal inferior segment (*yellow*) shows positive strain (ε) and strain rate (*SR*) (lengthening) at rest, shortening at low dose, and lengthening again at peak.

0.6/s is associated with recovery after revascularization. Signal noise is a particular problem for its application with peak-dose dobutamine. Only one small study has suggested it to be superior to wall motion assessment.[136] Others suggest that there may be some value for improving concordance or for less expert readers, without a major increment of accuracy.[137]

The use of speckle tracking (2D strain) offers smoother curves and avoids angle dependency,[138] but it operates at low frame rate and is dependent on good image quality. Limited results suggest it to be inferior to tissue velocity based strain for the assessment of viability.[139] Despite limited encouraging reports, low frame rate appears to limit its role in the diagnosis of ischemia, and image quality in the far field also appears to pose problems for tracking.[140]

## STRESS DOPPLER ECHOCARDIOGRAPHY

The use of Doppler to evaluate coronary flow permits the measurement of coronary flow reserve, effectively adding a marker of perfusion or vascular function to wall motion. The information provided can improve the sensitivity for detection of ischemia, as well as providing information about disorders of coronary vasomotor function and heart failure.[135,141,142] The technique seems most feasible with vasodilator stress but can be performed with dobutamine and after exercise.

Doppler responses to stress can examine systolic or diastolic blood flow alterations caused by ischemia. Unfortunately, this information is of limited value—changes in stroke volume occur mainly in the presence of extensive ischemia, and stress-induced alterations in global cardiac function are not specific for coronary disease. Similarly, ischemia-induced mitral regurgitation is uncommon.[143] However, the use of Doppler to assess low-output aortic stenosis is potentially useful in discriminating the relative contribution of impaired LV function and a stenosed valve; generally, the presence of LV contractile reserve is the most reassuring finding.[144] A stenotic valve usually demonstrates an increment of aortic valve gradient with a stable valve area (Fig. 16-14).

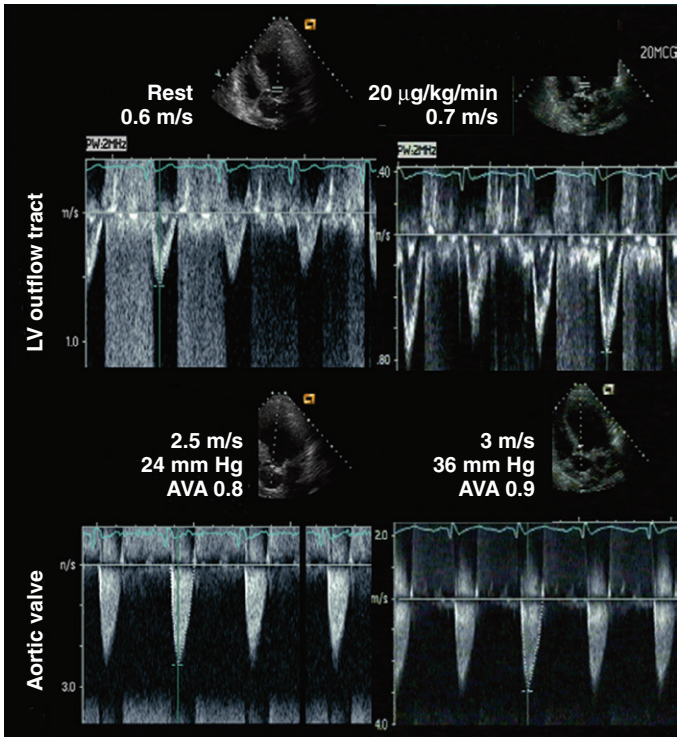

**Figure 16-14 Use of Doppler imaging with low-dose dobutamine stress to evaluate low-output aortic stenosis in a patient with contractile reserve.** Note stable outflow tract velocity with increment of valvular velocity. *AVA*, Aortic valve area.

LV relaxation may be altered by the development of myocardial ischemia. Reductions in passive LV filling (i.e., impaired relaxation secondary to ischemia) may be identified during

DSE[145] but are more feasible with stressors that provoke ischemia without tachycardia, such as dipyridamole and pacing. Tissue-Doppler assessment may be of value in examining regional diastolic function with less influence from left atrial pressure.[146] Changes of diastolic function in response to stress are not specific for ischemia and may be due to LV hypertrophy. An increment of filling pressure with exercise may be a means of identifying the contribution of increased filling pressure to dyspnea, but the value of assessing this during pharmacologic stress is undefined.

## Alternatives

### EXERCISE STRESS TESTING

In patients who are unable to exercise maximally, a nonexercise stressor is mandatory, as the sensitivity of exercise echocardiography is low. In patients who *are* able to exercise, exercise echocardiography is increasingly used instead of the stress electrocardiogram. Although this strategy is contrary to the ACC/AHA guidelines,[90] it may be cost effective.[147] The advantages of pharmacologic approaches are feasibility, better image quality, and ability to image the heart during stepwise increments of stress as well as at peak stress. Pharmacologic stressors probably give accuracy similar to that of exercise stress (Table 16-6).[24,25,27,29,148-151] The reported greater feasibility of nonexercise techniques may be colored by greater expertise in pharmacologic than in exercise echocardiography at some centers. The greater extent of ischemia with exercise than with dobutamine may reflect the greater cardiac workload imposed by exercise—this more extensive ischemia may lead the observer to be more confident in the results of exercise, despite the image quality being better with dobutamine. Electrocardiographic data are useful with exercise stress and less so with pharmacologic stressors, and data about exercise are readily extrapolated to everyday life. Exercise capacity data are prognostically important. Because exercise echocardiography offers more data than the nonexercise approaches, we limit the use of exercise-simulating techniques to patients who are unable to perform maximal exercise. However, the new techniques that are adjunctive to stress echocardiography (for example, contrast, tissue Doppler, and acoustic quantification echocardiography) are more easily performed in the stationary patient and may lead to an increase in the number of nonexercise studies in the future. The sensitivity and specificity of the tests in meta-analyses are compared in Figure 16-15.

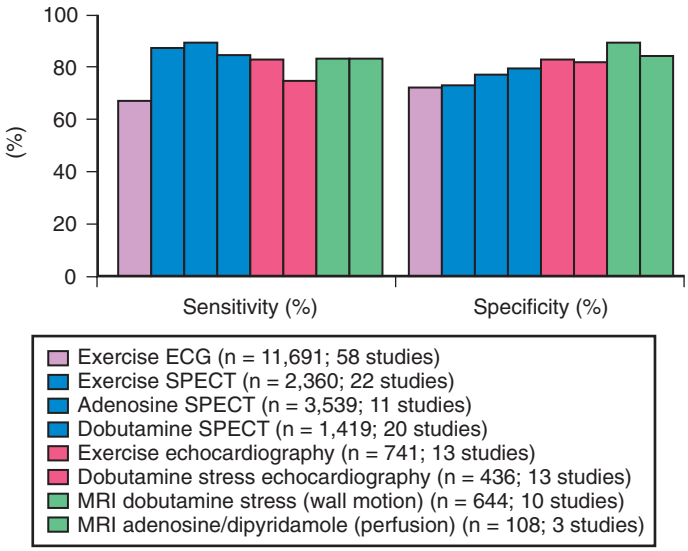

**Figure 16-15 Comparison of stress echocardiography techniques (*red*) with nuclear (*blue*) and magnetic resonance imaging (*green*) in meta-analyses of each technique.** *(Data obtained from O'Rourke RA, Fuster V, Alexander W, et al, editors:* Hurst's the heart: manual of cardiology, *ed 11. New York, 2005, McGraw-Hill.)*

### PHARMACOLOGIC STRESS ECHOCARDIOGRAPHY VERSUS PERFUSION SCINTIGRAPHY

Nuclear perfusion imaging is the most widely used technique for the noninvasive diagnosis of coronary artery disease and is technically easier to perform and interpret than stress echocardiography. However, nuclear imaging has disadvantages pertaining to specificity, cost, and patient convenience. Because there is a substantial variation in the reported accuracy of both stress echocardiography and nuclear imaging, based on variations in the population studied, their relative accuracy in those

who are unable to exercise can best be addressed by direct comparison.

### Diagnosis of Coronary Artery Disease

Scintigraphy and echocardiography have a concordance rate of 80% to 90% for the presence or absence of disease in most studies. A meta-analysis of vasodilator or dobutamine stress with either echocardiography or SPECT showed a consistent message of higher sensitivity with SPECT (especially for vasodilator stress) and higher specificity with echocardiography.[40] Studies comparing stress echocardiography and scintigraphy using dipyridamole, adenosine, dobutamine, or atrial pacing stress are summarized in Table 16-7.[5,35,152-156] Using dobutamine or pacing stress, the sensitivities are comparable, with most studies showing slightly greater sensitivity with scintigraphy. This difference is most evident in patients with single-vessel disease,[157] a finding that might be expected from the identification of flow heterogeneity with perfusion imaging, which is an earlier event in the ischemic cascade than regional dysfunction, identified by echocardiography. Similarly, antianginal therapy may compromise the results of echocardiography because it prevents the development of ischemia with less effect on perfusion scintigraphy. Vasodilator stress echocardiography is significantly less sensitive than perfusion scintigraphy. This difference is most marked in patients with single-vessel coronary disease and reflects failure to develop coronary steal in the absence of extensive coronary disease. This difference is less prominent in patients with multivessel disease.

The specificities of stress echocardiography and perfusion scintigraphy are comparable, with most series showing a small benefit for echocardiography. Two important sources of false-positive results are patients with left bundle branch block and patients with LV hypertrophy. Stress echocardiography appears to show greater specificity in patients with left bundle branch block.[158] Patients with hypertensive hypertrophy are prone to false-positive results with SPECT but not stress echocardiography.[52] Good scintigraphy is always better than poor stress echocardiography, and good stress echocardiography is always better than poor scintigraphy.

Stress MRI is an exciting technique that permits high-resolution imaging of both perfusion (including subendocardial perfusion) and wall motion. However, cost and availability make it seem unlikely that this will become a serious alternative to stress echocardiography for most patients in the near future. Although ischemia detection with MRI and echocardiography has a concordance rate of 80% to 90%, reports of higher accuracy with MRI are based on avoidance of nondiagnostic studies.[159] The evaluation of perfusion with MRI allows the detection of subendocardial abnormalities and may be helpful in the evaluation of disorders of the coronary microcirculation.

### Prognostic Assessment

Although a substantial amount of literature regarding the individual predictive abilities of echocardiography and perfusion imaging is available, comparative data are sparse. In patients undergoing surgery for vascular disease, dipyridamole stress thallium imaging has been shown to have a negative predictive value of more than 90% in most studies.[55] The occurrence of unexpected cardiac events in some patients is probably due to plaque instability at the site of nonsignificant stenoses (which do not cause abnormal perfusion results). The predictive value of ischemia at scintigraphy ranges from 30% to 50%, this result being attributable to positive perfusion studies in the context of mild (prognostically benign) coronary disease and false-positive results. Overall, these results are comparable to those of pharmacologic stress echocardiography (see Table 16-7). Direct comparisons of stress echocardiography and SPECT for the prediction of perioperative cardiac events have shown their prognostic value to be similar.[160,161] A meta-analysis of published work concluded that DSE and SPECT (mainly with dipyridamole stress) had comparable levels of accuracy, with cost effectiveness in favor of echocardiography.[162]

In patients with chronic stable coronary disease and after myocardial infarction, the relative prognostic roles of stress echocardiography and myocardial perfusion scintigraphy appear comparable. Ischemia may be difficult to identify within segments having abnormal resting function, and this is a source of discrepancy from the findings of perfusion scintigraphy.

### Diagnosis of Viable Myocardium

The comparison of positron emission tomography, thallium reinjection techniques, and DSE from meta-analyses is summarized in Figure 16-10; Table 16-8 summarizes matched data.[163-174] Most comparative studies show SPECT techniques to be more sensitive but of lower specificity for the prediction of functional recovery.

**TABLE 16-7 Comparison of Pharmacologic Stress Echocardiography and Single Photon Emission Computed Tomography for Diagnosis of Coronary Artery Disease (>50 patients)**

*NTG*, Nitroglycerin; *SPECT*, single photon emission computed tomography.
*Average ejection fraction 38%.

## The Future of Pharmacologic Stress Echocardiography

Just like the rest of echocardiography, pharmacologic stress echocardiography continues to evolve, and the only certainty in prediction of the future is that it will be different. The major themes of this evolution are likely to be efficacy, quality, and cost factors on one side, and new technologies on the other. As discussed in the chapter, the latter are likely to include perfusion, quantitation, and 3D imaging, with the intent of increasing accuracy, reproducibility, and reading speed. The more pressing (and less predictable) need relates to how the current cost pressures influence pharmacologic stress echocardiography. Part of this process will relate to the application of appropriateness criteria.[89] It will also relate in part to the development of standardized management algorithms, and stress echocardiography is likely to be favored over alternative techniques if quality is maintained.

### KEY POINTS

- Nonexercise stress tests with dobutamine, vasodilators, and pacing are all feasible, although interest in pacing has not been sustained, and all demonstrate satisfactory levels of accuracy.
- Despite greater ease in gathering images, pharmacologic stress is less potent than exercise stress. The resulting lesser extent of ischemia may paradoxically make the interpretation of these studies more difficult than that of exercise.
- The adoption of new technologies such as myocardial contrast, 3D, and myocardial deformation techniques is easier with pharmacologic than with exercise stress.
- Subjective interpretation remains the Achilles heel of stress echocardiography—perhaps even more so with pharmacologic stress echocardiography because of the subtleties of interpreting augmentation of function in viability studies. Measurement of myocardial velocity and deformation offers potential support to interpretation but remains in evolution.

# 17 Echocardiographic Evaluation of Coronary Blood Flow: Approaches and Clinical Applications

NOZOMI WATANABE, MD

**Coronary Anatomy**
**Doppler Evaluation of Coronary Flow**
Technical Aspects
Detection
**Assessment of Coronary Flow Profile**
**Clinical Applications**
Coronary Flow Velocity Reserve Measurement
Noninvasive Diagnosis of Coronary Stenosis
Coronary Flow Measurements in Acute Coronary Syndrome
Coronary Flow in the No-Reflow Phenomenon
Impaired Coronary Circulation in Hypertrophic Cardiomyopathy
Coronary Flow Reserve in Syndrome X and Chest Pain Syndrome
**Alternative Approaches**

Coronary flow velocity and coronary flow velocity reserve measurements provide useful clinical and physiologic information. Previously, coronary flow velocity has been assessed invasively by Doppler flow wire technique in the cardiac catheterization lab. Recent technologic advances in Doppler echocardiography provide noninvasive coronary flow detection by Doppler transthoracic echocardiography (TTE).[1,2] The accuracy of these new noninvasive transthoracic coronary flow and coronary flow reserve (CFR) measurements has been validated compared to Doppler flow wire.[3-7] Doppler TTE is widely available in the clinical setting, and this technique can be performed in an outpatient setting.[8,9] The majority of the clinical data regarding this technique has been reported by European and Japanese groups, but Takeuchi and colleagues[10] did a unique investigation testing the feasibility of transthoracic coronary flow detection in the relatively obese U.S. population and found a similar success rate for recording coronary flow and CFR. Intravenous contrast injection helps in detection of the coronary signal.[11-14] This new, noninvasive imaging technique of the coronary arteries promises to expand the field of diagnostic echocardiography and bring new insight into the pathophysiology of ischemic heart disease.

## Coronary Anatomy

It is important to understand the coronary arterial anatomy for assessment of coronary flow by Doppler TTE (Fig. 17-1). The left and right coronaries originate from the left and right coronary sinuses of the aortic root. The left main coronary artery bifurcates into the left anterior descending (LAD) artery, which runs over the anterior interventricular sulcus, and the left circumflex (LCx) artery in the left atrioventricular sulcus. The LAD artery often around beyond the apex. In this situation, the LAD artery extends up the posterior interventricular sulcus. The septal branches arise at an acute angle from the LAD artery, coursing close to the endocardium on the right side of the interventricular septum. The LCx artery is the other principal vessel originating from the left main coronary artery. It is covered by the left atrial (LA) appendage in its proximal portion, and then courses along the left atrioventricular sulcus. The right coronary artery (RCA) has its origin at the right coronary aortic sinus and follows the right atrioventricular sulcus. The posterior descending artery lies in the posterior interventricular sulcus.

## Doppler Evaluation of Coronary Flow

### TECHNICAL ASPECTS

There are some important technical issues for detecting coronary flow signals. First, a good high-resolution and high-sensitivity ultrasound system with a high-frequency transducer is required (7 to 12 MHz for mid to distal LAD artery; 2 to 5 MHz for proximal LAD artery, RCA, and LCx artery). Second, in color Doppler imaging, the Doppler velocity range should be set in the range of 10 to 30 cm/s to detect the coronary flow signal because the blood flow velocity is relatively slow. In cases in which it is difficult to detect a coronary flow signal, intravenous injection of contrast agent enhances the Doppler signal intensity.[5,11] The contrast enhancer used in the most studies was Levovist (Schering AG, Berlin, Germany). Levovist, at a concentration of 300 mg/mL, was administered intravenously by using an infusion pump. The infusion rate is adjusted from 0.5 to 2 mL/min, according to the quality and intensity of the Doppler signal enhancement achieved. By positioning the Doppler sample volume in the coronary flow stream under the guidance of color Doppler flow imaging, the characteristic coronary flow spectrum, with biphasic predominantly diastolic flow velocities, can be recorded. In the pulsed Doppler technique, angle correction is required depending on the direction of coronary flow.

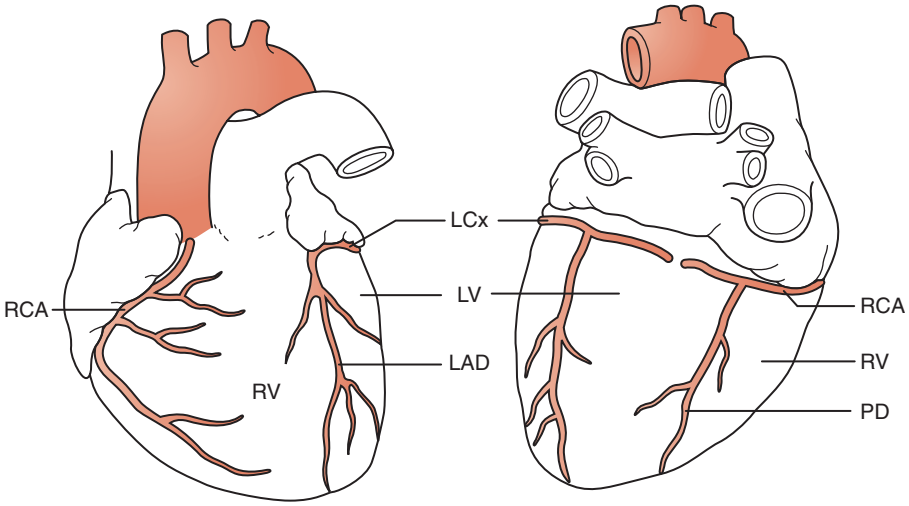

**Figure 17-1 Anatomic position of epicardial coronary arteries.** Left and right coronary arteries originate from the left and right coronary sinuses, respectively. Left anterior descending artery (*LAD*) runs over the anterior interventricular sulcus toward apex. Left circumflex artery (*LCx*) runs along the left atrioventricular sulcus. Right coronary artery (*RCA*) runs along the right atrioventricular sulcus, and the posterior descending artery (*PD*) runs in the posterior interventricular sulcus. Thus, landmarks for searching coronary flow by TTE are interventricular sulcus and atrioventricular sulcus.

## DETECTION

### *Left Main and Proximal Coronary Arteries*

Patients should be examined in the left lateral decubitus position. To visualize the left main trunk and proximal left anterior descending artery, start with the image plane at the level of the aortic root, in a short-axis view (Fig. 17-2, *A*). This part of the exam can be performed using a relatively low-frequency transducer (2 to 4 MHz). The left main trunk is identified as a tubular structure that originates from the left coronary sinus. By adjusting the orientation of the ultrasound beam toward the distal side of the left main trunk, the proximal LAD artery, which runs from the bifurcation toward the anterior wall of the heart, can be visualized using color Doppler flow mapping. At the level of the left main bifurcation, the proximal circumflex artery is detected by rotating the transducer clockwise.

The proximal RCA, which originates from right coronary sinus, can be identified at the aortic root, in short-axis or long-axis views (Fig. 17-3).

### *Left Anterior Descending Coronary Artery*

In the short-axis images of the left ventricle (LV), the midportion of the LAD artery can be identified as a cross section of the tubular structure containing the color Doppler flow signal, located in the anterior interventricular sulcus (see Fig. 17-2, *B* and *C*). The color Doppler signal in the LAD artery, which typically appears as a red color, is mainly seen in diastole. After confirming its position, rotate the transducer counterclockwise to image the LV in a long-axis view aligned with the intraventricular sulcus under the guidance of color Doppler flow imaging. To visualize the distal portion of the LAD artery, image the LV in a long-axis view starting from the apex and searching for the coronary flow signal around the intraventricular sulcus. In this view, pericardial fluid may appear similar to a coronary flow signal near the epicardium. However, pericardial fluid is seen mainly in systole and can easily be discriminated by pulsed Doppler recording. The coronary flow pattern by pulsed Doppler is biphasic, but pericardial fluid generally has a systolic, bidirectional signal. Once the LAD artery is found as a cross section of the tubular structure containing the color Doppler flow signal, rotate the transducer clockwise (toward the two-chamber view position) to detect the flow signal in the long-axis view (Fig. 17-4). Coronary flow detection in the distal portion of the LAD artery is important, as CFR should be measured distal to any stenosis. Coronary blood flow velocity profiles are recorded by positioning a pulsed sample volume on the color flow signal. The incident angle between the Doppler beam and direction of blood flow should be used to correct the velocity scale.

### *Posterior Descending Coronary Artery*

The posterior descending coronary artery usually is the distal extension of the RCA and runs along the posterior interventricular sulcus toward the apex. After obtaining an apical two-chamber image of the LV, angle the ultrasound beam superiorly to image the posterior interventricular sulcus (see Fig. 17-2, *C*). In this situation a lower frequency probe is recommended because this area is far from the transducer, compared to the anterior interventricular sulcus. Carefully examine this area using color Doppler flow imaging to locate the right posterior descending coronary artery (Fig. 17-5). Though the success rate in detecting coronary flow velocity profile in the right posterior descending coronary artery is lower compared with the LAD artery, a contrast-enhanced Doppler technique improves the success rate.[15]

### *Left Circumflex Coronary Artery*

The LCx artery can be found in the modified four-chamber view (see Fig. 17-2, *D*). It is normally distinguished as a color flow signal running along the basal lateral wall[16] (Fig. 17-6). However, visualization of circumflex arteries is relatively difficult because of their anatomic variations, and furthermore, these vessels are distant from the transducer.

## Assessment of Coronary Flow Profile

Doppler spectral tracings of coronary flow velocity can be recorded by the pulsed-Doppler technique by positioning a sample volume (1.5 to 2.5 mm wide) on the color Doppler signal. Angle correction is needed in each examination. Coronary flow profile provides some useful clinical information, such as coronary flow direction, coronary flow velocity, and coronary flow pattern. Normal coronary flow is characterized by a biphasic flow profile, which consists of a small systolic and a large diastolic flow signal (Fig. 17-7). It should be noted that pulsed-Doppler recording provides coronary flow velocity and not the absolute volume of coronary blood flow. CFR by

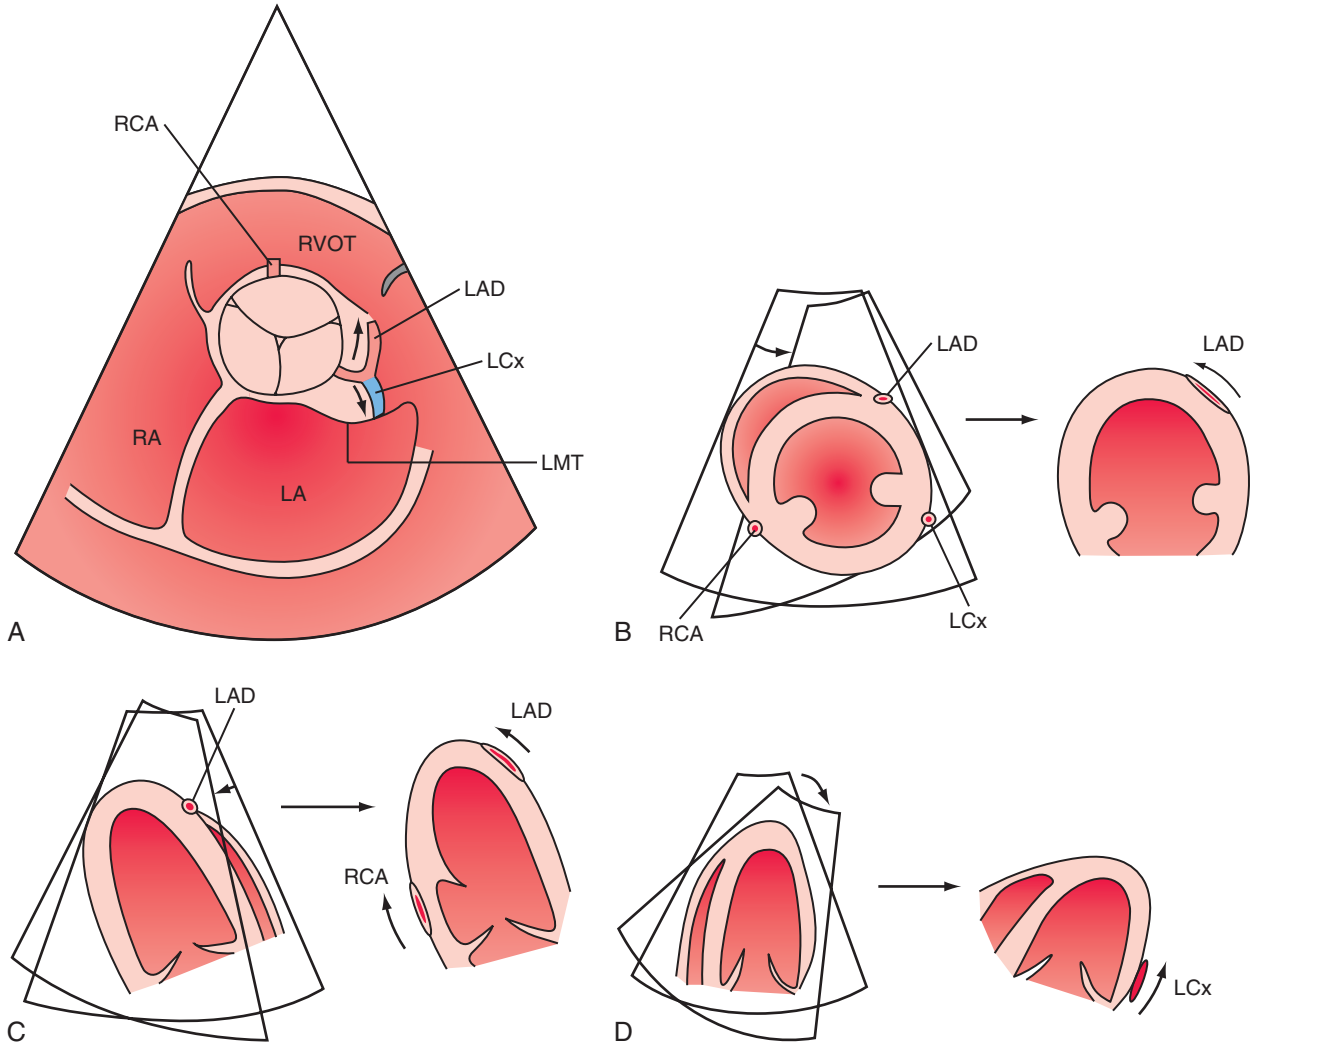

**Figure 17-2 Schematic illustrations of coronary flow detection by transthoracic Doppler echocardiography. A,** Proximal portion of left and right coronary arteries in short-axis view at the level of coronary sinus. The left main trunk (*LMT*) originates from the left coronary sinus, and the right coronary artery (*RCA*) originates from the right coronary sinus. **B,** Position of three coronary arteries in LV short-axis view. Cross-sectional coronary arteries can be observed by color Doppler. Left anterior descending artery (*LAD*) is positioned at anterior interventricular sulcus. LAD signal can be seen longer by counterclockwise rotation. Posterior descending artery (*RCA*) is seen at the position of posterior interventricular sulcus. Left circumflex artery (*LCx*) is seen in a varied position but generally can be found at lateral wall of the LV (3-o'clock to 5-o'clock position). **C,** Detection of distal portion of LAD artery by apical view. Posterior descending artery is visualized in posterior interventricular sulcus. In apical long-axis view, cross-sectional LAD flow can be found. The flow signal becomes longer by adjusting the transducer to look at the interventricular sulcus (clockwise rotation). **D,** Detection of LCx by apical view. The LCx is normally distinguished as a color flow signal running along the basal lateral wall in the modified four-chamber view. *RVOT*, Right ventricular outflow tract.

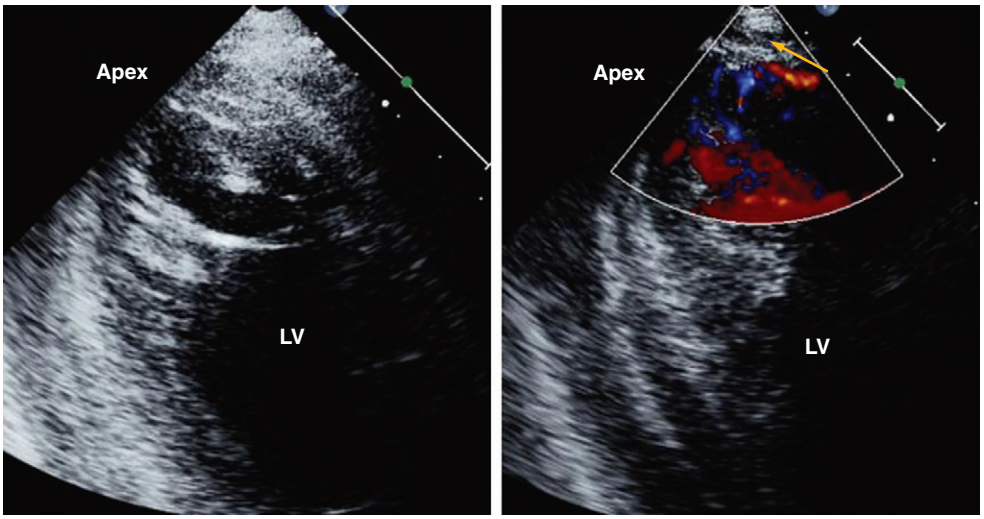

**Figure 17-3 Detection of the proximal portion of left and right coronary arteries (short-axis view at the level of coronary sinus).** The left main coronary artery (*LMT*) originates from the left coronary sinus, and the right coronary artery (*RCA*) originates from the right coronary sinus (*left* panel). Coronary flow signal in the LMT is observed by color Doppler (*right* panel). *Ao*, Aorta; *RVOT*, right ventricular outflow tract.

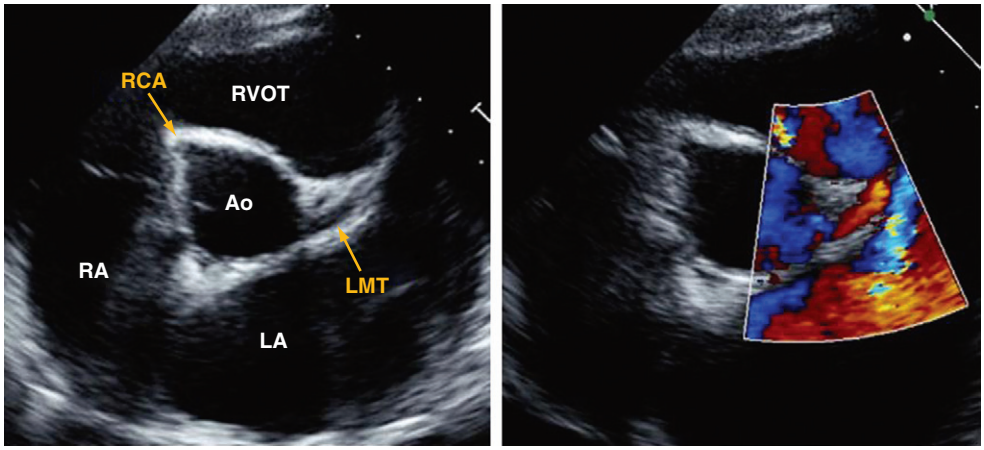

**Figure 17-4 Distal portion of the left anterior descending artery by color Doppler echocardiography.** In modified apical long-axis view, left anterior descending artery flow signal appears as *red* color signal in diastole.

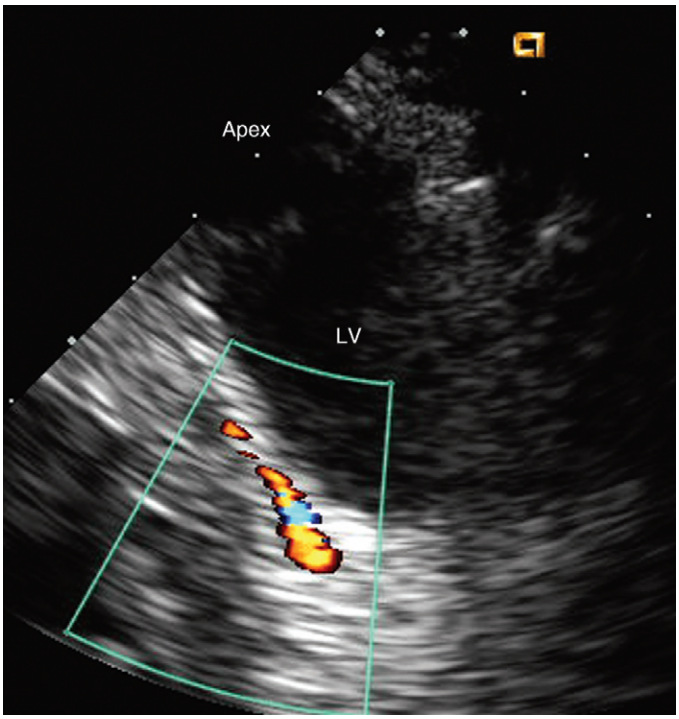

**Figure 17-5** Right coronary artery (posterior descending artery) by color Doppler echocardiography. In modified two-chamber view, posterior descending artery appears as *red* color signal in diastole.

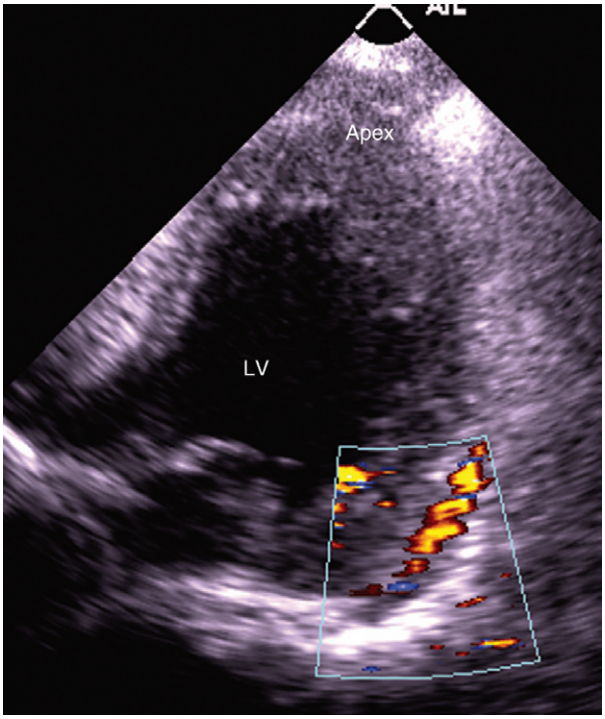

**Figure 17-6** Left circumflex artery by color Doppler echocardiography. Left circumflex artery flow signal is seen at the epicardial side in the lateral wall in modified four-chamber view.

Doppler TTE is derived from changes in the velocity of coronary blood flow, which has been shown to correlate with absolute CFR.

## Clinical Applications

### CORONARY FLOW VELOCITY RESERVE MEASUREMENT

CFR is expressed as a ratio of maximum flow to resting flow (Fig. 17-8). With a normal coronary artery, a vasodilatory stimulus results in an approximately fourfold increase in flow rate compared to baseline. With progressive coronary stenosis, baseline flow remains normal until the coronary artery is narrowed by 80% to 85% diameter stenosis. However, CFR begins to decrease at 40% to 50% diameter stenosis.[17] CFR decreases to two times baseline at approximately 75% diameter stenosis, which indicates myocardial ischemia.

Coronary flow velocity reserve can be alternatively assessed as the ratio of hyperemic to basal coronary flow velocity after drug-induced coronary vasodilatation. Measurements of coronary flow velocity reserve by Doppler TTE have already been established as feasible and accurate.[3,5,6]

After recording baseline spectral Doppler signals in the distal portion of the LAD artery, administer the vasodilator, either adenosine 140 mcg/kg/min as an intravenous infusion for about 1 minute or dipyridamole 0.56 mg/kg intravenously for about 4 minutes, to achieve maximum flow. Then spectral Doppler signals are recorded during hyperemic conditions

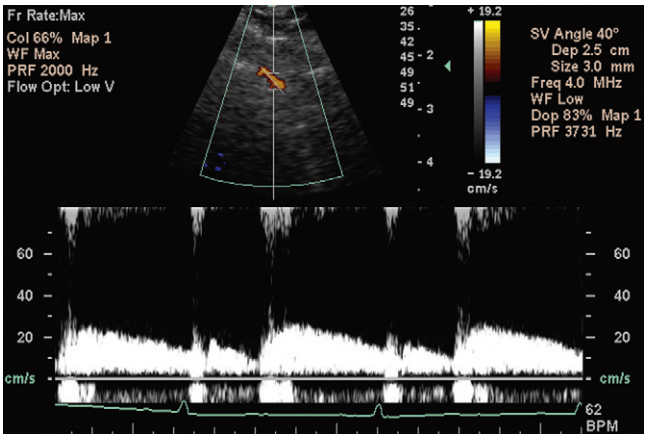

**Figure 17-7 Coronary flow velocity profile in normal subject.** Coronary flow velocity profile is characterized by biphasic flow pattern with small systolic and large diastolic components.

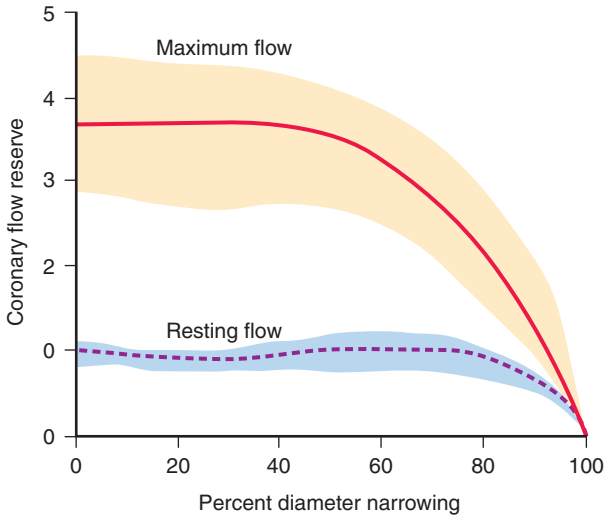

**Figure 17-8 Coronary flow reserve (CFR) and percent diameter stenosis.** With progressive coronary stenosis, baseline flow remains normal until the coronary artery is narrowed by 80% to 85% diameter stenosis. However, CFR begins to decrease at 40% to 50% diameter stenosis for a vasodilatory stimulus, increasing flow normally to four times baseline. CFR decreases to two times baseline at approximately 75% diameter stenosis. *(From Gould KL, Lipscomb K: Effects of coronary stenoses on coronary flow reserve and resistance.* Am J Cardiol *34:48-55, 1974.)*

(Fig. 17-9) with measurement of the mean diastolic velocity and peak diastolic velocity of each flow spectrum. Coronary flow velocity reserve by the transthoracic-Doppler technique is measured from only diastolic mean velocities and not mean velocities throughout the entire cardiac cycle because, in some cases, cardiac motion makes it difficult to obtain a complete Doppler spectral envelope throughout the cardiac cycle. However, previous studies have reported that the ratio of hyperemic to basal mean diastolic velocity and peak diastolic velocity was useful in the evaluation of functional coronary stenosis. Coronary flow velocity reserve is defined as the ratio of hyperemic to basal peak diastolic coronary flow velocity or the ratio of hyperemic to basal mean diastolic coronary flow velocity. Adenosine starts to act generally in 30 seconds, and the coronary flow velocity

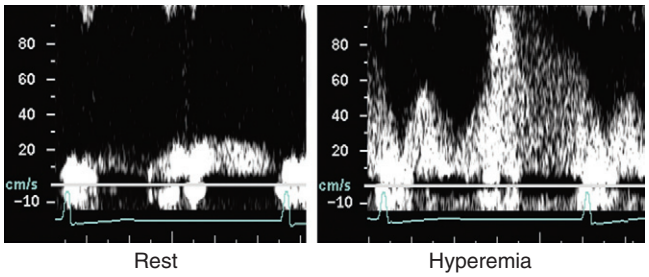

**Figure 17-9 Coronary flow velocity reserve measurement by pulsed-Doppler echocardiography in patient with a normal coronary artery.** Both systolic and diastolic flow velocity increase during hyperemia.

comes to maximum in 1 minute. Dipyridamole starts to act in 4 to 6 minutes and has a prolonged duration of action (about 30 minutes after administration). The short-acting effect is an advantage of adenosine. Although both vasodilators can cause flushing, headache, hypotension, or bradycardia, the adverse effects of adenosine are alleviated immediately after the infusion is finished.

In the clinical setting, some factors that are related to coronary risk factors have been known to affect CFR. Passive smoking has been reported to reduce CFR in healthy nonsmokers, not in active smokers.[18] Another study demonstrated that CFR was significantly higher in nonsmokers than in smokers, and interestingly, oral antioxidant vitamin C increased CFR in nonsmokers but not in smokers.[19] Patients with hypertension showed lower CFR than did normotensive controls[20]; CFR is reduced in diabetic patients, especially in patients with retinopathy[21,22]; and CFR decreased after a single high-fat meal in young healthy men.[23] Because of the noninvasive nature of transthoracic Doppler, it can be used for serial evaluation of drug effects on coronary microcirculation.[24-27] CFR is also reduced in metabolic syndrome[28] and nonalcoholic fatty liver disease.[29] Another study showed that in premenopausal women, CFR varies during the menstrual cycle, and in postmenopausal women, CFR increases after acute estrogen replacement.[30] Noninvasive CFR is expected to contribute to the evaluation of coronary microvascular function in various clinical situation other than ischemic heart disease, such as cardiomyopathy or heart failure.[31] Several papers have reported its usefulness in the assessment of cardiac allograft vasculopathy in patients after heart transplantation.[32,33]

## NONINVASIVE DIAGNOSIS OF CORONARY STENOSIS

### *Coronary Flow Velocity Reserve Measurement Approach*

Coronary flow velocity reserve defined as a mean diastolic velocity increase with hyperemia less than 2 had a sensitivity of 91% to 92% and a specificity of 75% to 86% for the presence of significant LAD artery stenosis.[34,35] Compared with thallium-201 single photon emission computed tomography (SPECT), a mean CFR derived from transthoracic Doppler greater than or equal to 2 predicted reversible perfusion defects, with a sensitivity and specificity of 92% and 90%, respectively.[36] CFR improves after coronary stenting,[37] and a CFR less than 2 had high sensitivity (91%) and specificity (95%) in the diagnosis of in-stent restenosis after coronary intervention.[38] Another paper

similarly reported that CFR less than 2 predicted restenosis determined by thallium-201 SPECT, with a sensitivity of 94% and a specificity of 100%.[39] Furthermore, Voci and colleagues[40] reported that a CFR less than 1, which may reflect coronary steal phenomenon, could discriminate high-risk patients with severe stenosis from patients with nonsevere stenosis. A CFR of 2 or less can be applied to the prediction of the outcome in patients with intermediate coronary stenosis. In the population of medically treated patients with intermediate LAD stenosis (51% to 75% diameter), 30-month event-free survival was higher in patients with normal CFR and lower in patients with decreased CFR (86% vs. 30%).[41]

For coronary stenosis in the right coronary territory, coronary flow velocity reserve measured in the posterior descending coronary artery is useful. Detection of the posterior descending artery is more difficult than that of the LAD artery, but the use of an intravenous contrast injection improves Doppler signal recording.[15] Using the cutoff value of 2 for coronary flow velocity reserve in the RCA, the sensitivity and specificity for detection of significant stenosis were 84% to 91% and 83% to 91%, respectively.[6,15,35] Coronary flow velocity reserve less than 2 in the LCx artery has been reported to have a sensitivity of 92% and specificity of 96% for reversible perfusion defect detected by SPECT.[16]

A Japanese group has tested the feasibility and usefulness of CFR measurements in the three major coronary arteries as a screening examination. They found that the noninvasive technique is a promising tool for the detection of coronary stenosis in patients with chest pain[42] and for the detection of restenosis after coronary intervention.[43] Although each coronary risk factor influences the result of coronary flow velocity reserve, a cutoff value less than 2 was still adequate in terms of the diagnosis of significant coronary stenosis. A cutoff value less than 2 for CFR had a sensitivity of 90%, a specificity of 93%, a positive predictive value of 77%, and a negative predictive value of 97% for the presence of significant coronary stenosis in a population that included patients with various coronary risk factors.[44]

### *Phasic Flow Characteristics and Coronary Stenosis*

Resting coronary flow pattern is characterized by a diastolic dominant biphasic flow. In severe coronary stenosis, diastolic flow decreases, and hence, diastolic to systolic flow velocity ratio decreases at rest.[45] Cutoff points of 1.6 for the ratio of peak diastolic to systolic velocity and 1.5 for mean velocities have high sensitivities and specificities in the detection of severe coronary stenosis (greater than 85%)[46] and of myocardial ischemia compared to thallium-201 SPECT.[47] The diastolic to systolic velocity ratio can be measured in the emergency setting as a simple screening of critical coronary stenosis.[48] Okura and colleagues[49] have reported that these ratio measurements were useful in the differentiation of the ischemic cardiomyopathy from the nonischemic dilated cardiomyopathy. In their study population, a peak or mean ratio less than 1.8 had a sensitivity of 77% and a specificity of 77% for detecting the presence of severe LAD.

## *Direct Measurements of the Coronary Flow Velocity in the Stenotic Site*

### Detection of Proximal Left Coronary Artery Stenosis

In the stenotic site of the coronary artery, color Doppler signal appears as "aliasing" or "mosaic flow." Although transesophageal echocardiography has an advantage in the assessment of left main coronary artery stenosis, mosaic flow and high velocity in the left main trunk can be observed by using transthoracic Doppler echocardiography. Significant left main stenosis can be diagnosed by a mosaic flow and/or peak diastolic velocity of at least 1.5 m/s (sensitivity of 85%, positive predictive value 82.5%).[50] In a similar study of a population with unstable angina, a velocity cutoff value of 47.5 cm/s or greater predicted significant coronary stenosis of the proximal left anterior descending or left main coronary artery with a sensitivity of 88% and specificity of 97%.[51] Okayama and co-workers[52] measured coronary flow velocity in the proximal and distal sites of the left coronary artery to calculate the distal averaged diastolic peak velocity to proximal averaged diastolic peak velocity ratio. A ratio less than or equal to 0.5 predicted significant coronary stenosis with a sensitivity of 91% and a specificity of 72% in their study. However, low success rate in the visualization of the left main coronary artery is a limitation of this technique.

### Prestenotic to Stenotic Flow Velocity Ratio

The location of the coronary artery stenosis can be identified based on "aliasing" of color Doppler. In the diagnosis of significant restenosis (greater than 50%) after coronary intervention in the LAD artery, a prestenotic-to-stenotic mean diastolic flow velocity ratio less than 0.45 had a sensitivity of 86% and a specificity of 93%.[53] Flow velocity measurements were possible for in-stent stenosis with high sensitivity and specificity as well.[54] Another study has investigated three major coronary vessels by color Doppler and pulsed-Doppler echocardiography. Overall sensitivity and specificity was 82% and 92%, respectively, for the detection of greater than 50% stenosis. The sensitivity and specificity were 73% and 92%, respectively, for the LAD artery, 63% and 96% for the RCA, and 38% and 99% for the LCx artery.[55]

### *Detection of Total Occlusion by Retrograde Coronary Flow*

Following occlusion of a major epicardial coronary artery, blood flow to the previously supplied myocardium must arrive via coronary collateral vessels. The retrograde blood flow velocity distal to a totally occluded coronary vessel represents collateral flow to the occluded region. Retrograde LAD flow by Doppler TTE had a sensitivity of 93% and a specificity of 100% for the detection of total LAD occlusion[56] (Fig. 17-10). Retrograde flow in the LAD or septal artery had a sensitivity of 96% and a specificity of 100% for the detection of total LAD occlusion.[57] Retrograde coronary flow detection is also useful in the RCA. Detection of reverse flow in the distal RCA and the inferior septal branches had a sensitivity of 100% and a specificity of 97.8% for identification of occluded RCA (Fig. 17-11).[58] Boshchenko and colleagues[59] have tested the diagnostic usefulness of detecting the total occlusion of coronary arteries by observing the coronary flow direction in the epicardial and intramyocardial collaterals in the three major coronary arteries. They found that the Doppler TTE was a sensitive and highly specific method for diagnosis of LAD and RCA occlusions. Transthoracic Doppler echocardiography can also evaluate intramyocardial collateral flow in patients with total occlusion of epicardial arteries. Pizzuto and co-workers[60] successfully measured collateral function by recording coronary flow velocity during adenosine stress (collateral flow reserve).

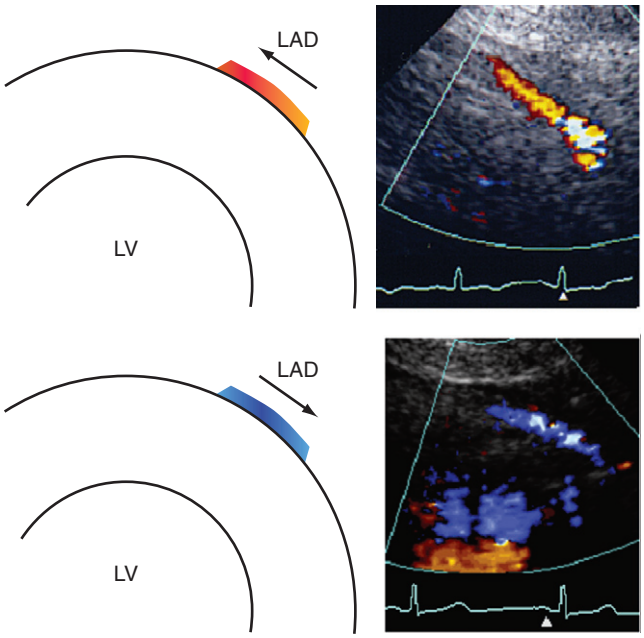

**Figure 17-10 Antegrade and retrograde flow signals.** Normal left anterior descending artery (*LAD*) flow (*upper panel*); retrograde left anterior descending artery flow in patient with total LAD occlusion (*lower panel*). In total LAD occlusion, retrograde coronary flow signal, which reflects the collateral flow, is observed as *blue* color. *(From Watanabe N, Akasaka T, Yamaura Y, et al: Noninvasive detection of total occlusion of the left anterior descending coronary artery with transthoracic Doppler echocardiography.* J Am Coll Cardiol *38:1328-1332, 2001.)*

### *Combination with Stress Echocardiography*

Coronary flow velocity reserve measurements are expected to contribute to the noninvasive diagnosis of coronary heart disease in combination with conventional dobutamine stress echocardiography (DSE). Transthoracic Doppler measurements of CFR with dobutamine have been proven to be comparable to CFR with adenosine in patients with a wide range of LAD diseases.[61] Coronary flow velocity reserve measurements are feasible during dobutamine stress[62] or before dobutamine stress[63] and provide useful additional information in the clinical diagnosis of coronary stenosis. Takeuchi and colleagues[64] have compared the diagnostic accuracy of the contrast-enhanced DSE and CFR measurements during the DSE in the diagnosis of LAD stenosis. They concluded that the diagnostic accuracy of CFR measurement was equivalent to wall motion assessment in the detection of LAD stenosis. Several studies have shown that CFR measurements can provide additional diagnostic or prognostic information over regional wall motion diagnosis by stress echocardiography. Rigo and co-workers[65] assessed the prognostic value of CFR in patients with known or suspected coronary artery disease and negative stress echo. In their study, CFR less than or equal to 1.92 was the best predictor of future events (area under the curve = 0.80, sensitivity = 77%, specificity = 85%), and the 3-year event-free survival was lower in patients with reduced CFR compared with normals (98% vs. 64%, P less than .0001).

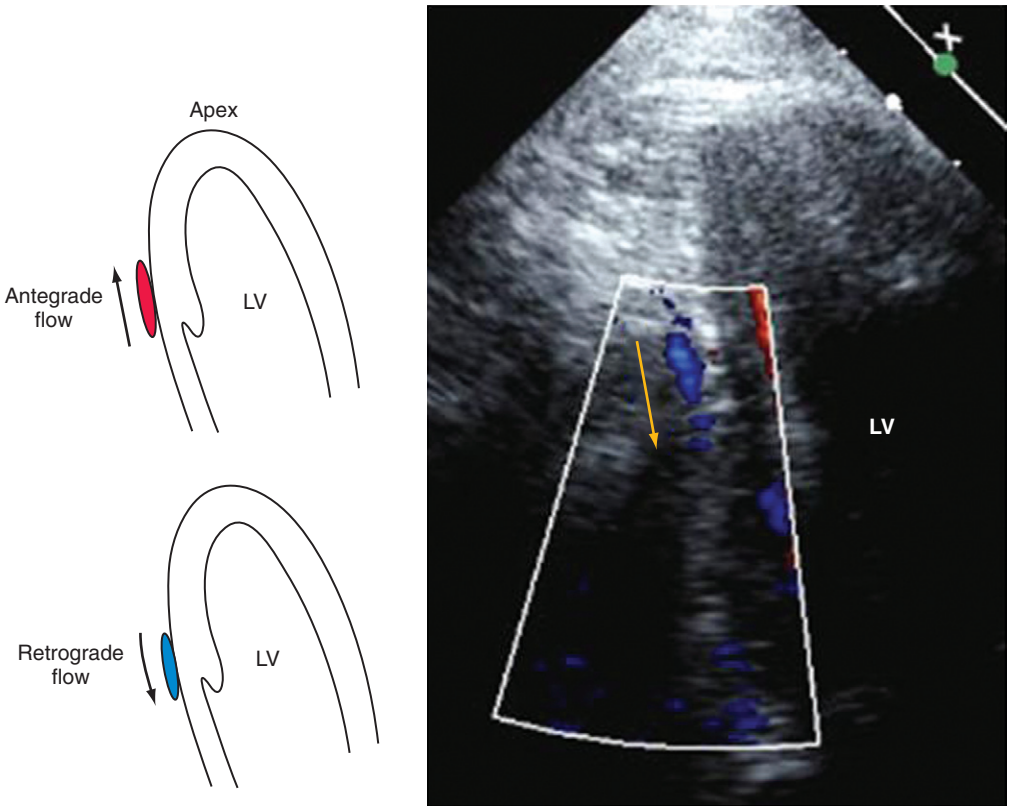

**Figure 17-11 Retrograde coronary flow signal in the distal right coronary artery (posterior descending artery).** Coronary flow signal is observed as *blue* color in patient with total RCA occlusion.

## CORONARY FLOW MEASUREMENTS IN ACUTE CORONARY SYNDROME

Suboptimal coronary reperfusion with thrombolysis in myocardial infarction (TIMI) grade 2 coronary blood flow in acute myocardial infarction adversely affects patient prognosis and requires additional procedures, such as thrombolysis or percutaneous coronary intervention. Doppler TTE enables a rapid noninvasive differentiation of TIMI 3 from TIMI 2 coronary reperfusion in patients with acute myocardial infarction in the acute phase before emergent coronary intervention. The diagnosis of TIMI 3 flow based on a diastolic peak distal LAD flow velocity of at least 25 cm/s by Doppler TTE had a sensitivity, specificity, and accuracy of 77%, 94%, and 89%, respectively.[66] Voci and colleagues[67] have proposed the "open perforator hypothesis" that presence of the perforator signals in the anterior-apical wall by color Doppler TTE reflects adequate myocardial reperfusion, and hence, perforators are early noninvasive markers of myocardial viability. In the coronary care unit, noninvasive transthoracic detection of coronary flow patterns is useful in the direct monitoring of coronary flow augmentation during intraaortic balloon pumping.[68] Evaluation of coronary flow by Doppler TTE gives important physiologic information in addition to the conventional diagnostic examination in acute coronary syndrome.

## CORONARY FLOW IN THE NO-REFLOW PHENOMENON

In no-reflow after coronary revascularization for acute myocardial infarction, coronary flow velocity shows a characteristic to-and-fro pattern, which consists of systolic reversal and rapid diastolic deceleration (Fig. 17-12). This low systolic flow velocity and rapid deceleration time of diastolic coronary blood flow spectrum immediately after primary coronary intervention reflects a greater degree of microvascular damage in the risk area, and evaluation of coronary flow profile after revascularization is useful in predicting recovery of regional left ventricular (LV) function. Optimal cutoff values to predict viable myocardium were 6.5 cm/s for average systolic velocity and 600 ms for diastolic deceleration time (sensitivity, 79% and 86%, respectively; specificity, 89% and 89%, respectively).[69,70] Doppler TTE allows recording of the temporal sequence of coronary flow pattern after coronary intervention. Serial evaluation of the coronary flow velocity profile showed that persistence of abnormal coronary flow pattern can predict LV remodeling after myocardial infarction.[71,72] Clinical studies using transthoracic Doppler echocardiography have proven that shorter diastolic deceleration time and/or lower CFR after percutaneous coronary intervention for the acute myocardial infarction can predict worse outcome of the LV function, myocardial damage, or cardiac events.[73-77]

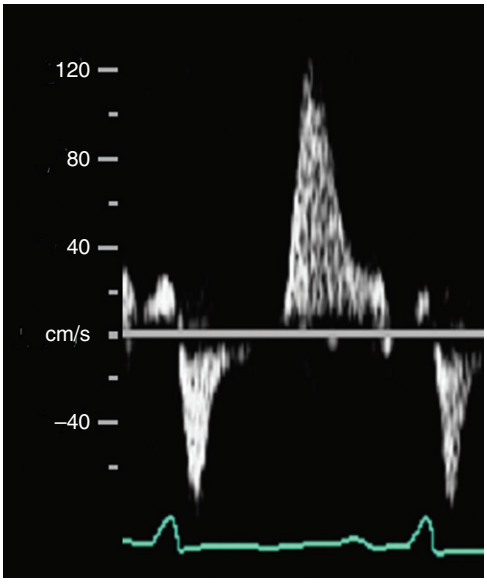

**Figure 17-12 To-and-fro pattern of coronary flow profile in no-reflow phenomenon.** Coronary flow velocity pattern in no-reflow is characterized by a systolic reversal flow followed by a diastolic flow with rapid deceleration. Short deceleration time is a predictor of long-term prognosis.

## IMPAIRED CORONARY CIRCULATION IN HYPERTROPHIC CARDIOMYOPATHY

CFR is reduced in hypertrophic cardiomyopathy (HCM).[78] Several reports have shown the unique coronary flow pattern in HCM, which is characterized by systolic flow reversal and high-velocity diastolic flow. Coronary flow abnormalities in HCM are related to myocardial thickness rather than the degree of outflow obstruction.[78-81] This characteristic is seen in intramyocardial small coronary arteries as well as in epicardial coronary arteries.[82] It has been reported that this unique to-and-fro pattern in the intramyocardial arteries is related to the myocardial ischemia and chest pain in HCM.[83] Serial measurements of the CFR in patients with HCM found that the administration of cibenzoline significantly improved CFR ($2.0 \pm 0.8$ to $3.0 \pm 1.0$), and reduction in the LV outflow tract pressure gradient ($55 \pm 30$ to $23 \pm 18$ mm Hg).[84] Noninvasive Doppler examination of the coronary circulation might contribute to further research in HCM.

## CORONARY FLOW RESERVE IN SYNDROME X AND CHEST PAIN SYNDROME

Several clinical studies have shown the microvascular disturbance in patients with syndrome X. Galiuto and associates[85] have reported that CFR in the LAD was significantly decreased in patients with syndrome X and even more in those with angina pectoris and ST-segment depression during adenosine testing. Lanza and colleagues[86] have evaluated CFR by transthoracic Doppler echocardiography in patients with syndrome X. They compared the data with myocardial perfusion defects detected during dobutamine stress test by cardiovascular magnetic resonance imaging (MRI). They proved the existence of the coronary microvascular dysfunction by reduced CFR that correlated with perfusion defects by MRI. CFR has also been evaluated in chest pain syndrome. Decreased CFR on LAD was associated with increased risk in chest pain syndrome and a normal result of stress echocardiography[87] or normal coronary angiography.[88]

# Alternative Approaches

There are advantages and disadvantages for each imaging modality in the assessment of coronary flow. The greatest advantage of Doppler TTE coronary imaging is that this examination is totally noninvasive and can be easily and repetitively

**TABLE 17-1 Alternative Approaches for Evaluation of the Coronary Arteries**

| | *Advantages* | *Disadvantages* |
|---|---|---|
| X-ray angiography | Full coverage of the coronary arteries; high resolution | Invasive; radiation exposure, needs nephrotoxic contrast agents |
| Transthoracic Doppler echocardiography | Noninvasive; no radiation exposure; portable; cost-effective; physiologic assessment of coronary stenosis (CFR measurement) | Limited sites of coronary detection; low success rate in RCA and LCx (need contrast agent); need vasodilator infusion in measuring CFR |
| Multislice CT | Noninvasive; relatively high resolution; anatomic assessment of coronary stenosis; tissue characterization; plaque volume measurements | Radiation exposure, motion artifacts; not available at calcified lesion; limited accuracy in the diagnosis of coronary stenosis; need a beta-blocker before examination; expensive; nephrotoxic contrast agents; not available in the heavily calcified lesion |
| MRI | Noninvasive; no radiation exposure; anatomic assessment of coronary stenosis; soft-tissue characterization; CFR measurement | Expensive; time consuming; slower acquisition, motion artifacts; interpretable segments are limited by the size of the artery; limited accuracy in the diagnosis of coronary stenosis |

*CFR*, Coronary flow reserve; *CT*, computed tomography; *LCx*, left circumflex artery; *MRI*, magnetic resonance imaging; *RCA*, right coronary artery.

performed at the bedside. The pulsed-Doppler technique is a simple and reliable method for detection of coronary flow profiles. Advantages and disadvantages of each coronary imaging examination are summarized in Table 17-1. An interesting clinical study by Pizzuto and colleagues[89] indicates that CFR can improve the diagnostic accuracy of computed tomographic coronary angiography to detect significant LAD stenosis.[89] In this era of noninvasive cardiac imaging, a combination of imaging modalities would be expected to provide a new standard. Assessment of coronary flow by Doppler echocardiography is a promising tool for an additional examination that can improve the diagnostic approach to all types of cardiac diseases.

## KEY POINTS

- For evaluation of coronary blood flow by Doppler echocardiography, it is important to choose a transducer with adequate frequency and set the color Doppler velocity range around ±20 cm/s.
- The coronary flow signal is mainly observed during diastole.
- The normal coronary flow pattern is characterized by diastolic dominant biphasic flow.
- CFR can be measured by adenosine or dipyridamole intravenous infusion.
- CFR decreases (ratio of hyperemia to rest less than 2) when significant coronary stenosis is present.
- In acute myocardial infarction, a coronary flow peak velocity < 25 cm/s predicts poor reperfusion with ≤ TIMI flow 2.
- CFR reflects intramyocardial coronary microcirculation. CFR is decreased when microvascular dysfunction is present.

Determination of Mechanism

Mitral regurgitation (MR) is a common valvular disorder that is a significant cause of morbidity and mortality in cardiovascular disease.[1-9] Population studies have estimated the prevalence rate of mild or greater MR to be approximately 20%.[10-12] Approximately 30,000 patients in the United States undergo mitral valve surgery annually for significant (moderate or severe) MR.[13] MR can be categorized as primary (valvular) or secondary (ischemic or functional). Primary MR results from abnormalities of the mitral leaflets and chordal structures, such as prolapse, flail, or endocarditis. Secondary MR results from abnormalities of the left ventricle (LV), from either ischemic or myopathic remodeling of the ventricular myocardium that underlies the papillary muscles, which support the mitral valve apparatus. The LV abnormalities result in tethering of the mitral leaflets and incomplete leaflet coaptation. It is important to distinguish the mechanism of MR because therapy is based on whether MR is primary or secondary.

Accurate quantification of MR plays an important role in clinical practice. The introduction of Doppler techniques to echocardiography in the early 1980s transformed the diagnosis and management of mitral valve disease, providing accurate quantification of MR performed noninvasively. Clinical decision making in patients with significant MR, generally considered to be moderate or greater, relies on accurate assessment of both etiology and quantification of MR. This chapter reviews the mechanistic basis and quantification of MR and how these factors guide clinical decision making.

## Mitral Valve Anatomy and Mechanisms of Mitral Regurgitation

### EMBRYOLOGY AND ANATOMY

The mitral valve apparatus forms from delamination of the ventricular myocardium after formation of the atrioventricular valves from the endocardial cushions. The mitral valve apparatus includes the mitral annulus, mitral leaflets, chordae tendineae, and papillary muscles. A detailed knowledge of the anatomy of the mitral valve apparatus is important in understanding mitral valve function and the mechanism of both primary and secondary MR.

#### *Mitral Annulus*

The mitral annulus is a D-shaped fibrous structure formed from the fibrous skeleton of the heart that serves to anchor the leaflets. The mitral annulus has a bimodal or saddle shape, with the anterior and posterior points superiorly oriented (toward the left atrium [LA]) and the medial and lateral points inferiorly oriented (toward the LV; Fig. 18-1).[14] In vitro testing and computer modeling studies have shown that a bimodal shape is optimal for minimizing stress on the leaflets during mitral leaflet opening and closing.[15-18] The anteromedial portion of the mitral annulus, which forms the straight edge of the "D," shares a common wall with the aortic annulus at the attachment of noncoronary and left coronary cusps. This shared wall is called the intervalvular fibrosa (also termed aortomitral curtain) and

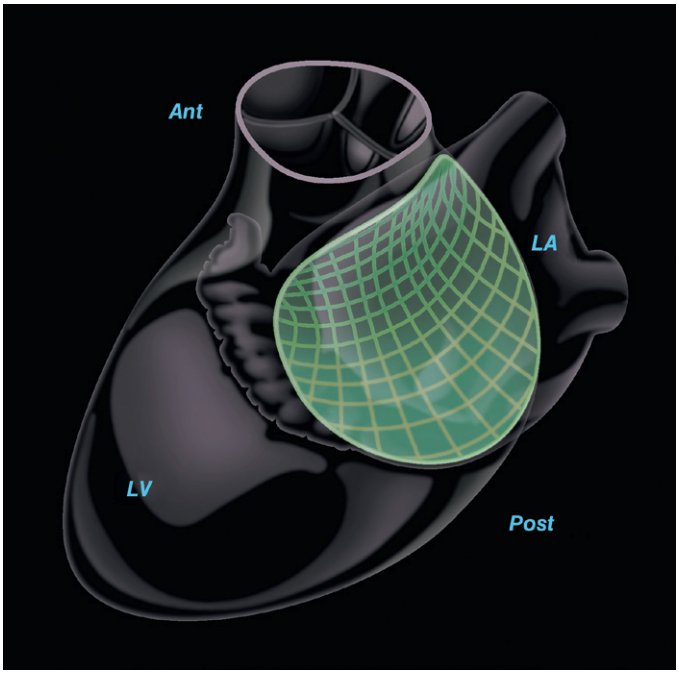

**Figure 18-1 3D reconstruction of the mitral valve annulus.** Image shows bimodal shape and orientation of the superior and inferior points. *Ant,* Anterior; *Post,* posterior.

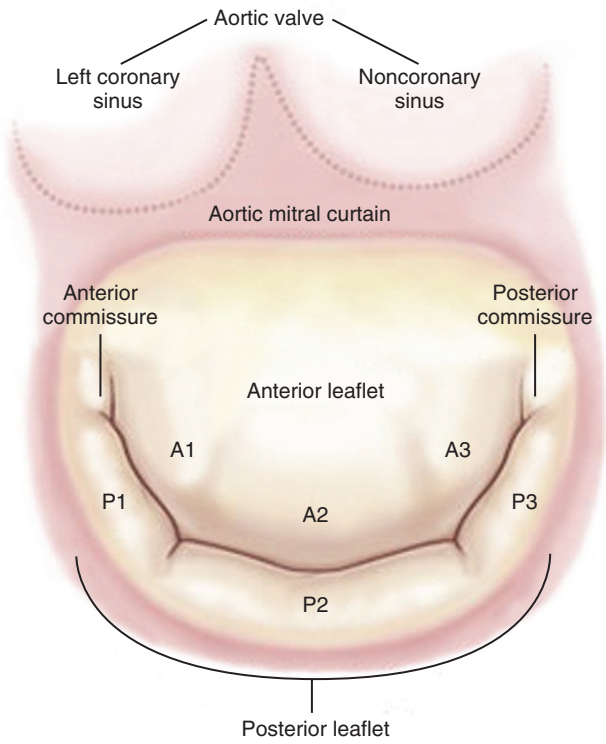

**Figure 18-2 Schematic of mitral valve from LA aspect.** The anterior leaflet is longer than the posterior leaflet but occupies less of the annular circumference. Each leaflet can be divided into three scallops, numbered from lateral to medial, which allows precise description of the location of valve dysfunction identified by echocardiographic imaging.

is more rigid than the posterior annulus as a result of these fibrous attachments. The posterior portion of the annulus accounts for a greater circumferential length than the anterior portion. Because the anterior annulus is relatively fixed compared with the posterior annulus, posterior dilation of the mitral annulus is predominant, although not exclusive; studies have shown that the anterior annulus does dilate, although not to as great an extent as the posterior annulus.[19] The mitral annular area is dynamic throughout the cardiac cycle and is influenced by LA contraction and filling mechanics throughout the cardiac cycle.

### *Mitral Leaflets*

The two leaflets of the mitral valve are referred to as anterior and posterior on the basis of their anatomic location. The broad anterior leaflet has a greater surface area and thickness than the posterior leaflet and accounts for most of the closing surface area of the mitral valve (Fig. 18-2). The anterior leaflet is attached to the anterior mitral annulus through fibrous continuity with the noncoronary and left aortic cusps. The posterior leaflet is crescent-shaped and has overall less surface area than the anterior leaflet, despite a greater circumferential attachment length to the mitral annulus. The shape of the posterior leaflet forms three scalloped segments that are separated by thin clefts between each segment. The anterior and posterior leaflets are attached at the posterior and anterior commissures. A common nomenclature for the leaflet segments divides each leaflet into three segments or scallops that are labeled 1 to 3, with 1 the anterolateral segment, 2 the middle segment, and 3 the posteromedial segment (see Fig. 18-2).

### *Chordae Tendinae and Papillary Muscles*

The mitral chordae tendinae, which typically number 25, are thin fibrous structures composed of collagen interwoven with elastin fibers, which extend from the papillary muscles to attach to the mitral leaflets. The chordae provide the critical functions of anchoring the mitral leaflets during systole, allowing for symmetric coaptation, and preventing prolapse of the leaflets into the LA.

The three types of mitral chordae are named primary, secondary, and tertiary. The primary chordae (also known as marginal chordae) extend from the papillary muscles in a branching pattern to attach along the coaptation line (margins) of the leaflet. These primary chordae are responsible for the primary role of the chordae, which is to maintain coaptation of the leaflets.[20] Rupture or elongation of the primary chordae results in loss of coaptation and development of prolapse or flail leaflet and invariably MR. The secondary chordae (also known as basal or strut chordae) attach at the mid body of the leaflets in the transition zone between the rough and smooth zone of the leaflets. Their main function is to provide the basic support length from the papillary muscle to the leaflet.[20] Secondary chordae are thicker and longer than primary chordae and do not have a branching pattern. Secondary chordae may rupture without compromising coaptation or development of severe MR. The body of each leaflet has a rough zone defined by where the primary chordae attach (the edge of the leaflets to approximately one third of the leaflet body) and a smooth zone (remainder of leaflet body). Tertiary chordae are small in number and arise from the basal myocardium, with attachment to the base of the leaflet to provide structural support.

The chordae are attached to the LV via the papillary muscles. During systole, the papillary muscles contract to facilitate closure of the leaflets via the chordae. The two papillary muscles in the LV are named by their location of origin: posteromedial and anterolateral. The anterolateral papillary muscle is somewhat a misnomer because it is actually located along the

posterolateral wall rather than the anterior wall. Each papillary muscle can have one head, multiple heads, or fused heads from which the chordae extend. Rarely, an accessory papillary muscle that arises from the anterior wall, often close to the septum, is present.[21] In case reports, accessory papillary muscles and associated chordae can insert directly onto the anterior leaflet, or even interventricular septum, resulting in mitral valve dysfunction.[22]

Equal numbers of chordae come from each papillary muscle to insert into each of the leaflets. Chordae that originate from the posteromedial papillary muscle attach to the medial half of each leaflet, and chordae from the anterolateral papillary muscle attach to the lateral half of each leaflet (Fig. 18-3).

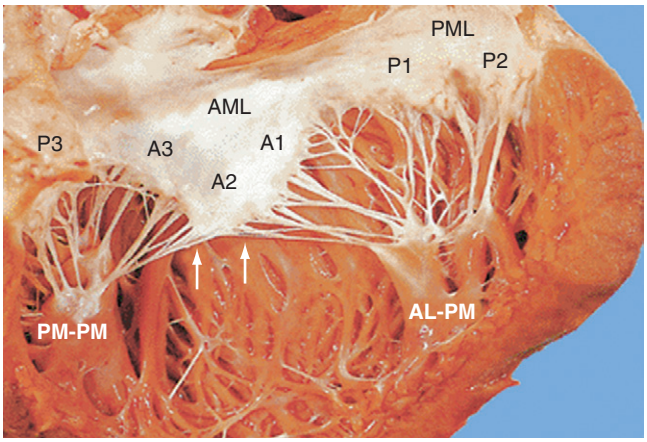

**Figure 18-3 Chordae originating from the posteromedial papillary muscle.** Chordae originating from the posteromedial papillary muscle (*PM-PM*) attach to the medial half of each leaflet (*A3* and half of *A2; P3* and half of *P2*), and chordae from the anterolateral papillary muscle (*AL-PM*) attach to the lateral half of each leaflet (*A1* and half of *A2; P1* and half of *P2*). Primary chordae (*white arrows*) have a branching pattern and insert at the edge of the leaflets. *AML,* Anterior mitral leaflet; *PML,* posterior mitral leaflet. *(Adapted from Mills SE, editor:* Histology for pathologists, *ed 3, Philadelphia, 2006, Lippincott Williams & Wilkins.)*

## MECHANISM OF MITRAL REGURGITATION

Mechanisms of MR can be broadly categorized as primary, in which valvular (leaflets and chordae) abnormalities result in MR, or secondary, in which mitral valve function is abnormal as a result of distortion of the geometric relationships of the mitral valve apparatus and the LV. In the latter, valvular structures are morphologically normal. Table 18-1 summarizes the etiologies of MR based on primary or secondary mechanism.

Mitral valve prolapse is the most common type of primary MR and is defined as displacement of the mitral leaflets during systole of at least 2 mm from the annular plane (Fig. 18-4).[14] Flail leaflet is defined as an eversion of the leaflet segment with loss of the normal concave shape of the leaflet (Fig. 18-5) and is associated with significant, frequently severe MR. Flail leaflet results almost always from rupture of the primary or marginal

**TABLE 18-1 Causes of Mitral Regurgitation**

| | |
|---|---|
| **Primary MR** | Valvular abnormality |
| Degenerative | Mitral valve prolapse, myxomatous changes<br>Ruptured chordae<br>Thickening/calcification |
| Infectious | Endocarditis, vegetations; leaflet perforations |
| Inflammatory | Systematic inflammatory disorders, valvulitis; Libman-Sacks lesions |
| Rheumatic | Leaflet thickening/restricted posterior leaflet mixed mitral disease: mitral stenosis/MR |
| Radiation | Leaflet thickening/restricted posterior leaflet mixed mitral disease: mitral stenosis/MR |
| Drugs | Leaflet thickening/restricted posterior leaflet mixed mitral disease: mitral stenosis/MR |
| Congenital | Cleft mitral valve/endocardial cushion defects |
| **Secondary MR** | Ventricular distortion of mitral apparatus from coronary artery disease or cardiomyopathy |

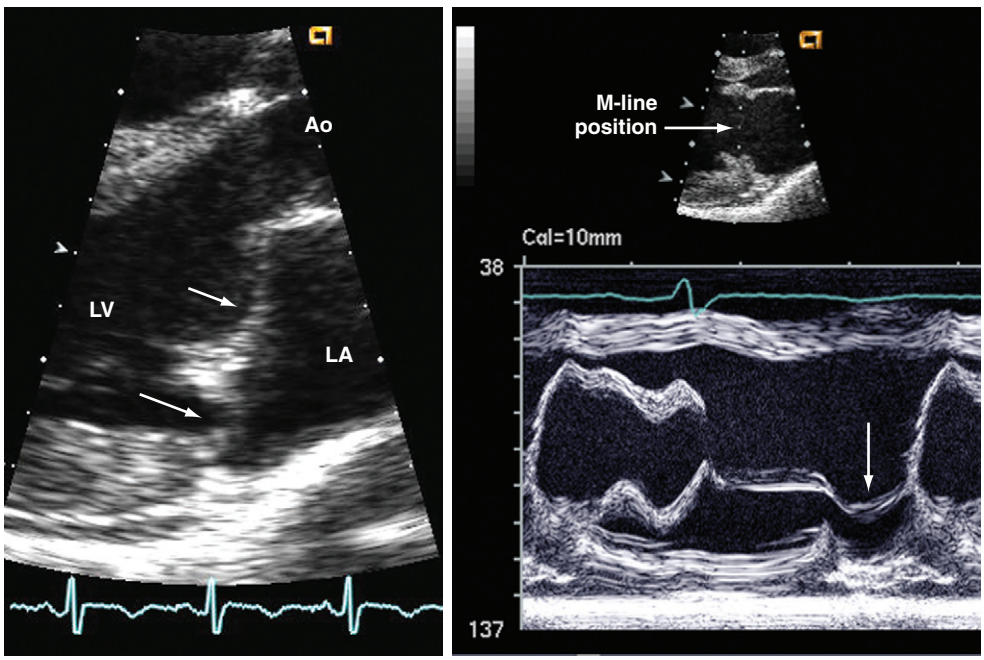

**Figure 18-4 Parasternal long-axis view (*left*) and M-mode recording (*right*) in a young woman with mitral valve prolapse.** Bileaflet prolapse is seen on 2D imaging (*arrows*), and the M-mode shows late systolic posterior motion of the leaflets (*arrow*). *Ao,* Aorta.

chordae. Rarely, elongation of the chordae without frank rupture can also result in flail leaflet. Both conditions lead to loss of leaflet coaptation with a gap at the coaptation line. The prevalence rate of mitral valve prolapse is approximately 2.4% in contemporary studies, and MR as a result of mitral valve prolapse accounts for most of the 10,000 isolated mitral valve surgeries performed annually in the United States.[13,23] With echocardiography, mitral valve prolapse encompasses a spectrum from minimal prolapse to flail leaflet. Leaflet thickness can vary from normal to diffusely thickened and redundant leaflets. The latter is also known as Barlow's disease of the mitral valve, named after Dr John Barlow, and is at the severe end of the spectrum of mitral valve prolapse.[24] Factors that are associated with worse prognosis in the mitral valve prolapse spectrum are leaflet thickness of more than 5 mm, moderate or greater MR, and LV ejection fraction of less than 50%.[4,25-27]

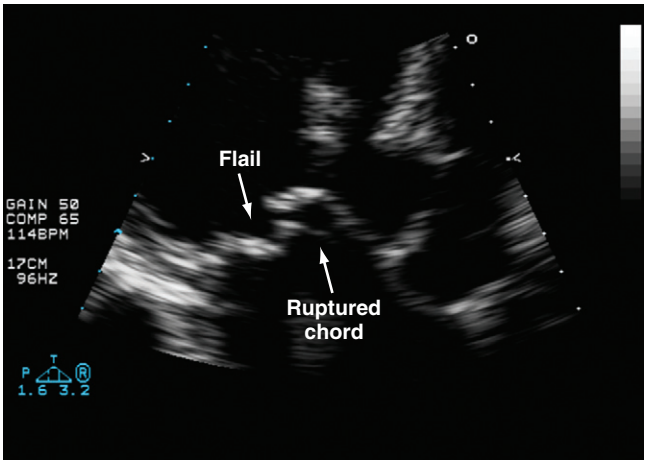

**Figure 18-5 Flail mitral leaflet.** Flail mitral leaflet (*arrow*) occurs when chordal disruption (*arrow;* either rupture or elongation) results in an eversion of the leaflet.

Other valvular causes of MR include endocarditis in which the mechanism includes destruction of leaflet, leaflet perforation, and inflammation with thickening of mitral leaflets that leads to poor coaptation. Less common causes are rheumatic disease (in developed countries) where the mechanism is the result of leaflet thickening and scarring and restricted posterior leaflet motion that prevents complete coaptation (Fig. 18-6), valvulitis from collagen-vascular disease, radiation, and drug-induced mitral valve disease. Calcific mitral annular disease in which annular calcification extends onto the leaflet bodies often results in mixed mitral valve disease with both stenosis and MR present. Congenital abnormalities of the mitral valve make up a small percentage of adult patients with MR. The most common congenital abnormality in the pediatric population that causes MR is mitral valve prolapse, with cleft mitral valve second most common.

Secondary MR results from ischemic or myopathic LV remodeling, which results in lateral displacement of the papillary muscles and tethering of the mitral leaflets and incomplete leaflet coaptation (Fig. 18-7). Secondary MR is a more common mechanism of MR than primary valvular etiologies because the prevalence of ischemic heart disease is much greater than primary mitral valvular disorders. The prevalence rate of development of mild or greater MR after myocardial infarction has been estimated to be up to 50% and is associated with worse prognosis.[5,6,28] Patients who present with congestive heart failure from systolic dysfunction have an approximately 50% incidence rate of moderate or greater MR.[7-9] Ischemic and functional MR are types of secondary MR. Ischemic MR specifically relates to MR that results from coronary artery disease. Papillary muscle rupture is an uncommon but dramatic type of ischemic MR, with 1.0% of patients with myocardial infarction having development of papillary muscle rupture.[29] Ischemic MR can also

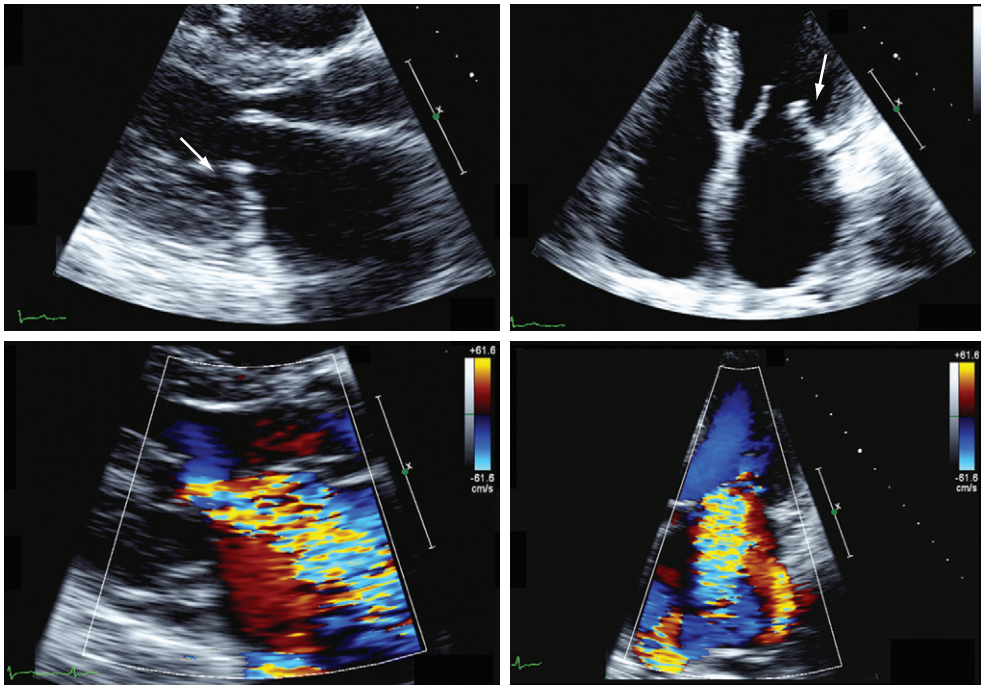

**Figure 18-6 Rheumatic mitral valve changes result in mitral regurgitation.** In rheumatic mitral valve disease, the posterior leaflet becomes rigid (*top panels, arrows*), which results in poor coaptation and mitral regurgitation (*bottom panels*).

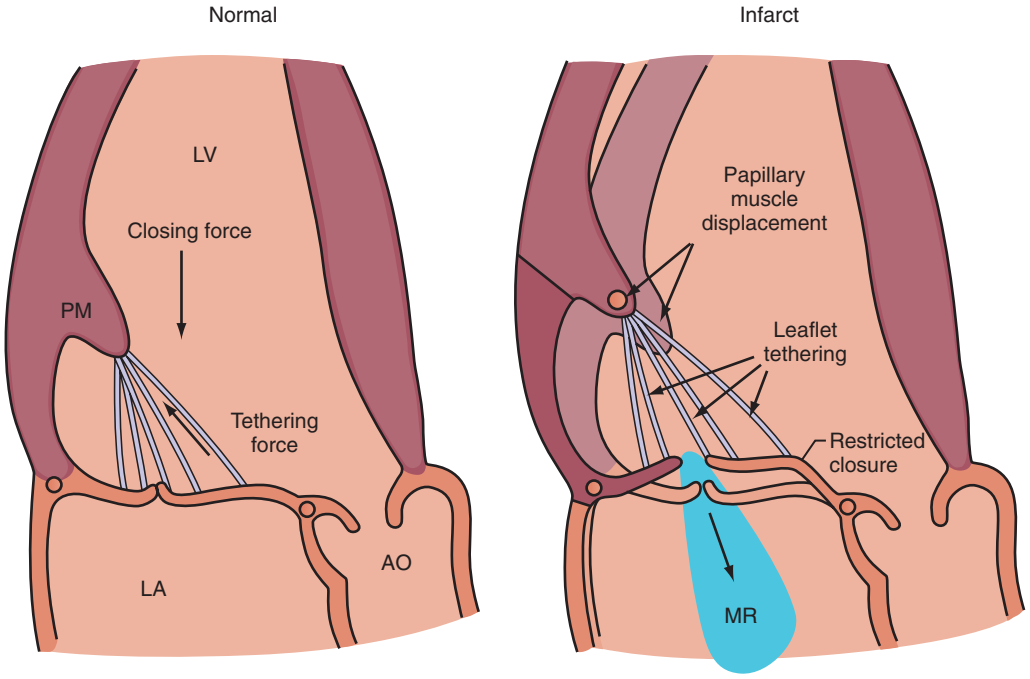

**Figure 18-7 Schematic of mechanism of secondary mitral regurgitation.** This diagram illustrates the mechanism of ischemic mitral regurgitation. *Left,* Balance of forces acting on mitral leaflets in systole. *Right,* Effect of papillary muscle displacement. *Dark shading* indicates inferobasal myocardial infarction. *(Modified from Liel-Cohen N, Guerrero JL, Otsuji Y, et al: Design of a new surgical approach for ventricular remodeling to relieve ischemic mitral regurgitation: insights from 3-dimensional echocardiography.* Circulation *101:2756-2763, 2000.) AO,* Aorta; *MR,* mitral regurgitation; *PM,* papillary muscle.

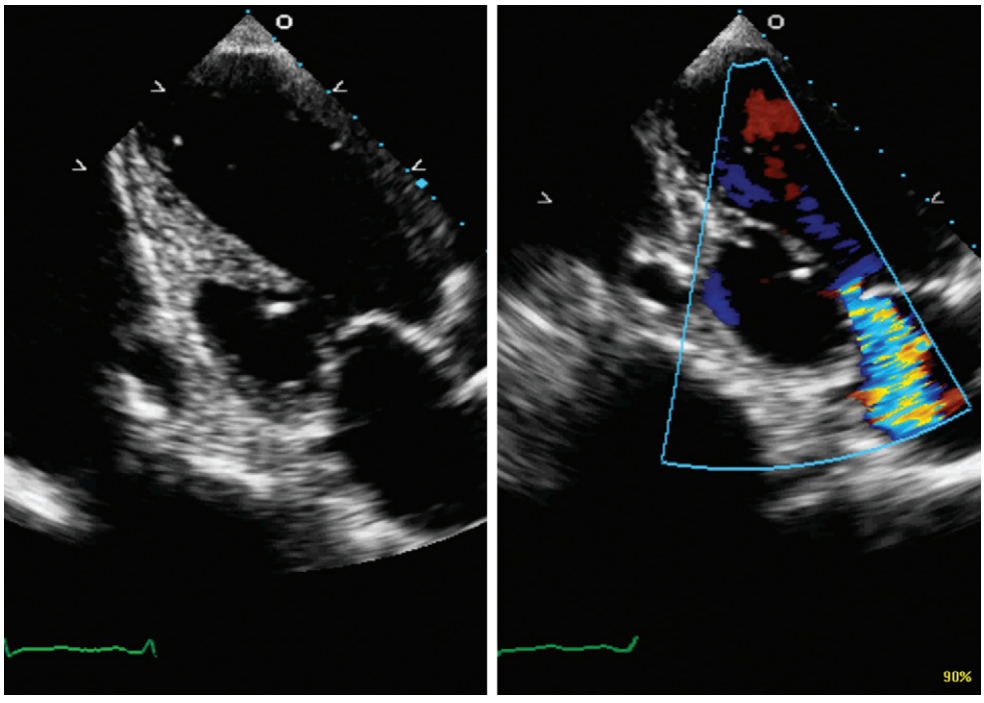

**Figure 18-8 Aneurysm of inferior wall from infarction.** *Left panel* shows aneurysm of inferior wall from infarction, which results in distortion of the LV wall leading to mitral leaflet tethering and restricted closure with development of mitral regurgitation (*right panel*).

develop from acute myocardial ischemia. The MR is in this case is usually transient, resolving once the acute ischemia subsides. By far the more common type of ischemic MR is a result of chronic LV remodeling after myocardial infarction that causes geometric distortion of the mitral valve apparatus.[30] Development of akinesis, scar, or aneurysm of the infarcted or ischemic myocardium underlying the papillary muscles results in lateral displacement of the affected papillary muscles, which in turn leads to tethering of the mitral leaflets and incomplete closure (Fig. 18-8). Echocardiographic features are apical tenting of the mitral leaflets, best imaged in the apical four-chamber view in mid systole; loss of normal convex shape into concave shape; and a bend noted in the anterior mitral leaflet from tethering of the anterior leaflet from a secondary (strut) chord (Fig.18-9). Because the papillary muscles are located along the inferior-posterolateral walls, the incidence of ischemic MR is greater in inferior myocardial infarctions than in anterior myocardial infarctions.[31] However, ischemic MR can develop with any large

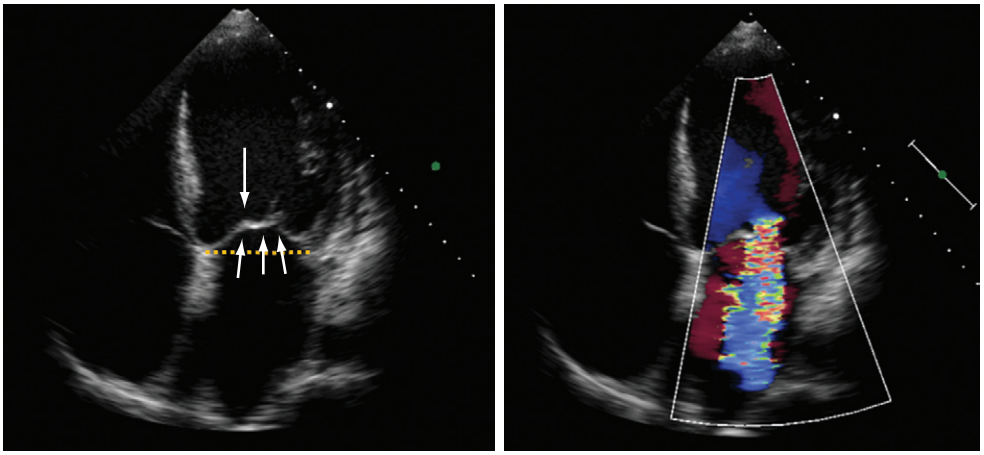

**Figure 18-9 Echocardiographic features of ischemic mitral regurgitation.** Features are apical tenting of the mitral leaflets (best imaged in the apical four-chamber in mid systole), where the mitral leaflets coapt apically instead of at the annular plane (*yellow dashed line*); loss of normal convex shape into concave shape (*small arrows*); and a bend (*large arrow*) noted in the anterior mitral leaflet from tethering of the anterior leaflet from secondary strut chords. These features result in ischemic mitral regurgitation (*right panel*).

myocardial infarction that results in significant LV dilation and remodeling to affect the mitral valve geometry.

Functional MR is a general term that indicates MR resulting from ventricular distortion of the mitral valve apparatus. This can be from a cardiomyopathy or coronary disease. However, functional MR is often used specifically to MR that develops from a cardiomyopathy, to distinguish from ischemic MR. From a mechanistic basis, ischemic (from coronary artery disease) and functional (from cardiomyopathy) MR are similar.

An alternate classification of MR mechanisms proposed by Alain Carpentier[32] is based on motion of the mitral leaflets. In type I, mitral leaflet motion is normal and the MR results from annular dilation. Type II MR is the result of excessive leaflet motion, such as prolapse or flail leaflet. Type III is from restricted leaflet motion and is subdivided into type IIIa and IIIb. In type IIIa, leaflets have restricted motion in both systole and diastole; rheumatic MR falls into this category. Ischemic and functional MR are grouped into type IIIb, where there is restricted motion during systole (Fig. 18-10).

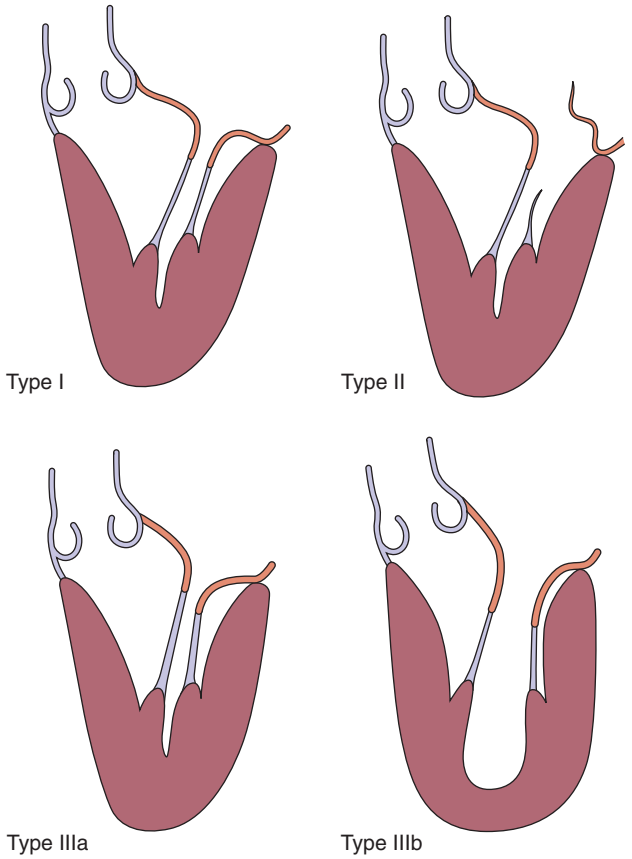

**Figure 18-10 Carpentier classification of mitral regurgitation.** In type I, mitral leaflet motion is normal and the MR results from annular dilation. Type II MR is the result of excessive leaflet motion, such as prolapse or flail leaflet. Type III is from restricted leaflet motion and is subdivided into type IIIa and IIIb. In IIIa, leaflets have restricted motion in both systole and diastole. Rheumatic MR falls into this category. Ischemic MR and functional MR are grouped into type IIIb, in which there is restricted motion during systole. ## Quantification of Mitral Regurgitation

Color Doppler techniques are the most commonly applied method for quantification of valvular regurgitation in clinical practice. The regurgitant color Doppler flow pattern has three components: the proximal flow convergence or proximal isovelocity surface area (PISA), the vena contracta, and the distal jet (Figure 18-11, *left* panel).[33] Principles of fluid dynamics can be applied to these components of regurgitant flow where flow can be considered to approach a finite orifice with flow distal to the orifice entering a constrained receiving chamber. The proximal flow convergence region occurs proximal to the regurgitant orifice (proximal to the leaflets). The vena contracta represents the narrowest point at the level or just distal to the leaflets and represents the effective orifice area and not the anatomic orifice area. The latter is defined as an orifice at the level of the leaflets, whereas the effective orifice area is defined by the narrowest point of the flow steam, which typically occurs just distal to the leaflets as flow continues to converge for a short distance beyond the anatomic orifice (Fig. 18-11, *right* panel).[33] The final component is the distal regurgitant jet, which represents the

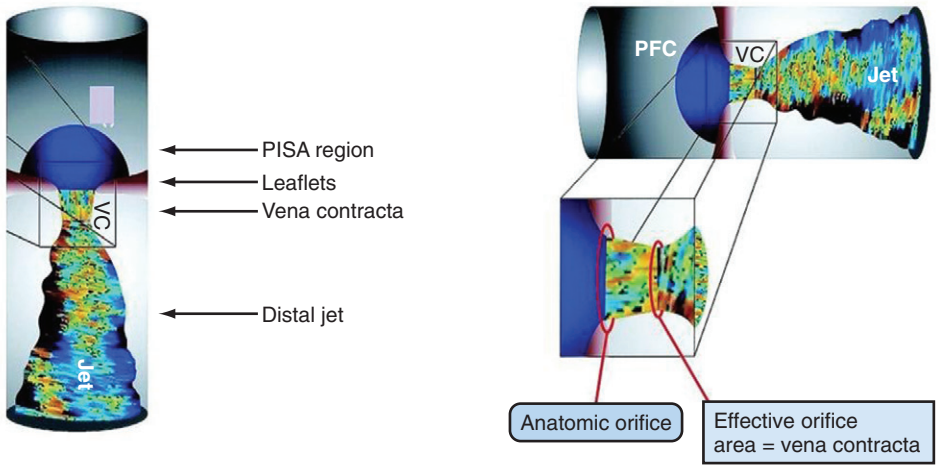

**Figure 18-11 The three components of a regurgitant jet (*left panel*).** The proximal isovelocity surface area (*PISA*) region, also referred to as proximal flow convergence (*PFC*) region; vena contracta (*VC*); and distal jet. *Right panel*: The effective regurgitant orifice area is the orifice area defined by the narrowest regurgitant flow stream and typically occurs distal to the anatomic orifice defined by the valve leaflets. *(Adapted from Roberts BJ, Grayburn P: Color flow imaging of the vena contracta in mitral regurgitation: technical considerations.* JASE *16:1002-1006, 2003.)*

regurgitant flow once it has passed the leaflets and into the receiving chamber. This distal jet is most readily detected and measured but also most subject to external influences present in the receiving chamber.

## COLOR DOPPLER METHODS

### *Distal Jet Area Method*

A standard method for assessment of MR is measurement of the distal MR jet area as it enters the LA.[34,35] The MR jet is defined as the turbulent mosaic color flow within the LA during systole that emanates from the mitral leaflets. Care should be taken to avoid including the low-velocity (nonturbulent) blood flows in the LA surrounding the turbulent jet because this falsely increases the MR jet area. The maximal jet area is traced in multiple views, and an average of the areas is calculated.

The distal jet area method is a relatively simple and commonly applied technique for the qualitative assessment of MR. However, a number of technical and physiologic factors should be taken into account. Assessment of the severity of MR with distal MR jet is based on the assumption that the color Doppler display of MR flow velocities can be a surrogate for MR regurgitant volume. On an empiric basis, this has been validated against angiographic standards. It is important to keep in mind limitations with the color display of the MR flow velocities as a substitute for mitral regurgitant volume. First of all, measurement of the regurgitant jet is taken as the maximal instantaneous valve, whereas regurgitant volume includes the time that the MR flow occurs. In addition, because MR flow occurs in a pulsatile manner, the flow rate is not constant; hence, the relationship between jet velocity and flow rate varies. Because the MR flow is entering a constrained chamber (LA), the behavior of the MR jet is influenced by a number of factors, including physical containment from the LA wall, entrainment of blood pool in the LA into the MR flow, and flow influences from the pulmonary veins.

Eccentric MR jets are subject to impingement from the LA wall, which can result in a decrease in the size of the mitral regurgitant jet. In addition, wall jets are subject to the Coandal effect, which is the tendency of flow to follow adjacent to or along a wall. This effect influences the direction, and ultimately the display, of the MR jet.[36,37] Eccentric jets in which the MR jet courses out of the plane of the ultrasound beam also are missed or underestimated. Because of the limitations with eccentric jets, the jet area method is probably best applied to centrally directed jets.[37,38] Machine settings can also influence the distal MR jet. Over gain, in which there is random color noise present, can overestimate the size of the jet. In contrast, too low gain settings underestimate the jet size. Low Nyquist settings can also overestimate the true MR jet as lower velocity blood flows present in the LA are merged into the true MR jet. In general, Nyquist limits should be at least 50 cm/s for color flow mapping of MR regurgitant jets.

Importantly, distal jet area is influenced by hemodynamic conditions.[38-43] Studies have shown that the size of the regurgitant jet depends to some extent on the driving pressure across the mitral valve, which is dictated by the LV systolic pressure to LA pressure gradient.[40,43] As this gradient is maximal at mid systole, the MR jet tends to be maximal at this time point in the cardiac cycle. Hemodynamic conditions that alter systemic arterial pressure or LA pressure can influence the overall jet size.[39,41]

Typically, the distal MR jet area is normalized relative to the LA area (Fig. 18-12). Comparison studies suggest that normalization for LA size correlates better than absolute jet area compared with angiographic standards.[37,44] The MR jet area and LA area are measured in the same systolic frame to obtain a ratio of jet area to LA area (see Fig. 18-11).[44,45] Fig. 18-13 shows examples of jet areas corresponding to mild, moderate, and severe MR. The maximal MR jet area is traced, and then this area divided by the LA area measured from the same frame. MR jet area to LA area ratios of less than 20% correspond to mild MR, whereas ratios of more than 40% correspond to severe MR (see Table 18-1).[38] Factors that affect the accuracy of the jet area to LA area method are that the jet area to LA area ratio method assumes a relatively linear relationship between jet area size and LA area. However, this is not always the case; in some situations, the actual MR volume is greater than suggested by the jet area/LA area, such as in cases of chronic MR where there has been extensive LA remodeling. Table 18-2 summarizes validation studies for distal jet area methods against comparable standards.

### *Vena Contracta Method*

The vena contracta is the narrowest portion of the mitral regurgitant jet and provides a simple linear measurement of the proximal MR jet.[33,45-51] The vena contracta can be considered to be a surrogate measure of the effective regurgitant orifice area because the vena contracta essentially represents the anterior-posterior dimension of the effective regurgitant orifice area. Measurement of the vena contracta is important to perform in views orthogonal to the coaptation line of the mitral leaflets, such as the parasternal long-axis or apical long-axis views, because this provides the optimal color resolution of the vena contracta as imaged in the anterior-posterior plane (Fig. 18-14). Views that display the MR jet along the coaptation line, such as the two-chamber view (medial-lateral dimension), falsely increase the width of the vena contracta (Fig. 18-15).

Because the vena contracta measurement inherently is within a narrow range, small differences in measurement can make a large impact on MR degree. Care must be taken to optimize the vena contracta region for measurement by magnifying and adjusting depth and sector settings for optimal color Doppler resolution. In addition, defining the "narrowest" portion of the MR jet can be difficult because, in some cases, the neck of the proximal MR jet is not easily seen or is obscured by the leaflets. Measurement of the width of the proximal jet either at the level of the leaflets or just distal to the coaptation line can sometimes

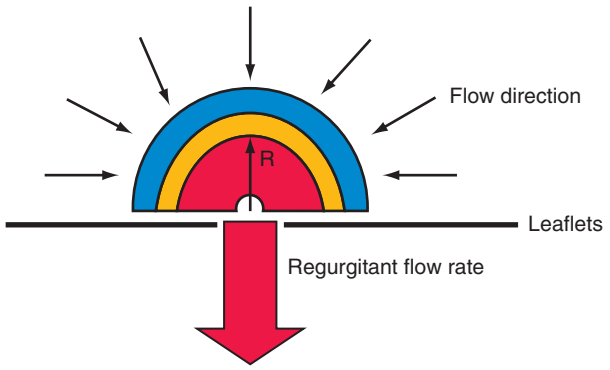

**Figure 18-15 Proximal isovelocity surface area.** Fluid dynamic theory predicts that as flow approaches a circular finite orifice, it forms a series of concentric hemispheric shells with gradually decreasing area and increasing velocity. *Arrows* refer to direction of flow as it approaches the proximal isovelocity surface area region. *R* is the radius of a hemispherical shell. With principle of conservation of mass, flow through the regurgitant orifice = flow through the isovelocity surface = $2\pi r^2 \times$ aliasing velocity.

circumvent this. The vena contracta is believed to be less influenced by physiologic loading conditions and thus may be more reproducible than jet area methods.[45] In vitro studies have shown that vena contracta is less dependent on hemodynamic factors than distal jet area.[46] Another potential advantage of vena contracta measurement over jet area may be in eccentric jets where the proximal jet is less affected by wall impingement. Table 18-2 summarizes validation studies of the vena contracta method against comparable standards.

Table 18-1 shows values for vena contracta corresponding to MR degree. Vena contracta measurements of less than 3 mm correspond to mild MR; 0.3 to 0.69 mm corresponds to moderate MR, and 0.7 mm or more corresponds to severe MR. A broad range for vena contracta is considered to be in the moderate range, which limits the vena contracta as a quantitative measure. Despite this, vena contracta remains a clinically useful semiquantitative measure of MR, which is simple in concept and measurement.

### *Proximal Isovelocity Surface Area Method*

The PISA method is based on the fluid dynamic principle that as flow approaches a circular finite orifice, it forms concentric hemispherical shells with gradually decreasing surface area and

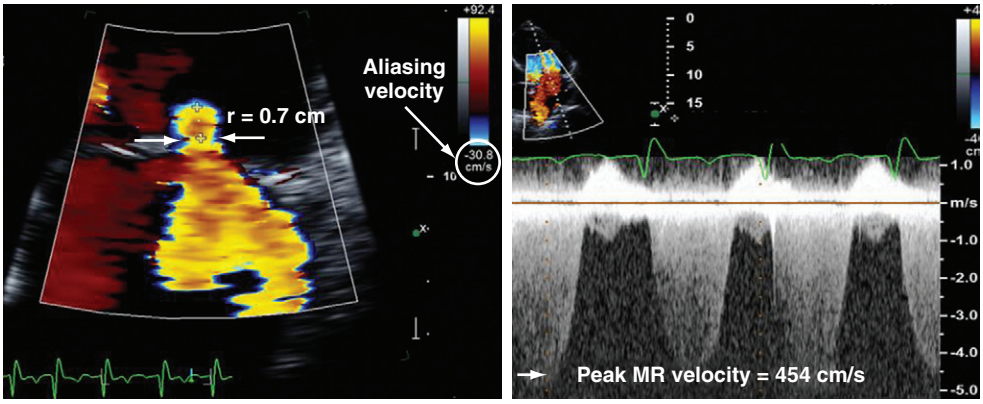

**Figure 18-16** **The proximal isovelocity surface area region (*left*) is displayed after baseline shifting and magnification.** The *arrows* point to the dropout in Doppler flow along the sides of the proximal isovelocity surface area region where the flow is perpendicular to the ultrasound beam. The radius of the proximal isovelocity surface area zone measures 0.7 cm. The aliasing velocity is 30.8 cm/s as displayed by the Nyquist limit. The peak regurgitant flow rate = $2 \times \Pi \times (0.7\ cm)^2 \times 30.8\ cm/s = 95\ mL/s$. The regurgitant orifice area = $95\ cm^3/sec \div 454\ cm/s = 0.21\ cm^2$.

increasing velocity (see Fig. 18-15).[52] This principle can be applied to mitral regurgitant flow, where the PISA region is the hemispheric shell that forms proximal to the mitral leaflets on the LV side and the finite orifice is the mitral regurgitant orifice at the level of the leaflets[42,52-58] With the conservation of mass principle, the flow rate of each of the isovelocity shells equals the flow rate at the regurgitant orifice. Assuming a hemispheric shape for the isovelocity shells, then flow rate = surface area of a hemisphere = $2\pi r^2 \times$ aliasing velocity, where $r$ is the radius of the hemispherical shell. The flow rate of the hemispheric shell equals the MR rate at the orifice with the conservation of mass principle. Once flow rate is calculated, the MR regurgitant orifice area and regurgitant volume can be derived with the following formulas: regurgitant orifice area = MR flow rate/peak MR velocity with continuous wave (CW; Fig. 18-16). As the regurgitant orifice area is calculated from an instantaneous peak flow rate, regurgitant orifice area obtained with the PISA method represents a maximal instantaneous regurgitation orifice area. For calculation of regurgitant volume, the effective regurgitant orifice area is divided by the time velocity integral of the MR: regurgitant volume = effective regurgitant orifice area × time velocity integral (MR jet). The regurgitant fraction is calculated as regurgitant volume divided by the stroke volume. Stroke volume can be calculated as: (end-diastolic volume—end-systolic volume)/end-diastolic volume. To optimize measurement of the radius r, baseline shifting of the Nyquist limit is recommended (Fig. 18-17). The baseline is shifted toward the direction of the regurgitant flow. The Nyquist limit should be relatively low compared with the regurgitant velocity or the hemispherical assumption can be invalid.[59] Thus, measurement of the radius of the PISA region at Nyquist limits much lower than flow rates is important. In general, 20 to 40 cm/s is the Nyquist limit range at which there is an optimal balance of maximal radius resolution and integrity of the PISA shape. Very low Nyquist limits overestimate the size of the PISA region, in which case, there is elongation in the axial dimension, and conversely high Nyquist limits minimize the PISA region, making accurate measurements difficult.[53,57,59-62] Mitral regurgitant flow rate and effective orifice area can be dynamic throughout systole depending on the etiology of MR,[63,64] which is an important consideration in the decision of at what time point during systole to measure the PISA radius. For example, with functional MR, there is typically a bimodal pattern with peak MR flow rates in early and late systole; MR flow rate is the least

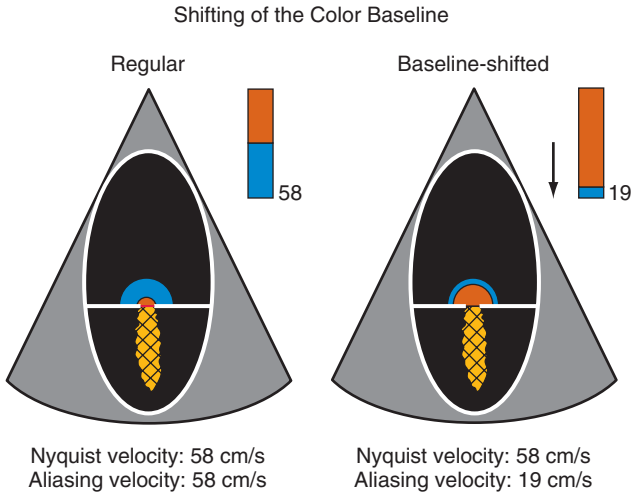

**Figure 18-17** **Baseline shifting of the Nyquist limit toward the direction of the regurgitant flow results in a larger proximal isovelocity surface area zone for optimal measurement of the proximal isovelocity surface area region radius (*right panel*).**

during mid systole. In patients with mitral valve prolapse, peak MR flow occurs mid to late systole. For rheumatic disease, the MR flow rate is constant during systole. PISA radius measurement should be avoided very early or very late in systole because these are times when the mitral leaflets are just closing or are about to open and the flow rate may not be at equilibrium. As a general rule, the PISA radius measurement should occur at the same time as the peak MR velocity (as measured with CW Doppler). This usually occurs at mid systole or at the T wave in the electrocardiogram pattern. In practice, precise alignment in time of the peak MR velocity with a PISA region suitable for accurate measurement can be difficult. In these situations, it is best to aim for accurate PISA region radius measurement at a time point that is closest to the peak MR velocity. Accuracy and reproducibility of the PISA method is highly dependent on careful attention to technique of acquisition and measurements. The PISA region should be magnified with sector and depth optimized for color Doppler resolution, with the PISA region and mitral leaflets encompassing most of the sector. Measurement of the PISA should be aligned parallel to flow rate direction because this optimizes Doppler resolution. MR regurgitant volumes of more than 0.40 $cm^2$ are consistent with severe

MR, whereas regurgitant volumes of less than 0.20 $cm^2$ are consistent with mild MR. Table 18-2 summarizes validation studies of the PISA method against comparable standards.

## Geometric Factors That Influence Proximal Isovelocity Surface Area Method

In theory, the PISA method provides an accurate quantitative measure of MR. However, some technical and practical aspects to the PISA method should be considered. The PISA region is influenced by the surrounding geometry of the orifice.[52] This principle is important in examination of eccentrically directed PISA regions, such as occur in flail mitral leaflet. This typically results in an overestimation of the PISA radius due to distortion of the PISA region from constraint from the LA wall, which results in a falsely increased radius.[54] To overcome this, an angle correction factor can be applied to the surface area calculation.[52] Angle correction is performed by multiplying the surface area calculation by $\alpha/180$, where $\alpha$ is the angle between the mitral leaflet and the end of the PISA region confined by the LA wall (Fig. 18-18).[65] Angle correction for eccentric PISA regions adds additional complexity to the MR flow rate calculation, creating additional opportunities for measurement error. Furthermore, accurate measurement of the $\alpha$ angle is not always possible because of LV wall confinement. The practical difficulties in applying angle correction have limited its use clinically.

## Technical Factors

One should measure the radius of the PISA region at Nyquist velocities, which are reliably displayed with color Doppler flow mapping. One major limitation of the PISA method has been that the calculated results vary widely when the radius is measured at different distances from the orifice because of varying three-dimensional (3D) shapes of the isovelocity surface. The contour of the PISA region changes depending on location of flow rate relative to the regurgitant orifice.[52,61,62] The contour flattens out close to the orifice, whereas the contour assumes an elongated or more oval shape furthest from the orifice. These variations in PISA contour result in systematic overestimation at flow rates farthest from the orifice and in underestimation closest to the orifice (Fig. 18-19). In addition, measurement of the radius should be avoided along the sides of the PISA region because flow here is perpendicular to the ultrasound beam, resulting in underestimation of the velocity component with frank dropout of flow display at angles perpendicular to flow. This dropout of color display where flow is perpendicular gives the PISA region a rounded appearance at its base. Figure 18-20 shows an ideal zone for PISA radius measurement to occur and zones in which to avoid measurement.

In vitro studies have shown that regurgitant orifice shape can impact the shape of the PISA region.[57] This important factor should be considered with application of the use of a hemispherical formula to the PISA contour because this assumes a circular regurgitant orifice. However, the regurgitant orifice may not be circular, particularly in view of the elliptical coaptation zone of the mitral leaflets, which may be especially important in functional MR where symmetric tethering of the mitral leaflets results in an elliptical regurgitant orifice. Hemispheric assumption of the PISA region underestimates the regurgitant flow rate, especially with rectangular regurgitant orifices.[57] Application of a hemielliptical formula to the PISA region has

shown improved accuracy MR quantification.[58,66] However, the hemielliptical surface area formula is complex, requiring measurement of three radii, which are orthogonally oriented, and integrated for surface area calculation. This adds considerable complexity to the PISA method and has limited clinical application of a hemielliptical formula for the PISA region.

The PISA region appears less influenced by changes in machine settings such as gain, wall filter, frame rate, and packet size compared with distal jet area methods.[53]

## VOLUMETRIC METHODS WITH PULSED DOPPLER IMAGING

Volumetric methods use pulse wave Doppler techniques to calculate flow rates and stroke volumes. The stroke volume across a valve annulus can be calculated as: time velocity integral across valve annulus multiplied by the cross-sectional area of the annulus. The MR regurgitant volume can be calculated from the flow across cardiac valves.[67-71] Although many combinations can be used, a common way to derive MR volume is: MR volume = mitral inflow minus aortic outflow (Fig. 18-21).

Mitral inflow volume is calculated as: (time velocity integral of mitral inflow) × (cross-sectional area) of the mitral annulus. The time velocity integral of mitral inflow should be measured at the level of the mitral annular plane because this is where the cross-sectional area is measured (Fig. 18-22). The cross-sectional area of the mitral annulus is assumed to be circular and calculated as $\pi r^2$, where $r$ is the diameter measured in the in apical four-chamber divided by 2. Anatomically, the mitral annulus is D-shaped, more like an ellipse than a circle. However, use of a circular assumption for the annulus is reasonable in patients who have at least moderate MR given the annular dilation that occurs with development of moderate or greater MR. Alternatively, the mitral annulus can also be calculated as an ellipse in which the area is $\pi ab$, with $a$ and $b$ being the diameters measured in the apical four-chamber and two-chamber views divided by 2. Aortic outflow is calculated as time velocity integral of aortic outflow × cross-sectional area of LV outflow tract. This method assumes that there is no aortic regurgitation; otherwise, pulmonary artery outflow can be used, assuming no significant pulmonary regurgitation. The MR regurgitant volume can also be obtained by calculating LV stroke volume and subtracting aortic outflow volume, assuming no aortic insufficiency is present. Table 18-2 summarizes validation of volumetric methods with pulsed Doppler against comparable standards.

Although straightforward in concept, volumetric methods are subject to increased variability related to the number of measurements necessary to calculate cardiac flows from pulsed Doppler and annular areas. For reproducible results, these methods generally require significant training. In addition, as the radius is squared in the area term, small errors in measurement are amplified,[67] and accurate resolution of the annulus is important to minimize measurement errors.

## SUPPORTIVE EVIDENCE IN THE ASSESSMENT OF MITRAL REGURGITATION

### *Pulmonary Venous Inflow Pattern*

The pulmonary venous inflow pattern provides confirmatory data in assessment of MR severity. Normal pulmonary venous inflow has forward flow during both systole and diastole, with

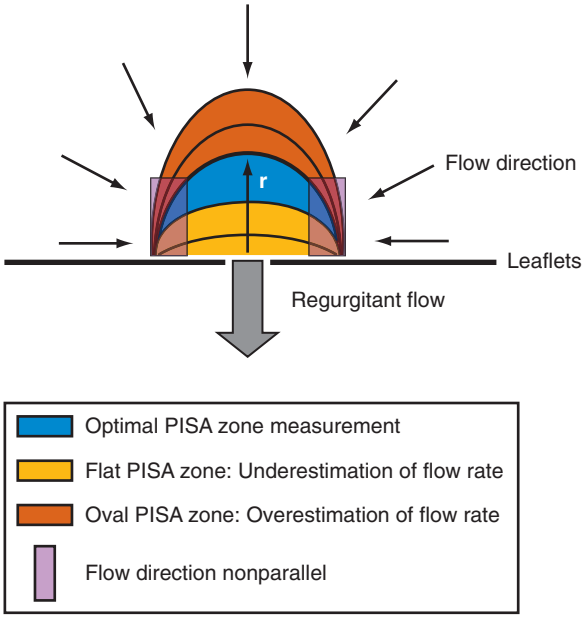

**Figure 18-20 The proximal isovelocity surface area (*PISA*) region is optimally measured where the region is hemispherical.** Flows farthest away from the orifice assume an elongated or oval contour and overestimate flows, whereas flows closest to the orifice assume a flat contour and underestimate flows. Measurement of the radius should be avoided along the sides of the PISA region because flow here is perpendicular to the ultrasound beam, which results in underestimation of the velocity component with frank dropout of flow display at angles perpendicular to flow.

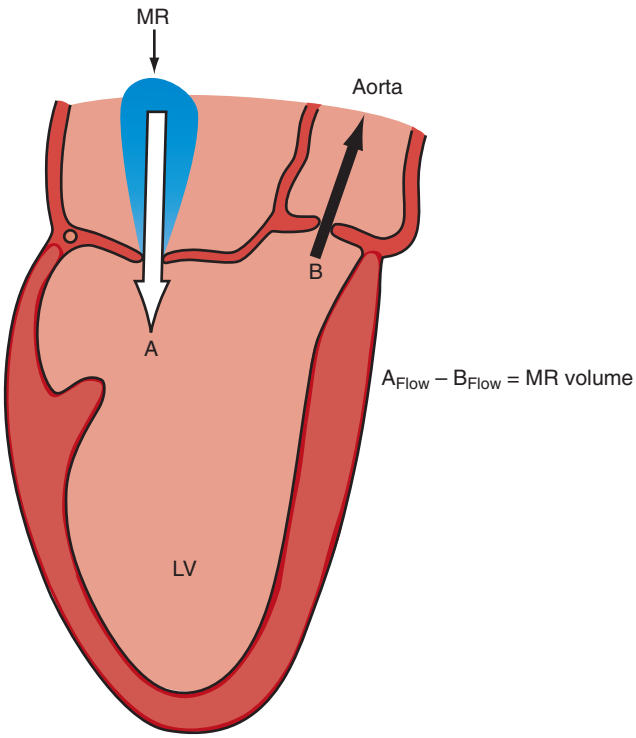

**Figure 18-21 Schematic shows volumetric method for calculation of mitral regurgitant (*MR*) volume.** Mitral inflow minus the aortic outflow equals the MR regurgitant volume, provided there is no significant aortic regurgitation.

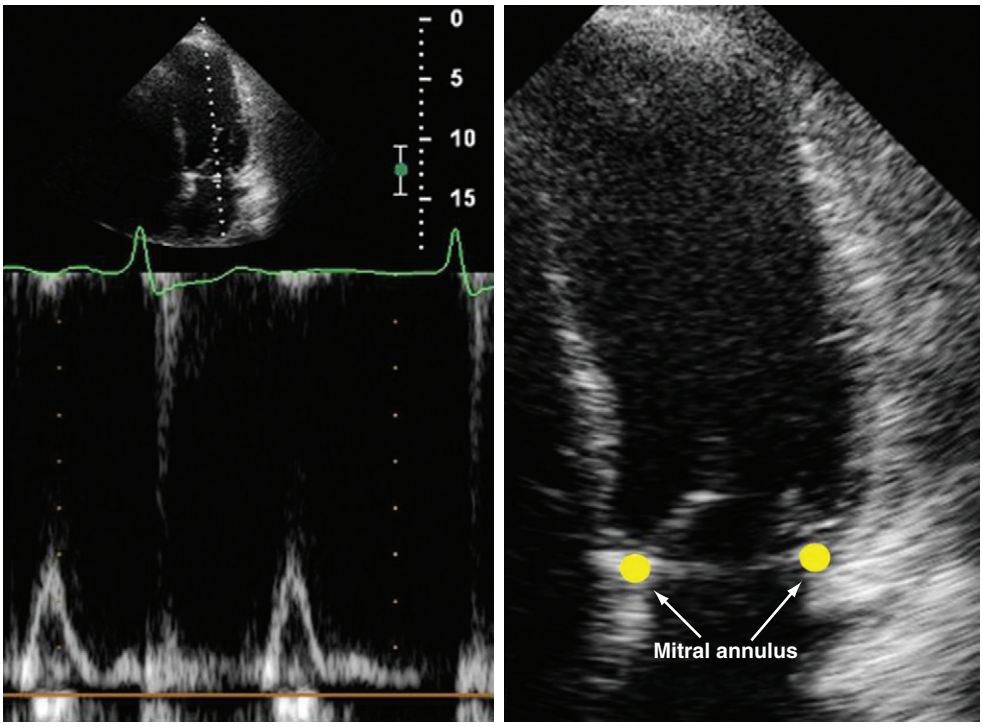

**Figure 18-22 Mitral inflow measured at the level of the mitral annulus (*left panel*).** *Right panel*: Diameter of the mitral annulus (*yellow dots*) measured in mid diastole.

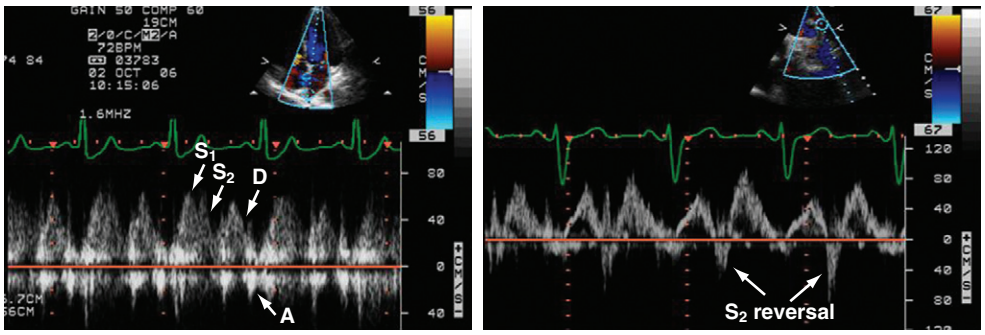

**Figure 18-23 Normal pulmonary venous pattern (*left panel*).** Pulmonary venous inflow into the LA occurs both in systole ($S_1$ and $S_2$) and diastole (*D*), with brief reversal of flow during atrial contraction (*A*). *Right panel*: Reversal of $S_2$ component (*arrows*) with severe mitral regurgitation.

a brief reversal of flow during atrial contraction (Fig. 18-23). Systolic flow (S wave) has two components: $S_1$ and $S_2$. The S wave is slightly larger than the D wave. Pulmonary veins are sampled in the apical four-chamber view with the sample volume placed approximately 1 cm from the orifice. Studies have shown feasibility of imaging the pulmonary venous inflow pattern with transthoracic imaging,[72-74] with a reported success rate of 95% for pulmonary venous systolic and diastolic flow velocity and 90% for the atrial reversal wave. Systolic flow reversal as detected with transthoracic imaging had a sensitivity of 61% and specificity of 92% for severe MR as measured with PISA method.[75] Limitations with transthoracic echocardiographic (TTE) imaging of the pulmonary venous inflow pattern occur where increased depth settings have resulted in inadequate pulsed-wave Doppler sampling.

Changes in the systolic pulmonary venous pattern can estimate the degree of MR severity. As MR increases, the systolic wave becomes blunted, decreasing to less than the D wave. As the MR volume increases, there is eventual reversal of first the $S_2$ wave (see Fig. 18-23, *right* panel) and then the entire S wave.[76] Changes in pulmonary venous pattern with increasing MR volume relates to initial blunting of the systolic wave from the propagation wave formed by the MR volume into the LA, with overt reversal of pulmonary systolic flow with increasing MR volume. Other studies have suggested that pulmonary venous inflow is best imaged with transesophageal echocardiographic (TEE) techniques. Studies with TEE have shown sensitivity of 82% to 90% and specificity of 100% for systolic flow reversal as indicative of severe MR.[77,78]

Systolic blunting of pulmonary veins without reversal of flow also provides confirmatory evidence of significant MR. However, the presence of systolic blunting is nonspecific as it can occur in a number of clinical situations where there is elevated LA pressures, such as in LV dysfunction or atrial fibrillation.[79,80] Consequently, the presence of systolic blunting is not a specific sign of MR severity and should be interpreted with this in mind.

On the other hand, systolic flow reversal is a fairly specific sign of severe MR. Flow reversal can be difficult to demonstrate with transthoracic imaging. In addition, the MR jet itself can flow directly into the pulmonary vein, contaminating the pulmonary venous Doppler signal. In eccentric MR jets, the right and left pulmonary veins can be differentially affected, depending on the direction of the jet. The best method is to pulse Doppler both right and left pulmonary veins to obtain a complete sampling.[76,81]

### *Continuous Wave Doppler Pattern*

Continuous wave Doppler of the MR jet provides an indirect assessment of MR severity. The more intense the CW signal of the MR, the greater number of red blood cell reflectors and hence, MR volume. In addition, the more complete the MR CW signal, the greater likelihood the MR is significant. Studies have shown that the signal intensity of the MR CW tracing correlates with MR severity compared with an angiographic standard.[82,83] Rapid equilibration of the LV-LA gradient that occurs with severe MR can result in a "V" shape pattern to the normal parabolic CW MR jet. CW intensity and pattern should be used as supportive evidence for MR severity because signal intensity and shape can vary greatly with machine settings and alignment of the CW beam along the regurgitant jet.

### *Other Supportive Factors*

Valve morphology can provide important clues in the assessment of MR. Apical tenting of the mitral leaflets is associated with functional MR, which develops in the setting of LV cardiomyopathy.[84-87] The presence of valvular vegetations, flail portion, and frank papillary muscle rupture are associated with severe MR. Increased LA and LV size are associated with significant MR, presumably from a volume effect in increasing chamber size. However, left-sided chamber enlargement results from a number of clinical situations, such as arrhythmias and cardiomyopathy, and thus is not specific for MR severity. An elevated right ventricular (RV) systolic pressure also suggests clinically important MR as a result of the regurgitant volume effect on the pulmonary vasculature. An increased E wave velocity is also supportive of significant MR.

## THREE-DIMENSIONAL ECHOCARDIOGRAPHY

3D echocardiography allows for direct planimetry of vena contracta area, a measure of the regurgitant orifice area. An advantage of 3D echocardiography is that it does not rely on geometric assumptions for measurement of regurgitant orifice area, which are necessary in two-dimensional (2D) regurgitant orifice area methods. For planimetry of the vena contracta area, a full-volume 3D color Doppler acquisition should be obtained 7 to 14 consecutive cardiac cycles with electrocardiographic gating. Sector size should be narrowed to maximize frame rate. With use of multiplanar reconstruction software available on commercial 3D analysis systems, two orthogonal image planes parallel to the regurgitant jet direction can be cropped across the regurgitant jet; then a third cropping plane oriented perpendicular to the jet direction can be aligned until the cross-sectional area at the level of the vena contracta is visualized. The frame with the largest vena contracta area in systole is measured with direct planimetry of the color Doppler flow signal (Fig. 18-24).[88]

Validation studies have shown that 3D guided direct planimetry of vena contracta area is feasible and correlates well with regurgitant orifice area derived with the volumetric Doppler approach.[88-90] More recently, Marsan and associates reported that 3D vena contracta area was highly accurate compared with MR volume measured with velocity-encoded cardiac magnetic resonance imaging in patients with functional MR.[89] An important limitation of 3D color-guided direct planimetry of vena contracta area is the relatively low 3D spatial resolution, particularly in the nonaxial planes. For optimization of spatial resolution, depth should be adjusted for maximal resolution and 3D data acquisitions should be performed with the highest number of cardiac cycles whenever possible. 3D color-guided planimetry of the vena contracta area is best applied for moderate or greater MR, given the limitations of 3D spatial resolution. This alternate measure of effective regurgitant orifice area can provide an alternative measure or complementary measure to 2D methods, especially in borderline cases.

Because there is no single reference standard for MR grading, and because each method has inherent limitations, the American Society of Echocardiography has recommended an integrated approach to grading MR, where multiple parameters are included rather than dependence on a single measurement in evaluation of severity of MR.[7] The integrative method includes quantitative and semiquantitative Doppler methods that include PISA method, vena contracta width, jet area to LA area ratio, and volumetric methods. In addition, supportive data such as pulmonary vein flow pattern and height of the E wave should be included in the grading of MR. Table 18-3 summarizes the echocardiographic criteria for quantification of MR.

# Timing of Surgical Intervention for Mitral Regurgitation

## PATHOPHYSIOLOGY

Mitral regurgitation results in a significant fraction of the LV ejection volume returning to the LA. To maintain the same forward stroke volume, the LV compensates by increasing the dilating and the ejection fraction, resulting in hyperdynamic LV function. Eventually, the LV becomes unable to compensate for the increased volume workload, and the LV ejection fraction begins to decrease while the LV end-systolic volume increases. The development of MR can be acute, such as in acute mitral valve endocarditis, or chronic, such as frequently occurs with mitral valve prolapse. In addition, acute MR can occur in the setting of chronic MR, such as with development of flail leaflet from ruptured chord in a patient with chronic MR from mitral valve prolapse. The presentation and pathophysiology of acute MR differs from that of chronic MR (Fig. 18-25). In acute MR, the LA cannot accommodate the sudden volume load because it has not had time to adapt. This results in acute pulmonary edema, elevated right-sided pressures, and severe dyspnea. The LV function becomes hyperdynamic to compensate but may not be able to dilate adequately to maintain forward stroke volume, resulting in decreased cardiac output and hypotension. Treatment for acute MR focuses on acute unloading with afterload agents if blood pressure allows or with insertion of an intraaortic balloon pump. These are often temporary measures because, ultimately, the primary treatment is surgical correction.

In chronic MR, the LV has time to remodel. The additional volume load on the LV leads to an eccentric hypertrophy pattern as part of the remodeling process. Histologic examination of the myocardium in this setting shows myocyte hypertrophy, predominantly through addition of sarcomeres in series, resulting in elongation of the myofibers. This remodeling process

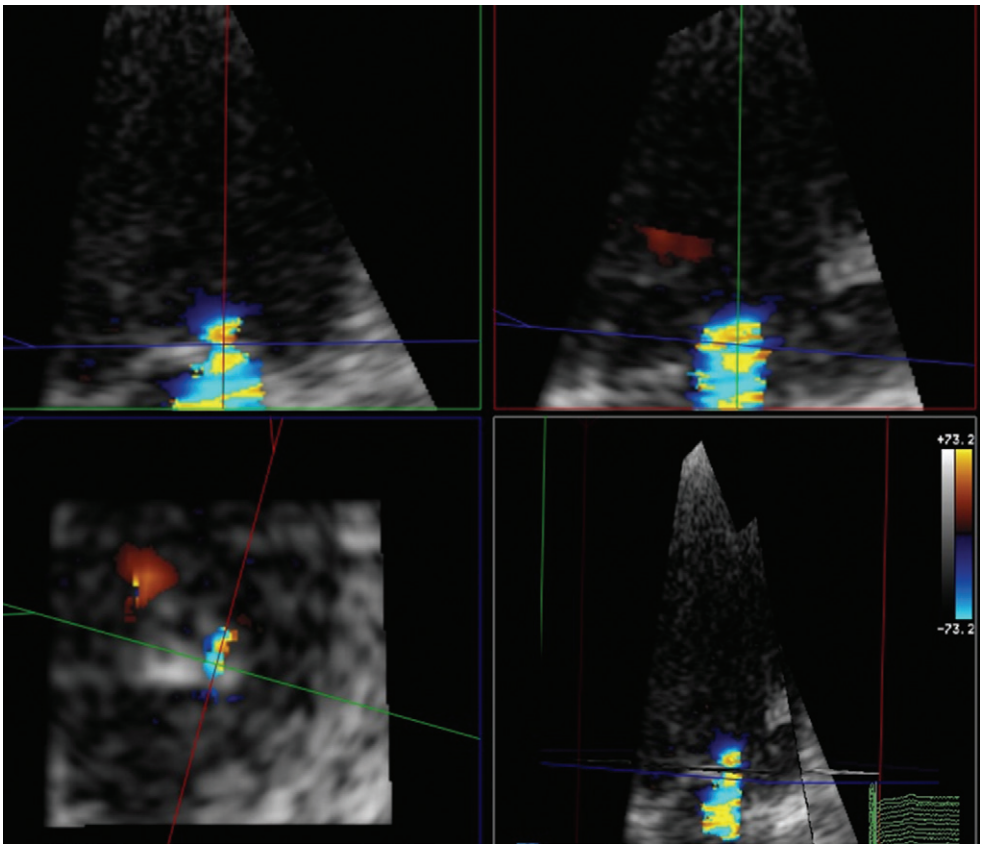

**Figure 18-24 3D guided direct planimetry of vena contracta area.** Two orthogonal image planes parallel to the regurgitant jet direction are displayed simultaneously (*top panels*). A third cropping plane, which is perpendicularly oriented to the jet direction, is moved along the jet direction until the cross-sectional area at the level of the vena contracta is visualized (*bottom right panel*).The vena contracta area is measured with direct planimetry of the color Doppler flow signal (*bottom left panel*). *(Adapted from Zeng X, Levine RA, Hua L, et al: Diagnostic value of vena contracta area in the quantification of mitral regurgitation severity by color Doppler 3D echocardiography.* Circ Cardiovasc Imaging *4:506-513, 2011. Epub Jul 5, 2011.)*

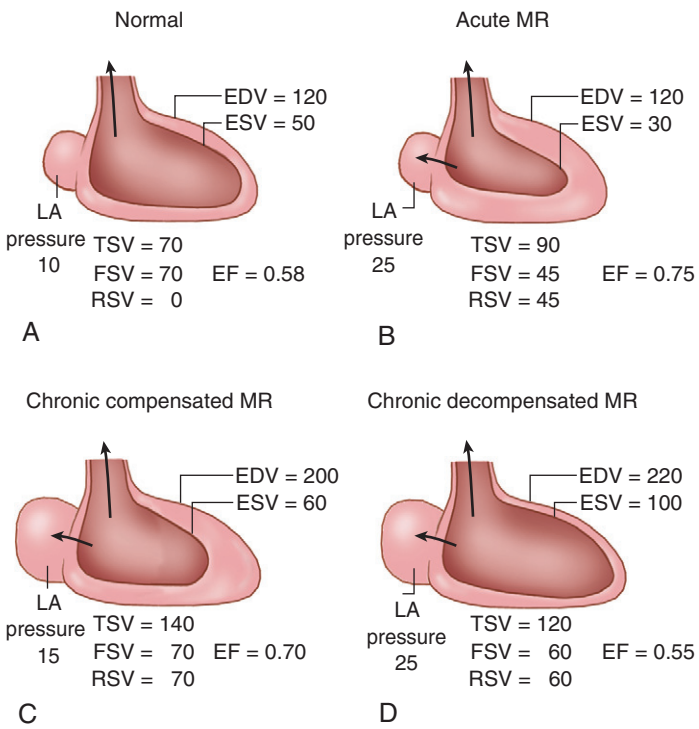

**Figure 18-25 Three phases of MR compared with normal physiology. A,** Normal physiology. **B,** In acute MR, an increase in preload and a decrease in afterload cause an increase in end-diastolic volume (*EDV*) and a decrease in end-systolic volume (*ESV*), producing an increase in total stroke volume (*TSV*). However, forward stroke volume (*FSV*) is diminished because 50% of the TSV regurgitates as the regurgitant stroke volume (*RSV*), resulting in an increase in *LA pressure*. **C,** In the chronic compensated phase, eccentric hypertrophy has developed and EDV is now increased substantially. Afterload has returned toward normal as the radius term of the Laplace relationship increases with the increase in EDV. Normal muscle function and a large increase in EDV permit a substantial increase in TSV from the acute phase. This, in turn, permits a normal FSV. LA enlargement now accommodates the regurgitant volume at lower LA pressure. Ejection fraction (*EF*) remains greater than normal. **D,** In the chronic decompensated phase, muscle dysfunction has developed, impairing ejection fraction, diminishing both TSV and FSV. The EF, although still normal" has decreased to 0.55, and LA pressure is reelevated because less volume is ejected during systole, causing a higher ESV. *(From Carabello BA: Progress in mitral and aortic regurgitation.* Curr Probl Cardiol *28:553, 2003.)*

**TABLE 18-3 Qualitative and Quantitative Parameters Useful in Grading of Mitral Regurgitation Severity**

| | *Mild* | *Moderate* | *Severe* |
|---|---|---|---|
| **Structural Parameters** | | | |
| LA size | Normal* | Normal or dilated | Usually dilated† |
| LV size | Normal* | Normal or dilated | Usually dilated† |
| Mitral leaflets or support apparatus | Normal or abnormal | Normal or abnormal | Abnormal/flail leaflet/ruptured papillary muscle |
| **Doppler Parameters** | | | |
| Color flow jet area‡ | Small central jet (usually <4 $cm^2$ or <20% of LA area) | Variable | Large central jet (usually >10 $cm^2$ or >40% of LA area) or variable size wall-impinging jet swirling in LA |
| Mitral inflow, pulsed wave | A wave dominant‖ | Variable | E wave dominant‖ (E usually 1.2 m/s) |
| Jet density, CW | Incomplete or faint | Dense | Dense |
| Jet contour, CW | Parabolic | Usually parabolic | Early peaking, triangular |
| Pulmonary vein flow | Systolic dominance¶ | Systolic blunting¶ | Systolic flow reversal§ |
| **Quantitative Parameters**** | | | |
| Vena contracta width (cm) | <0.3 | 0.3-0.69 | ≥0.7 |
| Regurgitant volume (mL/beat) | <30 | 30-44, 45-59 | ≥60 |
| Regurgitant fraction (%) | <30 | 30-39, 40-49 | ≥50 |
| EROA ($cm^2$) | <0.20 | 0.20-0.29, 0.30-0.39 | ≥0.40 |

*EROA*, Effective regurgitant orifice area.

*Unless there are other reasons for LA or LV dilation. Normal 2D measurements: LV minor axis, ≤2.8 $cm/m^2$; LV end-diastolic volume, ≤82 $mL/m^2$; maximal LA anteroposterior diameter, ≤2 $cm/m^2$; maximal LA volume, ≤36 $mL/m^2$.[2,33,35]

†Exception: acute mitral regurgitation.

‡At a Nyquist limit of 50 to 60 cm/s.

§Pulmonary venous systolic flow reversal is specific but not sensitive for severe MR.

‖Usually more than 50 years of age or in conditions of impaired relaxation, in the absence of mitral stenosis or other causes of elevated LA pressure.

¶Unless other reasons for systolic blunting (e.g., atrial fibrillation, elevated LA pressure).

**Quantitative parameters can help subclassify the moderate regurgitation group into mild-to-moderate and moderate-to-severe.

results in LV dilation and augmented contraction, which results in hyperdynamic LV function providing a larger total ejection volume to maintain forward stroke volume. Similarly, the LA remodels by dilating to increase compliance to accommodate the MR volume. This lessens the transmitted pressure from backward flow of blood directly into the pulmonary circulation and results in less elevation of right-sided pressures and dyspnea.

Eventually, the LV is unable to compensate with the gradual replacement of myocyte mass with interstitial fibrosis as the remodeling process progresses (Fig. 18-26).[91] LV volumes increase further but cannot fully compensate, resulting in a decrease in LV ejection fraction, predominantly by a relatively greater increase in end-systolic volume. The forward stroke volume falls, and without intervention, onset of heart failure occurs. Patients with chronic severe MR can be asymptomatic for a long period of time, with studies reporting an average of 5 to 10 years from time of diagnosis before signs of symptoms or other indications for surgical intervention develop.[2,92,93]

Treatment with afterload unloading agents for chronic severe primary MR has not been shown to be of benefit.[94,95] Because the pathophysiology of MR is not one of increased afterload, treatment with these agents does not address the mechanistic derangement and in fact may mask the development of LV dysfunction by unloading the ventricle.

## DETERMINATION OF MECHANISM

Determination of the mechanism of MR is important because it dictates the therapeutic course, especially as treatment options for primary versus secondary MR are different.

For primary severe valvular MR, consensus guidelines support a class I indication surgical intervention with mitral valve repair or replacement when symptoms develop or when evidence of LV dysfunction is present.[96] Consensus guidelines support an LV ejection fraction of 0.60 or less or LV end-systolic dimension of 40 mm or more as cutoff values for the presence of LV decompensation in severe MR.

A natural history study of 229 patients with MR from isolated flail mitral leaflet diagnosed from 1980 to 1989 with clinical follow-up period from 1994 to 1995 showed that patients with flail mitral leaflet had decreased survival rates compared with the expected survival rates of an age-matched and gender-matched control group (Fig. 18-27).[1] The incidence rate of surgical intervention or death was 90% at 10 years from diagnosis (Fig. 18-28). Factors associated with increased postsurgical morbidity and mortality were an LV ejection fraction of 0.60 or less and or New York Heart Association functional class 3 to 4.[97,98]

Asymptomatic patients with severe MR with preserved LV function are an important but challenging group. Early mitral repair in asymptomatic patients with chronic severe MR and preserved LV function is a class 2a indication in selected cases, with a high likelihood of mitral valve repair (more than 90%) with low operative mortality rate (1% or less). One of the challenges is determination of whether patients are truly asymptomatic because decreased functional capacity may be attributed to deconditioning and age or manifested as nonspecific symptoms. In addition, some patients reduce their activity subtly in response and may not be aware of or recognize a reduction in functional capacity. In these cases, exercise testing echocardiography can provide objective evidence of functional capacity and, if performed with echocardiography, can also provide hemodynamic data such as right-sided pressures changes and valvular and ventricular function in response to exercise.

Mitral valve repair is associated with improved survival rates in patients compared with mitral valve replacement. If mitral valve repair is not possible, then mitral valve replacement should be performed with chordal preservation. An algorithm for management of severe chronic primary (valvular) MR is displayed in Figure 18-29.[96]

For secondary MR, the therapeutic approach is less clear. The development of MR (even mild) after myocardial infarction is associated with decreased survival (Fig. 18-30).[3,4] Yet it is unknown whether the procedure to reduce the MR severity results in a decrease in cardiovasular morbidity and mortality or improvement in total survival. Medical management should be aimed toward primary LV dysfunction. Specifically, angiotensin-converting enzyme inhibitors and beta-blockers have shown a reduction in MR in this patient population, as has cardiac resynchronization.[99-102]

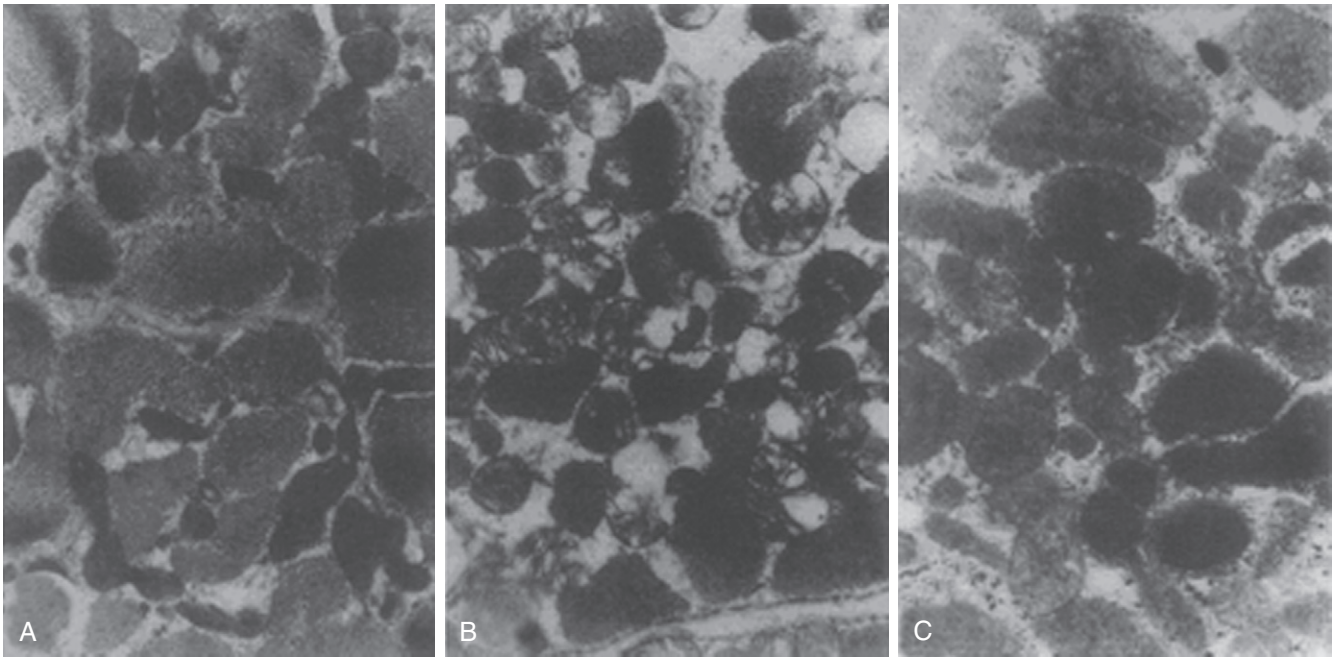

**Figure 18-26 Myocardial ultrastructures of normal dogs (A), dogs with severe mitral regurgitation (MR) (B), and dogs that had severe MR corrected surgically (C) are shown.** With severe MR, a loss of contractile elements is restored after surgery. *(From Spinale FG, Ishihara K, Zile M, et al: Structural basis for changes in left ventricular function and geometry because of chronic mitral regurgitation and after correction of volume overload.* J Thorac Cardiovasc Surg *106:1147-1157, 1993.)*

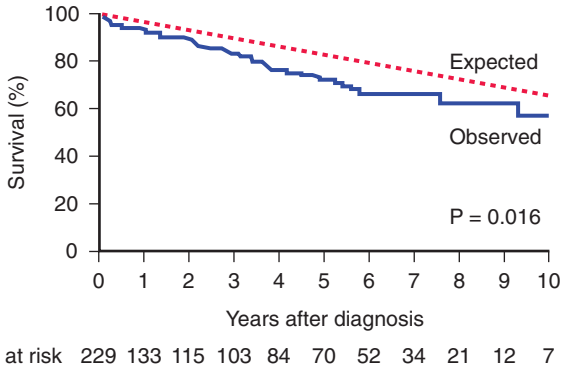

**Figure 18-27 Decreased survival of 229 patients with flail mitral leaflet with medial treatment alone compared with expected survival in an age-matched and gender-matched control group.** *(From Ling LH, et al: Clinical outcome of mitral regurgitation due to flail leaflet.* N Engl J Med *335:1417-1423, 1996.)*

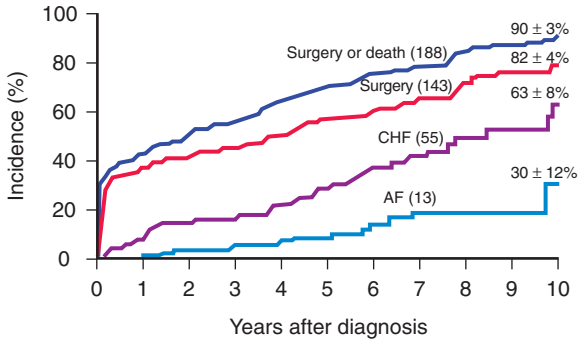

**Figure 18-28 Incidence rates of atrial fibrillation (*AF*), congestive heart failure (*CHF*), mitral-valve surgery, and surgery or death in adults with a flail mitral leaflet.** A total of 175 patients were initially at risk for atrial fibrillation, and 229 were initially at risk for the other endpoints. The numbers in parentheses are numbers of events for each endpoint. Plus-minus values are mean (±SE) event rates at 10 years. *(From Ling LH, et al: Clinical outcome of mitral regurgitation due to flail leaflet.* N Engl J Med *335:1417-1423, 1996.)*

Surgical mitral valve repair or replacement for ischemic MR is most often performed at time of coronary artery bypass graft surgery in patients with moderate to severe ischemic MR. Mitral valve repair seems preferable over replacement for ischemic MR in most patients; retrospective studies suggest improved survival in patients undergoing mitral valve repair compared with replacement.[103,104]

Much of the uncertainty regarding the therapeutic approach for secondary MR is the lack of consistent data that show improvement in survival or functional status in patient who undergo mitral valve repair at time of coronary artery bypass graft surgery.[105] Until recently, no prospective randomized trials have examined impact of mitral valve repair in patients undergoing coronary artery bypass graft surgery with moderate or greater MR. The Cardiothoracic Surgical Network (www.ctsnet.org) is currently conducting two randomized trials on this topic.[106] One examines the impact on end-systolic volume index of coronary artery bypass graft plus mitral valve repair or coronary artery bypass graft alone in patients with moderate ischemic MR. A second one examines the impact on end-systolic volume index of coronary artery bypass graft plus mitral valve repair or coronary artery bypass graft plus mitral valve replacement in patients with severe ischemic MR. Adding to the therapeutic uncertainty in ischemic MR is that there is a significant recurrence rate of MR of up to one third of patients after mitral valve repair.[107-109] This may result from progression of LV dilation or persistent tethering of the mitral leaflets despite ring annuloplasty.[110,111]

## KEY POINTS

- The mitral valve apparatus consist of mitral annulus, mitral leaflets, chordae tendineae, and papillary muscles.
- The mitral annulus shape is bimodal with superior (high) points oriented anterior-posterior and inferior (low) points oriented medial-lateral.
- The anterior leaflet accounts for most of the leaflet closing surface area. The posterior leaflet is crescent shaped and scalloped with small clefts between the scallop segments.
- The primary or marginal chordae attach along the edges of the leaflets and function to produce a level coaptation plane. Rupture of the primary chordae is associated with flail leaflet and significant MR.
- The assessment of MR should be performed in an integrative manner, with Doppler methods and supportive evidence taken into account.
- Distal jet area and vena contracta methods provide semiquantitative methods for assessment of MR.
- With eccentric MR jets, jet area methods may underestimate MR degree because of wall impingement.
- Quantitation of MR is performed by calculating effective regurgitant orifice area or regurgitant volume or fraction with PISA or volumetric pulsed Doppler methods when technically possible in moderate or greater degrees of MR.
- Pulmonary venous Doppler pattern provides supportive evidence of MR severity, particularly the presence of pulmonary venous systolic flow reversal.
- Supportive evidence such as LA and LV chamber enlargement, LV hypertrophy, elevated RV pressures, and peak mitral E wave velocity should be included in the overall assessment of MR.
- Direct planimetry of vena contracta area (a measure of the effective regurgitant orifice area) is feasible with 3D color-guided echocardiography and can be useful in determination of MR degree and as complementary data to 2D methods, especially in cases where MR grade is in a border zone.
- Clinical decision making for management of MR is predicated on echocardiographic assessment of mechanism, severity of MR, and LV function.
- It is important to distinguish the mechanism of MR as primary (valvular etiology) or secondary (ventricular abnormality) because the approach to therapy is different.
- Development of MR can be acute, chronic, or acute on chronic.
- For severe primary MR, class 1 indications for surgical intervention are for development of symptoms or evidence of LV decompensation (LV ejection fraction of 0.6 or less or LV end-systolic diameter of 40 mm or more).
- Early mitral valve repair can be considered for asymptomatic patients with severe primary MR and preserved LV function if there is a high likelihood (more than 90%) of mitral valve repair and low operative mortality (less than 1%).
- Therapy for secondary MR should focus on medical management of the primary LV dysfunction with angiotensin-converting enzyme inhibitors and beta-blockers showing a decrease in MR in this patient population.

The advent of transesophageal echocardiography (TEE) and innovations in ultrasound technology have led to progressive improvement in the outcomes of valve procedures, especially surgical and transcatheter interventions on the mitral valve.

## Indications for Intraoperative Echocardiography

Intraoperative echocardiography (IOE) has both diagnostic and monitoring functions that are useful in valve surgery, especially valve-sparing operations. The diagnostic functions of IOE are used before cardiopulmonary bypass (prepump) to determine the mechanism and severity of the mitral valvular dysfunction, identify lesions of other valves, and refine the surgical mission. After cardiopulmonary bypass (postpump), the diagnostic strengths of IOE are used again to determine the success of the surgical mission. IOE is essential in performing mitral valve repair and many other types of innovative heart surgery. In addition to its use in valve surgery, the diagnostic function of IOE also is used in the surgical management of congenital heart disease,[1,2] hypertrophic cardiomyopathy,[3,4] reconstruction of the ascending aorta,[5,6] and many other surgeries (Box 19-1).[7] In addition, echocardiography in preparation for and during transcatheter procedures is now an increasingly important and essential role.

## Technique of Intraoperative Echocardiography

TEE is the most widely used technique for IOE. TEE became available in 1987 and progressively supplanted the epicardial route for most studies. Compared with epicardial echocardiography, TEE has the advantage of allowing image acquisition without interfering with the surgical field or procedure. Immediately after induction of anesthesia and endotracheal intubation, the TEE probe is inserted and left in place throughout the operation.

Although the technique of intraoperative TEE is similar to TEE in the echocardiography laboratory or the intensive care unit, there are additional potential pitfalls. First, it is occasionally difficult to pass the probe, particularly if the patient has been draped and the ether screen has been positioned. Usually, laryngoscope and direct vision succeed in placement of the probe, but sometimes this problem cannot be overcome.

Inadequate imaging occurs with the transesophageal approach for a number of reasons. Anatomic causes include a hiatal hernia or the presence of an echodense structure such as a mechanical valve prosthesis, which can cause shadowing of other cardiac structures. With all TEE studies, there is a "blind spot" approximately 2 to 4 cm in size in the middle portion of the ascending aorta caused by interposition of the trachea

**Box 19-1**

**INTRAOPERATIVE ASSESSMENT OF REPAIR AND RECONSTRUCTIVE VALVE OPERATIONS**

**Prepump**
Assess severity of stenosis/regurgitation.
Assess mechanism of regurgitation and potential reparability of valve.
Measure dimensions of annulus, chambers, and valves.
Assess whether lesions other than the primary lesion require surgery.
Determine biventricular function.

**Postpump**
Assess severity and mechanism of residual regurgitation/stenosis.
Detect systolic anterior motion of the mitral valve and LV outflow obstruction.
Determine change in severity of other valve lesions.
Assess biventricular function.
Detect iatrogenic complications.

between the esophagus and the ascending aorta. Interference from electrical apparatus such as electrocautery leads to distortion of two-dimensional (2D) imaging and often renders spectral and color Doppler signals impossible to interpret. Fortunately, imaging may be resumed once the electrocautery is discontinued. Also, while the patient is on cardiopulmonary bypass, the incomplete filling and the absence of cardiac motion cause suboptimal images until the heart is filled with blood again and starts to eject during rewarming.

## ECHOCARDIOGRAPHIC EQUIPMENT

Ideally, an ultrasound machine devoted solely to IOE should be available. In addition to interfacing with transesophageal and transthoracic transducers, the machine should be capable of recording M-mode, 2D imaging, three-dimensional (3D) imaging, and all Doppler modalities (see Chapter 2). Sterile sleeves and acoustic gel should be available for epicardial imaging.[8] Cables should be available to input the electrocardiographic signal from the operating room monitoring system into the ultrasound machine. Many institutions have the capability of transmitting images from the operating room to a server for digital storage of images, which can be reviewed in a remote site such as the echocardiography laboratory in order to allow oversight or second opinions to be obtained in selected cases.[9]

Real-time 3D echocardiography acquisition using transesophageal and transthoracic transducers is currently an important component of intraoperative echocardiographic diagnosis (see Chapter 4).

The mitral valve can now be viewed en face as a complex saddle-shaped, anatomic structure and rotated into the surgeon's view orientation as viewed from the left atrium (LA) (Fig. 19-1; Video 19-1; see ExpertConsult.com). Assessment of mitral valve morphology using real-time 3D TEE and offline reconstruction 3D TEE showed similar accuracy in defining mitral leaflet prolapse but greater interobserver agreement compared with 2D TEE.[10] Recent studies have demonstrated the feasibility of intraoperative assessment of the mitral valve morphology by real-time 3D TEE, with superior accuracy to standard 2D TEE in defining leaflet pathology when both were later compared to surgical findings.[11]

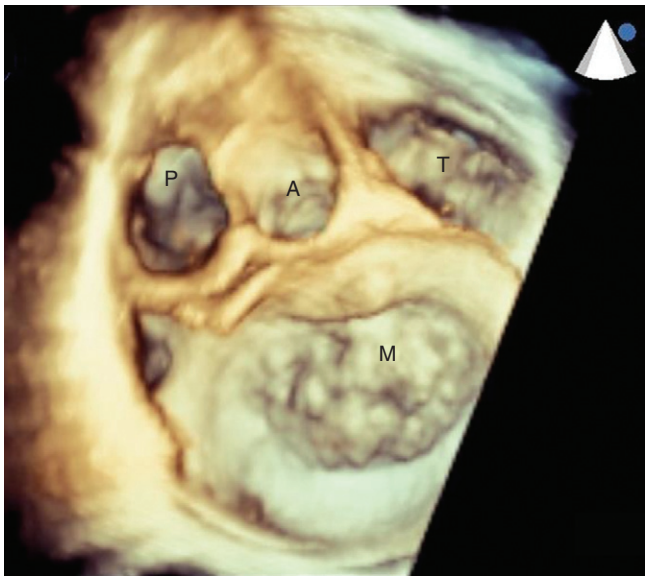

**Figure 19-1 3D TEE image of the atrioventricular and semilunar valves.** *A,* Aorta; *M,* mitral valve; *P,* pulmonic valve; *T,* tricuspid valve.

3D echocardiography has tremendous potential in the analysis of complex cardiac morphology, including the assessment of lesions in which mitral repair or reconstruction is being considered.[12] The complex 3D geometry of some valvular and congenital lesions is easier to display and understand using 3D echocardiography.[13,14] 3D reconstruction may allow more appropriate selection of patients, help determine the most appropriate surgical procedure, and potentially allow the surgeon to map out the reconstruction ahead of time in 3D computer space.[15-17] Importantly, 3D echocardiography allows additional slices to be derived at a later time from one stored volumetric data set. 3D data yielded incremental information to standard 2D TEE in up to 25% of patients.[18] 3D imaging can reconstruct structures such as the regurgitant orifice area[19] and the location of mitral valve prolapse.[20]

## INTRAOPERATIVE ECHOCARDIOGRAPHY EXAMINATION

Intraoperative TEE examinations should be performed in a standard comprehensive manner so that the acquisition of critical information is not omitted. It is important to do a complete TEE study, using imaging planes (Fig. 19-2) that allow long- and short-axis views of each intracardiac valve and chamber, as well as the great vessels.[21] Epicardial echocardiography is performed using a standard transthoracic transducer inside a sterile plastic sleeve with acoustic gel inside to eliminate the air. This technique is used in a minority of intraoperative cases, most commonly to evaluate the severity and location of atheroma in the ascending aorta, especially when it will affect the method of arterial cannulation for cardiopulmonary bypass. In cases where passage of the TEE probe is contraindicated or unsuccessful, a complete cardiac study can be obtained using four epicardial transducer positions as we have previously described.[8]

The entire prepump examination should be recorded to provide a durable record of the examination, especially as a reference for postpump studies and for medical-legal purposes. Storing key images in a cineloop facilitates rapid comparison at the end of the operation and in follow-up. In diagnostic (as

opposed to monitoring) studies, the structure of interest to the primary surgical mission should first be examined thoroughly in multiple planes, using imaging and Doppler modalities. If the echocardiographic study must thereafter be abbreviated because of pressing demands of the surgical agenda or the need to limit anesthetic and cross-clamp time, at least the primary concern, the raison d'étre of the echocardiographic study, has been addressed. Other structures of interest should then be examined, including long- and short-axis views of all four chambers, all four valves, and the great vessels. The entire aorta should be examined in all cases both prepump and postpump. We also advocate a routine intravenous contrast injection to look for intracardiac shunting.

Once the prepump study is completed, a written report of the examination detailing significant findings should be made. Although ultrasound has not been demonstrated to cause any significant damage to cardiac structures during prolonged examinations,[22] studies have shown that ultrasound waves can result in minor changes in pulmonary capillaries, so when imaging is not required, it is advisable to put the machine on freeze so that no ultrasound energy is transmitted. After cessation of cardiopulmonary bypass, a second comprehensive examination should be carried out and a second or updated report generated.

The intraoperative examination has several aspects that are different from a TEE or transthoracic echocardiography (TTE) study in the outpatient echocardiography laboratory:

1. The echocardiogram is performed simultaneously with the operation; therefore, the room conditions, including the lighting and the space for the machine, may be suboptimal. For example, radiofrequency interference from electrocautery or from other surgical equipment may mar the quality of echocardiographic images for long periods.

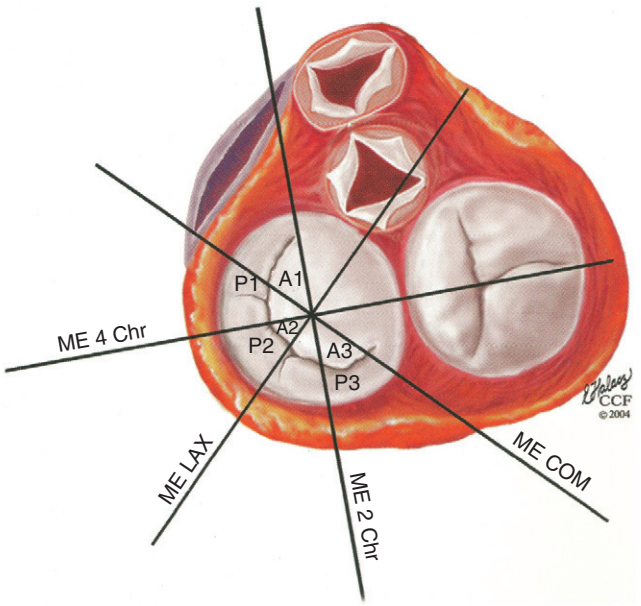

**Figure 19-2 Diagram oriented similarly to the transgastric short axis view of the mitral valve (posterior part of the heart toward the top of the screen).** The *solid lines* show the orientation of the midesophageal mitral valve planes as they can be rotated around the mitral circumference, including the midesophageal four-chamber view (*ME 4 Chr*) at about 0°, midesophageal commissural view (*ME COM*) at about 60°, the midesophageal 2 chamber view (*ME 2 Chr*) at about 90°, and the midesophageal long-axis view (*ME LAX*) at about 120°. *(Copyright CCF 2004.)*

2. The hemodynamic milieu may change quickly, and the echocardiographic appearance may differ from images acquired under "street conditions" outside the operating room. Changes in hemodynamics, such as intravascular volume, preload, and afterload, substantially affect the severity of valvular lesions and ventricular performance. If necessary, the hemodynamic situation should be manipulated to match preoperative conditions, in order to determine the true or potential severity of a valvular lesion.
3. The surgeon who requests the intraoperative study wants online interpretation. In fact, it is very tempting to "wing it" and give premature conclusions. Care must be maintained to make only diagnoses and conclusions that have been verified by examination from multiple imaging planes under appropriate imaging and hemodynamic conditions.

## Prepump Intraoperative Echocardiography in Patients Undergoing Valve Repair for Mitral Regurgitation

The prepump echocardiogram assessment of mitral regurgitation (MR) (Table 19-1) usually confirms findings made previously by preoperative echocardiography or cardiac catheterization. However, because of its improved resolution over TTE, TEE often improves on the accuracy and resolution of preoperative TTE of the component structures, the mitral valve, and the regurgitant jet. There are four main goals of IOE in mitral valve disease:

1. To assess the severity of MR and determine the need for mitral valve surgery
2. To assess the mechanism of MR and determine if a repair rather than prosthetic replacement is feasible and to determine the technique of repair
3. To determine the presence of other significant disease that may require surgical attention, such as tricuspid or aortic valve disease or intraluminal thrombi
4. To assess left and right ventricular function as a baseline with which to compare the postpump study

### SEVERITY OF MITRAL REGURGITATION

The severity of MR is assessed by IOE in the same manner as the use of echocardiography for other applications in other

**TABLE 19-1 Determination of the Mechanism of MR from Analysis of Jet Direction and Leaflet Mobility**

| | Leaflet Motion | | |
|---|---|---|---|
| *Jet Direction* | *Excessive* | *Restrictive* | *Normal* |
| Anterior | Prolapse/flail of posterior leaflet | | Perforation in posterior leaflet |
| Posterior | Prolapse/flail of anterior leaflet | Restriction of posterior > anterior leaflet | Apical tethering from LV dilation |
| Central | Prolapse/flail of both leaflets | Equal restriction of both leaflets | Apical tethering from LV dilation, annular dilation |
| Commissural | Rupture of commissural chordae or papillary muscle | | |
| Eccentric origin | | | Leaflet perforation or cleft |

parts of the hospital (see Chapter 18).[23-28] The intraoperative assessment of MR severity usually agrees with the preoperative assessment by contrast ventriculography or TTE[29,30]; however, it may reflect change, dependent on different loading conditions. In patients with ischemic MR, agreement between preoperative studies and the intraoperative assessment is less, possibly because the amount of regurgitation is more variable, dependent on hemodynamic conditions or differing degrees of ischemia. One study of patients with ischemic MR[31] showed that in 11% of patients, the preoperative and intraoperative assessments of MR severity differed by more than one grade, with discordance occurring in both directions. Discordance was more common in patients with clinical instability or those who received thrombolysis. MR resulting from any mechanism is a dynamic lesion, affected greatly by loading conditions. Reduction of afterload or intravascular volume at the time of the operation may reduce the true severity of the regurgitation. When less MR is found than expected, the intravascular blood volume should be expanded and systemic vascular resistance increased transiently using repeated boluses of intravenous phenylephrine, usually 100 mcg every 30 to 120 seconds. The velocity of MR, and therefore display of its jet by color Doppler, depends on the pressure difference between the LA and left ventricle (LV), which is higher with hypertension. The size of the jet in the LA is also variable based on changes in color gain (directly proportional) and pulse repetition frequency (inversely proportional) (see Chapter 18). Spatial mapping for the size of the MR jet in the LA should be performed at a Nyquist setting of 50 to 60 cm/s.

The transesophageal imaging window has advantages over transthoracic or epicardial imaging in the assessment of MR. A mitral prosthesis or severe mitral calcification causes acoustic shadowing of the regurgitant jet when the transducer is placed anteriorly, as in epicardial imaging or TTE. Excellent agreement, however, has been reported between the epicardial and transesophageal approaches in assessing MR.[32]

Semiquantitation of MR on a scale from 0 to 4+[23,24] is determined based on a weighted average of several criteria:

1. The size of the LA flow disturbance, based on the depth of penetration and area of the regurgitant jet in the LA cavity assessed in multiple imaging planes; a multiplane probe facilitates this process, especially in eccentric jets.
2. The geometry of the jet; eccentric jets tend to have a higher regurgitant volume than free jets of the same area.[25]
3. The size of the proximal convergence zone, by use of the proximal isovelocity surface area (PISA) technique. More severe regurgitation is associated with a larger radius of the proximal flow convergence.[26] Flow convergence can be used to calculate regurgitant flow, orifice area, and volume (see later).
4. The width of the proximal portion of the regurgitant jet ("vena contracta") on the LA side of the orifice is also useful and may be less load sensitive than mapping of the regurgitant jet in the atrium.[23]
5. The pulmonary venous pulsed Doppler tracing. Severe MR often leads to systolic reversal of flow in the pulmonary veins,[33] which is 69% sensitive and 98% specific in predicting a regurgitant orifice area of greater than 0.3 $cm^2$.[33] Blunting of pulmonary vein flow is somewhat reliable in predicting severe MR for patients in normal rhythm with normal LV function but is unreliable in patients with severe LV dysfunction or atrial fibrillation. A normal pulmonary vein flow pattern is useful in excluding severe MR and predicting a regurgitant orifice area of less than 0.3 $cm^2$. Importantly, in patients in whom the right and left pulmonary vein flow pattern is discordant (23% of patients), the more abnormal pattern is most predictive of MR severity.
6. Quantification of mitral regurgitant volume (RV) from the difference between Doppler echocardiography measurements of antegrade flow through the mitral and the aortic valves. Regurgitant fraction (RF) is the proportion of total mitral antegrade flow (MF) that is regurgitant:

$$RF\,(\%) = (RV/MF) \times 100$$

LV outflow tract flow and mitral valve flow can be assessed by the product of annular cross-sectional area derived from echocardiography and velocity derived from pulsed Doppler measurements at the same site. Mitral cross-sectional area is derived from two orthogonal diameters of the annulus, which is elliptical in shape.[34] This method has not been used routinely because of the time-consuming nature of the measurements required and the ease and general reliability of semiquantitative techniques (see Chapter 18).

The size of the regurgitant orifice area can be derived from Doppler echocardiography techniques in the operating room,[35] using either the antegrade flow difference method or the flow convergence method. The maximum regurgitant orifice area is calculated by dividing regurgitant flow rate by the maximum mitral regurgitant flow velocity ($V_{max}$) obtained from continuous-wave Doppler. The regurgitant orifice area is greater than 0.4 $cm^2$ in severe MR and greater than 0.30 $cm^2$ in moderately severe MR. It is hoped that 3D echocardiography will help with assessment of regurgitant orifice area in the future, though this is not feasible in most routine studies [36]

The flow convergence, or PISA, technique analyzes flow proximal (on the LV side) to the regurgitant orifice, assuming a hemispherical shape.[35,37] In this area, blood accelerates predictably as it moves toward the regurgitant orifice and forms a series of concentric shells of decreasing area and increasing velocity that are depicted clearly. The radius of these shells is easily measured on the color image because of the color aliasing of the accelerating flow. To the degree that the aliasing contours are shaped like a hemiellipse, the surface area of the hemiellipse can be calculated from $2\pi r^2$ for blood flow moving at velocity $v$ and at a radius $r$ from the regurgitant orifice, and the instantaneous flow rate $Q$ can be calculated from

$$Q = 2\pi r^2 v$$

The PISA method provides excellent estimation of regurgitant flow when the flow convergence is centrally located, elliptical, and well away from the walls. However, this method overestimates regurgitant flow when the proximal flow is constrained by the LV wall. Use of appropriate correction factors can compensate for this problem.[38] If the aliasing zone is hemispheric at an aliasing velocity of 40 cm/s, a simplified form of the PISA method can be used. Because 2 times $\pi$ times 40 divided by 500 is almost exactly 0.5, the mitral valve effective regurgitant orifice can be calculated from $1/2r^2$. This approximation also assumes that the peak mitral regurgitant jet velocity is 500 cm/s.

Other methods of assessing the severity of MR in the operating room include surgical palpation of the LA for the thrill of a mitral regurgitant jet, evaluation of the size of v waves on the LA pressure tracing, fluid filling of the arrested LV, and contrast

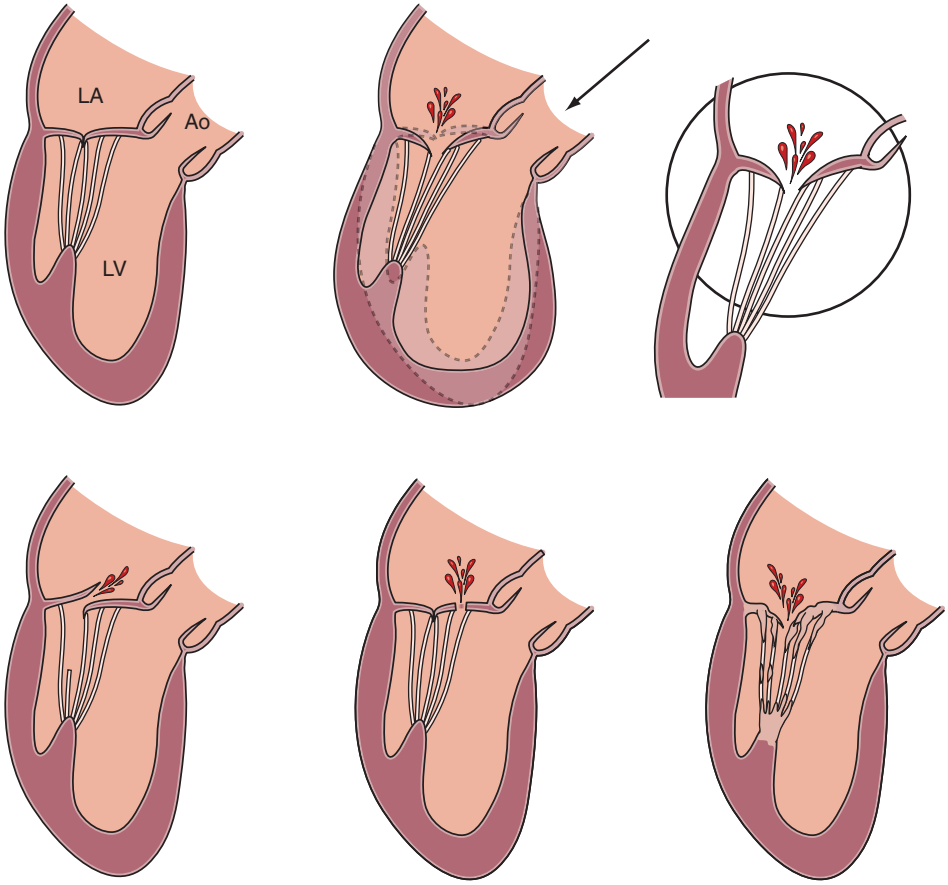

**Figure 19-3 Artist's drawings showing the morphology and echocardiographic demonstration of mechanisms of mitral regurgitation (MR).** A normal competent mitral valve is shown in the *upper left panel*. The *lower* three panels show "intrinsic valve mechanisms" of MR, including excessive leaflet motion (*lower left*) such as posterior leaflet flail due to ruptured chordae (Carpentier type 2), normal leaflet motion (*lower middle*) from a congenital cleft or leaflet perforation (Carpentier type 1), and restricted leaflet motion (*lower right*) due to fibrosis from rheumatic fever or chest radiation (Carpentier type 3A). Functional MR (FMR) is shown in the *upper middle panel*, with apical tethering of normal leaflets due to ischemic or nonischemic left ventricular systolic dysfunction (LVSD) (Carpentier type 3B) with outward displacement of the papillary muscles. The normal position of the leaflets, papillary muscle, and LV is shadowed behind the FMR anatomy. The *upper right panel* shows a close-up view of FMR.

echocardiography. These methods lack sensitivity and are not as reliable or as convenient as color flow Doppler techniques.[30,39,40]

## MECHANISM OF MITRAL REGURGITATION

Assessment of the cause and mechanism of MR[41] is of great importance in determining the suitability of the mitral valve for repair. Mitral valve repair is most likely in patients with MR due to myxomatous degeneration and is least likely in patients with regurgitation due to endocarditis or rheumatic valvular fibrosis. Repair is now successful in more than 90% of all patients with myxomatous disease. The probability of repair, however, is affected by the mechanism of regurgitation, especially whether the posterior leaflet, the anterior leaflet, or both leaflets are involved. Repair is most likely with posterior prolapse or flail, whereas isolated anterior leaflet prolapse is somewhat more difficult to repair.[42,43] Extensive chordal or leaflet disruption or the presence of mitral annular calcification also reduces the feasibility and likelihood of successful repair.[44]

### *An Organized Approach to Imaging the Mitral Valve*

To adequately assess the pathophysiologic mechanism responsible for MR, it is essential to perform a thorough examination of the mitral valve and mitral apparatus (Fig. 19-3) and to determine the origin and geometry of the regurgitant jet. The long-axis imaging planes are best for determining which mitral leaflet is involved. Long-axis views of the mitral valve are obtained by imaging from midesophageal TEE planes. Most basilar long-axis views around the entire multiplane sweep allow portions of both leaflets to be examined individually. The midesophageal intercommissural view[21] at approximately 50° to 60° in most patients, an imaging plane parallel to a line between the commissures, is very useful for determining which portion of the anterior or posterior leaflet is involved. Long-axis imaging at a multiplane angle of about 135° cuts perpendicular to this intercommissural line.

The short-axis views also are useful for determining which portion of the anterior or posterior leaflet is involved (Figs. 19-4 and 19-5). Useful views may be obtained from 3D echocardiography or from 2D planes recorded from the transgastric short-axis view.[45] A useful 3D volume set can be recorded from the midesophageal position by placing the border of the sampling zone for the "3D zoom view" just posterior to the mitral valve, so that no solid structures are within the data set posterior to the mitral valve. The derived data set, shaded for 3D viewing, is rotated around so it mimics the "surgeon's view" of the mitral valve (Fig. 19-6). Although 3D echocardiography is not as sensitive as 2D imaging in detection of small abnormalities,

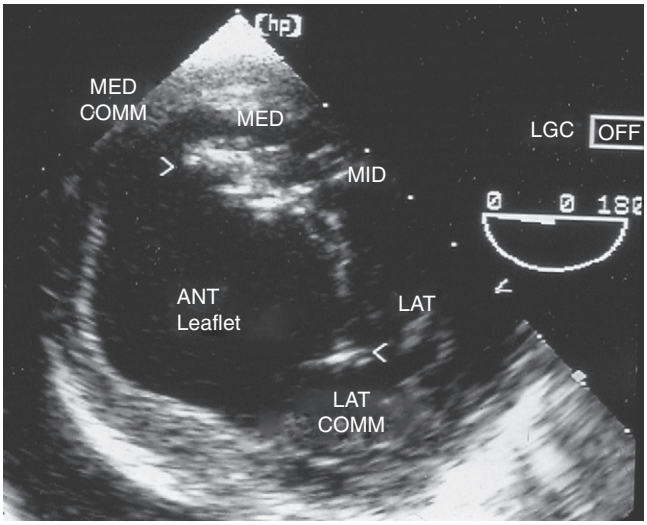

**Figure 19-4 The anatomy of the mitral valve in systole from a transverse transgastric short-axis view of the mitral valve.** The medial and lateral commissures (*MED COMM, LAT COMM*) and the positions of the medial (*MED*), middle (*MID*), and lateral (*LAT*) scallops of the posterior leaflet are shown. *ANT*, Anterior.

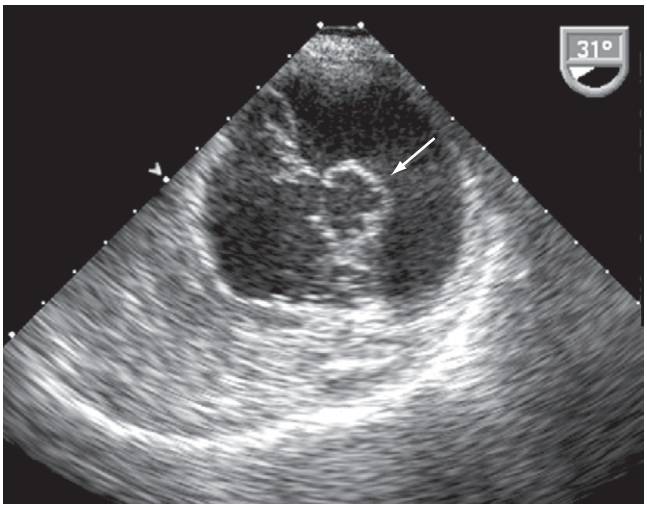

**Figure 19-5 P2 prolapse.** Transgastric short-axis view of the mitral valve in a patient with severe prolapse of the middle scallop of the posterior leaflet (*arrow*).

it facilitates understanding the exact locations and topographic relationships of the abnormalities.

The posterior leaflet has three divisions or scallops: the lateral, middle, and medial, respectively numbers P1, P2, and P3. The anterior leaflet is not scalloped but has a central portion known as the *bare area* between the insertions of the chordae from the anterolateral and posteromedial papillary muscles. Although there are no distinct scallops, the anterior leaflet is arbitrarily divided into segments that correspond to the segments of the posterior leaflet opposite them: the lateral, middle and medial segment, respectively A1, A2, and A3. In a similar way the posterior leaflet is also supported, about half each by chordae from the anterolateral and posteromedial papillary muscles. The papillary muscles lie below each mitral commissure. The papillary muscles and chordae usually are well visualized from the transgastric long-axis views of the LV.[46] In assessing the mitral valve and in providing the results to the surgeon, giving an accurate localization of the abnormality is important. A prospective study of 50 patients[47] used a segmental approach to the mitral valve, breaking each leaflet into three segments, and found that TEE was 96% accurate for localization compared with surgical findings. Other researchers have shown that localization of the defect to the posterior leaflet by TEE is 78% sensitive and 92% specific in myxomatous disease, with accuracy being least when the medial rather than the lateral or middle scallop is involved.[48] Assessment of the mechanism of MR is performed by analyzing the motion of the valve leaflets with 2D, and now more recently 3D echocardiography and the direction of the regurgitant jet with color flow imaging[49,50] (see Table 19-1). Four types of leaflet motion (see Fig. 19-3) may be associated with MR: (1) *normal motion* (Carpentier class 1) as seen with leaflet perforation, (2) *excessive motion* (Carpentier class 2) as seen with prolapse or flail valve such as chordal rupture or elongation, (3) *restricted motion* (Carpentier class 3) as seen in rheumatic mitral valve disease, and (4) *apical tethering of normal leaflets* (Carpentier class 3B) as seen in functional MR with ventricular and annular dilation.

IOE has been shown to be highly sensitive and specific in determining the mechanism of MR in patients undergoing mitral valve surgery. In a study of 286 patients undergoing mitral valve surgery in which the echocardiography mechanism was correlated with the surgical findings, echocardiography was highly accurate (86%) in determining the mechanism of MR.[49]

## Excessive Leaflet Motion (Carpentier Class 2)

Excessive leaflet motion occurs with elongation or disruption of any portion of the mitral valve or of the mitral apparatus,

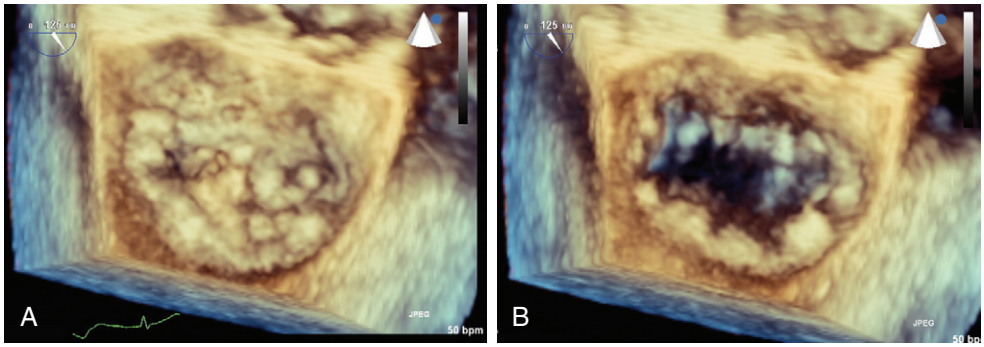

**Figure 19-6 3D TEE of the mitral valve.** The valve is viewed *en face* rotated to the "surgeon's view" shown in (**A**) systole and (**B**) diastole, demonstrating a P2 flail scallop.

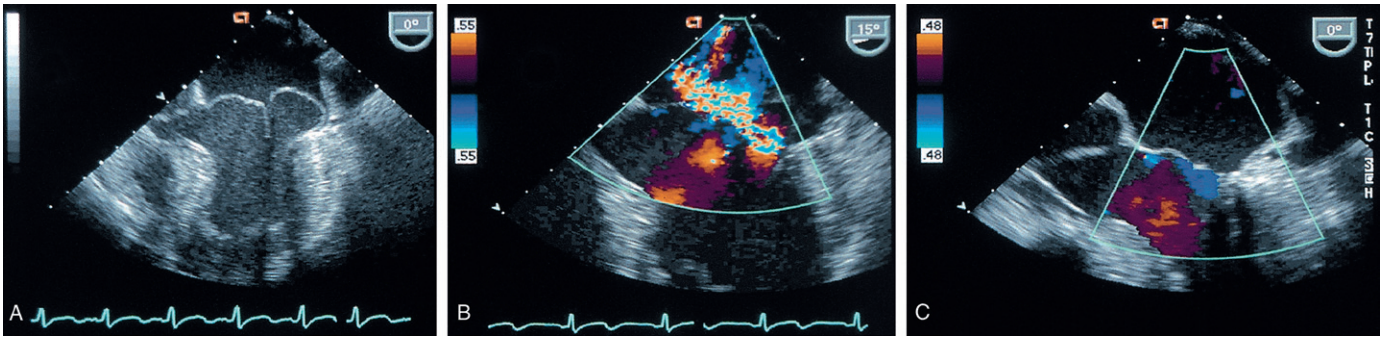

**Figure 19-7 Bileaflet prolapse.** The TEE four-chamber view shows prolapse (**A**) of the posterior, more than the anterior, leaflet causing severe MR (**B**) before mitral valve repair and no MR after successful mitral valve repair (**C**). The jet is deflected opposite the leaflet that has the most excessive leaflet motion.

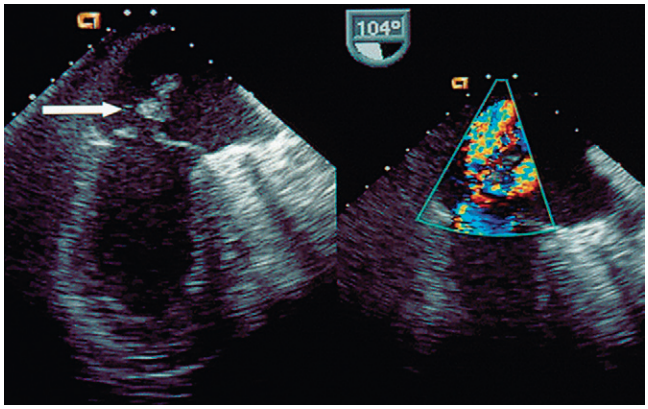

**Figure 19-8 Papillary muscle rupture with resulting severe mitral regurgitation (MR).** Ruptured portion of muscle is seen prolapsing into LA (*arrow*) in *left panel.* MR jet is seen in *right panel.*

including the papillary muscles and chordae. Myxomatous disease, endocarditis, and papillary muscle infarction all can lead to this abnormality. With excessive leaflet motion, the regurgitant jet is directed *away* from the affected leaflet. Thus, prolapse or flail of the posterior leaflet leads to an anteriorly directed jet (Fig. 19-7; see Fig. 29-6 and Video 19-2 at ExpertConsult.com). In bileaflet prolapse, the excessive motion is often asymmetric, and the jet direction is away from the more severely affected leaflet. When the amount of prolapse or flail is completely balanced between both leaflets, a central jet direction occurs. If the chordae to the commissures are ruptured, then a jet originating at the commissures is seen in the transgastric short-axis view. Jets originating at the commissure also are seen in infarction of a papillary muscle, most commonly the posteromedial one.[51] Excess motion with severe MR results when the head of a papillary muscle ruptures in an acute myocardial infarct. This type of rupture may be differentiated from acute chordal rupture by detecting a mass attached to the flail leaflet that is a portion of the muscle and by the appropriate clinical setting (Fig. 19-8).

Precise delineation of which portion of the valve has excess motion is important in planning the surgical repair. Rupture of the posterior chordae is the most common abnormality and is repaired by quadrilateral resection of the posterior leaflet (Fig. 19-9). Elongation of the chordae is repaired by chordal transfer or by implantation of artificial chordae. Papillary muscle elongation or disruption may be repaired by reimplanting, supporting, or shortening the affected muscle.[42] Postoperative prognosis is best in those with excessive leaflet motion.

### Restricted Leaflet Motion (Carpentier Class 3)

This pattern, involving leaflet thickening, is seen most commonly in rheumatic disease, but it also can result from ischemic heart disease, the chronic phase of lupus, radiation-induced valvular disease, or acquired disease caused by ergot derivatives or the fen-phen combination (fenfluramine and phentermine). If both leaflets are equally affected by the pathologic process, the jet direction is central. More commonly in rheumatic disease, the posterior leaflet is more severely affected than the anterior leaflet, and the relatively normal anterior leaflet "overrides" the restricted posterior leaflet. The direction of the regurgitant jet in this situation is posterior, *toward* the affected leaflet. The surgical approach to this condition includes débridement of the valve tissue and chordae, commissurotomy, and annuloplasty. This type of repair is more technically demanding, less often successful, and less durable because of postoperative progression of the fibrotic process.

### Apical Tethering of Normal Leaflets (Carpentier Class 3B)

In ischemic heart disease, the leaflets are usually structurally normal, but they are *tethered* and their motion is "relatively restricted," owing to apical displacement of the posteromedial papillary muscle. The leaflets themselves are not thickened but fail to coapt adequately (Fig. 19-10) because of tethering of the leaflets apically and outward by the LV enlargement. The surgical approach to this problem usually involves placement of an annuloplasty ring to reduce the size of the mitral annulus. Surgical treatment of ischemic regurgitation with apical tethering is less successful, and residual regurgitation is often more significant than after myxomatous valve repair.

Normal leaflet motion is commonly seen in patients with MR secondary to LV dilation of any cause, such as disease of other valves, dilated cardiomyopathy, or severe ischemic cardiomyopathy. We have previously termed this category *ventricular-annular dilation.* Ventricular enlargement causes displacement of the mitral coaptation point toward the apex with resultant impaired coaptation and leaflet "tenting." Annular dilation is seen in these patients, but it occurs in proportion to LV dilation, in contrast to myxomatous or rheumatic MR patients whose annulus size is often abnormally large. Annuloplasty with ring insertion is commonly used in the surgical management of these patients. An Alfieri stitch to support the valve also has been used instead of or in addition to the annuloplasty. There has been an upsurge in interest in the surgical management of severe MR in patients with dilated cardiomyopathy. Excellent functional improvement with a relatively low operative

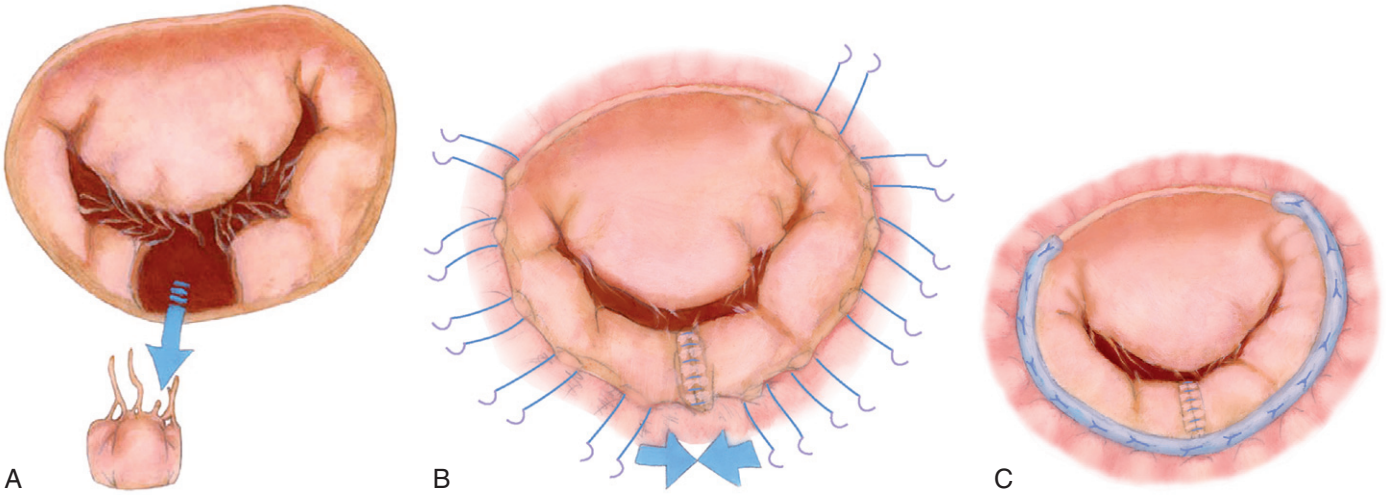

**Figure 19-9 Surgical mitral valve repair.** The first step is quadrilateral resection of the posterior leaflet (**A**) followed by repair of the posterior mitral valve leaflet, with placement of annular sutures (**B**), and then implantation of an annular ring (**C**). *(From Grewal KS, Malkowski MJ, Kramer CM, et al: Multiplane transesophageal echocardiographic identification of the involved scallop in patients with flail mitral valve leaflet: intraoperative correlation.* J Am Soc Echocardiogr *11:966-971, 1998.)*

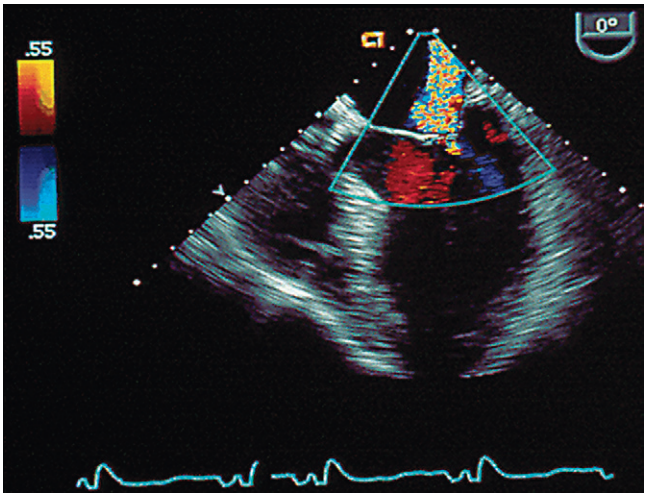

**Figure 19-10 Ischemic mitral regurgitation.** The TEE four-chamber view shows apical tethering, of normal mitral leaflets and a central to posteriorly directed jet of mitral regurgitation.

mortality has been reported even in selected patients with severe MR and severe LV dysfunction.

### Normal Leaflet Motion (Carpentier Class 1)

The least common type of MR occurs with normal leaflet motion either due to perforation of a valve leaflet, which occurs most commonly because of endocarditis, or because of a congenital cleft in the valve. Occasionally MR with normal leaflet motion is iatrogenic, after attempted repair. Typically, the jet origin is eccentric, arising from the midportion of the leaflets rather than from the coaptation line. The prejet flow acceleration also may be seen away from the coaptation line, along the affected leaflet. Leaflet perforation may be repaired in some instances by suture closure or with pericardial patch.[52]

One study of 248 patients undergoing mitral valve surgery showed that TEE was more than 90% accurate for defining the mechanism of regurgitation, localizing the origin of regurgitation, and detecting a flail segment. TEE was 88% accurate in detecting ruptured chordae. The TEE findings of valve function are highly predictive not only of valve reparability (Table 19-2), but also of long-term survival, which were independent of age, gender, ejection fraction, and coronary artery disease.[53]

**TABLE 19-2 Repairability and Durability of Repair for Mitral Regurgitation According to Mechanism and Morphology**

| *Carpentier Class* | *Morphology* | *>90% Repairable* | *Durable* |
|---|---|---|---|
| 1: Normal | Perforation | Yes | Variable |
| 2: Simple excessive | Flail, prolapse | Yes | Yes |
| 2: Complex excessive | Extensive flail, billowing, or calcium | No | Variable |
| 3A: Restricted | Fibrotic, retracted | No | Less |
| 3B: Apical tethering | Functional | Yes | Variable |

## Determining the Need for Mitral Valve Surgery in Patients Undergoing Cardiac Surgery for Other Reasons

IOE increasingly is used to determine the need for a mitral valve operation in patients undergoing aortic valve surgery or revascularization procedures; this is especially true in the assessment of patients in whom the severity of the MR preoperatively is significantly different by cardiac catheterization and echocardiography, when the severity of MR over time is variable (such as in ischemic heart disease), and when the MR is of moderate severity.

The following questions must be considered when determining the need for mitral valve surgery in addition to the primary surgery:

1. How severe is the MR?
2. Is there a primary abnormality of the mitral valve (such as a torn chord or prolapse)?
3. Will the MR change as a consequence of the primary operation?
4. Is the valve repairable or is prosthetic replacement necessary?

5. What is the additional risk imposed by the additional mitral valve procedure?

The final decision on what surgery is indicated is made by the surgeon; however, when the surgical plans are changed in the operating room, telephone consultation with the referring clinical doctor is advisable.

In many patients, especially those in whom the regurgitation is secondary to apical tethering from ischemic heart disease with LV dilation, the severity of the regurgitation may be variable. Sometimes, the severity of regurgitation detected at the time of operation is different from that recorded preoperatively. Frequently the difference in severity is due to a true physiologic change. Compared with ambulatory conditions, the loading conditions during surgery often entail a lower intravascular volume and less peripheral vasoconstriction, both of which may reduce the severity of valvular regurgitation and reduce stenotic valve gradients. On other occasions this discrepancy reflects the superior ability of esophageal and epicardial echocardiography to visualize MR compared to TTE.

In patient presenting with symptoms that might be due to MR, but severity is less than is expected or borderline, it is often useful to increase afterload with multiple boluses of phenylephrine (100 mcg every 30 to 120 seconds), and then to recheck the severity of regurgitation at a mean arterial pressure that is transiently as high as 120 mm Hg. Patients with 3+ or more MR at rest, or during this afterload stress test, are generally considered candidates for a mitral valve operation. The threshold for surgery on the mitral valve also is affected by other factors, including whether there is a primary structural abnormality of the valve. If the valve appears to be repairable, the threshold for surgery is lower, given the relatively low morbidity and mortality associated with repair as compared with valve replacement, whereas the threshold for surgery is higher in patients with valves that are not reparable. In patients undergoing surgery for aortic stenosis, improvement in the severity of the MR can be expected postoperatively; therefore, the threshold for concomitant mitral surgery is higher.[54,55] On any patient with valvular disease, a postpump assessment is made regardless of whether a surgical intervention on the mitral valve has been performed.

## Postpump Intraoperative Echocardiography in Mitral Repair

The most significant indication for IOE in mitral valve repair (see Box 19-1 and Table 19-3) is to determine the competency of the repair immediately after cardiopulmonary bypass. If the repair is inadequate, further repair or replacement can be performed immediately during the same thoracotomy.

### TIMING

To make a relevant assessment of valvular performance, postpump intraoperative echocardiographic assessment of valvular function should be done after loading conditions and ventricular function have reached their postoperative plateau, when the patient has returned to relatively normal loading conditions. The most appropriate time to image after repair is when the patient is off cardiopulmonary bypass, the intravascular volume is replete, and the loading conditions are similar to those in the ambulatory state. Imaging can be initiated earlier than that, after the aortic cross clamp is off and the LV is at least partially filled, but abnormal findings at this time may result from abnormal LV geometry. In particular, the surgeon should not act on these findings unless they are subsequently confirmed by further imaging after the cessation of cardiopulmonary bypass.

**TABLE 19-3 Management of Abnormal Findings on Doppler Echocardiography after Mitral Valve Repair**

| *Complication* | *Management* |
|---|---|
| Residual MR | Define mechanism. If ≤1+, accept. If 2+, give phenylephrine to recheck MR with increased afterload; if >2+, further surgery is required. |
| Systolic anterior motion with LVOT obstruction | Assess LVOT gradient and MR. Increase ventricular volume, stop positive inotropes. If these measures are not successful, further surgery is needed to revise repair. |
| Dehisced ring or leaflet perforation | Another pump run is needed to redo annuloplasty. |
| Residual mitral stenosis | Quantify severity. If mean gradient >5 mm Hg or area <1.5 $cm^2$, consider further surgery. |
| Significant tricuspid regurgitation | If 3+ or more, consider further repair. |
| Regional LV dysfunction | Assess intracardiac air; if not resolved after further time on pump, consider coronary bypass. |
| Global (right or left) ventricular dysfunction | Assess volume status, afterload, and response to medications. Assessment for coronary air emboli. |

*LVOT*, Left ventricular outflow tract; *MR*, mitral regurgitation.

### INTRAOPERATIVE FINDINGS

In most cases, with an experienced surgeon, mitral valve repair leads to a competent mitral valve with mild or no residual MR; however, there are potential complications of mitral valve repair that are readily recognized by postpump IOE. Many of these complications may not be apparent clinically or may take longer to accurately diagnose without echocardiography. If left untreated, these complications may interfere with the long-term success of the procedure and require early reoperation. Complications seen after mitral valve repair by IOE are shown in Table 19-3. In early experience with more than 6000 patients, the frequency of needing a second run of cardiopulmonary bypass in mitral repair was 7%, which was lower than the frequency of aortic repair (14.7%) and myectomy (17.9%), but greater than the frequency of tricuspid repair (5.1%), congenital heart disease (4.9%), and aortic aneurysm surgery (3.6%).

### INCOMPLETE MITRAL REPAIR

Significant residual MR is the most common postpump problem detected by IOE. Moderate (2+) or more MR, either at rest or following afterload challenge with phenylephrine as previously described, is generally considered excessive after mitral repair and is an indication for a further surgical procedure. The incidence of this complication varies with the cause of the valvular regurgitation, the complexity of the repair, the experience of the surgeon, and the threshold of the operative team to accept a suboptimal result. When residual MR is found, further repair of the valve may lead to an improved result with reduction or elimination of MR, particularly when the echocardiographer can define the mechanism of the residual regurgitation. In some patients, further repair is impossible or fails, and the patient requires a third pump run to implant a prosthesis.

If the regurgitation is mild (1+) or less on the postpump IOE, then the result is usually accepted, though individual surgeons vary in their willingness to accept even mild amounts of regurgitation. The severity of MR detected by immediate postpump

IOE correlates well with angiographic or TTE and TEE estimates of severity obtained later.[56,57] Rarely, changes in the early postoperative period such as progressive chordal rupture, suture dehiscence, or early postoperative endocarditis may cause acute worsening of the MR. Thus, IOE is a reliable measure of the severity of MR and the need for further intervention.

Other considerations in deciding whether residual MR should be accepted or subjected to another surgical procedure include the mechanism of the MR, the overall condition of the patient, and LV function. Postpump determination of the mechanism of the residual MR helps the surgeon to determine whether a further reparative procedure could lessen the regurgitation and yet conserve the valve. More MR than is usually desirable might be accepted when other surgical procedures such as aortic valve replacement or coronary artery bypass grafting have also been accomplished, particularly in elderly patients or those with significant LV dysfunction. For example, in patients with extensive mitral annular calcification, mitral prosthetic insertion may be technically more difficult and more hazardous for the patient than accepting a moderate amount of residual MR.[58]

In various studies of patients undergoing mitral valve repair, 4% to 11% have needed a second pump run. About half of these (for example, 3% of the total, less than half of the 8% in one study) had persistent MR that was greater than 2+.[29] In most of the patients in whom immediate failure of mitral repair is treated with a further run of cardiopulmonary bypass, further repair can be accomplished successfully, whereas a smaller percentage (10% to 15%) of the patients having a second pump run undergo mitral prosthetic implantation. In one study,[59] inadequate repair was associated with a degenerative cause of the MR and with the absence of an annuloplasty ring implantation at the time of initial repair. In another study,[60] the need for reoperation because of inadequate repair or systolic anterior motion (SAM) of the mitral valve was more common in patients with anterior mitral leaflet or bileaflet prolapse, as opposed to those with posterior prolapse. In still another study[61] with an 11% incidence of second pump runs, interscallop malcoaptation of the posterior leaflet was the most common cause of the initially persistent MR. In the previously cited large retrospective study by Click and colleagues,[62] the incidence of changes based on the postpump IOE was 6%, although only one third of those returned to cardiopulmonary bypass for further surgery.

### IMPACT ON CLINICAL OUTCOME

IOE has a positive impact on prognosis and the incidence of reoperation after mitral repair in large centers and in smaller community hospitals. Reoperations are lower when IOE is used,[63] and the percentage of valves that are repaired is improved by the use of IOE.[64]

The severity of residual MR after mitral valve repair, as assessed by IOE, is important for prognosis, as shown by several studies. In one of these studies,[64a] moderate or greater MR was associated with a higher incidence of congestive heart failure, repeat valve surgery, or postoperative death. In a study of ischemic MR,[31] residual regurgitation by postpump IOE was a strong predictor of survival after mitral valve repair. Postoperative recurrence of MR in ischemic heart disease, however, correlates more with the degree of apical tethering, annular dilation, and contractile impairment, rather than the technical success of the repair procedure.[65] In another study,[31] patients with 3+ MR as determined by postpump IOE who did not undergo a further pump run at the time of initial operation required reoperation within 5 days because of hemodynamic instability and the frequent inability to wean off mechanical ventilation.

Patients who undergo a second pump run for an initially inadequate repair have an in-hospital complication rate that is similar to that of patients who require a single pump run.[66,67] In one study,[68] residual MR of 1+ or 2+ did not increase hospital complications when compared with trivial or no regurgitation postoperatively. There was a trend for patients with 1+ or 2+ MR, however, to need more reoperations in late follow-up than those with trivial or no MR.

## Other Complications of Mitral Valve Repair

### SYSTOLIC ANTERIOR MOTION OF THE MITRAL VALVE

Significant LV outflow obstruction caused by SAM of the mitral valve has been recognized as a complication of surgery since the early days of mitral valve repair.[69,70] This abnormality simulates the physiology seen in hypertrophic obstructive cardiomyopathy, even though septal hypertrophy is absent. The SAM of the mitral valve after mitral repair in these patients is dynamic and is exacerbated by reducing the size of the ventricular chamber or augmenting contractility. SAM may cause pressure gradients of 100 mm Hg or more, severe hypotension, severe MR, and inability to wean the patient from cardiopulmonary bypass. In many cases, however, it is mild and is not the cause of congestive preload or decreased forward flow. Fortunately, this series of complications is readily recognized and quantified by an experienced echocardiographer on the postpump echocardiogram study (Fig. 19-11). If it is not recognized, in some patients it will cause postoperative problems and require reoperation. SAM was initially reported in 2% to 9% of patients undergoing mitral valve repair,[29,60,71] but it is now less common because of the ability to prevent it with better design of the initial repair procedure.

Several mechanisms have been proposed to explain SAM following mitral valve repair. These mechanisms include anterior displacement of the posterior ventricular wall, anterior displacement of the posterior mitral leaflet, and narrowing of the angle between the mitral and aortic valves.[72] It is clear that SAM occurs primarily in patients with degenerative mitral valve disease, those with large mitral leaflets, and in the presence of a hyperdynamic, small ventricle.[60] SAM is usually seen only after annuloplasty ring insertion, but it has been reported after a suture annuloplasty.[60] It is seen more commonly with stiff than with flexible annuloplasty rings.[60,71] One quantitative study[72] has shown that SAM is associated with anterior displacement of the mitral coaptation line. The anterior displacement is reduced or disappears after successful revision of the repair and elimination of SAM. The ratio of the length of the anterior and posterior leaflets during coaptation and the distance from the coaptation line to the septum, on preoperative TEE, were shown to be predictors of SAM. The smaller the ratio between anterior and posterior leaflet and the narrower the distance between the coaptation point and the septum, the greater the likelihood of SAM.[73]

When severe, SAM is easily recognized and may involve both leaflets. The LV outflow gradient and the severity of MR are important indicators of the hemodynamic severity. The best TEE view for measurement of the LV outflow gradient is the

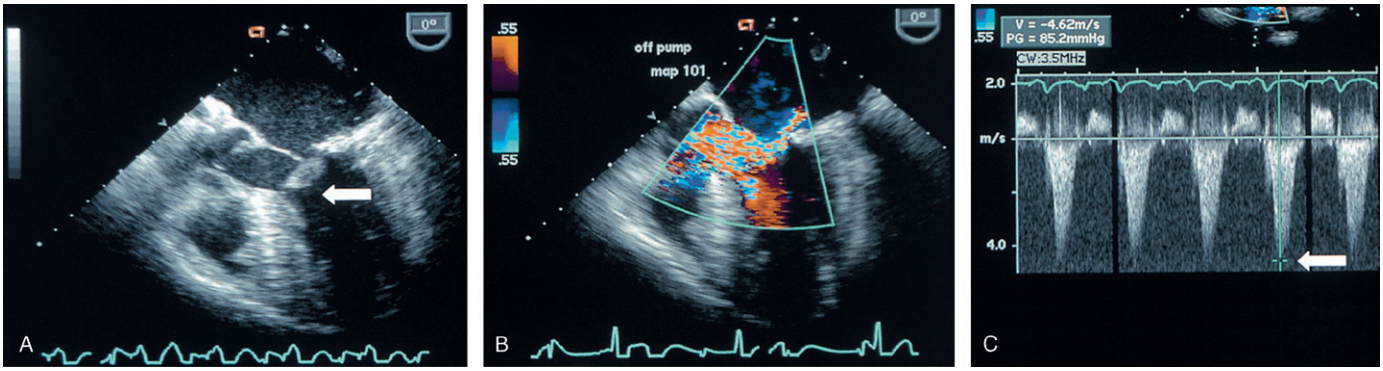

**Figure 19-11 Systolic anterior motion (SAM) of the anterior and posterior mitral valve leaflets at the end of the first pump run during mitral valve repair.** In the TEE four-chamber view, SAM is seen (**A,** *arrow*) leading to severe MR (**B**) and outflow obstruction. The maximal velocity measured in the outflow tract by continuous-wave Doppler (**C**) from the deep transgastric TEE view was 4.6 m/s, allowing estimation of an outflow tract pressure gradient of ≈85 mm Hg.

deep transgastric imaging window, which puts the heart in an orientation similar to a transthoracic apical five-chamber image and allows alignment of the continuous-wave Doppler cursor with the LV outflow tract jet. When this examination cannot be reliably performed with the transesophageal approach, the gradient can be measured with epicardial echocardiography. In many circumstances, the appearance on midesophageal images of marked SAM and significant persistent MR mandates a second pump run, without having to quantitate the gradient itself.

The initial management of patients with SAM and LV outflow obstruction after mitral repair should be to increase intracardiac volume by fluid repletion and to stop any positive inotropic agents that are being administered.[60] Systemic afterload can be supported by a pure alpha agonist (phenylephrine), avoiding any beta agonists such as dobutamine, dopamine, isoproterenol, or epinephrine. If these measures are inadequate to reduce the severity of SAM, another pump run to improve the SAM is indicated. A further procedure that may improve SAM is a sliding posterior leaflet advancement (sliding plasty), which reduces the anterior-posterior height of the posterior leaflet.

Sliding annuloplasty is currently used as a component of the primary operative procedure on patients who are considered at risk for developing SAM, particularly those with severe myxomatous leaflets with substantial redundancy, which has significantly reduced the incidence of this complication in those patients in whom it has been used.[74,75] If SAM persists despite these maneuvers, the final recourse is mitral prosthetic implantation. Patients in whom SAM is discovered by TTE days or longer after mitral valve repair, obviously a subset selected to have milder obstruction by successful weaning from bypass and extubation, may be treated medically with negative inotropic agents. Some patients show a late reduction in the LV outflow gradient, but obstruction may remain inducible by exercise, catecholamine infusions, or inhalation of amyl nitrite.[76]

## SUTURE DEHISCENCE, PERFORATION JET LESIONS, AND ANNULOPLASTY DEHISCENCE

Occasionally, suture dehiscence leads to significant MR after mitral valve repair. This complication was found by the post-pump IOE in 2% of operations in one series.[59] Kronzon and co-workers,[77] in a small case series of patients undergoing mitral valve repair or replacement, demonstrated that real-time 3D TEE provides additional information about the anatomic

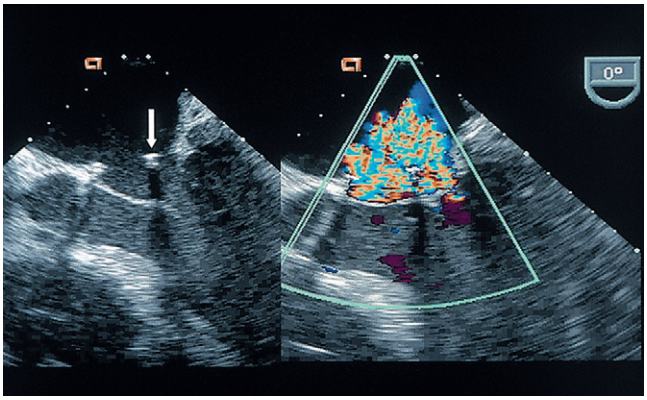

**Figure 19-12 Annular ring dehiscence.** Late failure of mitral repair due to annular ring dehiscence (*arrow, left panel*) leading to severe MR (*right panel*).

characteristics of mitral valve dehiscence and helps in planning appropriate corrective interventions. Dehiscence of a suture at the site of the leaflet resection or a suture line of the sliding plasty simulates a leaflet perforation mechanistically. This is now the most common cause of persistent MR after repair, and it is easily repaired on a second pump run. Another rare complication of mitral valve repair that can be detected by IOE is partial dehiscence of the annuloplasty ring. The annuloplasty ring shows increased mobility, and regurgitation may originate outside the ring (Fig. 19-12).

## LV SYSTOLIC DYSFUNCTION

Some reduction in LV function is often detected after mitral valve repair.[78,79] Early dysfunction after weaning from cardiopulmonary bypass may reflect the transient effects of cardioplegia and the suboptimal metabolic milieu. When dysfunction persists, it is most often global and may reflect the unmasking of LV dysfunction present preoperatively that had been concealed by the effects of increased ventricular preload and decreased afterload. In a minority of instances, a regional wall motion abnormality is detected, despite normal coronary vasculature preoperatively. This abnormality is usually caused by passage of air into a coronary vessel, most commonly a transient wall motion abnormality in the right coronary artery distribution, which usually but not always resolves without permanent infarction.[67,79a] Air within the LV cavity is readily detected by

echocardiography because it is echodense. The presence of large amounts of air on postpump IOE is an indication for increased surgical venting of the heart to prevent coronary embolization. Fortunately, most instances of air embolization of the coronary vessels resolve without significant long-term ventricular dysfunction. Because of its anterior position, air is more likely to travel to the right coronary artery in a supine patient, causing inferior wall motion abnormalities.

### TRICUSPID REGURGITATION

Tricuspid regurgitation is a common concomitant lesion to MR, More than moderate tricuspid regurgitation should treated with a ring annuloplasty at the time of mitral surgery. In all patients, whether tricuspid surgery is done or not, the amount of tricuspid regurgitation should be rechecked on the postpump intraoperative echocardiogram.[80] The success of the tricuspid surgery should be checked only after the intravascular volume status has been normalized.[81] Occasionally, tricuspid regurgitation that did not appear to be significant preoperatively may appear to be more severe on the postpump study and require a further pump run for tricuspid repair.

### MITRAL STENOSIS

In performing a mitral valve repair in a nonrheumatic valve, the surgeon may remove a significant portion of the leaflet or perform an annuloplasty that reduces the size of the mitral annular orifice. Despite these anatomic derangements, it is very unusual to have any significant stenosis in degenerative or ischemic mitral valve repair, because there is not any fusion of the mitral commissures or narrowing at the subvalvular level. The normal annulus area is 5 to 10 $cm^2$, varying with the size of the annuloplasty ring inserted. In contrast, residual stenosis of mild degree is common after rheumatic mitral valve repair because of the thickened leaflets and fusion of subvalvular chordae and commissures. The mitral valve gradient should be measured using continuous-wave Doppler after every mitral valve repair. A mean gradient in excess of 5 mm Hg should arouse suspicion of some degree of stenosis of the valve. Additional physiologic alterations with pharmacologic intervention may be needed to best demonstrate a transvalvular mitral valve gradient.

## Mitral Valve Repair Involving Commissurotomy

Mitral repair with open commissurotomy is used with decreasing frequency because of a progressive decline in the United States of the frequency of rheumatic valvular disease, and the recognition that repair of such valves is fraught with recurrence due to postoperative progression of the postinflammatory fibrosis. Balloon valvuloplasty is also a more common method of treating patients with isolated mitral stenosis. (See Chapter 21.) Nevertheless, mitral repair with open commissurotomy still has a place, especially in patients with mild or moderate valve calcification, or combined mitral stenosis and significant MR. It is especially useful when nonprosthetic outcomes are desirable, for example, in anticipation of future pregnancy. Before surgery, IOE is used to determine the severity of stenosis as a reference to assess the success of surgery. The severity of mitral stenosis is determined from the continuous-wave Doppler recording by planimetry of the diastolic velocity envelope, to measure the transmitral pressure gradient, and by measuring the pressure half-time.[82-84] An epicardial approach using a parasternal short-axis equivalent view may be used to obtain views suitable for planimetry of the mitral orifice itself, but most TEE short-axis views of the mitral valve from the transgastric window are not of sufficient quality for quantitative purposes. The mechanism of the stenosis, whether valvular or subvalvular, should also be determined. A splitability score generated in a manner similar to the transthoracic method used for percutaneous mitral valvuloplasty may help to determine the degree of valvular fibrosis and calcification and whether a valve-sparing procedure is feasible.[85] Because the surgeon can débride the valve under direct vision, open commissurotomy is sometimes possible even with a moderately high splitability score of 9 to 11, when a balloon valvuloplasty is not as likely to be effective or durable (see Chapter 21). The presence of MR and its mechanism, which is usually restricted leaflet motion, are also determined. It is important also to detect LA appendage thrombus preoperatively so that the surgeon can remove it.

On the postpump echocardiogram, the mitral valve gradient and area and MR are again assessed. The presence of residual MR of 2+ or greater, or a mitral valve area of less than 1.5 $cm^2$ by pressure half-time, is an indication for a further pump run, either to improve the repair or to implant a prosthesis. Frequently, when the patient has atrial fibrillation, a Maze procedure or pulmonary vein ablation will be performed. The LA appendage may be ligated in an effort to reduce the embolic risk, although in up to one third of patients, blood may still enter and leave the appendage.[86]

## TEE in Minimally Invasive and Robotic Mitral Valve Repair

Guidance by imaging is more important when the therapy involved is new or for some reason associated with more risks of mistaken objectives or faulty outcome. With the ongoing development of percutaneous leaflet repair and annuloplasty, along with minimally invasive valvular surgery, IOE continues to be a vital component in ensuring the success of these new techniques. (See Chapters 5 and 6.)

One such emerging arena is less invasive valve procedures. The vast majority (over 80%) of isolated minimally invasive mitral surgeries performed in the past 15 years have been done using a hemisternotomy, which involves a vertical incision about 8 to 10 cm long. This operation causes less chest trauma and bleeding and is associated with more rapid return to work, but it also involves less visual exposure of the heart, which is largely compensated for by intraoperative TEE.[17] In minimally invasive operations in which smaller incisions are used, surgical venting may be difficult or impossible. In this situation, resumption of cardiopulmonary bypass may be necessary for a period of time in order to allow slow resolution of the air.

Robotic heart surgery is a new field that requires very special techniques and technology. Again, robotic valve surgery relies heavily on IOE.[87] Recent studies have demonstrated the valuable adjunct role that TEE plays in the assessment of robotic MV repair. Wang and associates[28] recently performed intraoperative TEE in 22 consecutive patients at the General Hospital in Beijing, China, over a 2-year period and demonstrated that all patients (100%) had successful robotic MV repair with the use of intraoperative TEE.

## TEE in Transcatheter Mitral Valve Repair

Another innovation involves percutaneous valve procedures, which are done entirely via endovascular access. Percutaneous valve replacement has been developed, though only for the aortic and pulmonic valves thus far.[88-90] For severe MR, although endovascular valve replacement is not yet available, both direct and indirect percutaneous repair of the native mitral valve can now be accomplished.

The primary form of surgical mitral repair is annuloplasty. The placement of a ring or annuloplasty band in the mitral annulus, fixed by sutures, is the technique most commonly used. Percutaneous therapies for MR have paralleled many of these same surgical techniques. Percutaneous annuloplasty are under investigation through both direct and indirect approaches. Direct annuloplasty is significantly more challenging technically and associated with greater morbidity. A guide catheter must be passed retrogradely across the aortic valve and positioned within the LV on the undersurface of the posterior mitral leaflet. Current systems in development use either radiofrequency wires over which pledgets are passed and then connected via a string that is then plicated drawing the pledgets closer together, or Nitinol anchors that are placed directly in the mitral annulus and tethered together to draw the anchors closer together. Indirect annuloplasty fundamentally involves the placement of a device in the coronary sinus, which parallels the posterior mitral leaflet, and creates tension that is then transmitted to the mitral annulus. Given the relatively long history of implantation of devices in the coronary sinus, this approach is the less technically challenging. There are several limitations that are common to the indirect approach. Because of significant mechanical stresses causing significant torsional forces, there have been several cases of device fracture. Further, given the proximity of the circumflex coronary artery to the coronary sinus, compression is a potential concern. Alternative techniques for surgical mitral repair involve annuloplasty with leaflet resection and sliding annuloplasty.

### PERCUTANEOUS EDGE-TO-EDGE REPAIR OF MITRAL REGURGITATION

Though it is used less commonly for surgical repair, the edge-to-edge approximation technique is a leaflet maneuver first described by Alfieri and colleagues[91] in the early 1990s. A percutaneous method of direct mitral valve repair has been developed that uses this edge-to-edge approach via transseptal access[92] (Fig. 19-13). The MitraClip system consists of a guide catheter, a clip-delivery catheter, and an implantable dual-arm cobalt-chromium clip. The open clip can grasp the mitral leaflets via small grippers. When the edges of the two leaflets are attached, the intact chords to the anterior leaflet support the prolapsing posterior leaflet, or vice versa. TEE is essential for online assessment of the degree of reduction in MR in real time. The clip can be opened and closed multiple times for proper positioning, and if needed, a second clip can be placed if the reduction in MR is felt to be insufficient (Fig. 19-14). The EVEREST Phase I clinical trial evaluated 24 patients in whom the MitraClip was placed and followed them for 6 months.[93] In 13 of 14 patients where reduction of MR was 2+ or less after 1 month, the reduction was maintained at 6 months. The EVEREST II trial was a multicenter, randomized controlled trial that was designed to evaluate the benefits and risks of the MitraClip device for endovascular mitral valve repair compared with open surgery in patients with

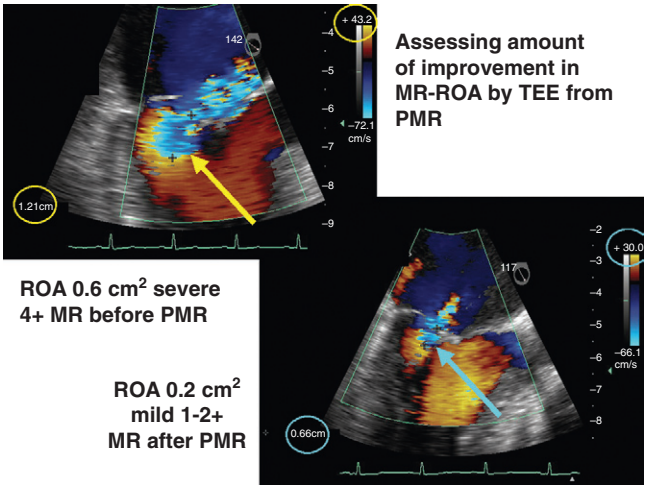

**Figure 19-13 Improvement in the amount of mitral regurgitation (MR) in a patient undergoing percutaneous mitral repair (PMR) is illustrated.** At *upper left*, the flow convergence zone is measured in a patient with severe prolapse of the posterior leaflet in a midesophageal TEE view from which the aliasing radius, at a Nyquist of 43 cm/s, permitted calculation of a regurgitant orifice area (*ROA*) of 0.6 $cm^2$. After percutaneous edge-to-edge repair (*lower right*), the MR has been reduced to mild or 1-2+ with an ROA of 0.2 $cm^2$, based on an aliasing radius of 0.66 cm at a Nyquist of 30 cm/s.

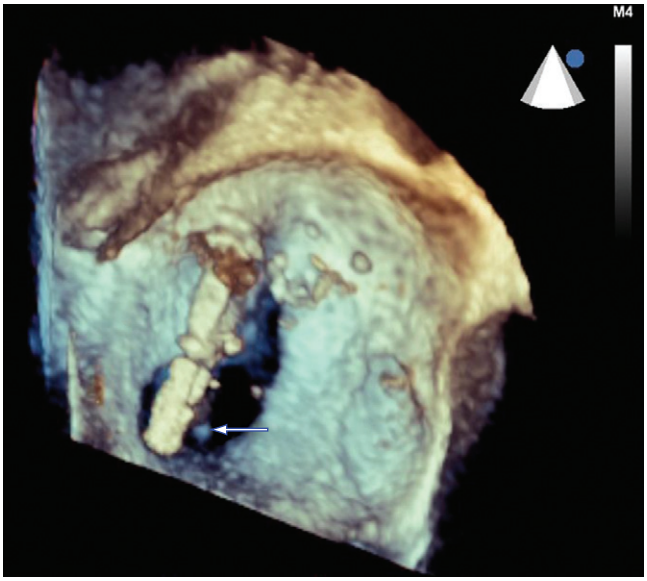

**Figure 19-14 3D TEE online still image of a patient with severe MR undergoing insertion of a percutaneous MitraClip via transseptal puncture.** The dual-arm cobalt-chromium clip (*arrow*) is seen at the end of the clip-delivery catheter.

moderate or severe MR.[94] A total of 279 patients were enrolled and evaluated for 12 months. The 1-year efficacy endpoint of the combined incidence of death, mitral valve surgery, or reoperation for mitral valve dysfunction was reached in nearly 75% of surgical patients and 66% of MitraClip patients, which met the noninferiority hypothesis for efficacy.

### PERCUTANEOUS CLOSURE OF PARAVALVULAR MITRAL REGURGITATION

Development of paravalvular leak is a well-known complication of mitral valve replacement surgery occurring in 1% to 5% of

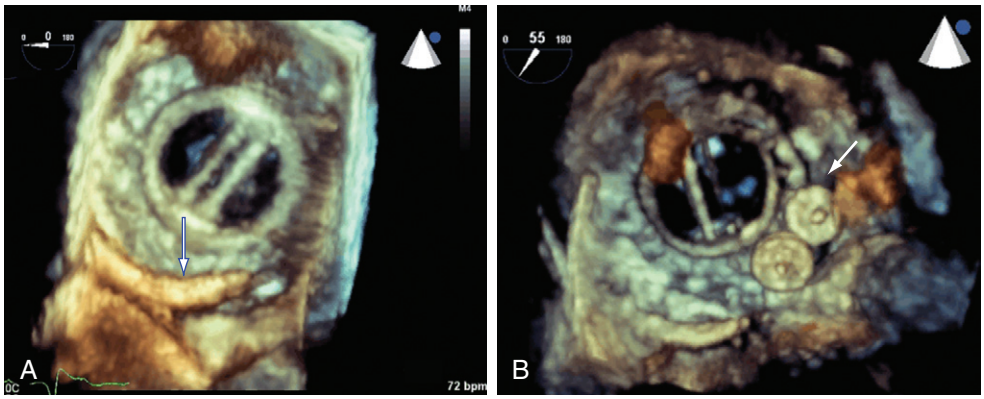

**Figure 19-15 3D TEE image of mechanical bileaflet mitral valve prosthesis in a patient with known paravalvular mitral regurgitation. A,** The transseptal sheath is seen within the LA (*arrow*) with guidewire positioned across the paravalvular orifice. **B,** Following percutaneous closure of the paravalvular leak using multiple Amplatzer occluder devices (*arrow*) within the defect.

patients.[95] Percutaneous transcatheter closure of mitral paravalvular leak has to date only achieved variable success ranging from 60% to 90% in the literature, as well as a need for repeat intervention in up to 40% of patients.[95] Part of the reason for the limited success rate in the percutaneous closure of paravalvular leaks stems from a major challenge, namely the ability to visualize the 3D nature of the defect (Fig. 19-15, Video 19-3 at ExpertConsult.com). Additionally, there is no one-size-fits-all device available for closure of these defects. Multiple devices approved by the U.S. Food and Drug Administration for closure of other cardiovascular defects are being used in an off-label fashion for this indication.[96] Advanced imaging guidance with 3D TEE is useful in guiding placement and defining the amount and location of paravalvular MR at each stage of the procedure.[97]

These percutaneous procedures are pushing the envelope of therapy for valvular heart disease, into cardiac interventional procedures in the catheterization laboratory. Imaging before, during, and after such procedures typically involves TEE.

## KEY POINTS

- IOE is useful before mitral valve repair to determine the mechanism and severity of the MR, determine the presence of other significant disease that may require surgical attention, establish baseline left and right ventricular function, and, after repair, to determine the success of the surgical procedure.
- The mechanism of MR, discerned from leaflet by 2D echocardiography and the jet direction by color Doppler, allows prediction of the feasibility of mitral valve repair and the surgical techniques of doing so.
- When residual MR is noted on the postpump TEE, further repair of the valve during a second pump run often improves the surgical result and has a positive impact on postoperative survival and freedom from reoperation.
- Real-time 3D TEE now provides incremental information and may allow more appropriate selection of patients. It may also help determine the most appropriate surgical procedure.

Other Infrequent Causes of Acute Aortic Regurgitation

## Background

Aortic regurgitation (AR) is characterized by diastolic reflux of blood from the aorta into the left ventricle (LV). The clinical presentation is variable and depends on several factors, including acuity of onset, aortic and LV compliance, hemodynamic conditions, and severity of the lesion. Although chronic AR is generally well tolerated for many years, acute AR may lead to rapid decompensation and, if untreated, to early death. Doppler echocardiography is the primary modality for evaluation of the presence and severity of AR. However, two-dimensional (2D) and M-mode echocardiography are useful in evaluation of the mechanism of AR. The prevalence of AR depends on age, aortic root diameters, and ethnic group. The overall prevalence of chronic AR is 5% to 10%, with most cases being trace or mild; moderate or severe AR is less common (0.5% to 2.7%).[1,2] Precise determination of the severity of the regurgitation and its repercussions on LV function is essential for clinical management and appropriate timing of surgical intervention. Echocardiography has become the most frequently used noninvasive method for AR assessment, including not only the etiology, with evaluation of ascending aortic dilation, but also determination of the severity of regurgitation along with its effect on ventricular function.

## Etiology

AR results from numerous causes, with malcoaptation of the aortic leaflets due to abnormalities of the leaflets themselves or of the supporting structures, such as the aortic root and annulus, or both (Box 20-1). Although rheumatic heart disease remains the most common etiology in developing countries, ascending aortic diseases are becoming a more frequent cause in developed countries.[3,4]

Echocardiographic evaluation of the anatomy of aortic leaflets, annulus, and aortic root is important not only in defining the etiology but also in the prognosis and management of AR.

### LEAFLET ABNORMALITIES

There are several diseases that result in AR due to leaflet abnormalities:

1. Rheumatic disease is characterized by commissural fusion, thickening, and retraction of the aortic leaflets, which usually induces a central regurgitation jet.
2. Aortic valve sclerosis results in AR due to calcifications located in the central part of the cusps, which is more prevalent in the elderly population.
3. Congenital abnormalities include bicuspid and, more rarely, unicuspid or quadricuspid valves. In these congenital abnormal valves, abnormal stress on the leaflets modifies valve structure and causes AR, mainly due to valve prolapse. The long-axis view reveals an asymmetric closure line and systolic doming or diastolic prolapse of the leaflets. The short-axis view is more specific. The diagnosis is confirmed when only two leaflets are seen in systole with two commissures framing an elliptical systolic orifice[5-7] (Fig. 20-1). The diastolic image may mimic a trileaflet valve when a raphe is present. The most frequent abnormality is fusion of the right and left coronary cusps. Three-dimensional (3D) echocardiography may better define morphologic details of the

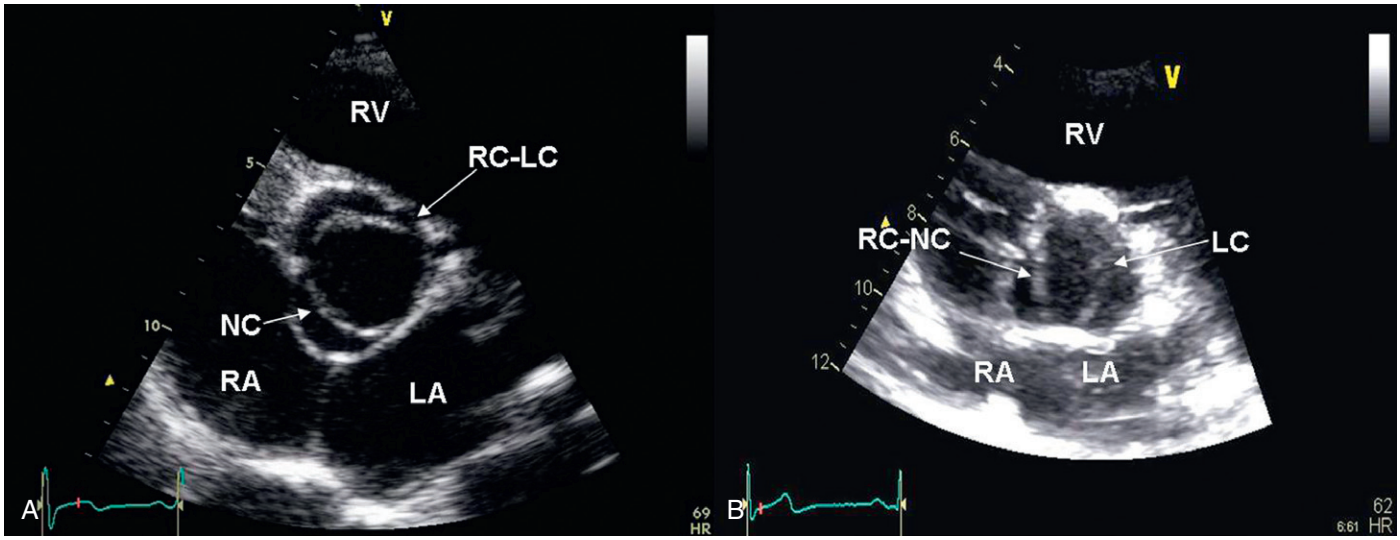

**Figure 20-1** **Parasternal short-axis view of a bicuspid aortic valve (BAV). A,** Fusion of the right and left coronary cusps (anterior-posterior BAV). **B,** Fusion of the right coronary and noncoronary cusps (right-left BAV).

## ETIOLOGY OF CHRONIC AORTIC REGURGITATION

**Abnormalities of Aortic Leaflets**
Bicuspid aortic valve and other congenital abnormalities
Aortic valve sclerosis
Rheumatic heart disease
Myxomatous valve disease
Systemic inflammatory disorders
Antiphospholipid syndrome
Anorectic drugs
Subaortic stenosis

**Diseases of the Aortic Root**
Idiopathic aortic root dilatation
Aortoannular ectasia
Marfan syndrome
Ehlers-Danlos syndrome
Osteogenesis imperfecta
Aortic dissection
Syphilitic aortitis

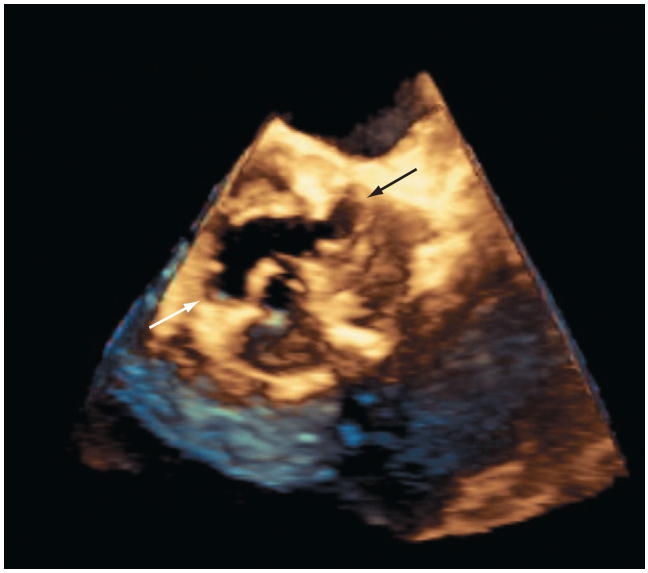

**Figure 20-2** **3D TEE image looking at the aortic side of a bicuspid aortic valve.** The two commissures (*arrows*) are seen with the slitlike valve opening in systole. The larger anterior leaflet has a prominent raphe.

bicuspid aortic valve (BAV)[8] (Fig. 20-2). Other congenital disorders such as ventricular septal defect or subvalvular aortic stenosis may also induce AR secondary to jet lesions.

4. Endocarditis results in acute AR either by leaflet perforation due to the infectious process (see Chapter 22) or to diastolic leaflet closure deformity caused by the presence of a valvular vegetation.[9]
5. Myxomatous valve disease can affect the aortic as well as the mitral valve. The leaflets are thickened and redundant with slight sagging into the LV outflow tract (LVOT) in diastole[10] (Fig. 20-3).
6. Less common abnormalities include congenital or iatrogenic leaflet fenestrations. In addition, leaflet thickening may be induced by drugs[11] or radiation, nonbacterial thrombotic endocarditis, lupus erythematosus, and other inflammatory diseases.[12]

## AORTIC ROOT ABNORMALITIES

AR may be caused, even when the leaflets themselves are normal, by alteration in the geometry of the structures supporting the leaflets. These conditions may now be more common than primary leaflet disease in patients undergoing surgical treatment for isolated AR in developed countries.[4] The aortic annulus is a complex crown-shaped structure where the leaflets attach to the aortic valve with the three points of the crown at the commissures and the three lowest points at the midsection of each leaflet (Fig. 20-4). Dilatation of this area at the base of the aortic root results in AR owing to inadequate coaptation of the stretched leaflets[13]. Aortic root dilatation may be due to a variety of causes[14] including chronic hypertension,[15] Marfan syndrome,[16] aortoannular ectasia (Fig. 20-5), Ehlers-Danlos syndrome, osteogenesis imperfecta, atherosclerotic aneurysms,

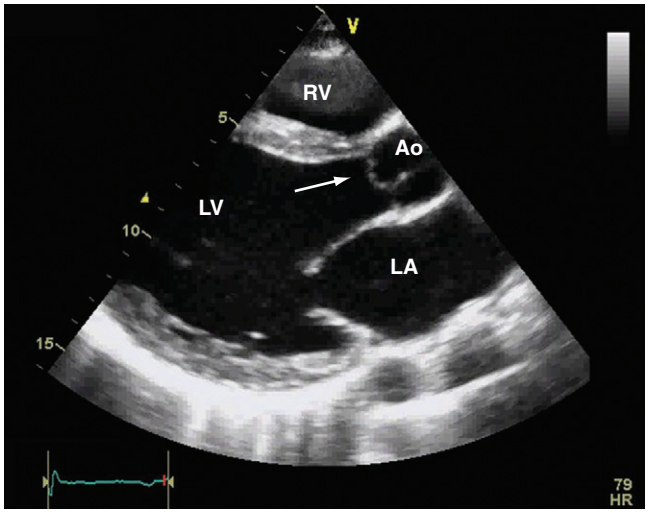

**Figure 20-3** Myxomatous aortic valve with a prolapse of right coronary cusp (*arrow*). Note that LV is severely dilated (end-diastolic diameter = 68 mm) due to chronic severe aortic regurgitation. *Ao*, Aorta.

aortic dissection (Fig. 20-6), syphilitic aortitis, or various systemic inflammatory diseases.[14,17-19] (See Chapters 37 and 39.) Interestingly, in some studies, hypertension did not predict AR on multivariate analysis, thereby confirming the results of earlier studies showing hypertension to be associated with modest increases in aortic root size but not AR when age is included in the model.[15] Remarkably, Roberts and colleagues[4] analyzed the causes of pure AR in 268 patients undergoing isolated aortic valve replacement and showed that the cause was unclear by echocardiography, angiography, or histologic findings in more than 30% of cases. The group with unclear causes of AR was the oldest; 91% had hypertension, and 29% showed small calcific deposits in the valve cusp.

### COMBINED VALVE AND AORTIC ROOT ABNORMALITIES

Some diseases, such as BAV or ankylosing spondylitis, may share both leaflet and aortic root abnormalities. In fact, more than 50% of patients with BAV have echocardiographic evidence of aortic dilatation. Controversy exists as to whether aortic wall changes in BAV are caused by a congenital defect or whether they are due to the abnormal hemodynamic stress on the aortic wall secondary to abnormal helical systolic flow in the ascending aorta.[20,21] It has been suggested that type 1 BAV (fusion of right and left coronary cusp) is related to larger sinus diameter than type 2 (right and noncoronary fusion) and type 3 (left and noncoronary fusion). Type 2 morphology shows mid–ascending aortic dilatation[5] more frequently (see Fig. 20-1). However, other studies have not shown a significant relationship between aortic dimensions and morphologic valvular variables.[22] Finally, chronic severe AR of any etiology may lead to progressive enlargement of the aortic root and further worsening of AR over time.[23]

## Aortic Regurgitation Severity

### COLOR DOPPLER ECHOCARDIOGRAPHY

Color Doppler echocardiography is the key method for the diagnosis and quantification of AR in clinical practice.[24-26] Pulsed- and continuous-wave Doppler are used as complementary

methods. The regurgitant color Doppler flow pattern has three components: the proximal flow convergence or proximal isovelocity surface area (PISA), the vena contracta, and the distal jet.

1. *Color jet area and length* correlate only weakly with the degree of AR, mainly in acute or subacute AR, as they are particularly affected by the aortic-to-LV diastolic pressure gradient and LV compliance.[27-30] Despite these limitations, the difference between mild and significant AR may be estimated whenever the same instrument settings are used and complete visualization of the jet extension using different apical projections is used[31] (Fig. 20-7). When the AR jet is directed toward the mitral valve, the use of the apical long-axis view permits better visualization of the jet area. In our experience,[31] in chronic AR, a jet area less than 4 $cm^2$ or greater than 7 $cm^2$ is specific for mild or significant regurgitation, respectively. However, this method is associated with high intermachine variability.[31-33] In addition, in the presence of mitral stenosis or mitral valvular prosthesis, AR jet size is difficult to evaluate.[31,34]

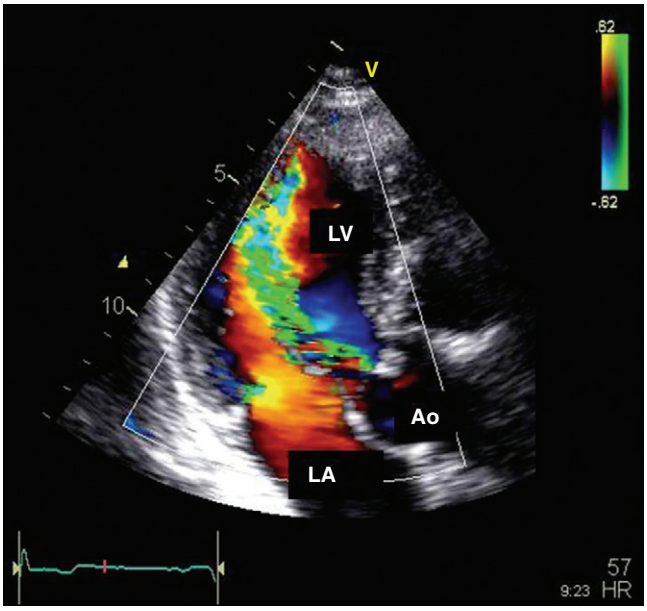

**Figure 20-7 Eccentric jet of aortic regurgitation directed toward mitral valve.** The jet is well visualized by apical three-chamber view. *Ao,* Aorta.

2. *Proximal regurgitant jet width* and its ratio to LVOT diameter is obtained from the long-axis views measured immediately below the aortic valve (at the junction of the LVOT and aortic annulus). A ratio less than 25% is consistent with mild AR, whereas a ratio greater than 65% is consistent with severe AR.[35] However, the absolute value of jet width has similar accuracy and better reproducibility than this ratio, indicating that jet width alone may be sufficient and more practical in the follow-up of patients. A jet width greater than 10 mm is indicative of severe AR and less than 7 mm of nonsignificant AR[31] (Fig. 20-8). This method has some limitations. Jet width should be measured perpendicular to the direction of the jet. However, eccentric jets directed predominantly toward the anterior leaflet of the mitral valve or the septum tend to occupy a small portion of the proximal outflow tract and may thus appear narrow and underestimate regurgitation severity.[31] Conversely, central jets tend to expand fully in the outflow tract (the spray effect) and may be overestimated. This method works best when the regurgitant orifice is relatively round in shape. When it is elliptical, as in BAV, jet width can lead to underestimation of AR severity.[25] The short-axis view is helpful in identifying regurgitant orifice shape (Fig. 20-9).
3. *Cross-sectional area of the jet* from the parasternal short-axis view and its ratio to the LVOT area are also indicators of AR severity. A ratio less than 25% is consistent with mild AR, whereas a ratio greater than 65% is consistent with severe AR.[24,25] In our experience an area greater than 1 $cm^2$ is indicative of severe AR[31] (see Fig. 20-9). The short-axis jet area has limitations because small changes in the level of the LVOT result in significant differences in jet area. In addition, image quality is suboptimal in more than 20% of cases in this view.

The combination of jet width greater than 10 mm with an apical color jet area greater than 7 $cm^2$ or cross-sectional area greater than 1 $cm^2$ has been considered a strong argument for severe AR. Unfortunately, concordance in severity grades among these Doppler methods was only 60%.[31]

4. *Vena contracta width* is one of the best methods for grading AR severity.[24,25] The vena contracta represents the smallest flow diameter at the aortic valve level, immediately below the flow convergence region. It provides, thus, an estimate of the size of the effective regurgitant orifice area (EROA) and is smaller than the regurgitant jet width in the LVOT. The vena contracta is measured in the parasternal long-axis view

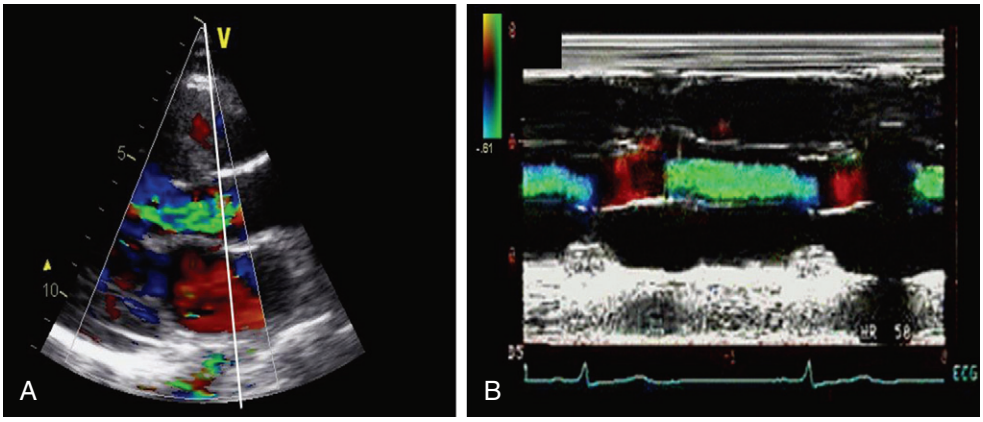

**Figure 20-8 Severe aortic regurgitation in parasternal long-axis view. A,** Color Doppler 2D. **B,** Color-coded M-mode depicting the time dependency of flow signal (*white line*) during the heart cycle.

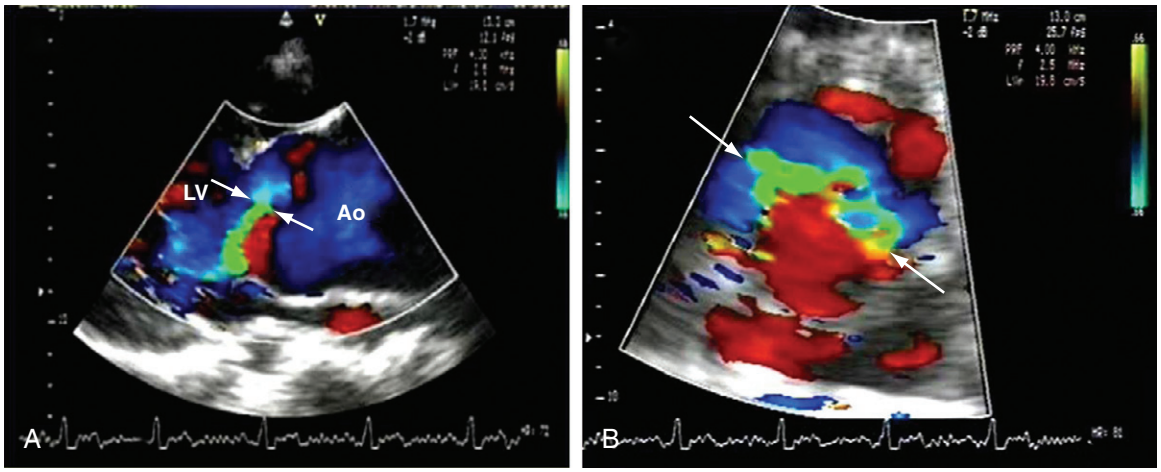

**Figure 20-9 Severe aortic regurgitation secondary to bicuspid aortic valve.** Although the vena contracta (**A,** *arrows*) of eccentric jet, directed toward mitral valve, is 5 mm, the short-axis view shows the elliptical shape (*arrows*) of the regurgitant orifice, suggesting a greater severity of AR (**B**). *Ao,* Aorta.

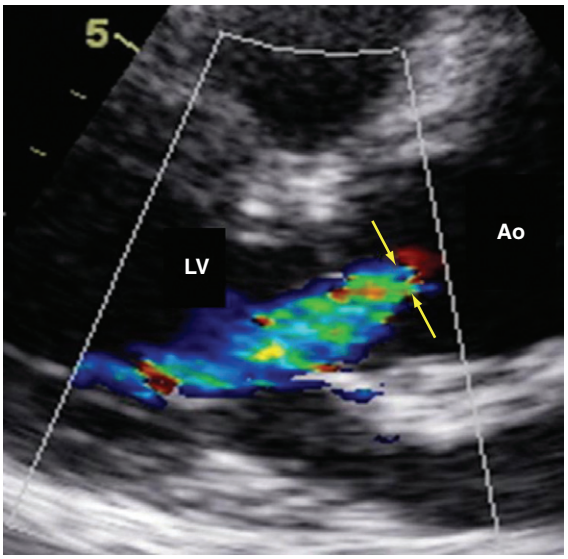

**Figure 20-10 Vena contracta of aortic regurgitation jet** (*arrows*). In the parasternal long-axis view, the vena contracta is the narrowest waist of the jet (7 mm in this example) just downstream from the aortic orifice. *Ao,* Aorta.

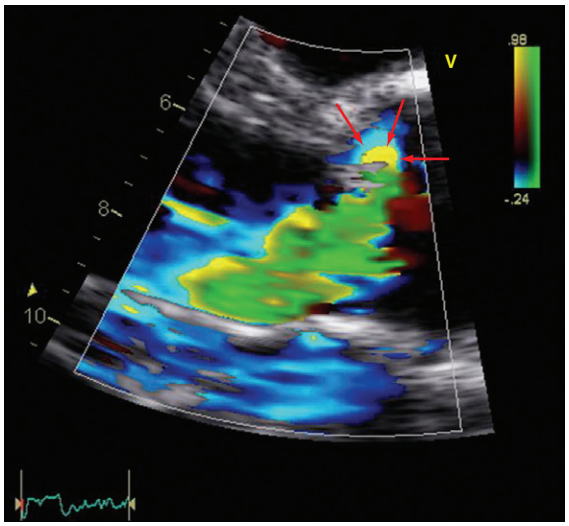

**Figure 20-11 Quantitative assessment of aortic regurgitation severity using the proximal isovelocity surface area (PISA) method.** Downward shift of zero baselines to obtain a hemispheric PISA.

(Fig. 20-10). A narrow color sector scan and zoom mode are recommended to optimize this measurement. Using a Nyquist limit of 50 to 60 cm/s, a vena contracta width of less than 3 mm correlates with mild AR, whereas a width greater than 6 mm indicates severe AR.[36,37] Because the vena contracta is often obscured by the leaflets, it can be difficult to measure accurately, mainly in calcified valves. The vena contracta method is also limited when the regurgitant orifice is elliptical or irregular. With 3D echocardiography, vena contracta areas less than 20 $cm^2$ and greater than 60 $cm^2$ have been proposed to define mild and severe AR, respectively.[38]

5. *The flow convergence method* is less commonly used to identify a clear proximal flow convergence in AR compared with mitral regurgitation. When feasible, the PISA method is less sensitive to loading conditions,[39-41] although this method is more technically demanding. The PISA region is imaged ideally in apical or right parasternal views (Fig. 20-11). The area of interest is expanded using the zoom mode, and the sector size is reduced as narrowly as possible to maximize the frame rate. The Nyquist limit should then be shifted in the direction of the AR jet to optimize measurements of the PISA radius. A clearly visible, hemispheric PISA is required for calculation. Peak flow is calculated as $2\pi r^2$ multiplied by the aliasing velocity ($V_{aliasing}$). The EROA is obtained by dividing the peak AR flow rate by the peak instantaneous AR velocity ($V_{AR}$) obtained by continuous-wave (CW) Doppler.

$$\text{EROA} = 6.28 \times r^2 \times V_{aliasing}/\text{peak } V_{AR}$$

The regurgitant volume is calculated from the EROA by multiplying by the velocity-time integral (VTI) of the AR jet. Possible accumulated errors of each variable of the equation for calculation of the regurgitant orifice do not render this method advisable for groups with limited experience in its routine use. Grading of AR severity classifies an EROA less than 10 $mm^2$ or an AR regurgitant volume less than 30 mL/beat as mild AR, and an EROA greater than 30 $mm^2$ or an AR regurgitant volume greater than 60 mL as severe AR.[41]

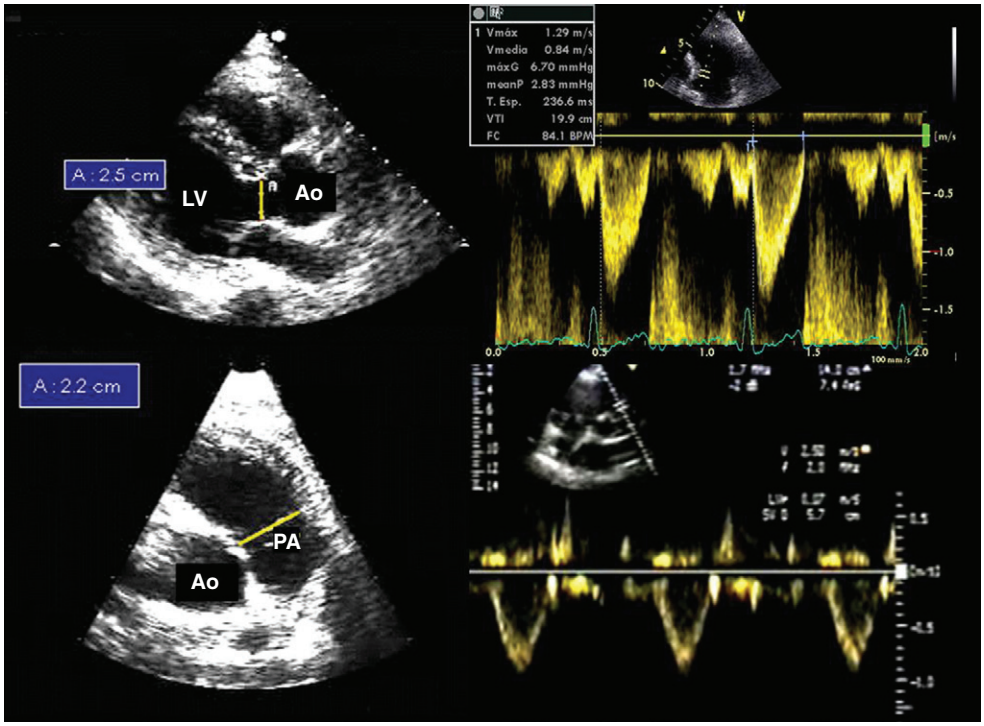

**Figure 20-12 Quantification of regurgitant fraction.** Stroke volume obtained in the left ventricular outflow tract (LVOT) (*top*) and RV outflow tract (*bottom*). Aortic annular diameter (*top right*) is 25 mm. Velocity-time integral (VTI) of LVOT (*top left*) is 20 cm; pulmonary annular diameter (*bottom right*) is 22 mm; VTI of RV outflow (*bottom left*) is 13 cm. LV outflow stroke volume is 98 mL, RV outflow stroke volume is 44 mL; thus, regurgitant volume is 54 mL and regurgitant fraction 55%. *Ao*, Aorta; *PA*, pulmonary artery.

When imaged from the apical window, the PISA method significantly underestimates AR severity in the presence of eccentric AR jets. In this situation, imaging the flow convergence zone from the parasternal long axis improves the accuracy of the PISA method.[24-26]

## VOLUME FLOW CALCULATIONS

*The pulsed Doppler volumetric method* can be used as an alternative method to quantify AR severity. The difference between LVOT flow volume and mitral or pulmonary flow volume facilitates estimation of regurgitant volume and regurgitant fraction.[31] Mitral inflow is calculated as VTI of mitral inflow (at annulus level) multiplied by the mitral annular area, assuming there is no more than mild MR. Mitral annular area is calculated as $\pi(D/2)^2$, in which D is the diameter of the mitral annulus measured in the apical four-chamber view in middiastole.[42] Measurement of stroke volume of right ventricular (RV) outflow is calculated as VTI of the RV outflow tract multiplied by the pulmonary annular area obtained from the parasternal short-axis view (Fig. 20-12). This approach is time consuming and is associated with drawbacks such as low reproducibility. In general, a regurgitant fraction greater than 50% indicates severe AR.[24,25]

## AORTIC HOLODIASTOLIC FLOW REVERSAL

*Diastolic flow reversal in descending aorta:* AR determined at the aortic isthmus level using the suprasternal view by pulsed Doppler is an easy method for identifying significant AR. A pulsed Doppler sample volume should be placed just distal to the origin of the subclavian artery, aligning it as far as possible along the major axis of the aorta. It is important for diastolic

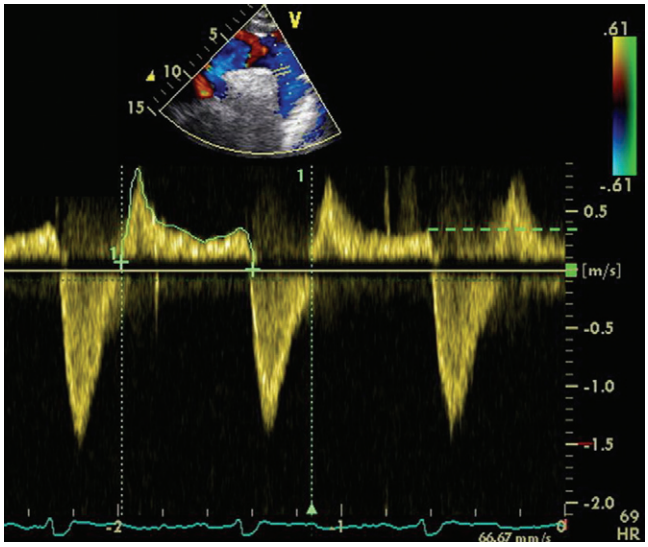

**Figure 20-13 Holodiastolic flow reversal in descending thoracic aorta with severe regurgitation.** Note that end-diastolic velocity is 35 cm/s.

flow reversal to occur throughout most of diastole, because there can be brief early diastolic flow in the ascending and descending aorta resulting from elastic recoil in a normal aortic Doppler pattern, particularly in young children and adults. As the degree of regurgitation increases, so do the duration and velocity of reversal flow.[43] End-diastolic velocity exceeding 20 cm/s is indicative of severe AR. In our experience, holodiastolic flow reversal with a diastolic VTI greater than 15 cm or with a similar value to the systolic antegrade VTI is a reliable qualitative sign of severe AR (Fig. 20-13). In addition,

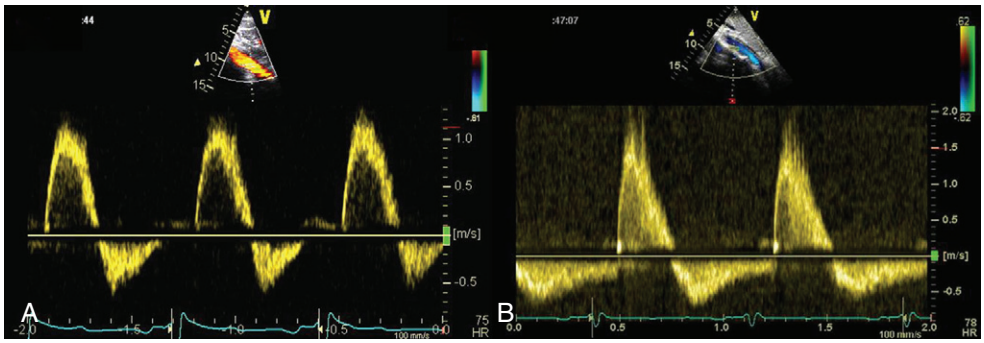

**Figure 20-14** **Abdominal aortic flow. A,** Brief diastolic flow in nonsevere aortic regurgitation (AR); **B,** pandiastolic flow reversal in severe AR.

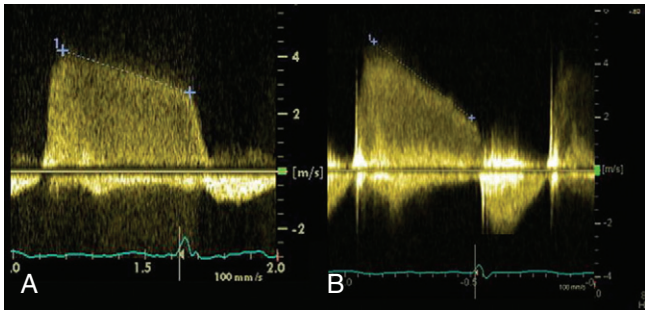

**Figure 20-15** **CW Doppler signal of aortic regurgitation (AR) with different diastolic deceleration slopes. A,** Moderate AR; **B,** severe-acute AR. Note that pressure half-time is significantly shorter in **B** than in **A.**

significant holodiastolic reversal in the abdominal aorta is also a specific sign of severe AR (Fig. 20-14).[24-27] However, these methods are influenced by heart rate, diastolic period duration, and aortic distensibility.

## CONTINUOUS WAVE DOPPLER ULTRASOUND

CW Doppler of the AR jet provides an indirect assessment of AR severity. The more intense the CW signal of the AR compared to systolic antegrade flow, the greater number of red blood cell reflectors and AR volume.

### *Deceleration Time of Regurgitant Flow*

The deceleration rate of the AR jet assessed by continuous wave Doppler provides supportive evidence when the degree of AR is assessed. The deceleration slope of the AR jet reflects the pressure difference between the aorta and the LV during diastole. It is classically best obtained from the apical five-chamber view (Fig. 20-15). The method is limited in mild AR and in the presence of eccentric jets because an adequate spectral envelope is not easy to obtain. Significant overlap exists between moderate and severe regurgitation.[31] The deceleration rate of the diastolic regurgitation jet and the derived pressure half-time (PHT) reflect both the degree of regurgitation and ventricular end-diastolic pressures. As the degree of AR increases, aortic diastolic pressure decreases and the LV end-diastolic pressure increases. The late diastolic jet velocity is thus reduced and the PHT shortened. A PHT of less than 200 ms is consistent with severe AR, whereas a value of greater than 500 ms suggests mild AR.[44-47] However, this method is influenced by chamber compliance, chamber pressure, peripheral resistance, or aortic compliance.[48,49] PHT assessment is less reliable in the setting of chronic AR in which the LV has been able to adapt to the chronic volume load.[48,49] PHT can underestimate AR in which LV end-diastolic pressure is elevated as a result of concurrent conditions such as LV systolic dysfunction. The use of PHT may be better in acute AR before changes in LV compliance occur with chronic volume load.[27]

## INTEGRATING DOPPLER INDEXES OF SEVERITY

The best way to evaluate AR severity is to integrate several Doppler methods. Based on literature data, a scheme of Doppler parameters for AR severity quantification has been proposed (Table 20-1, Fig. 20-16).[50-52] AR severity is easy to grade when results from the different parameters are congruent, particularly jet and vena contracta width and holodiastolic flow reversal in the proximal descending aorta and abdominal aorta.[31] When different parameters are contradictory, one must carefully seek technical and physiologic reasons for these discrepancies and rely on the components that have the best quality in the primary data. Quantitative parameters can help to subclassify the moderate regurgitation group into mild-to-moderate and moderate-to-severe and overcome certain limitations of some semiquantitative methods.[41] However, quantitative methods are more technically demanding, require adequate experience, and are also vulnerable to the accumulated errors of each variable when image quality is not perfect.[24,25]

## ALTERNATIVE APPROACHES

Transesophageal echocardiography (TEE) is the reference examination for AR quantification in nonechogenic patients (Fig. 20-17). Vena contracta imaging by TEE color flow mapping in the long axis (130°) is an accurate marker of AR severity.[53] In the absence of significant aortic annulus calcification, TEE permits planimetry of the regurgitant jet using color Doppler.[54,55]

Regurgitant vena contracta width greater than 6 mm and area greater than 7.5 $mm^2$, respectively, favor severe AR. Diastolic flow reversal at multiple sites in the descending aorta with biplane TEE may be useful to confirm severe AR.[55]

### *3D TTE*

Recent studies demonstrated the feasibility and accuracy of 3D TTE in quantifying AR (Fig. 20-18). Systematic cropping of the acquired 3D TTE data set is used to measure the vena contracta. The first step is to obtain the best AR jet in the long axis or from the apical view and, if the parasternal window is poor, by posterior-to-anterior cropping of the 3D TTE data set. The 3D TTE color Doppler data set is cropped from the aortic side to

**TABLE 20-1 Qualitative and Quantitative Parameters Useful in Grading Aortic Regurgitation Severity**

| *Structural Parameters* | *Mild* | *Moderate* | | *Severe* |
|---|---|---|---|---|
| LV size | Normal* | Normal or dilated | | Usually dilated† |
| Aortic leaflets | Normal or abnormal | Normal or abnormal | | Abnormal/flail, or wide coaptation defect |
| *Doppler Parameters* | | | | |
| Jet width in LVOT—color flow | Small in central jets | Intermediate | | Large in central jets; variable in eccentric jets |
| Jet density—CW | Incomplete or faint | Dense | | Dense |
| Jet deceleration rate—CW (PHT, ms)‡ | Slow >500 | Medium 500-200 | | Steep <200 |
| Diastolic flow reversal in descending aorta—PW | Brief, early diastolic reversal | Intermediate | | Prominent holodiastolic reversal |
| *Quantitative Parameters*§ | | | | |
| VC width, cm¶ | <0.3 | 0.3-0.6 | | >0.6 |

Philadelphia, 2009, Elsevier.)*

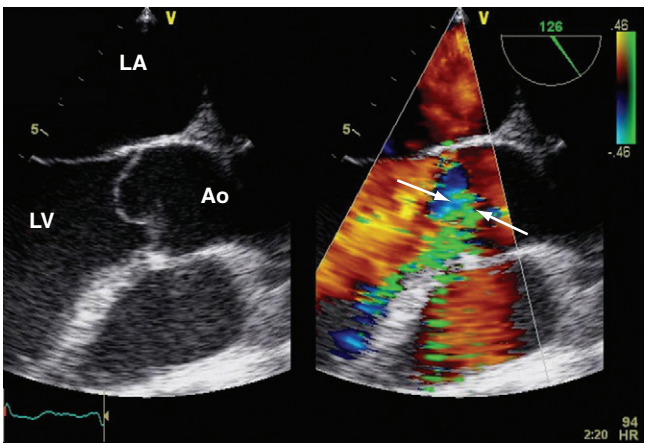

**Figure 20-17 Aortic valve prolapse.** TEE shows the presence of aortic leaflet prolapse (*left*), which leads to significant aortic regurgitation (*right*). Vena contracta (7 mm) of aortic regurgitant jet (*arrows*). *Ao,* Aorta.

the level of the vena contracta, just below the aortic leaflets, in a plane that is exactly perpendicular to the AR jet.[38,56] The image is tilted en face, and the cropped portion of the data set is added back to obtain the maximum area of vena contracta viewed in the short axis in systole. The vena contracta area can be multiplied by the VTI to accurately estimate the instantaneous regurgitant volume.

### *Magnetic Resonance Imaging*

Current recommendations consider cardiac magnetic resonance imaging (MRI) for the noninvasive evaluation of AR when echocardiography is not diagnostic (Fig. 20-19). Regurgitant volume can be calculated from the difference in the antegrade and retrograde flow volume rates in ascending aorta by phase-contrast sequences.[57-59] The good reproducibility of velocity cine MRI for the quantitative assessment of RV and RF indicates the potential of this technique for follow-up and monitoring of response to therapy.[52] Like echocardiography, MRI can also evaluate the presence of holodiastolic flow reversal in the descending aorta.

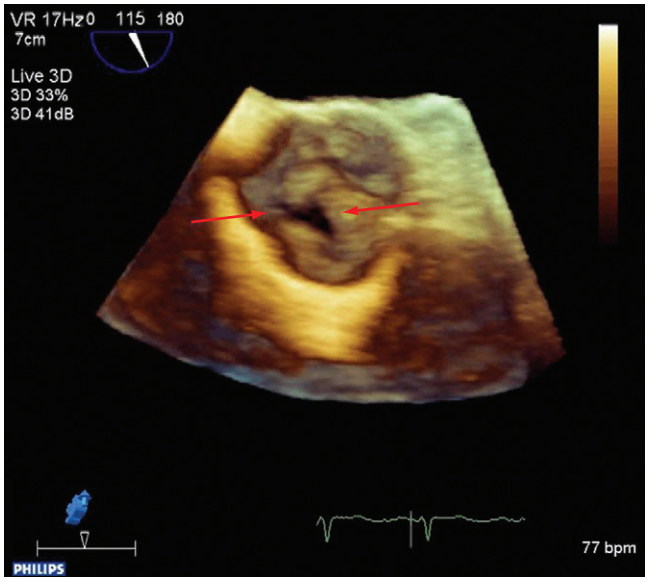

**Figure 20-18** 3D TTE showing the regurgitant orifice (*arrows*) in diastole.

## Left Ventricle Size and Systolic Function

### DIMENSIONS AND VOLUMES

Echocardiography is the diagnostic tool most widely used to assess LV dimensions, volumes, and ejection fraction (EF) (see Chapter 9). End-diastolic and end-systolic dimensions are measured using the LV minor axis from the parasternal long-axis view. 2D or 3D imaging is used to optimize alignment; however, the most accurate measurements with higher reproducibility are still taken using guided M-mode owing to the clear identification of endocardial borders[60] and excellent temporal resolution. M-mode may complement 2D images in separating structures such as trabeculae adjacent to the posterior wall, false tendons on the left side of the septum, and tricuspid apparatus or moderator band on the right side of the septum from the adjacent endocardium. However, even with 2D guidance, it may not be possible to align the M-mode cursor perpendicular to the long axis of the LV, which is mandatory to obtain a true minor axis (Fig. 20-20). Alternatively, chamber dimension and wall thickness can be acquired from the parasternal short axis at the mitral chordae level using direct measurements or targeted M-mode echocardiography, provided that the M-mode cursor can be positioned perpendicular to the septum and LV posterior wall. End-diastolic and end-systolic volumes are obtained according to Simpson's biplane rule using

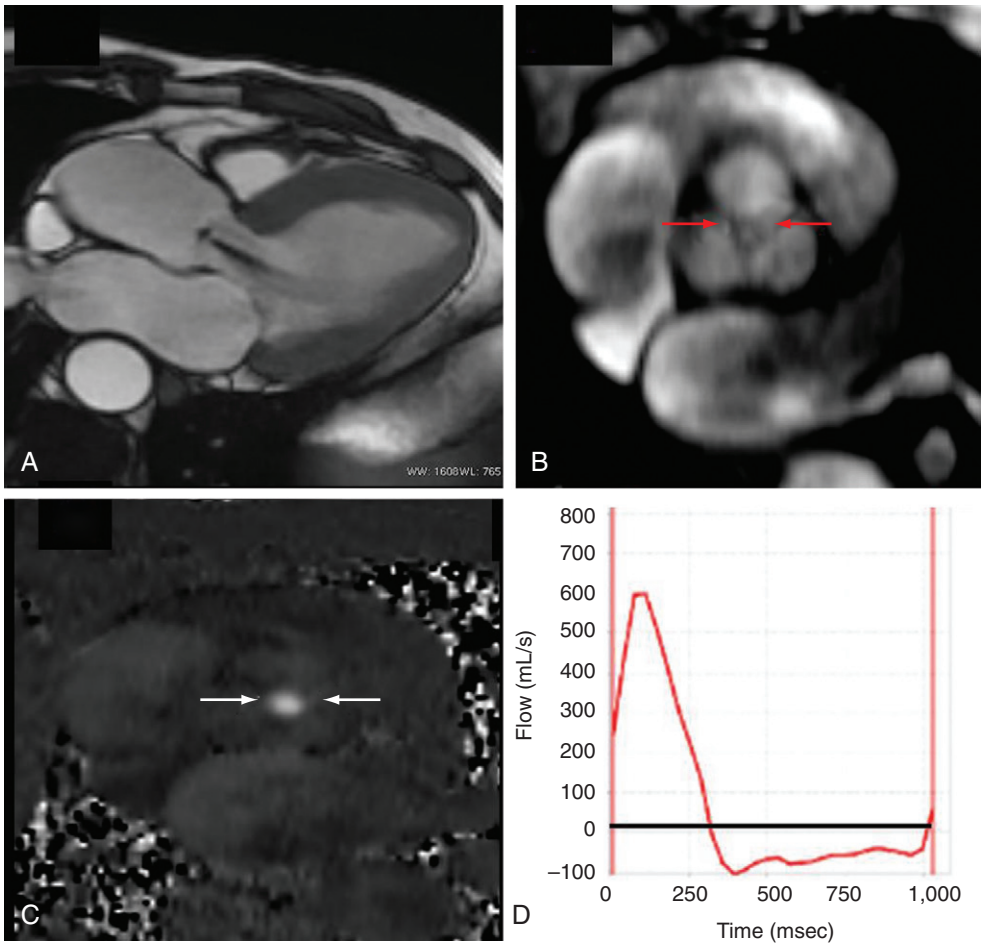

**Figure 20-19** **Cardiac magnetic resonance imaging in a patient with aortic regurgitation (AR). A,** Balanced steady-state free precession image. Oblique axial LV inflow/outflow view, showing grade 2 AR. **B,** Oblique axial plane in the aortic root, just above the aortic valve at the level of the coronary artery change (opening for ostia)(*arrows*). **C,** Phase-contrast velocity mapping. The central jet of AR is seen in white (*arrows*). **D,** Flow versus time plot for the ascending aorta. Antegrade flow was 121 mL/beat, retrograde flow was 43 mL/beat, and aortic regurgitant fraction was 36%.
